
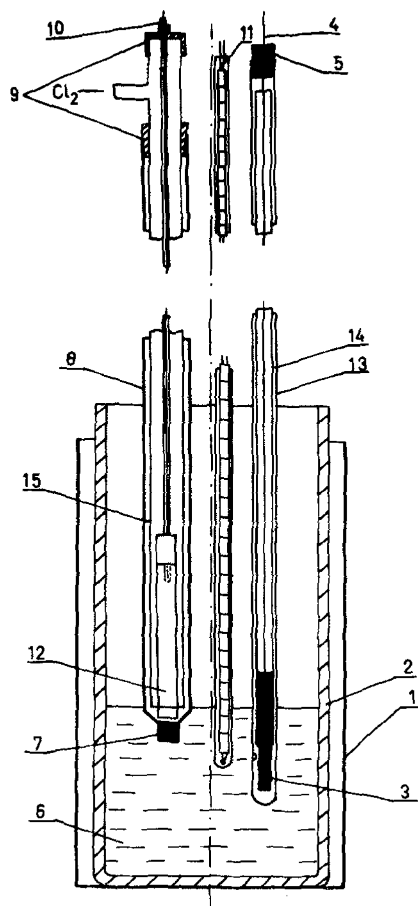

Fig. 1. Scheme of the experimental cell

chlorine electrode consists of a graphite rode, 12, connected with a high melting glass tube, 15, and a Pt wire. Seals, 9, were made of Teflon.

The results of emf measurements obtained for increasing temperatures (open circles) and decreasing (solid circles) are shown in Fig. 2. As these plots show the linear dependence of emf *vs.* temperature, the least squares method was used for averaging the data.

From the resulting linear equations presented in Table I, the emf values at the chosen temperatures of 873°-973°K were calculated each 20°. These emf data were used for calculations of silver chloride activities employing the Nernst equation with $P_{Cl_2} = 1$ atm and with the activity of silver taken as unity. The activity coefficients of silver chloride are calculated from the following relation

$$E_{AgCl} - E^{\circ}_{AgCl} = -\frac{RT}{n\mathbf{F}} \ln \gamma_{AgCl} - \frac{RT}{n\mathbf{F}} \ln X_{AgCl} \quad [2]$$

where E°_{AgCl} is the standard cell potential obtained with pure AgCl (bottom line in Fig. 2) and E_{AgCl} is the emf value of the formation cell.

The obtained experimental values of $\ln \gamma_{AgCl}$ were described by Krupkowski's relation

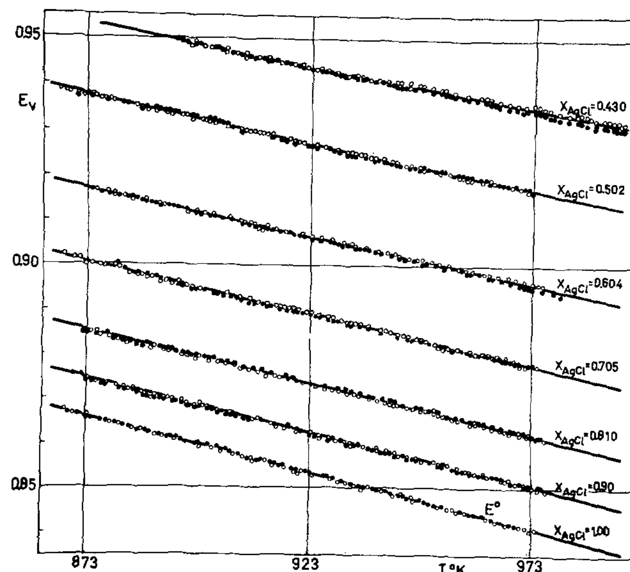

Fig. 2. EMF_{volts} vs. temperature in the system AgCl-KCl

$$\ln \gamma_{AgCl} = \omega(T)(1 - X_{AgCl})^m \quad [3]$$

The value of m ($m = 1.72$) was obtained from the plot $\log|\ln \gamma_{AgCl}|$ *vs.* $\log(1 - X_{AgCl})$ as the slope, and $\omega(T)$ as intercept. Next, the relation of $\omega(T)$ *vs.* temperature [$\omega(T) = -863/T + 0.1468$] were calculated. In this manner the following relations for $\ln \gamma_{AgCl}$ and $\ln \gamma_{KCl}$ were obtained in the form

$$\ln \gamma_{AgCl} = \left(-\frac{863}{T} + 0.1468\right)(1 - X_{AgCl})^{1.72} \quad [4]$$

$$\ln \gamma_{KCl} = \left(-\frac{863}{T} + 0.1468\right)[(1 - X_{AgCl})^{1.72} - 2.389(1 - X_{AgCl})^{0.72} + 1.389] \quad [5]$$

The form of $\omega(T)$ with $\alpha = -863$ and $\beta = 0.1468$ results in equations for partial ($\Delta\overline{H}_{AgCl}$) and integral enthalpy ($\Delta H'$) of the following form

$$\Delta\overline{H}_{AgCl} = -RT^2\left(\frac{\partial \ln \gamma_{AgCl}}{\partial T}\right) = R\alpha(1 - X_{AgCl})^{1.72} = -1714(1 - X_{AgCl})^{1.72} \quad [6]$$

$$\Delta H' = R\alpha \frac{1}{m-1}[1 - (1 - X_{AgCl})^{0.72}]X_{KCl} = -2381[1 - (1 - X_{AgCl})^{0.72}]X_{KCl} \quad [7]$$

The experimental data and those calculated from Eq. [4]-[7] as well as thermodynamic data at 973°K presented by Pelton and Flengas (4) are compared in Table I. Besides the partial thermodynamic properties of AgCl there also exists a good agreement of integral enthalpy when compared with Hersh and Kleppa's (5) calorimetric data (at $X_{AgCl} = 0.5$; $\Delta H' = -550$ cal/mole).

In addition it should be mentioned that similar parameters of $\omega(T)$ and m in Eq. [4] and [5] were

obtained when Krupkowski's method was applied to the data of Pelton and Flengas (4): $\omega(T) = -863/T + 0.054$; $m = 1.80$ as shown previously by Moser and Fitzner (2). The same method was also used by Ptak and Szczygiel (6) for interpretation of emf data of concentration cells applied to AgCl-KCl liquid solutions. The obtained values of $\omega(T) = -917/T$ and $m = 1.87$ also lead to data similar to those presented in Table I.

Surface Tension Measurements of Liquid AgCl, KCl, and AgCl-KCl Solutions

Measurements of surface tension have been carried out by the maximum bubble pressure method. Experimental arrangements were similar to those for liquid metals (7), but some modifications were introduced to limit the vapor transport effect. This limitation is an important factor as it was shown that measurements of surface tension of liquids with significant vapor pressure may result in erroneous data, in the case when the equilibrium of the gaseous with the liquid phase is not attained (8, 9). This phenomenon has been proved in the present investigations as liquid KCl and solutions AgCl-KCl rich in KCl have, in experimental conditions, sufficiently high pressure to influence the surface tension measurements, especially those carried out with free evaporation.

To limit this evaporation a crucible with tested salt was placed in special graphite vessel, 4, with a screwed cover in which an orifice for capillary introduction had been made. The other parts of experimental arrangements are presented in Fig. 3. They consist of a manometer filled with dibutylphalate, 1, a gas train for the purification of argon, 2, a quartz capillary, 3, a crucible vessel with the salt sample, 4, Pt-PtRh10 thermocouple, 5, a resistance furnace, 6, an arrangement to move the crucible with the salt up and down, 7, and a micrometer screw, 8. A quartz capillary with a diameter of 0.7-1 m/m was used. It was initially wetted in liquid salt which improves the reproducibility of results. First, a sample of the investigated salt was placed in the furnace which was then closed. In the meantime the gas train system was open and argon passed through this closed system for a minimum of 24 hr. Next, the furnace was switched on until the first desired temperature was attained. Then, the surface tension measurements were initiated after immersing the capillary at one or two chosen depths. The maximum pressure required for forming and detaching several bubbles was measured. The average value of this measurement was taken for the first approach of surface tension calculations using the relation

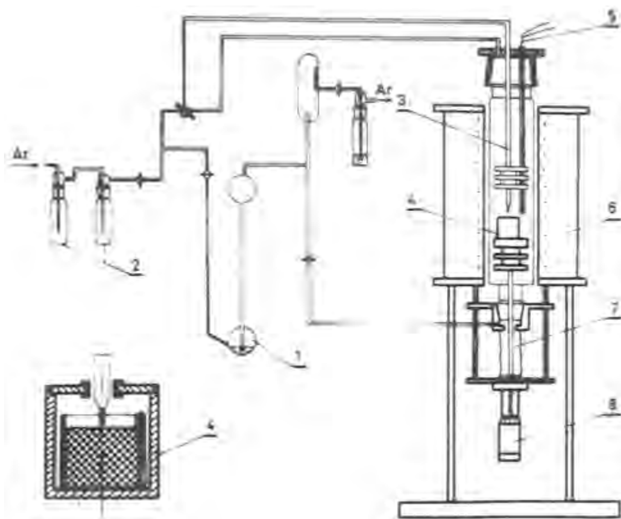

Fig. 3. Scheme of the experimental arrangements for the surface tension measurements.

$$P = \frac{1}{2} r P_{\max} \quad [8]$$

where P is the surface tension in dynes per centimeter, r the capillary radius, and $P_{\max}$ the maximum pressure required for forming and detaching bubble.

The real values of surface tension were obtained using Sudgen's correction method (10). For measurements, AgCl and KCl of high purity were used. Salts were stored in the heater at a temperature of 150°C for about 24 hr and, next, after transferring to the furnace, melted in a stream of gaseous dry HCl. HCl passed through the melt for about 0.5 hr. To obtain a homogeneous mixture of AgCl + KCl the weighed amounts of purified salts were also melted together in a stream of purified HCl and next cast in a quartz form, quickly cooled, and stored in a dessicator. The preparations of the salts for formation cells in the first part was analogical.

The results of surface tension measurements of pure AgCl *vs.* temperature are plottted in Fig. 4. The surface tension decreases linearly with the increase of temperature, also the obtained results are in good agreement with data from monograph (11) and are slightly different in comparison with Ref. (12). It should be added that the results for the different runs from this paper were averaged together by the least squares method as shown by the thick continuous line. The results for pure KCl shown in Fig. 5 were averaged in a similar way and the surface tension also changes linearly *vs.* temperature. Figure 5 presents the results obtained in this investigation for both limited evaporation (solid line) and free evaporation (dashed line). Differences appear between both sets, as at the investigated temperatures KCl has clearly noticeable pressure and the apparatus used enabled measurements in conditions approaching equilibrium between the liquid and gaseous phases. Our results for free evaporation are in good agreement with Ref. (13-15) as shown in Fig. 6.

As in the case of surface tension measurements of pure liquid KCl, our results with limited transport effect for AgCl-KCl mixtures show divergences in

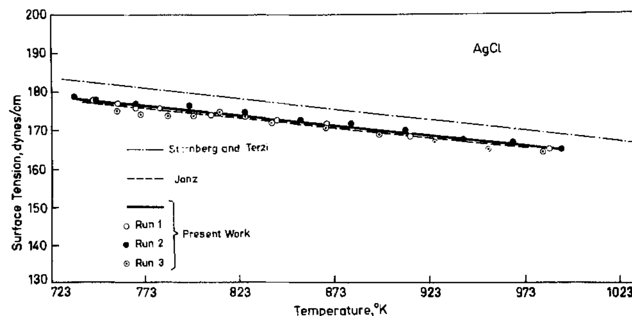

Fig. 4. The surface tension of AgCl *vs.* T°K

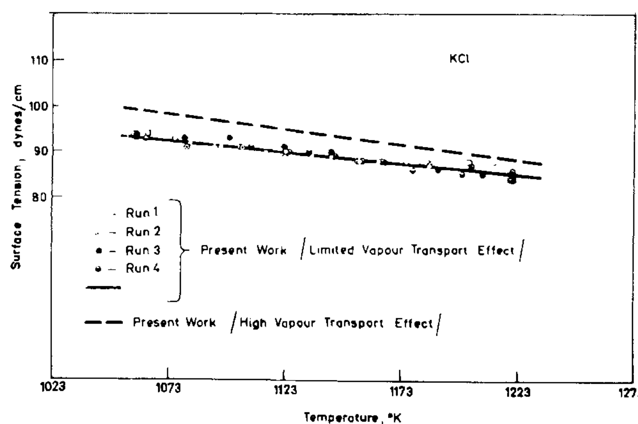

Fig. 5. The surface tension of KCl *vs.* T°K for limited and free evaporation.

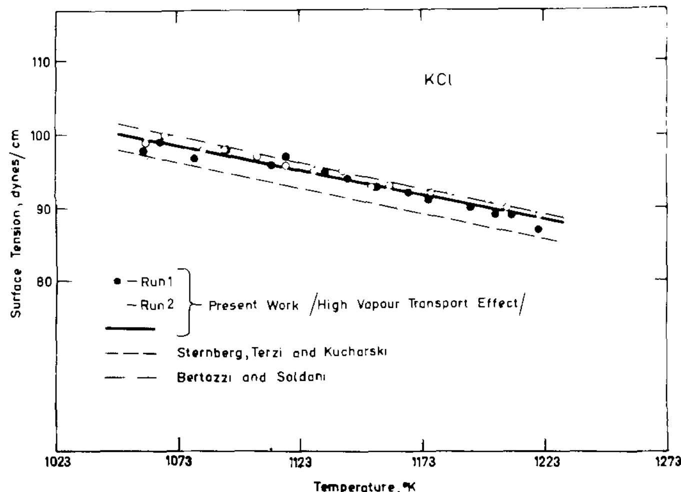

Fig. 6. The surface tension of KCl vs. T°K for free evaporation compared with the data from different sources.

comparison with literature data (13) for AgCl-KCl. Our data also decrease linearly with the increase of temperature. For both pure salts and AgCl-KCl solutions the relations of surface tension *vs.* temperature were described by linear dependences $\sigma = a - bt$°C, where a is the intercept and b the slope of the line. The values of both parameters for pure salts and mixtures, respectively, are summarized in Table II with the standard error of estimate and the temperature range of measurements.

On analyzing the maximum bubble pressure method it appears that it is less precise in comparison, for instance, with the pin method and, taking into account the standard error of estimate, errors in surface tension measurements are of the order of $\pm$2-3 dynes. These errors, however, and the different influence of limitation of evaporation in respect to the composition of investigated salt compositions were sufficient to introduce in linear equations of surface tension *vs.* temperature (Table II) the lack of fluid change in slopes from pure AgCl to KCl.

Using the linear equation from Table II, surface tension was calculated at 973°K and a relation of σ *vs.* X_{AgCl} was plotted in Fig. 7 as shown by circles. The continuous line on this plot refers to Eberhart's relation (16). Eberhart has presented an equation for the surface tension of binary liquid mixtures based on the assumption that the surface tension is a linear function of the surface layer mole fraction. The condition for equilibrium between the surface layer and the bulk liquid phase gives a relationship between the surface and the bulk compositions and results in the following equation

$$\sigma = \frac{X_{AgCl}\sigma_{AgCl} + SX_{KCl}\sigma_{KCl}}{X_{AgCl} + SX_{KCl}} \qquad [9]$$

where σ_{AgCl} and σ_{KCl} are the surface tensions of the pure salts, and S is the coefficient dependent on temperature which gives the extent of surface layer enrichment of the component of lower surface tension. For results of surface tension at 973°K the value of the coefficient $S = 6.21$ was determined according to the procedure presented in Ref. (16).

Composition of the Surface and the Relation Between the Thermodynamic Properties of the Bulk and Surface Phase

The basic relation which combines the surface tension with the activities of components in the surface layer and in the bulk phase according to (17) takes the form

$$RT \ln a_{AgCl^{\bar{\omega}}} = RT \ln a_{AgCl} + \frac{\overline{V}_{AgCl^{\bar{\omega}}}}{\tau}(\sigma - \sigma_{AgCl}) \qquad [10]$$

where $a_{AgCl^{\bar{\omega}}}$ and a_{AgCl} are the activities in the surface layer and in the bulk phase, respectively, τ is the assumed thickness of the surface layer, $\overline{V}_{AgCl^{\bar{\omega}}}$ is the partial molar volume of AgCl in the surface phase assumed to be equal molar volume V_{AgCl}, σ_{AgCl} is the surface tension of pure AgCl, and σ is the surface tension of AgCl-KCl solutions.

To obtain results of $\gamma_{AgCl^{\bar{\omega}}}$ in the surface phase a knowledge of the composition of the surface phase is necessary for interpretation by Krupkowski's method as in the case of the bulk. Various procedures for the computation of concentrations of both AgCl and KCl in the surface phase are presented below. On the basis of the assumption of the existence of the surface phase (18) it is possible to calculate the relative adsorption $\Gamma_{AgCl(KCl)}$ by the following relation

$$\Gamma_{AgCl(KCl)} = \Gamma_{AgCl} - \frac{X_{AgCl}}{X_{KCl}}\Gamma_{KCl} = -\frac{d\sigma}{d\mu_{AgCl}} \qquad [11]$$

where Γ_{AgCl} and Γ_{KCl} are the number of moles of AgCl and KCl, respectively, in the surface phase per unit area, μ_{AgCl} is the chemical potential of AgCl in the bulk phase, σ is the surface tension, and X_{AgCl} and X_{KCl} are the mole fractions of AgCl and KCl in the bulk phase.

The value of $\Gamma_{AgCl(KCl)}$ is independent of the arbitrarily assumed areas which separate from the solu-

tion the surface area to which we ascribe the properties of the phase. The only limitation is that the adsorption area must be contained between these two areas. The values of Γ_{AgCl} and Γ_{KCl} may be calculated if certain additional assumptions are made concerning the structure of the surface layer. One such assumption (9) may be represented by the equation

$$\Gamma_{AgCl}\overline{V}_{AgCl^{\bar{\omega}}} + \Gamma_{KCl}\overline{V}_{KCl^{\bar{\omega}}} = \tau \qquad [12]$$

where $\overline{V}_{AgCl^{\bar{\omega}}}$ and $\overline{V}_{KCl^{\bar{\omega}}}$ are the partial molar volumes of AgCl and KCl in the surface phase and τ is the thickness of the surface layer.

Basing on Eq. [10] and [12] values of adsorption Γ_{AgCl}, Γ_{KCl} may be calculated as follows

$$\Gamma_{AgCl} = \frac{X_{AgCl}\tau - X_{KCl}\overline{V}_{KCl^{\bar{\omega}}}\dfrac{d\sigma}{d\mu_{AgCl}}}{X_{KCl}\overline{V}_{KCl^{\bar{\omega}}} + X_{AgCl}\overline{V}_{AgCl^{\bar{\omega}}}} \qquad [13]$$

and

$$\Gamma_{KCl} = \frac{X_{KCl}\left(\tau + \overline{V}_{AgCl^{\bar{\omega}}}\dfrac{d\sigma}{d\mu_{AgCl}}\right)}{X_{KCl}\overline{V}_{KCl^{\bar{\omega}}} + X_{AgCl}\overline{V}_{AgCl^{\bar{\omega}}}} \qquad [14]$$

Considering Eq. [11], [12], [13], and [14], thermodynamic properties of AgCl-KCl solutions (Eq. [4]), and the results of surface tension measurements, the relative adsorption as well as adsorption of respective components were calculated assuming that $\overline{V}_{AgCl^{\bar{\omega}}} = V_{AgCl}$ and $\overline{V}_{KCl^{\bar{\omega}}} = V_{KCl}$. The molar volumes of AgCl and KCl were computed from densities of these salts, taken from monograph (11). Calculations were carried out for thicknesses of the surface phase, namely $\tau = 4.29 \times 10^{-8}$ cm and $\tau = 8.58 \times 10^{-8}$ cm. They are equal to a single and double diameter of a KCl molecule. Then the concentrations of AgCl and KCl in the surface phase were calculated from the relations

$$X_{AgCl^{\bar{\omega}}} = \frac{\Gamma_{AgCl}}{\Gamma_{AgCl} + \Gamma_{KCl}}$$

and

$$X_{KCl^{\bar{\omega}}} = \frac{\Gamma_{KCl}}{\Gamma_{AgCl} + \Gamma_{KCl}} \qquad [15]$$

When analyzing the results of the calculations, adding to the calculated number of moles of the respective components in the first layer of molecules of the thickness $\tau = 4.29 \times 10^{-8}$ cm the number of moles of the second layer of the same thickness but of bulk composition, the values of the AgCl concentration obtained were identical to those in calculations when it was assumed that $\tau = 8.58 \times 10^{-8}$ cm. This proves that the adsorption refers only to the first layer of molecules. The results of the calculations for the monomolecular layer are shown in Fig. 8.

The composition of the surface phase in the case of weak adsorption may also be calculated by the procedure assuming that the differences between the composition of surface and bulk phase take place only in the first layer of atoms. In such a case (18) the following relation is valid

$$\Gamma_{AgCl}A_{AgCl} + \Gamma_{KCl}A_{KCl} = 1 \qquad [16]$$

where A_{AgCl} and A_{KCl} are the partial molar areas of AgCl and KCl in the surface monomolecular layer, respectively. Using Eq. [16] and [11] the composition of AgCl in the surface layer was calculated and is also presented in Fig. 8.

In addition, the composition of the surface phase may be calculated as proposed by Eberhart (16) given the coefficient S and considering relations

$$S = \frac{X_{AgCl^{\bar{\omega}}}}{X_{KCl^{\bar{\omega}}}} \cdot \frac{X_{KCl}}{X_{AgCl}} \qquad [17]$$

and

$$X_{AgCl^{\bar{\omega}}} + X_{KCl^{\bar{\omega}}} = 1 \qquad [18]$$

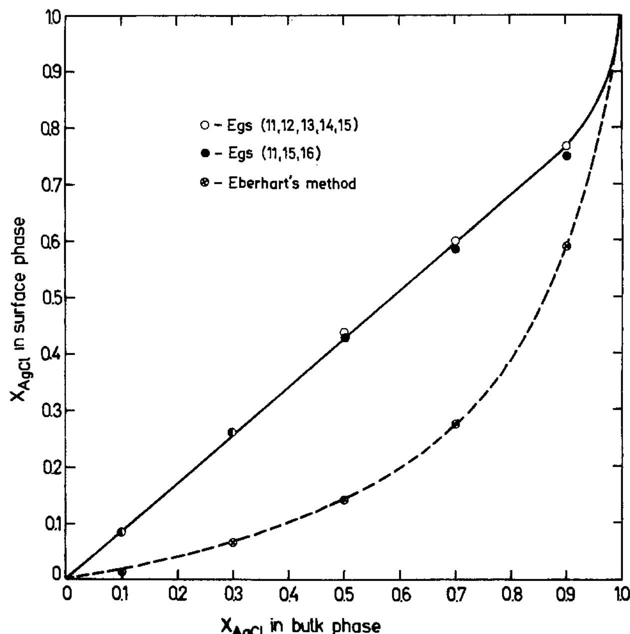

Fig. 8. Computed concentrations of AgCl in the surface phase vs. X_{AgCl} in the bulk phase.

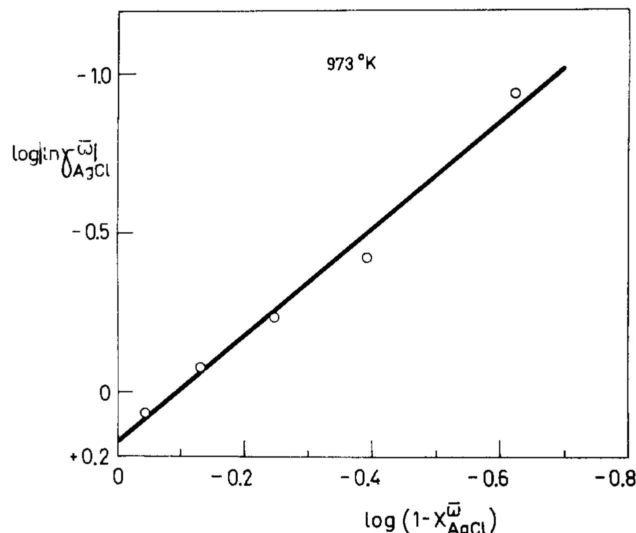

Fig. 9. The relation of log (ln $\gamma_{AgCl^{\bar{\omega}}}$) vs. log (1 − $X_{AgCl^{\bar{\omega}}}$) for the surface phase of the AgCl-KCl liquid solutions at 973°K.

Using Eq. [10] with the activities of the bulk calculated by Eq. [3] assuming that $\overline{V}_{AgCl^{\bar{\omega}}} = V_{AgCl}$ and $\tau = 4.29 \times 10^{-8}$ and taking into account $X_{AgCl^{\bar{\omega}}}$ (Eq. [15]), activity coefficients of the surface monomolecular layer were computed. The obtained results were described as for the bulk by Eq. [3]. Figure 9 shows a fit of calculated values of activity coefficients ln $\gamma_{AgCl^{\bar{\omega}}}$ to Eq. [3] as log (ln $\gamma_{AgCl^{\bar{\omega}}}$) vs. log (1 − $X_{AgCl^{\bar{\omega}}}$).

In this procedure at 973°K, the following values were obtained: m = 1.67 and $\bar{\omega}(T)$ = −1.44. By comparison with similar values of the bulk phase, m = 1.72 and $\omega(T)$ = −0.74 it is concluded that the asymmetry of thermodynamic properties connected with parameter m is almost similar, and the main significant difference in the thermodynamic properties of the surface and bulk phase appear in the values of function $\omega(T)$.

The same conclusion may be reached using different values for surface tension obtained experimentally by Sternberg and Terzi (12). The calculated parameters m and $\omega(T)$ for the surface phase are equal to 1.87 and −1.32 at 973°K, respectively.

Conclusions

The results of surface tension measurements obtained with limited evaporation giving conditions approaching equilibrium between the liquid and gaseous phase are lower for KCl and liquid AgCl-KCl solutions in comparison with Ref. (12) and (19). The main reason for these differences lies in the fact that the experiments in Ref. (12) and (19) were not carried out in equilibrium between the liquid and gaseous phases. This is confirmed by the fact that the results of our measurements performed in conditions of free evaporation are close to literature data.

A similar influence of experimental conditions has been observed in surface tension measurements for liquid metals with high vapor pressures (8, 9).

In view of these facts it is desirable to conduct further research in order to elaborate the experimental method for surface tension measurements ensuring full equilibrium between liquid and vapor. Calculated values of the logarithm of the activity coefficients of AgCl in the surface phase interpreted by Krupkowski's method show that the thermodynamic asymmetry of this phase and the bulk phase of AgCl-KCl solutions is the same within the range of experimental errors, but the differences in the values of the $\omega(T)$ function of both phases suggest in the case of the surface phase much higher deviations from ideality than in the bulk phase. Differences in partial enthalpy and excess entropies of components in both phases may also be suggested.

Manuscript submitted Aug. 17, 1977; revised manuscript received Jan. 3, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Design of an Electrocoating Cell for Constant Current Density Operation

A Fourier-Transform Method of Solution of the Laplace Equation

Rodney L. LeRoy*

Noranda Research Centre, Pointe Claire, Quebec H9R 1G5, Canada

ABSTRACT

Continuous electrocoating is normally carried out by passage of a foil, strip, or wire substrate between parallel electrodes in a coating cell. It has been shown that improved unformity of deposition in such a cell, and thus improved dielectric properties of the product, can be achieved using a converging electrode geometry. A method is described for deriving the optimal electrode geometry based on solution of the Laplace equation in the electrolyte region. A semianalytical solution is used, with boundary conditions on the converging cathode being applied by a novel Fourier-transform method. For the electrocoating cell the resulting optimal geometry is well approximated by a simple result which assumes that current flow is perpendicular to the moving substrate.

Commercial application of electrodeposition of organic coatings has expanded rapidly over the last 15 years, first in the automotive industry and more recently in applying coatings to the products of the electrical, heating and cooling, furniture, aluminum extrusion, and other industries (1). The electrocoating process is particularly suited to application of thin, nonporous organic coatings to continuous foil, strip, or wire (2-4). In some applications, production speeds of 300-500 cm/sec have been achieved with uniform coating thicknesses of 2.5-5 μm.

* Electrochemical Society Active Member.

The electrodeposition process is characterized by simultaneous occurrence of electrophoresis, electrolysis, and electroendosmosis (5, 6). All practical resin systems developed to date have been anaphoretic, involving deposition of the organic coating on a stationary or moving anode. The basic resin types used have thus been acidic and include carboxylated drying oils, alkyds and epoxy esters of high acid value, carboxyl-bearing acrylic copolymers, phenolics and triazine condensates. Typical coating baths consist of approximately 80-85% deionized water, 2-3% co-solvent, and 1% solubilizing base, with the balance being the anionic

polymer. The potential applied to the electrocoating cell is typically 100-250V.

When potential is applied to the electrodes of the coating cell, the negatively charged polymer ions migrate toward the anode under the influence of the electrical field by the processes of ionic migration and electrophoresis. In the immediate vicinity of the anode several reactions can occur. For polycarboxylic acid polymers as were used in this work, direct decarboxylation can occur by the Kolbe reaction

$$2RCOO^- \rightarrow R{-}R + 2CO_2 + 2e \quad [1]$$

This reaction, however, is believed to be relatively unimportant, with the majority of the applied current being consumed by anodic dissolution of the anode substrate

$$M \rightarrow M^{z+} + ze \quad [2]$$

and by the anodic decomposition of water to give hydrogen ions and oxygen gas

$$2H_2O \rightarrow O_2 + 4H^+ + 4e \quad [3]$$

Some polymeric carboxylate ions are precipitated or coagulated in the vicinity of the anode by reaction with the ions of the substrate metal which are produced by reaction [2]. However, the principal anodic process is believed to be reaction [3], with polymer coagulation occurring by reaction with hydrogen ions in the low pH region in the immediate vicinity of the electrode. The local pH near the anode can drop to about 2, while most resins used for electrocoating will coagulate at pH values between 4 and 5 (7).

Thus anodic resin deposition occurs concurrently with vigorous evolution of oxygen gas. When an anode substrate is moved continuously through a coating cell between parallel cathode plates, a highly nonuniform current density distribution is established along the substrate in the coating cell. Deposition is rapid when the uninsulated substrate first enters the cell, but falls off as electrical insulation of the substrate by the deposited resin increases the resistance to the flow of current. These effects result in less than optimal coating properties. Resin deposition occurs at a very high rate at the entrance to the cell with simultaneous evolution of oxygen, resulting in a less homogeneous coating on the final product than would be achievable under more controlled conditions.

The final process occurring in the coating cell is electroendosmosis. This is the phenomenon by which much of the water in the film deposited on the anode substrate migrates in the direction of the cathode under the influence of the applied potential, resulting in water contents as low as 5-15%. On emergence from the cell, the electrocoated film is normally baked at between 150° and 200°C to promote further drying and, in many cases, oxidative cross-linking.

It has been found that use of a converging electrode geometry in an electrocoating cell can result in improved deposit properties by enabling a relatively constant current density on the anode substrate throughout the cell. The purpose of this paper is to describe a method of designing an electrode to achieve this constant current density objective. The method is based on solution of the Laplace equation within the electrolyte.

Basis of the Method

No calculations to derive optimal cathode geometries are possible until the boundary conditions in the electrocoating cell are defined. The cathode presents no problem in this regard, as the reaction here is simply hydrogen evolution. For typical substrates (*e.g.*, stainless steel) the overvoltage for this reaction will always be less than 1V in the range of current densities which are used. This is small compared with the potential applied to the cell, which is normally greater than 100V. Thus the cathode-electrolyte interface can be treated as being at the same potential as the cathode itself. The oxygen overvoltage on the anode and the reversible potential for the water decomposition reaction (totaling less than 1.6V) can be similarly neglected.

However, the potential on the anode-electrolyte interface varies strongly with position in the cell due to the deposition of the insulating polymer. In a parallel-electrode electrocoating cell, it would be difficult to deduce this anode interface potential as a function of position in the cell. For the converging electrode geometry, if it is assumed that a constant anode current density can be achieved, the problem becomes more amenable to solution. In this case, the constant electrocoating current density is under the control of the operator, so the variation of the anode film-electrolyte interface potential with time can be determined in a static experiment for the resin which is being used.

A typical result is illustrated in Fig. 1 for an aluminum substrate. The resin used was BASF Lewipal No. E-33, a mixed acrylate ester/acrylic acid resin solubilized with polyamines. The operating current density was 9.3 mA/cm^2. The film voltages measured in the static cell were obtained as a function of deposition time, but this result is readily translated into film voltage as a function of position in the continuous electrocoating cell as has been done in Fig. 1. This method is valid if the mass-transfer limiting current density is appreciably larger than the value selected. Provided this condition is satisfied, such static experiments allow translation of a desired constant current density of operation into a film voltage profile as a function of position in the electrocoating cell.

The conductivity of the resin-containing electrolyte must also be determined for use in the calculations described below. The conductivity of the BASF E-33 resin solution was 0.00056 Ω^{-1} cm^{-1}.

Derivation of the Cathode Geometry

A first approximation.—If it is assumed that current flows directly across the cell, perpendicular to the anode, the electrode geometry can be approximated using the equation

$$\text{total resistance } (R_t) = \text{solution resistance } (R_s) + \text{film resistance } (R_f) \quad [4]$$

Consider a small segment of the anode substrate, the length of which is $1/N$th of the total cell length L. Assuming that the current density is constant along the anode, the total resistance between this segment of the substrate and the corresponding segment of the cathode (on one side) is

$$R_t = U/(I/2N) \quad [5]$$

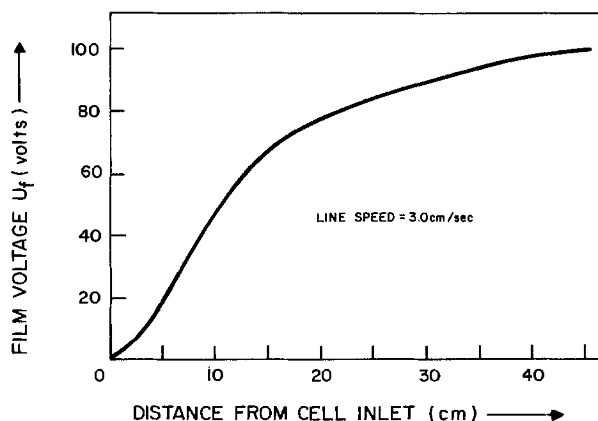

Fig. 1. Film voltage as a function of distance from the inlet of the continuous electrocoating cell. Data is translated from a static experiment assuming a constant current density in the cell of 9.3 mA/cm^2. The resin used was BASF E-33 of conductivity 0.00056 Ω^{-1} cm^{-1}.

where U is the total voltage applied to the cell, and I is the total current. By a similar argument, the film resistance on the segment of the anode being considered is

$$R_f = U_f/(I/2N) \quad [6]$$

where U_f (cf. Fig. 1) is the film voltage determined from static measurements. By definition the solution resistance is

$$R_s = \frac{d}{\kappa \left[\frac{W_a + W_c}{2}\right] \frac{L}{N}} \quad [7]$$

where d is the desired anode-cathode separation, κ is the solution conductivity, and W_a and W_c are, respectively, the widths of the anode and the cathode.

Substitution of the resistance factors from Eq. [5] to [7] into Eq. [4] gives the desired result for the anode-cathode separation as a function of position in the cell

$$d = \frac{\kappa L(W_a + W_c)}{I}(U - U_f) \quad [8]$$

The electrode configuration calculated from the film-voltage data of Fig. 1 using Eq. [8] is sketched as a broken curve in Fig. 2. Cell dimensions were $L = 45.7$ cm, $W_c = 10.2$ cm, and $W_a = 3.2$ cm, and the total current for a constant current density of 9.3 mA/cm^2 was set at $I = 2.7A$. An applied cell voltage of $U = 135V$ was assumed. However, polarization effects and the reversible potential for the over-all cell reaction have been ignored, so in practice it would be necessary to adjust the applied potential until the required current density was achieved.

Solution of the Laplace equation.—Introduction.— The electrode geometry calculated using Eq. [8] is an approximation, because current does not flow directly across the cell perpendicular to the anode substrate. The current flowing at any point in the electrolyte is sensitive to the potentials at all points on the enclosing electrodes.

This problem is solved as follows. Assuming that the current is not significantly limited by mass-transfer effects, the potential $\phi(x, y)$ can be accurately represented by the Laplace equation in the region between the anode and the cathode (8, 9). This is

$$\frac{\partial^2\phi(x, y)}{\partial x^2} + \frac{\partial^2\phi(x, y)}{\partial y^2} = 0 \quad [9]$$

Rectangular coordinates are used for the cell geometry being considered here, with the x and y directions defined in Fig. 3 for an arbitrary, converging electrode geometry.

Laplacian problems are commonly encountered in aerodynamics, hydrodynamics, heat transfer, electrostatics, and many other physical problems as well as in electrochemical applications, so considerable effort has been devoted to their solution. One approach is to use experimentally based analogical or graphical methods (10, 11). However, such methods are time consuming to use and are not well adapted to iterative determination of an optimal electrode design. Also, with the availability of high-speed digital computers, numerical solutions of Eq. [9] can be obtained. Such brute force solutions depend on a process of iteration (12) and for a complex geometry, such as that of Fig. 3, solution can require several minutes of computer time and thus a substantial cost.

Analytical solutions are, therefore, to be preferred in many instances, even if they entail major approximations. Examples of such solutions abound (9, 13-15).

Once the potential distribution has been established, the current density J normal to the anode can be calculated directly from the gradient of the potential perpendicular to the substrate, from the Ohm's law expression

$$J = -\kappa \frac{\partial\phi(x, y)}{\partial x}\bigg|_{x\to 0} \quad [10]$$

The process of determination of an optimal cathode geometry is as follows. A particular geometry is selected, Eq. [9] is solved for the potential in the electrocoating solution, and current density values along the anode substrate are calculated from Eq. [10]. If these values differ significantly from constancy, appropriate modifications are made in the electrode geometry and the process is repeated until relatively constant current density is achieved.

A suitable general form of the solution to Eq. [9] is

$$\phi(x, y) = \sum_{m=0}^{\infty} (A'_{1m}e^{ax} + A'_{2m}e^{-ax}) (B_{1m}\sin(ay) + B_{2m}\cos(ay)) \quad [11]$$

where the infinite set of constants A'_{1m}, A'_{2m}, B_{1m}, B_{2m} and a must be determined from the boundary conditions. Thus, on the cathode, whatever its geometry, $\phi(x,y)$ must reduce to the value of the applied potential U, while on the anode substrate at $x = 0$ it must reduce to the film voltage U_f (cf. Fig. 1). In the method of solution which has been selected here, these boundary conditions are applied by identifying Eq.

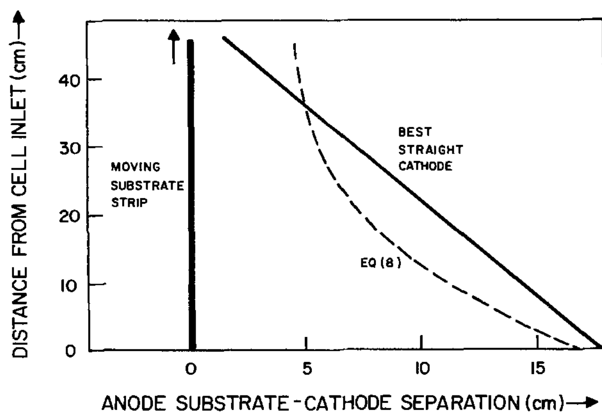

Fig. 2. Representative converging electrode geometries in the electrocoating cell. The broken curve is the cathode whose geometry is calculated from Eq. [8], based on the variation of film voltage with position in the cell which is given in Fig. 1. For the same film-voltage variation, the solid line is the linear electrode giving closest to constant current density.

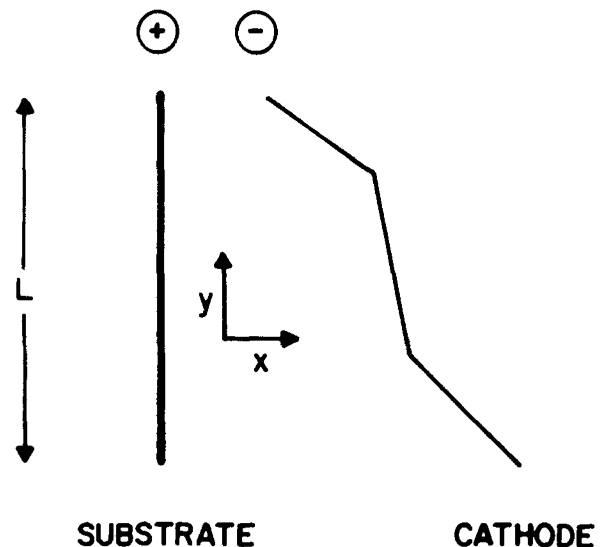

Fig. 3. A typical converging electrode geometry, with the cathode consisting of 3 straight-line segments.

[11] with Fourier expansions of the known potential on each of the two electrodes.

A third boundary condition applies at $y = 0$ and $y = L$. These are the insulating walls of the cell, and the lines of equipotential must be perpendicular to them. This condition may be expressed as (12, 15)

$$\left.\frac{\partial\phi(x,y)}{\partial y}\right|_{y=0,L} = 0 \qquad [12]$$

Examination of Eq. [11] reveals that Eq. [12] would be satisfied if all of the constants B_{1m} were 0, and the period of the function were L, *i.e.*, if $a = m\pi/L$. In this case, $\phi(x, y)$ would reduce to

$$\phi(x,y) = \sum_{m=0}^{\infty}\left[A_{1m}e^{\frac{m\pi x}{L}} + A_{2m}e^{-\frac{m\pi x}{L}}\right]\cos\frac{m\pi y}{L} \qquad [13]$$

The two series of constants A_{1m} and A_{2m} would then be determined by application of the boundary conditions on the electrodes.

It was found that Eq. [13] would not converge to a sufficient degree of accuracy with a reasonable number of terms in the series. This was because the identification of the boundary conditions using Fourier series resulted in sharp discontinuities at $y = 0$ and $y = L$.

An approximate solution was, therefore, used. Boundary conditions were applied for a cell which was twice as long as the actual cell (Fig. 4). The anode potential outside the "true" cell was taken to be a constant at each end, equal to the value just inside the cell. The cathode potential was set equal to its constant value U over its entire length. In this way the potential lines were forced to be approximately perpendicular to the insulating walls at $y = L/2$ and $y = 3L/2$, even though $\partial\phi/\partial y$ was not analytically equal to zero at these points.

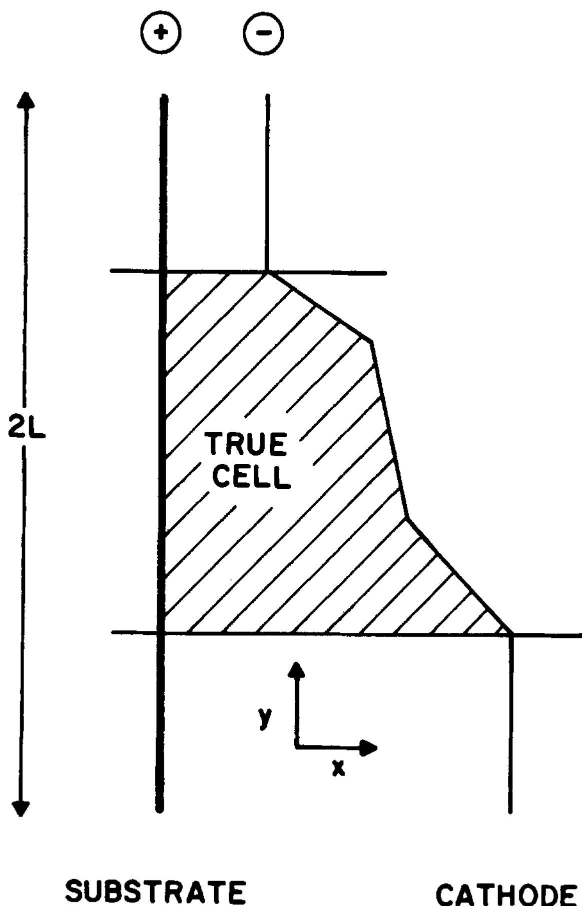

Fig. 4. Schematic representation of the geometry assumed in applying the boundary conditions to Eq. [14].

With this expanded cell geometry, the sine series of Eq. [11] was used as an approximation to the potential $\phi(x, y)$

$$\phi(x,y) = \sum_{m=1}^{\infty}\left[A_{1m}e^{\frac{m\pi x}{2L}} + A_{2m}e^{-\frac{m\pi x}{2L}}\right]\sin\frac{m\pi y}{2L} \qquad [14]$$

Boundary condition on the anode substrate.—The variation of film voltage U_f with position in the cell, exemplified by the result in Fig. 1, can be accurately approximated by a quadratic equation of the general form

$$U_f(y) = c_1y + c_2y^2 + c_3y^3 \qquad [15]$$

The parameters c_i are determined for the particular resin composition being used by least squares fitting of the data from the static experiment by Eq. [15]. For the data of Fig. 1, these constants are $c_1 = 5.799$ V cm^{-1}, $c_2 = 0.1180$ V cm^{-2}, and $c_3 = 0.000847$ V cm^{-3}.

The general expression for the potential (Eq. [14]) reduces on the anode substrate to

$$\phi(x = 0, y) = \sum_{m=1}^{\infty}(A_{1m} + A_{2m})\sin\frac{m\pi y}{2L} \qquad [16]$$

The potential on the anode is already known to be

$$\begin{aligned} U_f(y) &= 0, && 0 < y < L/2 \\ &= c_1\left(y - \frac{L}{2}\right) + c_2\left(y - \frac{L}{2}\right)^2 + c_3\left(y - \frac{L}{2}\right)^3 && L/2 < y < 3L/2 \\ &= c_1L + c_2L^2 + c_3L^3 && 3L/2 < y < 2L \end{aligned} \qquad [17]$$

Equations [16] and [17] are equated by expanding Eq. [17] as a Fourier series in $\sin(m\pi y/2L)$. The result, when identified with the series of Eq. [16], gives a general expression for $T_{1m} = A_{1m} + A_{2m}$

$$T_{1m} = \frac{1}{L}\int_0^{2L} U_f(y)\sin\frac{m\pi y}{2L}\,dy \qquad [18]$$

The integral of Eq. [18] is recorded in Eq. [A-1] of Appendix A. Although somewhat formidable in appearance, the result depends only on the parameters c_1, c_2, and c_3 of the film voltage U_f. The expression is readily evaluated by computer and has a single value for each term of the Fourier series.

Boundary condition on the cathode.—Although the cathode geometry is not assumed at this time to be known, it can be defined in general terms by writing the anode-cathode distance d as a function of y, $d = T(y)$. Thus, the Laplace solution on the cathode may be written as

$$\phi(x = T(y), y) = \sum_{m=1}^{\infty}\left[T_{1m}e^{\frac{m\pi T(y)}{2L}} - A_{2m}\left(e^{\frac{m\pi T(y)}{2L}} - e^{-\frac{m\pi T(y)}{2L}}\right)\right]\sin\frac{m\pi y}{2L} \qquad [19]$$

where A_{1m} has been eliminated by writing it in terms of A_{2m} and the known parameter (Eq. [A-1]) T_{1m}.

The infinite series of constants A_{2m} are the only remaining unknowns in Eq. [19]. These constants are evaluated by equating Eq. [19] to the known value of the potential on the cathode, U. This constant potential is readily expanded in a Fourier sine series

$$U = \sum_{n=1}^{\infty} T_{2n} \sin \frac{n\pi y}{2L} \quad [20]$$

where

$$T_{2n} = \frac{1}{L}\int_0^{2L} U \sin \frac{n\pi y}{2L} dy$$

$$= \frac{2U}{n\pi}(1 - \cos n\pi) \quad [21]$$

At first glance it would appear that the parameters A_{2m} could be immediately calculated by identifying the coefficients of the sine terms in Eq. [19] and [20]. In the general case where $T(y)$ is not a constant this is not possible because the coefficient in Eq. [19] is itself a function of y. This difficulty is circumvented by expanding the summation of Eq. [19] itself as a sine series. Although the result appears cumbersome, it can be efficiently used in a digital machine for solution of the boundary condition and, thus, for calculation of the current density distribution from Eq. [10].

The general term of the Fourier expansion of the right-hand side of Eq. [19] may be written as follows, and equated to T_{2n}

$$\frac{1}{L}\int_0^{2L} \left\{ \sum_{m=1}^{\infty} \left[T_{1m} e^{\frac{m\pi T(y)}{2L}} - A_{2m} \left[e^{\frac{m\pi T(y)}{2L}} - e^{-\frac{m\pi T(y)}{2L}} \right] \right] \sin \frac{m\pi y}{2L} \right\} \sin \frac{n\pi y}{2L} dy = T_{2n} \quad [22]$$

This result can be rewritten as an infinite set of linear equations in the parameters A_{2m}

$$\sum_{m=1}^{\infty} K_{1m} A_{2m} = K_{2n} - L\,T_{2n} \quad [23]$$

where

$$K_{1m} = \int_0^{2L} \left\{ e^{\frac{m\pi T(y)}{2L}} - e^{-\frac{m\pi T(y)}{2L}} \right\} \sin \frac{m\pi y}{2L} \sin \frac{n\pi y}{2L} dy \quad [24]$$

and

$$K_{2n} = \int_0^{2L} \left\{ \sum_{m=1}^{\infty} T_{1m} e^{\frac{m\pi T(y)}{2L}} \sin \frac{m\pi y}{2L} \right\} \sin \frac{n\pi y}{2L} dy \quad [25]$$

The procedure used for solution of Eq. [23] is to truncate the summations (Eq. [23] and [25]) at a finite number of terms, for example 20. The parameters K_{1m} and K_{2m} are then evaluated for values of m from 1 to the cut-off value of m. Using these values, and the known values of T_{2n} (Eq. [21]), the linear Eq. [23] are solved for the parameters A_{2m}.

The Laplace solution.—Using the results of the preceding sections for T_{1m} and A_{2m}, the potential may be calculated at any point in the electrocoating solution

$$\phi(x, y) = \sum_{m=1}^{m'} \left[T_{1m} e^{\frac{m\pi x}{2L}} - A_{2m} \left[e^{\frac{m\pi x}{2L}} - e^{-\frac{m\pi x}{2L}} \right] \right] \sin \frac{m\pi y}{2L} \quad [26]$$

where m' is the cut-off value selected for truncating the series.

The current density perpendicular to the anode, at a distance x from it, can be written directly from this result and Eq. [10]

$$J = -\kappa \sum_{m=1}^{m'} \left(\frac{m\pi}{2L}\right) \left[T_{1m} e^{\frac{m\pi x}{2L}} - A_{2m} \left[e^{\frac{m\pi x}{2L}} + e^{-\frac{m\pi x}{2L}} \right] \right] \sin \frac{m\pi y}{2L} \quad [27]$$

It would theoretically be possible to evaluate the current density on the anode substrate by setting $x = 0$ in Eq. [27]. However, it has been found that better accuracy is achieved for reasonable values of the truncation parameter m' when J is evaluated for a small positive value of x, for example, between 0.2 and 0.5 cm. A similar effect has been noted by Waber for a related problem (16).

Definition of the cathode geometry.—The method of solution of the Laplace equation which has been developed here is most efficiently carried out if the parameters K_{1m} and K_{2m} can be expressed in analytical form. This is possible if the arbitrary cathode geometry being considered, $d = T(y)$, is expressed as a series of straight lines.

The cathode geometry is defined as follows in the computer program written to carry out this analysis. The number of straight line segments to be used, l, is entered first followed by the defining parameters of each segment as they are given in Fig. 5. The two parameters for each junction point are f_i, the fraction of the substrate length from the cell entrance, and d_i, the anode-cathode separation at this point. With the cathode defined in this way, Eq. [24] and [25] can be written in analytical form, the parameters A_{2m} and T_{1m} can be evaluated, and the current density distribution calculated from Eq. [27]. The analytical results for K_{1m} and K_{2n} are recorded in Appendix B.

Results and Discussion

Parallel electrodes.—The Laplace solution is simplified substantially when the anode-cathode separation is a constant, d. In this case the coefficients of sin $(m\pi y/2L)$ in Eq. [19] and [20] can be equated giving the following result for A_{2m}

$$A_{2m} = \frac{T_{1m} e^{\frac{m\pi d}{2L}} - T_{2m}}{e^{\frac{m\pi d}{2L}} - e^{-\frac{m\pi d}{2L}}} \quad [28]$$

Figure 6 records a typical potential distribution obtained for a cell having a parallel electrode configuration. In this case, the applied potential was $U = 100$V, and the film voltage U_f was assumed to increase linearly from 0 at the cell inlet ($y = L/2$) to 50V at the outlet ($y = 3L/2$).

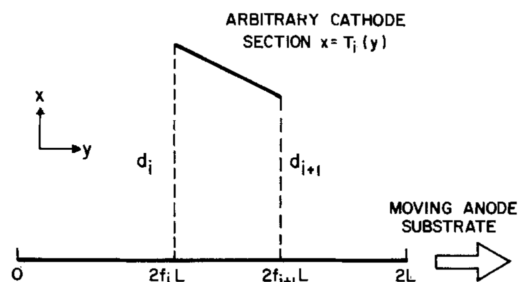

Fig. 5. Definition of the parameters used in representing a cathode of arbitrary geometry as a series of straight-line segments.

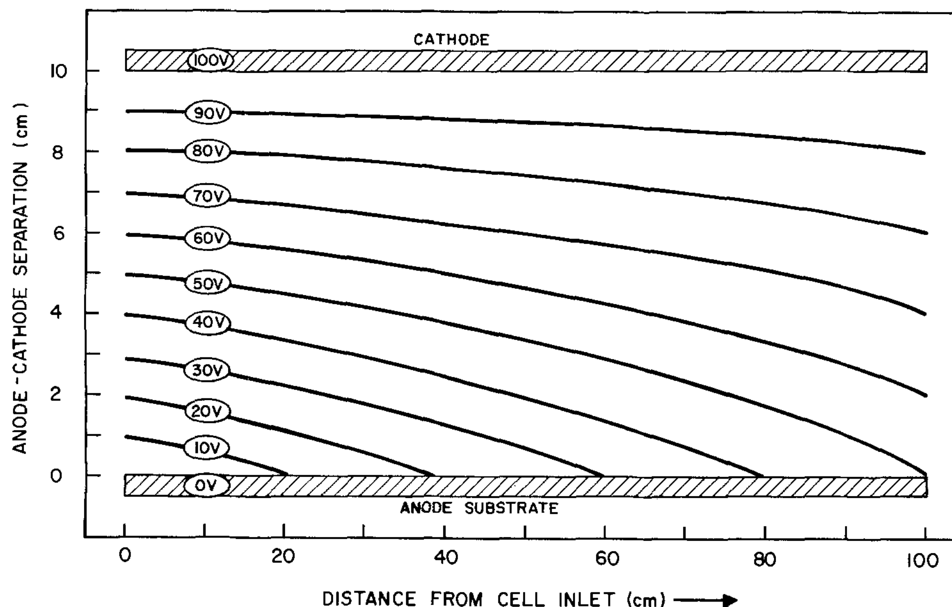

Fig. 6. Equipotential lines in an electrocoating cell between parallel electrodes, for an applied potential of 100V. The film voltage is assumed to rise linearly from zero volt at the cell inlet to 50V at the outlet. Anode-cathode separation is 10 cm, while the cell length is 100 cm.

Solution of the boundary condition on the substrate is simplified for such a linear film-voltage variation. In general, if the film voltage rises from 0 at the inlet to a fraction F of the total applied potential U at the outlet, Eq. [A-1] reduces to ($c_1 = FU/L$; $c_2 = c_3 = 0$)

$$T_{1m} = \frac{2FU}{m\pi}\left\{\frac{2}{m\pi}\left(\sin\frac{3m\pi}{4} - \sin\frac{m\pi}{4}\right) - \cos m\pi\right\} \quad [29]$$

For the example of Fig. 6, $FU = 50\text{V}$.

The potential distribution of Fig. 6 indicates that the current flow is strongly concentrated on the end of the anode at the cell entrance for the parallel electrode configuration. In fact, the current density at the entrance in this example is twice as great as it is at the exit.

Converging, straight electrodes.—An obvious "first guess" at a cathode geometry which would give more constant current density on the anode than a parallel configuration is a single straight converging element. This is illustrated, for example, by the solid lines of Fig. 2.

Several examples were worked out to delineate the qualitative effects of such a converging structure on the current density distribution. Results are summarized in Fig. 7. A total cell voltage of 100V was assumed, with the film voltage increasing linearly from zero at the cell entrance to 50V at the cell exit. Because of this assumed linearity in the film voltage, the result of Eq. [29] could be used, but the nonparallel structure of the electrodes necessitated the use of the full solution of Eq. [23] for A_{2m}. Current densities were calculated from Eq. [27] for $x = 0.5$ cm. Initial calculations were carried out with the potential (Eq. [14] and subsequent results) truncated at $m' = 20$ and 40 terms. Essentially identical results were obtained for both series lengths, so $m' = 20$ terms were used in all subsequent calculations.

The assumed cell length was 100 cm. The calculated current densities are expressed divided by the conductivity, so as not to introduce an extraneous arbitrary factor to these illustrative results.

In Fig. 7a the anode-cathode separation at the cell exit was set equal to 10 cm, and the current-density variation was calculated for electrode separations at the entrance of 10, 15, 20, and 40 cm. The parallel configuration ($d_1 = 10$ cm) gave a strong variation of current density with position in the cell, as was anticipated from Fig. 6. Increasing the entrance separation to 20 cm improved the constancy of the current density, while increasing it to 40 cm resulted in a

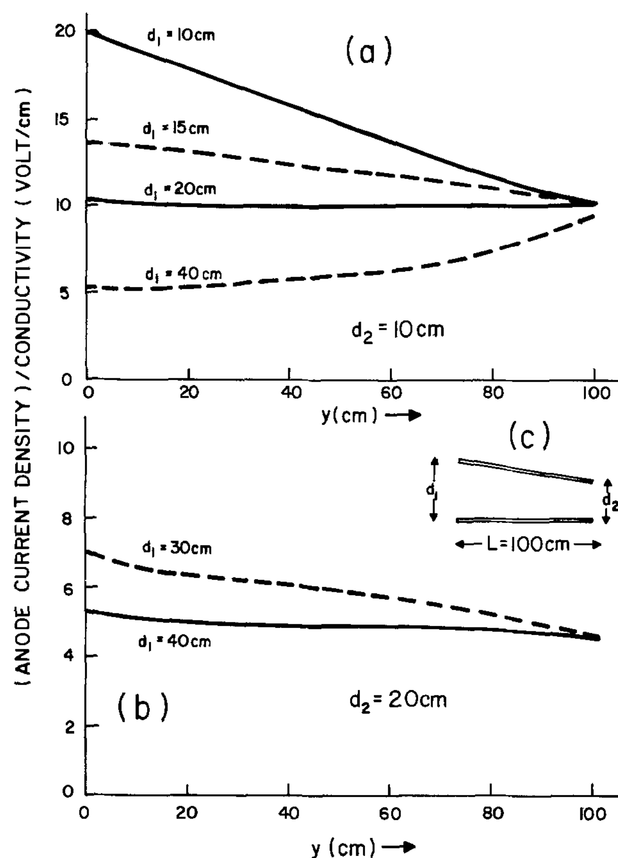

Fig. 7. Variation of anode current density with position in an electrocoating cell having converging, straight electrodes. An applied potential of $U = 100\text{V}$ is assumed. Cell length is 100 cm, with the anode-cathode separation as defined in Fig. 7c. Results in Fig. 7a were computed for an electrode separation of 10 cm at the cell exit, while those in Fig. 7b assumed an electrode separation at the exit of 20 cm.

relatively high current density at the cell exit. Similar results are recorded in Fig. 7b for an anode-cathode separation of 20 cm at the cell exit. Solution for each configuration required approximately 1.4 sec (core) on the McGill University IBM 360 computer.

Further calculations were carried out using the experimental film voltage data of Fig. 1. This necessitated use of the full results of Eq. [A-1] for application of the boundary condition on the anode substrate. The nonlinearity of the film voltage variation resulted in

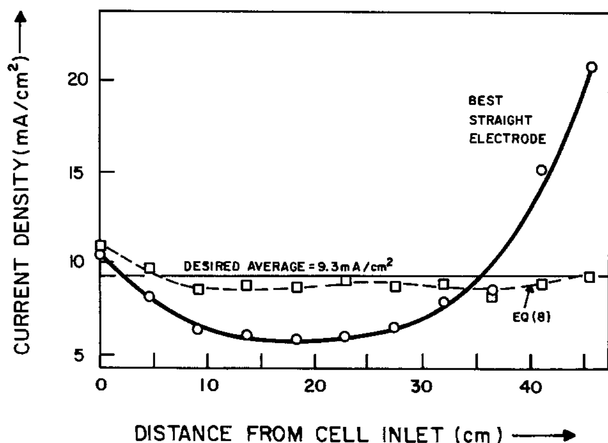

Fig. 8. Variation of current density with position in the electrocoating cell, for the variation of film voltage with position in the cell which is recorded in Fig. 1, and the electrode geometries drawn in Fig. 2. Both curves correspond to an applied potential of 135V. The broken curve is derived for the electrode geometry of Eq. [8], while the solid curve is for the "best" converging, straight electrodes (solid lines, Fig. 2).

relatively higher current densities near the cell entrance, and relatively lower current densities near its exit. The converging solid electrode drawn in Fig. 2 was derived in an iterative program which minimized the sum of the squares of the deviations of the current density from the desired average value. The corresponding current-density variation is plotted as a solid curve in Fig. 8. Clearly a single straight electrode can only very approximately compensate for the film voltage variation as it occurs in the practical cell.

In spite of the imperfect establishment of constant current density within the cell, use of the converging configuration of Fig. 2 resulted in substantially improved properties of electrocoated strip. Table I records a comparison of the properties of strips prepared in a continuous electrocoating cell with conventional, parallel electrodes (substrate-cathode separation 3.3 cm) and with the converging straight-line electrodes of Fig. 2. The continuous strip was 3.2 cm wide × 0.005 cm thick aluminum, run at a line speed of 3.3 cm/sec with the BASF E-33 resin. Both sets of electrodes were 10.2 cm wide, and the cell length was 45.7 cm. The current to each cell was kept constant at 2.7A, or 9.3 mA/cm² of substrate area.

The average build was 12% greater for the converging electrodes compared to the parallel electrodes, for the same average applied voltage. More important, the electrocoated deposits on the strips treated in the converging cell were of superior quality, containing fewer gas bubbles.

Table I. Comparison of parallel and converging electrode electrocoating cells

Electrode configuration	Run number	Applied voltage (V)	Coating thickness* (10^{-3} cm)
Converging**	1	131	3.81
	2	121	4.06
	3	125	3.81
	4	120	4.19
	Average	124	3.97
Parallel†	1	128	3.56
	2	126	3.56
	3	122	3.56
	4	121	3.56
	Average	124	3.56

* Measured after drying and curing.
** Linear cathode. Anode-cathode separation 17.8 cm at the entrance and 1.5 cm at the exit (Fig. 2).
† Anode-cathode separation was 3.3 cm.

Curvilinear cathode geometry.—No experiments were performed using a curvilinear cathode geometry. However, a calculation was made to test how closely a cathode designed according to the approximate Eq. [8] gives a constant current density through the cell.

Using the parameters for the BASF E-33 resin, Eq. [27] was solved by the method of this paper for the electrode defined by Eq. [8]. This electrode (the broken curve of Fig. 2) was approximated by 10 straight-line segments when applying the boundary condition on the cathode as described in Appendix B.

The resulting current-density variation in the cell for an applied potential of $U = 135$V is plotted as a broken curve in Fig. 8. The corresponding potential distribution in the electrocoating solution is sketched in Fig. 9. It is apparent that the calculation of Eq. [8] gives a good approximation to the desired electrode geometry. It is likely that converging cathode geometries derived using this equation could give further improvements in the properties of continuously electrocoated products.

Acknowledgments

I am indebted to Dr. M. A. Dudley for suggesting that improved electrocoating quality could be achievable using a converging electrode geometry. Mr. G. Bersolami carried out the experiments reported in Table I and Fig. 1. This work was supported by Canada Wire and Cable Limited. The work described in this paper is the subject of U.S. Patent No. 3,933,611 and equivalent patents granted or pending in other countries.

APPENDIX A

Evaluation of the General Term in the Fourier Expansion of the Potential on the Substrate

The general term (Eq. [18]) is

$$T_{1m} = \frac{1}{L}\int_0^{2L} U_f(y)\sin\frac{m\pi y}{2L}\,dy \qquad [18]$$

Substituting for the substrate potential $U_f(y)$ from Eq. [17] and integrating yields the result

$$\begin{aligned}
T_{1m} = {} & \frac{2}{m\pi}(c_1L + c_2L^2 + c_3L^3)\left(\cos\frac{3m\pi}{4} - \cos m\pi\right) \\
& + \frac{2}{m\pi}\left(-\frac{c_1L}{2} + \frac{c_2L^2}{4} - \frac{c_3L^3}{8}\right)\left(\cos\frac{m\pi}{4} - \cos\frac{3m\pi}{4}\right) \\
& + \frac{2}{m\pi}\left(\frac{2L}{m\pi}\right)\left(c_1 - c_2L + \frac{3c_3L^2}{4}\right)\left(\sin\frac{3m\pi}{4} - \sin\frac{m\pi}{4} - \frac{3m\pi}{4}\cos\frac{3m\pi}{4} + \frac{m\pi}{4}\cos\frac{m\pi}{4}\right) \\
& + \frac{2}{m\pi}\left(\frac{2L}{m\pi}\right)^2\left(c_2 - \frac{3c_3L}{2}\right)\left(\frac{3m\pi}{2}\sin\frac{3m\pi}{4} - \frac{m\pi}{2}\sin\frac{m\pi}{4} - \left[\left\{\frac{3m\pi}{4}\right\}^2 - 2\right]\cos\frac{3m\pi}{4} + \left[\left\{\frac{m\pi}{4}\right\}^2 - 2\right]\cos\frac{m\pi}{4}\right) + \frac{2}{m\pi}c_3\left(\frac{2L}{m\pi}\right)^3 \\
& \left(\left[3\left\{\frac{3m\pi}{4}\right\}^2 - 6\right]\sin\frac{3m\pi}{4} - \left[3\left\{\frac{m\pi}{4}\right\}^2 - 6\right]\sin\frac{m\pi}{4} - \left[\left\{\frac{3m\pi}{4}\right\}^3 - 6\left\{\frac{3m\pi}{4}\right\}\right]\cos\frac{3m\pi}{4} \right. \\
& \left. + \left[\left\{\frac{m\pi}{4}\right\}^3 - 6\left\{\frac{m\pi}{4}\right\}\right]\cos\frac{m\pi}{4}\right) \qquad [A\text{-}1]
\end{aligned}$$

APPENDIX B

Evaluation of the Cathode Boundary Condition for an Arbitrary Cathode

The equation of the straight line segment of Fig. 5 is

$$T_i(y) = a_i - b_i y \qquad [B\text{-}1]$$

where

$$a_i = d_i + \frac{d_i - d_{i+1}}{f_{i+1} - f_i} f_i \qquad [B\text{-}2]$$

and

$$b_i = \frac{1}{2L}\,\frac{d_i - d_{i+1}}{f_{i+1} - f_i} \qquad [B\text{-}3]$$

Substituting this expression for $T_i(y)$ in Eq. [24] gives the general result for K_{1m}

$$\begin{aligned}
K_{1m} = {} & \sum_{k=1}^{l}\left\{ e^{\frac{m\pi a_k}{2L}} \int_{2f_kL}^{2f_{k+1}L} e^{-\frac{m\pi b_k y}{2L}} \sin\frac{m\pi y}{2L}\sin\frac{n\pi y}{2L}\,dy \right. \\
& \left. + e^{-\frac{m\pi a_k}{2L}} \int_{2f_kL}^{2f_{k+1}L} e^{\frac{m\pi b_k y}{2L}} \sin\frac{m\pi y}{2L}\sin\frac{n\pi y}{2L}\,dy \right\} \\
= {} & \sum_{k=1}^{l}\left\{ e^{\frac{m\pi a_k}{2L}} I_1(k,m,n) - e^{-\frac{m\pi a_k}{2L}} I_2(k,m,n) \right\} \qquad [B\text{-}4]
\end{aligned}$$

where the two integrals $I_z (z = 1, 2)$ are defined by the second equality. A similar result can be written for K_{2n}

$$\begin{aligned}
K_{2n} = {} & \sum_{m=1}^{m'} T_{1m}\left\{ \sum_{k=1}^{l} e^{\frac{m\pi a_k}{2L}} \int_{2f_kL}^{2f_{k+1}L} e^{-\frac{m\pi b_k y}{2L}} \sin\frac{m\pi y}{2L}\sin\frac{n\pi y}{2L}\,dy \right\} = \sum_{m=1}^{m'} T_{1m} \\
& \left\{ \sum_{k=1}^{l} e^{\frac{m\pi a_k}{2L}} I_1(k,m,n) \right\} \qquad [B\text{-}5]
\end{aligned}$$

where $I_1(k, m, n)$ has the same value as in Eq. [B-4].

Evaluation of K_{1m} and K_{2n} in this general case is completed by recording the value of the integral $I_z(k, m, n)$

$$I_z(k, m, n) = \xi(2f_{k+1}L) - \xi(2f_kL) \qquad [B\text{-}6]$$

where

$$\xi(y) = \frac{e^{\alpha y}}{2}\left\{ \frac{\beta\sin\beta y + \alpha\cos\beta y}{\alpha^2 + \beta^2} - \frac{\gamma\sin\gamma y + \alpha\cos\gamma y}{\alpha^2 + \gamma^2} \right\} \qquad [B\text{-}7]$$

α, β, and γ are defined by

$$\alpha = (-1)^z\frac{m\pi b_k}{2L} \qquad [B\text{-}8]$$

$$\beta = \frac{(m-n)\pi}{2L} \qquad [B\text{-}9]$$

$$\gamma = \frac{(m+n)\pi}{2L} \qquad [B\text{-}10]$$

The Influence of Carbon Matrix Characteristics on the Performance of Sulfur Electrodes for Sodium-Sulfur Cells

M. P. J. Brennan

Chloride Silent Power Limited, Astmoor, Runcorn, England

ABSTRACT

Sodium-sulfur cells of the central sulfur configuration, though free from the problems of case corrosion, can still exhibit capacity losses of up to 50% over 100 cycles of operation. This is mainly due to a failure to recharge fully in the two-phase regime of the operating cycle. This paper describes an investigation of the relationship between rechargeability and the surface properties of the carbon matrix employed as the current-collecting member in the sulfur electrode. The influence of cell constructional variants is also considered.

The earliest sodium-sulfur cells tested by Chloride Silent Power were of the tubular central sodium type, incorporating a beta-alumina tube of 13 mm diam. With these cells, sulfur utilization was found to diminish with time and cycling, typical values being 56% utilization after 300 cycles (100% being defined as conversion of the sulfur charge to Na_2S_3). At the time, a major contributory factor to the decline in utilization was recognized to be corrosion of the cell case by the molten sulfur and sodium polysulfide reactant contained within it. This could affect utilization both by tying up sulfur in the form of metal sulfides, and by breaking the electronic contact between the case and the carbon felt matrix dispersed within the sulfur electrode, leading to premature polarization on both charge and discharge. With the development of larger electrolyte shapes, it was possible to change the cell configuration, locating the sulfur electrode reactant within the beta-alumina tube, so that the cell case came into contact only with sodium. Current collection from the sulfur electrode was achieved by a carbon or graphite pole, located co-axially within the ceramic electrolyte.

With these central sulfur cells, it was found that despite the elimination of case corrosion, the utilization of sulfur still showed a declining trend with cycling, with effective capacity losses of up to 50% over 100 cycles being not uncommon. This was found to be mainly due to failure of the cells to recharge fully in the two-phase region of the operating cycle.

One theory advanced to explain the poor rechargeabilities linked this phenomenon to the relative wetting propensities of sulfur and sodium polysulfides on carbon surfaces. It was suggested that sulfur wets carbon more effectively than does molten sodium polysulfide, so that sulfur formed during recharging has a tendency to spread out over the carbon fibers as a continuous insulating film. As the proportion of occluded surface will be expected to increase as charging proceeds, this phenomenon should manifest itself as a rising cell resistance, which could lead to the cell failing to fully recharge either within a time limit (constant voltage charging) or voltage limit (constant current charging).

Chemical modification of the wettability of carbon fibers is a process well known in the fiber-reinforced composites industry (1, 2). It is generally found that the wetting of carbon fibers by epoxy resins is enhanced by subjecting the fibers to a preoxidation procedure. This can be either a wet oxidation, using nitric acid, permanganates, dichromates, etc. (2-4), or a dry oxidation in air, oxygen, or ozone (2, 5).

Were such treatments to preferentially enhance the wetting of carbon fibers by the predominantly ionic component of a two-phase sulfur/sodium polysulfide melt, then the performance of cells with modified matrices should be significantly improved. Conversely, if the pretreatment promoted wetting by the sulfur-rich phase, then a deterioration in cell performance could be expected.

It is an unresolved question as to whether the improvement in wetting observed with epoxy resins is due principally to changes in surface chemistry, or whether the roughening of the fiber surfaces which accompanies the oxidation process is the major factor. For this reason two pretreatments were employed in this section of the work. One, (oxidation with $Na_2Cr_2O_7/H_2SO_4$) is known to oxidatively etch carbon, whereas the other (neutralization with aqueous NaOH) was expected to change only the surface chemistry.

Another pretreatment investigated in this work involved subjecting carbon felt for cells to exposure to reagents known to intercalate in well-ordered graphite. There are many such reagents, falling into two broad groups, the electron donors, such as the alkali metals, and the electron acceptors. The latter group is more numerous, and includes some of the halogens, interhalogens, and transition metal chlorides. The formation of an intercalation compound is accompanied by a change in the electronic band structure of the graphite to produce a more metallic material (6) as evidenced by changes in electrical conductivity (7), and Hall effect coefficient (8). Surface properties are also altered (9). Full conversion of a graphite sample to an intercalation compound is possible only with highly ordered graphites, containing a minimum of lattice defects. Carbon fibers do not fall in this category, however lattice resolution studies with the electron microscope have shown the surfaces of the fibers to be more ordered than the interior (10), and lattice parameters close to those of pure graphite have been obtained by electron diffraction studies of fiber edges (11). Since the aim was to produce changes in the surface wetting characteristics of the fibers, restriction of the intercalation reaction to the surface layers was acceptable.

For a permanent effect on cell performance it was necessary that the intercalated felt be stable in the cell environment. This requirement at once ruled out the use of n-type lamellar compounds, based on alkali metal insertion, because in these the inserted species can usually be totally desorbed by the application of heat. Complete desorption of the inserted material in p-type compounds is usually impossible, and a certain amount remains forming the so-called residue compound. In particular chromyl chloride is capable of extensive fixation to form a permanent lamellar compound (12) and this reagent was chosen for this work. Also selected was antimony pentachloride, for its ease

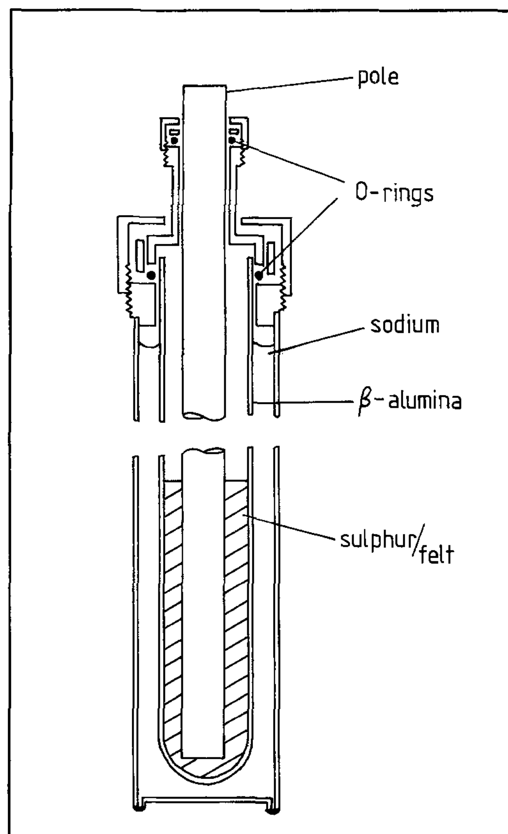

Fig. 1. Schematic diagram of the sodium-sulfur cell design used in this work.

of handling (like chromyl chloride it is a liquid), for its reported high reactivity (13), and because the intercalation reaction of $SbCl_5$ has been extensively studied (14).

Experimental

The cell design used in this work is shown in Fig. 1. It is a central sulfur cell based on an electrolyte tube of diameter 26 mm. The felt in the sulfur electrode was introduced in the form of rings surrounding the central graphite rod pole. RVC 4000 (Le Carbone) was the felt material, and the rings were held under an axial compression of 2:1. The cell operated in a temperature gradient, so that the electrodes could be sealed with silicon rubber O-rings; however, the 10 cm working length of the electrolyte was held at a temperature of 340° ± 15°C throughout. For the cells incorporating intercalated felt the graphite pole was drilled and tapped at the top end to accept a stainless steel (316) insert, upon which the upper O-ring seal was made. This produced a hermetic seal. In the other cells, the upper seal was made to the graphite rod and was not as leak-tight.

The felt variants were prepared as follows. (*i*) Oxidation: The felt rings were refluxed in an aqueous solution of sodium dichromate (0.3M) and sulfuric acid (2.0M) for 24 hr. They were then thoroughly washed with deionized water until the washings had a pH of 7. (*ii*) Neutralization: The felt rings were refluxed for 24 hr in an aqueous solution of sodium hydroxide (0.4M), then washed with deionized water as above. (*iii*) $SbCl_5$: The felt was predried for 2 days at 110°C and then refluxed with antimony pentachloride at 80°C for 12 hr. The felt was then washed with constant boiling point hydrochloric acid in a soxhlet extractor for 2 days, followed by extraction with deionized water until the washings had a pH of 7. (*iv*) CrO_2Cl_2: The felt was predried as above, then refluxed with chromyl chloride at 100°C for 2 hr. The washing procedure was the same as for antimony pentachloride. (*v*) Control: Because the cell design differed slightly for the two groups of pretreatments, control cells were made up to each design. In both cases the felt was refluxed with deionized water for 12 hr, then extracted with deionized water as above.

Samples of the oxidized felt were analyzed to obtain a quantitative estimate of the degree of surface oxidation induced. The method employed was that recommended by Ludtke (15) for the determination of carboxylate functions in oxycelluloses and adapted by Donnet *et al.* (16) for the determination of the same functions on carbon blacks. The method consists of refluxing the carbon material with an aqueous solution of calcium acetate, which effects an ion-exchange reaction liberating acetic acid, which is then estimated by titration. It was found that as-received felt did not liberate sufficient acetic acid for estimation by this technique, however the oxidized material was found to have an acidity of 0.45 mequiv. g^{-1}, slightly less than the figures reported by Donnet *et al* (16) for oxidized carbon blacks (0.62-1.2 mequiv. g^{-1}).

Two cells of each variant were constructed and cycled to the following regime at a temperature of 340° ± 15°C. (*i*) Discharge—via a fixed resistor arranged to give a discharge rate of approximately 0.3-0.2C (current density 40-60 mA-cm^2) and (*ii*) Recharge—via a series resistor for the remainder of the 24 hr cycle, with a cell voltage limit of 2.6V. Recharge was essentialy complete in 11 hr at an average current density of 20 mA-cm^{-2}.

For some cycles the cells were controlled by a computer, the discharge being terminated when the instantaneous open-circuit voltage fell to 1.76V. When not under computer control discharge was terminated at a load voltage of 1.35V.

Two cell characteristics were recorded for analysis; first the discharge capacity to 1.76V, and second the cell resistance at an open-circuit voltage of 2.00V on the discharge half-cycle. It was found that the resistance of a cell did not vary much from this value except at extremes of charge and discharge.

Cell Performances

Oxidized and neutralized felt.—The sulfur utilization for these cells was measured over a period of approximately 3000 hr ≡ 100 cycles. The data was analyzed for the following periods: 0-1000 hr, 1000-2000 hr, 2000-3000 hr. Table I lists the mean values recorded for each cell during each period, as a percentage of theoretical capacity. These figures suggest that the cells can be ranked in order of merit with respect to sulfur utilization as follows: control>neutralized> oxidized. The significance of this trend was determined by subjecting the data to variance analysis. Table II lists the values of the *F*-statistic and corresponding

Table I. Mean sulfur utilization

		0-1000 hr		1000-2000 hr		2000-3000 hr	
Cell	Type	Mean	SD	Mean	SD	Mean	SD
395	Control	76.9	4.3	72.2	4.4	62.8	9.0
398*	Control	77.3	2.9	76.1	1.3	See note*	
394	Neutralized	72.2	4.5	58.2	4.8	42.1	4.7
397	Neutralized	71.3	3.0	66.1	4.4	57.8	2.6
393	Oxidized	69.1	6.5	54.0	4.2	46.9	5.2
396	Oxidized	63.2	8.6	58.7	3.9	49.4	5.1

* This cell failed after 1944 hr on test.

Table II. Variance analysis

Time period (hr)	*F*	Significance level (%)
0-1000	10.05	95.3
1000-2000	9.92	95.2
2000-3000	1.22	55.0

significance level for each time period. Table III lists two-tailed probabilities derived from the t-test for the comparison of mean performance and shows that the ranking of felt treatments is significant in the early cycles, but the distinction becomes less clear at longer times.

The cell resistances were treated in the same way. Table IV lists the summary data. The resistances are quoted in the Ω-cm^2 form, derived by multiplying the total cell resistance by the area of beta-alumina carrying the current.

Although the trend is apparent in the early period that the cells can be ranked control<neutralized<oxidized in terms of resistance, variance analysis of the data indicated a significance of not greater than 82% at any time. A correlation between utilization and resistance is indicated, particularly in the first period, and this was evaluated by a least squares fit analysis of data. Table V gives the parameters in the linear regression equation $U = aR + b$, where U = utilization, R = resistance. "r" is the correlation coefficient for the regression which is seen to diminish with increasing time. The data is also shown graphically in Fig. 2.

Intercalated felt.—These cells were tested over a similar time period, but owing to experimental difficulties a limited amount of information was gathered during the period 1000-2000 hr. For this reason the data for these cells is grouped into only two periods for analysis, 0-1000 hr and 1000-3000 hr. Table VI lists the summary data for mean utilization, as a percentage of theoretical capacity. Only one cell of the $SbCl_5$ variant is quoted, the other having been recorded as an early failure. The data do not appear to indicate any correlation between cell type and performance, a conclusion borne out by the analysis of variance, which indicated less than 50% significance for either period. The resistance data also lacked any discernable trend, as shown in Table VII. Significant correlation with utilization was absent, the regression coefficients for a least squares fit being 0.2 and 0.4 for 0-1000 hr and 1000-3000 hr, respectively.

Discussion

For the first group of cells, the control cells gave consistently better performances than either of the pretreated variants. The differences between the groups were significant up to 2000 hr, but thereafter the confidence level diminished considerably. Considering these results in terms of the differential wetting hypothesis, one would conclude that the pretreatments enhance the preferential wetting of felt by sulfur, a result not unexpected. However there is an alternative interpretation which does not involve wetting effects. Sulfur is known to react with carbon surfaces at temperatures as low as 350°C (17, 18), giving rise to carbon-sulfur complexes of high stability, and accompanied by the evolution of small quantities of hydrogen sulfide and carbon disulfide. This chemical fixation of sulfur is hindered by the presence of oxygen (18, 19), suggesting some degree of competition for similar sites. It is highly likely, therefore, that a carbon surface saturated with oxygen functions will experience partial displacement of the oxygen on immersion in sulfur at 350°C, and the oxygen displaced therefrom will most likely be converted to sulfur dioxide. Mechanisms exist therefore whereby a sulfur electrode may contain vapor species which under the conditions of liquid flow set up during charging and discharging may combine to form macroscopic bubbles, as shown in Fig. 3. The presence of such bubbles will have a deleterious effect on sulfur utilization, by isolating reactive materials in pockets, as shown. Substantive evidence for this hypothesis may exist in the cell resistance data, for clearly any bubble large enough to isolate reactive material will also, by virtue of the "shadow" cast on the

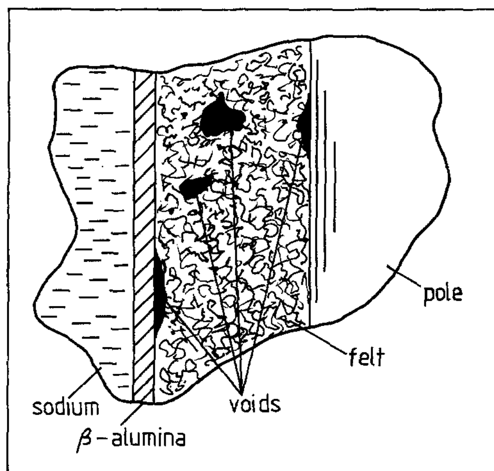

Fig. 3. Representation of the disposition of voids within the sulfur electrode.

electrolyte and pole, reduce the over-all conductance of the sulfur electrode. It is interesting, therefore, to note the correlation between utilization and resistance shown in Fig. 2 and tabulated in Table V. At short times the correlation is good, but becomes less clear over a longer period of test, as does the distinction between cell types, which indicates a common deterioration mechanism.

The cells which incorporated felts treated with intercalating agents did not appear to be distinguishable on the basis of utilization over 3000 hr. Neither did there appear to be the same relationship between utilization and resistance. The conclusion is drawn, therefore, that the variation in resistances for this group of cells must arise from a different cause to that proposed above. A likely cause of the variation is the contact resistance between the carbon pole and steel insert used in these cells, an enlarged detail of which is shown in Fig. 4. Carbon thread was compressed between the pole and the shoulder of the insert. The effectiveness of this arrangement in producing a reproducibly good contact between the two components was doubtful, and while it is not possible to state definitely that here was the cause of the variation in resistances, nevertheless it is a strong possibility.

One clear picture which emerged when the data for the oxidized/neutralized cells were compared with that for the intercalated cells was that superimposed on the performance variations within the two groups was a significant difference between them. In order to analyze this difference the data for the oxidized/neutralized cells were rearranged to cover the same time

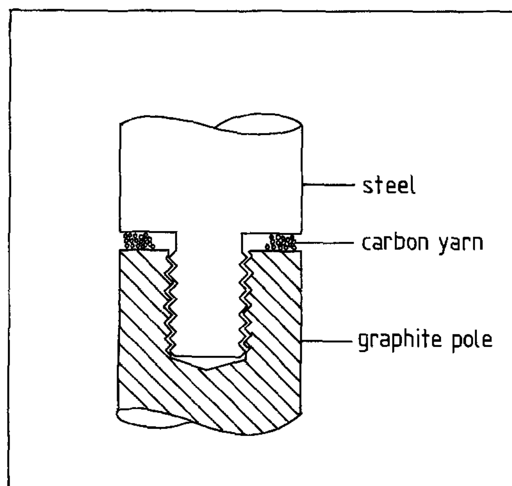

Fig. 4. The steel-to-carbon joint used on the current collectors of the later cells.

Table VIII. Mean utilization

581	CrO_2Cl_2	77.9	4.58	77.4	3.18

periods as the intercalated cells, viz., 0-1000 hr and 1000-3000 hr. Mean utilization data are summarized in Table VIII.

Comparison of the two groups by the Student's t-test revealed that the differences between groups were significant at the 99.3% level for the period 0-1000 hr, and at the 99.9% level for the period 1000-3000 hr. The superiority of the latter group at longer periods is shown also in Fig. 5, where utilization data for this group are given over 5000 hr of cycling. The same conclusion is reached if only the control cells in each group are compared, indicating that the differentiating factor is unrelated to the felt characteristics. It is most likely that the cause of the improved capacity retention in the second group of cells is the much better quality of the sulfur electrode seal which resulted from compressing the sealing O-ring against a smooth steel member in these cells, rather than against a graphite rod as in the first group. It is clear, therefore, that efforts directed at improving sulfur electrode performance should not be undertaken in poorly sealed cells even when the experimental period is limited to 1000 hr of cycling.

Insofar as utilization is concerned, none of the felt pretreatments resulted in an improvement in this parameter, and two of them were found to have an adverse effect. However in the case of the second group of cells, it is hardly surprising that the control cells were not surpassed in view of the remarkably good performances they exhibited. When one bears in mind the fact that the cells were cycled to an instantaneous open-circuit voltage value of 1.76V, the 20% utilization loss which most of these cells incurred is not an unreasonable amount to ascribe simply to polarization at the 5 hr rate. We believe that the sustained high utili-

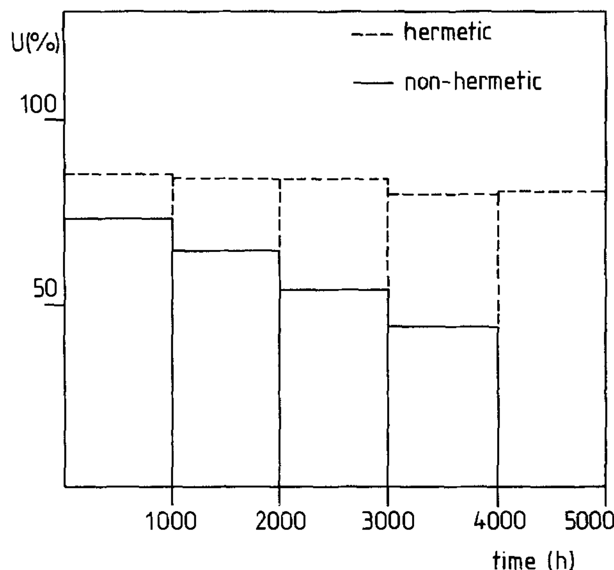

Fig. 5. A bar chart showing the mean percentage utilization (U) as a function of cell life for the hermetically sealed and non-hermetically sealed cells.

zation rates which these cells have operated at for more than a year now is a significant advance on the sulfur electrode position of 12 months ago, and gives tremendous encouragement for the further development of the sodium-sulfur battery to a commercially viable product.

Photooxidation of Water at α-Fe_2O_3 Electrodes

John H. Kennedy* and Karl W. Frese, Jr.

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Photoelectrochemical properties of high purity α-Fe_2O_3 and TiO_2-doped α-Fe_2O_3 were investigated. Photocurrent efficiencies were measured in various electrolytes and found to depend on the electrolyte used. Direct measurement of spectrophotometric absorption coefficients showed them to be significantly higher than those deduced from i-V curves indicating that only a fraction of the light absorbed resulted in electrochemically reactive holes. When the lower absorption coefficients were employed the current-potential curves could be fit within $\pm 1\%$ to the depletion layer theory of Gärtner.

Recent interest in the photoelectrochemistry of semiconductor electrodes has led to the discovery of new materials capable of sustaining the photoelectrolysis of water (see for example Ref. (1-3) and references contained therein). Among these materials is α-Fe_2O_3 with a sufficiently low bandgap to be of practical interest and first reported on as CVD films by Hardee and Bard (3, 4). Later, Quinn *et al.* (5) reported on the properties of the flux-grown single crystal α-Fe_2O_3. However, a detailed study of the photoelectrochemical properties of polycrystalline ceramic α-Fe_2O_3 has been lacking, and therefore a study of ultrapure and TiO_2-doped α-Fe_2O_3 was undertaken.

We report here: (*i*) the effects of electrolyte on measured photocurrent efficiencies; (*ii*) quantitative comparison of absorption coefficients from spectral and photoelectrochemical methods; (*iii*) the effects of donor density on photocurrent efficiency; and (*iv*) a fit of the i-V characteristics to the depletion layer theory of Gärtner (6). Flatband potentials and donor densities for the polycrystalline α-Fe_2O_3 electrodes in this study have been previously reported (7). These polycrystalline electrodes appear to behave in a similar fashion to single crystal electrodes including photocurrent efficiencies and flatband potentials.

Key words: absorption coefficient, α-Fe_2O_3, TiO_2-doped α-Fe_2O_3, photooxidation, water.

Experimental

Electrode preparation.—The details of the preparation of high purity (99.999%) and TiO_2-doped reagent α-Fe_2O_3 electrodes are given elsewhere (7).

Illumination.—The procedures used for monochromatic light intensity measurements are given elsewhere (2). Polychromatic light intensities, $300 \leq \lambda \leq 540$ nm $= E_g$, were determined with the Reinecke salt actinometer (8) for which the quantum yield ($\sim$0.30) is practically independent of wavelength. The equivalent photon current for the system including the 150W Xe lamp, infrared filter, and quartz lens was found to be 49.6 mA (300-540 nm) at the electrode surface. Lower light intensities were obtained using neutral density screens.

Electrical measurements.—The general cell arrangement, measurement of i-V curves, and calculation of photocurrent efficiencies were described previously (2).

Optical measurements.—The spectrophotometric absorption coefficient of polycrystalline α-Fe_2O_3 was measured using a KBr pellet technique (9-12). Pellets containing up to 500 ppm w/w α-Fe_2O_3 were made and had dimensions $\sim$0.03 cm thick $\times$ 1.29 cm diam. Absorbance measurements were made with a Beckman Model B spectrophotometer with a spectral slit width of $\leq$5 nm. Samples were run *vs.* a KBr blank

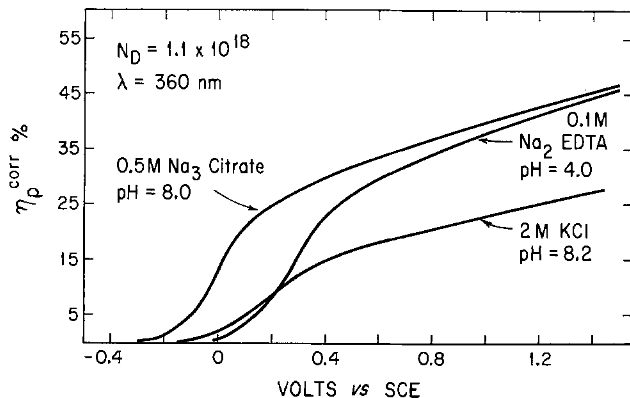

Fig. 1. Current-potential curves in various electrolytes. Polycrystalline α-Fe_2O_3; 23°C.

of comparable thickness utilizing a sample in-sample out technique. Suitable corrections for bulk scattering by α-Fe_2O_3 particles were applied and are discussed later.

Results

Photocurrent efficiency, η_p, curves obtained in 2*M* KCl, 0.1*M* Na_2 EDTA, and 0.5*M* Na_3 citrate are shown in Fig. 1. These efficiencies have been corrected for light reflection at the Fe_2O_3-solution interface according to well-known procedures (13). This correction amounted to 15-20%.

A significant enhancement of the efficiency was found for the chelating-type electrolytes. Comparison of the curves for citrate and EDTA solutions shows that the photocurrent efficiency is practically identical when compared at the same overvoltage. The rate of change of the potential at zero efficiency, V_o*, was −60 mV/*p*H. This potential (turn-on voltage) for the 2*M* KCl solution was 100 mV more anodic than the citrate solution at about the same *p*H (8.0 *vs.* 8.2), and the efficiencies at any given overvoltage in EDTA and citrate solutions were considerably higher than in KCl solution. Efficiencies comparable to those for KCl solutions were found in 0.5*M* Na_2SO_4 and 0.5*M* sodium acetate, and somewhat lower values in 0.5*M* KNO_3. The enhanced efficiency in the presence of citrate may be due to the interaction of these anions with the α-Fe_2O_3 electrodes and is discussed below.

The effect of the bulk citrate concentration on the increase in efficiency was investigated for three different electrodes resulting in qualitatively similar results as shown in Fig. 2. The effect had a threshold at 10^{-6}-10^{-5}M. The increase in efficiency was initially proportional to log[citrate]; with increasing concentration a saturation effect was observed. For all electrodes, both citrate and EDTA had no effect on the dark current at all concentrations studied. Finally, no effect was found with TiO_2 and $SrTiO_3$ polycrystalline electrodes, materials for which the valence bands are 0.7-0.8 eV below the valence band of α-Fe_2O_3.

Photocurrent efficiency curves at various wavelengths are shown in Fig. 3 for 0.5M citrate solution.

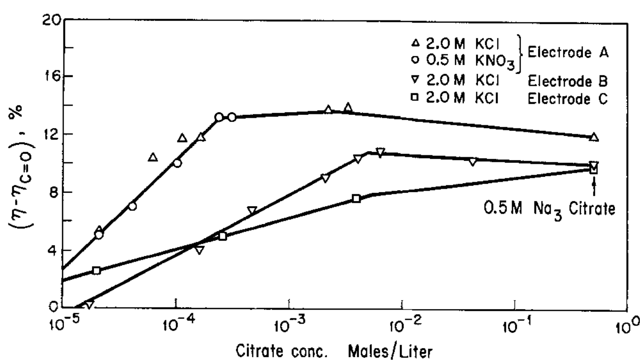

Fig. 2. Effect of bulk citrate concentration on photocurrent efficiency. 1.0V overvoltage; 23°C; 360 nm.

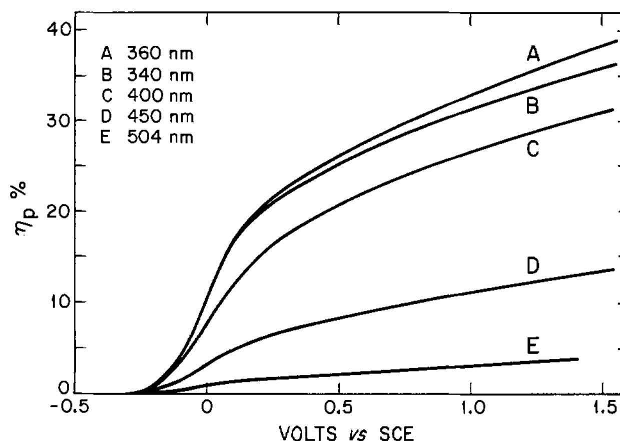

Fig. 3. Effect of wavelength on photocurrent efficiency. Polycrystalline α-Fe_2O_3; 0.5M Na_3 citrate; *p*H 8.0.

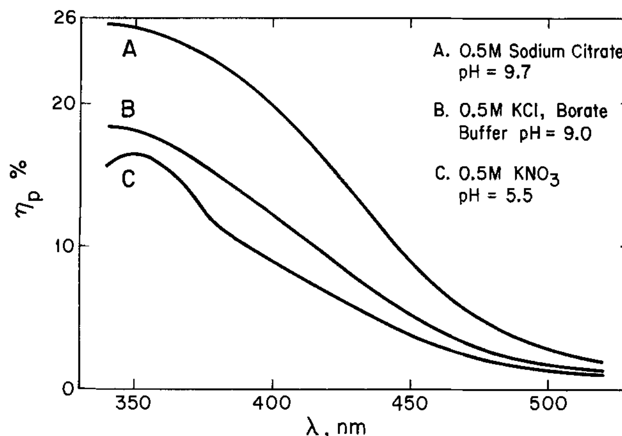

Fig. 4. Effect of electrolyte on photocurrent spectrum. 1.0V overvoltage; polycrystalline α-Fe_2O_3.

The photocurrent spectra in three different electrolytes are shown in Fig. 4. The relative efficiency in each electrolyte appears to follow the order of extent of surface adsorption (14) expected on the basis of chemical consideration. That is, the extent of complexing of the anions with Fe^{3+} should be in the order citrate > Cl^- > NO_3^-. A maximum in the photocurrent spectrum at ~350 nm is evident from Fig. 3 and 4. Light absorption by KNO_3 may be responsible for the more pronounced maximum for curve C in Fig. 4. Efficiencies observed in citrate and EDTA solutions agreed well with published (5) photocurrent efficiencies at single crystal α-Fe_2O_3 electrodes.

Photocurrent efficiencies for polychromatic light (300-540 nm) are shown in Fig. 5 at various *p*H

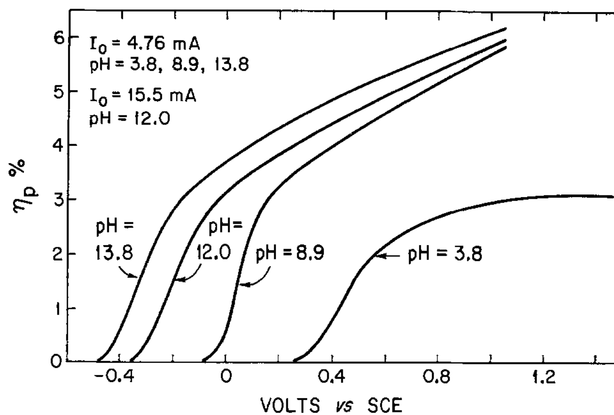

Fig. 5. Effect of *p*H on photocurrent efficiency for polychromatic light. Polycrystalline α-Fe_2O_3; 23°C.

values. In basic solutions the i-V characteristics were nearly identical showing a lack of saturation and comparable efficiencies at the same overvoltage. At pH 3.8, on the other hand, the efficiency was considerably lower and tended toward a saturation value. This could reflect a change in the rate-limiting step at high light intensities from solid-state process control (diffusion and/or conduction) to electron transfer control at the semiconductor-electrolyte interface. This change in mechanism could occur because of a reduced concentration of oxidizable species (*e.g.*, OH^-) either at the electrode surface or at the outer Helmholtz plane. It should be noted that the polychromatic light intensity of 4.76 mA in Fig. 5 was about 60 times the monochromatic intensity at 400 nm in Fig. 3 and 4.

Some experiments were carried out at higher light intensities utilizing the complete photosensitive range of α-Fe_2O_3. The variation of photocurrent with light intensity at 1.0V overvoltage is shown in Fig. 6. For both low intensity monochromatic light (lower line) and for high intensity polychromatic light (upper line) the photocurrent was proportional to the first power of light intensity within experimental error. This result shows that one photogenerated hole is involved in the rate-limiting step of the over-all electrode process.

Data for α-Fe_2O_3 highly doped with TiO_2 are shown in Fig 7 in which photocurrent efficiency at $(V - V_{fb}) = 1.25V$ is compared with doping level. The points for $N_d > 10^{19}$ cc^{-1} correspond to TiO_2 levels of 0.05-2.0% (Ti/Fe). The donor densities calculated from doping stoichiometry agreed well with N_d calculated from Mott-Schottky plots reported previously (7). The i-V curves for these samples were characterized by a sudden onset of a large dark current similar to those observed by Hardee and Bard (4). It was observed that lower doped samples exhibited less dark current under similar conditions. After subtraction of the dark current, normal-shaped i-V curves were obtained except that the turn-on voltage was shifted several tenths of a volt anodic, the shift increasing with TiO_2 concentration. This effect was probably due to the narrow-space charge layer at low overvoltages, resulting in photocurrents too small to be measured until sufficient space charge depth was established. However, an anodic shift of the flatband potential with the high level doping cannot be ruled out.

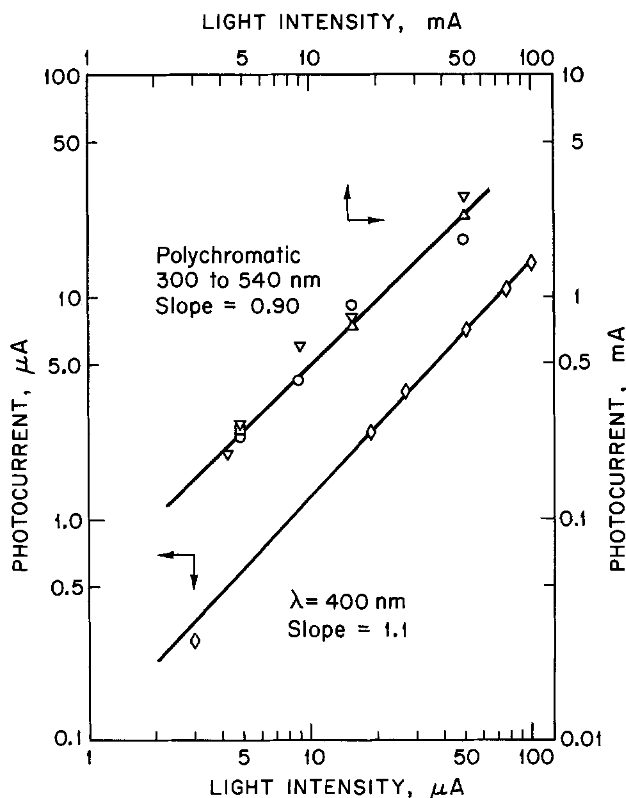

Fig. 6. Effect of light intensity on photocurrent. 1.0V overvoltage

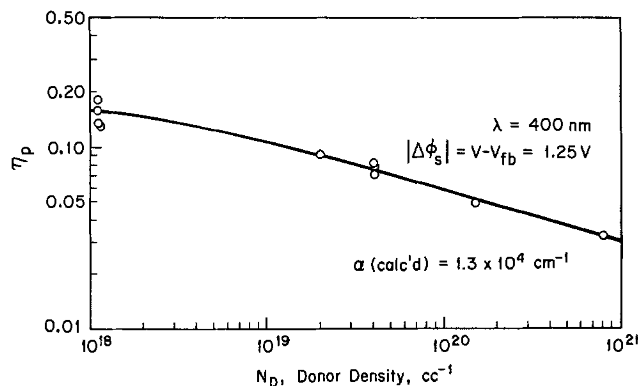

Fig. 7. Effect of donor density on photocurrent efficiency. Polycrystalline α-Fe_2O_3.

Absorption coefficients obtained directly from spectrophotometric data are shown in Fig. 8 (curve A) and compared with apparent absorption coefficients (Fig. 8, curve B) obtained by fitting the current-potential curves to the depletion layer theory of Gärtner (6). The spectrophotometric data are in good agreement with published data (15, 16) for polycrystalline α-Fe_2O_3 films. Correction for bulk scattering was made by assuming the validity of the equation

$$I = I_0 \exp - (St_1 + \alpha t_2) \quad [1]$$

where I and I_0 are the transmitted and incident light intensities, S is the coefficient of scattering, α is the absorption coefficient, t_1 is the KBr pellet thickness, and t_2 is the apparent thickness of the α-Fe_2O_3 (volume of Fe_2O_3 in pellet/pellet area).

The scattering coefficient is related to scattering particle properties through the relation (17)

$$S = \pi a^2 N Q_S \quad [2]$$

where a is the particle radius (assumed spherical), N is the particle density, cc^{-1}, and Q_S is the dimensionless efficiency factor for scattering. The efficiency factor represents the ratio of the effective surface area of a sphere which is available for light scattering to the cross-sectional area (18). In the limit of geometrical optics $Q_S \rightarrow 2$. Calculation of Q_S from the Mie scattering theory (17) is an involved but straightforward procedure. However, La Mer *et al.* (19) dis-

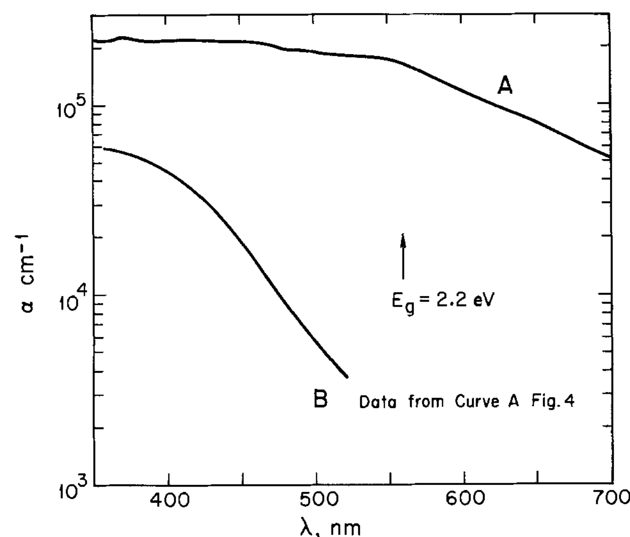

Fig. 8. Comparison of absorption coefficients calculated from spectral data and current-potential curves. Polycrystalline α-Fe_2O_3; 23°C. (A) Absorption coefficient from direct measurement. (B) Absorption coefficient calculated from photocurrent.

covered that both Mie calculations and their experimental values of Q_S could be plotted on one curve forming a universal scattering curve. The curve (18, 19) shows Q_S (K_S their notation) plotted *vs.* the dimensionless parameter, $[n_1 d/\lambda (m^2 - 1)/(m^2 + 2)]$, where m is the relative refractive index, n_2/n_1; n_1 is the refractive index of the medium; n_2 is the refractive index of the scattering particle; and d/λ is the ratio of scattering particle diameter to the wavelength of light. The iron oxide particles were found by microscopic examination to have a diameter of 2.0 ± 0.5 μm. With $m = 3.0/1.56 = 1.9$, Q_S becomes a constant value of 2.0 for the wavelengths studied.

It is seen from Fig. 8 that in the case of α-Fe_2O_3 the absorption coefficient from optical measurements does not correspond to the absorption coefficient for the excitation process giving rise to the photocurrent. Further discussion of this point is given later.

Discussion

The mechanism by which complexing ions such as citrate and EDTA enhance the photocurrent at α-Fe_2O_3 electrodes is not known. However, the effect of citrate concentration on the increase in photocurrent followed a Temkin isotherm relationship. For intermediate coverage, $0.2 < \theta < 0.8$, the isotherm is usually written as (20)

$$r\theta = -q\Delta\phi + kT \ln K + kT \ln c \quad [3]$$

where r is an interaction energy parameter, θ is the surface coverage, $\Delta\phi$ is the potential difference between the electrode surface and the solution, K is the equilibrium constant for adsorption in the absence of interaction between the adsorbing particles, and c is the bulk concentration of adsorbate. If it may be assumed that the increase in photocurrent efficiency is proportional to surface coverage, then $\eta - \eta_{c=0} \propto \ln$ [citrate] and Eq. [3] accounts for the linear portions of the curves in Fig. 2. The saturation effect is of course a property of the Langmuir isotherm which applies as $\theta \rightarrow 1$. The results did vary for different electrodes as can be seen in Fig. 2 even when compared in the same electrolyte, and they probably reflect the different surface conditions present. Consideration of these observations makes specific adsorption of citrate and EDTA on α-Fe_2O_3 a reasonable conclusion especially in view of the very high stability constants for these ions with Fe^{3+} in aqueous solution.

It would be expected that specific adsorption of strong complexing anions might shift the turn-on voltage and thereby cause an increase in photoefficiency. In actual fact, the flatband potentials and turn-on voltages did not shift sufficiently (<100 mV) to cause the observed change in efficiency. In addition, the efficiencies were measured at a given overvoltage so that any change in turn-on voltage would not be included. However, because the higher energy level of the valence bandedge of α-Fe_2O_3 compared to TiO_2 or $SrTiO_3$ may result in better energy overlap, photooxidation of citrate and EDTA by photogenerated holes at the α-Fe_2O_3 surface cannot be ruled out without evidence of the reaction products distribution in the various electrolytes. The additional possibility of "current doubling" also exists. In this mechanism (21, 22) photooxidation by a hole in the valence band leads to a radical species which then injects an electron into the conduction band in a chemical step. Thus two current carriers are produced for a single photon leading to the term "current doubling." This reaction is well known on other semiconductors with reactants containing the carboxylate group. This mechanism would lead to decomposition of the citrate or EDTA solute and probably not enhance the oxidation of water. Again, detection of decomposition products is needed and will be investigated in the future.

The η_p-V curves (*e.g.*, Fig. 1 and 3) were fit to the depletion layer theory of Gärtner (6) which leads to the following equation for the photocurrent efficiency

$$\eta_p = 1 - \exp(-\alpha L)/(1 + \alpha Lp) \quad [4]$$

In a previous (2) the application of this equation to i-V-λ data for polycrystalline $BaTiO_3$ electrodes was discussed and it was shown how Lp and N_d could be calculated using the following equation

$$\ln(1 - \eta_p^{corr}) = -\alpha \left(\frac{2\epsilon\epsilon_0}{qN_d}\right)^{1/2} (V - V_o^*)^{1/2} - \ln(1 + \alpha Lp) \quad [5]$$

A similar approach was taken with α-Fe_2O_3 data except that V_o^* has now been taken as a best fit parameter for the plots of $\ln(1 - \eta_p^{corr})$ *vs.* $(V - V_o^*)^{1/2}$, and values of N_d from Mott-Schottky plots (7) were used to calculate α, the absorption coefficient for the process giving rise to active holes. Equation [5] was applied for $(V - V_o^*) \gtrsim 250$ mV.

In order to obtain a good fit at low overvoltages (<250 mV) Eq. [4] was used with the value of L calculated from the parallel plate capacitor Eq. [23]

$$L = \frac{\epsilon\epsilon_0}{C} \quad [6]$$

where C is given by the more general equation of Dewald (24)

$$C = \left(\frac{q^2 N_d \epsilon\epsilon_0}{2kT}\right)^{1/2} \frac{|e^y - 1|}{(e^y - y - 1)^{1/2}} \quad [7]$$

The term y measures the space charge overvoltage, *i.e.*, $y = q\Delta\phi_S/kT$ and is negative for anodic bias. It was assumed that

$$V - V_o^* = |\Delta\phi_S| \quad [8]$$

Equations [6] and [7] give the more familiar $|\Delta\phi_S|^{1/2}$ dependence for L under sufficient anodic bias corresponding to the Mott-Schottky regime. Typical calculated curves are compared with experimental points in Fig. 9. The experimental data correspond to those in Fig. 3 and have been corrected for reflection. The fit is seen to be usually ±1% even at low overvoltages. The values for the various quantities determined from the data are summarized in Table I. An important point not yet fully understood is that V_o^* from best fit did not correspond to the flatband potential or the turn-on voltage for the photocurrent but was several tenths of a volt more anodic. This may be due in part to the fact that the Gärtner model implies an irreversible photocurrent. That is, no account is taken of possible cathodic current either in the valence band or conduction band. These effects would become more important at electrode potentials near the point of zero photocurrent.

It was also found that the theory could be fit to data with polychromatic light even though the theory was derived for monochromatic light. From this fit the calculated absorption coefficient was 1×10^4 cm^{-1} as would be expected if α represented some sort of

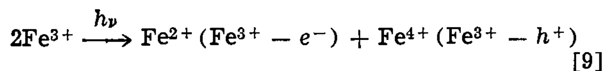
* Polychromatic light (300-540 nm), intensity 4.76 mA.

average value over the 300-540 nm spectral range. The diffusion lengths found for α-Fe_2O_3 were 2-4 $\times$ 10^{-7} cm and were considerably lower than values found for TiO_2 (1×10^{-5} cm) and the barium and strontium titrates ($3\text{-}6 \times 10^{-6}$ cm) (25). Possible reasons for these differences will be discussed in a future publication.

The absorption coefficients calculated from the data in Fig. 8 curve A using Eq. [5] and Lp data from Table I and Mott-Schottky values for N_d are compared with spectrophotometric α in Fig. 8. It is seen that the absorption coefficient from optical measurements did not correspond to the absorption coefficient for the excitation process giving rise to the photocurrent. It is reasonable to presume that the absorption coefficient derived from i-V characteristics corresponds to the ligand to metal-charge transfer ($O^{2-} \rightarrow Fe^{3+}$), yielding reactive holes on the oxygen sites (valence band). The spectrophotometric measurements show that another process with comparable absorption is occurring, *i.e.*, there is an overlap of at least two absorption bands. The large absorption coefficient indicated for this overlapping process may mean that another type of charge transfer is occurring—possibly metal to metal, which can be envisaged as



$$2Fe^{3+} \xrightarrow{h\nu} Fe^{2+}(Fe^{3+} - e^-) + Fe^{4+}(Fe^{3+} - h^+) \quad [9]$$

This process would give rise to a second type of hole, now on an iron site with a different energy level than the hole in the oxygen valence band. Indeed it has been suggested (27, 28) that this process is responsible for the intrinsic conductivity in α-Fe_2O_3 with $E_g \sim 1.7\text{-}2.0$ eV. The Fe^{4+} hole may no longer be capable of evolving oxygen from water while at the same time the electron trapped on iron (Fe^{2+}) may not be free to conduct and therefore would yield no photocurrent.

The validity of using absorption coefficients determined from i-V curves is supported by the plot shown in Fig. 10 calculated from data in curve B, Fig. 8. It is well known that for semiconductors the dependence of α on energy near the absorption edge usually follows the form (28)

$$\alpha h\nu = A(h\nu - E_g)^{n/2} \quad [10]$$

where A is a constant and n depends on the nature of the transition ($n = 1$ for a direct transition and $n = 4$ for an indirect transition). The slope in Fig. 10 is 2.07 giving $n = 4.1$, indicating an indirect transition requiring phonon support.

A further test of the plausibility of the absorption coefficient found for α-Fe_2O_3 was made by plotting the data in Fig. 7 in the form

$$\ln(1 - \eta_p^{corr}) = -\alpha\left(\frac{2\epsilon\epsilon_0\Delta\phi_S}{q}\right)^{1/2} \Big/ N_d^{1/2} - \ln(1 + \alpha Lp) \quad [11]$$

For $\lambda = 400$ nm, α was found to be 1.3×10^4 cm^{-1} in reasonable agreement with the value of 4.4×10^4 cm^{-1} from Fig. 8. This result supports the conclusion stated earlier that α for the charge transfer process

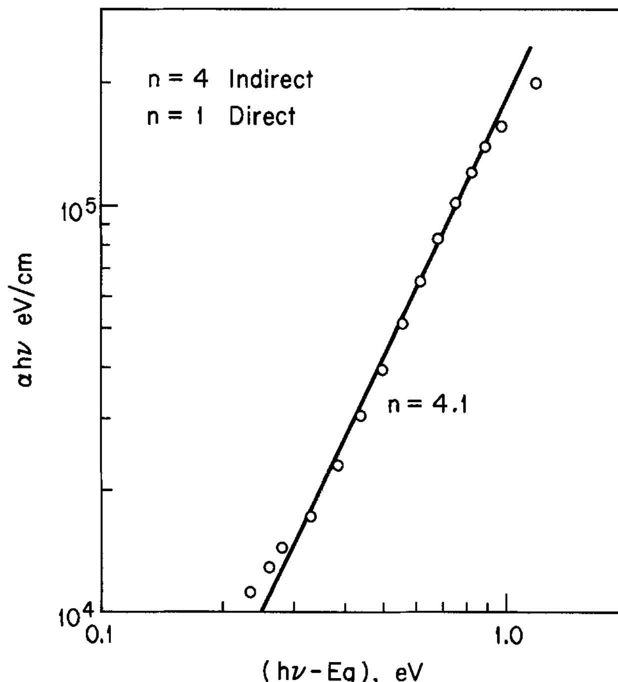


Fig. 10. Test for nature of electronic transition on absorption edge. Polycrystalline α-Fe_2O_3.

leading to photocurrent is considerably smaller than the spectrophotometric value.

ABSTRACT

The authors' d.c.-polarographic study [*Anal. Chim. Acta.* **82**, 29 (1976)] has been extended to include a coulometric investigation of the cathodic reduction of six substituted dinitroanilines: 4-(trifluoromethyl)-2,6-dinitro-*N*,*N*-dipropylaniline (I) was measured in 40% aqueous ethanol buffered at four *p*H values (1.5, 5.1, 7.4, 9.2), and *N*-butyl-*N*-ethyl-4-(trifluoromethyl)-2,6-dinitroaniline (II), 2,6-dinitro-4-isopropyl-*N*,*N*-dipropylaniline (III), N^1,N^1-diethyl-4-(trifluoromethyl)-2,6-dinitro-*m*-phenylenediamine (IV), 4-(methylsulfonyl)-2,6-dinitro-*N*,*N*-dipropylaniline (V), and 3,5-dinitro-N^4,N^4-dipropylsulfanilamide (VI) were measured in 40% aqueous ethanol buffered at one *p*H value (1.5). Preparative scale runs and product analyses indicate that the electroreduction mechanism is *p*H dependent, as evidenced by substantial benzimidazole formation at 1.5 *p*H and little production of this compound at 7.4 *p*H.

Controlled potential coulometry (1-4) utilizes the modern instrumental capabilities of potentiostats and is a powerful electroanalytical technique that makes possible the elucidation of certain chemical reaction paths by allowing direct measurement of the number of Faradays taken up by a given amount of a compound (5-7). Similar information has been obtained on occasion from d-c polarograms (8-10); whereas in favorable circumstances, it is possible to arrive at the correct number of electrons involved (n), examination of the Ilkovic equation

$$i_d = kncD^{1/2}m^{2/3}t^{1/6}$$

reveals that n can be expressed only in terms of several constants or parameters whose cumulative uncertainty affects n. Indeed, it is customary to use the Ilkovic equation to find the diffusion coefficient D—a procedure which in turn assumes that n is known. An alternative procedure that uses the slope of a polarogram to find n is not applicable to quasireversible systems, and hence to many systems, including the substituted dinitroanilines of our study.

Coulometry in nonaqueous media often employs electrodes fabricated from the platinum metal family (5), but in aqueous solvents the problem of hydrogen discharge curtails their utility and mercury becomes the common choice, as was discussed in the report of our previous polarographic study (11). It should be mentioned that there are specific problems associated with controlled potential coulometry and large mercury pool cathodes; these are discussed later on in the paper.

[1] Present address: Visiting Exchange Scientist, U.S. National Academy of Sciences—Hungarian Academy of Sciences, Szeged, Hungary.

Key words: cathodic reduction, controlled potential coulometry, mercury pool, substituted dinitroaniline.

Experimental

The general instrumental link-up in the coulometric experiments is presented in a simplified manner in Fig. 1. A buffered ethanol:water solution (40%:60% by vol.) similar to the polarographic solutions discussed previously (11), containing 50.0 μmoles of solute in the 150 ml total volume used in the "working" compartment of the coulometry cell (Fig. 2), was thoroughly

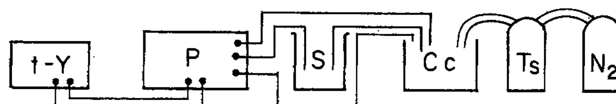

Fig. 1. Simplified block diagram of instrumental layout. Legend: *t-Y:* time-base X-Y recorder; P: potentiostat; S: silver coulometer; Cc: coulometry cell; Ts: bubbler-tower containing ethanol:water; N_2: purging gas tank.

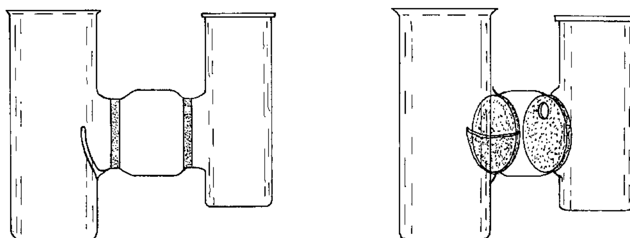

Fig. 2. Coulometry cell

purged with nitrogen, followed by applying a potential selected as appropriate from known $E_{1/2}$ values (11) in the three-electron mode. The actual mercury pool cathode (working electrode)-platinum coil anode (auxiliary electrode) voltage, reflecting IR losses due to the two medium porosity frits as well as solution resistance, was intermittently monitored with a Hewlett-Packard[2] 34703A/34740A DCV/DCA/Ω measurement system (the maximum voltage recorded was ~20V, far short for causing troublesome voltage-limiting conditions with the GBE Wenking 61-R potentiostat). In a number of experiments, the current output of the potentiostat was recorded on a Hewlett-Packard 7044-A X-Y recorder equipped with a time-base accessory. Because of the full-current output feature of the Wenking 61-R, measuring resistors and multipole switches were selected with special care. Product analysis for compound (I) at pH 1.5 and 7.4 was performed using a Perkin-Elmer 621 spectrophotometer and Varian HA-100 NMR spectrometer.

The coulometry cell (Fig. 2) containing the alcohol: water mixtures was preceded by a saturation tower containing a similar alcohol: water mixture, so that the purging nitrogen gas would not significantly alter the composition of the mixed solvent. A special feature of the coulometry cell was the glass lip protruding from the frit toward the center of the cathodic compartment; its purpose was to reduce the voltage drop along the surface of the mercury pool as a function of distance from the frit.

In a typical experiment, the 100 ml solution (60 ml aq. buffer + 40 ml ethanol) to be used in the auxiliary compartment and the 145 ml solution (90 ml aq. buffer + 55 ml ethanol) to be used in the working compartment were deaerated for 1 hr in separatory funnels placed above the coulometry cell; simultaneously, the coulometry cell itself was purged with N_2. After deaeration, the solutions were introduced and the background current was measured under the chosen conditions of stirring rate and applied potential; values ranged between 40 and 70 μA, with an observable slight decrease with time. Addition of 5 ml of alcohol containing the 50.0 μmoles of solute produced initial currents of less than 20 mA; electrolysis was continued past the 99% completion stage to background. Total time for an experiment was 12-15 hr, with the exception of silver coulometry and preparative scale (100 mg solute) runs which required up to 24 hr.

Silver coulometry was done using a 250 ml beaker containing 150 ml solution, 1M in $AgNO_3$ and 5M in $NaNO_3$ (alternately, 1M $AgNO_3$ and 2M KCN). The outside of the beaker was taped with black PVC tape to prevent photochemical decomposition and the top was also shielded from direct light. The electrodes (Ag wire or Ag foil) were suspended from a ⅛ in. diam glass rod that had an elongated W shape, and fit reasonably snugly on the spout and beaker rim. (Ideally the least number of sharp surfaces should produce best results, and the foil is preferable to the coiled wire.)

[2] Mention of tradenames is for the convenience of the reader and does not constitute any preferential endorsement by the U.S. Department of Agriculture over similar products available.

Only about 2/3 of the electrode was immersed in the solution to protect the contacts; voltage drop across the system, connected in series onto the auxiliary electrode, was about 2V. In silver coulometry weight is measured before the experiment, and after the experiment the electrodes are removed with Teflon-tipped forceps, washed thoroughly and gently in a stream of distilled water followed by acetone, then dried for 15 min at 50°C before weighing again. For reuse the electrodes were soaked in 1M KCN for over an hour, and the gaining electrode was polished with a piece of fine sandpaper (00) to remove loosely adhering silver. The losing electrode will eventually need replacement—for best results the two electrodes should never be interchanged. By measuring both the loss and gain values of the electrodes, a precision better than 0.5 mg was routinely observed, and with special care 0.1 mg can be expected according to our results. In case of higher discrepancy the loss figure was regarded as the more accurate because the gaining electrode often acquires crystalline deposition which may not adhere.

The present report is based on 56 coulometric determinations, with 36 runs on 4-(trifluoromethyl)-2,6-dinitro-N,N-dipropylaniline (I). Nine out of the 36 runs were preparative scale, including isolation and identification of product. Additional information concerning experiments is given in Table I and the following section.

Results and Discussion

Appropriate voltages for use in controlled potential coulometry can be selected from polarographic or sweep voltammetric information. Our polarographic study (11) gave the following $E_{1/2}$ values (−mV *vs.* SCE) at pH 1.5, 5.1, 7.4, and 9.2, respectively: (I) 190, 430, 700, 810; (II) 190, 430, 700, 810; (III) 170, 360, 720, 810; (IV) 230, 510, 720, 1010; (V) 160, 480, 710, 790; (VI) 160, 530, 680, 810. These values correspond to the second polarographic wave when it was distinguishable; at pH = 1.5 all compounds displayed a single wave whose height closely corresponded to the sum of the two wave heights for the compound observed at the higher pH's. A salient feature of the polarograms was the similarity in which pH affected all six compounds; for this reason, we felt that the essential coulometric information could be obtained by investigating all compounds at one pH and, in addition, one compound at all four pH's. The results are given in Table I.

The difference between our combined average value of ne^- ($7.53 \pm 0.16_6$) and the $8e^-$ required ideally to reach the dihydroxylamine stage was large enough that we interpret the difference as an indication of some kinetic perturbation rather than as an instrumental artifact. The assignment of two $4e^-$ reduction steps (11) on the basis of simple d-c polarography is, therefore, seen in the perspective of coulometry as a close approximation rather than an ultimate conclusion.

The chemistry of nitroaromatics is known to be complex. Peltier and his co-workers (12-14) have extensively studied the controlled potential electroreduction of a large number of substituted mono- and dinitro

Table I. Summary of coulometric experiments

Compound	E(V *vs.* SCE)	pH	ne^-
4-(trifluoromethyl)-2,6-dinitro-N,N-dipropylaniline (I)*	−0.600	1.5	7.45
	−0.700	5.1	7.74

* Preparative scale runs gave ne^- value estimates that compare favorably: pH 1.5: 7.43 (5 runs); pH 7.4: 7.68 (3 runs).
** Standard deviation of the mean.

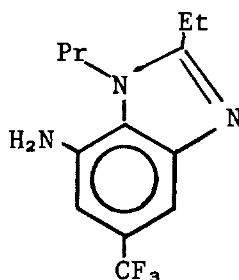
compounds. Their investigations, which included product identification, give evidence of the stepwise reduction of nitroaromatics. Their work also reveals complicating factors; n-values less than the theoretical seem to be characteristic of the nitroanilines.

Further insight into the electrochemistry of nitroaromatics is provided by the classical example of the reduction of picric acid in HCl; Lingane (2) found that 34 electrons are involved in the production of the primary product bis-(3,5-diamino-4-hydroxyphenyl) hydrazine, but subsequently Bergman and James (15), as well as Meites and Meites (16), demonstrated that ne^- is a function of both the initial picric acid concentration and the hydrochloric acid concentration.

In order to analyze the products of the pH 1.5 reduction, the pH of the reaction solution was adjusted to 7, the ethanol removed with a nitrogen stream, and the aqueous residue extracted with ether. Drying the extract with sodium sulfate and evaporation to dryness with nitrogen yielded an oily-solid red-brown residue. Thin layer chromatography (silica gel GF-254, benzene: ethyl acetate, 2:1) of the residue showed several u.v.-absorbing (254 nm) spots along the length of the plate and a single major spot ($R_f = 0.14$) which exhibited bright blue fluorescence under u.v. light. The residue gave the following spectroscopic data: infrared (film) 1620 cm^{-1}; NMR ($CDCl_3$) δ 7.50 (*s*, 1, ArH), 6.72 (*s*, 1, ArH), 4.20 (*t*, 2, CH_2), 3.75 (broad, 2, NH_2), 2.85 (quadruplet, 2, CH_2), 1.87 (*m*, 2, CH_2), 1.44 (*t*, 3, CH_3), and 0.99 ppm (*t*, 3, CH_3). These peaks in the NMR spectrum were observed almost to the exclusion of other absorptions and are similar to those reported for 2-ethyl-7-nitro-1-propyl-5-trifluoromethylbenzimidazole by Leitis and Crosby (17), who identified the benzimidazole as a product of the photochemical degradation of compound I.

Preparative thin layer chromatography of the residue on silica gel by developing three times with benzene: ethyl acetate, 2:1, afforded a chromatogram with the blue fluorescent spot at R_f 0.31-0.44. From this area a pale yellow solid was isolated which gave the following mass spectrum, m/e (%); 272 (15), 271 (100, M+), 256 (22), 252 (11), 243 (14), 242 (92), 229 (74), 228 (44), 227 (18), 214 (31), (212 (12), 159 (10).

We conclude from these spectroscopic data that the major product of the pH 1.5 reduction is 7-amino-2-ethyl-1-propyl-5-trifluoromethylbenzimidazole, compound VII



VII

Identification of a benzimidazole in our work at low pH is consistent with the studies of Peltier and co-workers (12c, 14), who observed benzimidazole formation in the electrochemical reduction of N,N-disubstituted-o-nitroanilines in 1N sulfuric acid: ethanol, 1:1.

The pH 7.4 reaction was worked up in a similar manner except without adjustment of the pH before ether extraction. Thin layer chromatography of the residue showed several u.v.-absorbing spots and a small fluorescent blue spot at $R_f = 0.14$. In addition to benzimidazole peaks, which were usually minor, the NMR spectrum ($CDCl_3$) of the resulting residue showed the following singlets in the aromatic region: δ7.68, 7.45, 7.14, 6.99, 6.73, 6.68, and 6.56 ppm. From one reaction to another the relative sizes of these peaks varied. We are continuing our study of the products of the pH 7.4 reduction. With regard to our NMR work, we plan to look into temperature-δ relationships for additional analytical capability.

Although the compounds of the present study are amenable to photodecomposition (17, 18), we found no evidence that exclusion of roomlight altered the polarographic or coulometric results at any of the four pH values. To our knowledge a converse study, involving the electrochemical investigation of photolysis products of these compounds (I-VI), has not been reported.

Conclusion

The present coulometric study of the number of electrons involved in the cathodic reduction of the substituted dinitroanilines, 4-(trifluoromethyl)-2,6-dinitro-*N,N*-dipropylaniline; *N*-butyl-*N*-ethyl-4-(trifluoromethyl)-2,6-dinitroaniline; 2,6-dinitro-4-isopropyl-*N,N*-dipropylaniline; N^1,N^1-diethyl-4-(trifluoromethyl)-2,6-dinitro-*m*-phenylenediamine; 4-(methylsulfonyl)-2,6-dinitro-*N,N*-dipropylaniline; and 3,5-dinitro-N^4 N^4-dipropylsulfanilamide in aqueous ethanol gave n values in close agreement with those previously estimated from polarographic measurements. The slight deviation of the experimentally obtained n value ([7.53 ± 0.16$_6$] e^-) from the number of electrons ideally required to reach the dihydroxylamine form (8e^-) is considered to be of chemical rather than artifactual origin and is not unexpected in view of the known complex chemistry of the species involved. The coulometric results necessitate a refinement of the previous mechanistic interpretation (11) based on d.c. polarography. Although there is only a relatively slight change in n values as a function of pH, preparative scale runs and product analyses reveal that the apparent merging of the two polarographic waves at low pH in effect involves a change in the reduction mechanism. Results of a separate study planned to provide information on this detail with the aid of additional electroanalytical techniques (5) will be presented subsequently.

Kinetics of the Electrochemical Reduction of Dicyanoaurate

E. T. Eisenmann

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

The mechanism of the electrochemical reduction of dicyanoaurate was studied by means of steady-state and relaxation methods in combination with a rotating disk electrode. The deposition of soft gold, lead-doped soft gold and cobalt-hardened gold was found to proceed via one common mechanism that involves adsorption equilibria preceding and following the electron transfer step. Special effects, such as epitaxy and preferred orientation of soft gold, the small-grained texture of hard gold, and the lead-induced depolarization of soft gold plating are explained in terms of the energetic states of the adsorbed, oxidized, and reduced gold species. The effect of lead is to lower the activation energy of the electron transfer, which results in the accelerated establishment of a preferred orientation. Cobalt increases the activation energy of the electron transfer and gives rise to a high nucleation rate. The proposed mechanism is shown to explain equally well the anodic behavior of gold in alkaline cyanide electrolyte.

The importance of gold plating in electronic device technology has led to greatly diversified, usually proprietary plating formulations. Yet apart from the description of particular bath features, there is a definite scarcity of the documentation of fundamental processes involved in the electrodeposition of gold. Cheh and Sard (1) used galvanostatic techniques to study the morphology of gold deposits on a rotating-disk electrode from various electrolytes. Harrison and Thompson (2) employed voltammetric techniques and postulate a reaction mechanism that involves AuCN as reacting species. Recently, McIntyre and Peck (3) reported with considerable detail on the depolarization of the deposition of soft gold through heavy metal ions. Numerous publications are available on the effects of codeposited impurities on the physical properties of gold plates (4-6). The review of the literature indicates that kinetic studies have been practically limited to soft gold systems. Although soft gold as well as hard gold is almost universally deposited from electrolytes containing dicyanoaurate, there is no indication that a unifying kinetic study of the two types of gold baths was ever attempted. Recent work on the deposition of gold on the reeds of sealed contacts (7) suggested such a unifying study. Using predominantly potentiostatic, steady-state, and relaxation techniques in combination with a rotating-disk electrode various aspects of the electrode kinetics were investigated.

Experimental

The following solutions were used in the present study: (*i*) Commercial hard gold baths (Selrex CI and Technic Orosene 999), operated at pH = 4 and 30°C; (*ii*) Soft gold bath, containing 0.1M $KAu(CN)_2$, 0.3M potassium phosphate, and no or 2 ppm Pb, operated at pH = 7 and 30°C or 65°C. Polarization measurements were carried out in these electrolytes either with Pt rods of 0.5 cm^2 area (under constant convection) or with a rotating Pt disk of 0.32 cm^2.

It was assumed that the gold deposition would usually proceed with less than 100% current efficiency. The gold partial currents were, therefore, determined by means of a coulometric analysis of the gold deposit. This approach was, evidently, quite time consuming and precluded current or voltage scanning techniques. It is believed, however, that superior accuracy of the data was achieved in this manner.

Key words: electrocrystallization, electrode adsorption processes, epitaxy, lead-induced depolarization.

Potentiostatic Polarization

A Pt disk electrode was polarized under constant potential conditions for various lengths of time in the electrolytes described above. The gold partial currents were evaluated from plots of the (coulometrically determined) electrical equivalents of the gold deposits *vs.* the plating time. For the hard gold baths, these plots were found to yield straight lines, indicating that the gold partial current at constant potential is independent of the plating time. In contrast to this behavior, the same kind of plots for soft gold deposition were curved, corresponding to an acceleration of the rate of deposition with time.

The slopes of the straight lines obtained for one of the hard gold baths and the limiting slopes of the curves at short plating times obtained for the soft gold baths were plotted semilogarithmically *vs.* the deposition potential, Fig. 1. The straight portions of these curves have slopes of $-4.4V^{-1}$ at 30°C and $-3.6V^{-1}$ at 65°C, the difference being accountable by the thermal energy difference. The shift in the deposition potential at equal current density for soft gold at 65° and 30°C is explained by the increased solubility of HCN at the lower temperature, which results in a decrease of the equilibrium potential. The similar shift observed for hard gold *vs.* soft gold at 30°C may be due to any of several differences in the makeup of the baths. However, because of the very striking difference in the grain size of the two types of gold deposits, it is postulated that the cobalt content in the hard gold bath increases the activation energy of the electron transfer, and consequently the nucleation rate of the gold deposition.

Time Dependence of the Deposition Rate

The observed increase of the deposition rate of soft gold with time at constant potential corresponds to the "depolarization effect" studied by various authors (8, 9) under galvanostatic conditions. Since it was unknown to what extent the soft gold bath was contaminated with heavy metal ions, which are capable of inducing the depolarization, an addition of 2 ppm lead

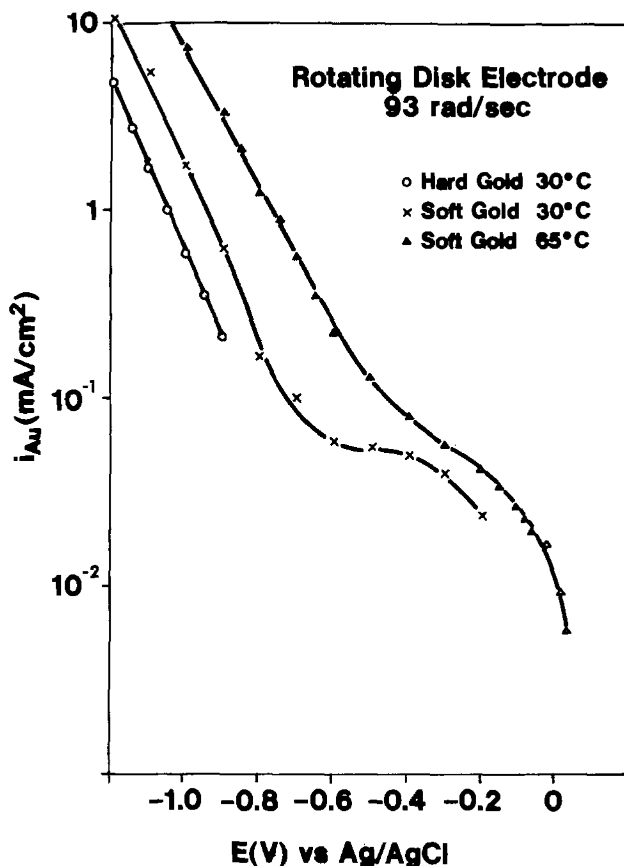

Fig. 1. Current density-potential curves at short polarization times.

was made to the plating solution. With this modified bath, gold was deposited potentiostatically for various lengths of time. Figure 2 shows the coulometric equivalents of the gold deposits in dependence of the deposition time. It is seen that at all potentials the gold deposit grows initially in proportion to t^2 and later in proportion to t, where t is the deposition time. Basically, the same behavior is also obtained for a soft gold bath without the intentional lead addition. However, the deposits grow for an extended period proportional to t^x, where $1 < x < 2$. Figure 2 indicates that in the case of lead-doped gold the time required for the current density to stabilize is practically independent of the deposition potential. Also, the steady-state condition is achieved at increasingly thicker deposits as the deposition potential assumes more negative values.

Generation of Polarization Curves under Steady-State Conditions

According to Fig. 2, steady-state conditions of the deposition of lead-doped gold are attained within about 5 min. Polarization curves were, therefore, derived from the slope of current density-time product *vs.* t curves for various potentials, at $t = 1000$ sec. A similar procedure was employed for the deposition of lead-free gold, measuring the slope between the plating times $t = 3$ and $t = 5$ hr. The results are given in Fig. 3. A considerable difference in the deposition potential between the two curves is noted at the center of the graph, which decreases, however, at very high and very low values of the deposition potential.

Both curves seem to approach the slope of the curves in Fig. 1 at extreme negative potentials, suggesting that the same mechanism is operative. The steep sections at the center of the graph are tentatively identified as the result of the proximity to the equilibrium potential, which is controlled by the concentration of cyanide at the electrode surface. In order to confirm this assumption it is necessary to explain the plateau which is evident at the right of the steep portions.

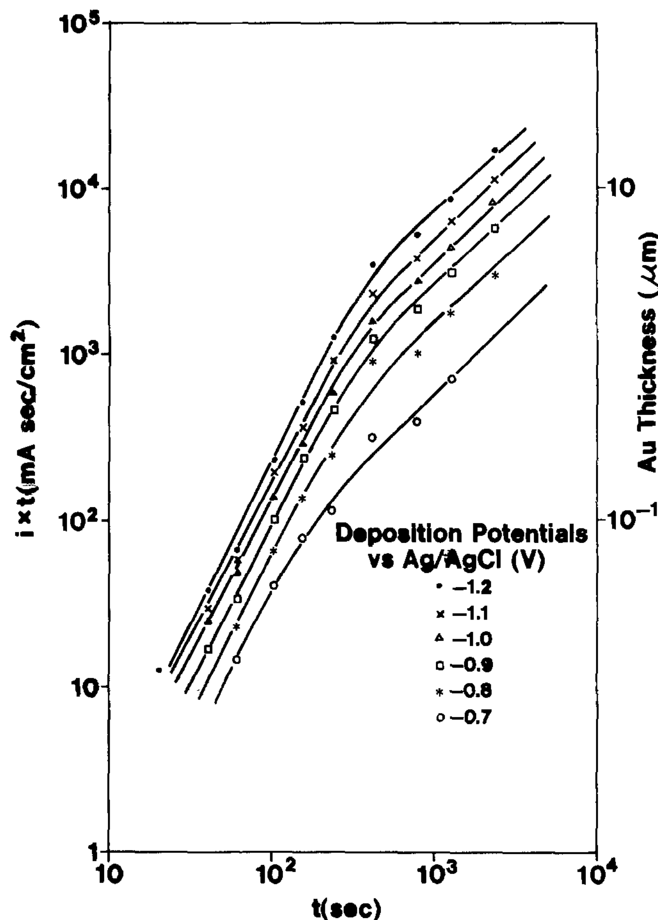

Fig. 2. The growth of Pb-doped soft gold

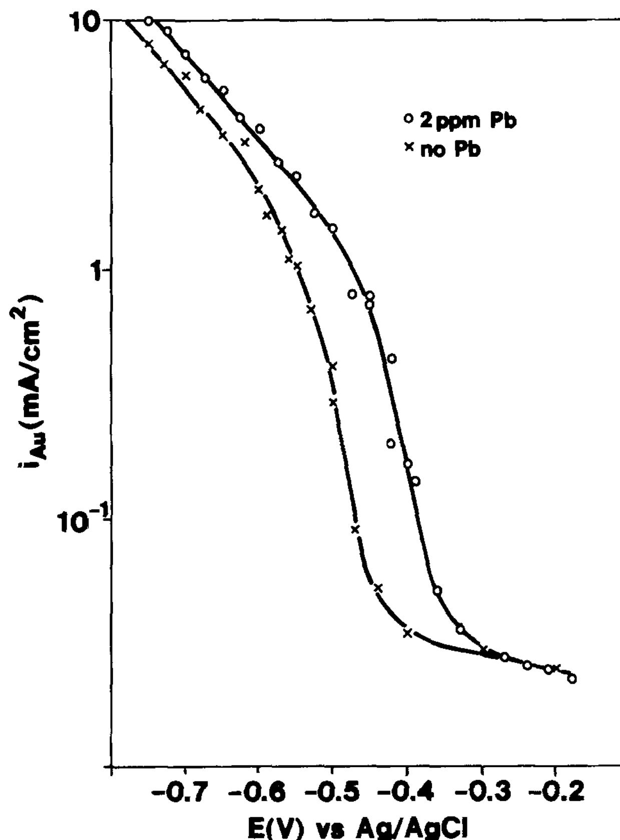

Fig. 3. Current density-potential curves for soft gold at long polarization times.

Evidence of Mixed Potential and Electroless Deposition at the $Au/Au(CN)_2^-$ Electrode

Rotating-disk experiments were designed to explain the plateau section in Fig. 1 and 3. In order to minimize the effect that may result from the accumulation of cyanide during plating, a large volume of electrolyte (2.5 liters) was circulated through the plating cell.

Under open-circuit conditions, a Pt disk electrode assumed a potential of +0.043V *vs.* Ag/AgCl at 65°C at a rotation velocity of 94 rad/sec. The potential increased with increasing rotation velocity. After prolonged exposure, the Pt disk was coated with gold. The rate of gold deposition appeared to be strongly dependent on the history of the bath (*e.g.*, previous use), but was constant within a given test series over many hours. This result proves that the open-circuit potential of the gold electrode corresponds to a mixed potential.

Discussion and Additional Results

Electroless deposition of gold.—The electron donor that causes the reduction of the $Au(CN)_2^-$ ions is hypothesized to be the cyanide ion, according to

$$CN^- \rightleftarrows 1/2(CN)_2 + e \quad [1]$$

$$Au(CN)_2^- + e \rightleftarrows Au + 2CN^- \quad [2]$$

or after adding Eq. [1] and [2]

$$Au(CN)_2^- \rightleftarrows Au + 1/2(CN)_2 + CN^- \quad [3]$$

It is seen that the cyanide ion has the dual role of promoting reaction [1] and retarding reaction [2]. The kinetics of the over-all reaction [3] is, therefore, strongly dependent on the cyanide concentration. The oxidation potentials of reactions [1] and [2] can be expressed by the Nernst equation (brackets indicate activities or, approximately, concentrations)

$$E_{(CN)2} = E^\circ_{(CN)2} - \frac{RT}{\mathbf{F}} \ln [CN^-] + \frac{RT}{2\mathbf{F}} \ln [(CN)_2] \quad [4]$$

$$E_{Au} = E^\circ_{Au} - 2\frac{RT}{\mathbf{F}} \ln [CN^-] + \frac{RT}{\mathbf{F}} \ln [Au(CN)_2^-] \quad [5]$$

where

$E^\circ_{Au} = -0.84V$ *vs.* Ag/AgCl[10]

$E^\circ_{(CN)2} = -0.46V$ *vs.* Ag/AgCl[10]

Reaction [3] is at equilibrium if

$$E_{Au} = E_{(CN)2} \quad [6]$$

From Eq. [4] and [5] it follows that equilibrium is achieved in a soft gold bath at room temperature if

$$\ln [CN^-][(CN)_2]^{1/2} = -16.8$$

i.e., if the cyanide and cyanogen concentrations are about 10^{-5} moles/liter.

Under equilibrium conditions, the mass balance of reaction [3] is shifted to the right as the concentration of cyanide decreases. Continuous removal of CN^- and $(CN)_2$ species from the reaction surface, *e.g.*, under the conditions of a rotating-disk electrode, allows continued deposition of gold. Favorable conditions for the reaction were generated in the experiments by continued degassing of the electrolyte. At pH = 7, the cyanide ion is protonated to form HCN, which along with cyanogen tends to escape into the gas phase. A large surface to volume ratio and agitation of the solution were used to promote this transition.

For the system under consideration, the deposition rate of gold i_{Au}, is equal to the mass fluxes of $Au(CN)_2^-$, CN^-, and $(CN)_2$

$$i_{Au} = \frac{k_1}{\delta}\Delta[Au(CN)_2^-] = -\frac{k_2}{\delta}\Delta[CN^-] = -\frac{k_3}{\delta}\Delta[(CN)_2] \quad [7]$$

The Δ's indicate the difference between bulk and surface concentrations; k_1, k_2, and k_3 are constants and δ represents the diffusion layer thickness. At a rotating-disk electrode, the velocity of rotation, w, influences the diffusion layer thickness δ in the inverse proportion to $\sqrt{w}$ (11)

$$\delta = 1.61 \frac{D^{1/3}}{\nu} \frac{\nu}{w} \quad [8]$$

(D = diffusion coefficient, ν = kinematic viscosity).

Concerning the concentration differences, $\Delta[CN^-]$ and $\Delta[(CN)_2]$, the following inequalities may be both true, both false, or either of them true.

$$[CN^-] \text{ (bulk)} << [CN^-] \text{ (surface)} \quad [9]$$

$$[(CN)_2] \text{ (bulk)} <<](CN)_2[\text{ (surface)} \quad [10]$$

If both are true then

$$\Delta[CN^-] = [CN^-] \text{ (surface)} \quad [11]$$

$$\Delta[(CN)_2] = [(CN)_2] \text{ (surface)} \quad [12]$$

From Eq. [7] together with Eq. [8], [11], and [12] (dropping the specific reference to the surface in Eq. [11] and [12]) it follows that

$$\frac{d \log i_{Au}}{d \log w} = \frac{d \log[CN^-]}{d \log w} + \frac{1}{2} \quad [13]$$

$$\frac{d \log i_{Au}}{d \log w} = \frac{d \log[(CN)_2]}{d \log w} + \frac{1}{2} \quad [14]$$

The concentration terms in Eq. [13] and [14] are expected to deviate from zero for the conditions of the electroless gold deposition.

In a carefully executed experiment at two velocities of the rotating-disk electrode, the rate of gold deposition was found to vary proportionally to $w^{1/4}$. This result indicates that the concentration terms in Eq. [13] and [14] are $-1/4$. Correlated with the variation of the deposition rate, the electrode potential was measured to increase by 0.032V per decade increase in rotation velocity. The combination of this information with the derivatives of Eq. [4] and [5] yields for 65°C (assuming that Eq. [9] and [10] are both true)

$$\frac{d E_{Au}}{d \log w} = -0.134 \frac{d \log[CN^-]}{d \log w} = 0.033V \quad [15]$$

$$\frac{d E_{(CN)2}}{d \log w} = -0.067 \frac{d \log[CN^-]}{d \log w} + 0.033 \frac{d \log[(CN)_2]}{d \log w} = 0.0084V \quad [16]$$

Comparing Eq. [15] and [16] with the observed value of 0.032V per decade increase in rotation velocity it is evident that only Eq. [15] and, therefore, Eq. [9] and [13] are consistent with the experimental results. Hence E_{Au} is the controlling potential and reaction [2] is closer to its equilibrium than the electron donor reaction [1]. At potentials corresponding to the plateau section of Fig. 3 the deposition rate of gold was also found to follow the $w^{1/4}$ dependence as demonstrated in Fig. 4. It is noted that Eq. [7]-[9] may be insufficient to account for the observed transport process because the rate of cyanide removal from the reaction surface is most certainly enhanced by the protonation reaction

$$H^+ + CN^- \rightleftarrows HCN \ (pK_A = 9) \quad [17]$$

Assuming either extreme or minimal deviation from the equilibrium of reaction [17], the concentration of free cyanide at the surface of the rotating-disk electrode was calculated by means of Eq. [7] and [8]. Inserting the results into Eq. [5] yields the equilibrium potential for each polarization condition.

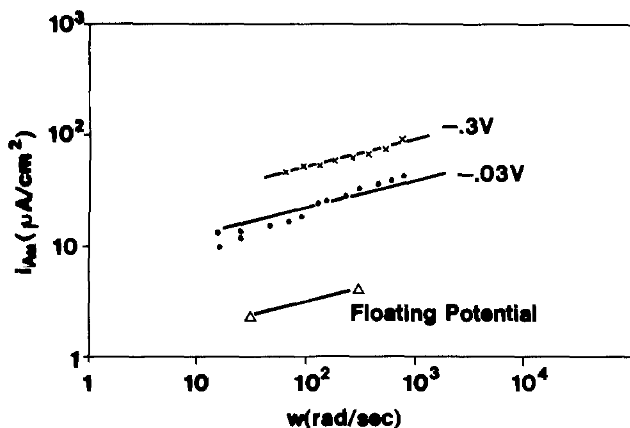

Fig. 4. Dependence of the Au deposition rate in the plateau range on convection.

The following is concluded from the comparison of the calculated with the applied electrode potentials. Under electroless and mildly polarized conditions at 65°C between 0.043 and −0.02V *vs.* Ag/AgCl, reaction [17] and electrode reaction [2] are practically at equilibrium. At current densities within the linear portion of the polarization curve, between −0.5 and −0.9V *vs.* Ag/AgCl, reaction [17] is far from its equilibrium and the difference between the calculated and the applied potential exceeds 0.1V, *i.e.*, the deposition of gold is activation controlled. The plateau section of the polarization curve is identified, therefore, as the result of the influence of the cyanide protonation on the equilibrium electrode potential.

Deposition of gold under activation control.—The equation describing the rate of a cathodic electrode process that proceeds under activation control at potentials far from the equilibrium potential in the absence of the double layer effect has the general form (12)

$$i = i_o \exp\left[-\alpha n \frac{\mathbf{F}}{RT}(E - E^e)\right] \quad [18]$$

with

$$i_o = n\mathbf{F}k^\circ \, a_{ox}^{(1-\alpha)} \, a_R^{\alpha} \quad [19]$$

where α = transfer coefficient; n = number of electrons exchanged; E = electrode potential; E^e = equilibrium electrode potential; a_{ox} = activity of the oxidized species; a_R = activity of the reduced species; and k° = apparent standard rate constant.

This equation may be used to correlate the slope of the polarization curves in Fig. 1 and 3 with specific reactions involved in the electrode process. From Eq. [18] and [19] it follows

$$\frac{d \ln i}{d E} = \frac{d \ln i_o}{d E} - \alpha n \frac{\mathbf{F}}{RT} + \alpha n \frac{\mathbf{F}}{RT}\frac{d E^e}{d E} \quad [20]$$

$$\frac{d \ln i_o}{d E} = (1-\alpha)\frac{d \ln a_{ox}}{d E} + \alpha \frac{d \ln a_R}{d E} \quad [21]$$

In the present application, E^e is identical with E_{Au} of Eq. [5]. For constant hydrodynamic conditions the cyanide concentration at the electrode surface is proportional to the gold partial current, i_{Au}. Therefore, with Eq. [5], at constant convection

$$d E_{Au} = -2\frac{RT}{\mathbf{F}} d \ln [CN^-] = -2\frac{RT}{\mathbf{F}} d \ln i_{Au} \quad [22]$$

Combining Eq. [20]-[22] yields for the deposition of gold (converting to the common logarithm)

$$\frac{d \log i_{Au}}{d E} = \frac{0.434}{1+2\alpha}\left[(1-\alpha)\frac{d \log a_{ox}}{d E} + \alpha \frac{d \log a_R}{d E} - \alpha \frac{\mathbf{F}}{RT}\right] \quad [23]$$

In many metal deposition reactions, α is found to be approximately 0.5. Accordingly, the slopes of log i *vs.* E curves usually show a slope that is equal to a simple fraction of $S = 0.434\mathbf{F}/2RT$. This is also observed in Fig. 1 and 3 for strong cathodic polarization, where the slopes amount to $-4.4V^{-1}$ at 30°C and $-3.6V^{-1}$ at 65°C. Considering the precision of the measurements, these slopes agree well with the assumption of $\alpha = 0.5$ and with

$$\frac{d \log i_{Au}}{d E} = -\frac{0.434\mathbf{F}}{4RT} \quad [24]$$

By comparison with Eq. [23] it is concluded that

$$\frac{d \log a_{ox}}{d E} = -\frac{d \log a_R}{d E} \quad [25]$$

Two distinct reaction paths can be visualized, which both conform with Eq. [25]:

The electron transfer proceeds without prechemical adsorption of the oxidized species ($Au(CN)_2^-$), to form Au atoms whose energetic state is not significantly different from that of their final lattice site. In this case

$$d \log a_{ox} = -d \log a_R = 0 \quad [26]$$

The electron transfer is preceded by the chemisorption of the oxidized species and followed by the dissociation of the reduced species in the adsorption layer, according to the following sequence:

Prechemical adsorption equilibrium

$$Au(CN)_2^- \rightleftarrows (AuCN)ad + CN^- \quad [27]$$

Electron transfer step (rate limiting)

$$(AuCN)ad + e \rightleftarrows (Au^\circ CN)^- ad \quad [28]$$

Postchemical desorption and crystallization

$$(Au^\circ CN)^- ad \rightleftarrows Au(lattice) + CN^- \quad [29]$$

Equilibria [27] and [29] may be dependent on the crystal orientation of the substrate as well as on various solution properties, *e.g.*, the presence of cobalt or lead. All modifications of equilibria [27] and [29] may result in a modification of the electron transfer probability. For each energetic condition, however, Eq. [25] is applicable. If the electrode is saturated with the adsorbates, then a_{ox} and a_R are independent of concentration variations in the aqueous phase and

$$d \log a_{ox} = -d \log a_R = 0 \quad [26a]$$

Observations relating to effects of adsorption.—The effect of adsorption on the crystal size and preferred orientation of electrodeposits is, qualitatively, well known, as evidenced by the commercial use of addition agents and brighteners. Certain features of the gold-plating system are also indicative of adsorption processes and are discussed here.

The structure of soft gold is commonly referred to as "columnar," because etched cross sections show longish crystallites whose length axes coincide with the growth direction of the deposit. The nucleation rate is, evidently, small, and the tendency toward preferred growth orientation is large. If soft gold is deposited on the polished surface of a polycrystalline, annealed fcc metal, a strong epitaxial effect is observed. Substrate grains with the "right" orientation produce well-formed gold crystals at a substantially higher rate than adjoining grains, which do not have the "right" orientation, as shown in Fig. 5. Hard gold deposits, in contrast, have a grain size in the submicron range and exhibit, intrinsically, featureless surfaces. The nucleation rate during hard gold deposition is many orders of magnitude higher than during soft gold deposition.

It is noted that the principal difference between soft gold and hard gold lies in the crystallization behavior, while the electron transfer step is activation controlled in both cases. The role of adsorbed species is, therefore, that of either increasing or decreasing the activation

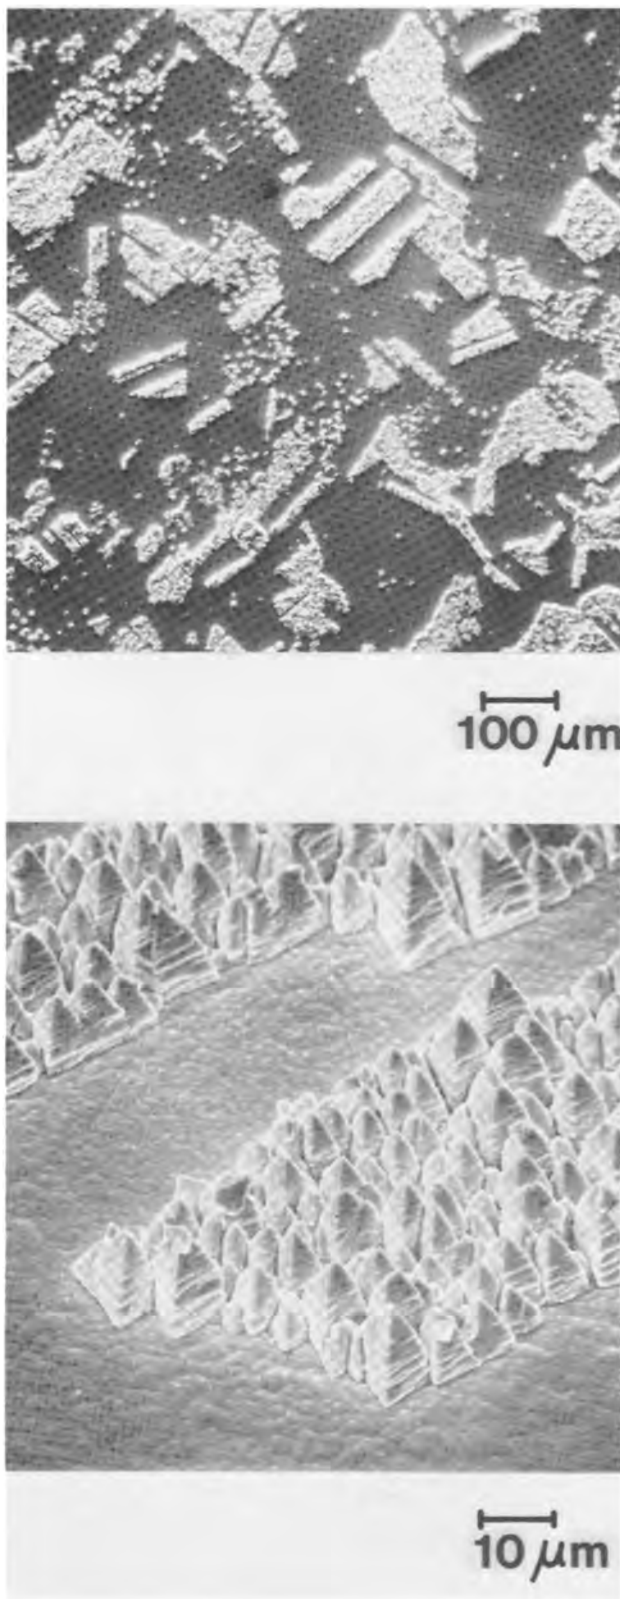

Fig. 5. Epitaxial growth of Au crystals on the surface of an annealed fcc metal.

energy of the electron transfer step. In terms of electrode processes, each crystal orientation has, at constant potential, a typical crystallization current density $i\{a, b, c\}$ (13), where for example

$$i\{100\} \neq i\{110\} \neq i\{111\} \quad [30]$$

Dependent on the relative magnitude of the crystallization current densities, more or less pronounced preferential orientation of the gold deposit results. The experimental current density, i_{Au}, is equal to the average of the various crystallization current densities. If the crystallization process is initiated on randomly oriented nuclei, preferential deposition tends to generate more surface area of equivalent orientation and an increase in i_{Au} results. This is observed during the deposition of regular and lead-doped soft gold. If the differentiation between the crystallization current densities is enhanced, *e.g.*, under the condition that coadsorbed lead lowers the activation energy of the electron transfer, Eq. [28], then one crystallization current density may become dominant. With negligible growth in all but one orientation, the increase in reactive surface area, and as a result the increase of i_{Au}, is proportional to the deposition time. This condition of extreme differentiation between the crystallization current densities is observed in Fig. 2 ($it \propto t^2$).

The deposition of hard gold proceeds without noticeable variation in i_{Au}. This result is consistent with the size of the crystallites formed, whose growth period is limited to a few seconds. In terms of Eq. [28], and in contrast to the effect of lead, the coadsorption of cobalt provides for an increase in the activation energy of the electron transfer. Under this condition, the differentiation between the crystallization current densities may be minimized, but more importantly, the nucleation rate is increased, thus explaining the texture of hard gold deposits.

Perturbation of the adsorption layer.—The transient behavior of the gold-cyanoaurate electrode has, to some extent, been described earlier (7). Additional experiments were deemed necessary to clarify the common and contrasting features of the deposition of soft gold, lead-doped soft gold, and hard gold. The potential transients of a rotating-disk electrode, after prepolarization at constant potential, were recorded, therefore, for a variety of conditions.

Regardless of the specific experimental conditions the potential transients were always found to follow the same pattern. After the interruption of the cathodic (*i.e.*, negative) polarization, the potential was found to increase in at least three distinctly different modes. The initial, fastest variation of the potential has been identified with double layer charging effects. The subsequent, slower variation was recognized to depend on the potential and the duration of the prepolarization period, as well as on the rotation velocity of the electrode. The third mode of potential variation proceeded at constant rate, dependent only on the temperature; however, the range over which the variation occurred was also dependent on other variables. Figure 6 shows the transients for hard gold, prepolarized for 3 min at potentials ranging from -1.1 to -0.4V *vs.* SCE in 0.1V steps. On the time scale used, the double layer charging effect is not discernible (regime 1).

The potential transients are strong indication that the electrochemical reduction of $Au(CN)_2^-$ proceeds via chemisorbed species (14, 15). Details of the curves

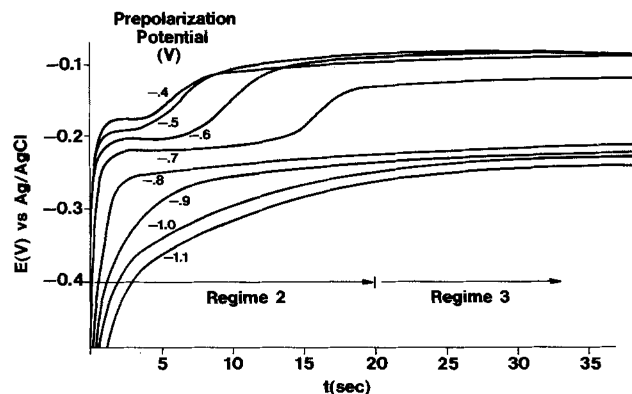

Fig. 6. Potential transients of the $Au/Au(CN)_2$-system (hard gold) after prepolarization.

shown in Fig. 6 are interpreted in terms of the sequence of reactions [27]-[29] as follows:

During the prepolarization period, reactions [27] and [29] are at equilibrium, while reaction [28] is not. At the instant of the current interruption, reaction [28] starts to approach equilibrium at a rate limited only by the recharging of the double layer. Once equilibrium is achieved, reactions [27] and [29], which were previously independent, are now coupled through reaction [28] in correspondence with Eq. [2]. Thermodynamic equilibrium with respect to the bulk of the electrolyte is, however, not achieved yet, mostly because the surface concentrations of CN^-, (AuCN)ad, and $(Au^\circ CN)ad^-$ are higher than when in equilibrium with the bulk. Removal of CN^- tends to shift both equilibria, reactions [27] and [29], to the right. (AuCN)ad remains constant, therefore, while $(Au^\circ CN)ad^-$ decomposes. This occurs within the range of regime 2 of Fig. 5. The process appears to be diffusion controlled, as evidenced by the strong dependence of the potential decay upon the rotation velocity of the disk electrode. At all times, the potential is controlled by the ratio of (AuCN)ad: $(Au^\circ CN)ad^-$. Predictably, $(Au^\circ CN)ad^-$ as source of cyanide will be depleted after some time. Due to the lack of CN^-, the excess amount of (AuCN)ad cannot revert to its origin, $Au(CN)_2^-$. The removal of (AuCN)ad has to proceed via the electron transfer reaction [28], which seems impossible without a source of electrons. An electron source is available, however, as evidenced by the electroless deposition of gold. In preference to reaction [3] the process may be formulated as

$$(AuCN)ad \rightarrow Au(lattice) + \tfrac{1}{2}(CN)_2 \qquad [31]$$

It has been discussed earlier that the electron donor reaction [1] is not at equilibrium. Reaction [31] is, therefore, not at equilibrium either and the removal of (AuCN)ad from the surface should be a first-order reaction. This is confirmed by the observation that the potential decay in regime 3 shows a close to linear dependence on time.

Addressing the potential variation in regime 3 of Fig. 6, it is noted that for prepolarization potentials $< -0.8V$ the curves nearly coincide, while for potentials $> -0.8V$ substantially deviating curves are obtained. This dispersion signifies the change of the surface concentration of the adsorbate from a saturated to a less-than-saturated state. The corresponding behavior, obtained with the other electrolytes, leads to the conclusion that the electrodeposition of gold proceeds, in practice, under surface saturation with (AuCN). It is assumed that surface saturation means a nearly complete monolayer of the adsorbate, regardless of the type of electrolyte. From the potential level, at which the desorption of (AuCN)ad starts in the three different electrolytes, it follows with equilibrium [28] that the surface concentration of $(Au^\circ CN)ad^-$ is greatest for regular soft gold and about equal for lead-doped soft gold and hard gold. It should be mentioned that these results were obtained under prepolarization conditions where the deposition of lead-doped soft gold was far better equilibrated ("depolarized") than that of regular soft gold. In view of the crystallization phenomena discussed earlier, it is concluded that the establishment of a preferred crystal orientation is accompanied by a shift of equilibrium [29] from left to right. Concerning the behavior of the hard gold system, it is concluded that equilibrium [28] is shifted to the left relative to the conditions of soft gold deposition.

Reversibility of the electrode processes.—The electrochemical oxidation of gold in cyanide solution should, doubtlessly, follow the sequence of reactions [27]-[29] in reverse. An experiment was carried out accordingly in which a gold disk electrode was polarized anodically in 0.5M KCN solution at 55°C and two rotation velocities. Figure 7 shows the results which are interpreted as follows. Near the equilibrium potential at about $-0.9V$ *vs.* Ag/AgCl the anodic current

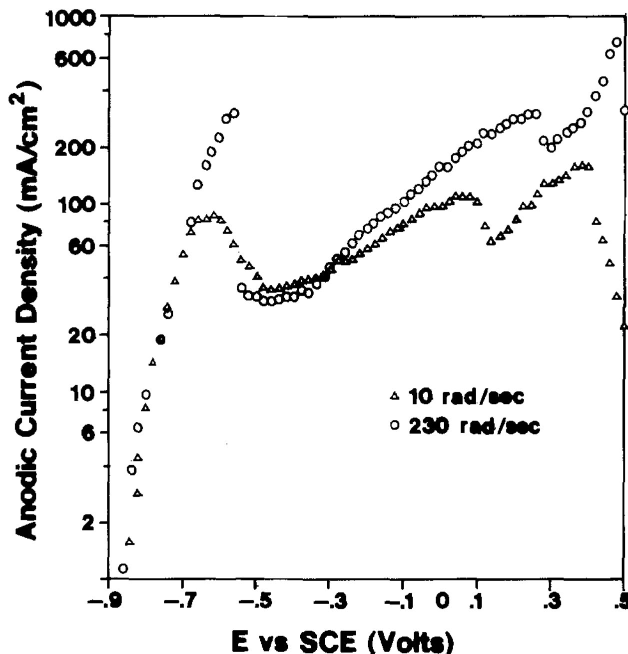

Fig. 7. Anodic dissolution of gold in 0.5M KCN at 55°C

density rises, as expected, very steeply. With increasing potential three maxima and minima are passed. The maxima at $-0.6V$ and 0-0.2V are caused by diffusion limitation of the cyanide ions. As the surface concentration of CN^- approaches zero, the concentration of $(Au^\circ CN)ad^-$ also approaches zero, which results in a rapid drop of the current density. Thereafter, even though the surface concentration of CN^- is not zero anymore, the dissolution rate at $-0.5V$ is controlled by the formation of $(Au^\circ CN)ad^-$. Over the potential range, where in previous experiments the surface concentration of (AuCN)ad was found to deviate from saturation, the current density rises again. The decrease in coverage with AuCN promotes, necessarily, the reaction of gold in lattice sites with cyanide, and hence the rate of dissolution. At the point where once again the concentration of CN^- at the electrode surface drops to zero a change in mechanism occurs. At 0.1-0.2V it appears that trivalent gold is formed, as the current density at 225 rad/sec reaches 1.5 times the value observed at the other maxima. The minimum at 0.5V was positively identified with the onset of passivation since at still higher potentials no dissolution of gold was observed.

The features of the anodic dissolution of gold in cyanide solution are evidently compatible with the existence and the controlling nature of chemisorbed layers postulated for the cathodic reduction of dicyanoaurate.

Summary and Conclusions

The mechanism of the electrochemical reduction of dicyanoaurate was studied by means of steady-state and relaxation methods combined with rotating-disk electrode techniques. The experimental results permit the following statements:

1. The deposition of soft gold, lead-doped soft gold, and cobalt-hardened gold proceeds via one common mechanism that involves adsorption equilibria preceding and following the electron transfer step.

2. Special effects such as the epitaxy and preferred orientation of soft gold deposits, the small grained texture of hard gold, and the lead-induced depolarization effect during soft gold deposition can be explained in terms of the energetic states of the adsorbed, oxidized, and reduced gold species. These are influenced by the crystal orientation of the deposition site and by the coadsorption of cobalt and lead ions, respectively.

3. The proposed mechanism explains readily the features of the anodic dissolution of gold in alkaline cyanide electrolyte.

Flatband Potentials and Donor Densities of Polycrystalline α-Fe_2O_3 Determined from Mott-Schottky Plots

John H. Kennedy* and Karl W. Frese, Jr.**

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Capacitance and conductivity measurements were made on high purity α-Fe_2O_3 and TiO_2-doped α-Fe_2O_3 in liquid junction cells. Flatband potentials and donor densities were determined from Mott-Schottky plots and evidence for deep and shallow donors is presented. Potentials of zero photocurrent were determined using chopped light and were in excellent agreement in basic solution with flatband potentials calculated from 1 kHz capacitance measurements.

Detailed studies of flatband potentials and their correlation with photoeffects have been carried out to date largely on single crystal samples. Also, it is not clear that space charge layer capacitance theories would apply to polycrystalline electrodes in electrochemical cells and that photoeffects could be obtained from polycrystalline samples comparable to single crystal samples. To help answer these questions we report here on capacitance data for the α-Fe_2O_3-electrolyte junction. Current-potential characteristics of these polycrystalline samples will be published separately. In a previous paper (1) we reported on the flatband potential (and photocurrents of) polycrystalline sintered $BaTiO_3$ electrodes with results which agreed well with published data for single crystal samples (2). The techniques used for the studies of $BaTiO_3$ have now been extended to the studies of other metal oxides, in particular, α-Fe_2O_3.

Experimental

Electrode preparation.—Alpha-iron(III) oxide n-type semiconductor electrodes were prepared from either high purity, 99.999% (Apache Chemical Company) or analytical reagent-grade (Mallinckrodt) material. The ultrapure material was pressed and sintered in air at various temperatures from 1050° to 1320°C for 4 hr and then quenched in room temperature air. This treatment resulted in electrodes with apparent densities of 75-85% of theoretical and conductivities ranging from 8×10^{-6} to 2×10^{-4} Ω^{-1} cm^{-1}. Attempts to make semiconducting electrodes from the reagent-grade material by air quenching always resulted in nonconductive material even for sintering temperatures of up to 1300°C. This was probably due to the presence of Cu^{2+}, Zn^{2+}, and Mg^{2+} impurities which would tend to compensate the n-type conductivity. However, the reagent-grade material could be made highly conductive ($\sigma \sim 1$ Ω^{-1} cm^{-1}) by heating in a stream of N_2 for temperatures $\gtrsim$ 1100°C. The conductivities were difficult to control, and therefore TiO_2 doping was used to obtain highly doped samples. Also, the N_2 reduced samples showed virtually no photoeffect, probably due to the very thin space charge layer. The reagent-grade material doped with TiO_2 was sintered at 1150°-1200°C in air for 14 hr and quenched in room temperature air. Densities were 95-99% of theoretical. The TiO_2 doping level was varied from 0.05% to 2% (Ti/Fe). No further treatment was given the electrodes after sintering.

A copper wire electrode lead was attached to the semiconductor electrodes by applying Ag epoxy (Epoxy Technology). The electrode and wire were then sealed in a glass tube with epoxy resin.

Capacitance measurements.—Capacitance measurements of the cell, α-Fe_2O_3/electrolyte/Pt, were made

** Electrochemical Society Student Member.
Key words: semiconductor, photo conductivity, capacitance.

using a General Radio 1650-A impedance bridge operated at 1 kHz. Electrode potential measurements were made (*vs.* SCE) with a Keithley 610-C electrometer.

Dielectric constant measurements.—Dielectric constant measurements of high density, insulating α-Fe_2O_3 were made at various frequencies in the range 1-50 kHz. The dielectric cell was a parallel plate type with the area of one plate much larger (~150X) than the other. The cell was connected to the GR 1650-A impedance bridge and the capacitance measured with and without the α-Fe_2O_3 disk. Electrodes of conducting Ag epoxy were applied to each face of the α-Fe_2O_3 disks. A sine wave a-c voltage (10 mV amplitude) was applied to the bridge using a Hewlett-Packard Function Generator, Model 3311A.

Pulsed photocurrent.—Pulsed photocurrent measurements were made by using polychromatic light from a 300W tungsten source and a rotating-disk chopper. The chopping frequency was 40-60 Hz. The photocurrent was measured as the voltage drop across a precision 5 kΩ resistor with a Tektronix Model 564B storage oscilloscope with a Type 3A6 dual trace amplifier and Type 3B3 time base. The α-Fe_2O_3 electrode was biased cathodically until the voltage amplitude decreased to zero. The minimum photocurrent pulse which could be detected was $\lesssim 0.1\ \mu A$.

Resistance measurements.—The resistance of the cell α-Fe_2O_3/electrolyte/Pt was measured under zero applied voltage with the impedance bridge at 1 kHz. The resistance was predominantly due to the α-Fe_2O_3 electrode since the contributions to the cell resistance from the Pt electrode and the electrolyte were negligible.

Results

Flatband potentials.—Mott-Schottky plots (3) were constructed from capacitance *vs.* electrode potential measurements at 1 kHz and are shown in Fig. 1 and 2 for undoped α-Fe_2O_3. The flatband potentials were obtained from the intercepts of $1/C^2$ *vs.* V by subtracting $kT/q = 0.025$V from the intercept. The flatband potentials and donor densities calculated from these plots are given in Table I.

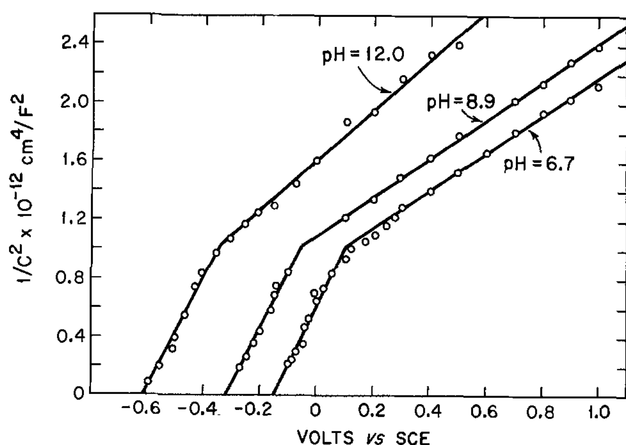

Fig. 1. Mott-Schottky plots for polycrystalline α-Fe_2O_3. Electrode No. 5. In dark, $t = 23°C$.

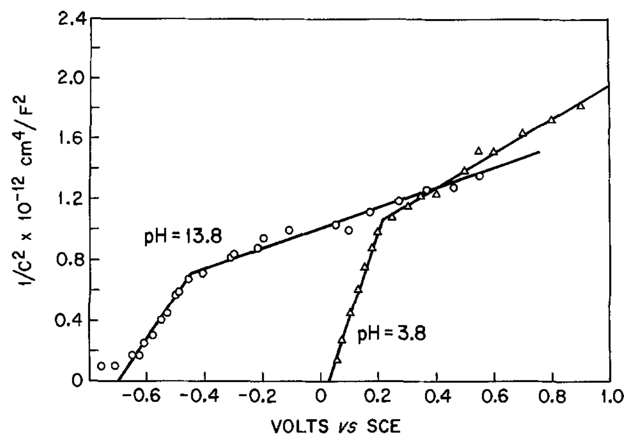

Fig. 2. Mott-Schottky plots for polycrystalline α-Fe_2O_3. Electrode No. 4. In dark, $t = 23°C$.

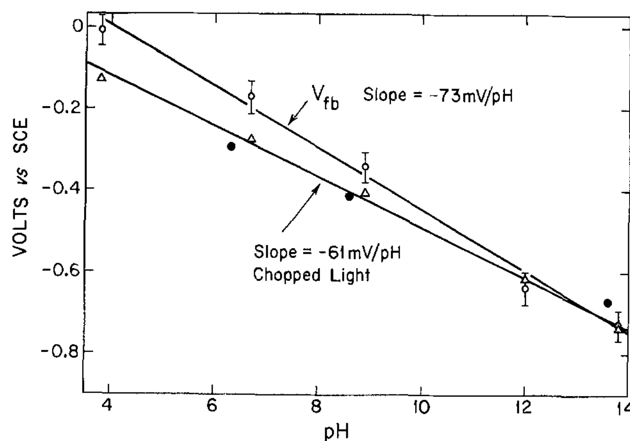

Fig. 3. Flatband potential and zero photocurrent potential of polycrystalline α-Fe_2O_3 *vs.* pH, $t = 23°C$. Solid circles from Ref. (4).

The flatband data are in remarkably good agreement with the data reported by Quinn *et al.* (4) for single crystal α-Fe_2O_3 differing by less than 0.1V. However, these authors did not correlate their data with *p*H. Flatband potentials for our polycrystalline samples at various *p*H values are shown in Fig. 3 together with the single crystal data (solid circles) given in Ref. (4). It is not clear whether or not the deviation of the *p*H dependence of the flatband potential from −59 mV/*p*H was significant. The deviation appears to increase in more acidic solutions indicating that electrode instability may be a factor. Another possible reason could be specific adsorption of chloride ions.

A striking feature of the Mott-Schottky plots is the sharp break at about +0.3V *vs.* flatband. Values

of the critical potential (V_C) for the break are given in Table I. The break was observed for three different samples at *p*H values from 3.8 to 13.8 in both KCl and NaOH solutions. This interesting feature can be explained by assuming the existence of two kinds of donors, one very close to the conduction band and the other at about 0.6V below the conduction band, and will be discussed in detail.

The potential of zero photocurrent was measured with pulsed illumination (nearly full output of 300W tungsten lamp) for the samples used in the capacitance measurements and the points shown in Fig. 3 represent averages at each *p*H. These potentials varied regularly with *p*H at a rate of -61 mV/*p*H. In the more basic solutions (*p*H $=$ 12.2-13.8) the net current at zero photocurrent was cathodic whereas in more acidic solutions (*p*H 3.8-8.9) the net current was anodic.

Typical Mott-Schottky plots for TiO_2-doped α-Fe_2O_3 are shown in Fig. 4, and Table II summarizes the data for the total donor densities, N, TiO_2 stoichiometry, the bulk ionized donor densities, N^+, calculated from conductivity data, and the apparent fraction of ionized donors.

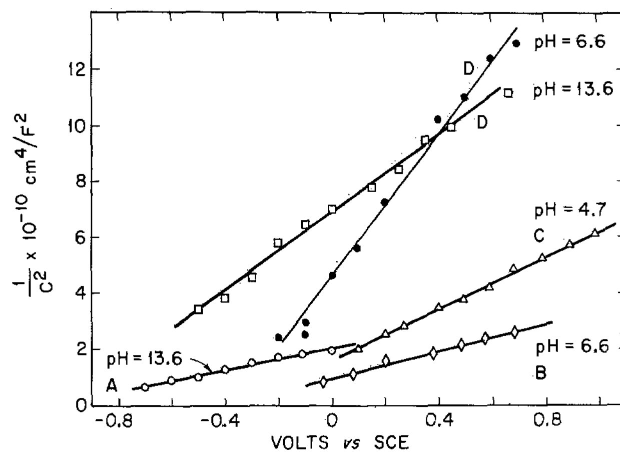

Fig. 4. Mott-Schottky plots for polycrystalline α-Fe_2O_3 at various TiO_2 doping levels and *p*H values. A, B, C, D refer to different TiO_2 doping levels as shown in Table II.

Dielectric constant.—The dielectric constant, ϵ, was calculated from capacitance data according to the following equation

$$\epsilon = 9.0 \times 10^{11} \frac{4\pi t}{A} \Delta C \qquad [1]$$

where t and A are the disk thickness and area and ΔC is the difference in the capacitance with and without the sample. A dielectric constant value of 80 was obtained. Quinn *et al.* (4) reported a value of 120 for the dielectric contact for α-Fe_2O_3 for an unspecified single crystal face.

Discussion

The two slopes for each of the plots in Fig. 1 and 2 suggest that the Mott-Schottky slope may be written (5) as

$$s_1 = \frac{2}{\epsilon\epsilon_0 q N_1} \quad \text{for} \quad V < V_C \qquad [2]$$

and

$$s_2 = \frac{2}{\epsilon\epsilon_{0}q (N_1 + N_2)} \quad \text{for} \quad V > V_C \qquad [3]$$

where N_1 and N_2 are the densities of the shallow and deep donors, respectively, and V_C is a critical voltage for ionization of the deep donors in the space-charge layer. The existence of a critical voltage can be traced to the nature of the Fermi-Dirac distribution function governing the number of ionized donors. The relation (3)

$$N^+(x) = N_2 \left[\frac{1}{1 + g_e\,(E_F - E_D + e\Delta\phi(x)/kT)} \right] \qquad [4]$$

gives the number of ionized donors as a function of position, total deep donor density, donor energy level, and the space-charge potential drop. The degeneracy factor, g, is usually assumed to be two, however, for transition metal ion donors it could be larger due to spin-orbit coupling. It is characteristic of the Fermi-Dirac distribution function that a large change in occupancy is realized over a narrow voltage range, in fact according to Eq. [4] the fraction ionized changes from 0.1 to 0.9 within a $\sim$100 mV change in $\Delta\phi(x)$. If V_C is arbitrarily identified with $N^+/N_2 = 0.5$ then

$$e(V_C - V_{fb}) \cong E_F - E_{D_2} \qquad [5]$$

within $\sim$50 mV. The data show that the deep donor is located about 0.3V below E_F. Flatband data can give the position of the Fermi level relative to the bottom of the conduction band (E_C) provided the density of states in the conduction band, N_C, is known (5)

$$E_C - E_F = kT \ln \frac{N_C}{N_1} \qquad [6]$$

assuming each shallow donor donates one electron to the conduction band. For iron oxide N_C has been assumed to be 4×10^{22} cm^{-3} (6), the number of cations in the lattice. This is consistent with the model of phonon-assisted hopping for the conductivity mode in narrow *d*-band semiconductors. The Fermi level is calculated to be 0.3V (for $N_1 = 4 \times 10^{17}$ from Table I) below the conduction band. The position of the deep donor level is then 0.6V below the conduction band.

The conductivity and spectroscopic studies of Morin (7) were consistent with a deep donor at 0.6-0.8 eV below the conduction band. Gardner *et al.* (8) also found their low temperature conductivity data gave an activation energy of 0.7 eV that could be associated with the energy for carrier formation. A summary of the energy level data is shown in Fig. 5. It should be noted that since the chemical or physical identity

of the donor level at E_2 is not known at present, it may not be an intrinsic property of α-Fe_2O_3 reduced to the level, $N_D \approx 10^{18}$ cm^{-1}. The indirect evidence presented, however, supports the assignment of the deep donor level as being Fe^{2+}.

Evidence for incompletely ionized donors and thus a deep donor level was also found for the TiO_2-doped α-Fe_2O_3 samples. The evidence was gained by comparing ionized donor densities calculated from conductivity and mobility data with donor densities calculated from Mott-Schottky slopes.

Advantage was taken of the fact that the bulk-ionized donor density, N^+, can be calculated from the standard conductivity equation

$$\sigma = N^+ q \mu_n \qquad [7]$$

and that electron mobility (μ_n) remains relatively constant with the doping level (9).

The value of electron mobility to be used in Eq. [7] was calculated by measuring the conductivity of three samples of thermally doped n-type α-Fe_2O_3 (99.999%) at room temperature. The values were 2.35×10^{-4}, 2.95×10^{-4}, and 5.62×10^{-5} $(\Omega\text{-cm})^{-1}$. These three samples showed two distinct Mott-Schottky slopes and the higher slope together with an assumed roughness factor of 2 were used to calculate N^+ for the thermally doped samples. From these values the mobility was calculated. The results for μ_n were 0.012, 0.017, and 0.034 cm^2/V sec for $t = 23°C$ and ionized donor densities of 4×10^{16} to 2×10^{17} cc^{-1}. The average value of 0.021 cm^2/V sec was adopted.

Measurement of the conductivity activation energy for these polycrystalline samples gave values of 0.05-0.10 eV (23°-100°C). Both the mobility and activation energies are in good agreement with the electron mobility equation suggested by Gardner *et al.* (10)

$$\mu_n = \frac{232}{T} e^{-0.1(\text{eV})/kT} \qquad [8]$$

This equation gives a room temperature mobility of 0.016 cm^2/V sec for TiO_2-doped samples.

The value of μ_n could now be used along with conductivity measurements on TiO_2-doped samples (Table II) to calculate N^+, the concentration of ionized donors from Eq. [7]. The values are given in Table II.

The total donor density, N, was calculated from the Mott-Schottky slope according to

$$S = \frac{2}{\epsilon\epsilon_0 q N} \qquad [9]$$

using slopes shown in Fig. 4. As can be seen from Table II the fraction of ionized donors, $N^+/N \sim 5 \times 10^{-3}$. We take this value as strong evidence for a deep donor in TiO_2-doped α-Fe_2O_3. The deep donor level was estimated to be 0.4 eV below the conduction band by using an equilibrium constant approach and the concentrations of ionized and total donors given in Table II.

The flatband potentials extrapolated from the plots in Fig. 4 are about 0.2V more cathodic than those shown in Table I. Two factors could account for this difference. One is that the flatband potential is known (11) to depend on donor density increasing more cathodic by 60 mV per order of magnitude of donor density. This effect amounts to ~0.1V from comparison of the donor densities in Tables I and II. The second effect, pointed out by De Gryse *et al.* (12) is that the extrapolation of $1/c^2$ *vs.* V plots leads to a voltage, V_o, given by

$$V_o = V_{fb} + \frac{kT}{q} - \frac{\epsilon\epsilon_0 q N_D}{2C_H^2} \qquad [10]$$

where C_H is the Helmholtz layer capacitance ~10^{-5} F/cm^2. This effect is magnified by high donor densities such as in our TiO_2-doped samples. The estimated shift in V_{fb} for the samples shown in Fig. 3 is 0.1V. Thus, the observed shift of ~0.2V is adequately accounted for by the theory.

We conclude that flatband potential data can be obtained from sintered polycrystalline α-Fe_2O_3 which are consistent with single crystal results, and that donor densities accurate to within a factor of four or less may be obtained without surface roughness corrections.

Structure and Cyclic Discharge Behavior of LiAl Electrodes

C. A. Melendres* and C. C. Sy

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

Considerable interest exists in the use of lithium-aluminum alloys as negative electrodes in molten salt secondary batteries (1). A number of recent investigations have dealt with the electrochemical characterization of this binary alloy system. Equilibrium potentials as a function of alloy composition were measured by Yao *et al.* (2) and by Selman and co-workers (3). L'vov *et al.* (4) determined the diffusion coefficient of Li in LiAl at 450°C to be $\sim 10^{-6}$ cm^2/sec from measurements of transition times during discharge. Similarly, James (5) has obtained a value of 5×10^{-5} cm^2/sec at 450°C from discharge curves. In a study of the kinetics of the electrochemical incorporation of lithium into aluminum (6), we obtained a value for the Li diffusivity in LiAl on the order of 10^{-8} cm^2/sec from galvanostatic charging curves. Values obtained on discharging the electrochemically formed LiAl electrodes were one to two orders of magnitude higher than on charging and were poorly reproducible. Realizing that this discrepancy may be due to changes in electrode morphology which accompany the incorporation or extraction of Li, we have conducted the present investigation on the structure of LiAl electrodes. We also hoped to obtain information on the role of electrode structure in determining the cycle life of LiAl electrodes in engineering prototype cells.

Experimental

The electrochemical measurements were carried out inside a glovebox under high purity helium atmosphere. The cell consisted of a 5.5 cm diam alumina crucible with three electrodes (Fig. 1): an Al or LiAl wire working electrode, a LiAl coil counterelectrode, and a reference electrode consisting of a cast Li-Al alloy [40 atomic percent (a/o) Li] that is 0.5 cm diam $\times$ 1.2 cm long. The composition of the latter is in the $\alpha + \beta$ region of the phase diagram (7); its potential at 450°C is about 290 mV anodic of Li/Li^+. The counterelectrode was prepared by electrochemically charging a 0.318 cm diam Al rod (previously formed into a coil) with Li to the $\alpha + \beta$ composition range. The Al working electrode was a 1.6 mm diam wire of 99.99% purity (Marz grade material purchased from Materials Research Corporation, Orangeburg, New York). The LiCl-KCl eutectic electrolyte was polarographic grade and was obtained from Anderson Physics Laboratories (Champaign, Illinois). The electrochemical and associated instruments that were used consisted of a Princeton Applied Research (PAR) Model 173 Potentiostat/Galvanostat, a PAR Model 179 Digital Coulometer, a Hewlett-Packard Model 7040A X-Y Recorder, and an R5103N Oscilloscope. Charged and discharged electrodes were mounted on plastic and examined using standard metallographic techniques. The mounted samples were ground successively through silicon carbide paper of grit sizes 120-C, 180-C, 240-A, 400-A, and 600-A, respectively. Polishing was done with alumina powder of 0.3 and 0.05 μm particle size. The last two operations were

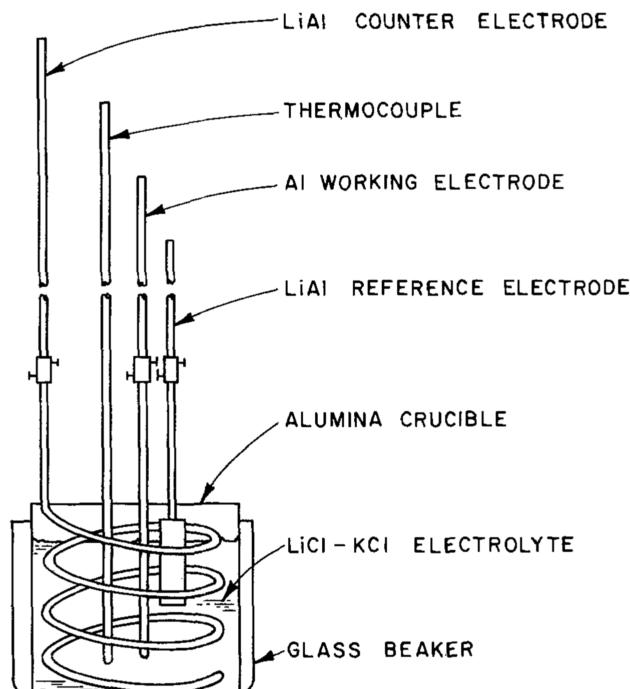

Fig. 1. Experimental apparatus

both done under oil using a Dow Corning 200 fluid (a dimethylpolysiloxane). Samples for electron microprobe analysis were ground with silicon carbide paper using HYPRES OS lubricant (Engis Equipment Company, Morton Grove, Illinois), polished with dia-

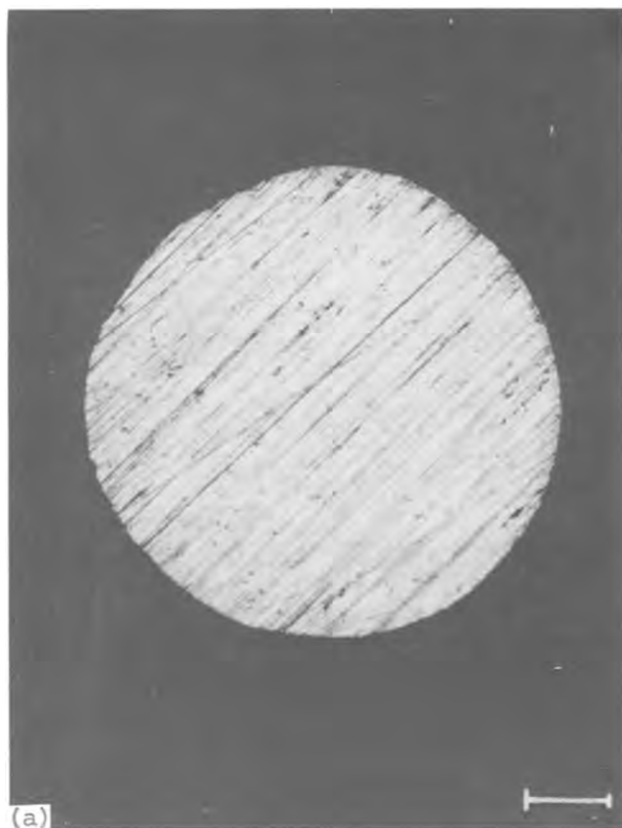
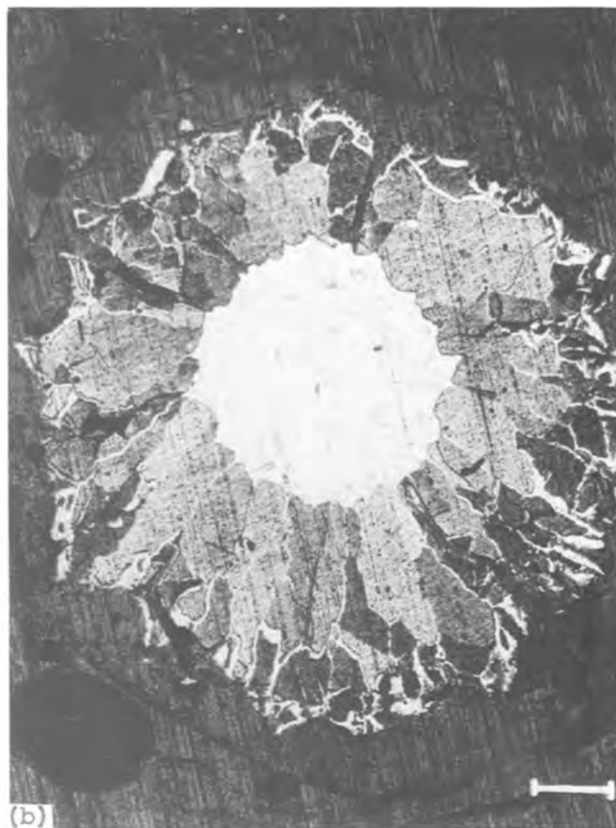
mond paste, and then ultrasonically washed with Freon-113 (Matheson Gas Products).

Results and Discussion

Cyclic discharge behavior of LiAl wire electrodes.— Figure 2 shows typical polarization behavior on cyclic discharge of LiAl wire electrodes that have been initially charged to the β-phase (48 a/o Li). As can be seen from this figure the anodic overpotential remains flat for some time and then increases rapidly. On subsequent discharges (following replacement of the Li removed by recharging at the same current density as initially used), a decrease in anodic polarization and an increase in transition time is observed. Coulometric determination of the charge passed at the transition point shows that the Li extracted anodically is 66, 78, and 81% of the initial loading for the first, second, and third cycles, respectively. The occurrence of a transi-





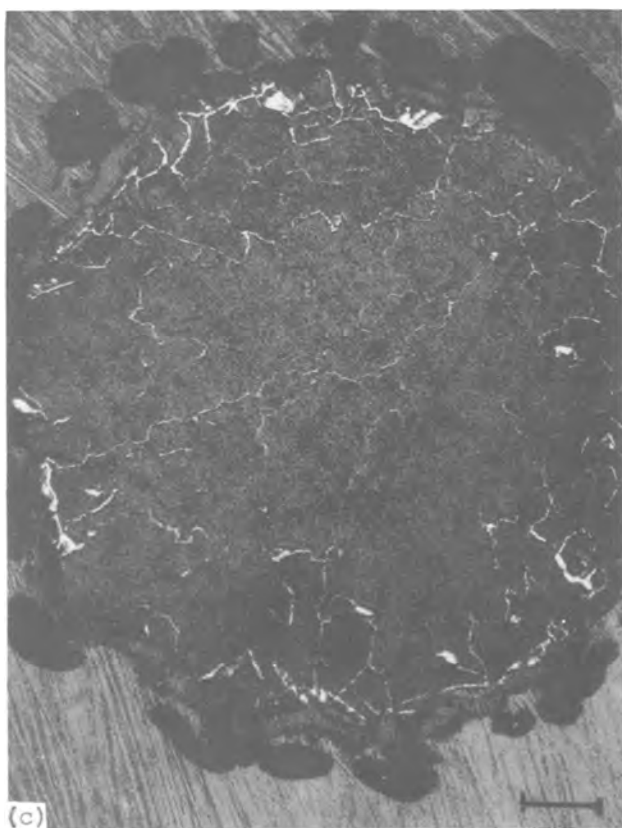


Fig. 3. (a) Photomicrograph of original Al wire (marker = 0.025 cm); (b) photomicrograph of partially charged wire, i = 80 mA/cm^2 (marker = 0.025 cm); (c) photomicrograph of fully charged wire, i = 105 mA/cm^2 (marker = 0.025 cm).

tion time in the discharge curves has been attributed by L'vov (4) and James (5) to diffusional limitation in the solid state. The increase in transition time with cycling indicates an apparent increase in Li diffusivity. Using Sand's equation (8) the values calculated for the curves shown correspond to 1.6×10^{-6}, 1.9×10^{-6}, and 2.02×10^{-6} cm²/sec, respectively. This "development" of the electrode during cycling is presumably associated with structural changes in the electrode or the creation of defects. Difficulty in obtaining reproducible results was encountered in our attempts to carry out further cycling. In addition the electrode would not maintain its physical integrity. A slight decrease in the cathodic overpotential is also observed with cycling, but is not as pronounced as that on discharge.

Microstructure of charged electrodes.—Figure 3b shows a metallographically polished cross section of an aluminum wire partially charged with Li to 70% of capacity (based on conversion of the wire to β-LiAl, *i.e.*, 48 a/o Li). For comparison, a section of the original Al wire (0.145 cm diam) is shown in Fig. 3a. The light central core of Fig. 3b represents the unreacted portion of the wire (Al), whereas the annular region corresponds to that portion which converted to the β-phase (LiAl). A difference in optical reflectivity of some areas in the latter region is apparent. The presence of a "vein-like" structure emanating from the core is particularly striking. Such "veins" appear to persist even in the fully charged electrode (Fig. 3c). Electron microprobe analysis showed that areas of different optical reflectivity vary in aluminum content, *i.e.*, lighter areas are richer in Al (lower Li) than darker ones. This is illustrated by the Al K_α x-ray map (Fig. 4b) of area X in Fig. 4a. The intensity of white dots in the x-ray picture is proportional to the amount of Al present. Therefore, during charging, the incorporation of Li does not appear uniform throughout the electrode. Even in the fully charged state, Al-rich areas represented by the "veins" are present. Two other features worth pointing out here are: the presence of cracks on charged electrodes and the increase in diameter from 0.145 cm for the original Al wire to 0.213 cm for the fully charged LiAl electrode. This latter exemplifies the lattice expansion that accompanies the transition from pure Al or α-phase (lattice constant = 4.05Å) to β-LiAl (lattice parameter = 6.36Å). The cracks observed in the photomicrographs may be due to the mechanical stresses set up during the volumetric expansion.

Discharged electrodes.—Figures 5a and 5b show the structure of partially and nearly fully discharged electrodes, respectively. The breakdown of electrode structure is evident, and is obviously more prominent on discharge than on charge. The α-phase on the near surface layers of Fig. 5a (light areas) was confirmed by microprobe analysis. A β-LiAl core remains in the electrode of Fig. 5b as shown in the enlarged picture of Fig. 5c. It appears that, on anodic extraction of Li, the Al structure is not able to reform to the original and does so only in patches resulting in the broken-up appearance shown. The effect of depth of discharge on structural breakdown is also brought to light in these pictures. It appears in Fig. 5b that the β-phase holds the radial structure together. Presumably if the discharge can be carried to completion (*i.e.*, 100% Li recovery), the structure would fall into pieces. The progressive increase in electrode area on discharge probably counteracts the increasing anodic polarization with time giving rise to the relatively flat portion of the discharge curve.

Structure after cycling.—Figure 6 shows the microstructure of a LiAl electrode after three charge-discharge cycles. The anodic polarization curves for this electrode are the ones shown in Fig. 2. It is obvious that the observed decrease in electrode polarization with cycling must be due to comminution of the electrode. The presence of unutilized Li is shown by the β-core (center) in the picture.

Effect of current density and potential on structure.—In order to examine the effect of charging potential and current density on electrode structure, Al wires were charged completely to β-LiAl composition

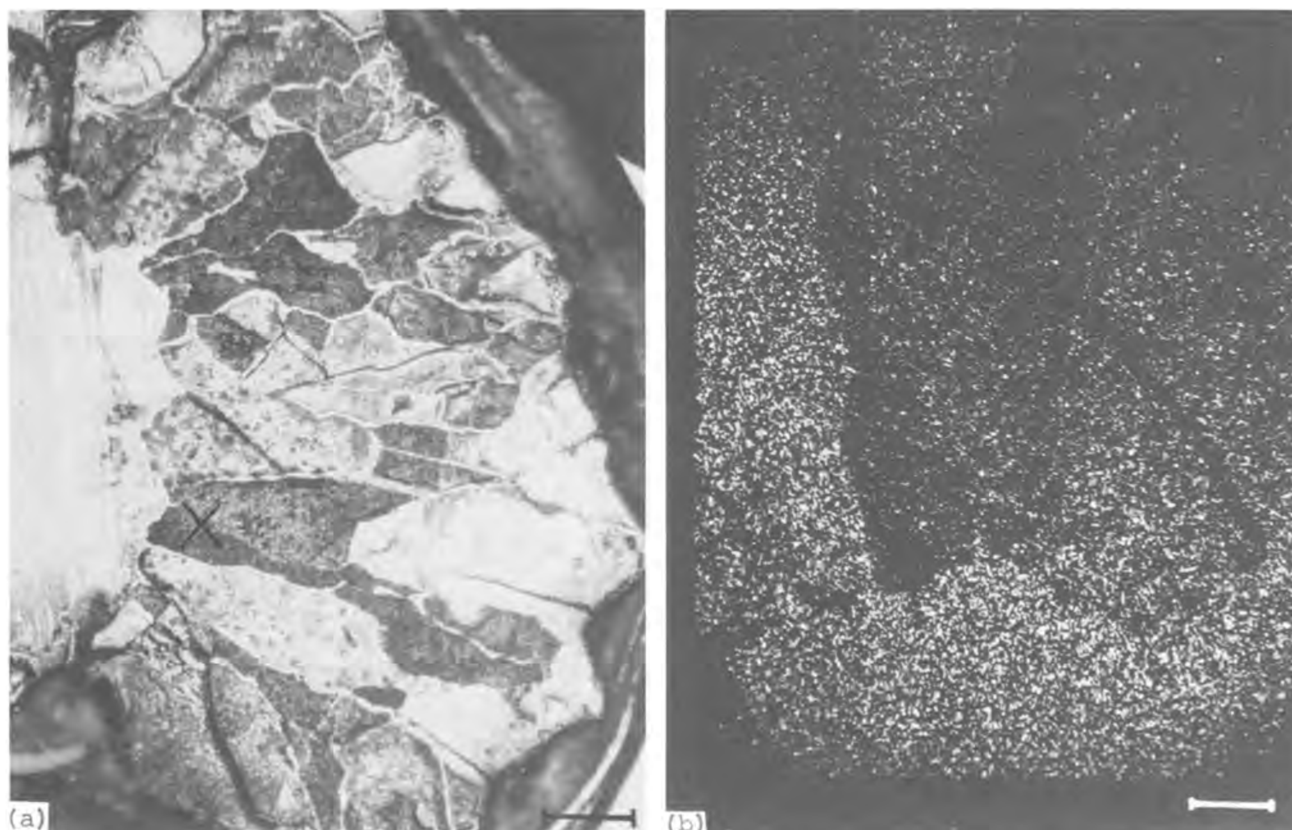

Fig. 4. (a) Enlarged area of portion of Fig. 3b (marker = 0.0125 cm); (b) aluminum K_α x-ray map of area "X" in 4a

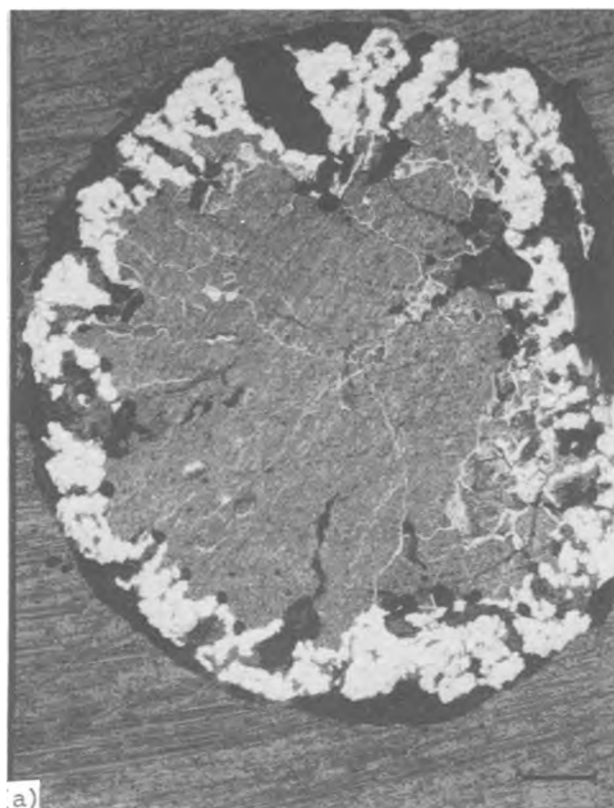

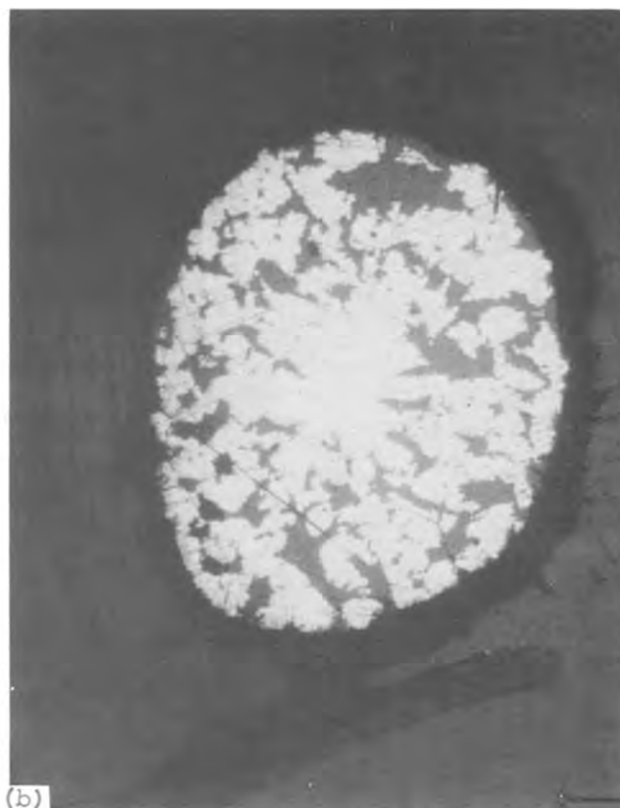

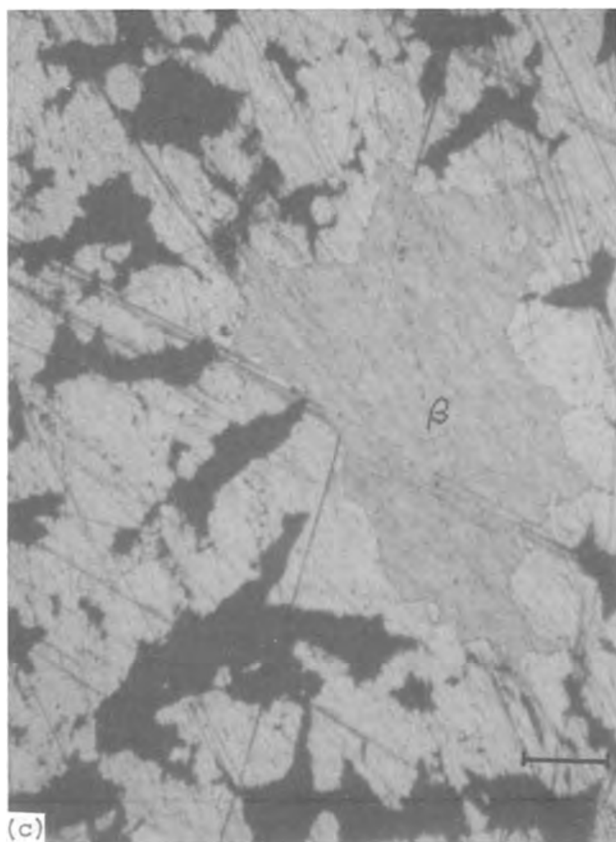

Fig. 5. (a) Photomicrograph of partially discharged LiAl electrode, $i = 380$ mA/cm^2 (marker = 0.025 cm); (b) photomicrograph of nearly fully discharged LiAl electrode, $i = 70$ mA/cm^2 (marker = 0.03125 cm); (c) photomicrograph of β-LiAl core portion of 5b (marker = 0.01 cm).

at constant potentials of −10, −20, −30, −40, −50, and −80 mV *vs.* LiAl and at current densities of 25, 50, 100, 150, 200, 300, and 500 mA/cm^2, respectively. The charged electrodes were mounted in plastic, then ground and polished metallographically. While a difference in structure among the electrodes is observed, we were unable to obtain any systematic correlation between the extent of structural breakdown and the charging potential or current density. Samples were also charged at a constant current density of 100 mA/cm^2, then discharged at current densities of 50, 100, 150, 200, and 300 mA/cm^2. A progressive decrease in the thickness of the outer α-phase layer (cf., Fig. 5a) is observed with increasing current density due to the shorter transition times and progressively lower utilization. The effect on structure is roughly the same as that observed with varying the depth of discharge at constant current.

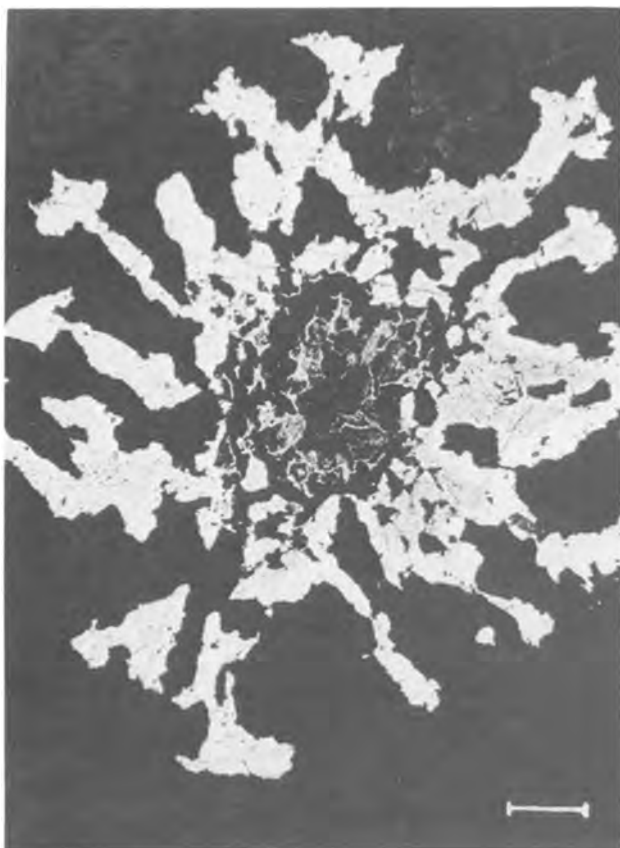

Fig. 6. Photomicrograph of discharged LiAl electrode after three cycles, $i = 107$ mA/cm^2 (marker = 0.025 cm).

Summary

A study of the anodic polarization behavior of LiAl wire electrodes shows a decrease in overpotential and an increase in transition time for Li extraction on successive discharge cycles. This appears to correlate with changes in the electrode structure as examined by metallographic techniques. The degree of electrode breakdown was found to be more pronounced on discharge than on charge and to depend mainly on the depth of discharge. Li distribution in wire electrodes during charging appears to be nonuniform. The results obtained show the need to consider structural changes in the interpretation of measurements of transport properties in solid alloy electrodes. Electrode comminution can lead to current collection problems and loss of active material in engineering-type cells; these can be important factors in determining the cycle life of such cells.

Acknowledgments

The authors are grateful to Dr. F. A. Cafasso for his continued interest and support of this work. We are indebted to Dr. A. Martin and F. Mrazek for assistance in metallography and to W. Shinn for the electron microprobe analysis. Valuable discussions were held with Dr. S. Siegel. Propagation of Pitting on Aluminum Alloys

Steven Dallek*,[1] and R. T. Foley*

Department of Chemistry, The American University, Washington, D.C. 20016

Previous reports from this laboratory have dealt with the effect of anions on the pitting of aluminum (1, 2). The technique employed was based on a derived relationship between the pitting induction time, t_i, and the concentration of the halide ion and it yielded a stoichiometric number, n, the number of halide ions associated with an aluminum reaction site during the primary pitting process. This number for several aluminum alloys varied between one and four, dependent on the halide and the pH of the solution. The current-time curve obtained from the experiment also allows an observation with respect to the kinetics of the propagation of the pit which, with microscopic examination, produces some understanding of the influence of anions in promoting pitting. This is the subject of the present note.

Experimental

The method of investigation (2) involves holding the metal sample potentiostatically in the passive anodic range in an appropriate electrolyte, rapidly injecting into the cell a specific concentration of halide solution, and then measuring the resulting current flowing at the electrode as a function of time. Following an induction period, t_i, which is a measure of the rate of pit initiation, the anodic current increases exponentially coinciding with the onset of visible pitting. The resulting current-time curve is a measure of the faradaic reactions associated with the growth of pits on the electrode surface. Furthermore, the shape of the curve can provide information on the morphology of the resulting pits, as discussed below. Experiments were conducted with aluminum alloys 1199 (99.997% Al) and 7075 (Zn, 5.1-6.1; Mg, 2.1-2.9; Cu, 1.2-2.0; Cr, 0.18-0.40; Fe, 0.7; Si, 0.5, Mn, 0.3; remainder Al) at pH's of about 1 and 6. The halides injected into the $1N$ H_2SO_4 solution were solutions of NaF, NaCl, NaBr,

and NaI. Experiments were conducted over the temperature range of 15°-60°C.

Results and Discussion

Microscopic observations of the pits formed on aluminum alloy 7075 in halide solutions, excluding fluoride solutions, showed that the pits were predominantly hemispherical. The rate of propagation expressed as current as a function of time took the form

$$i - i_p = a\,(t - t_i)^b$$

where i = the dissolution current; i_p = the passive current; t = time; t_i = induction time; a = a constant dependent on the halide; and b = a constant dependent on the geometry of the pit. In Fig. 1 the current-time curve for pitting initiation and propagation by Br^- ion in $1N$ H_2SO_4 is presented as a typical curve. A plot of log $(i - i_p)$ *vs.* log $(t - t_i)$ the slope of which is "b", is given in Fig. 2. An equation similar to the above was obtained experimentally and derived theoretically by Engell and Stolica (3) for the pitting of iron by chloride solution. In their derivation they assumed that the pitting sites are hemispherical, that the dissolution current density is much greater than the passive dissolution current density and is proportional to the sum of the pit cross sectional areas, and that the rate of development of new pits is linearly dependent on time. According to the derivation, when the number of pits is constant with time, b is 2; when the number of pits is proportional to time, b is 3. The data plotted for the aluminum alloy in Fig. 2 apparently meet or approximate these specifications, as the data fit the cubic equation quite well.

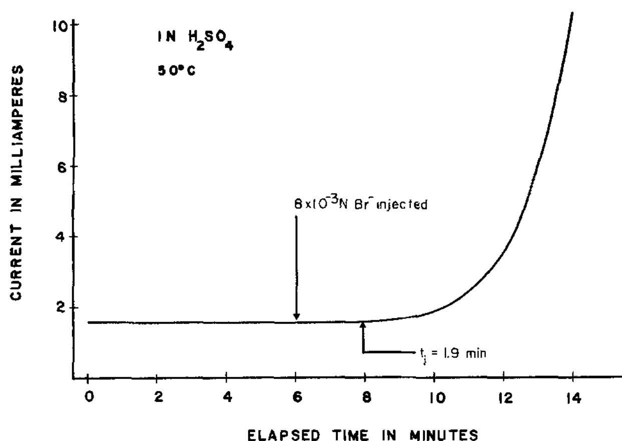

Fig. 1. A typical pitting initiation and propagation curve

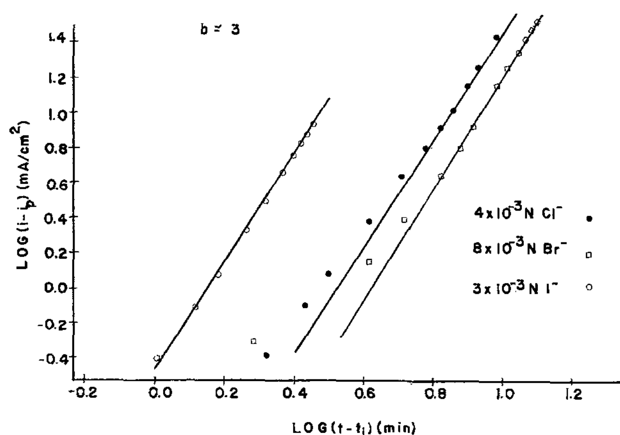

Fig. 2. Determination of "b" in pit growth equation. ●, Chloride solution, □, bromide solution, ○, iodide solution.

The data plotted in Fig. 2 follow the equations

for $3 \times 10^{-2}N\ I^-$ $(i - i_p) = 0.073\ (t - t_i)^3$
for $4 \times 10^{-3}N\ Cl^-$ $(i - i_p) = 0.0051\ (t - t_i)^3$
for $8 \times 10^{-3}N\ Br^-$ $(i - i_p) = 0.00195\ (t - t_i)^3$

It is important to recognize that the behavior of aluminum alloys described here probably represents a special case insofar as the curves experimentally yield a $b = 3$ or exhibit cubic behavior. Tousek (4, 5) investigating the pitting corrosion of iron and nickel, developed equations for different current-time dependencies and then used the equations to describe the dimensions of the active pits. For iron, a value of $b = 3$ was obtained, but for a Cr-Ni-Fe alloy we obtained a value of $b = 2$. Stolica (6), investigating a number of Cr-Fe alloys, found that $b = 3$ for a 5.6% Cr-Fe alloy and a 14.9% Cr-Fe alloy, but for several others the current-time curves were too irregular to yield consistent exponents. The literature on the kinetics of pitting has been extensively reviewed by Szklarska-Smialowska (7, 8) and she has concluded that the Engell-Stolica treatment is oversimplified to apply in a general way to all cases of pitting. Rather, the pits should be placed in one of the three categories (8): (*i*) Case I: The pits are hemispherical and the radius of the pit approximates the pit depth; (*ii*) Case II: The pit is nonhemispherical, the radius is greater than the depth; (*iii*) Case III: The pit has a cylindrical shape with the radius less than the height of the cylinder. For this reason, experimentally, b values varying from 0.5 to greater than 5 have been obtained. Moreover, in the pitting of Ni in solutions containing various concentrations of $SO_4^=$ and Cl^- the b value changes with the ratio of the two ions (9). From the foregoing, it is concluded that a value of $b = 3$ conforms with hemispherical pits growing in cross section linearly with time with the number of pits also increasing linearly with time.

It is generally accepted that the morphology of the pits bears directly on the kinetics of pit growth. From the present study it is possible to record some qualitative trends from microscopic examination of the pitting specimens. The hemisphericity of pits propagated in chloride solution was always greater than those formed in bromide or iodide solution. In fluoride solution, pitting corrosion did not occur, but rather uniform surface corrosion resulting in the formation of an insoluble fluoride compound on the surface. Hemisphericity was also enhanced by going from near-neutral solution (pH = 5.8) to an acidic medium (pH = 0.3). The greatest deviations from hemisphericity were always observed in pits developed in bromide solution.

In addition to aluminum alloy Type 7075, experiments were performed with chloride and bromide on alloy Type 1199 to test the effect of alloy composition on pit morphology. The pits produced in chloride solution became almost perfectly hemispherical, although the most striking change occurred in bromide solution where the pit morphology also became hemispherical as compared with some iregularly shaped figures observed on alloy Type 7075.

There has been very little reported in the literature regarding the morphology of the pit as affected by the nature of the aggressive anion. Politycki and Fischer (10) described the different etching patterns formed on high purity aluminum by attack in HCl, HBr, HI, and HF. Cubic cavities were formed in HCl and HBr solutions, cubooctahedral cavities in HI, and no well-defined etch figures in HF solution. These patterns were explained in terms of steric relationships that derive from the direct contact between halide ions of a given radius with surface aluminum atoms separated by a given distance in the metallic lattice.

Tokuda and Ives (11) studied the pitting corrosion on nickel by chloride ion in sulfuric acid solution and analyzed the pit morphologies by simulation of dis-

solution, based on the assumption that a metal atom which has fewer nearest neighbors, and hence fewer bonds, is removed preferentially. However, this simple model failed to adequately account for the observed pit morphologies, and the authors thus incorporated into their model the concept of dissolution based on the accessibility of aggressive ions, a concept which correctly predicted the pit morphologies.

Conclusions

Pit propagation on aluminum alloys in chloride, bromide, and iodide solutions follows a cubic time expression due to the approximate hemisphericity of the pits. This is considered to be a special case in the general pitting of metals. The different pit morphologies obtained on aluminum depend on both the nature of the agressive anion in solution and on the composition of the metal sample.

An Instrumental Gravimetric Method for Indexing Materials, Contaminants, and Corrosion Products According to Their Hygroscopicity

J. D. Sinclair*

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

The moisture pickup characteristics of selected dusts, contaminants, corrosion products, and aged insulation and substrate materials have been determined in a dynamic humid environment by instrumental gravimetric analysis. These are compared with pure salts and other standard materials to categorize their relative hygroscopicities during the initial adsorption stage and subsequent stages of moisure pickup. In addition, the minimum relative humidities at which some pure salts and a variety of other substances will pick up moisture are reported.

Humidity has long been recognized as a dominant factor in the rate of deterioration of electronic devices. Degradation may occur as a result of inappropriate choice and design of materials, or because of in-service contamination or corrosion problems. In spite of the importance to the electronics industry of knowledge about the moisture pickup characteristics of components, contaminants, and corrosion products, the "hygroscopicity" of most substances is generally not known. This is due in part to the lack of a uniform concept of hygroscopicity. There are nearly as many definitions of the term as there are papers on the subject.

Since Vernon's (1) recognition nearly 50 years ago that significant corrosion of most materials will only occur above a "critical relative humidity" (CRH), attempts to predict the effects of humidity on devices have usually been based on knowledge or an estimate of this number. In many cases, Vernon's CRH relates to the thermodynamic CRH of the surface components. For composite materials, contaminants, and some corrosion products, it is generally not appropriate to apply the thermodynamic concept of the CRH because of the insoluble nature of the substances. In this work, the term will usually be used broadly to describe an effective relative humidity (RH) at which a surge in moisture pickup occurs.

Some information is available on the over-all moisture pickup at elevated humidity of substances often encountered in the electronics industry. In some early work, Mulder (2) found that $CaCl_2$ on exposure to water-saturated air at 16°-20°C increased its weight by 712% in an unspecified period. A 0.6% weight increase is documented by Mellor (3) for sodium chloride exposed to air, but the RH and exposure time were not specified.

Preston and Sanyal (4) reported that $CaCl_2$ and NaCl showed weight increases of 625 and 314%, respectively, during exposure to an atmosphere maintained at 97% RH (at room temperature) for 14 days. Lindsay (5) has studied the moisture content at intervals from 0 to 100% RH of fibrous materials used for electrical insulation, including manila paper, press board, leatheroid paper, silk, empire cloth, and asbestos paper. Excess water content ranged from 1 to 6% by weight at 30% RH and from 4 to 18% at 90% RH. Asbestos paper was the least hygroscopic material examined.

Alkali halides have been recently studied by Kanazawa *et al.* (6). The "hygroscopicity" of powdered NaCl, KBr, and KI, prepared by recrystallization from ethanol, was studied by comparing the surface conductivity of the salts with their water adsorption isotherms. Water molecules which were adsorbed to a thickness of less than two monolayers were stated to be physisorbed. Water films thicker than two monolayers were thought to dissolve salt and form mobile hydrated ions. The vapor pressures at which the adsorbed water molecules were said to form hydrated ions at 30°C were 33, 36, and 27%, respectively. Hara *et al.* (7) studied the effects of crystal structure and surface energy on the hygroscopicity of $NaClO_3$ and found that increasing strain within the crystal was coincident with an increase in hygroscopicity.

A number of workers have studied the moisture pickup of ammonium salt formulations used for fertilizers and explosives. Pawlikowski *et al.* (8) have studied the effect of grain size on "the velocity of water sorption" of ammonium nitrate fertilizers. Vakhrusev and Gradinar (9) have found that the "hygroscopic point" of ammonium nitrate fertilizers decreases from 63.3% RH for granulated material to 55.6% RH for fine grained material. Further, he finds the "hygroscopic point" decreases with increasing urea concentration by as much as 20% from 65% RH. On the other hand, Trzesniowski (10) found by gravimetric methods that granule size, mole ratio, and phosphoric acid content had no effect on the CRH of N-P fertilizers, though the CRH increased somewhat with increasing ammonium sulfate content. Shokin and Solov'eva (11) determined that coating ammonium bicarbonate ferti-

* Electrochemical Society Active Member.
Key words: moisture pickup, deliquescence, critical relative humidity, device deterioration.

lizers with petroleum products was very effective in reducing the rate of moisture "absorption." Runge (12) has developed equations based on percent weight changes for calculating the moisture pickup capacity of similar fertilizers based on the initial moisture and composition. Yee (13) has studied the CRH of water soluble fertilizers by measuring the RH over saturated salt solutions with an electric hygrometer.

Puri and Bhushan (14) have examined the moisture pickup capacity by percent weight gain of zinc, nickel, chromium, and cobalt oxides prepared in a variety of ways. At 50% RH, moisture pickup for zinc oxide ranged from 0.5 to 2.4%, for nickel oxide from 2.7 to 10.3%, for chromium trioxide from 0.9 to 4.8%, and for cobalt oxide from 0.2 to 2.5%. At 99% RH, the moisture pickup for zinc oxide ranged from 0.7 to 9.1%, for nickel oxide from 5.9 to 32.5%, for chromium trioxide from 3.8 to 15.2%, and for cobalt oxide from 3.2 to 30.0%. These wide variations indicate that the hygroscopicity of many substances cannot generally be estimated from a single physical measurement.

Kearsley and Birch (15) recently measured the hygroscopicity of glucose syrup fractions as percent weight gain at saturation (approximately 14 days at 75% RH) and found that the moisture content increased from 14 to 34% as the glucose fraction increased from 0.3 to 61.6%. The method of drying was found to affect the initial rate of moisture pickup but not the final moisture content of the sample. The presence of inorganic contaminants was determined to increase the rate of pickup and the capacity. Whittier and Gould (16) used vapor pressure meaurements for saturated solutions as the basis for comparing "hygroscopic tendencies" and determined the equilibrium humidities for sucrose, glucose, galactose, and lactose to be 77, 81, 81, and 93% RH, respectively.

Grebennikova *et al.* (17), Twomey (18), and Bakhanova and Ivanchenko (19) have investigated the growth of hygroscopic dust particles and droplets in moisturized air streams by *in situ* microscopic examination. Unkown dust particles were often identified by the relative humidity at which visible moisture collected on their surfaces.

Markowitz and Boryta (20) have determined "hygroscopicity potentials," for saturated salt solutions at various temperatures. These authors defined the hygroscopicity potential (HP) as being $RT \ln (p_{H_2O,\,pure}/p_{H_2O,\,system})$. By this procedure the thermodynamic imbalance in chemical potential between ambient water and system water is emphasized. Pawlikowski *et al.* (21) prefer a "hygroscopic value" $\Delta p = pn\text{-}pr$, where pn is the vapor pressure of the saturated salt solution and pr is the ambient water vapor pressure.

Modrzejewski and Pokora-Bartyzel (22) have defined the "hygroscopic point" of pulverized pharmaceutical substances as the RH at which the material takes on 1% moisture in 24 hr. They state that the value is somewhat lower than the CRH of saturated solutions but that it is constant and characteristic of each substance. Moisture pickup was monitored gravimetrically for samples stored in 10 chambers maintained at uniformly distributed RH's between 10 and 100%. The "hygroscopic point" was determined from a percent moisture *vs.* relative humidity plot.

Shen and Springer (23) presented expressions for moisture content as a function of time for homogeneous and composite materials exposed to humid air or water. Test data for graphite T-300 Fiberite 1034 composites supported the mathematical analysis. The method requires knowledge of the maximum moisture content and the moisture diffusivity and unfortunately is readily applicable only if the initial moisture concentration inside the material is uniform and the temperature and moisture content of the environment is constant. Balarev *et al.* (24) have recently tabulated 140 inorganic salts according to their increasing hygroscopicity. The rankings were based on the equilibrium vapor pressures of saturated salt solutions. Phipps and Rice (25) have described an extremely sensitive gravimetric method employing a quartz crystal oscillator to detect monolayers of water on thin metal films. Unfortunately, the technique is readily useful only under vacuum conditions and consequently is not directly applicable to the measurement of moisture pickup rates and capacities of contaminants, corrosion products, and many electronic materials. Very recently Foster and Arbach (26) used a recording microbalance to measure the moisture pickup characteristics of β''-sodium gallate as a function of particle size at 50% RH and found finely divided powder picked up approximately one mole of water for each gram-atom of sodium whereas monocrystals showed no measureable water pickup.

Mansfeld and Kenkel (27), Sereda (28), and Gutman (29) have developed atmospheric corrosion monitors which measure the "time-of-wetness" which local environmental contaminants produce under extended exposure to atmospheric humidity. The time-of-wetness is an experimental determination of the summation of time intervals during which the CRH of the surface contaminants is exceeded. Berukshtis and Klark (30) have attempted to correlate time-of-wetness and pollutant concentrations with corrosion rates of steel, aluminum, zinc, cadmium, and copper for several urban environments.

In ranking substances according to their experimental hygroscopicities, a number of factors should be considered, including the magnitude and rate of moisture pickup in a selected time interval and the temperature, RH, and flow characteristics of the test atmosphere. In this work the moisture pickup parameters for several pure salts were examined in a static moisture-saturated environment to gain further understanding of the factors which have, in the past, led to classifying pure substances as hygroscopic or nonhygroscopic. From this data and the work of the authors already described, gravimetric measures were recognized as being best suited to estimating moisture pickup characteristics. Subsequently, an instrumental gravimetric method was developed for rapidly measuring the CRH and moisture pickup rates for samples of electronic materials, corrosion products, dusts, and other contaminants. Through this information an indexing method evolved for ranking substances according to their hygroscopicities and, thereby, for assessing corrosion or device failure hazards.

Experimental

Static atmospheres.—Measurement of the moisture pickup of pure salts in a static environment was accomplished with small bell jars sealed through ground glass joints with Apiezon N. A beaker of distilled water and a beaker containing 1.0g of a reagent grade anhydrous salt were placed in each bell jar. The RH was presumed to equilibrate at 100% in a time frame which was negligibly small relative to the interval between measurements. The salts analyzed were $CaCl_2$, $ZnCl_2$, $CuCl_2$, $FeCl_2$, and NaCl. The bell jars were periodically opened and the water pickup by the salts was monitored gravimetrically. The time required for complete dissolution of each salt was noted.

Flowing atmospheres.—Rapid determination of the moisture pickup characteristics of pure salts, composite materials, contaminants, and corrosion products was accomplished with a du Pont 951 thermogravimetric analyzer coupled to a 990 thermal analyzer. Continuous moisture pickup rates for the various materials at nearly 100% RH at 23°C were determined by passing a stream of air, which had been moisturized by bubbling it through distilled water, through the microbalance sample tube (2.5 cm diam × 12 cm long). It was found that flow rate strongly affected the moisture pickup rate. Commercial "Arizona Road Dust" (AC

Fine prepared by the AC Spark Plug Division of General Motors Corporation) was analyzed at flow rates of 10, 100, and 1000 ml/min and was found to increase its weight by 1.0% after 570, 55, and 18 min, respectively. The substantial acceleration possible at rapid flow rates was offset by the reduced sensitivity and resolution caused, in part, by increased turbulence in the balance housing. A flow rate of 10 ml/min provided sufficient acceleration for the work anticipated for this study. Relative to flow rates found in buildings housing electronic equipment, a flow rate of 10 ml/min, when translated to linear dimensions, is about an order of magnitude lower than those typically encountered. The apparatus is capable of handling samples weighing from 0.1 to 110 mg and, if the atmosphere and sample are properly equilibrated prior to loading, the minimum detectable weight change is approximately 10 μg/hr.

Weight was recorded graphically as a function of time, and each run was allowed to proceed until the rate of weight gain approached zero or reached an extended steady state. It is impractical to provide weight *vs.* time profiles for every sample examined, but the general characteristics of each sample can usually be sufficiently described through knowledge of the initial, final, and average percent weight gain rates along with sample weight and total exposure time or total weight gain. Field samples were generally equilibrated for several days or weeks with the laboratory atmosphere (RH approximately 30%) before they were analyzed in the microbalance. Weight increase with time at 23°C was initially recorded for 19 pure chemicals whose hygroscopicities spanned a wide range. Sample weight for the laboratory samples varied from 25 to 107 mg with only two samples weighing less than 50 mg. The amount of water vapor passing through the sample chamber was in very large excess of the amount of water picked up by the samples. Therefore, the sample size effect is probably minimal except perhaps for the smaller samples. The texture and crystallinity of the samples were variable and probably contribute to the results.

CRH measurements were made using the same balance with a modified air stream apparatus. A minimum RH in the balance housing (maintained at 23°C) of 22% was achieved by passing a stream of dry air through a dispersion frit submerged in distilled water cooled to 0°C. By allowing the water to warm from 0°C to nearly 23°C under ambient control, the RH increased from 22% to nearly 100%.

The RH *vs.* time profile is shown in Fig. 1. Flow rates ranging from 10 to 5000 ml/min were examined. The lag time in establishing in the balance housing the specific RH created at the humidity source was substantial at the slower flow rates, but the faster flow rates caused severe turbulence. A flow rate of 1500 ml/min was found to be rapid enough to insure rapid response in the sample chamber to humidity variations without producing a severe loss of sensitivity or resolution because of turbulence. The unloaded apparatus including the sample pan registered a weight increase of 0.02 mg on increasing the RH from the minimum to the maximum level, which is a negligible correction for most of the samples encountered. A recording of weight *vs.* time was translated to weight (normalized to 20 mg) *vs.* RH using hand recorded data of water temperature *vs.* time. The relative humidity at which an onset in weight gain occurred was taken to be the CRH. For the pure salts examined, the moisture pickup process was reversible and the measured CRH remained constant.

Discussion

At least three different stages of moisture pickup, each of which should have a characteristic rate behavior, can be considered in evaluating the hygroscopicity of a pure dry salt which becomes exposed to a humid atmosphere. Initially, presuming the water vapor pressure in the atmosphere is greater than that of adsorbed water or water of hydration, water will be chemisorbed and physisorbed on the surface. The surface area and surface energetics of the salt will be dominating rate factors at this stage. Included in this phase will be the formation of possible hydrates. Secondly, as the hydration layers continue to physisorb, a thin continuous film of water will form on the surface. At this stage the thin continuous film will be a saturated salt solution and the water pickup rate will be a function of the difference between the vapor pressure of the saturated salt solution and the vapor pressure of the atmosphere. Eventually the salt will completely dissolve and the solution will begin to dilute. The rate of moisture pickup will then decrease as the solution dilutes and its vapor pressure increases. These stages are denoted phase one, phase two, and phase three in the following discussion.

Hygroscopicity of pure salts in a static environment.—The rate of moisture pickup of a substance will depend in part on its initial state, which will generally be either a phase one or phase two condition. It will also depend on the temperature, the humidity, and the moisture transport processes taking place at the surface. Moisture transfer in a static environment will be diffusion controlled but in an environment where convective transport processes occur, the air flow rate over the surface will be important.

The acquisition of moisture by 1.0g samples of 5 salts at 100% RH was monitored for 133 days. These results are shown in Fig. 2. The amount of moisture pickup registered for $CaCl_2$ or NaCl after 14 days is about one-third of that found by Preston and Sanyal (4). This discrepancy is probably caused by differences

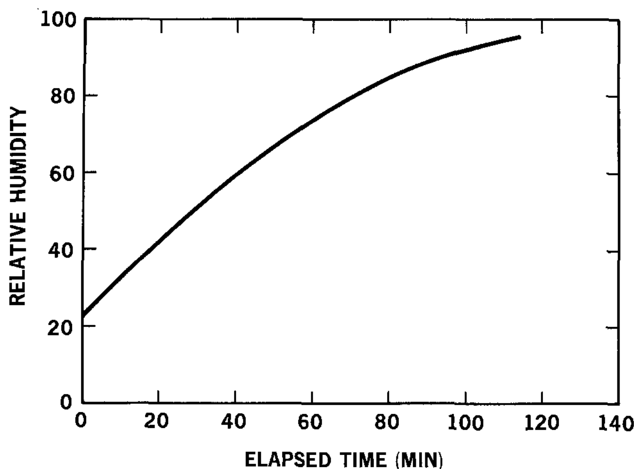

Fig. 1. Relative humidity program

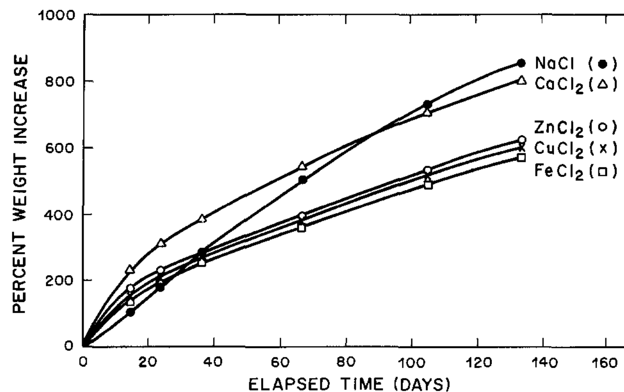

Fig. 2. Hygroscopicity of 1g samples of selected salts at 100% RH as measured by the percent weight increase.

in the experimental configurations. In both experiments $CaCl_2$ picked up twice as much moisture as NaCl in 14 days. $ZnCl_2$ and $CaCl_2$ picked up a sufficient amount of moisture to completely dissolve in 3 and 6 days, respectively, while $CuCl_2$, NaCl, and $FeCl_2$ dissolved in 20, 34, and 46 days, respectively. These observations are consistent with the usual expectation that $ZnCl_2$ and $CaCl_2$ are very hygroscopic materials while the other salts are moderately hygroscopic. Once a film of water has collected on the dry salt, a saturated salt solution will form. A saturated $ZnCl_2$ solution (CRH approximately 10% and vapor pressure approximately 2.4 mm Hg at 25°C) and a saturated $CaCl_2$ solution (CRH 31% and vapor pressure 7.3 mm Hg at 25°C) are expected to exhibit a stronger tendency to pick up water from a water-saturated atmosphere than a saturated NaCl solution (CRH 75.7% and vapor pressure 18.0 mm Hg at 25°C). The initial quantitative weight gains, as indicated by the percent weight increases, reflect this expectation but also indicate that the differences in solubility of these salts are partially responsible for the hygroscopicities commonly ascribed to them. The solubilities of $ZnCl_2$, $CaCl_2$, and NaCl are 4320, 819, and 350g solute/1000g water. If NaCl were as soluble as $ZnCl_2$ it can be very roughly estimated from the solubilities and the dissolution times that NaCl would have required about the same amount of time as $ZnCl_2$ to dissolve. Similarly, the dissolution time for NaCl, if it were as soluble as $CaCl_2$, would have been only two or three times that of $CaCl_2$. Dry NaCl, then, gains weight at a rate which is initially somewhat slower than $ZnCl_2$ and $CaCl_2$, but not nearly as slowly as the usual recognition of its hygroscopicity implies.

After dissolution of all the salt has occurred, the ionic molality of the solution is expected to determine the rate of moisture pickup more or less independently of the salt involved. If the magnitude of the water pickup is calculated in terms of the reciprocal of the ionic molality, which is a measure of the water pickup potential per ion present in solution, then the time required to attain a selected minimum value of this reciprocal may also be a useful method of expressing hygroscopicity. The reciprocal of the ionic molality is specified as a function of time in Fig. 3. The nonuniform behavior found for NaCl using pure percent weight gain information is no longer apparent. If the selected value for the reciprocal is arbitrarily chosen to be 0.20, the hygroscopicity is found to decrease in the order $CaCl_2 > ZnCl_2 > CuCl_2 > NaCl > FeCl_2$. For salts of only moderate solubility a higher minimum for the selected reciprocal value would be required to permit comparisons. The data suggest that selection of moderately higher values will lead to only minor variations in the relative order. For all the salt solutions the rate at which water vapor is condensed in the beakers decreases in a uniform manner consistent with a uniform increase in the vapor pressure of the solution as the salt concentration decreases.

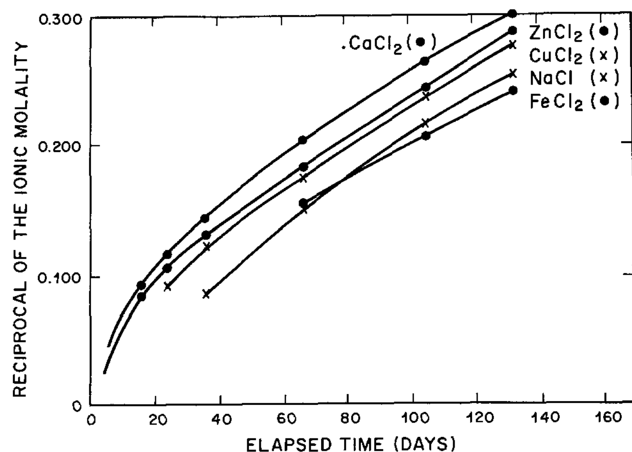

Fig. 3. Hygroscopicity of saturated solutions of selected salts at 100% RH as measured by the reciprocal of the ionic molality.

Interpretations based on solution concentrations are probably most useful and informative in analyzing laboratory data for pure salts, but the total capacity to pick up moisture in specific time intervals may be more useful in analyzing field samples, including dust, silt, and corrosion salts, since the amount of hygroscopic material in the sample may be very small. In this case, the extent to which the nonhygroscopic constituents can be dissolved and dispersed by the total amount of water present may be the dominant factor in terms of corrosion potential and other deleterious effects. It is apparent from the percent weight increase data given in Fig. 2 that once dissolution of the salts occurs, a beaker containing 1g of NaCl will pick up more water than a beaker containing 1g of $ZnCl_2$. This trend is expected to continue indefinitely. Similarly, a beaker containing 1g of NaCl will gain more weight than a beaker containing 1g of $CaCl_2$ for exposures to water-saturated air in a static environment of over 90 days. For some humid field environments, this suggests that contaminants and corrosion products containing NaCl in an otherwise nonhygroscopic matrix could be more hazardous than samples containing comparable amounts of $ZnCl_2$ or $CaCl_2$.

Table I summarizes some data for various procedures which could be used to estimate the hygroscopicity of pure salts. All the rankings, except those based on the CRH and solubility, were experimentally determined in this work.

The rank orders based on percent weight gain after 10, 40, and 100 day exposures are identical except for the position of NaCl, which ranges from the least to the most hygroscopic salt. It is surprising that $ZnCl_2$ appears somewhat less hygroscopic than $CaCl_2$ by either the percent-weight-gain or reciprocal-of-the-ionic-molality methods in that, because of its low CRH, dry $ZnCl_2$ becomes wet in all but the very driest of atmospheres, whereas $CaCl_2$ remains dry at RH's less than about 30%. Similarly, nonuniform characteristics are found for the set $FeCl_2$, $CuCl_2$, and NaCl. Their CRH's are 40, 69, and 75%, respectively, but the rank order of their hygroscopicities based on the reciprocal of the ionic molality is $CuCl_2 > NaCl > FeCl_2$. In a humid atmosphere, the CRH of a substance is apparently not always a satisfactory indicator of its hygroscopicity, but weight gain data by themselves, particularly if only one measurement period is examined, are not sufficient either. The length of the exposure affects the relative ranking and will be important in estimating moisture hazards with electronic devices. Whether a macroscopic method should be chosen or one which implicitly includes the effects of each ion in solution will depend on the circumstances and rather arbitrary preferences.

For most substances of interest to the electronic devices field, methods requiring measurements in solution will not be applicable. Modern instrumental gravimetric procedures readily provide a precise recording of weight change information which can be used

Table I. Relative hygroscopicities

Criteria for estimation	Rank order
1. Dissolution time	$ZnCl_2 > CaCl_2 > CuCl_2 > NaCl > FeCl_2$
2. Solubility (g solute/1000g water)	$ZnCl_2 > CaCl_2 > CuCl_2 > FeCl_2 > NaCl$
3. Percent weight gain after 10 days	$CaCl_2 > ZnCl_2 > CuCl_2 > FeCl_2 > NaCl$
4. Percent weight gain after 40 days	$CaCl_2 > NaCl > ZnCl_2 > CuCl_2 > FeCl_2$
5. Percent weight gain after 100 days	$NaCl > CaCl_2 > ZnCl_2 > CuCl_2 > FeCl_2$
6. Reciprocal of the ionic molality	$CaCl_2 > ZnCl_2 > CuCl_2 > NaCl > FeCl_2$
7. Critical RH	$ZnCl_2 > CaCl_2 > FeCl_2 > CuCl_2 > NaCl$

for ranking substances according to their hygroscopicity. The remainder of this paper describes such a procedure. By employing a flowing atmosphere, variable accelerations are feasible. Measurement of an effective CRH can be accomplished with RH programming of the flow system.

Critical relative humidities of pure salts and field samples.—Corrosion products and other contaminants contain varying amounts of hygroscopic materials, and consequently their moisture pickup characteristics are less predictable than those of pure salts. The surface area of the nonhygroscopic substances in the contaminant mixture, particularly if these substances are of low solubility, may be sufficient to chemisorb and physisorb most of the hygroscopic substances and all the moisture picked up by these substances, effectively stopping the moisture pickup process before a thin continuous film of water forms. For this and other reasons one of the most important moisture-related factors in considering corrosion and contamination problems with electronic devices is the rate at which a substance collects moisture in the first few hours of exposure to humidity levels above its CRH. Initial experimentation established that a significant weight change in a salt could be produced at the CRH starting with either a dry sample and increasing the RH or starting with a moist sample and decreasing the RH. For pure salts which were stable to moisture and did not react significantly with the aluminum sample pan, reproducible minima and maxima were recorded at the same RH for repetitive scans of the same sample. However, for corrosion products, dusts, and some materials the weight *vs.* RH plots were often complex and repetitive scans were not always reproducible. Generally, this behavior was caused by chemical or physical changes associated with the moisture pickup which were irreversible at reasonable conditions. For these reasons, the usual procedure for most samples was to equilibrate the sample at 22% RH and then to record a single run from low (22%) to high (nearly 100%) RH.

The results for four pure salts are shown in Fig. 4. The literature values for the CRH of KCNS and $NaNO_2$ (31) are 47 and 66%, respectively, at 20°C. The onset of weight gain for these salts in this work (23°C) occurred at 46 and 66%, respectively, establishing that the method is sufficiently sensitive and accurate to measure the CRH of many substances. The onset of weight gain for NaCl occurred at 84%, which is somewhat higher than the literature value of 76% (31), but NaCl was later found, as is discussed below, to pick up moisture at a slower rate during the initial adsorption phase than during the later stages controlled by the solution vapor pressure. It is anticipated that if the RH programming had proceeded at a slower rate the observed critical RH would be lower for this salt. This measurement requires development of more sophisticated humidity control equipment which is in progress. Moisture pickup for CrO_3 is initiated at 29% RH, which is somewhat below the literature value of 35% (31). This discrepancy may be due in part to the procedure used to determine the RH of the system. The vapor pressure of water in the air stream was assumed to be identical to the vapor pressure of the distilled water bath. The vapor pressure of the bath was estimated from its temperature. The temperature differential between the input air stream and the water bath for the low humidity readings was substantial and could lead to significant warming of the water at the surface of the air bubbles, thereby increasing the vapor pressure and the corresponding RH. The determined RH would be low consistent with the observation for CrO_3. An improved apparatus which will eliminate this uncertainty is under construction.

The results for several field samples are shown in Fig. 5-8. The electrolytic corrosion product samples No. 1 and 2, shown in Fig. 5, each exhibited two weight gain onsets but are otherwise very different. The electrolytic corrosion products from sample No. 2 were produced with relatively clean water and consisted primarily of copper and nickel oxides and carbonates with minor amounts of chloride salts. The weight onset at approximately 27% RH is probably associated with dust that was unavoidably collected with the corrosion products. The second onset at about 50% RH could be due to chloride salts. The concentration of such salts must be low, however, since the weight gain rapidly approaches saturation at approximately 65% RH. Corrosion product No. 1 was the result of water contamination from a water line serving an air conditioning system. The water contained chromate salts and possibly other additives for rust inhibition. The initial onset at 23% RH saturated at about 32%. The identity of this contaminant was not clear. The second onset is somewhat obscured but appears to occur at roughly 30% RH. This onset appears to be caused by a major hygroscopic component in the corrosion product as there is no indication that saturation is approached during the remainder of the run. The identity of this product was ascertained from chemical analysis

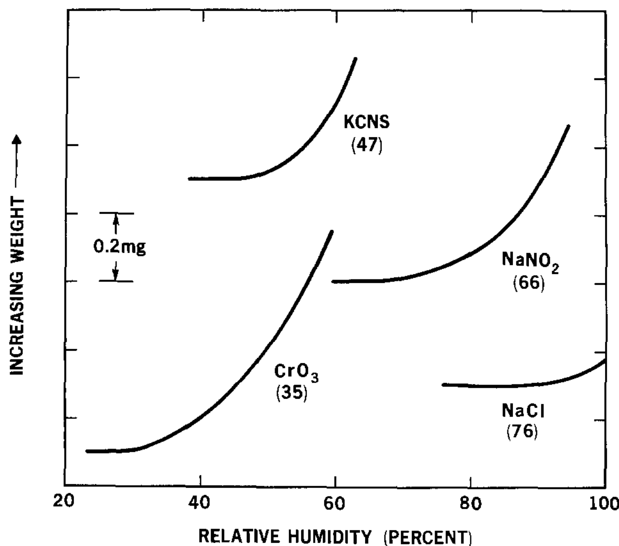

Fig. 4. Moisture pickup onset for selected salts on exposure to increasing RH.

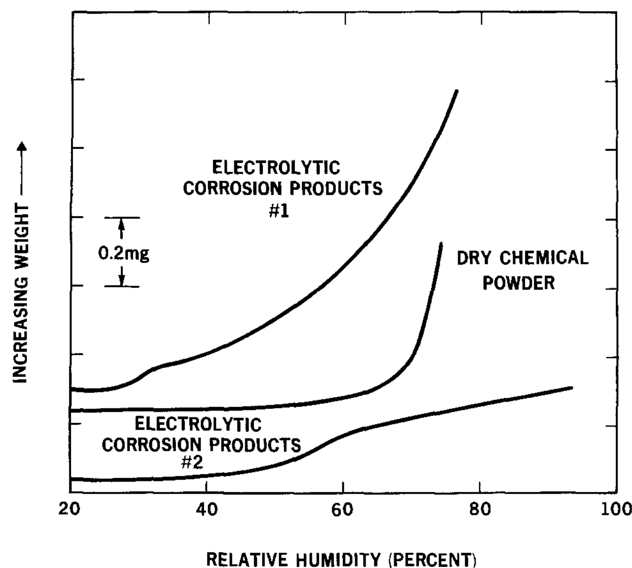

Fig. 5. Moisture pickup onset for corrosive contaminants on exposure to increasing RH.

to be a combination of copper, zinc, and calcium chromates.

The data for a contaminant found on an electromechanical switching device after a nearby battery fire had been extinguished with "dry chemical powder" are also shown in Fig. 5. Again, two onsets occur. The first onset at 27% RH is probably due to adsorption on dust present before the fire and on soot and dry chemical powder. The second onset at 55% RH can be attributed to the formation of a thin aqueous film on the dry chemical powder and the subsequent initiation of rapid moisture pickup. The dry chemical powder was primarily sodium bicarbonate.

The results for dust samples from Holmdel (No. 1) and two locations in New York City (No. 2 and 3) are shown in Fig. 6. The samples exhibited similar characteristics with initial moisture pickup occurring at about 26% RH. These dusts are not known to have caused significant moisture-induced problems on electromechanical switching equipment except at elevated humidity levels, suggesting that moisture pickup is primarily limited to an adsorption process. The large surface area and complex composition typical of dusts permit a significant weight increase to occur before appreciable thin films of aqueous salt solutions are created.

The information summarized in Fig. 7 and 8 demonstrates the utility of this method in ascertaining the quality of materials for electronic devices and assessing contamination or corrosion problems. Data for insulating materials used as substrates and for other purposes are shown in Fig. 7. A number of phenol fiber samples were examined and they exhibited widely variable behavior. The data for a typical sample are shown. An alumina ceramic material exhibited a moderate tendency to pick up moisture at very high RH. The epoxy glass sample was only slightly susceptible to moisture pickup at high RH. Aged textile insulation materials removed from copper wire from two locations in New York City are compared in Fig. 8 with recently manufactured product. Sample No. 1 is from a location which experienced contamination from hydrochloric acid. The onset point at 26% is substantially more pronounced than that of sample No. 2 (which was of similar vintage) or that of the new material. This difference is attributable to the presence of chloride salts in sample No. 1.

Hygroscopicity of substances in a dynamic environment.—Information on the moisture pickup characteristics of substances at high RH is useful for assessing contamination and corrosion hazards and for engineering equipment specifications and building environments. In this study these measurements were accomplished rapidly for a wide variety of substances using a 10 ml/min flow of air nearly saturated with water vapor to simulate typical indoor environments in an accelerated time frame. The substances are ordered on a time-averaged weight-percent basis in Tables II and III according to the increasing tendency of the various materials to gain weight through pickup of water from the nearly saturated air stream. The samples span a broad range of hygroscopicities and are arbitrarily categorized as strongly, moderately, or weakly hygroscopic according to whether their average weight gain rate is greater than 0.110, 0.011-0.110, or less than 0.011 %/min, respectively.

While ordering the samples on this basis seems generally most appropriate, examination of the data indicates this arrangement disguises some factors. For instance, $FeCl_3$ was determined to undergo an average percent weight gain of 0.421 %/min, but the rate decreased over the 94 min exposure period from 0.58 to 0.19 %/min. On the other hand, $CuCl_2 \cdot 2H_2O$ gained weight at an average rate of 0.087 %/min throughout a 324 min exposure period, and the weight gain rate for $FeCl_2 \cdot 4H_2O$ and NaCl actually increased slightly over the duration of the experiments. While it is pos-

sible to measure or, in principal, calculate the percent weight increase of an initially dry sample maintained at a specific relative humidity until equilibrium is attained, the hazards of estimating corrosion rates of contaminated surfaces solely from such determinations are apparent. Thus, NaCl exposed to 95% RH has a theoretical potential to increase its weight to 1136% of its dry weight (see Table II), while $ZnCl_2$ will increase to only 610% of its dry weight. In a practical sense, however, a surface contaminated with NaCl gaining weight at the rate of 0.035 %/min at 100% RH would require about 48 hr to gain its own weight in water, while a similar amount of $ZnCl_2$ picking up moisture at the rate of 0.19 %/min (the experimental rate at termination of the experiment) would achieve the same weight gain in less than 6 hr. At these rates a 100 mg sample of $ZnCl_2$ (solubility 4320g/1000g H_2O) would completely dissolve in about 90 min, while a 100 mg sample of NaCl (solubility 350g/1000g H_2O) would require about 140 hr to completely dissolve.

A number of samples of corrosion products and contaminants, as well as materials used by the electronics industry, are ranked in Tables II and III with the pure chemicals. The manner in which the data can be used for assessing corrosion and contamination problems can be illustrated with a few examples.

Electrolytic corrosion products which contaminated equipment in an Albuquerque switching center that had been flooded are seen by this ranking procedure to be more hygroscopic than $CuCl_2 \cdot 2H_2O$ and of similar hygroscopicity to Drierite and silica gel. SEM/x-ray analysis of the contaminants indicated that a major component, in addition to sandy soil, was copper chloride or oxychloride. The data indicate the contamination on the Albuquerque equipment could produce serious consequences in the event a high humidity condition occurs. Caution must obviously be exercised, however, to avoid drawing unjustified conclusions based only on the average weight gain rates. For instance, the Albuquerque sample initially picks up moisture at a rate of 0.30 %/min but the rate decreases to essentially zero after 323 min. $CuCl_2 \cdot 2H_2O$ was found, though, to gain weight at a constant rate of 0.09 %/min throughout a 320 min run. Although the average weight gain rate is significantly higher for the Albuquerque sample, it would be inappropriate to predict, on this basis alone, that the Albuquerque sample would pose a greater hazard than contamination by pure $CuCl_2 \cdot 2H_2O$. In a humid environment the $CuCl_2 \cdot 2H_2O$ would eventually pick up moisture equivalent to several times its initial dry weight, while the Albuquerque sample would pick up a maximum of 39.5% of its initial weight. The sandy soil and other insoluble components present in the Albuquerque sample adsorb the cupric chloride and disperse the moisture picked up by the cupric chloride very effectively. Exposure to humidity levels above the calculated CRH for cupric chloride of 69% is rare for heated indoor environments in Albuquerque, so that the hazard posed by this contaminant was estimated to be minimal. Several years of successful operation of most of the equipment since the flood occurred indicates that this is indeed the case.

The electrolytic corrosion sample from the Belle Harbour (New York) equipment, in contrast to that from Albuquerque, contains only traces of chloride salts and is substantially less hygroscopic than the Albuquerque sample. On this basis, only minimal problems were anticipated if exposure to high humidity could be eliminated. The Belle Harbour switching

center is located in a very humid environment one block from the Atlantic Ocean, but, unfortunately, at the time this water damage occurred, the method described above for determining the CRH was not available and it was not feasible to estimate the CRH by other means. Consequently, specific recommendations concerning the maximum tolerable humidity were not possible.

Recently an electronic switching center in Philadelphia was contaminated with water containing a rust inhibitor. The equipment was powered and electrolytic corrosion occurred. The CRH of the primary contaminant was found to be about 30%, which suggests a serious problem could exist, since the local humidity would nearly always exceed that value. However, the over-all hygroscopicity based on average weight gain rate and total moisture pickup after 1350 hr (16%) was low. This information, coupled with the successful operation of most of the equipment for several weeks after the flood indicated that the restored equipment would continue to operate normally without the need for extensive modifications to the building humidity control.

The equipment installation in White Plains (New York), which suffered the small battery fire described earlier, was analyzed for moisture pickup by this procedure. The contaminant was found to be less hygroscopic than the Philadelphia sample in terms of the average weight gain rate, but this average was based on roughly 10 times the sampling period. The total pickup before an extended steady state was reached was 78.7%. This result, coupled with the dramatic increase in moisture pickup observed above 50% RH, shown in Fig. 5 and discussed above, indicated that cleaning or replacement of the equipment was necessary.

The dust samples from the New York City locations and from Holmdel behave similarly, though the dust from the rural Holmdel environment is, surprisingly, somewhat more hygroscopic. None of these dusts has caused particular problems with electronic equipment. The large surface area of the dusts permits relatively large amounts of moisture adsorption to occur without creating thin films of water. The texture of the Arizona Standard Dust sample was much finer and less fibrous than the dust found in New York City and Holmdel, suggesting the surface area per unit weight is probably greater. The hygroscopicity of the Arizona Dust is, however, about an order of magnitude lower than the other dusts. As more locations are sampled, it is anticipated that unusual dusts bearing localized hygroscopic components will be distinguishable from "ordinary" dusts.

All of the insulation and substrate materials examined fit into the category of substances of low hygroscopicity. Obviously, only nonhygroscopic substances are reasonable candidates for such uses. Within this category, however, a range of moisture pickup rates was found, even for similar materials. For instance, phenol fiber No. 3 picked up moisture at an average of 0.0002 %/min, while phenol fiber samples No. 2 and 4 exhibited rates of 0.0008 and 0.002 %/min, respectively. There appears to be no correlation between age and hygroscopicity, and apparently the dif-

ferences are manufacturing in origin for these samples. Except for one phenol fiber sample, the least hygroscopic substrate materials are the epoxy glass and the alumina ceramic. More data would be needed to draw firm conclusions about the relative hygroscopcity of these substrate materials, and these results should not be extrapolated to all epoxy glass, alumina, and phenol fiber substrates available. Wide variability is likely to exist for different manufacturers and in some cases for different lots. These data demonstrate, however, that instrumental gravimetric methods can be effectively employed in distinguishing the hygroscopic characteristics of a variety of substrate materials that might be considered for device applications.

The behavior of three textile material samples from insulated wire was very similar at the high humidity level at which these experiments were run. Samples 1 and 2 had been exposed approximately 35 years to an urban environment. Sample 2 is of particular interest, as mentioned earlier, because of its unique exposure to hydrochloric acid fumes. Textile insulation typically performs poorly at high humidity levels in terms of insulation resistance. Normally, these humidity levels are not encountered at indoor installations. Unfortunately, the present apparatus is not readily suited to monitoring weight gain characteristics at an intermediate RH, where the effects of contamination on sample 2 would be pronounced. It would also be interesting to know if the freshly manufactured sample would be distinguishable from sample 1 at an intermediate RH.

Conclusion

This work was carried out to determine whether instrumental gravimetric analysis is suited to readily measure the moisture pickup characteristics of materials and substances important to the electronics industry. It was found that many substances initiate moisture pickup processes that are detectable at discrete relative humidities. Furthermore, it was found that moisture pickup characteristics measured gravimetrically at high humidity levels can be used to rank substances in a manner which is useful for assessing hygroscopicity and corrosion hazards. Unknown mixtures of materials weighing only a few tenths of a milligram can be readily analyzed. Moderately to strongly hygroscopic materials can probably be analyzed with even smaller samples. The rate of hygroscopicity change was found, in some cases, to be a signature of the material analyzed, which may prove useful when analyzing samples of unknown composition. The information gathered here clearly demonstrates the need for and the usefulness of an expanded system capable of precise relative humidity programming. Such a system is now under development. Further experiments will include the effects of pollutant gases introduced into the air stream on the measured CRH and moisture pickup rates of substances.

Kinetics of the Slow-Trapping Instability at the Si/SiO_2 Interface

A. K. Sinha* and T. E. Smith

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The slow-trapping instability can be a potentially major threat to reliability of p-channel enhancement-mode IGFET's. We have determined the kinetics of slow trapping for Al-gate MOS structures on (111) n-Si and evaluated the role of surface states, N_{SS}, for n- and p-type Si of (111) and (100) orientation. Slow trapping, as revealed by negative bias-temperature aging, generates a characteristic distribution of N_{SS} with a peak near the midgap. This effect is responsible for the fact that for n-Si, the threshold shift, $\Delta V_T >> \Delta V_{FB}$, the flatband shift, and for p-Si, $\Delta V_T < \Delta V_{FB}$. In the regime where ΔV_{FB} is less than the saturation value, our data on slow-trapping kinetics can be represented by the factorial relationship

$$\Delta V_{FB} \sim A|V_B|^n t^{0.2} \exp\left(-\frac{\epsilon_a}{kT}\right)$$

where V_B is the applied negative bias (10-40V), t is the time (10-10^3 min), T is the temperature (373°-573°K), k is the Boltzmann constant, $n = 4.76 - 5.3 \times 10^{-3}T$, $A \sim 1.6 \times 10^3$, and ϵ_a is the thermal activation energy ($\sim$0.64 eV). This equation emphasizes the strong field dependence of ΔV_{FB} at lower temperatures.

The so-called slow-trapping instability [instability No. VI of XVII compiled by Deal (1)] can be a potentially major threat to reliability of p-channel enhancement mode IGFET devices (1-4). This instability is revealed by a negative bias-temperature aging test which causes a negative shift in the flatband voltage and hence in the threshold voltage of the device. The exact mechanism of slow trapping has not been established. But it is known that slow trapping is more pronounced for MOS structures with a high fixed charge, Q_{SS} (4). Slow-trapping instability can be also aggravated by radiation damage (5) and by a low temperature post Al-metallization H_2 anneal (6).

Accelerated aging tests are commonly used to compare the slow-trapping characteristics of different MOS structures and also to evaluate the effectivity of various processing improvements [such as high temperature H_2 annealing (6)] aimed at reducing the slow trapping. However, a knowledge of kinetics is also obviously necessary in order to estimate the lifetime under device operating conditions and to stimulate work on understanding of slow-trapping phenomena.

The objective of the present work is twofold. First, the role of surface states, N_{SS}, was investigated in the slow-trapping phenomena. It is shown that a characteristic distribution of N_{SS} is generated as a result of slow trapping, and depending upon whether the Si is n- or p-type, the flatband shift ΔV_{FB} can be less than or greater than ΔV_T. Second, detailed kinetics measurements were made of slow trapping in $Al/SiO_2/$(111) n-Si capacitors. The effect of applied bias (for a given time and at lower temperatures) is found to be more severe than previously believed.

Experimental

Slow-trapping measurements were made on both n- and p-type Si wafers [(111 and 100) orientation, 2 in. diam, $N_{D,A} \sim 10^{15}$ cm^{-3}]. The wafers were cleaned and then oxidized to 1000Å thickness at 1100°C in a dry oxygen ambient in an HCl-cleaned quartz tube. The oxidized wafers received an *in situ* Ar-anneal at 1100 C for ½ hr. An array of MOS capacitors was fabricated by filament evaporating Al-field plates (20 mil diam) through a mechanical shadow mask. The SiO_2 was etched off from the back side and an Al back contact was formed also by filament evaporation. The samples were then H_2-baked at 450°C, ½ hr.

MOS measurements were made in a test facility consisting of an electroglas 910 prober equipped with a Temptronix TP 35 thermochuck and enclosed in a dry N_2 glove box (7). High frequency (1 MHz) C-V measurements were made at a sweep rate of 100 mV/sec. Quasistatic measurements were made at 20 mV/sec using the slow-ramp technique (8). The data were analyzed in the usual manner to give the Si-doping level (9), the flatband capacitance and voltage, the oxide fixed charge Q_{SS}, and the surface-state density as a function of the relative surface potential, ψ_S. The surface-state density was obtained from the high-low frequency capacitance technique (10) and ψ_S found as a function of bias using the Berglund techniques (11).

The extent of slow trapping was evaluated through measurements of negative shift in the flatband voltage, ΔV_{FB}, following bias-temperature aging at various temperatures in the range 100°-300°C, with applied negative bias of 10-40V, and for times of 10 min-16 hr.

Results and Discussion

Positive bias-temperature aging under conditions (10^5 V/cm, 200°C, 30 min) where slow trapping is very small caused little or no negative shift (<0.1V) in the C-V curves, signifying that the mobile charge contamination levels were below 2×10^{10} cm^{-2}.

Representative C-V curves.—Figure 1 shows typical C-V curves for a MOS structure on (111) n-Si in the as-received condition and after B-T aging at -23.5V, 250°C, for 15 min. The as-received sample had a Q_{ss} of 2×10^{11} cm^{-2} and a midgap N_{SS} of $\sim 5 \times 10^{10}$ cm^{-2} eV^{-1}. Upon negative B-T aging, the slow trapping is revealed in three ways: (*i*) the high frequency C-V curve is shifted to more negative values reflecting an increase in the apparent Q_{SS} and a ΔV_{FB} of -0.8V; (*ii*) the initially single minimum in the quasistatic C-V curve is split into two minima which now occur at significantly higher C/C_{ox}; this higher C/C_{ox} is the result of an order of magnitude increase in the N_{SS} which has a peak near the midgap, as shown in Fig. 2; (*iii*) there is an increase (by $\sim$1.5V) in the negative threshold voltage from V_{T1} to V_{T2}, as indicated by the vertical

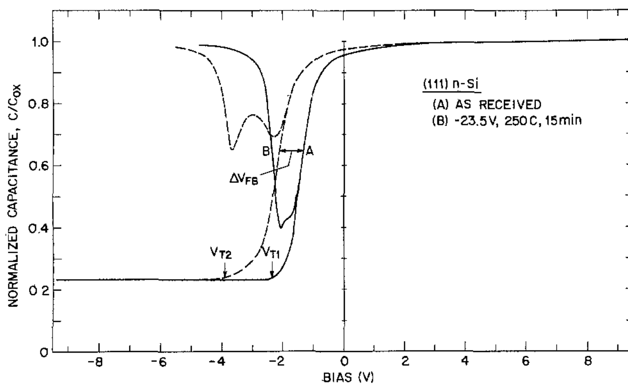

Fig. 1. *C-V* curves for $Al/SiO_2/n(111)Si$ capacitors: (A) as-received; (B) after −23.5V, 250°C, 15 min bias-temperature aging.

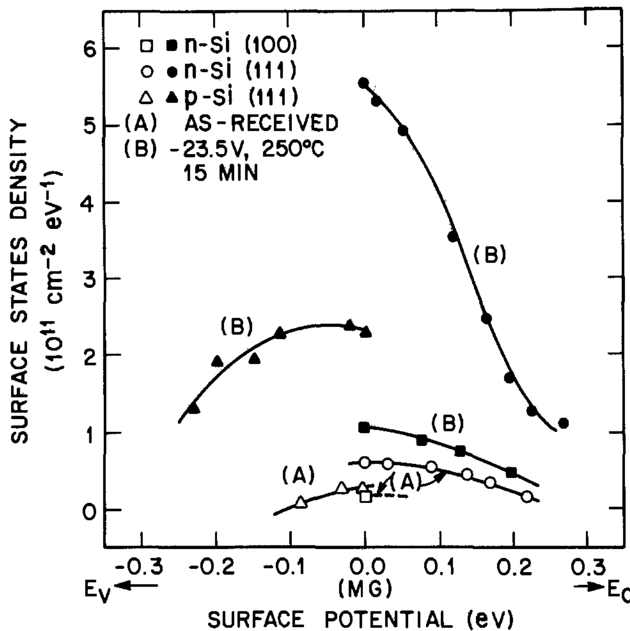

Fig. 2. Distribution of surface states in various $Al/SiO_2/Si$ structures: (A) as-received; (B) after −23.5V, 250°C, 15 min B-T aging.

arrows in Fig. 1, with $\Delta V_T >> \Delta V_{FB}$. This is due to the fact that increases in both Q_{SS} and N_{SS} due to slow trapping with n-Si cause threshold shifts in the same direction, which are therefore additive. Moreover, for n-Si, there are fewer occupied surface states at V_T than at flatband voltage. For p-Si, there are more occupied states at T than at flatbands.

Figure 3 shows the effects of slow trapping in an Al-gate MOS structure on (111) p-Si. Here too there is a negative shift in the flatband voltage, ΔV_{FB}, which is nearly equal in magnitude to that observed with (111) n-Si. There is also a significant increase in N_{SS} and a tendency toward splitting of the minimum in the quasistatic *C-V* curve. However, in this case, ΔV_T is much smaller than ΔV_{FB}, since the apparent ΔV_T components due to additional Q_{SS} and N_{SS} now are in opposite directions. The distribution of $N_{SS}(\psi_S)$ for the (111) p-Si sample before and after B-T aging is shown in Fig. 2 and is similar to that for (111) n-Si.

Figure 4 shows *C-V* data for (100) n-Si before and after B-T aging. The magnitudes of both ΔV_{FB} and ΔV_T are smaller by a factor of four than those for (111) n-Si. It should be also noted that the initial Q_{SS} ($\lesssim 10^{10}$ cm^{-2}) and N_{SS} at midgap ($\sim 10^9$ cm^{-2} eV^{-1}, see Fig. 2) for this sample were lower by an order of magnitude when compared with (111) n-Si.

This and other recent work support the conclusion that the initial Q_{SS} may be a major factor controlling the slow-trapping instability—a small Q_{SS} correlates with reduced slow trapping. For (111) n-Si samples, the Q_{SS} can be decreased to $\lesssim 1 \times 10^{11}$ cm^{-2} by a high temperature H_2 anneal (800°-900°C, ½-1 hr). These samples show a very small ΔV_{FB} of $\sim$0.2V after 250°C, −20V, 15 min aging. On the other hand, a low temperature H_2 anneal (450°C, ½ hr), which lowers the N_{SS}, tends to enhance the slow-trapping instability (6).

Kinetics data.—Kinetics measurements were made for (111) n-Si samples which had received the post-Al H_2-bake (450°C, ½ hr) but no high temperature H_2 anneal. The ΔV_{FB} was measured for various conditions of negative-bias temperature aging in which two of the three variables, namely, time, temperature, and bias, were kept constant and the third one was changed.

Figure 5 shows the effect of applied bias V_B on ΔV_{FB} induced by slow trapping. Results are shown for various temperatures (80°, 150°, 200°, 250°, and 300°C) for a fixed time of 15 min and for bias voltages ranging from −4 to −80V. [Although bias voltages are quoted in this paper, it should be understood that the field across the oxide and not the voltage is the parameter that determines ΔV_{FB} for various oxide thicknesses (4).] At a given temperature, ΔV_{FB} is a strong function of V_B, with

$$\frac{\partial \log (\Delta V_{FB})}{\partial \log |V_B|} \approx n \qquad [1]$$

where the exponent n ($1.5 < n < 3.2$) is an inverse function of the aging temperature T (°K), as shown in Fig. 6. According to this figure, n will approach unity around 400°C, at which temperature ΔV_{FB} will be a simple linear function of V_B. This is the form of ΔV_{FB} (V_B) relationship reported by Deal *et al.* (4) who plotted the maximum flatband shift measured at $\sim$400°C. At this temperature, saturation in ΔV_{FB} is reached in a relatively short time of few minutes. For the temperatures used in the present work, 15 min was too short a time to reach saturation or steady-state

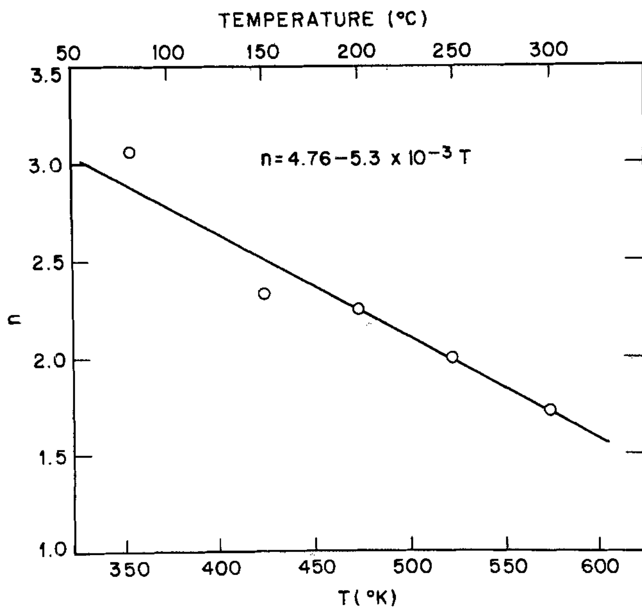

Fig. 6. Temperature dependence of exponent n in Fig. 5

conditions, yet it was adequate to reveal a ΔV_{FB} of 0.1-5V provided the bias fields were large enough.

The nonsteady-state conditions investigated in the present work were preferred because they were convenient and also because they correspond more closely to the device behavior during its operation. Thus, slow-trapping shifts usually cause the device threshold voltage to go out of specification long before the saturation value has been attained.

Figure 7 shows the variation with time of ΔV_{FB} at various temperatures, keeping V_B constant at −20V. It

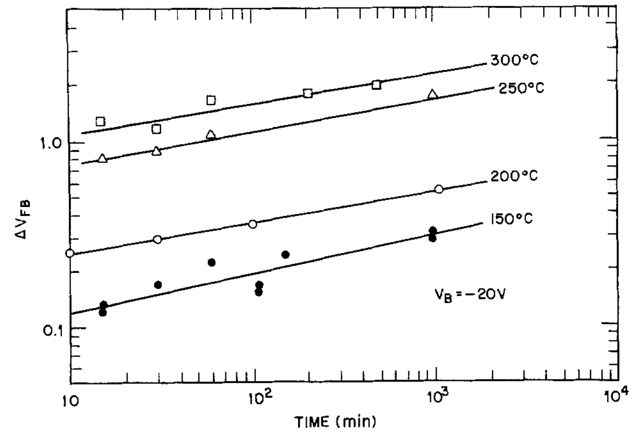

Fig. 7. Time dependence of flatband shift due to slow trapping at various temperatures and for an applied bias of −20V.

may be seen that a substantial portion of the slow trapping shift is revealed in 15 min; however, there continue to be additional shifts with increasing time. For the present samples, the time dependence ($t > 10$ min) was relatively weak, with

$$\frac{\partial \log \Delta V_{FB}}{\partial \log t} \approx 0.2 \quad [2]$$

This form of time dependence again relates to ΔV_{FB} data below the saturation value.

Figure 8 shows an Arrhenius plot in which ΔV_{FB} has been normalized with $|V_B|^n$ and $t^{0.2}$. A remarkably good fit is obtained for the present set of samples, giving an apparent thermal activation energy of ~0.64 eV. Also shown in Fig. 8 are certain results taken from the work by Broydo and Waggener (12). The combined data show a relatively large degree of scatter, indicating that the slow-trapping kinetics are also a sensitive function of the starting material and that

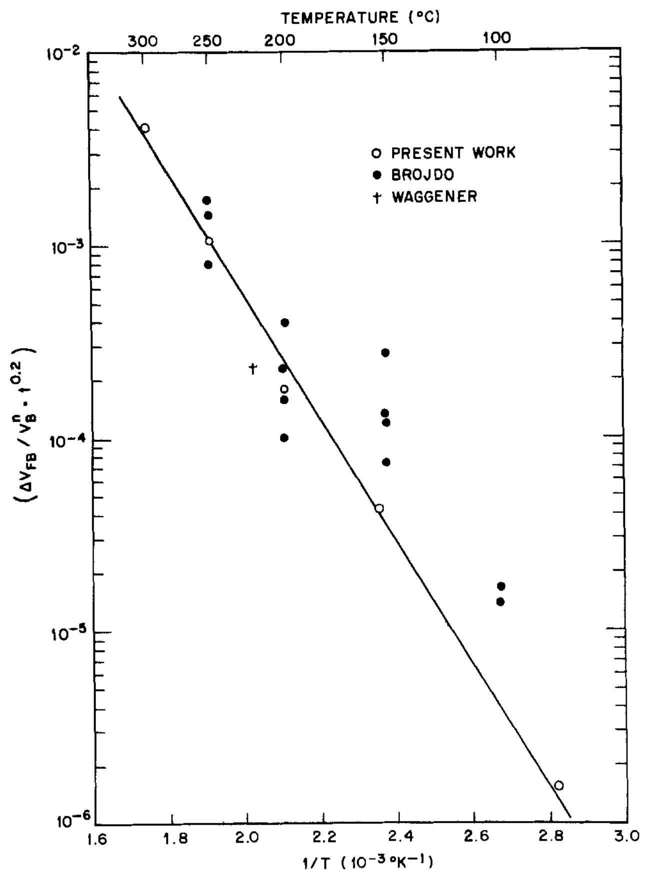

Fig. 8. Arrhenius plot of normalized ΔV_{FB} due to slow trapping

it may not yet be possible to provide a universal equation for ΔV_{FB}.

Results in Fig. 8 for the present samples (a single lot of six wafers) do indicate, however, that it is possible to rationalize over 30 measurements of ΔV_{FB} in terms of the following simple factorial relationship

$$\Delta V_{FB} = A|V_B|^{n(T)}t^{0.2} \exp\left(-\frac{\epsilon_a}{kT}\right) \quad [3]$$

where, $A = 1.576 \times 10^3$, $\epsilon_a = 0.64$ eV, $n = 4.76 - 5.3 \times 10^{-3}T$. Equation [3] contains only a single thermal activation energy term and it gives proper weight to the effects of applied bias and time. As noted earlier, the above functional dependence is valid only for ΔV_{FB} values prior to saturation.

The theoretical implications of Eq. [3] are not clear. We believe that the present results lend some support to the model of Deal (1), namely that slow trapping is caused by field-temperature induced structural rearrangements at the Si/SiO_2 interface. In Deal's model (1), a displaced oxygen atom which would otherwise bridge two Si atoms at the interface can simultaneously lead to a positive charge in the oxide and a surface state (dangling bond) in the Si. The ease of such a displacement would depend on the microstrain initially present in the Si-O bond at the interface. It is conceivable that the interfacial strain is related to the magnitude and screening distance of the fixed charge (excess Si atoms?) always present at the SiO_2/Si interface. It appears that this (compressive) strain also provides the driving force for slow trapping. The roles of temperature and applied field in causing dissociation of strained O-Si bonds appear to be complementary. Thus, as the temperature gets smaller, V_B tends to have a more pronounced effect on ΔV_{FB}.

Summary and Conclusions

The slow-trapping instability has been investigated for n- and p-type (111) Si and for n-type (100) Si.

1. For well-annealed MOS structures, negative bias-temperature aging causes a characteristic splitting of the quasistatic C-V curve; the resulting N_{SS} has a peak near the midgap. This N_{SS} effect is responsible for the fact that for n-Si, $\Delta V_T > \Delta V_{FB}$ whereas for p-Si, $\Delta V_T < \Delta V_{FB}$.
2. For a given time and temperature and ΔV_{FB} less than the saturation value, ΔV_{FB} increases with the applied field. The field dependence gets stronger at lower temperatures.
3. For a given field and temperature, and time greater than 10 min, there is a relatively slow variation ΔV_{FB} with time.
4. For a given set of identical samples, it is possible to normalize ΔV_{FB} with respect to the applied bias and time, the resulting temperature dependence yields a single-valued activation energy equal to 0.64 eV for the presently studied $Al/SiO_2/n(111)Si$ structures.

Two-Layer Model for Heat-Treated Anodic Tantalum Oxide

A. Climent, J. M. Martinez-Duarte and J. M. Albella[1]

Departamento de Física Aplicada e Instituto de Física del Estado Sólido (C.S.I.C.), Universidad Autónoma de Madrid, Cantoblanco, Madrid, Spain

ABSTRACT

The dielectric properties of Ta_2O_5 thin films, grown anodically in a phosphoric acid solution and subjected to heat-treatment, have been investigated as a function of frequency in the range 0.1-100 kHz and temperatures from $-100°$ to $300°C$. The experimental evolution of tan δ and series capacitance with the frequency and temperature is reproduced theoretically assuming that the anodic oxide has two layers with a different exponential conductivity gradient. The imaginary part of the dielectric constant shows a relaxation process of the Maxwell-Wagner type, which is also explained by the above model for the oxide.

In the manufacture of tantalum capacitors the anodic oxide is normally subjected to temperatures above 200°C in the process of the pyrolytic deposition of the manganese oxide solid electrolyte. The dielectric properties of the resulting oxide have been thoroughly investigated by Smyth *et al.* (1), who reached the conclusion that a gradient in the electrical conductivity

[1] Permanent address: Instituto de Optica Daza de Valdés (C.S.I.C.), Serrano, 121, Madrid-6, Spain.
Key words: dielectric properties, Maxwell-Wagner model, tantalum capacitors, heat-treatment in anodic oxides.

across the oxide is formed due to the migration of oxygen atoms which are partially dissolved in the tantalum substrate. Furthermore, the incorporation of phosphorus in the outer part of the oxide during anodization in the standard phosphoric acid electrolyte has been well established by several techniques such as radiotracer measurements (2), Auger electron spectroscopy (3, 4), and infrared reflectance spectroscopy (5). For these samples, the heat-treatment results in two layers in the oxide with different electrical conductivity gradients (1). The outer layer presents a steeper gradient and lower conductivity than the inner layer as a consequence of a smaller diffusion of the oxygen atoms due to the phosphorus incorporation.

Based on the previous work of Smyth *et al.* (1), the two-layer exponential gradient model has been quantitatively applied in this paper to tantalum oxide anodized in a phosphoric solution. From the experimental results obtained in this work, all the parameters which characterize the dielectric properties of each layer have been evaluated. Then, according to the model, the curves of the dependence of capacitance and loss factor with frequency and temperature are computed and compared to the experimental values, resulting in a good agreement. In addition, it has been mathematically shown in detail how a relative maximum in the dependence of the loss factor with frequency arises in the two-layer exponential gradient model.

Experimental

Tantalum foil from Reframet Hoboken with a thickness of 0.1 mm and 99.96% purity was anodized in a 0.01% H_3PO_4 electrolyte at a current density of about 10A m^{-2}. Previous to anodization, the samples were thoroughly degreased and chemically etched in a 5:2:2 mixture of sulfuric, nitric, and fluorhydric acids. Samples of 1.5 $\times$ 0.5 cm were cut and three gold counterelectrodes with a diameter of about 2 mm were evaporated along each of the samples. A thin copper wire was attached to the gold spot by means of a gold paint. Finally, the samples were subjected to a 350°C heat-treatment for 20 min under high vacuum.

The series capacitance, C_s, and the loss factor, tan δ, $\pi/2 - \delta$ being the angle between the current and the voltage, were measured with a General Radio 1620-A capacitance bridge in which the oscillator was substituted by a Hewlett Packard 3310-A sinusoidal generator in order to increase the frequency range to 100 kHz. All the measurements were performed with the samples inside a cryostat connected to a vacuum pump. The temperature was controlled by means of a Chromel-Chromel Alumel thermocouple.

Results and Theoretical Model

Figures 1-4 show the dependence of the capacitance and tan δ with temperature and frequency. These results suggest the existence of a conductivity profile (1) with two different exponential gradients. They also imply the existence of a critical level of conductivity σ_c such that the portion of the dielectric film with $\sigma > \sigma_c$ is short-circuited acting as part of the electrode. σ_c is given by

$$\sigma_c = \omega\epsilon\epsilon_0 \quad [1]$$

where ω is the angular frequency, ϵ the dielectric constant, and ϵ_0 the permittivity of vacuum. From Eq. [1] we can get an idea of the variation of the conductivity across the oxide by plotting the logarithm of frequency as a function of $1/C$, since $1/C$ is proportional to the effective thickness of the dielectric. Figure 5 shows such plots, obtained from Fig. 1, at different temperatures. It can be appreciated that for a temperature of 193°K and in the frequency range studied, σ_c should be above the value of σ at the $Ta-Ta_2O_5$ interface (conductivity profile at T_1 in Fig. 6a). As the temperature is raised to 303°K, the conductivity increases and the most conductive portion of the profile raises above σ_c (relative position as for the profile at T_2 in Fig. 6a). As the temperature is further increased to 383°K, the most resistive or outer layer of the film starts to appear and at 433°K

the conductivity of an important part of this layer is above σ_c (conductivity profile at T_3 in Fig. 6a).

The oxide's equivalent circuit chosen for our model is shown in Fig. 6b. It is formed by two capacitance-resistance series circuits, each representing one portion of the film, connected in series. Young (6) has obtained expressions for the series capacitance C_s and

the equivalent series resistance R_s of a dielectric with an exponential gradient conductivity profile of the form

$$\sigma = \sigma_0 \exp(-ax) \qquad [2]$$

These expressions are

$$R_s = \frac{1}{aA\omega\epsilon\epsilon_0}\left(\tan^{-1}\frac{\omega\epsilon\epsilon_0}{\sigma_0 e^{-ad}} - \tan^{-1}\frac{\omega\epsilon\epsilon_0}{\sigma_0}\right) \qquad [3]$$

$$\frac{1}{C_s} = \frac{1}{2aA\epsilon\epsilon_0}\log\left[\frac{1+\left(\frac{\omega\epsilon\epsilon_0}{\sigma_0 e^{-ad}}\right)^2}{1+\left(\frac{\omega\epsilon\epsilon_0}{\sigma_0}\right)^2}\right] \qquad [4]$$

where A is the electrode's area and d is the thickness of the dielectric. In this derivation ϵ is supposed to be a constant, that is, the influence exerted on the capacity as a consequence of the variation of ϵ with frequency will be neglected in comparison to the influence due to a change in the effective dielectric thickness when $\sigma > \sigma_c$. We will apply next Eq. [3] and [4] to each of the layers in the dielectric.

At a distance x from the Ta-Ta_2O_5 interface and at a temperature T, the conductivity of the oxide can be expressed as

$$\sigma_{x,T} = B\exp\left(-\frac{E_x}{kT}\right) \qquad [5]$$

where E_x, the activation energy of the conductivity (7), is given by

$$E_x = E_o + bx \qquad [6]$$

In this equation, E_o is the activation energy at the Ta-Ta_2O_5 interface and the value of the coefficient b depends on the value of the slope of the exponential gradient. We will also take into account the variation of the dielectric constant with temperature according to

$$\epsilon = \epsilon_c + \alpha T \qquad [7]$$

The values of ϵ_c and α can be deduced from the experimental values of Fig. 1 in the region of low temperatures where $\sigma_c > \sigma_{x=0}(T)$ and the decrease of the effective dielectric thickness has not occurred yet.

Taking into account the dependence of σ and ϵ with temperature by means of Eq. [5] and [7] and defining R_s and C_s for each layer of the dielectric by Eq. [3] and [4], we get

$$C_s(T,\omega) = \frac{C_{s1}(T,\omega)\cdot C_{s2}(T,\omega)}{C_{s1}(T,\omega) + C_{s2}(T,\omega)} \qquad [8]$$

$$R_s(T,\omega) = R_{s1}(T,\omega) + R_{s2}(T,\omega) \qquad [9]$$

$$\tan\delta(T,\omega) = R_s(T,\omega)C_s(T,\omega)\omega \qquad [10]$$

The theoretical results predicted by the double layer conductivity profile model are obtained from Eq. [8] and [10] and later on compared to the experimental results. The parameters $\sigma_{x=0}(T)$, $\sigma_{x=1}(T)$, $a_1(T)$, and $a_2(T)$ in Eq. [8]-[10] are obtained from the experimental values. The dependence of a_1 and a_2 on temperature can be derived from Eq. [2], [5], and [6]

$$a_1 = \frac{b_1}{kT}; \quad a_2 = \frac{b_2}{kT} \qquad [11]$$

The values of the electrical parameters shown in Table I have been obtained by the procedure just indicated from the results of Fig. 1 and 2. The position l within the oxide (see bottom of Table I), where the exponential conductivity gradient changes, is first obtained from the break in slope of the lines in Fig. 5 and further adjusted by fitting the curves obtained from Eq. [8] and [10] to the experimental values.

The dependence of the capacitance and tan δ with temperature, at several frequencies, which is given by Eq. [8] and [10], has been calculated by means of a computer and are compared in Fig. 7 and 8 with the experimental results.

l (distance between the Ta-Ta_2O_5 interface and the layer I-layer II interface): 1063Å

Discussion

The agreement between the values deduced from the two-layer conductivity profile model and the experimental values is quite good as it can be appreciated from Fig. 7 and 8. The maxima in the tan δ *vs.* T curves are usually higher and more pronounced for the computed curves. This is attributed to the hypothesis that the dielectric is only formed by two layers, the exponential conductivity gradient being constant in each layer. In practice, at the two metal-oxide junctions as well as at the junction between the two layers in the dielectric, the conductivity might have values quite different from the assumed ones. One refinement, therefore, could be to assume that the dielectric is divided into three zones, with one intermediate in which the exponential gradient has a slope with a value between a_1 and a_2.

The evolution with frequency of some of the parameters characterizing each of the two layers is represented in Fig. 9. From Eq. [8] and [9], tan δ can be written as

$$\tan\delta = \omega(R_{s1} + R_{s2})\frac{C_{s1}C_{s2}}{C_{s1} + C_{s2}} \qquad [12a]$$

or

$$\tan\delta = \tan\delta_1\frac{C_{s2}}{C_{s1} + C_{s2}} + \tan\delta_2\frac{C_{s1}}{C_{s1} + C_{s2}} \qquad [12b]$$

where $\tan\delta_i = \omega R_{si}C_{si}$, $(i = 1, 2)$.

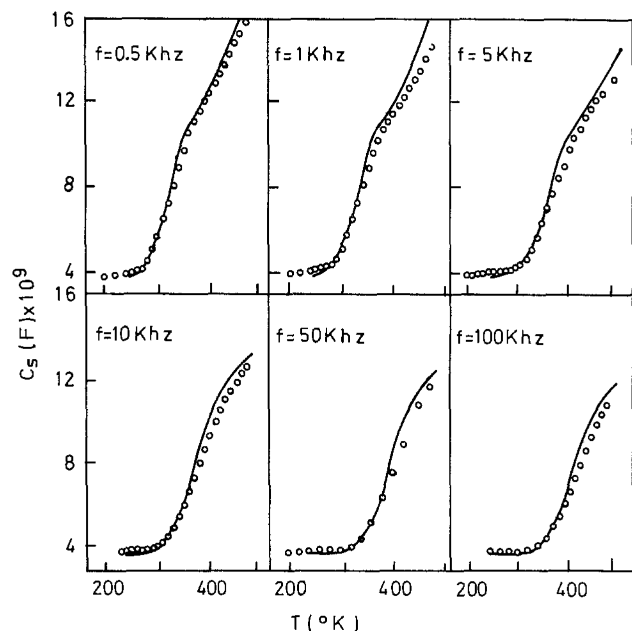

Fig. 7. Temperature dependence of capacitance for the sample of Fig. 1. The dots represent the experimental values and the lines represent the values computed from Eq. [8].

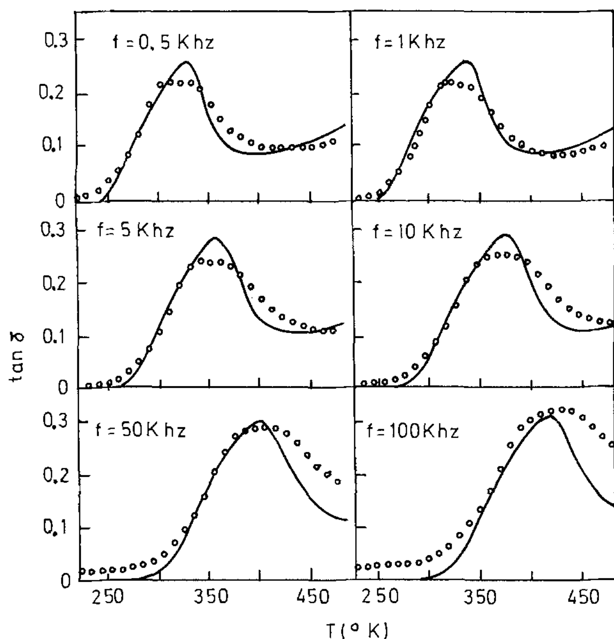

Fig. 8. Temperature dependence of tan δ for the sample of Fig. 1 (The symbols as in Fig. 7).

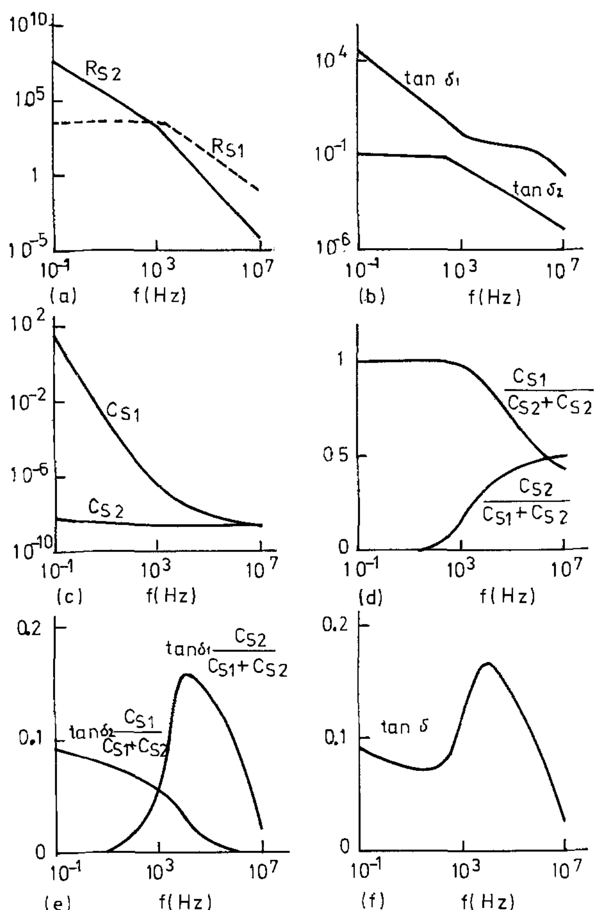

Fig. 9. Frequency dependence at $T = 68°C$ of several parameters computed from the double layer model for the dielectric (same sample as in Fig. 3).

At low frequencies (much lower than the frequency at which log σ changes its slope, about 1 kHz in this particular case), it can be observed in Fig. 9a that $R_{s2} >> R_{s1}$, and according to Eq. [12a]

$$\tan\delta \simeq \tan\delta_2 \frac{C_{s1}}{C_{s1} + C_{s2}} \quad [13]$$

In addition, for these frequencies, $C_{s1} >> C_{s2}$ (Fig. 9c) and therefore

$$\tan\delta \simeq \tan\delta_2 \quad [14]$$

For frequencies much higher than the frequency at which $R_{s1} = R_{s2}$ in Fig. 9b, we have $R_{s1} >> R_{s2}$ and

$$\tan\delta \simeq \tan\delta_1 \frac{C_{s2}}{C_{s1} + C_{s2}} \quad [15]$$

In this case, as the frequency gets higher, $C_{s2}/(C_{s1} + C_{s2})$ increases much slower than tan δ_1 decreases and as a result of this tan δ given by Eq. [15] presents a maximum (Fig. 9f).

As the frequency increases, C_{s1} decreases and becomes comparable to C_{s2} (Fig. 9c), thus having a more important contribution to the total capacitance. All of this is in agreement with the existence of a critical level of conductivity σ_c as proposed by Smyth *et al.* (1). It is also interesting to notice that the graph of tan δ *vs.* log f is the specular image of the graph of tan δ *vs.* T as it should be expected from the conductivity profile model and has been experimentally checked (Fig. 4 and 8).

Figure 10 represents log f as a function of the value of $1/T$ for the occurrence of the maxima of tan δ in Fig. 8. From the slope of this line, an activation energy $E_\delta = 0.726$ eV can be gotten by assuming the following expression for the angular frequency

$$\omega = \omega_0 \exp\left(-\frac{E_\delta}{kT}\right) \quad [16]$$

It can be easily shown that E_δ is the activation energy of the conductivity at the point in which the conductivity profile corresponding to the temperature for the occurrence of the maximum intersects the line $\sigma = \sigma_c = \omega\epsilon\epsilon_0$ and that the distance from this point to the Ta-Ta_2O_5 interface is the same for every temperature. Accordingly, it is not surprising that the value found for E_δ is of the same magnitude as the value reported for E_1 in Table I since the appearance of the maximum is related to the point where the exponential conductivity gradient changes its slope from a_1 to a_2. Similarly, a value for ω_0 equal to 8.6×10^{14} sec^{-1} is obtained from Eq. [16], which multiplied by $\epsilon\epsilon_0$ yields a value of the constant B which is very close to the one reported in Table I.

It can be concluded from this work that the two-layer exponential gradient conductivity profile model predicts, in the case of thermally treated Ta_2O_5 films anodized in phosphoric acid solutions, a dependence with frequency and temperature of the electrical parameters which is in satisfactory agreement with

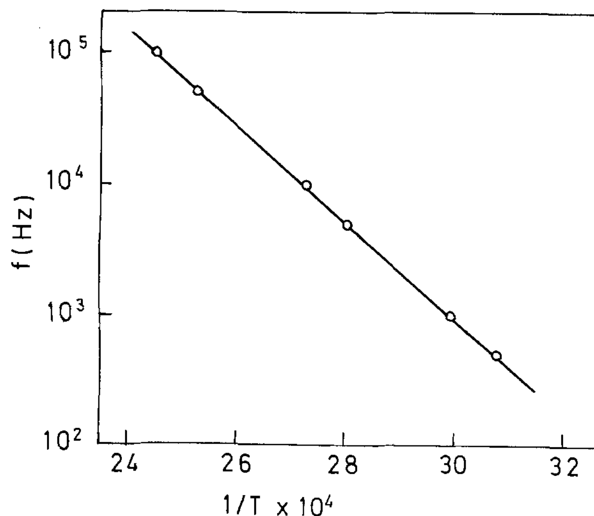

Fig. 10. Log f vs. $1/T$ for the occurrence of the maxima of tan δ in Fig. 8.

the experimental results. The agreement could still be improved by introducing some additional zones in the dielectric, the computations still being straightforward. The two-layer model can be assimilated to a generalized Maxwell-Wagner model (8) with a distribution of resistivity values and just one value for the dielectric constant. The behavior of tan δ with frequency found in this work is similar to the one predicted by the Maxwell-Wagner model.

As far as the value found for l in the present work (Table I), which implies that the boundary between the two layers in the oxide is closer to the oxide-counterelectrode interface, it is in qualitative agreement with the conclusions reached by Smyth *et al.* (1) for anodization in a low concentration phosphoric acid electrolyte. Applying the infrared reflectance spectroscopy technique, Kihara-Morishita (5) measured the relative thicknesses of the phosphorus-free and phosphorus-contaminated layers and found that, for Ta_2O_5 films of the thickness employed in this work, the boundary between the two layers is around the location computed in this paper. The conditions of anodization, *i.e.*, the concentration of the electrolyte and the current density, influence the amount of phosphorus incorporated, which in our case might be estimated as 0.03 moles of phosphorus per mole of Ta^{5+} (2).

Young (6) applied the one-layer exponential conductivity gradient to explain the behavior of R_s and C_s with frequency and obtained a straight line for the plot of $1/C_s$ as a function of log f. Winkel and Groot (9), advocating the multiple distribution of relaxation times model of Gevers and du Pré (10), emphasize that in some experimental results a curvature of the $1/C_s$ plots is observed at frequencies above 1 kHz, thus deviating from Young's simple model. In this context, it is interesting to observe that the curvature in the $1/C_s$ curves can also be explained by assuming a conductivity exponential gradient with two or more different slopes as proposed by Smyth *et al.* (1). In addition, it can be concluded from this work that the double-layer conductivity profile model can quantitatively account for the values of the dielectric properties of anodic tantalum oxide thermally treated. However, we do not believe that this model will substitute in every case the more general model of multiple relaxation times.

Direct Determination of the Electrical Conductivity-Nonstoichiometry Relationship in Ionically Conducting Metallic Oxides

J. Fouletier and M. Kleitz*

E.N.S. d'Electrochimie et d'Electrométallurgie de Grenoble, Domaine Universitaire, 38401 St Martin d'Hères, France

ABSTRACT

The small quantities of oxygen driven off zirconia solid solutions by solid-state electrolysis were accurately measured and the relevant departure from stoichiometry determined by using oxygen gauges and pumps. The variations in the electronic conductivity and in the ionic transport number were determined as functions of temperature and deviation from stoichiometry. By measuring the rate of oxygen release during the first stage of the electrolysis of prereduced and homogenized samples, the ionic transport number was also determined according to another independent method. The two sets of results compared quite favorably. These methods of measurement offer the possibility of investigating nonstoichiometric oxides, especially in experiments involving small departures from stoichiometry and very reducing conditions.

In solid-state electrochemistry, an oxide is traditionally characterized by the variation of its conductivity as a function of equilibrium oxygen pressure and temperature $\sigma(p_{O_2}, T)$. Recently, Blumenthal and Hofmaier (1) proposed a technique of measuring the variation of conductivity with temperature at fixed values of the stoichiometric ratio.

A sound demonstration of a point defect model further requires another independent set of data, for

* Electrochemical Society Active Member.
Key words: electrical conductivity, ionic transport number, nonstoichiometry, zirconia.

example, the variation of the stoichiometric ratio as a function of the same parameters $x(p_{O_2}, T)$ (2). This can be determined by using a thermobalance when the corresponding weight changes are sufficiently large (3-5).

In this paper we propose a method of measurement which allows us to directly determine the variation of conductivity as a function of the stoichiometry ratio and temperature $\sigma(x, T)$. We also report on experimental observations which could lead to a second, complementary method of measurement of the ionic transport number employing the same parameters $t_i(x, T)$.

These methods, which are based on the utilization of solid-state oxygen pumps and gauges, can now be applied because of the recent improvements (6-7) in the performances and reliability of these devices. For example, a 10 ppm variation of the oxygen content in an inert gas stream can be measured within 5%. A straightforward calculation shows that such a variation occurring over a period of 5 min in a gas streaming at 5 liters·hr^{-1} flow rate corresponds to an extraction (or addition) of only 6 μg of oxygen. If this change results from oxygen pickup by a 100g sample, the measured variation corresponds to a relative change in its weight of 6×10^{-8}. This simple calculation indicates how attractive the use of these devices can be.

Experimental Setup

The experimental setup is essentially composed of a gas circuit (Fig. 1) involving a gas cylinder, an oxygen electrochemical pump, the experimental vessel, an oxygen gauge, and an accurate flowmeter connected in series. The oxygen content in the inert gas is established by the electrochemical pump and measured with the oxygen gauge on bypassing the experimental vessel. It is also measured by the gauge after the gas passes over the sample. Argon was used as the carrier gas. The flow rate ranged from 5 to 20 liters·hr^{-1} which corresponds to average linear velocities of 8-31 cm·sec^{-1}. All the details regarding the pump and gauge characteristics have been given in previous papers (6-11).

The oxygen gauge was composed of a laboratory-made closed-ended electrolyte tube of composition $(ZrO_2)_{0.91}(Y_2O_3)_{0.09}$. The electrodes were obtained by painting with platinum the outer and inner surfaces of its flat bottom. Air in contact with the outer electrode was used as a reference gas. The temperature of the cell was 650°C. The oxygen pressure in the working gas which circulates inside the tube was deduced from the voltage, E, measured between the electrodes by application of the Nernst law, the numerical expression of which was

$$E(\text{mV}) = 19.89 \times \ln \frac{p(\text{atm})}{0.201} \quad [1]$$

The oxygen pump was formed of a simple tube of the same composition as the gauge. The electrodes coated on the inner and outer surfaces were also of porous platinum. Its operating temperature was 750°C. The working gas was circulated inside the tube. The amount of oxygen added or extracted from it per second was simply correlated to the current passing through the pump by the Faraday law

$$q(\text{l}_{\text{NTP}} \cdot \text{sec}^{-1}) = 5.803 \times 10^{-8} \times I(\text{mA}) \quad [2]$$

The time lag of the gauge voltage after a rapid variation in oxygen concentration became significantly longer than 1 min with oxygen contents lower than 10 ppm. This could have greatly limited the methods we proposed. To avoid this difficulty, the experimental conditions were selected so that the oxygen content was either very low (purified argon) or higher than 10 ppm, apart from short transitions between these two states.

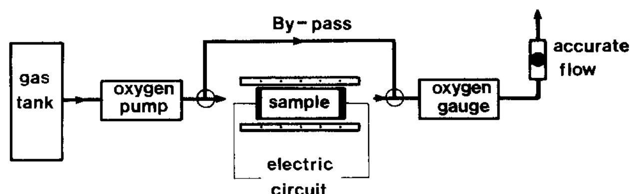

Fig. 1. Experimental setup

The sample was a small cylinder 2.2 cm long and 1.1 cm in diameter with porous platinum electrodes at both ends. These electrodes were connected either to an impedance meter for measuring the sample resistance or to a direct current source for electrolyzing the sample. Its composition was $(ZrO_2)_{0.87}(Y_2O_3)_{0.12}(CeO_2)_{0.01}$ or $(ZrYCe)O_{1.893}$. It was prepared by dry mixing of the oxide powders (ZrO_2, Merck, purity 99.9%; Y_2O_3, Pechiney; CeO_2, Pechiney), pressing at 1.5 tons·cm^{-2} and sintering at 2000°C for 2 hr.

For oxygen pressures higher than 10^{-7} atm, the electronic transport number of this material has been evaluated to a few percent (12). It was neglected in the following derivations.

Nonstoichiometry Measurement and Control

The intentional modifications of the stoichiometry and the corresponding measurements of the stoichiometric ratio variation were performed as follows.

The argon carrier gas flowing around the sample was purified by applying a suitable voltage of about −1.5V to the pump (13). Thus, all traces of free oxygen in the gas were eliminated and the traces of water vapor and carbon oxides partly reduced. The oxygen gauge exhibited a voltage around −0.9V. Then, a suitable constant current, I, was passed through the sample for a time, δ_e. The applied voltage (which included the ohmic drop in the sample and the decomposition voltage) greatly depended on the temperature. In the experiments reported below, it varied between a few volts and 200V. It was applied in such a way that oxygen evolved from the downstream side of the sample (positive electrode on this side). After a certain delay, which corresponded to the flow rate of the gas, the gauge indicated an enrichment in oxygen which lasted for a time, δ_e, and then sharply decreased (Fig. 2). From the plot of the gauge voltage *vs.* time, the determination of the amount of oxygen released by the sample during the electrolysis was calculated. The oxygen flux released at a given time was obtained by multiplying the gas flow rate, D ($\text{l}_{\text{NTP}} \cdot \text{hr}^{-1}$), by the ratio of the measured oxygen pressure p to the total pressure, p_{total}, in the gauge. The total amount of oxygen, Q, is simply determined by integration according to the equation

$$Q(\text{mole}) = \frac{D}{22.4} \cdot \int_0^{\delta_e} \frac{p}{p_{\text{total}}} \cdot dt \quad [3]$$

It is straightforward to deduce from Q the induced deviation from stoichiometry x. Accordingly the formula of the reduced sample was written $(ZrYCe)_{1.893-x}$.

This technique constitutes an easy means to control the stoichiometric ratio by appropriately selecting the parameters I and δ_e. The sensitivity in the adjustment of these parameters is obviously far greater than the sensitivity in the stoichiometric ratio measurements and does not limit the performance of the method.

Initially we verified the validity of the method of measurement. The point to be checked concerned the possible errors due to measurement of oxygen pressure during transient periods. For that purpose we also measured the amount of oxygen picked up by the sample during its reoxidation. The sample was initially kept under pure argon. The experimental vessel was bypassed and the oxygen content in the gas fixed at a value in the range 10-100 ppm. Then the gas was passed through the experimental vessel and the gauge voltage recorded. The amount of oxygen absorbed by the sample was determined as for the reduction proc-

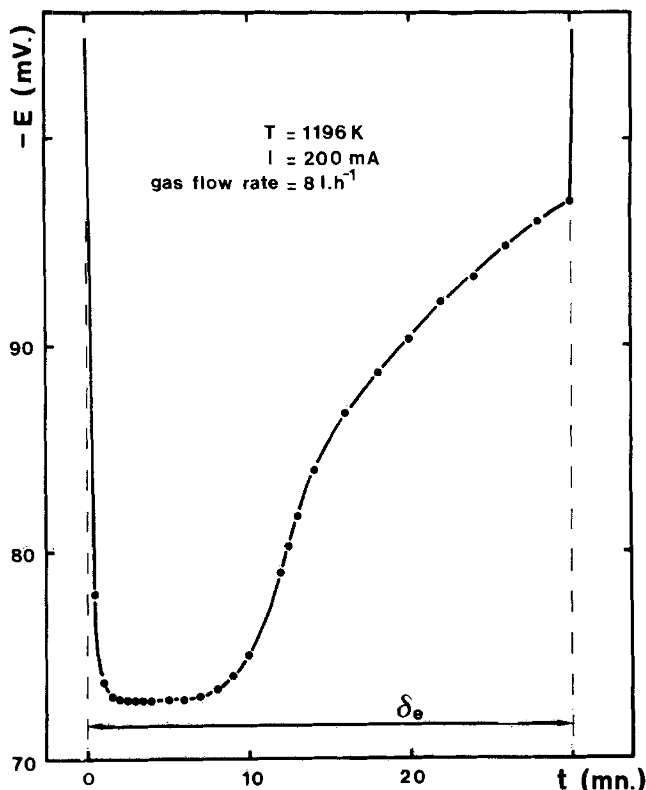

Fig. 2. Typical curve of the gauge voltage vs. time recorded during electrolysis of the sample.

ess. Some reoxidation runs were performed in several partial steps: purified argon, enriched argon, purified argon, enriched argon, etc., in order to increase the number of transient periods and to determine their effects as a possible source of error. Such experiments were carried out many times and have been reported in a previous paper dealing with an oxygen getter (10). For oxygen concentrations in the oxidizing gas higher than 10 ppm, the calculated amounts of oxygen lost during electrolysis and dissolved during reoxidation were always within 5%.

One of the assumptions of this measurement technique is that the sample exchanges no significant amount of oxygen when it is kept under pure argon, *i.e.*, its over-all stoichiometric ratio is fixed. This assumption which has also been made by Blumenthal and Hofmaier (1) was clearly confirmed by the fact that the equality mentioned above was also verified for delays of several days between the electrolysis and reoxidation runs.

Experimental Results: $\sigma(x,T)$ Relationship

After electrolysis, the sample resistance was measured in purified argon using the so-called impedance diagram method (14). In the experiments reported, several measurements were made after each electrolysis. The first measurements indicated a variation due to the homogenization of the sample. After a certain time (always less than a few hours in the runs reported), the results were stable. An example of the dependence of the resistance of the homogenized sample on the deviation from stoichiometry x is given in Fig. 3.

With the sample investigated, we could further derive the following. In all the experiments reported, the concentrations of the vacancies created by the reduction (less than 3×10^{20} cm^{-3}) remained small compared to the initial concentration (6.3×10^{21} cm^{-3}) which resulted from the cationic composition of the material. So, we could reasonably assume that the reduction process did not alter the ionic conductivity. If this assumption is correct, the variations of the measured resistance $R(x)$ concerned only the electronic

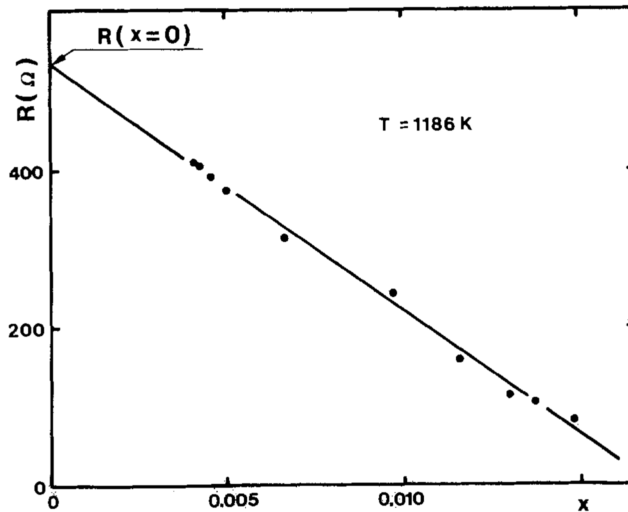

Fig. 3. Resistance variation as a function of the deviation from stoichiometry x.

conductivity. Consequently, the electronic resistance $R_e(x)$ of the sample at a given deviation from stoichiometry can be approximately calculated from

$$1/R(x) = 1/R_e(x) + 1/R_{\text{ionic}}(x) \quad [4]$$

or with our assumption

$$1/R(x) = 1/R_e(x) + 1/R(x = 0) \quad [5]$$

The deduced variations of the electronic resistance as functions of temperature are shown in Fig. 4. A similar trend toward lower activation energies as the departure from stoichiometry increases has been observed by Casselton (15). Figure 5 shows the variations of the ionic transport number $t_i(x)$ calculated from the data in Fig. 3 using the equation

$$t_i = 1 - R(x)/R_e(x) \quad [6]$$

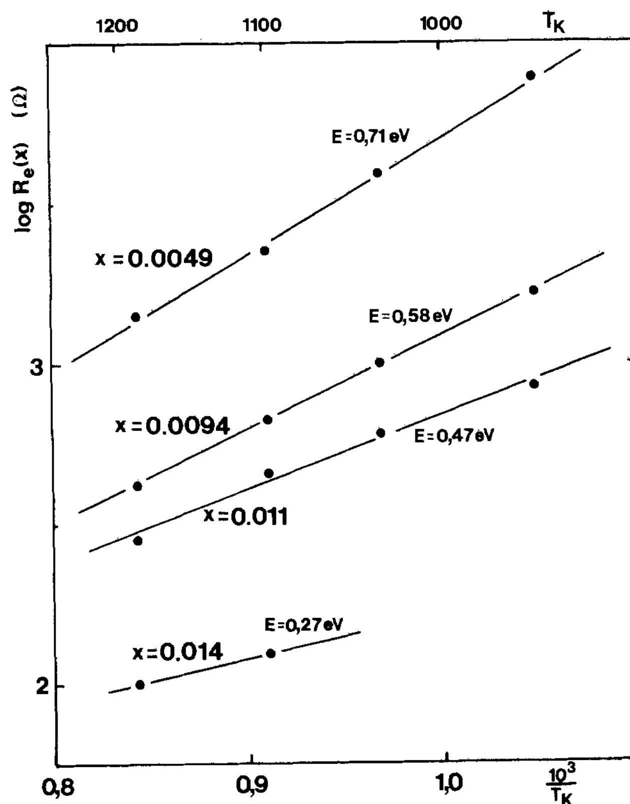

Fig. 4. Arrhenius plot of the electronic resistance of the sample for various deviations from stoichiometry x.

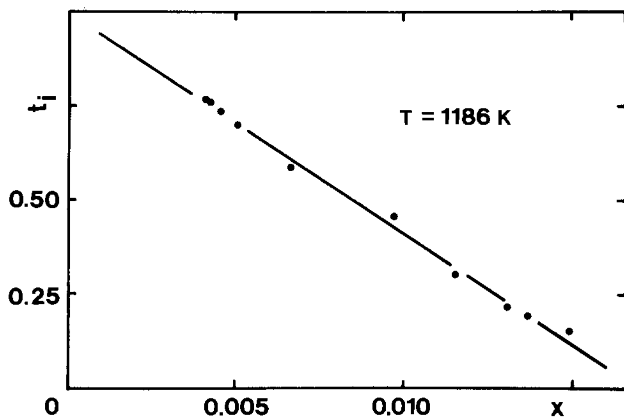

Fig. 5. Variation of the ionic transport number as a function of deviation from stoichiometry.

Direct Determination of $t_i(x,T)$ Relationship

This determination is based on a measurement of the rate that oxygen is driven off the reduced sample during its electrolysis.

When a solid oxide electrolyte is a pure anionic conductor, the quantity of oxygen carried by the ions and the relevant oxygen flow, J, released at the anode of the cell obeys Faraday's law

$$J = I/4\mathbf{F} \quad [7]$$

where I is the current. This has been accurately checked with oxygen pumps (8).

The results reported above, on electrolysis experiments, also obeyed Faraday's law under appropriate conditions. This is consistent with the observations (16-18) that, during a certain lapse of time, no electrochemical coloration occurs on the anodic side. The ionic transport number remains locally equal to 1 (the small electronic transport number induced by the presence of 1% ceria in the zirconia solid solution is neglected). An example of the oxygen flow released from the sample, at a constant current, is given in Fig. 6 ($x = 0$). In a certain interval, the plot exhibits a plateau, the ordinate of which obeys formula [6]. After longer times the reduced zone had reached the anode, the local value of the ionic transference number markedly decreased

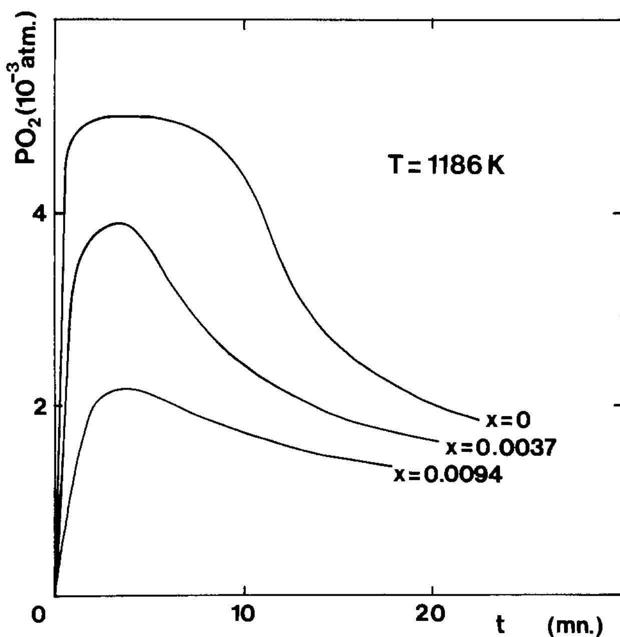

Fig. 6. Oxygen flow released from the sample during the electrolysis, for various initial deviations from stoichiometry.

Table I. Comparison of the ionic transport numbers deduced from Eq. [6] and [8] as functions of the deviation from stoichiometry x of the sample at 1186°K

x	t_i (resistance)	t_i (electrolysis)
0.0048	0.71	0.71
0.0094	0.44	0.42
0.014	0.16	0.13

and consequently so did the oxygen flow. This behavior also explains the shape of Fig. 2.

A simplistic approach to the general problem for a mixed conductor would allow us to conclude that the rate of oxygen evolution from the anode is given by

$$J = J_{th} \cdot t_i \quad [8]$$

where t_i is the ionic transport number in the close vicinity of the anode and J_{th} the theoretical value corresponding to Faraday's law.

In order to see whether Eq. [8] was indeed obeyed, we carried out the following experiment. After the reduction of the sample to a certain degree (curve $x = 0$ in Fig. 6), the sample was maintained for a while in pure argon under open-circuit condition to let it homogenize. Then a new electrolysis experiment was performed, according to the same procedure, on this prereduced sample. Instead of a plateau, the oxygen flow *vs.* time plot exhibited a simple maximum located at lower oxygen pressure (Fig. 6). From the value of this maximum, which was assumed to represent the initial rate of oxygen evolution, we calculated an ionic transport number t_i (electrolysis) according to formula [8].

To verify the validity of Eq. [8], we compared such values of the ionic transport number to the values deduced from the resistance measurements reported above: t_i (resistance). Three results obtained for various degrees of prereduction are reported in Table I; there is good agreement. This suggests that the material was homogeneous up to the electrode surfaces before the electrolysis voltage was applied and the evolution of oxygen obeyed formula [8].

If this result is confirmed by further experimental results obtained under more appropriately defined conditions, such measurements could lead to a convenient estimation of ionic transport numbers. It would be especially appropriate for average ionic transport numbers for which the traditional emf method is frequently questionable (17, 19). It would also have the advantage of complementing the first type of measurement as the emf method complements conventional conductivity measurements.

It is emphasized that both types of measurement proposed can be performed however reducing the system may be. That is a great advantage over the gas-equilibration technique which is limited on the low oxygen pressure side, and over the use of metal-oxide electrodes which requires tedious manipulations. An obvious deficiency, however, is the lack of information they can provide about equilibrium oxygen pressures.

Electronic Conductivity in Solid CaF_2 at High Temperature

J. Delcet, R. J. Heus, and J. J. Egan

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

Polarization measurements have been made on CaF_2 using cells of the type

Ca-Pb(l) | CaF_2(s) | Fe(s) (I)
$x_{Ca} = 0.9$

and

Fe(s) | CaF_2(s) | Ca-Bi(l) (II)
$x_{Ca} = 0.25$

Steady-state values of the currents at various applied voltages yielded the electronic conductivity in CaF_2 as a function of calcium activity. Results are presented between 800° and 950°C. The experimental arrangement is described and appropriate equations are presented. Values of the transference number of ions are given as a function of temperature and the activity of Ca in CaF_2.

Calcium fluoride has proven to be a useful solid electrolyte for high temperature emf studies (1-20). A review has been given by Tretyakov and Kaul (21). It remains an ionic conductor under very reducing conditions and is useful for measurements with electropositive metals such as U, Th, and Mg in contrast to solid oxide electrolytes.

The problem of electronic conduction in CaF_2 has previously been studied by Wagner (22) and by Hinze and Patterson (23). Using the measurements of Mollwo (24) on the number of color centers in CaF_2 and their mobility, Wagner has calculated the transference number of electrons as a function of calcium activity. Hinze and Patterson have measured the total electrical conductivity as a function of the partial pressure of fluorine. They have concluded that CaF_2 exhibits negligible electronic conductivity even when equilibrated with Ca metal. Baukal (25) has measured the electronic conduction in CaF_2 doped with NaF at temperatures between 490° and 550°C.

In this study the electronic conductivity of pure CaF_2 is measured directly using a polarization technique developed by Wagner (26, 27). This technique has previously been used to study copper halides (28-32), silver halides (33-36), thallium bromide (37), doped oxides of zirconium, thorium, and hafnium (38-41), and lead fluoride (42).

General Approach

The general ideas and detailed equations for the polarization technique to measure electronic conductivity in ionic crystals are discussed in detail in Ref. (27). Cells are employed having a reversible reference electrode and an inert electrode. Ionic conductivity is suppressed by operating at potentials below the onset of ionic currents.

To study CaF_2 the following cell was employed

Ca-Pb(l) | CaF_2(s) | Fe(s) (I)
$x_{Ca} = 0.90$

where the reference electrode is the Ca-Pb alloy. The current at various applied voltages, where the Ca-Pb alloy is negative, is given by the expression

$$i = \frac{RT}{FG}\left\{ \sigma_e' \left[1 - \exp\left(-\frac{EF}{RT}\right)\right] + \sigma_h' \left[\exp\left(\frac{EF}{RT}\right) - 1\right]\right\} \quad [1]$$

Here G is the cell constant (thickness of CaF_2 crystal divided by the area of the electrodes), σ_e' and σ_h' are the electron and electron hole conductivities of CaF_2 equilibrated with the reference electrode and E is the potential applied to Cell (I). A Ca-Pb alloy was used instead of pure Ca metal for experimental reasons. Ca-Pb (x_{Ca} = 0.90) is liquid at 800° and could be contained in iron cups which fit closely onto the CaF_2 crystals. Electrodes of solid Ca formed a conducting film on the CaF_2 surface and interfered with the measurements. The activity of Ca in the Ca-Pb alloy was calculated from the heat of fusion of Ca and the Ca-Pb diagram.

If the electron hole conductivity is very small under highly reducing conditions and the voltage applied to Cell (I) is small compared to the potential at which FeF_2 forms, Eq. [1] reduces to

$$i = \frac{RT}{FG}\sigma_e'\left[1 - \exp\left(-\frac{EF}{RT}\right)\right] \quad [2]$$

* Electrochemical Society Active Member.

Key words: electrical conductivity, transport properties, solid electrolyte, electrolyte, mass transport.

Results of current-potential curves on Cell (I) yield the value of σ_e'. To obtain the electronic conductivity at other activities of Ca one may use the equation

$$\sigma_e = \sigma_e' \left(\frac{a_{Ca}}{a_{Ca}'} \right)^{1/2} \quad [3]$$

Polarization experiments on cells of type (II) where the inert iron electrode is made negative also yield electronic conductivity

$$Fe(s)|CaF_2(s)|Ca\text{-}Bi(l) \quad (II)$$
$$x_{Ca} = 0.25$$

Under reducing conditions, the steady-state current of Cell (II) at various applied voltages is given by

$$i = \frac{RT}{FG} \sigma_e'' \left[\exp\left(\frac{EF}{RT}\right) - 1 \right] \quad [4]$$

where σ_e'' is the electronic conductivity of CaF_2 whose Ca activity is the same as that for Ca-Bi($x_{Ca} = 0.25$). The activity of Ca in the Ca-Bi alloy is obtained from emf measurements on the auxiliary cell

$$Ca\text{-}Pb(l)|CaF_2(s)|Ca\text{-}Bi(l) \quad (III)$$
$$x_{Ca} = 0.90 \qquad x_{Ca} = 0.25$$

The emf of Cell (III) is given by the expression (43)

$$E = \frac{1}{2F} \int_{\mu_{Ca}''}^{\mu_{Ca}'} t_{ion} d\mu_{Ca} \quad [5]$$

where

$$t_{ion} = \frac{\sigma_{ion}}{\sigma_e + \sigma_{ion}} = \frac{\sigma_{ion}}{\sigma_e^o a_{Ca}^{1/2} + \sigma_{ion}} \quad [6]$$

Here σ_e^o is the electronic conductivity of CaF_2 with $a_{Ca} = 1$. Equation [5] may then be expressed as

$$E = \frac{RT}{2F} \int_{a_{Ca}''}^{a_{Ca}'} \frac{\sigma_{ion}}{a_{Ca}(\sigma_e^o a_{Ca}^{1/2} + \sigma_{ion})} da_{Ca} \quad [7]$$

$$E = \frac{RT}{2F} \ln \frac{a_{Ca}'}{a_{Ca}''} + \frac{RT}{F} \ln \frac{\sigma_e'' + \sigma_{ion}}{\sigma_e' + \sigma_{ion}} \quad [8]$$

where

$$\sigma_e' = \sigma_e'' \left(\frac{a_{Ca}'}{a_{Ca}''} \right)^{1/2} \quad [9]$$

This equation can be solved for a_{Ca}'' or the activity of Ca in the Ca-Bi alloy if one determines σ_e'' from steady-state measurements on Cell (II), knowing the activity a_{Ca}' from the phase diagram. The activity a_{Ca}'' is given by the expression

$$a_{Ca}''^{1/2} = \frac{\exp\left(-\frac{\eta F}{RT}\right) - \sigma_e'' a_{Ca}'^{1/2}}{\sigma_{ion}} \quad [10]$$

where

$$\eta = E - \frac{RT}{2F} \ln a_{Ca}' - \frac{RT}{2F} \ln (\sigma_{ion} + \sigma_e'') \quad [11]$$

Polarization cells of type (II) were found very useful for the measurements above 800°C. After determining a_{Ca}'' the electronic conductivity may be calculated at any activity by use of the equation

$$\sigma_e = \sigma_e'' \left(\frac{a_{Ca}}{a_{Ca}''} \right)^{1/2} \quad [12]$$

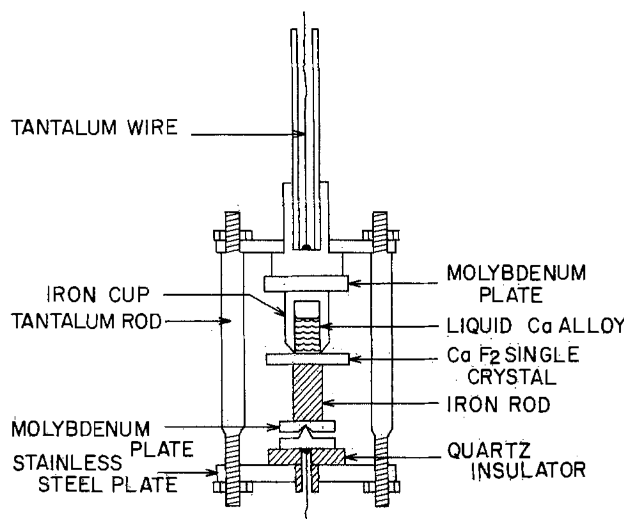

Fig. 1. Experimental arrangement for polarization cells

Experimental Details

The experimental setup for both Cell (I) and (II) is shown in Fig. 1. The iron cup is filled with either a Ca-Pb alloy or a Ca-Bi alloy. The open end of the cup is machined to a sharp edge so that it digs into the CaF_2 single crystal under pressure. CaF_2 softens somewhat around 600°C. The pressure arises from the cell arrangement, since the iron rod and cup expand more than the holder made of tantalum rods. The CaF_2 crystals were generally between 0.1 and 0.2 cm thick. The diameter of the inert iron electrode is 1.0 cm for Cell (I) and 1.6 cm for Cell (II). In order to minimize the edge effect caused by the CaF_2 diameter being larger than the iron electrode diameter, the ratio of the crystal thickness to the electrode area was kept small in accordance with Barrer, Barrie, and Rogers (44). Cell (III) used essentially the same arrangement as shown in Fig. 1 except that two iron cups were used and the cell operated in a horizontal position. The entire cell arrangement was contained in a vacuum-tight Vycor tube filled with purified argon.

Results and Discussion

Steady-state currents obtained at various applied voltages for Cell (I) operated at 800°C are shown in Table I. Steady values were obtained only after several days of cell operation at a given voltage. Values of σ_e' were calculated from Eq. [2] and values of σ_e^o from Eq. [3] with $a_{Ca} = 1$. Only currents measured on the plateau of the current voltage curve yielded consistent values of t_{ion}.

Attempts to operate Cell (I) at voltages lower than 0.300V proved unsuccessful. It is believed that the

greater solubility of Ca in the crystal at lower voltages caused a density change in CaF_2 which breaks the seal formed between the cup holding the alloy and the CaF_2 crystal.

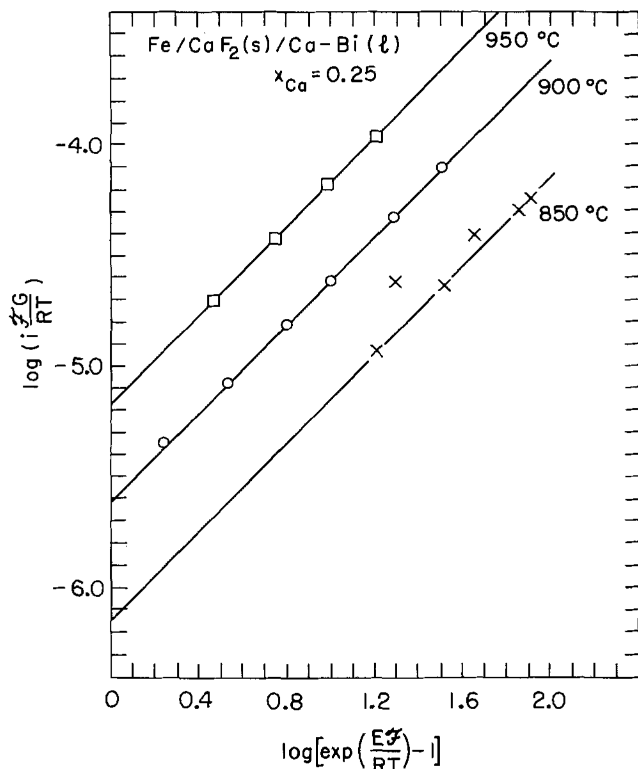

Fig. 2. Results of polarization measurements on Cell (II)

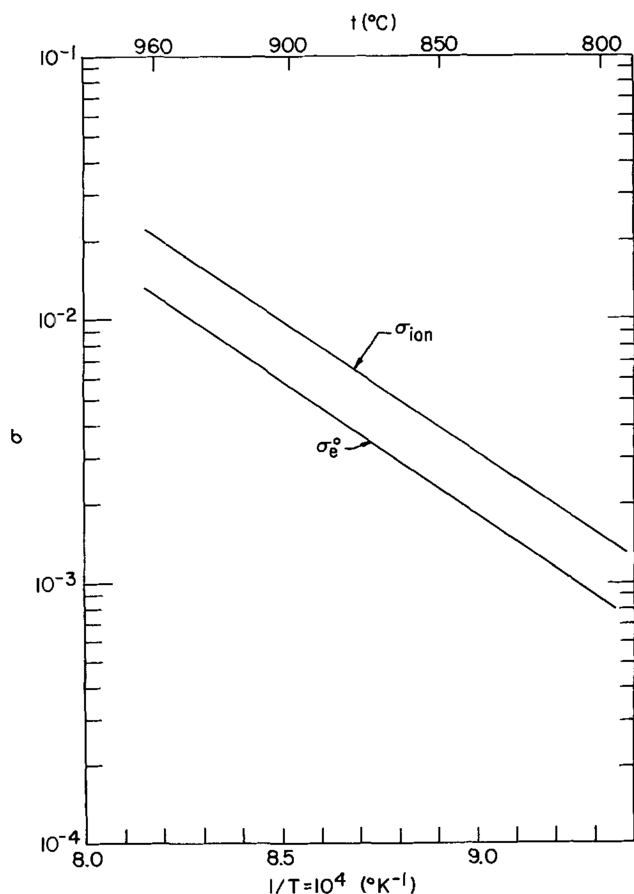

Fig. 3. Ionic and electronic ($\alpha_{Ca} = 1$) conductivity of CaF_2 at various temperatures.

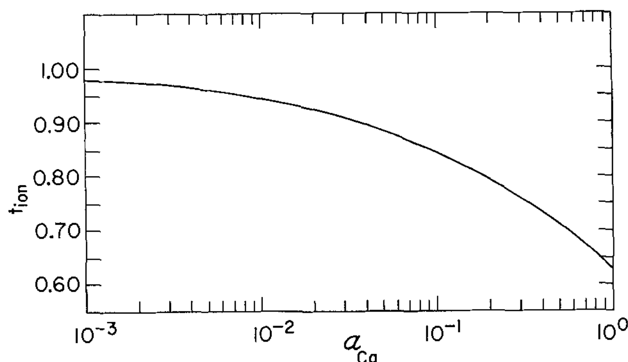

Fig. 4. The transference number of ions in CaF_2 at various Ca activities.

Results from Cells (II) and (III) are shown in Table II at temperatures between 800° and 950°C. Steady-state currents from Cell (II) are shown graphically in Fig. 2. One expects a slope of one for this plot and experiments showed this to be true. Cell (III) was operated between 800° and 900°C, the value of 950°C being an extrapolation.

Values of $t_{ion}°$ were calculated in all cases with Eq. [6], using the results of Ure (45) for the ionic conductivity of CaF_2. The values of the electronic and ionic conductivity in CaF_2 are plotted in Fig. 3, the electronic conductivity being for CaF_2 equilibrated with Ca metal. Figure 4 shows the transference number of ions in CaF_2 at various activities of Ca.

ABSTRACT

Measurements on the solid electrolyte cell

$$(Ar + H_2 + H_2S/CaS + CaF_2 + (Pt)//CaF_2//(Pt) + CaF_2 + CaS/H_2S + H_2 + Ar)$$

show that the emf of the cell is directly related through the Nernst equation to the difference in sulfur potentials established at the two $Ar + H_2 + H_2S/$ electrode interfaces. The electrodes are designed to convert the sulfur potential gradient across the calcium fluoride electrolyte into an equivalent fluorine potential gradient with the aid of the reaction, $CaF_2(s) + \frac{1}{2} S_2(g) \rightarrow CaS(s) + F_2(g)$. The response time of the probe varies from approximately 9 hr at 990°K to 2.5 hr at 1225°K. The conversion of calcium sulfide and/or calcium fluoride into calcium oxide should not be a problem in anticipated commercial coal gasification systems. Suggestions are presented for improving the cell for such commercial applications.

The ability to continuously monitor the sulfur potential in coal gasification reactors is of crucial importance for efficient gasifier operation and for accurate life prediction of corroding construction materials. From an engineering point of view, *in situ* solid-state sensors that directly measure the sulfur potential are preferable to devices that employ liquid electrolytes or involve sampling of gases for low temperature analytical procedures. Despite the concerted efforts of many laboratories during the last decade to find suitable sulfide electrolytes, analogous to $CaO\text{-}ZrO_2$ or $Y_2O_3\text{-}ThO_2$ for oxygen potential measurements, no acceptable material has been identified in which the ionic transport number is higher than 0.99 over a large range of sulfur potentials and temperatures.

Key words: sulfur probe, calcium fluoride sensor for sulfur, galvanic cell, solid electrolyte cell, coal gasification-sulfur control.

The prospect of designing a suitable sulfide electrolyte does not appear promising in the near future because the bandgaps in the sulfides are generally narrower than in the corresponding oxides (1). An alternate approach may be to use calcium fluoride (CaF_2) as the electrolyte in a solid-state cell, in which the electrodes are designed to convert the sulfur potential in the gas into an equivalent fluorine potential.

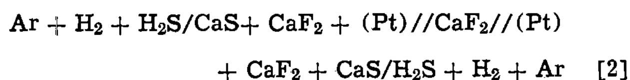
Calcium fluoride has been found to be a suitable electrolyte at high temperatures and over a large range of fluorine potentials (2-7). Colorless, pure CaF_2 contains virtually equal concentrations of interstitial anions and anion vacancies. The fluoride ions are the mobile species, and they migrate as interstitials and vacancies. At very low fluorine potentials or in the presence of calcium vapor, an excess of calcium dissolves in CaF_2 according to the reaction

$$Ca(g) + 2F_F{}^x \rightarrow CaF_2 + 2e_F{}^x \quad [1]$$

where $F_F{}^x$ is a fluoride ion on a regular anion site,

and e_Fx is an electron substituted for an anion, producing a color (F) center. Wagner (8) has given an analysis of the onset of electronic conduction in CaF_2 due to the dissolution of calcium metal. Patterson (9) has also discussed the electrolytic conduction domain for CaF_2 at high temperatures. Because of the extreme electronegativity difference between Ca^{2+} and F^- ions and the correspondingly large forbidden bandgap for CaF_2, positive hole conduction will not be significant until the fluorine pressure is increased to several atmospheres. The open-circuit emf (E) across the electrolyte is a direct measure of the chemical potential difference, provided the fluorine pressures at the electrodes and the temperatures of operation lie within the electrolytic conduction domain (that is, the transport number of electrons or holes is less than 0.01).

An advantage of the solid electrolyte sensors is that the output is an electric potential that can readily be used to actuate a control circuit. It was, therefore, decided to study the efficiency of the solid electrolyte cell



$$Ar + H_2 + H_2S/CaS + CaF_2 + (Pt)//CaF_2//(Pt) + CaF_2 + CaS/H_2S + H_2 + Ar \quad [2]$$

as a part of our program on the development of a sulfur probe. The experimental results, the limitations of this technique to coal gasification systems, as well as anticipated improvements are presented in this paper.

Experimental

Materials.—High purity $Ar + H_2 + H_2S$ gas mixtures and their analyses were obtained from Matheson. A slight decrease in the H_2S concentration of the gases was observed over extended periods of storage, presumably due to the reaction of H_2S with the storage tank. Correction factors for gas ratios were obtained by periodically observing the ion intensity ratios of H_2S to H_2 in a mass spectrometer. For the electrolyte, optical grade single crystals of CaF_2, in the form of disks of 1.5 cm in diameter and 0.2 cm thick, were obtained from Harshaw Chemical Company. Ultra pure anhydrous CaF_2 (99.999%)[3] and CaS (99.99%) powders were supplied by Apache Chemical Company and Ventron Corporation. Fine platinum powder and porous platinum sheet with porosity of 29% were obtained from Johnson-Matthey Company. The electrode pellets were made by double end compression of an intimate mixture of −200 mesh size powders of CaF_2, CaS, and Pt in the molar ratio 1.5 : 1 : 0.2. The pellets were sintered in evacuated silica capsules at 1225°K for 12 hr.

Apparatus.—A schematic diagram of the apparatus is shown in Fig. 1. A disk of CaF_2 electrolyte was spring loaded against an alumina tube with a gold O-ring between them to obtain a gastight joint. The alumina tube was held firmly in a water-cooled brass head, to which the springs were attached. Since gold softens at the high temperatures used in these experiments, low tension springs were sufficient to produce a gastight joint. Thus, the ceramic components of the assembly were not subjected to high applied stresses. Electrode pellets containing CaF_2 + CaS + Pt were spring loaded on either side of the electrolyte, with a thin porous platinum sheet sandwiched between the pellet and the electrolyte. Platinum leads, flame sprayed with alumina, were spot-welded to the porous platinum sheets. At the low sulfur potentials used in the experiments, no chemical attack on the platinum was observed in the hot zone of the furnace. At the cooler end, however, there was some evidence of reaction between platinum and H_2S gas. Therefore, in this region, the platinum leads were protected by an alumina sheath closed on both ends by alumina cement.

[3] CaF_2 contained the following elements in parts per million level: 0.5 Pb, 0.5 Ni, 0.5 Cd, 0.5 Mn, 500 Sr, 100 Ba, 5 Li, 10 Sn, and 5 K.

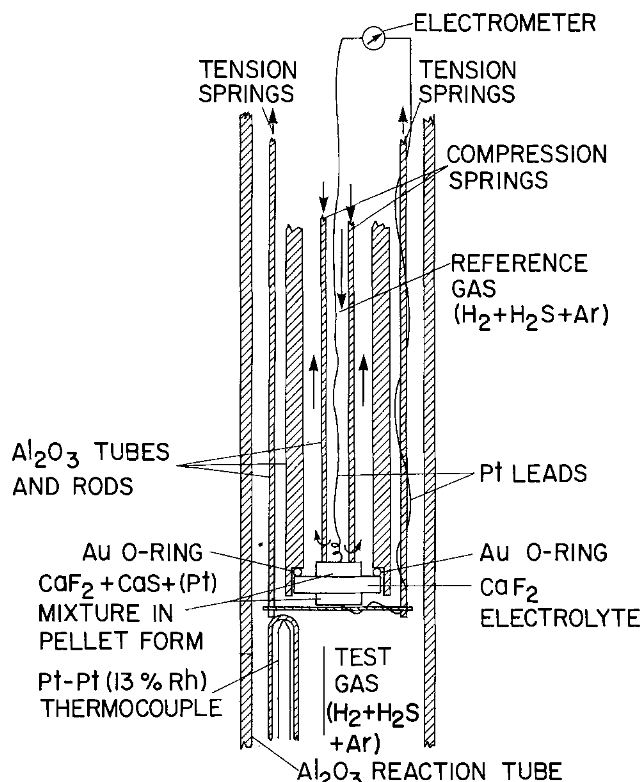


Fig. 1. Schematic diagram of the apparatus used for testing the CaF_2 electrolyte-based sulfur probe.

The cell was designed to provide two separate gastight compartments around the two electrode pellets. Separate gas streams with differing sulfur potentials were passed through these compartments. The test gas was admitted to the system at the lower end of the reaction tube and flowed past the outer electrode pellet at a rate of 250 ml min^{-1}. The reference gas was passed around the inner electrode at a flow rate of 100 ml min^{-1}. The two gas streams were isolated in the reaction tube and escaped through different ports in the brass head. The escaping gases were bubbled through two 25 cm high columns of NaOH solution to remove H_2S and HF. The exit gases were further scrubbed before being pumped through the fume exhaust system.

The entire cell assembly, attached to the brass head, was lowered into a vertical alumina reaction tube. The cell was electrically shielded by connecting a platinum foil, wrapped around the reaction tube, to ground. The reaction tube was heated by a Kanthal resistance furnace. Temperatures of the furnace and of the cell were measured by two separate Pt-Pt (13% Rh) thermocouples. The furnace temperature was controlled to ±1°K by use of a stepless current-compensating controller.

Procedure.—The test cell was assembled as shown in Fig. 1, and the reaction tube was evacuated by a mechanical pump to a pressure of 0.5 Nm^{-2} and then backfilled with purified argon. The argon purification train consisted of magnesium perchlorate (to absorb the residual moisture) and copper turnings at 700°K and titanium turnings at 1100°K (to remove residual oxygen). The cell was heated to 500°K, evacuated, and refilled with argon. The temperature of the cell was then raised to 1225°K. The reference gas was introduced into the inner gas compartment of the cell, while argon flow was maintained through the outer reaction tube. Gastightness of the O-ring seal was checked by analyzing the argon stream exiting from the reaction tube for traces of H_2S. After ensuring that the test cell was leaktight and the two gas streams were isolated, the test gas was introduced into the reaction tube. Cell voltage was monitored using a Keithley digital voltmeter with an internal impedance

of $10^{12}\Omega$. After the start of the experiment, approximately 5 hr were required to obtain a steady emf.

Two procedures were followed during the investigations: (*i*) During isothermal runs, cell temperature was kept constant at 1073° or 1173°K and the steady, reversible emf corresponding to different test gases was measured, and (*ii*) for two selected test gases, the temperature dependence of the steady, reversible emf was measured.

Results

Response time.—Composition of the test gases and the reference gas and the emf obtained at 1073° and 1173°K are shown in Table I. Generally, the response time of the cell at 1225°K, after a small change in temperature or gas composition, was 2.5 hr, while at a lower temperature of 990°K the response time was approximately 9 hr. The cell emf was insensitive to moderate increase in the flow rate of the test gas and/or the reference gas. However, when the flow rate of one of the streams was increased by factors greater than two, while keeping the flow rate of the other stream constant, significant changes in the emf were noted: about 20 mV during the transient period and about 15 mV during the steady-state period. The changes were, however, not always reproducible. When the flow rates of both streams were changed simultaneously by the same amount, the cell emf remained virtually constant. It is likely that a substantial increase in the flow of gas through one stream may have resulted in differential cooling, thus creating a thermal gradient across the electrolyte. Changes in emf resulting from the presence of a steady-state thermal gradient are quantitatively related to the partial entropy of fluorine in the gas phase, as discussed by Fitzner, Jacob, and Alcock (10).

Reversibility of the emf was checked by passing small currents (5 μA) through the cell in either direction for 2 min. It was found that the emf returned to the steady value before the titration in approximately 30 min. After several days of use, the electrode pellets became fragile and fractured easily.

Calculation of sulfur potentials.—Experimental emf's obtained at 1073° and 1173°K for different test gases are compared in Fig. 2 with known values calculated from the difference in sulfur potential between the test gas and the reference gas. The emf developed across a CaF_2 electrolyte can be related through the Nernst equation to the partial pressure of fluorine (fluorine potential) across the electrolyte, provided the ionic transport number is close to unity

$$E = \frac{\Delta\mu_{F_2}{}^R - \Delta\mu_{F_2}{}^T}{n\mathbf{F}} = \frac{RT}{n\mathbf{F}} \ln \frac{p_{F_2}{}^R}{p_{F_2}{}^T} \quad [3]$$

where E is the emf, $\Delta\mu_{F_2}{}^R$ and $\Delta\mu_{F_2}{}^T$ are the fluorine potential at the reference and the test electrodes, $\mathbf{F}$ is the Faraday constant, n is the number of electrons ($= 2$) involved in the transfer of one molecule of F_2 gas between the two electrodes, R is the gas constant, T is the absolute temperature, and p_{F_2} is the fluorine partial pressure. The gas phase containing Ar + H_2 + H_2S establishes a partial pressure of sulfur (sulfur potential) over the electrode, depending on the ratio of H_2 to H_2S, by virtue of the reaction

Table I. Composition of the test gas mixtures and the corresponding cell emf's

Test gas	Composition (vol. %)			EMF (mV)	
Number	H_2	H_2S	Ar	1073°K	1173°K
1	40.6	8.3	51.1	−32	−34
2	50.4	2.05	47.55	43	47
3	54.0	0.79	45.21	87	96
4	55.1	0.18	44.72	160	174
5*	25.2	2.52	72.28	—	—

* Reference gas.

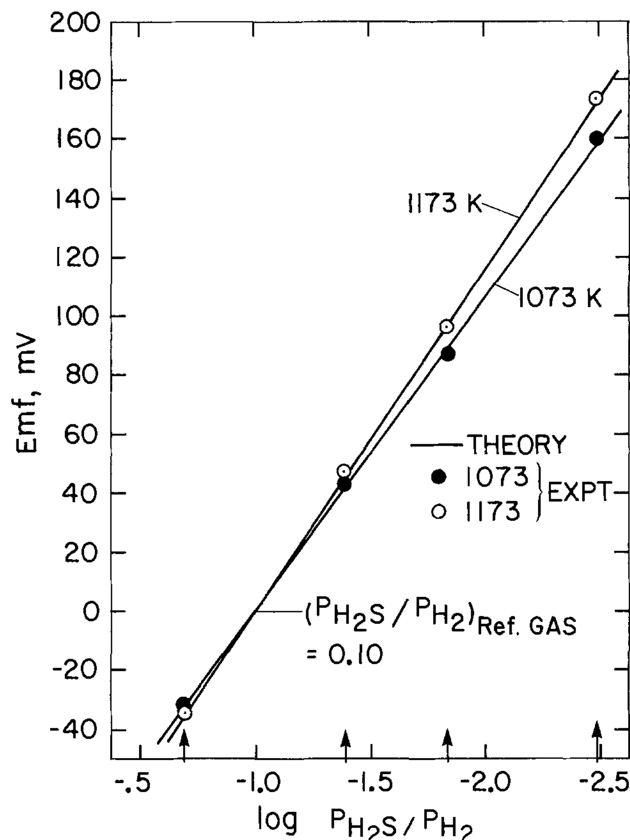

Fig. 2. Variations of the emf with H_2S/H_2 ratio of the test gas at 1073° and 1173°K; — theoretical values Eq. [9].

$$H_2(g) + \tfrac{1}{2} S_2(g) \rightarrow H_2S(g) \quad [4]$$

$$\tfrac{1}{2}\,\Delta\mu_{S_2} = RT \ln p_{S_2}{}^{1/2} = \Delta G°_4 + RT \ln (p_{H_2S}/p_{H_2}) \quad [5]$$

where $\Delta G°_4$ is the standard Gibbs' free energy change for reaction [4] (11). The sulfur potential established by the gas phase, when in contact with the electrode pellet consisting of CaS and CaF_2, fixes a fluorine potential through the reaction

$$CaF_2(s) + \tfrac{1}{2} S_2(g) \rightarrow CaS(s) + F_2(g) \quad [6]$$

$$\Delta\mu_{F_2} = \tfrac{1}{2}\,\Delta\mu_{S_2} - \Delta G°_6 \quad [7]$$

where $\Delta G°_6$ is the standard Gibbs' free energy change for reaction [6]. The platinum in the electrode pellet acts as a catalyst for the reaction. Since there is neither a ternary compound nor significant solid solubility in the CaF_2-CaS system, the condensed phases in the electrode pellets are present at unit activity. Combining Eq. [3] and [7], an expression is obtained relating the emf to the difference in the sulfur potential between the electrodes

$$E = \frac{\Delta\mu_{S_2}{}^R - \Delta\mu_{S_2}{}^T}{2n\mathbf{F}} = \frac{RT}{2n\mathbf{F}} \ln \frac{p_{S_2}{}^R}{p_{S_2}{}^T} \quad [8]$$

Equation [8] may also be expressed in terms of the ratio of H_2S to H_2 in the gas phase over the two electrodes

$$E = \frac{RT}{n\mathbf{F}} \ln \frac{(p_{H_2S}/p_{H_2})^R}{(p_{H_2S}/p_{H_2})^T} \quad [9]$$

The measured emf's as shown in Fig. 2, do not deviate by more than 2.5 mV from that calculated using Eq. [9]. Deviations from theoretical values have the same sign at different temperatures for each test gas. Thus, it is likely that these deviations arise from small errors in gas analysis.

The variation of the emf of the cell with temperature and with two test gases (3 and 4 in Table I) is shown

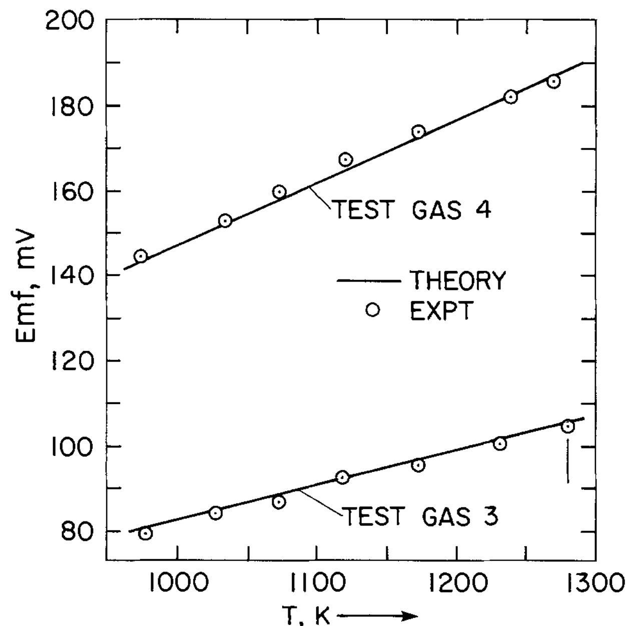

Fig. 3. The temperature dependence of the reversible emf with test gases 3 and 4 passing through the cell; — theoretical values Eq. [10].

in Fig. 3. Again, measured temperature dependence is in agreement with the theoretical value given by the derivative of Eq. [9] with respect to temperature

$$\frac{dE}{dT} = \frac{R}{n\mathbf{F}} \ln \frac{(p_{H_2S}/p_{H_2})^{R}}{(p_{H_2S}/p_{H_2})^{T}} \qquad [10]$$

Discussion

The activity of calcium at the electrodes, during the present investigation, can be evaluated by considering the reaction

$$CaS(s) + H_2(g) \rightarrow H_2S(g) + Ca(s) \qquad [11]$$

The activity of calcium, a_{Ca}, is given by

$$a_{Ca} = (p_{H_2}/p_{H_2S}) \exp(-\Delta G^\circ_{11}/RT) \qquad [12]$$

where ΔG°_{11} is the standard Gibbs' free energy change for reaction [11] (11). It can readily be shown from known thermodynamic data that the activity of calcium varies from 9.5×10^{-19} to 6.0×10^{-17} at 1113°K over the range of test gas composition (gases 1 and 4, respectively, Table I). Wagner (8) has suggested that the electronic transport number of CaF_2 is 10^{-2} when the activity of calcium is 6×10^{-6} at 1113°K. It is apparent, therefore, that the electronic transport number is much less than 10^{-2} and contributes very little to the results of the present study.

The exact factors affecting the slow response time of galvanic cells based on a CaF_2 electrolyte have not yet been determined. The length of the electrolyte may influence the response time. In the present investigation the dimensions of the electrolyte were unaltered and a further study is necessary to relate the response time with electrolyte length. The more important are that the kinetics of the electrode reaction [6] may be rate controlling, or the transport of ions in CaF_2 may be slow, such that the composition gradient across the electrolyte cannot readjust rapidly after a perturbation in the chemical potential at the electrode. Additionally, since the fluorine potentials are low ($p_{F_2} \simeq 10^{-24}$ to 10^{-28} Nm^{-2}), gas phase polarization at the electrolyte-electrode interface may be the rate-limiting step. This latter possibility seems rather improbable, however, because sufficient concentration of HF gas should be created by the reaction of H_2S with CaF_2 to transport the fluorine potential to the electrolyte surface.

Electrical current techniques, such as voltage recording after a galvanostatic pulse or impedance measurement at low frequencies, can be used to determine whether the kinetics of the electrode reaction is responsible for the slow response of the cell (13). Heyne and Engelson (14) have recently suggested that for oxygen probes containing calcia-stabilized zirconia as the electrolyte, the uptake or release of oxygen by the electrolyte, when the partial pressure of oxygen in the ambient atmosphere is altered, is the main reason for the sluggishness in response and variation with time of the emf developed. If a similar mechanism is valid for CaF_2, a reduction in the thickness of the electrolyte or doping, to increase the effective diffusion coefficient, may accelerate the response of the probe to changes in sulfur potential. Another alternative is to use β-alumina as the electrolyte (15). β-alumina has much higher conductivity than CaF_2, especially at lower temperatures. Further, the electrodes would be redesigned to convert the sulfur potential gradient into an equivalent sodium potential gradient.

Although systematic studies on the catalytic behavior of platinum or other materials have not been undertaken, it was found in preliminary experiments that approximately 0.2 moles of platinum per mole of CaS is the optimum amount of catalyst in the electrode pellets. To use the cell for sulfur potentials higher than those studied in this investigation, a more suitable catalyst than platinum is needed. Platinum readily forms sulfides at higher sulfur potentials (12). Transition metal sulfides that do not react with CaS and in which cations exist in multivalent states may prove to be good catalysts.

Typical compositions of the raw gases in some coal gasification processes are shown in Table II. It can readily be shown that under the conditions of coal gasification, the conversion of CaS to CaO, according to the scheme

$$CaS(s) + H_2O(g) \rightarrow CaO(s) + H_2S(g) \qquad [13]$$

is not thermodynamically favorable. However, the reaction of $H_2S(g)$ with CaF_2

$$CaF_2(s) + H_2S(g) \rightarrow CaS(s) + 2HF(g) \qquad [14]$$

will result in a partial pressure of HF in the immediate neighborhood of the electrode that can vary from 2.8×10^2 to 80 Nm^{-2}. Since all the gas passing through the probe is not saturated in HF, the average HF concentration in the exit gas is estimated to be approximately 200 ppm and, therefore, must be scrubbed for the removal of HF. Additionally, for commercial application, the probe must be designed in such a way as to prevent particulate material in the gas from depositing on the electrodes of the sensor.

Conclusion

The theory, design, and operation of a solid-state sulfur probe based on CaF_2 electrolyte has been demonstrated. The cell responds to changes in sulfur potential in a manner predicted by the Nernst equation. Further research is needed to determine the main reason for the slow response of the cell. The rate-limiting steps may be either the kinetics of electrode reactions or the

rate of transport through the electrolyte. If the reaction kinetics is rate controlling, suitable catalysts may be developed to overcome the problem. If the slow transport of ions in the electrolyte is the reason for the sluggish response, a cell based on β-alumina electrolyte may be more suitable.

Reduction of Excess Phosphorus and Elimination of Defects in Phosphorus Emitter Diffusions

B. L. Morris and L. E. Katz*

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

The successful production of LSI bipolar circuits requires that a high level of transistor junction yield be maintained. One of the chief causes of junction degradation is the defects induced by the high concentration of phosphorus normally used in the emitter diffusion of bipolar transistors. This diffusion results in a total phosphorus concentration that is greater than the electrically active phosphorus; precipitates and other defects result from this excess phosphorus. These defects can cause crystal damage which in turn can degrade junction integrity, and in the worst case lead to emitter-collector shorts. The purpose of this work was to find processing parameters which may be used to minimize the excess phosphorus in an emitter diffusion. We have studied the effect of bubble rate, the amount of preheat time, thickness of preformed barrier oxide, percent oxygen in the gas stream, and percent time that the bubbler is on for a 1000°C phosphorus diffusion using PBr_3. The diffusions were characterized by sheet resistance, junction depth, total surface concentration (as measured by an electron microprobe), and Sirtl etching. It is shown that the proper choice of diffusion processing parameters minimizes the excess phosphorus, eliminates etching defects, improves transistor junction yield, and results in only a small increase in final sheet resistance. This occurs when the total phosphorus concentration, averaged over 0.34 μm from the surface, is kept below 4.0 to 4.5 $\times$ 10^{20} cm^{-3}.

The most common n-type dopant used in silicon integrated circuit (SIC) processing is phosphorus, and the two most widely used phosphorus diffusion sources are $POCl_3$ and PBr_3. A considerable amount of work exists (1-4) on the relationship between the electrical properties of these diffusions and the process parameters. It is well known that for high concentrations of phosphorus ($C_{atomic} \geqq 10^{20}/cm^3$) the amount of electrically active phosphorus is less than the total amount introduced during diffusion (5). The explanation given in the literature for this difference is that the excess phosphorus forms precipitates which are not electrically active (6-9). Although a large amount of work has been done on the relationship between the electrical properties of phosphorus diffusions and processing parameters, very little work has been reported on how to minimize this excess phosphorus (8).

The work presented here was undertaken to determine the processing parameters which would result in a minimum amount of excess phosphorus for the typical emitter diffusions used in bipolar digital SIC's. This is important since the excess phosphorus can cause crystal damage resulting in the creation of recombination-generation centers (9-11) in the region of the emitter-base junction, and/or emitter collector shorts. At the same time, the electrically active con-

* Electrochemical Society Active Member.

centration should be as high as possible since in many cases the emitter diffusion is used as a diffused cross-under and a sheet resistance as low as possible is desired to minimize parasitic voltage drops. For circuits operated at low current levels such as injection logic and low power transistor-transistor logic, an increase in the sheet resistance of approximately 50% or less should not have any effect on the noise immunity of the circuits.

All of the work described in this paper was done on 3 in. diam slices using standard bipolar processing. The goal was to determine processing which can reduce the electrically inactive phosphorus concentration without appreciably changing the sheet resistance (*i.e.*, the electrically active phosphorus concentration).

Experimental

The diffusion system used for PBr_3 predepositions is shown schematically in Fig. 1. The bubble rate is the amount of nitrogen that is bubbled through a flask of liquid PBr_3. The oxygen is needed to form a phosphorus-doped glass on the silicon surface. It is this glass which acts as the diffusion source. The main N_2 is adjusted if bubble rate or O_2 content is changed, so that the total gas flow is always 8.0 liters/min. This flow has been found sufficient to assure uniformity and eliminate backstreaming.

The processing variables which control the total amount of phosphorus are: diffusion temperature; total diffusion time; bubble rate (nitrogen flow: liters/min); percent oxygen in gas stream; percent time bubbler is on; temperature of PBr_3 source; preheat time (time elapsed before bubbler is turned on). In a typical bipolar process, the desired emitter junction depth is ≈ 1.2 μm. Typical total diffusion time and temperature to achieve this junction depth are 35-40 min at 1000°C. To first order, all of the other parameters listed above have a secondary effect on this junction depth, and hence on the active base width of the transistor. Although it has been shown that higher phosphorus diffusion temperatures can result in a smaller amount of excess phosphorus than lower temperatures (8), due to the higher phosphorus solubility at higher temperatures, use of higher temperatures is ruled out due to the very short, and hence poorly controllable, total diffusion times.

Two approaches were initially taken to reduce the electrically inactive phosphorus concentration. The first of these involved lowering the amount of phosphorus in the gas stream by varying the bubble rate, percent time that the bubbler is on, and percent of oxygen. The second approach was to grow a thin layer of thermal oxide on the silicon just prior to the phosphorus diffusion. This may be done in a separate oxidation furnace or *in situ* in the phosphorus diffusion furnace by using a relatively long preheat time and a high O_2 level.

All diffusions except those used in junction yield studies were into p-type bulk wafers with a <111> orientation and a resistivity in the range of 0.5-1.0 Ω-cm. The diffusions were performed at 1000°C for total times of 36 or 60 min which correspond to emitter junction depths of 1.2 and 1.6 μm, respectively. The nitrogen bubble rate was varied from 0.5 to 2.0 liters/min. The oxygen flow was varied from 0 to 20% of the total gas flow. Bubbler time was varied from 16 to 92% of the total diffusion time.

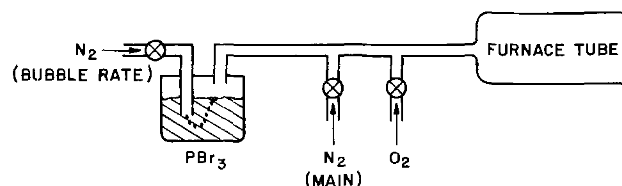

Fig. 1. Diffusion system used for PBr_3 predepositions

Three lots of 24 n-type epitaxial wafers each (0.5 Ω-cm, 5-6 μm thick, <111> oriented) were run to observe the effect of the emitter diffusion on transistor junction yield, which we define as the percent of transistors with $BV_{CEO} \geqq 5V$ at 10 μa. The first lot was split four ways; two different low phosphorus methods, a "worst case" high phosphorus diffusion, and an intermediate phosphorus diffusion which is the standard currently used in production. The second and third lots were split two ways; standard diffusion and low phosphorus diffusion. Twenty large transistors, emitter area 270 mil^2, were measured on each wafer. The transistor junction yield, the base pinch sheet resistance (the sheet resistance of the base under the emitter), and final (*i.e.* reoxidized) emitter sheet resistance were also measured.

Results and Discussion

Sirtl etching of wafers following the phosphorus diffusions was used to reveal dislocation size and density for the different diffusion conditions. Since defect analysis is performed at high magnification (200×), the statistical variation from sample to sample for these wafers was considerable, hence large areas from each of the wafers within a particular run must be examined. Typical defects from such an examination using Normarski interference contrast microcopy are shown in Fig. 2 and 3. The diffusion conditions of the various samples will be discussed later. It is possible to prepare samples with no defects (Fig. 2a), with small defects (Fig. 2b and 2c), and with large defects (Fig. 2d and Fig. 3a-3d). These defects, as mentioned earlier, are dislocations arrays. Their sizes, as revealed by etching, range from ~3-5 μm for the small defects to 50-60 μm for the large ones. Because of the range in size and position of these defects, no quantitative estimate of their density has been attempted. All results are presented in a qualitative and comparative manner.

Table I shows the effect of the total phosphorus concentration on the defects produced by the emitter diffusion as observed by Sirtl etching. The phosphorus concentration was varied by varying the percent of time the bubbler is on, the bubble rate, and the percentage of oxygen in the gas flow.

This table indicates that a reduction of the phosphorus concentration below 4.0 to 4.5 × $10^{20}/cm^3$ (averaged over the first 0.34 μm) by appropriate choice of diffusion parameters is sufficient to produce defect-free emitters.

The second approach used to reduce the phosphorus induced defects involves growing a thin oxide prior to the phosphorus diffusion. Table II shows the results for a separate oxidation, and once again it is found

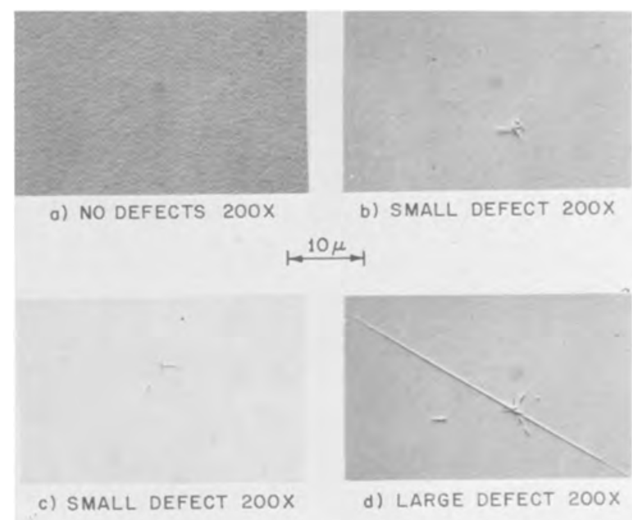

Fig. 2. Defects produced by phosphorus predeposition (1000°C)

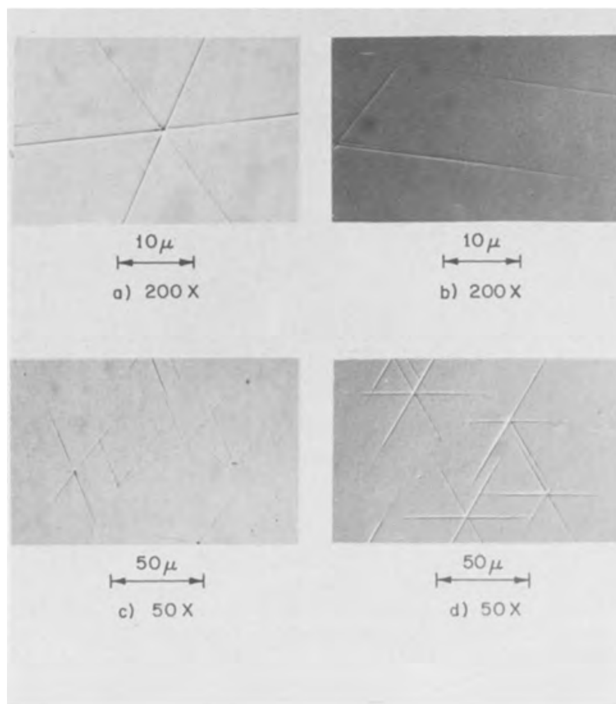

Fig. 3. Large defects produced by phosphorus predeposition (1000°C).

that reducing the phosphorus concentration below 4.0 to 4.5 × $10^{20}/cm^3$ (averaged over 0.34 μm) results in the elimination of phosphorus-induced defects. Table III shows results for thin, $\lesssim$ 110Å, oxides grown *in situ* in the phosphorus diffusion furnace in dry O_2. In this case the number of defects decreases as the oxide thickness increases, but there is no apparent decrease in the total phosphorus concentration. This apparent contradiction of the previous correlations may be understood by recalling that: (*i*) the electron microprobe measurement gives an average concentration

Table I. Effect of total phosphorus concentration on defects

(Total diffusion time 60 min)

Sheet resistance Rs (Ω/□)	Total phos. conc.* per cm³	Etching results (refer to Fig. 2 and 3)
5.6	3.3 × 10^{20}	No defects
4.4	4.5 × 10^{20}	Small defects at center, large defects at edge
4.2	5.4 × 10^{20}	Small and large defects at center, large defects at edge

4.0	7.5 × 10^{20}	Small and large defects at center, large defects at edge

* Averaged over 0.34 μm depth (electron microprobe results).

Table II. Diffusion through previously formed thin oxide

(Total diffusion time 60 min)

Barrier oxide thickness (A)	Sheet resistance Rs (Ω/□)	Total phos. conc.*	Etching results (refer to Fig. 2 and 3)
0	3.9	5.9 × 10^{20}	Large defects throughout
165.0	4.2	5.4 × 10^{20}	Large defects but lower density than above
290.0	4.6	4.9 × 10^{20}	Small defects
450.0	5.4	4.3 × 10^{20}	None
700.0	8.3	2.9 × 10^{20}	None
1000.0	17.8	$<1 \times 10^{20}$	None

* Averaged over 0.34 μm.

Table III. Diffusion through an *in situ* oxide

(Total diffusion time 60 min)

Oxide formed (A)	Sheet resistance Rs (Ω/□)	Total phos. conc.* (cm^{-3})	Etching results (refer to Fig. 2 and 3)
50	4.5	4.8 × 10^{20}	Low density of small defects
66	4.5	4.4 × 10^{20}	Low density of small defects
110	4.2	4.7 × 10^{20}	Very few, small defects

* Averaged over 0.34 μm depth.

over ≈0.34 μm from the surface; and (*ii*) it is the maximum phosphorus concentration which occurs at the surface that is the cause of the SiP precipitates and dislocation networks. It appears, therefore, that even a thin oxide ($\lesssim$110Å) over the silicon acts to decrease the surface phosphorus concentration and "flatten out" the profile, with very little effect on the total amount of phosphorus that is diffused into the silicon.

The *in situ* oxidation method has a number of advantages over a preformed oxide layer; it eliminates the need for an additional process step, it eliminates the possibility of accidental removal of the thin oxide during a reclean, and it results in a reproducibly thin oxide (≈100Å) which decreases the defect density while resulting in a minimal increase in the sheet resistance.

The results of combining these two approaches (lowering the amount of phosphorus in the ambient and growing an SiO_2 layer prior to diffusion) are shown in Table IV. In three "low phos" examples, the phosphorus glass thickness is not appreciably different from the "standard" condition for any of these cases. After the emitter reoxidation, 900°C for 60 min in steam, the final sheet resistance of low phos III is slightly greater than standard, while the other two cases have appreciably larger values. The amount of oxide grown over the emitter, which is known to depend on the phosphorus concentration, is also shown in the table.

Table IV. Some characteristics of "optimum" emitter diffusion

(Total diffusion time 36 min)

	Diffusion conditions		After predep			After reox			
Emitter diffusion	Oxygen (%)	Bubble rate (l/min)	Glass thickness (Å)	Rs (Ω/□)	Total phos conc.*	Rs (Ω/□)	Total phos conc.*	Oxide thickness (Å)	Etching results
Low phos I	10	0.5	670	11.4	2.4 × 10^{20}	16.5	1.7 × 10^{20}	3450	No defects
Low phos II	10	0.75	715	8.8	3.1 × 10^{20}	12.7	2.7 × 10^{20}	3700	No defects
Low phos III	10	1.0	720	7.7	3.4 × 10^{20}	11.0	3.5 × 10^{20}	3860	Some small defects
Standard	3	1.0	600	6.2	4.3 × 10^{20}	9.0	4.6 × 10^{20}	4020	Small defects at center, large defects near edges

* Averaged over 0.34 μm depth.

Table V. Effect of emitter diffusions on transistor junction yield

(Total diffusion time 36 min)

Diffusion emitter	Diffusion conditions		Junction yield (% BV_{CEO} > 5^v at 10 μA)	Base pinch sheet res. (kΩ/□)	Final emitter sheet res. (Ω/□)	Total phosphorus concentration* (cm^{-3})
	Bubble rate (l/min)	Oxygen (%)				
Lot No. 1						
Low phos I	0.5	10	90%	4.1	13	2.9×10^{20}
Low phos III	1.0	10	83%	5.0	10	4.1×10^{20}
Standard	1.0	3	52%	5.3	9.2	4.4×10^{20}
High phos	2.0	3	52%	5.0	7.0	1.1×10^{21}
Lot No. 2						
Low phos I	0.5	10	69%	5.7	14.0	2.6×10^{20}
Standard	1.0	3	43%	5.8	9.4	4.6×10^{20}
Lot No. 3						
Low phos III	1.0	10	83%	3.3	9.8	Not measured
Standard	1.0	3	67%	3.7	8.5	Not measured

* Averaged over 0.34 μm from surface.

The results of the transistor junction yield experiments previously described are shown in Table V. For Lot 1 the low phos I results may be too optimistic due to the wide basewidth of this part of the split lot (as indicated by the low base pinch sheet resistance). However the results of low phos III *vs.* standard clearly show a real improvement.

Conclusion

To increase transistor junction yield the amount of excess, electrically inactive, phosphorus in the emitter diffusion must be kept to a minimum. Two approaches to this are: (*i*) minimize the amount of phosphorus in the gas stream; and (*ii*) grow a thin layer of thermal oxide over the silicon prior to the diffusion. These two approaches have been combined into "optimum" diffusion schedules which produce total phosphorus concentrations (averaged over 0.34 μm from the surface as measured by electron microprobe) less than or equal to approximately 4.0 to 4.5 $\times 10^{20}$ cm^{-3}. As a result, defect-free surfaces are obtained and transistor junction yield is significantly increased (up to ~80%) as compared to higher concentration phosphorus diffusions.

Formation and Properties of Thin Tunnelable SiO_2 Films Using a Vaporized O_2 Source at Liquid N_2 Temperature

Masatada Horiuchi, Yoshiaki Kamigaki, and Takaaki Hagiwara

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

A high temperature (700°-1100°C) oxidation process for the formation of thin tunnelable SiO_2 (20-70Å) is described. This oxidation process uses liquid O_2 at liquid N_2 temperature as a source of oxidant and oxygen is vaporized just before the furnace tube to supply a water-free oxidant ambient. The activation energy (20.2 kcal/mole) of oxidation rate differs from that previous (43.9 kcal/mole) which has been evaluated for thin oxide growth using the O_2/N_2 partial pressure method. By the use of this technique we can control thickness to ±0.5Å accuracy. The rate of oxidation has been found to be governed by the inverse-logarithmic growth law, *i.e.*, Mott-Cabrera's field-assisted diffusion law. Electrical characteristics, such as dynamic conductance, capacitance, and tunnel current, are measured and discussed. The increment of the oxidation temperature is found to result in the decrease of surface-state density at the Si-SiO_2 interface. The process described enables the way for wider application of thin oxide devices.

There has been a good deal of recent interest in thin oxide nonvolatile memory devices such as metal-nitride-oxide silicon (MNOS) devices. This is because of the proposed use of MNOS devices in electrically alterable read-only memories as well as for various other applications (1). In these devices, a thin tunnelable oxide plays a very important role in governing several properties of the memory actions, such as switching speed, retention characteristics, and degradation phenomena. Although there is a considerable amount of information available about the kinetics and electrical properties of relatively thick (0.02-1 μm) SiO_2 layers (2-4), there has been comparatively little published on thin (<200Å) SiO_2 films (5-7). Most importantly, there is little information on the reproducibility of the formation and quality control of thin tunnelable oxides.

This paper presents a study of the growth of thin tunnelable oxides (20-80Å) on freshly etched Si at 700°-1100°C in dry oxygen. It describes the successful development of a technique for reproducibly fabricating thin tunnelable SiO_2 films (on Si) and for improving the Si-SiO_2 interface properties.

Experimental Procedures

Sample preparation.—Most of the single crystal silicon wafers in this study were 8-12 Ω-cm p-type with a chemmechanically polished (100) face. Conductance measurements were carried out using sample wafers of 0.002 Ω-cm p^{++}-type or 0.009 Ω-cm n^{++}-type (111) face. The wafers were cleaned by a standard ammoniacal peroxide process as a preoxidation wafer treatment after the field oxide was etched off to expose the gate region. Wafers for studying the rate of formation of thin tunnelable SiO_2 films did not have a field oxide, so only the cleaning sequence was carried out.

All thickness measurements were made ellipsometrically. The films formed in air during 7-10 min measurement time on freshly etched Si wafers were measured to be about 6.0Å (assuming that the films were SiO_2 films). In this study, the refractive indexes of $n_{SiO_2} = 1.47$ and $n_{Si} = 4.08\text{-}0.028i$ were assumed.

The oxidation was carried out in a resistance-heated 3 zone oxidation furnace tube with a specially prepared oxygen source for the desired amount of oxidation time. The oxidation apparatus for formation of thin tunnelable SiO_2 is shown in Fig. 1. In this oxidation process, the oxygen source is liquid O_2 vaporized at the temperature of liquid N_2 and carried into a conventional oxidation furnace with purified N_2 gas. N_2 gas does not bubble through liquid O_2 but simply passes over liquid O_2 face. The oxygen vaporization just before the furnace tube inherently decreases impurity content in the oxidant ambient. Oxidation was carried out at 700°-1100°C.

After oxide growth samples to be used for measurement of the electrical properties were placed in a vacuum system. Aluminum was evaporated with a resistive heater and gate electrodes were formed by photoetching. Contact with the back side of the structure was accomplished by N^+ diffusion before formation of the thin SiO_2 films.

Measuring procedure.—Dynamic conductance and capacitance measurements are made by properly adjusting the phase shifter of the lock-in amplifier (8). A ramp voltage supply provides d-c voltage to the sample, thereby enabling data to be plotted automatically. Signal frequency is about 19.2 Hz and peak-to-peak voltage is about 5 mV. The absolute measurement of conductance or capacitance is made by a substitution technique in which the system is first calibrated to give a certain deflection for a known conductance or capacitance. After calibration the sample is switched into the circuit. This system can verify conductance values of more than 2×10^{-8} mho.

Results and Discussion

Thickness evaluation.—The vapor pressure of oxygen does not stabilize for about two days after liquefaction at liquid N_2 temperature. The fluctuation of the formed oxide thickness under these conditions is plotted

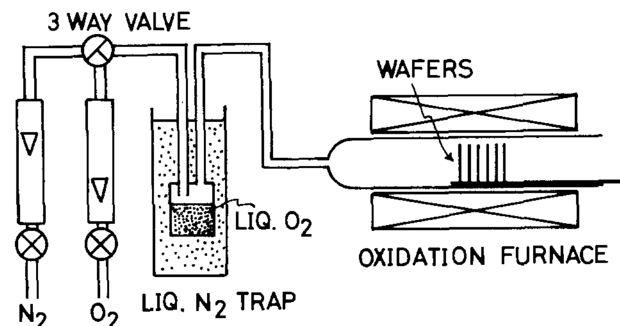

Fig. 1. Oxidation apparatus for formation of thin tunnelable SiO_2 with liquid O_2 source vaporized at liquid N_2 temperature.

Key words: high temperature oxidation, excellent accuracy, inverse-logarithmic growth law, surface-state density decrease.

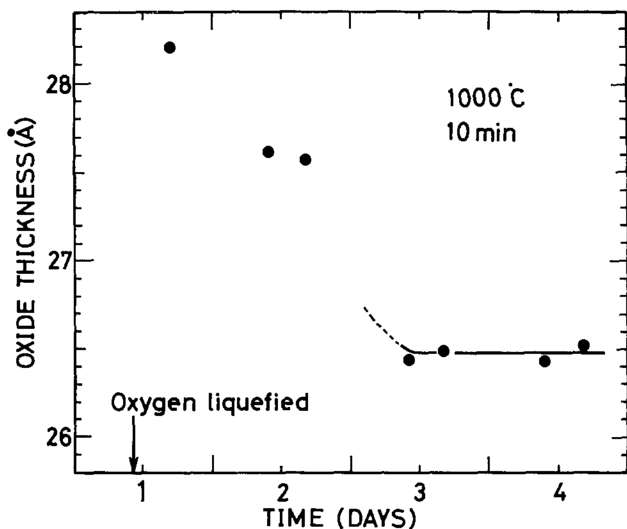

Fig. 2. Fluctuation of the oxide thickness under the same conditions (1000°C, 10 min). Oxide thickness is reproducible within ±0.5Å accuracy after three days from oxygen liquefaction.

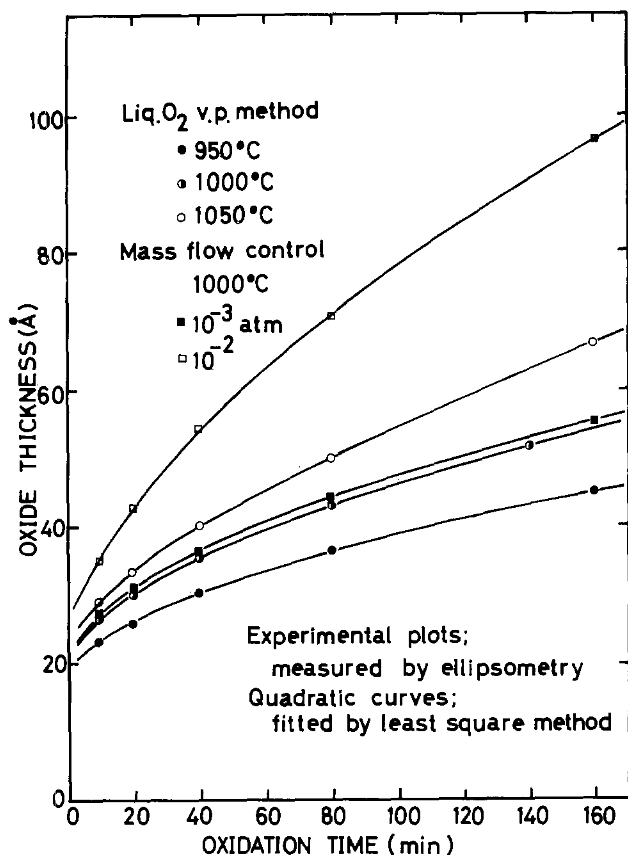

Fig. 3. Rate of formation of thin tunnelable SiO_2 films using a liquid O_2 source vaporized at liquid N_2 temperature. The results of the O_2-N_2 mixture method varying oxygen concentration at 1 atm total pressure by mass-flow controller are shown for comparison.

against time after liquefaction in Fig. 2. After three days, the oxygen vapor pressure reaches a steady-state condition and good reproducibility can be obtained within ±0.5Å accuracy.

The rate of formation of thin tunnelable SiO_2 films using liquid O_2 oxidant source is shown in Fig. 3. The results of the O_2-N_2 mixture method (varying oxygen concentration at 1 atm total pressure by mass flow controller) are shown in this figure for comparison. By comparison with the O_2-N_2 mixture method, partial pressure of O_2 is verified as being nearly equal to 10^{-3} atm for the liquid O_2 vapor pressure method.

In this figure, the Deal-Grove linear parabolic relationship, $X^2 + AX = B(t + \tau)$ is not applied as an analytical procedure, but the second-order regression curves $t = a_0 + a_1X + a_2X^2$ are fitted to the experimental data plots using the least squares method. This is because the Deal-Grove relationship cannot actually be applied in the case of thin oxide growth involving field and space charges within the oxide layer thinner than oxide-Debye length (9, 10).

It has been reported in the previous paper (10) that the thin oxide growth under low oxygen partial pressure is governed by the inverse-logarithmic growth law $dX/dt = u \exp (X_1/X)$, *i.e.*, one case ($X_1 >> X$) of the Mott-Cabrera's field-assisted diffusion law $dX/dt = 2u \sinh (X_1/X)$, where $u \propto \exp(-W/kT)$ and X_1 are the characteristic velocity and distance, respectively (11).

The results of the experimental and analytical data at 950° and 1000°C oxidation temperature are presented in detail in Table I. Average relative error $\overline{dX/X}$ is as small as 0.34%. Average thickness error $\overline{dX}$ is remarkably small, *i.e.*, 0.11Å. The Deal-Grove's rate constants can easily be calculated from Table I. The resulting rate constant A has negative values in our experimental range. This means that the Deal-Grove linear parabolic relationship cannot be accepted in our experimental range. The relation between oxidation velocity and oxide thickness is also given in Table I. The log $(d\overline{X}/dt)$ *vs.* $1/X$ plots at 950°, 1000°, and 1050°C are shown in Fig. 4. It is clear that a strictly linear relation can be obtained in this figure. The values u and X_1 can be obtained from Fig. 4, *i.e.*, u by extrapolating the straight line back to $1/\overline{X} = 0$. The gradient of this line gives X_1. The good linear relationship, as is seen in Fig. 4, proves that the oxide growth using liquid O_2 vapor pressure method is also governed by the inverse-logarithmic law, *i.e.*, Mott-Cabrera's field-assisted diffusion growth law.

All values obtained for u can be plotted as a function of oxidation temperature. Activation energy (W) in the Arrhenius expression is about 20.2 kcal/mole.

This value is smaller than 43.9 kcal/mole, that of previous study (10) where O_2-N_2 partial pressure method was used as a thin oxide formation. However, it may be compared with 25.8 kcal/mole for the thicker oxide formation as referred to by Revesz and Evans (3). They obtained this value by rf heating oxidation with dry O_2 containing less than 0.1 ppm of water. According to them, the water and sodium content in the oxidizing ambient greatly affects the rate constant and its activation energy. The activation energy increases with the increment of sodium and water content. In their study or in the previous studies (2, 12), 43.3-44.0 kcal/mole were presented as the largest values of activation energy.

In our experiment liquid O_2 is vaporized just before the furnace tube, and water vapor in the oxidant

source at liquid N_2 temperature is less than 2×10^{-26} atm, *i.e.*, water-free oxidant source. According to this, the liquid O_2 vapor pressure method may apparently be distinguished from other thin oxide formation methods for impurity content in the formed oxide.

Electrical properties.—A typical capacitance *vs.* voltage characteristic measured by a lock-in amplifier with 100 kHz superposed frequency is shown in Fig. 5. Thickness of this film measured by ellipsometry is 57.2Å. Maserjian *et al.* (13) provided a method to evaluate the value of the density of states-effective

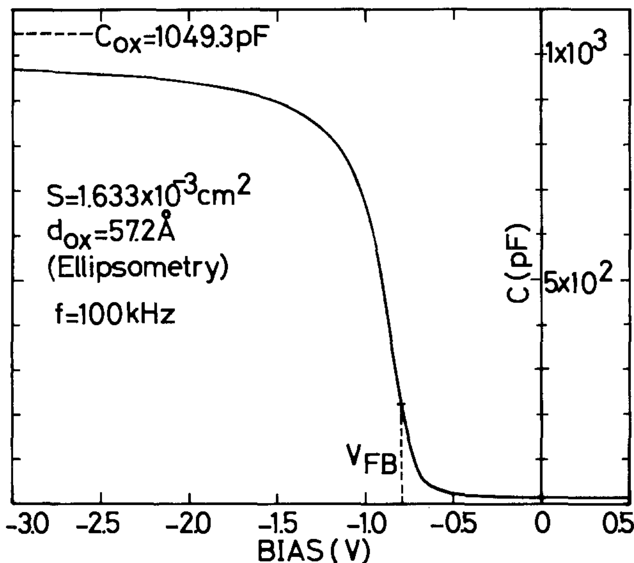

Fig. 5. A typical capacitance *vs.* voltage characteristic. Oxide thickness measured by ellipsometry is 57.2Å. Capacitance fails to saturate at the oxide capacitance C_{ox}. Thus, the C_{ox} value is estimated after Ref. (13) exactly.

mass m_D for the valence band. According to their method, m_D is evaluated as 0.296 m_o. The value of m_D obtained from this method differs considerably from the bulk density of states mass which is $m_D = 0.55\ m_o$ for the valence band. Maserjian *et al.* suggested that one possible reason for this is surface quantization effects. They calculated $m_D = 0.29\ m_o$ for the valence band of the (100) surface assuming the triangular potential approximation for a strongly accumulated semiconductor surface. Quite good agreement can be seen between the value found from surface quantization and our calculated value in spite of measurement at room temperature.

The flatband voltage value is nearly −0.8V and discrepancy from the Al-Si work function difference (14) is less than 0.05V. No hump caused by the interface state density distribution (15, 16) can be observed in this capacitance curve. These facts prove the quality of the thin oxide films described in this paper.

Tunnel current is measured in a "transistor structure" with a N^+-diffused region instead of the usual diode structure. The use of the transistor permits the estimation of the amount of charge transfer between the Si substrate and trap sites in thin oxide nonvolatile memory devices. A cross-sectional view of this transistor is shown in Fig. 6. In this figure, the current between the Si surface inversion layer and counter-electrode can be distinguished from the conventional MOS diode tunnel current.

Typical current density *vs.* voltage (*J-V*) curves for various oxide thicknesses are shown in Fig. 6 for two different current paths. The broken lines show the *J-V* characteristics between Al electrode and Si substrate (N^+-diffused region is electrically in floating condition). The dotted lines show the *J-V* characteristics between the Al electrode and N^+-

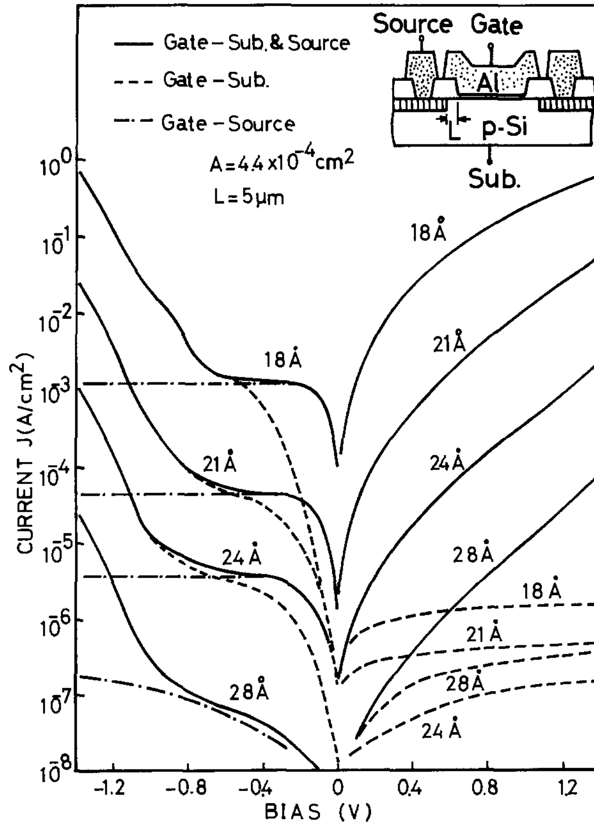

Fig. 6. Typical current density J *vs.* voltage V curves with various oxide thickness. Oxide films are formed at 1000°C. Broken lines show the *J-V* curves between Al and Si substrate. Dotted lines show the *J-V* curves between the Al and N^+ diffused region through the surface inversion layer. Solid curves indicate the *J-V* curves between Al and Si substrate by shorting the N^+-diffused region and substrate.

diffused region through the surface inversion layer (the substrate is electrically in floating condition). The solid lines indicate data summarizing the above two curves (current densities are measured between the Al electrode and substrate by shorting the N^+ region and substrate). The dotted lines in the positive voltage regime coincide exactly with the solid curves.

When the oxide is moderately thin (<40Å) and the electron supplement source is the only generation current in the depletion layer, electrons can more easily transit from the Si surface to the metal electrode than maintain the inversion layer at the Si surface (Si surface is strongly depleted). The broken lines in the positive direction show this generation-limited current. This current density is independent of the applied voltage and oxide thickness. Furthermore coincidence of the dotted curves with the solid one in the positive direction indicates that most electrons are supplied from the N^+-diffused regions. The current in the positive direction may be limited by the length L of the offset region and the conductance value at this regime or by the tunnel transition probability. These currents are functions of the oxide thickness and applied voltage. The solid curves correspond to the real behavior of tunnel transitions for the switching actions in thin oxide nonvolatile memory devices.

To improve switching speed, especially in the case of electron injection from the substrate to trap sites, it is desirable that devices adopt thinner tunnelable oxide, if possible, without any fatal demerit to other device properties. Another recommendation is decrementation of the offset length, L, *i.e.*, providing a large conductance value without leakage or degradation of thin oxide films over the N^+-diffused regions.

To evaluate another feature of thin tunnelable oxide prepared by the liquid O_2 vapor pressure method, a-c conductance of MOS diode is measured with 30-22Å thick oxide over p^{++}- or n^{++}-degenerate substrates. The electrode is a mask-evaporated 1 mm diam Al dot. A typical a-c conductance dI/dV *vs.* applied voltage V curves with 30Å thick oxide over p^{++}-degenerate substrates are shown in Fig. 7. As an experimental parameter, oxidation temperature is varied from 700° to 1100°C. Conductance values for the low temperature (700°C) oxidized sample increase rapidly with increment of applied voltage in the negative direction. For a sample oxidized at 900°C, a little hump in the conductance curve can be observed for the negative bias regime corresponding to the forbidden band. For the higher temperature (1100°C) oxidized sample, only an abrupt conductance increment corresponding to the electron injection from the metal electrode to the lower edge of the conduction band can be observed. The discrepancy for positive-biased conductance curves may be caused by the fact that the heavy degeneration effect and the valence bandedge become obscure in p^{++} substrates with over 10^{19} impurities/cm^3 (17).

The frequency dependence of a-c conductance for p^{++} substrates with 22Å thick tunnelable oxide is shown in Fig. 8. The tunnelable oxide is formed at 900°C. The significant properties of these humps in the conductance curves are that (*i*) the location of the humps along the voltage axis is independent of frequency over the range 19.2 Hz-19.2 kHz; and (*ii*) the magnitude of the hump increases a little with increasing frequency. Because of property (*i*), this hump cannot due to inversion layer coupling (18). It must be due either to tunneling to interface states or to charge exchange between the interface states and the majority carriers at the valence band.

In case of a MOS tunnel diode with p^{++} substrate and thin (20-40Å) oxide film, metal carriers tunnel through the oxide into interface states and then rapidly recombine with the majority carrier at the valence band for bias corresponding to the forbidden bandgap. Thus, the current through the interface states is tunneling controlled ($\tau_{tunnel} >> \tau_{recombine}$) (19). Then the humps in Fig. 8 may be due to tunneling to interface states.

Frequency response of a-c conductance characteristic depends on the transition probability of an elec-

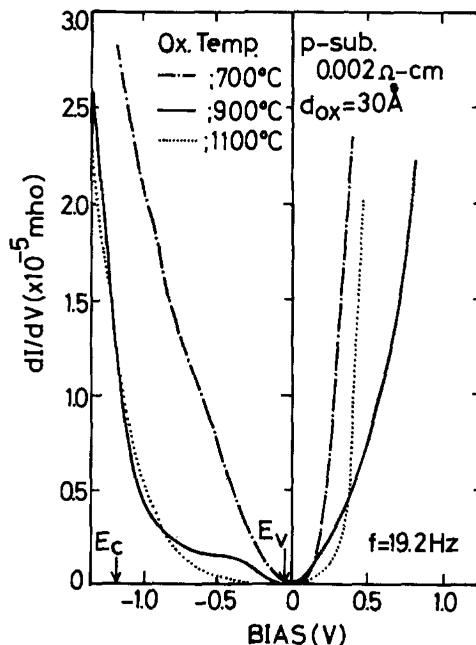

Fig. 7. A typical a-c conductance vs. applied voltage curves with 30Å thick oxide over p^{++} substrates.

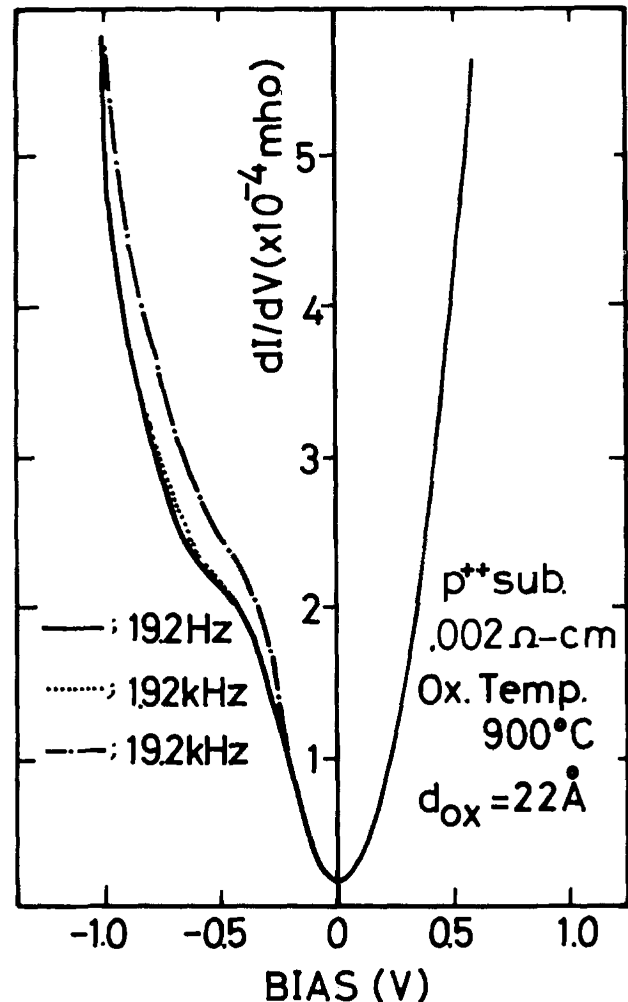

Fig. 8. Frequency dependence of a-c conductance for p^{++} substrates with 22Å thick oxide. The oxide is formed at 900°C.

tron from the metal into the interface states. The characteristic frequency depends linearly on the density of interface states (18). Thus, little frequency dependence indicates that there are few interface states in that sample.

D-c and a-c conductance distinctly reflect the effect of the semiconductor band structure and the density of interface states. Freeman and Dahlke provided a theoretical analysis (19) to evaluate the d-c and low frequency a-c conductance characteristics assuming various energy distributions of interface states. In the case of degenerate substrate, surface potential is usually a negligible correction and the variable range of surface potential at maximum is less than 3×10^{-3}V for p^{++} substrates with the applied voltage range in Fig. 7. According to this fact and Freeman's theoretical evaluation, tunneling conductance is approximately proportional to the density of interface states. This indicates that humps or increments in conductance curves shown in Fig. 7 correspond to the distribution map of interface state density. An energy band diagram and distribution map of interface state density derived from Fig. 7 is shown in Fig. 9. In this figure, the vertical axis is expressed in arbitrary units. This is because the magnitude of experimental results does not coincide with the calculated one. This discrepancy may be caused by the misestimation of values such as capture cross section of interface state or average attenuation constant at the interface.

The a-c conductance curves for a sample having an n^{++} degenerate (0.009 Ω-cm) substrate with a 22Å thick oxide is shown in Fig. 10.

The tunnelable oxide is formed at 900°C. The approximate voltages corresponding to bandedges are also shown in this figure as E_v and E_c. As can be seen in Fig. 10, conductance values increase simply as a result of increment in the positive and negative applied voltage.

For n^{++} substrate, the effective oxide barrier is expected to be smaller than for those of p^{++} sample (14). For a negative bias on the gate electrode, electrons tunnel from the gate to empty states of the semiconductor conduction band, resulting in a large, rapidly increasing current. A small positive bias on the gate produces increased electron tunneling from the semiconductor conduction band into the gate electrode. In addition to this current component, electron tunneling from the interface states into the metal gate is generated by a further increase in bias. This second component (19) is due to the decrease in effective oxide barrier.

For larger voltage additional tunneling from the valence band to the gate electrode occurs. However, this tunneling has a comparatively small influence on the total conductance characteristic on account of the high oxide barrier, *i.e.*, p^{++} sample. This is why

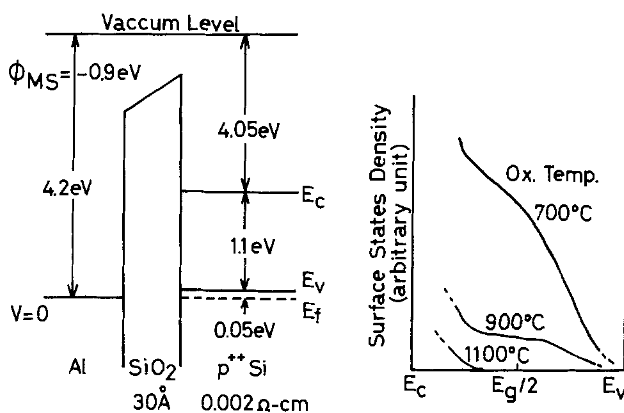

Fig. 9. Energy band diagram of MOS tunnel diode with 30Å thick oxide over p^{++} substrates and a distribution map of $Si\text{-}SiO_2$ surface state density evaluated from Fig. 7.

the Si band structure has a much smaller influence on the conductance characteristics of the n^{++} sample (Fig. 10) compared to the p^{++} one (Fig. 7 and 8).

Conclusion

Thin tunnelable oxides (20-80Å) are formed by a high temperature (up to 1100°C) oxidation method within ±0.5Å accuracy. This oxidation process uses liquid O_2 as an oxidant source at liquid N_2 temperature. The partial pressure of vaporized O_2 in steady-state conditions is verified as being nearly equal to 1×10^{-3} atm. The oxidation kinetics in our experimental range are governed by the inverse-logarithmic relation which is caused by the field-assisted diffusion law.

The activation energy of oxidation rate is evaluated as 20.2 kcal/mole and this value is smaller than previous data. The smaller value of the activation energy may suggest that the described process is distinguished from other formation methods of thin oxide films for impurity content in the oxide films.

Electrical properties such as effective mass in the valence band and $Si\text{-}SiO_2$ interface state density are evaluated and discussed by capacitance and a-c conductance measurements. Results obtained are; $m_D = 0.296\ m_o$ and interface state density decreases with increasing oxidation temperature. No hump can be observed in the capacitance curve for the sample oxidized at higher temperature. This indicates that less interface state is originated by the oxidation process described. Interface state density for p^{++} substrate increases as the energy level approaches the lower edge of the conduction band within the forbidden

band for samples oxidized at low temperature. However, for n^{++} substrate, interface state density cannot be estimated because interface states are filled with conduction electrons due to recombination.

To estimate the real behavior of charge transition in the thin oxide nonvolatile memory devices, tunnel currents are measured in an actual transistor structure. This permits the current between the Si surface inversion layer and the counterelectrode to be distinguished from the conventional MOS diode tunnel current. As a result, it is predicted that channel conductance near the source region may play an important role in governing the electron injection rate into the trap sites.

The thin tunnelable oxide layers described have been and are being used in FTMIS (floating silicon gate tunnel injection metal-insulator-silicon) memory devices. They are tunnel-mode type nonvolatile memory devices (20, 21). In the thin oxide memory devices, memory characteristics such as fatigue phenomena depend strongly on the properties of the thin oxide and most devices have degradated after 10^6-10^8 cycles of operation (1). However, FTMIS memory devices with thin tunnelable oxide described can operate without any fatigue phenomena after 2×10^{12} cycles endurance operation (21). Thus, this oxidation process is best fit for fabrication of various kinds of thin oxide devices.

The Effect of Chloride Etching on GaAs Epitaxy Using TMG and AsH$_3$

Rajaram Bhat*,[1] and Sorab K. Ghandhi*

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

A study has been made of the effect of *in situ* etching of (100) Cr-doped semi-insulating and Te-doped n$^+$-GaAs substrates on epitaxial layers, grown by the reaction of trimethylgallium and arsine. It is shown that *in situ* etching enables the growth rate to be increased by a factor of two while retaining a specular surface. In addition, the Hall mobility is higher in epitaxial layers grown on *in situ* etched substrates than on unetched ones. Epitaxial films on both $AsCl_3$ and HCl gas-etched substrates had a room temperature mobility that decreased from $\simeq$6100 cm^2/V-sec in 5.5 μm layers to $\simeq$5100 cm^2/V-sec in 1 μm layers. However, for layers grown on substrates which were not *in situ* etched, the mobility decreased from $\simeq$5800 to $\simeq$3800 cm^2/V-sec for layer thicknesses from 5.5 to 1 μm, respectively. Further it is shown that the carrier concentration profile is more abrupt near the epitaxial layer/Te-doped GaAs substrate interface when the substrates were *in situ* etched. Finally, experiments with chloride etching during growth were disappointing because it was not possible to obtain simultaneously good surface morphology, low carrier concentration, and high mobility for any given set of reactor conditions.

The growth of epitaxial layers of III-V semiconductors using organometallic compounds as sources of the group III element and hydrides as sources of the group V element was first reported by Manasevit (1). Since that time, the inherent simplicity of organometallic systems has been exploited in the growth of many other materials. One of their many advantages is that the

[1] Present address: General Electric Company, Semiconductor Products Department, Syracuse, New York.

metal alkyl-hydride reaction is an irreversible one, so that etching and autodoping effects are notably absent. Unfortunately, however, this feature necessitates the use of an *in situ* etch step prior to epitaxial growth, which has been recognized by many workers as an essential step in the growth sequence to improve the quality of the epitaxial deposit (2, 3, 4). In GaAs epitaxial growth systems using trimethylgallium (5), this necessitates the use of etchants such as HCl gas or $AsCl_3$ vapor to incorporate this capability. The experimental conditions under which vapor-phase etching and polishing of GaAs substrates can be achieved have been established earlier (6, 7). In this paper, we report the effects of *in situ* etching on the properties of the subsequently deposited GaAs layer. It is demonstrated that *in situ* etching enables an increase in the growth rate while still retaining a specular surface. In addition, it is shown that this etching step results in an improvement in the electrical properties of the epitaxial layers, especially when they are thin (1-2 μm). Hall measurements, in conjunction with layer-by-layer stripping, were used to characterize epitaxial layers deposited on semiinsulating Cr-doped substrates. *C-V* and *dC/dV-V* measurements on Au-GaAs Schottky barrier diodes were used to obtain the free carrier concentration profiles in epitaxial layers grown on n^+ Te-doped GaAs.

Finally, we report on the results of GaAs epitaxy involving the reaction of TMG and AsH_3 in the presence of HCl gas or $AsCl_3$ vapor. The experimental results were disappointing, however, since we found that it was not possible to achieve simultaneously good morphology, low carrier concentration, and high mobility for any given set of reactor conditions.

Experimental Conditions

Apparatus.—*In situ* etching and epitaxial growth were carried out in a conventional rf heated, cold-wall reactor whose schematic is shown in Fig. 1. The reactants were introduced into a 50 mm ID, 37 cm long, horizontally positioned quartz reaction chamber containing a pyrolytic graphite-coated graphite susceptor. A baffle (not shown) was used to mix the reactants prior to their entry into the hot zone. The temperature was monitored using a Pt/Pt-13% Rh thermocouple enclosed in a quartz sheath and inserted into the susceptor, and verified by infrared pyrometric measurements. Gases were delivered to the reaction chamber through stainless steel tubing, except in the case of HCl gas and $AsCl_3$ vapor where Monel and Teflon, respectively, were used to minimize contamination.

Reactants.—Technical grade hydrogen (99.95% purity) was successively passed through an oxygen-removing catalyst,[2] a molecular sieve,[2] a palladium purifier,[2] and a cold trap at 77°K to obtain the carrier gas used in this investigation. This carrier gas was passed through a stainless steel bubbler containing electronic grade trimethylgallium[3] at 0°C. The arsine gas used was a 10% mixture of electronic grade arsine (99.998% purity) in six nines hydrogen.[4] The etchants used were either a 1% mixture of electronic grade HCl gas (99.995% purity) in six nines hydrogen[3] or vapors of $AsCl_3$[5] (99.9999% purity) produced by passing hydrogen through a Pyrex bubbler, containing the liquid at room temperature.

Substrates.—Experiments were carried out on chromium-doped semi-insulating and tellurium-doped n^+-GaAs substrates, with 2° off (100) towards (110) orientation. The wafers were obtained with one side chemimechanically polished by the vendors.[6] These were degreased in hot methanol, boiled in hydrochloric

acid for 2 min, rinsed in methanol, and blown dry in filtered nitrogen. They were then etched in Caro's etch [$10H_2SO_4$ (97%):$1H_2O_2$ (30%):$1H_2O$] at 60°C for 30 sec, rinsed in DI water, rinsed in methanol, and blown dry in filtered nitrogen.

Procedure.—Substrates measuring 5 × 10 mm were placed on the susceptor such that they were nearly perpendicular to the direction of gas flow. The system was evacuated with a mechanical pump before establishing a flow of hydrogen (5 liters/min). The susceptor was then heated to 900°C (in those cases where an *in situ* etch was performed), after introducing the required amount[7] of arsine (30 ml/min) to prevent decomposition of the GaAs substrates. The etching was performed using either a flow of 4.2 ml/min of HCl gas or a hydrogen flow of 80 ml/min through the $AsCl_3$ bubbler. These processes removed a 4.5 μm thick layer from the substrate surface at a rate of 2.25 μm/min. The temperature was then stabilized at 700°C before commencing epitaxial growth. Subsequent GaAs epitaxial layers were deposited using a total hydrogen flow of 5 liters/min, an arsine flow of 15 ml/min, and a hydrogen flow through the TMG bubbler of up to 12 ml/min. The growth rate was determined by cleaving and staining.

In a second series of experiments GaAs layers were also grown on *in situ* etched substrates in the presence of HCl gas or $AsCl_3$ vapor. The introduction of HCl gas during deposition resulted in an increase in the free electron concentration by at least an order of magnitude. This was attributed to the impure nature of the gas, and all further experiments were restricted to the use of high purity $AsCl_3$ vapors during the growth. In these experiments, GaAs was deposited on (100) Cr-doped substrates at 700°C, using a hydrogen flow of 5 liters/min, a hydrogen flow through the TMG bubbler of 10 ml/min, and arsine flow of 15 ml/min. The hydrogen flow through the $AsCl_3$ bubbler was varied between zero and 80 ml/min.

Surface Morphology and Growth Rates

Effect of in situ etching on surface morphology.—Epitaxial layers were deposited on both *in situ* etched and unetched substrates. Layers on unetched substrates exhibited specular surfaces at low growth rates ($\leq$ 0.25 μm/min), corresponding to a H_2 flow through the TMG bubbler of $\leq$ 5 ml/min. With *in situ* etching, however, mirror-like surfaces could be achieved for growth rates as high as 0.5 μm/min. This is shown in the Nomarski interference micrographs of Fig. 2 for layers grown at 0.4 μm/min, both with and without *in situ* etching. Furthermore, differences in surface quality of layers deposited on HCl gas and $AsCl_3$ etched GaAs substrates were very slight, as shown in this figure.

[7] In this paper, flow rates for AsH_3 and HCl gas are all quoted in terms of the actual arsine and hydrogen chloride gas content of the diluted gas.

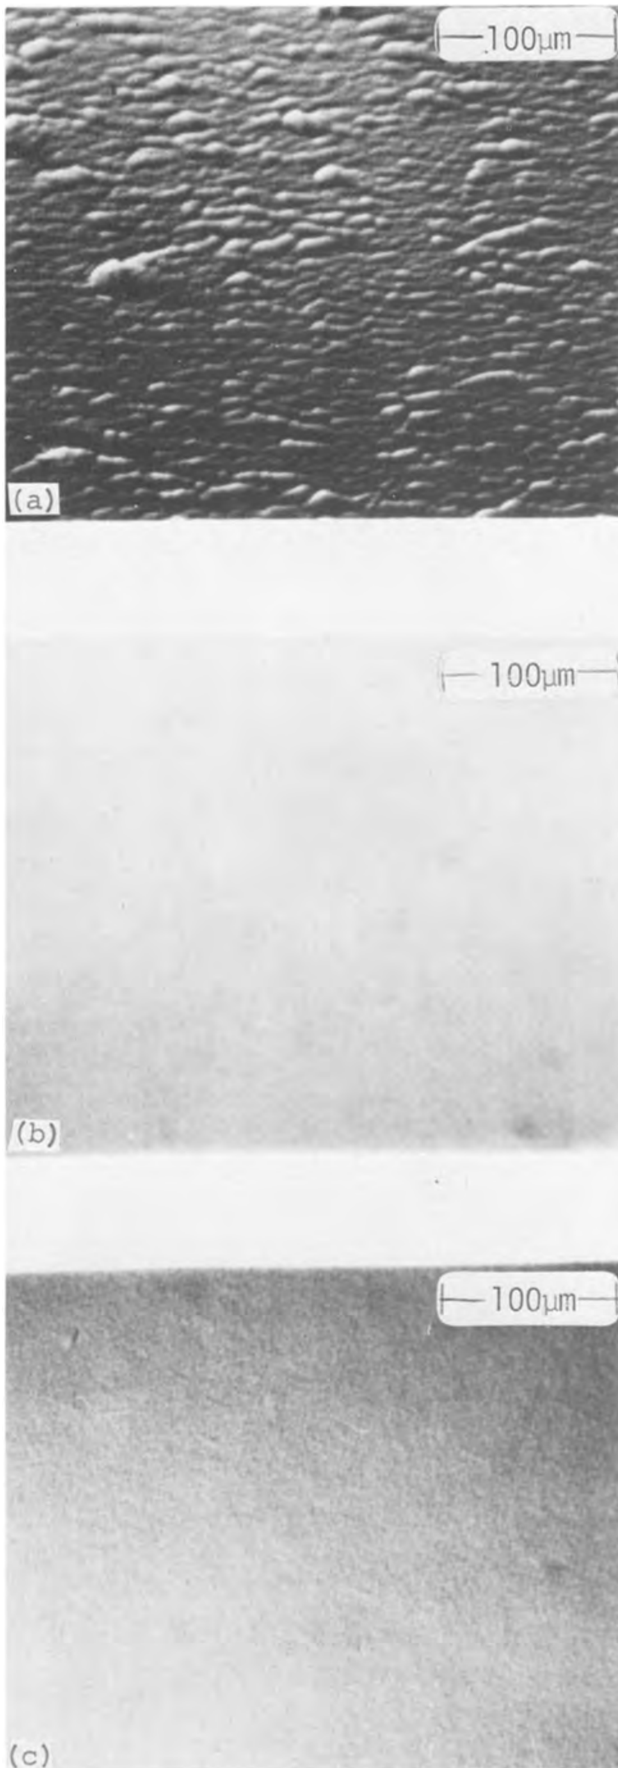

Fig. 2. Typical Nomarski interference photomicrographs showing the effect of *in situ* etching of GaAs substrates on the surface morphology of epitaxial layers (a) no *in situ* etch; (b) HCl gas etch; and (c) $AsCl_3$ etch (growth rate: 0.4 μm/min).

Effect of introducing $AsCl_3$ vapor during epitaxy.—The growth rate of layers deposited at 700°C in the presence of $AsCl_3$ fell linearly with increasing hydrogen flow through the $AsCl_3$ bubbler, varying from 0.4 μm/min for no $AsCl_3$ to 0.2 μm/min for a hydrogen flow of 80 ml/min. There was considerable scatter in the data, however, accompanied by a deterioration in surface morphology at low growth rates. Better surfaces were obtained for layers deposited at 900°C. However, this temperature is far from the optimum for growth using TMG and AsH_3, and resulted in layers with low mobility and high compensation.

Electrical Properties

Epitaxial layers on Cr-doped substrates.—Epitaxial layers were deposited at 700°C on unetched and on *in situ* etched (100) Cr-doped semi-insulating substrates. A total hydrogen flow of 5 liters/min, an arsine flow of 15 ml/min, and a hydrogen flow of 10 ml/min through the TMG bubbler were used to obtain a growth rate of 0.4 μm/min. Tables I and II list[8] the carrier concentration and mobility of epitaxial layers of varying thickness, as obtained by Hall measurements on successively etched layers. Room temperature values of mobility ranged from 6150 cm^2/V-sec for thick (5.5 μm) layers for substrate etching with $AsCl_3$, to 3800 cm^2/V-sec for thin (1 μm) layers with no substrate etching. Results at liquid nitrogen temperature showed a similar trend.

Hall measurements were also made on 5 μm thick GaAs layers, grown at 700°C in the presence of $AsCl_3$ vapor. As expected, the increase of hydrogen flow through the $AsCl_3$ resulted in a fall in carrier concentration, as shown in Fig. 3. However, this fall in elec-

[8] Error limits on this data are ±10% on thickness, ±5% on mobility, and ±15% on carrier concentration. Layer thickness variations over the surface of the Hall samples were undetectable.

tron concentration was accompanied by increasing compensation in the films, as evidenced by the disparity in the 300° and 77°K data. Figure 4 shows that the compensation ratio (8) changed from below 0.5 for no $AsCl_3$ to as high as 0.95 for 80 ml/min hydrogen flow through the $AsCl_3$ bubbler.

Experiments with films grown at 900°C showed a similar trend. Consequently, the quest for making films of improved quality (lower carrier concentration, lower compensation ratio, and higher mobility) by epitaxy in the presence of $AsCl_3$ vapor was abandoned.

Epitaxial layers on Te-doped substrates.—GaAs epitaxial layers were deposited on unetched and *in situ* etched Te-doped (100) substrates, the deposition and *in situ* etching being performed simultaneously with those on Cr-doped substrates used for obtaining the Hall measurement data presented earlier. The layers were chemically thinned to approximately 1 μm to allow carrier concentration profiling of the epitaxial layer-substrate interface using Au-GaAs Schottky barriers. The free carrier concentration profiles were obtained from C-V and dC/dV-V data using the relation

$$n(x) = \frac{C^3}{q\epsilon_r\epsilon_0 A^2 (dC/dV)}$$

where $n(x)$ is the free carrier concentration at a depth x below the surface, C is the capacitance of the Schottky barrier, of area A, ϵ_0, ϵ_r are the permittivity of free space and relative permittivity of GaAs, respectively, q is the electronic charge, and V is the reverse voltage applied across the Schottky barrier.

Figure 5 shows normalized plots of the free carrier concentration profiles obtained [any effect due to the presence of traps (9) has been ignored]. The carrier concentration in these layers was approximately 5×10^{15} per cm^3. Doping profiles obtained for *in situ* etched substrates are seen to be far more abrupt than for the case with no substrate etching.

Discussion

Epitaxial layers on Cr-doped substrates.—A number of observations can be made from a study of the data of Tables I and II. Thus:

(*i*) The mobility was higher in those layers deposited on substrates which were vapor etched than

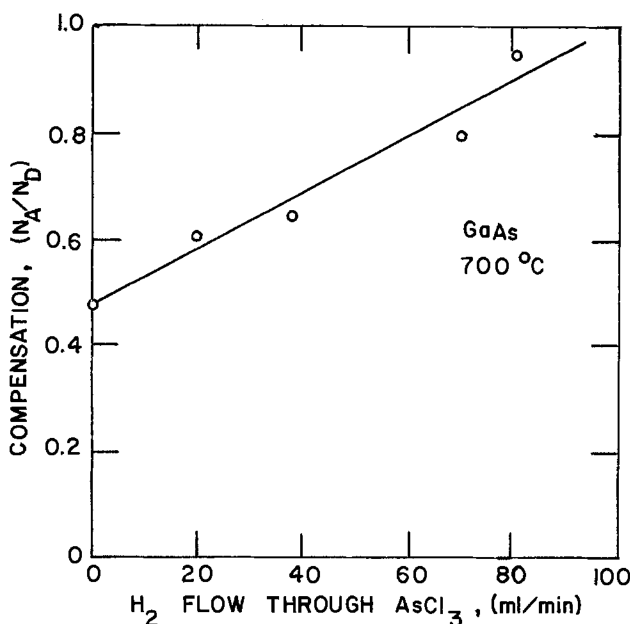

Fig. 4. Compensation ratio vs. hydrogen flow rate through the $AsCl_3$ bubbler during epitaxy.

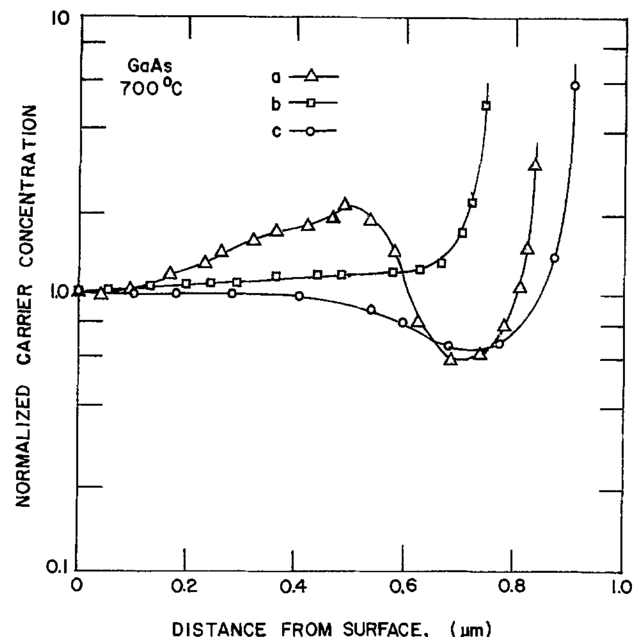

Fig. 5. Normalized carrier concentration profiles of epitaxial layers on (100)Te-doped GaAs substrates (a) unetched substrates; (b) HCl gas etched substrates; and (c) $AsCl_3$ etched substrates.

in those which were not vapor etched. *In situ* etching of substrates, therefore, enables the growth of epitaxial layers of superior crystalline quality. The room temperature mobility was comparable for epitaxial layers on $AsCl_3$ and HCl etched substrates. The slightly higher 77°K mobility obtained for layers on $AsCl_3$ etched substrates is due to the lower carrier concentration in these layers.

(*ii*) The mobility in all cases decreased with epitaxial layer thickness, the decrease being most rapid for layers grown on unetched substrates. A decrease in mobility with epitaxial layer thickness has also been observed by other investigators (10-12), and has been attributed to the increasingly important role of space-charge scattering effects at the epitaxial layer-substrate interface. The results obtained in this study indicate that *in situ* etching of substrates prior to growth results in a cleaner surface and thus reduces, but does not eliminate, the space charge centers due to defects created in the epitaxial layers. It should be noted that growth instabilities exist even when ideally clean and perfect GaAs substrate surfaces are used. These will set a lower limit to the density of space charge centers, and are inherent to the growth process. The decrease in mobility with epitaxial layer thickness can also be due to increasing compensation, and hence ionized impurity concentration, with decreasing thickness. However, the relative contributions of ionized impurity and space charge scattering in thin layers cannot be estimated from the available data.

(*iii*) The free carrier concentration is highest in layers grown on HCl etched substrates, particularly in thin layers. This is probably due to contamination of the substrate surface by n-type impurities present in the HCl gas. In contrast, the $AsCl_3$ used for this study was better than six nines purity, so contamination of the substrate surfaces by this etchant is not expected. This is borne out by the fact that the lowest carrier concentrations are observed in layers grown on $AsCl_3$ etched substrates (except for the 1 μm layers, where strong compensation effects are present, as described below).

(*iv*) The carrier concentration decreased with decreasing layer thickness for both unetched and $AsCl_3$ etched substrates. This effect was, however, significantly more rapid for layers grown on unetched substrates. Acceptor-type defects introduced in the early stages of growth are believed to be responsible for this behavior, since substantially more defects are expected to occur in epitaxial layers grown on unetched than on etched substrates. With HCl gas etching, contamination of the substrate surface masks the compensation due to these acceptor-type defects, and results in an increase in carrier concentration at the epitaxial layer-substrate interface.

Epitaxial layers on Te-doped substrates.—It is seen from Fig. 5 that the carrier concentration for layers on HCl gas etched substrates increased monotonically as the epitaxial layer-substrate interface was approached. However, a slight fall in carrier concentration was noted near the interface for epitaxial layers on $AsCl_3$ etched substrates. These observations can be explained by noting that instabilities during the early stages of growth cause acceptor-type defects to be created. The effect of these acceptor-type defects is not observed in the case of epitaxial layers on HCl gas etched substrates because of the n-type contaminants introduced by this etchant in the interface region. However, substrates etched with $AsCl_3$ were not contaminated since this etchant was ultrapure. As a result, epitaxial layers on these substrates showed a decrease in carrier concentration near the interface because of these acceptor-type defects. In contrast, the carrier concentration profile exhibited a pronounced undulation near the interface for layers grown on unetched substrates. A possible explanation for this behavior can be based on the fact that a large concentration of acceptorlike defects can be expected to occur for this case. In addition, the unetched surface of GaAs is highly reactive, and probably has a large concentration of adsorbed sulfur (an n-type impurity) on its surface because of the Caro's etch prior to growth (13). The competing decay of these impurities with distance may, in this situation, lead to the observed undulation in the impurity profile.

Epitaxial layers deposited in the presence of $AsCl_3$ vapor.—There are a number of possible explanations for the increase in the compensation of epitaxial layers from TMG and AsH_3 in the presence of $AsCl_3$ vapor. Of these, the most plausible is that the $AsCl_3$ removes donor impurities faster than acceptor impurities from the source materials. The major acceptor impurity in GaAs grown from TMG and AsH_3 is carbon, whereas the major donor impurity is silicon (14, 15). The change in Gibbs free energy for the reaction of these impurities with the etchant species (HCl) is negative for silicon, so that only silicon chlorides are stable at growth temperatures. Consequently, silicon is selectively removed during epitaxy in the presence of $AsCl_3$ vapor, resulting in an increase in the compensation ratio. In marked contrast, the principal impurities in the halide transport system are silicon and zinc, both of which have stable chlorides at deposition temperatures. Consequently, increasing the $AsCl_3$ concentration in halide transport systems is a highly successful technique for reducing the free electron concentration with no increase in the compensation ratio (16).

Conclusions

In summary, *in situ* etching of GaAs substrates prior to epitaxy enables the growth of epitaxial layers with specular surfaces at higher growth rates than are otherwise possible. The mobility, particularly in thin ($\simeq$ 1 μm) layers, was higher for layers on substrates which were *in situ* etched. The carrier concentration profiles for epitaxial layers on Te-doped substrates were more abrupt at the interface for layers on substrates which were vapor etched than on those which were not. Epitaxial layers on $AsCl_3$ and HCl gas-etched substrates had comparable mobility. Further, the carrier concentration, particularly in thin layers, was higher in epitaxial layers on HCl gas-etched substrates due to n-type contaminants introduced by this etchant. Finally, experiments with epitaxial growth in the presence of $AsCl_3$ showed that it was possible to obtain a reduction in the free electron concentration by this technique. However, this was accompanied by an increase in the compensation ratio and a general deterioration in the crystal quality. This result is in marked contrast to that obtained by workers with halide transport systems.

Effect of Proton Damage on Optical Modulation Spectra of Gallium Arsenide

Moshe Oren,[1] A. R. Quinton, and Claude M. Penchina

Department of Physics and Astronomy, University of Massachusetts, Amherst, Massachusetts 01003

ABSTRACT

We studied the effect of proton bombardment on the electroreflectance (ER), electroabsorption (EA), and transmission (T) spectra of high resistivity Cr-doped single crystal GaAs. The high resolution of ER and EA and their sensitivity to crystalline order make it possible to study shift, broadening, and gradual distortion of the spectral peaks as disorder increases with successive irradiations. The sample is bombarded with 150 keV protons. We have measured ER and EA at the absorption edge E_0, ER at the E_1 critical point, and d-c optical absorption. All these measurements are sensitive to proton irradiation of the sample; the most sensitive one is ER at E_0. In the range of 3×10^{14} to 5×10^{15} protons/cm^2, optical absorption just below the energy gap increases sublinearly with proton dose; the peak-to-peak amplitudes of ER at E_0 and E_1 vary linearly with the logarithm of the dose and hence can be used to measure the degree of damage in the sample. The EA signal at E_0 develops a tail toward the low energy side of the spectrum. The ER at E_0 has a peak shift of $\approx$4 meV to higher energy while the peak of the ER signal at E_1 shifts by about 15 meV to lower energy. Broadening is evident in the ER signals at E_0 and E_1. Annealing at 300°C for up to 2 hr only partially recovers the unbombarded state. A model based on the gradual amorphization of the sample by an increasing number of proton damaged, amorphous islands with well-defined boundaries can partially explain the experimental results.

Lattice damage in single crystals plays a major role in device applications. Lattice damage caused by ion implantation received special attention in recent years following the introduction of ion implantation as a method for doping semiconductor materials. There are several experimental techniques that can be applied to study radiation damage in semiconductors, among others: optical (1), electrical (2), Rutherford back scattering (3), and electron paramagnetic resonance (4).

The optical absorption and reflection of GaAs were found to be sensitive to ion bombardment damage but the sensitivity of such measurements (reflectivity in particular) is low, and quantitative results are difficult to obtain.

In the present work we use electromodulation (EM) spectroscopy to study the effect of proton bombardment on single crystal, semi-insulating GaAs. In electromodulation one measures the change in reflectance (ΔR) or transmittance (ΔT) when an external electric field is applied to the sample (5). The EM response is spectrally concentrated around the critical points in the band structure. A phase sensitive detection system tuned to the frequency and phase of the external field greatly enhances the sensitivity of the measurement to critical points in the spectrum. These critical points are a manifestation of the long range order in the crystal; a change in the EM signal on successive bombardment would indicate, therefore, the gradual relaxation in this long range order. This relation allows a semi-quantitative measure of lattice damage to be made.

EM has been applied to date primarily to problems of intrinsic band-structure analysis (5), but as a powerful spectroscopic method it is now finding new areas of applications. Jonath *et al.*, (6) studied electroabsorption (EA) of oxygen impurities in GaAs. Bauer (7) used EA to study the symmetry properties of defect states in nitrogen-doped GaP and their interaction with the host band structure. Gavrilenko *et al.* studied the influence of low energy argon ion bombardment on the electroreflectance (ER) and photoluminescence spectra of n-type $Al_xGa_{1-x}As$ solid solution (8) and Si (9). Anderson *et al.* (10) used ER to detect shallow impurity levels in GaAs doped with Si, Te, Zn, or Cd impurities. A disadvantage of this method is that different types of lattice damage cannot be distinguished.

Experimental

High resistivity, n-type GaAs:Cr single crystal was used in this experiment. The sample had $\approx 10^8$ Ω-cm room temperature resistivity. For radiation damage experiments it is preferable to have the sample front surface free of any evaporated electrode or insulating layer. For that reason, the sample geometry used in the ER and the EA measurements is based on the transverse configuration (11). Slices were cut from the GaAs crystal, lapped, polished with 0.3μ alumina powder, and then etch polished with Monsanto Syton solution. For contacts, two Au films were evaporated on the

[1] Present address: Spire Corporation, Bedford, Massachusetts 01730.

Key words: electroreflectance, electroabsorption, GaAs-Cr, amorphous GaAs, ion implantation.

polished sample surface forming a gap 1 mm wide (see insert in Fig. 1). The current voltage characteristics up to 900V show good ohmic behavior. The light beam was incident in the [111] crystal direction. The magnitude of the ER signal is a function of surface potential. Therefore, it varies from sample to sample due to slight changes in surface preparation, which may alter considerably the surface potential. To avoid this complexity, only half of the gap between the field electrodes was bombarded and the other half was used as a reference for all successive measurements. The gap height is more than twice the height of the incident light beam in order that the light will not overlap the bombarded and nonbombarded regions.

The system used for the ER and EA measurement is shown in Fig. 1. It includes the following components: 250W tungsten halogen lamp, monochromator, optics, dewars, and detectors. All measurements were made at LN_2 temperature. Two photomultipliers (PM) were permanently mounted in the sample chamber, 1P28 PM to measure ER at E_1 critical point and 7102 PM for ER at the E_0 critical point. A removable front surface aluminum mirror directs the reflected beam into the PM in use. A PbS detector was used for the EA and transmission measurements. The two PM's were wired such that higher voltage was impressed between the last dynode and the anode than on the intermediate stage of the voltage divider. This allows greater linear swing of the anode voltage, which is desirable when a small a-c signal, superimposed on a large d-c signal, is to be measured. The voltage applied to the sample was 1 kHz, 2000V peak-to-peak sine wave superimposed on 1000V d-c. For the ER measurement a d-c photon flux was used, a lock-in amplifier measured the a-c signal ($I_o \cdot \Delta R$) and an electrometer measured the d-c reflection ($I_o \cdot R$). For the transmission (T) and EA measurements the incident light beam was chopped at 147 Hz; two lock-in amplifiers tuned at 1 kHz and 147 Hz measured the ΔT and T signal, respectively.

Sample bombardment was done with a 150 keV proton beam. The sample was mounted on a water-cooled holder. An in-line cold trap was used to remove oil vapor that may otherwise be carried along with the proton beam to contaminate the sample surface. In addition when a high dose was used ($\gtrsim 5 \times 10^{15}$ p/cm^2), a thin carbon film (≈ 20 μm) was inserted in front of the sample, to further prevent possible oil contamination.

Isothermal annealing of the sample was done at 300°C in an oil-free vacuum system ($\approx 5 \times 10^{-7}$ Torr).

Results

Transmission.—The sample transmission in the range of the fundamental absorption edge was measured at LN_2 temperature for various bombardment doses. In order to determine more conveniently the effect of proton damage on the sample transmission, the ratio of the transmitted intensity from the bombarded (T_b) and nonbombarded (T_o) regions was determined at one wavelength. Such a graph is shown in Fig. 2 (insert). Taking into account reflection losses, R, from the sample front and back surfaces, one can write

$$T_o = (1 - R)^2 \exp(-\alpha_o d_o) \quad [1]$$

α_o and d_o are the sample absorption coefficient and thickness, respectively (multiple internal reflections are neglected). The transmission through the bombarded region is

$$T_b = (1 - R')(1 - R) \exp(-\alpha_o d_o - \alpha_b d_b) \quad [2]$$

where R' is the reflectivity coefficient from the front surface of the bombarded region, α_b is the average value of the change in absorption coefficient over the bombarded layer thickness d_b. Measurement of $I_o \cdot R$ (when R is the reflectivity and I_o is the incident intensity) in the vicinity of the absorption edge shows a change of less than 5% due to proton bombardment. Similarly, Kalma (12) found no change in reflectivity in the vicinity of the absorption edge of GaAs following a 1 MeV electron irradiation; Sell and MacRae (1b), found a change of $\sim 3\%$ in reflectivity at 2.5 eV in argon-implanted GaAs. We assume therefore $R \approx R'$. Then

$$\ln(T_o/T_b) = \alpha_b d_b \quad [3]$$

α_b can be related to the number, N, of the optically active defects produced in the bombarded layer (13)

$$\alpha_b = N\sigma_b \quad [4]$$

where σ_b is the cross section for optical absorption by these defects. The best straight line fit to the data in the log-log plot of Fig. 2 (insert) provides the relation

$$T_o/T_b = \gamma\phi^\beta \quad [3a]$$

with $\ln \gamma = -16.9$ and $\beta = 0.48$. Therefore, from Eq. [3], [3a], and [4]

$$d_b N\sigma_b = d_b\alpha_b = \ln \gamma + \beta \ln \phi \quad [5]$$

The production rate of defects is sublinear in dose. This is due to damaged regions overlapping and possible room temperature annealing (14, 15).

If we approximate the damaged layer thickness, d_b, by the projected range (16) ($\approx 1.5\mu$) of the proton beam, the wavelength dependence of the added absorption due to bombardment can be expressed using Eq. [3]. Such a graph is presented in Fig. 2. The featureless increase in absorption indicates that the bombardment generates a continuous distribution of energy levels right below the bandgap with no evidence of discrete levels in this range. Kalma (12) studied electron irradiated GaAs, Si, Ge, InSb, and PbTe and

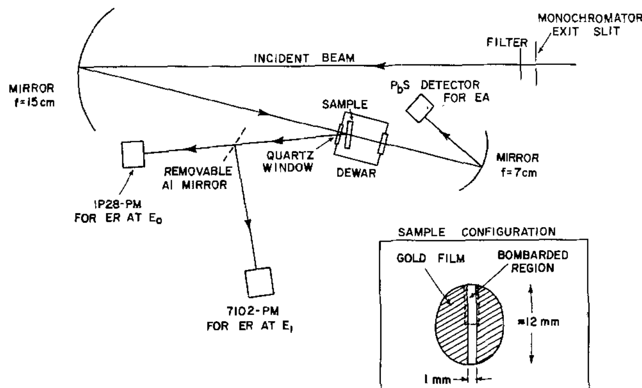

Fig. 1. Optical system used for the ER and EA measurements

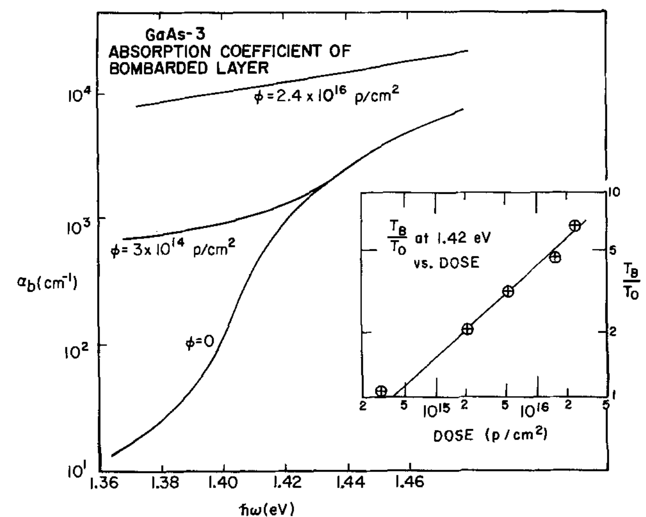

Fig. 2. Absorption coefficient of bombarded and not-bombarded regions.

suggested that increased absorption near the bandedge observed in GaAs can be attributed to tailing of the density of states into the bandgap. Note that the range of α_b ($\approx 10^4$ cm^{-1}) is about two orders of magnitude higher than the absorption coefficient observed in neutron damaged GaAs (17).

Theoretical Model

A simple picture of gradual amorphization of the sample by the incident radiation was used by a number of workers (3, 18) to describe the process in which long-range order in the bombarded layer is destroyed. In such a picture each incident proton produces a highly disordered region along its track in the sample. Assuming these regions have well-defined boundaries, at low dose they are separated from each other except for random overlapping. As the dose increases the overlapping increases until a completely amorphous layer is formed. The added absorption coefficient in this picture will be due to the introduction of amorphous islands with higher absorption

$$\alpha_b = \frac{A}{A_o}(\alpha_a - \alpha_c) \quad [6]$$

where A is the area of the amorphous regions, A_o is the total sample area exposed to the beam, and subscripts a, b, and c correspond to amorphous, bombarded, and crystalline, respectively.

Based on this description we can define a quantity $\sigma(\phi)$ which is the cross section for added amorphization per proton which hits a previously undamaged area. The probability that an additional incident proton will not hit the amorphous region A is $1 - (A/A_o)$. In terms of this cross section, the change in A per incident proton, dA/dP will be therefore

$$\frac{dA}{dP} = \frac{A}{A_o}\frac{dA}{d\phi} = \left(1 - \frac{A}{A_o}\right)\sigma(\phi) \quad [7]$$

and after integration

$$1 - \frac{A}{A_o} = \exp[-\int\sigma(\phi)\,d\phi] \quad [7a]$$

Using Eq. [6] and [7a]

$$\exp[-\int\sigma(\phi)\,d\phi] = 1 - \frac{A}{A_o} = 1 - \frac{\alpha_b}{\alpha_a - \alpha_c} \quad [8]$$

Using the experimental data for α_b as expressed in Eq. [5] and taking the logarithmic derivative of Eq. [8], we get

$$\sigma_{TR}(\phi) = \frac{1}{\phi(K_2 - \ln\phi)} \quad [9]$$

with

$$K_2 = \frac{d(\alpha_a - \alpha_c)}{\beta} - \frac{1}{\beta}\ln\gamma \quad [10]$$

For $h\nu = 1.42$ eV, $\alpha_a H >> \alpha_c$, thus α_a approximated by α_b at high dose (where $A \rightarrow A_o$)

$$\alpha_a(1.42\text{ eV}) \cong \alpha_b(1.42\text{ eV}, \phi = 2.4 \times 10^{16}\text{ p/cm}^2) = 1.24 \times 10^4\text{ cm}^{-1} \quad [11]$$

this gives

$$K_2 = 38.9 \quad [10a]$$

This same picture will be applied for the ER data, and the result compared with the results above.

ER at E_o and E_1 Critical Points

Figure 3 shows the ER at the absorption edge E_o and Fig. 4 shows the ER response at the E_1 critical point. The most obvious feature of the bombarded spectrum is the reduction in signal intensity in both cases compared to the unbombarded spectrum. To better evaluate this effect, the peak-to-peak amplitude (PPA), Δ_b, of the bombarded region, normalized to the

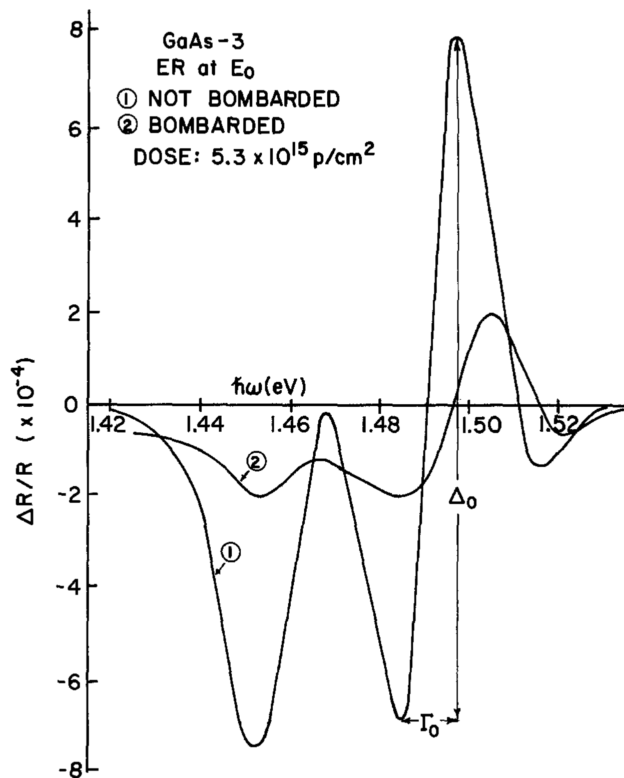

Fig. 3. ER at E_o from the bombarded and not-bombarded regions

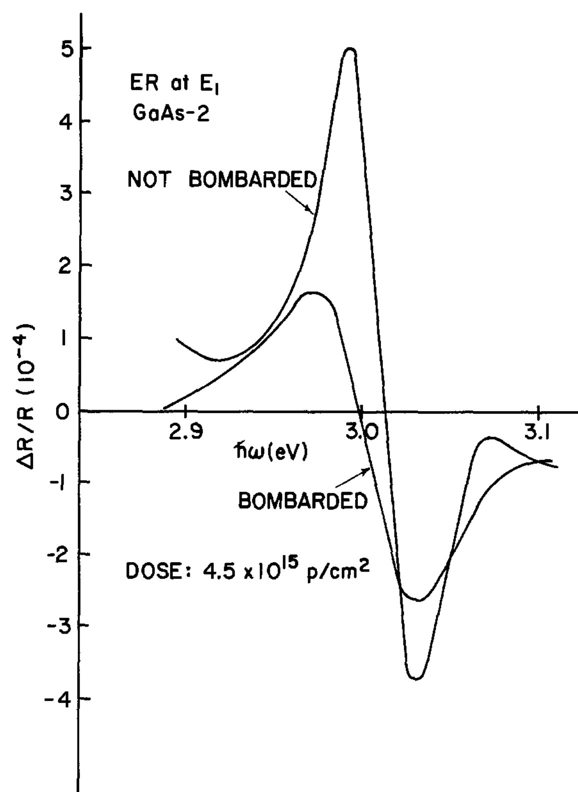

Fig. 4. ER at E_1 from the bombarded and not-bombarded regions

PPA from the nonbombarded region, Δ_o, is plotted *vs.* dose in Fig. 5 for both E_o and E_1 critical points.

It is apparent that the attenuation of Δ for a given dose is larger at E_o than at E_1. This can be explained qualitatively by the higher penetration depth of the light beam at E_o. At the bandgap transition, the penetration depth of the light is of the same order as that of the proton beam range, $\approx 1.5\mu$ (19), where the induced crystalline damage is mostly concentrated. At the E_1 transition the light penetration depth is only

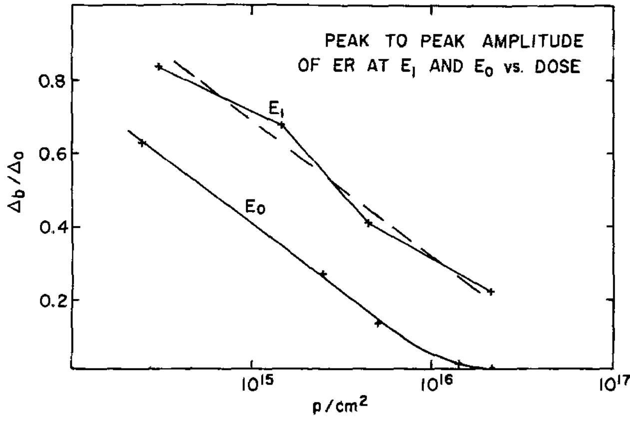

Fig. 5. Peak-to-peak amplitude (PPA) of the ER at E_1 and E_0 normalized to the PPA from the not-bombarded region.

0.017μ (19). The ER signal at E_0 is reduced to below the detection limit ($\approx 10^{-6}$) for dose $\gtrsim 2.4 \times 10^{16}$. This increased sensitivity of ER at E_0 to irradiation damage can be a useful tool for damage detection. The PPA will be used to give a semi-quantitative value for the amount of damage introduced into the sample, averaged over the damaged layer thickness. The ER will not distinguish, though, between the various types of damage in the sample. It is of interest to note that the linear fits of Eq. [3] to both E_0 and E_1 data are parallel, although the data at the E_1 critical point are more scattered. Between 2.5×10^{14} p/cm² and 5×10^{15} p/cm² the decrease in Δ_b/Δ_o for E_0 is linear in the logarithm of the dose ϕ

$$\Delta_b/\Delta_o = a \ln(\phi/\phi_o) \qquad [12]$$

with: $a = -0.16$ and $\ln \phi_o = 36.9$. For the E_1 critical point we get

$$\Delta_b/\Delta_o = a' \ln(\phi/\phi_o') \qquad [13]$$

with: $a = a' = -0.16$, $\ln \phi_o' = 38.0$.

Proton bombardment resulted in a small shift of about 15 meV toward the low energy in the ER peak at E_1, and 4 meV shift toward higher energy in the ER peak at E_0. A contribution to the shift at E_0 may come from the uneven attenuation of the ER peak due to strong variation in the penetration depth of the light beam near the absorption edge combined with the fact that the damaged layer peaks about 1.5μ below the surface.

Gavrilenko *et al.* (9) found that bombardment of Si with 1 keV He^+ ions causes a shift in the E_1 ER peak to higher energy; 1 keV Ar^+ bombardment of $Al_xGa_{1-x}As$ solution shifts the ER peak at E_1 to lower energy (8). Figure 6 shows the increased broadening in the E_1 and E_0 ER peaks *vs.* bombardment dose. Here too, note the higher values obtained for E_0 compared to E_1. Various sources can contribute to broadening of the ER signal, among others, temperature effect, local random electric field, and microstress due to defects. In our case a local electric field can be created by the proton doping of the damaged crystal.

The ER signal disappears at high dose. Based on the gradual amorphization model, the ER peak-to-peak amplitude, Δ_b, at a given dose, will be proportional to the area fraction which is still in the crystalline state

$$\Delta_b = \Delta_o\left(1 - \frac{A}{A_o}\right) \qquad [14]$$

Thus from Eq. [7a], [12], and [14]

$$\exp[-\int\sigma(\phi)\, d\phi] = 1 - \frac{A}{A_o} = \frac{\Delta_b}{\Delta_o} = a \ln(\phi/\phi_o) \qquad [15]$$

Taking the logarithmic derivative on both sides

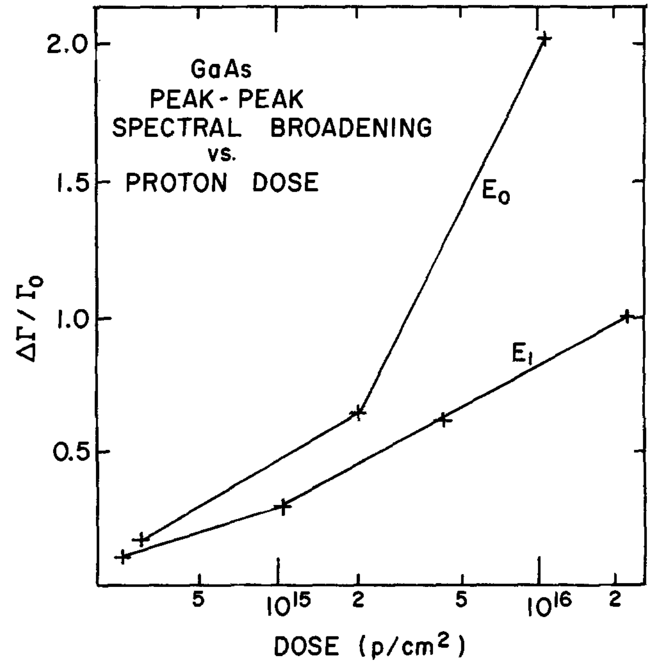

Fig. 6. Spectral broadening vs. proton dose of the ER signals at E_0 and E_1.

$$\sigma_{ER} = \frac{1}{\phi(K_o - \ln \phi)} \qquad [16]$$

where $K_o = \ln \phi_o$.

We previously found (Eq. [12]) that

$$K_o = \ln \phi_o = 36.9 \qquad [17]$$

Thus, from electroreflectance at E_0, at a dose of $\phi = 10^{15}$ p/cm² we get (Eq. [12], [16], and [17])

$$\sigma_{ER}\ (\phi = 10^{15}\ \text{p/cm}^2) = 4 \times 10^{-16}\ \text{cm}^2$$

Similarly, from transmission measurements, at this same dose we get (Eq. [9] and [10a]

$$\sigma_{TR}(\phi = 10^{15}\ \text{p/cm}^2 = 2 \times 10^{-16}\ \text{cm}^2$$

The relatively small discrepancy between the values obtained for σ_{ER} and σ_{TR} indicates that the simple picture used to describe the amorphization process is essentially correct in the first approximation. The result $\sigma_{ER} > \sigma_{TR}$ is to be expected because the ER is more sensitive to bombardment; partially damaged regions, neglected in the simple model, will affect the ER more than the transmission. It was suggested (20) that such partially damaged regions are caused by diffusion of defects from the outer portion of the ion track, into the undamaged bulk.

EA at the Absorption Edge E_o

The effect of proton bombardment on the band-to-band electroabsorption (EA), $\Delta T/T$, of the sample is shown in Fig. 7. Just below the bandgap, $\Delta T/T$ is negative, corresponding to a red shift of the absorption edge on application of the electric field as expected from the Franz Keldysh theory (5). Due to the high value of αd ($\sim 10^2$-10^3) the expected (5) oscillations in $\Delta T/T$ above the bandgap, have not been observed. Such oscillations have been seen previously by workers studying EA in thin films of GaAs (21).

The peak in the $\Delta T/T$ spectrum around 1.45 eV gradually disappears with increasing proton bombardment dose; ΔT also develops a tail toward the low energy side which is also seen in the $\Delta T/T$ spectrum below 1.45 eV. This newly created tail in the EA spectrum suggests the creation of a tail in the joint-density of states of the conduction and valence bands. This assumption is also in agreement with the results for α_b, the added absorption coefficient of the bombarded layer.

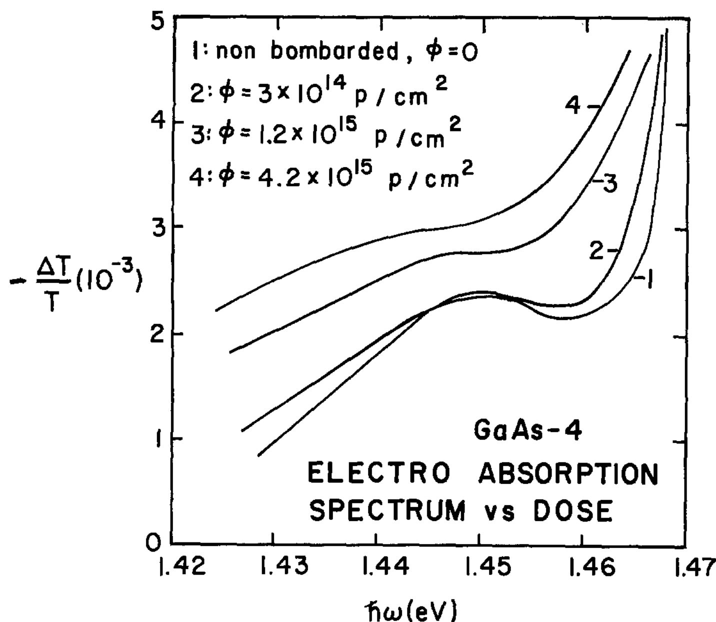

Fig. 7. EA vs. dose of bombarded and not-bombarded regions

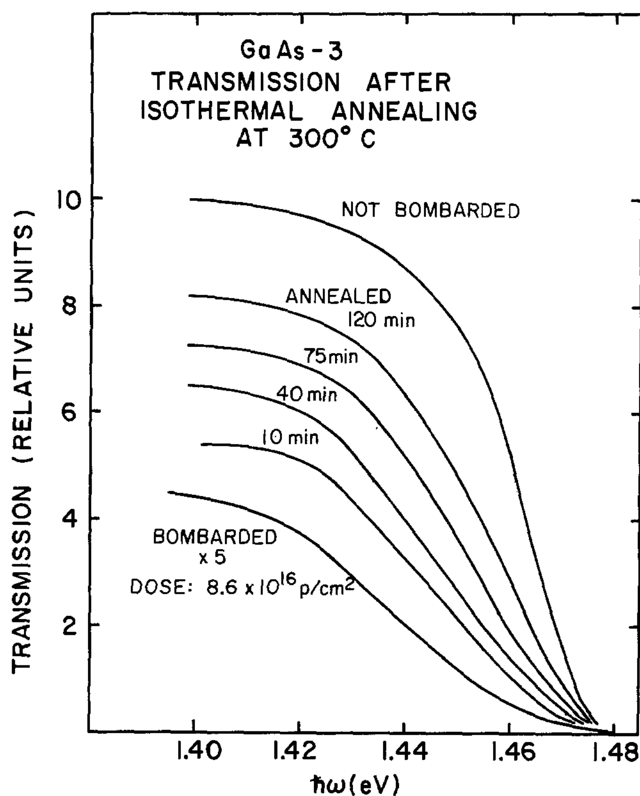

Fig. 8. Transmission from the bombarded region after isothermal annealing at 300°C.

Annealing

The effect of heat-treatment on the sample transmission in the vicinity of the E_0 critical point is shown in Fig. 8.

The sample was subjected to a bombardment dose of 8.6×10^{16} p/cm^2 (which completely eliminated its ER signals) and then isothermally annealed in vacuum at 300°C for up to 2 hr. The heat-treatment only partially recovers the transmission (Fig. 8) and ER signals before bombardment. For a given annealing time, the recovery of the ER signal is smaller than the recovery of the transmission; this is in agreement with our previous finding that the ER at E_0 is more sensitive to crystalline damage than the transmission and does not necessarily indicate that different types of defects are involved.

Dyment *et al.* (22) showed that the optical absorption of proton bombarded GaAs can be annealed more easily than the resistivity. They concluded that there must be at least two types of defects involved in the bombardment process.

Summary and Conclusions

All electromodulation signals decrease in intensity following proton bombardment of the sample. Due to better overlap of the incident light beam and the damaged region, the ER at E_0 is the most sensitive to proton bombardment. The added absorption just below the energy gap increases sublinearly with dose in the dose interval between 3×10^{14} and 5×10^{15} p/cm^2. In the same dose interval, the peak-to-peak spectral amplitude, Δ, of the ER at E_0 and E_1 critical points both vary linearly with the logarithm of the dose and thus can be used as a measure for the degree of the sample amorphicity.

The EA at E_0 develops a tail toward the low energy side of the spectrum. The ER at E_0 has a shift of ≈ 4 meV to higher energy while the peak of the ER signal at E_1 shifts by ≈ 15 meV to lower energy. The origins of these shifts are not yet clear.

Annealing at 300°C for up to 2 hr only partially recovers the unbombarded state. The recovery is not linear in time.

A model based on the gradual amphorization of the sample by an increasing number of proton-damaged amorphous islands with well-defined boundaries was considered. The change in absorption coefficient, α_b, or the change in the ER signal, in this model, depends on the volume fraction, A/A_0, made amorphous by the bombardment. Assuming a layer of average thickness d_b to be damaged, the number of unit cells made amorphous per incident proton will be

$$N = d_b \cdot \frac{dA}{dP}/a_0^3 = d_b\left(1 - \frac{A}{A_0}\right)\sigma(\phi)/a_0^3 \quad [18]$$

where a_0 is the lattice constant for GaAs (5.65Å).

Using Eq. [12] and [15]-[18], we find from the E_0 ER data

$$N = -\frac{\alpha d_b}{\phi a_0^3} = \frac{1.3 \times 10^{17}/\text{cm}^2}{\phi}$$

which corresponds to 26 unit cells amorphized per incident proton for $\Phi = 5 \times 10^{15}$ p/cm^2. Wempe *et al.* (3) found that in a 300 keV proton bombardment of GaP a similar number of unit cells was made amorphous per incident proton: *i.e.*, 10 for a dose of 10^{15} or 10^{16} protons/cm^2. The ER signal at E_0 is reduced below the detection limit ($\Delta R/R \sim 10^{-6}$) at $\phi \sim 2.5 \times 10^{16}$ p/cm^2 while the ER at E_1 is reduced to that level only at $\phi \sim 10^{17}$ p/cm^2. According to our model this implies that a dose of about 10^{17} p/cm^2 amorphizes the sample throughout the damaged layer of thickness ~ 1.5 μm, whereas 2.5×10^{16} p/cm^2 amorphizes it only in the region near 1.5 μm away from the surface.

The electronic band structure of a tetrahedrally bonded amorphous material is expected to have tails in the density of states which extend from the valence and conduction bands into the bandgap (23, 24). The tail in the EA signal at E_0 is tentatively attributed to transitions between these tails of the density of states.

Surface Electrical Properties of the Wustite Phase

J. Nowotny and I. Sikora

Research Laboratories of Catalysis and Surface Chemistry, Polish Academy of Sciences, ul. Niezapominajek, 30-239 Kraków, Poland

ABSTRACT

The iron-oxygen system has been studied using work function measurements between 675° and 950°C, the stability range of the wustite phase. The work function of wustite *vs.* nonstoichiometry indicates a decrease of the Fermi energy below 850°C while for the temperatures between 900° and 950°C an initial decrease is followed by the final increase. The measured work function data depend only on the temperature and oxygen partial pressure. This indicates that the system is well equilibrated. The values of the partial pressures of oxygen corresponding to the wustite phase equilibria with iron and with magnetite determined in this work agree well with the reported literature data. A short equilibration time favors the work function method as a convenient one for investigating phase diagrams of oxide systems. The experimental data do not confirm the p- to n-type transition postulated for $Fe_{1-y}O$ on the basis of earlier measurements of the Seebeck coefficient.

Electrical properties of wustite have been the subject of several papers dealing mainly with the Seebeck coefficient and electrical conductivity measurements (1-11). Several essential questions, however, concerning electrical data as well as their correlation with structural properties of this phase have not been sufficiently explained. There are still essential contradictions concerning the conductivity mechanism within the wustite phase field and its defect structure *vs.* nonstoichiometry. Moreover, there is a general lack of thermodynamic data for temperatures below 900°C at which the system wustite-oxygen requires considerably longer times to achieve its equilibrium state. On the other hand, the rare experimental data available for the phase diagram of the iron-oxygen system below 900°C show many discrepancies.

One of the most extensively studied problems of the wustite phase concerns its defect structure. As is known, wustite exhibits a very large nonstoichiometry varying from 5 atom percent (a/o) at the iron-wustite boundary up to about 15 a/o at the wustite-magnetite phase boundary. This nonstoichiometry may simply be related to the concentration of cation vacancies. Taking into account, however, interactions between these simple defects leading to the formation of Roth's complexes ($V_{Fe}Fe_iV_{Fe}$) (12), clusters n ($V_{Fe}Fe_iV_{Fe}$) (13, 14), and even structural domains (15-19), the real concentration of defects involving both cation vacancies and interstitial cations may reach 30 a/o. This significant value implies a complex picture of the defect structure of wustite, especially at its higher nonstoichiometry.

Numerous works concerning the defect structure of the wustite phase are based mainly on either gravimetric investigations, leading directly to deviations from stoichiometry, or electrical conductivity, giving information about the concentration and mobility of

Key words: work function, ferrous oxide, surface potential, Fermi energy, nonstoichiometry.

electron carriers as well as about the degree of ionization of ionic defects.

Bransky and Tannhauser (7) have found that electrical conductivity of wustite above 1000°C, for lower nonstoichiometry is proportional to the sixth root of the oxygen partial pressure. Such dependence fits the simple model involving formation of doubly ionized cation vacancies when oxygen is incorporated into the wustite lattice

$$\tfrac{1}{2}\, O_{2/g/} \rightleftharpoons O_O{}^x + V_{Fe}{}^z + zh^{\cdot} \quad [1]$$

where according to the Kroger-Vinck notation $O_O{}^x$ denotes the oxygen in the anion sublattice, $V_{Fe}{}^z$ the cation vacancy, z the degree of ionization, and $h^{\cdot}$ the electron hole.

Applying the mass action law and assuming that interactions among defects may be neglected as well as supposing appropriate electroneutrality conditions of the lattice, the deviation from stoichiometric composition may be expressed as the following function of temperature

$$y = V_{Fe}{}^z = \text{const}\, p_{O_2}{}^{1/n} \exp\left[-\frac{\frac{1}{z+1}\Delta H_f}{RT}\right] \quad [2]$$

where $1/n$ is the parameter depending on the ionization degree of cation vacancies and ΔH_f is the enthalpy of formation of the vacancies. The parameter $1/n$ may thus be determined by measuring directly the changes of the deviation from stoichiometry, or any parameter that can be correlated with the concentration of cation vacancies (*e.g.*, electrical conductivity) as a function of oxygen partial pressure p_{O_2}

$$\frac{1}{n} = \frac{\partial \ln y}{\partial \ln p_{O_2}} = \frac{\partial \ln \sigma}{\partial \ln p_{O_2}} \quad [3]$$

Equation [3] is valid only when the mobility of electron carriers is independent of their concentration.

The simple model illustrated by Eq. [1] has been supported by the gravimetric studies of Hauffe and Pfeiffer (20). Also Smyth (21) postulated doubly ionized cation vacancies as predominant defects. More detailed investigations of this phase, however, have shown that the parameter $1/n$, determined both gravimetrically and by electrical conductivity (22, 23), changes from 1/4, for the smallest deviation from stoichiometry, to 1/6, or even below, with increasing y, thus indicating that the effective charge of defects *vs.* y changes continuously. According to the present knowledge of the defect structure of wustite this phenomenon can be attributed to association (12) and clustering (13) of defects. Vallet and Raccah (15), Kleman (16), and Fender and Riley (17) postulate the existence of three separate "phases" or structural domains within the wustite phase field; however, they do not give a defect structure for these domains. Moreover, numerous investigations of several structure-sensitive properties of wustite (*e.g.*, electrical conductivity) *vs.* oxygen partial pressure do not indicate a drastic change of defect structure at compositions corresponding to the postulated domain boundaries (24). Thus the existence of the domains still remains an open question.

Bransky and Tannhauser (7) have found a change of sign of the Seebeck coefficient of wustite for the composition O/Fe = 1.09. The authors suggest that this effect, observed above 900°C, can be attributed to the transition of the conductivity from p-type at low stoichiometry to n-type at high oxygen content. The change of sign of the Seebeck coefficient above 900°C has been confirmed by Wagner and co-workers (5, 6) for both poly- and single-crystalline samples of wustite. This effect has also been observed by Meussner, Richards, and Fujii at 1000°C (4), but at much higher oxygen content than that observed by Bransky and Tannhauser or by Wagner and co-workers (5). Nevertheless the supposition concerning p- to n-type transition is in strong contradiction to electrical conductivity data which show no minimum in the whole range of the wustite homogeneity range *vs.* oxygen content. This would indicate that only one type of electron carriers (electrons or holes) predominate throughout the whole wustite field. Recently, the p-type conductivity of the wustite phase has been confirmed by Bowen, Adler, and Auker (11). Seltzer and Hed (9) have proposed an original interpretation of these apparently conflicting data. The authors involved a "negative term" describing the temperature dependence of the scattering mechanism in the transport of charge carriers through the crystal lattice. Their calculation based on this assumption gives good agreement with the literature data of the electrical conductivity and Seebeck coefficient reported for the wustite phase.

Statement of the Problem

The discussion of the literature data shows that the electronic properties of the wustite phase still remain the subject of dispute and require additional investigation for an explanation of the electronic phenomena as well as the correlation between structural and electronic data for this highly defect crystal. The purpose of the present work is to apply the work function technique which may supply direct information about the chemical potential of electrons (Fermi energy level) for the surface layer of investigated oxide sample.

The work function technique has been widely used for investigations of adsorption properties of oxides and metals. The measurements have generally been carried out in the range of low and moderate temperatures. However, under these conditions most of the oxides are in a "quenched" state. Thus the measured work function data gave information concerning the surface oxide layer, which because of kinetic reasons was not equilibrated with either the crystalline bulk or the gaseous phase. Under these conditions, the nonstoichiometry of the surface layer is in a continuous change as the oxide crystal tends toward an equilibrium state (25). Thus the measured work function values depend essentially on the experimental procedure applied and the sample history.

It should be emphasized that the absolute value of the work function of metal oxides, as well as of most of the binary compounds, has no physical meaning when measured at temperatures where the compounds are not equilibrated with the gas phase. In these cases the state of the surface depends on many uncontrolled factors, such as surface coverage by adsorbed impurities, surface topography, and nonstoichiometry of the layer near the surface. Each of these factors has a strong influence on the measured value of the work function. Relative work function changes may be used for monitoring some surface processes, *e.g.*, chemisorption of gases. Then the measured electronic effect accompanying chemisorption represents the chemical affinity between the investigated surface and the adsorbate. In this kind of study, the absolute value of the work function may be used as a monitor for adjusting the standardized procedure to a reproducible surface state, or for following the kinetics of any surface process accompanied by electronic transitions. As the temperature increases, however, the whole crystalline grain is being brought into thermodynamic equilibrium with the coexistent gas atmosphere. Under these, conditions the surface state, and thus the work function, are independent of the experimental procedure applied before the measurement and are determined by the parameters of the experiment, such as temperature and gas composition.

The work function measurements commonly reported for studies of the surface electrical properties of metal oxides are based on the dynamic condenser

method. This method, proposed by Kelvin (26) and improved by Zisman (27) and numerous other investigators (28-39), is the most convenient one for studying oxides under a controlled gaseous atmosphere. The dynamic condenser method described in the literature operates in a temperature range up to about 400°C; however, this range is too low for such transition metal oxides as NiO, CoO, MnO, or FeO. Thus the purpose of the present work was to perform the work function measurements at a sufficiently high temperature that the investigated crystal could be equilibrated with oxygen. The relatively well-known ferrous oxide (wustite) seemed to be a very interesting system for the present studies because this oxide phase shows the largest nonstoichiometry among the other transition metal oxides of the series exhibiting the NaCl-type structures as NiO, CoO, or MnO. It was also expected that the work function data of the wustite phase might supply interesting material for comparison with other available electrical data involving the electrical conductivity and the Seebeck coefficient. In the present studies the work functions of the iron-oxygen system were measured *vs.* the oxygen activity in the gaseous phase. Experimental conditions were adjusted in order to cross the wustite phase field from metallic iron to the magnetite phase.

Experimental

Apparatus.—The dynamic condenser method was used for the work function measurements (40, 41). It is illustrated schematically by the block diagram in Fig. 1. The method is based on the measurement of the constant potential difference (CPD) existing between the plates forming the condenser, 3, whose capacity varies with time. The vibration of the condenser generates an a-c voltage across the resistance, 4. The value of this voltage is proportional to CPD. The a-c voltage is then amplified, 5, and monitored, 6. When CPD is compensated by an external d-c voltage, $V_{d.c.}$, 2, from the compensator, 1, a minimum in the signal is observed on the monitor

$$V_{CPC} - V_{d.c.} = 0 \quad [4]$$

Thus the CPD is equal to the value of $V_{d.c.}$ with the opposite sign. The plates of the dynamic condenser are the sample being investigated, 1, and the reference electrode, 2. The CPD is equal to the difference in the work function of the plates of the dynamic condenser

$$V_{CPD} = \frac{\Phi_1 - \Phi_2}{e} \quad [5]$$

Hence an increase of the CPD corresponds to an increase in the work function of the oxide. The measurement of changes in the work function of the oxide sample *vs.* oxygen pressure are possible only when the surface potential of the reference electrode is known or is constant in the experimental conditions applied

$$\Delta\Phi_1 = e(\Delta V_{CPD}) + \Delta\Phi_2 \quad [6]$$

A platinum plate was used as the reference electrode. Changes in the work function of the platinum plate for high temperatures may be calculated as for the oxygen electrode

$$\Delta V_{Pt} = \frac{\Delta\Phi_2}{e} = \frac{RT}{4F} \ln \frac{p_{O_2}^{(1)}}{p_{O_2}^{(2)}} \quad [7]$$

where values $p_{O_2}^{(1)}$ and $p_{O_2}^{(2)}$ correspond to the extreme oxygen pressures of the experimental conditions.

The oxygen partial pressure in the reaction chamber is controlled by the ratio of the CO-CO_2 gas mixture at a total pressure of 1 atm. The experimental compositions of the CO_2-CO gas mixture are indicated in Fig. 2 by the dividing spots on the isothermal (dotted) lines. The lowest oxygen activity is determined here by pure carbon monoxide limiting investigations of the iron-oxygen system to the right side from line 1 in Fig. 1. Thus at temperatures below 750°C the experiments concern only the phase boundary wustite-magnetite.

Figure 3 shows the experimental setup including both the gas flow system for adjusting required composition of CO_2-CO mixture and the schematic of the dynamic condenser. The details of the construction

of the dynamic condenser were described previously (42). The powdered, spectroscopically pure iron sample (prepared by Johnson-Matthey) was spread over the lower stainless steel electrode. The sample formed a layer about 0.5 mm thick. The gas mixture entered the upper part of the chamber of the dynamic condenser, passed down over the sample, and was exhausted near the bottom. The gas flow velocity was about 0.9 cm/sec as recommended by Darken and Gurry (43) to prevent the formation of a concentration gradient in the experimental gas mixture. Oxygen partial pressures corresponding to the appropriate compositions of the CO_2-CO mixture were calculated using the data of Jacobi (44)

$$\frac{p_{CO}}{p_{CO_2}} = [p_{O_2} \exp (68,100T^{-1} - 20.9)]^{-0.5} \qquad [8]$$

The reading accuracy of the CPD was about 0.05V.

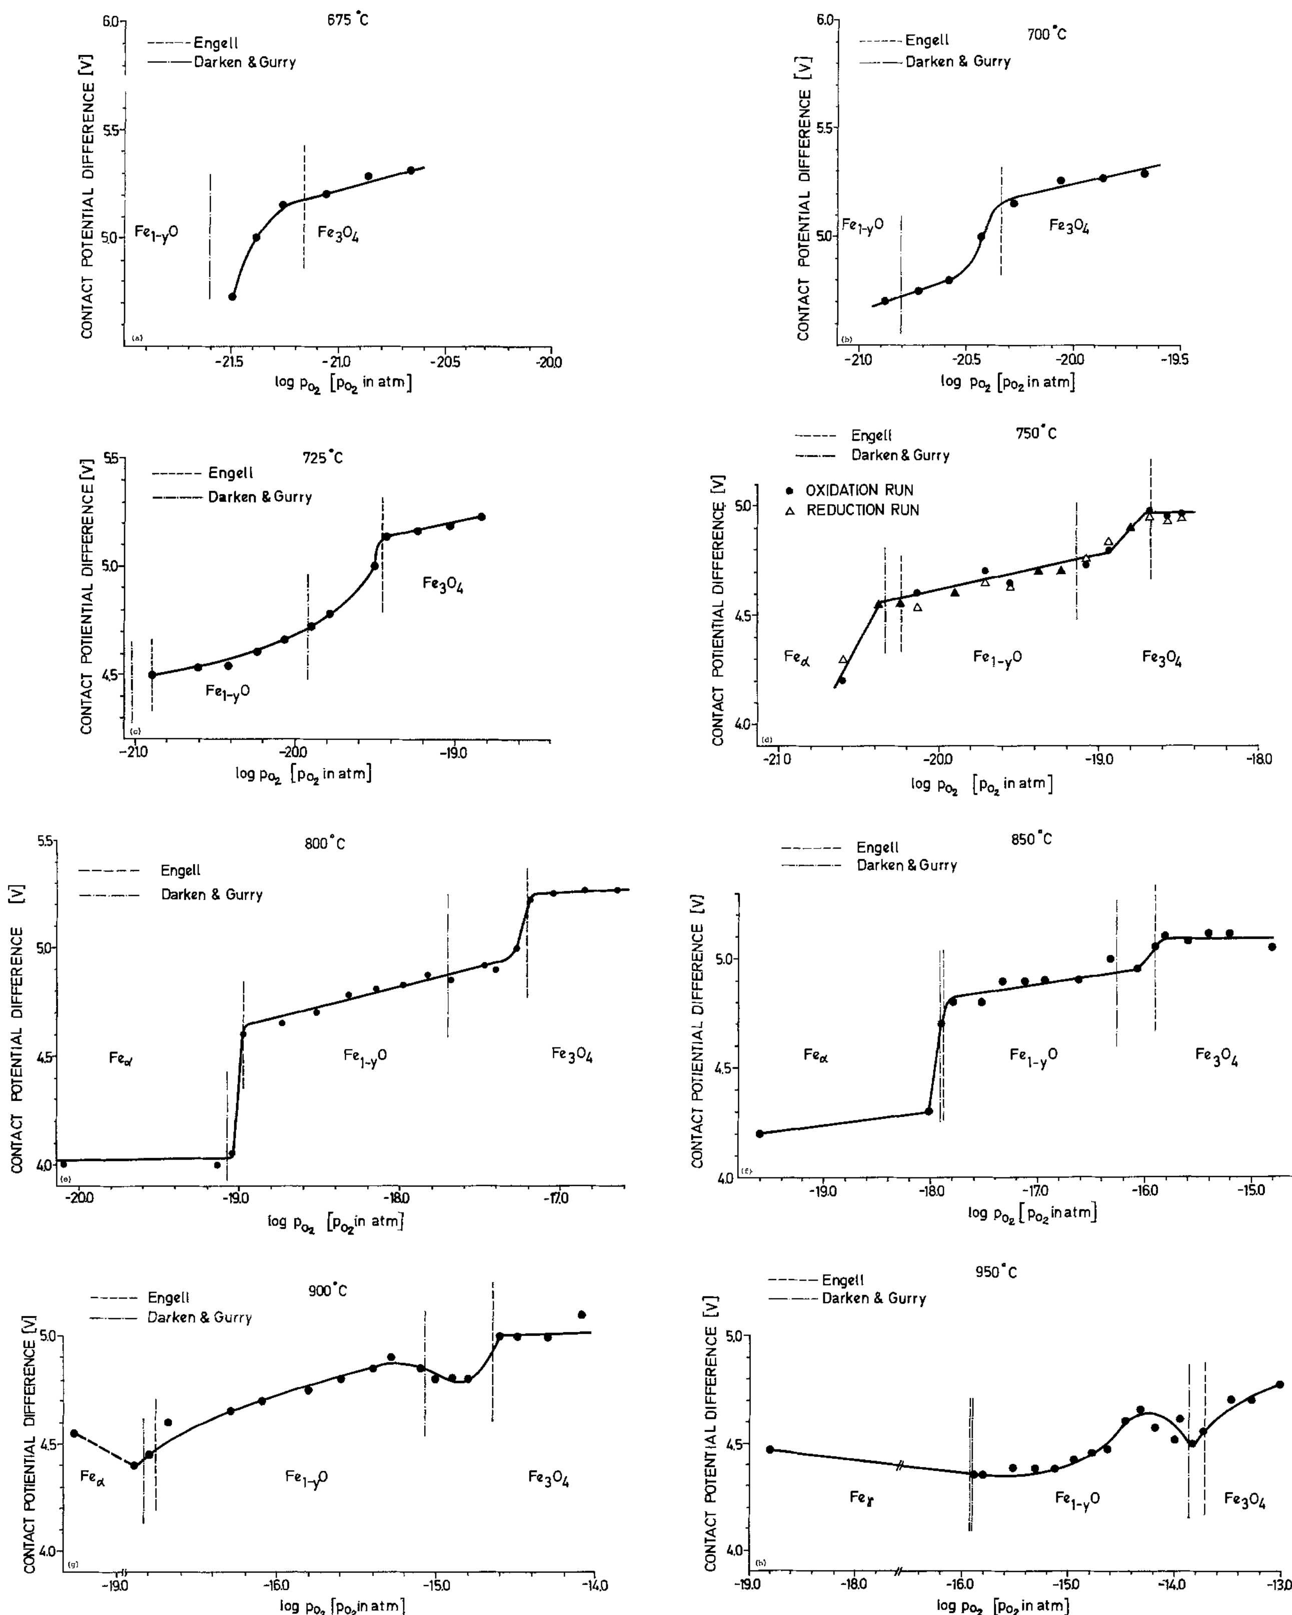

Fig. 4. Contact potential difference CPD for the iron-oxygen system measured at different temperatures vs. gas composition corresponding to the stability range of the wustite phase for temperatures: a, 675°C; b, 700°C; c, 725°C; d, 750°C; e, 800°C; f, 850°C; g, 900°C; h, 950°C. Oxygen partial pressures corresponding to equilibria at the phase boundaries Fe-$Fe_{1-y}O$ and FeO-Fe_3O_4 are indicated after Engell (3) and Darken and Gurry (29).

Procedure

The reaction system was heated to the required temperature in the gas mixture corresponding to the magnetite phase. Then the gas composition was gradually changed toward decreasing oxygen activity as illustrated by the dotted lines in Fig. 2. Experiments for which oxygen activity decreased or increased in successive readings were termed reduction or oxidation runs, respectively. The CPD was measured when a constant value was reached, *i.e.*, in 5-10 min after the new ratio of the CO_2-CO mixture was fixed on the new level. The experimental values of the CPD were taken from two to three independent readings. The data are reproducible within 0.1V.

Results and Discussion

Figures 4a-h illustrate the measured values of CPD as the function of oxygen partial pressure for a series of the temperatures between 675° and 950°C within the phase field of wustite as indicated in Fig. 2. The experimental data were found to be the same for both oxidation and reduction runs, as can be seen in Fig. 4d for 750°C. For other temperatures the CPD data for the oxidation runs are given. The dotted, vertical lines indicate the literature values of equilibrium oxygen partial pressures corresponding to the phase boundaries iron-wustite and wustite-magnetite, according to Engell (31) and Darken and Gurry (29). The observed sharp CPD changes fit the literature data well, thus indicating that the work function is a parameter very sensitive to the crystalline structure.

The change in the surface potential of the platinum reference electrode, calculated according to Eq. [7] for extreme oxygen pressures corresponding to Fe/FeO and FeO/Fe_3O_4 phase boundaries, was equal to about 0.05V. According to Eq. [7], these changes are linear in the coordinates used for plotting the experimental data in Fig. 4a-h. According to Eq. [6], the work function changes of the investigated sample are the sum of the measured CPD changes and $\Delta\Phi_2$. Because of the very small $\Delta\Phi_2$ values, however, the CPD changes are practically equal to $\Delta\Phi_1$.

As seen in Fig. 4c-f, the work function increases almost linearly within the wustite phase *vs.* oxygen partial pressure between 725° and 850°C. This is in accordance with the reported defect structure of wustite showing cation vacancies forming acceptor centers in the energetic model of wustite according to Eq. [1]. An increase in their concentration shifts the Fermi level downward. Since the energetic model of the wustite phase is not sufficiently developed it is difficult to indicate the form of the defects and their acceptor "activity." These may be both doubly and singly ionized cation vacancies as well as complexes. The observed increase of the work function indicates that the p-type conductivity should dominate within the whole wustite range if p-type is assumed at the lowest nonstoichiometry. This effect is in contradiction to the data of Bransky and Tannhauser (7) as well as of Wagner and co-workers (5) who reported a monotonous decrease of Seebeck coefficient (referring to the increase of the Fermi level) *vs.* increase of nonstoichiometry.

Figures 4g and 4h refer to 900° and 950°C, respectively. For 900°C and at low nonstoichiometry, the CPD changes linearly with oxygen pressure as was found for the experimental runs below 900°C. A slight decrease of the work function is observed at higher nonstoichiometry. This effect is even more pronounced at 950°C. In both cases, however, the final work function value is still higher than the initial one. Thus the postulated change of the conductivity type from p-type, at low nonstoichiometry, to n-type, at higher oxygen content (3-6) cannot be confirmed in the present investigations. The maxima of the work function observed at 900° and 950°C for higher nonstoichiometry may correspond to the change of sign of the Seebeck coefficient which was found by Bransky and Tannhauser (7) as well as Geiger, Levin, and Wagner (5). Both work function and Seebeck coefficient indicate an increase of the Fermi level *vs.* oxygen pressure at higher O/Fe ratios than those referring to the maxima. The discrepancy in the results of the Seebeck effect and the work function observed at lower nonstoichiometry, however, requires additional investigation involving the simultaneous measurement of the electrical parameters. It should be emphasized, however, that a good qualitative agreement between the work function and the electrical conductivity data was found for lower defect concentrations (both parameters indicating decrease of the Fermi energy *vs.* oxygen content), although the maxima of the work function *vs.* oxygen pressure was not confirmed.

Over the temperature range studied in this work, no effect was observed that could be ascribed to structural "regions" which have been postulated by Vallet and Raccah (15), Kleman (16), and Fender and Riley (17).

All of the experimental studies of CPD *vs.* log p_{O_2} show, more or less, sharp changes of the work function. These changes occur at values of oxygen partial pressures corresponding to the expected phase transformations of wustite into the metallic iron phase, on one hand, and into the magnetite phase, Fe_3O_4, on the other. The parameters of temperature and oxygen partial pressure determined in the present studies for the appropriate phase equilibria are plotted in Fig. 5 and compared with other literature data. The equilibrium data of oxygen partial pressure obtained from the work function measurements were recalculated after Engell (45) into corresponding values of nonstoichiometry y in order to compare the presently obtained results with the literature data reported in this measure (Fig. 6). As seen the data obtained from the work function agree very well with the data obtained by Engell (31), Marion (46), Vallet and Raccah (15), and other investigators (47). The results obtained here may be helpful in more precise determinations of the wustite phase boundary especially at lower temperatures (between 575° and 800°C) for which great discrepancies are observed among the available data.

Conclusions

1. The work function values of the iron-oxygen system measured at temperatures above 675°C were determined from the temperature and oxygen partial pressure and are independent of the experimental procedure applied. This indicates that the sample was equilibrated, and the work function data is characteristic of the studied materials.

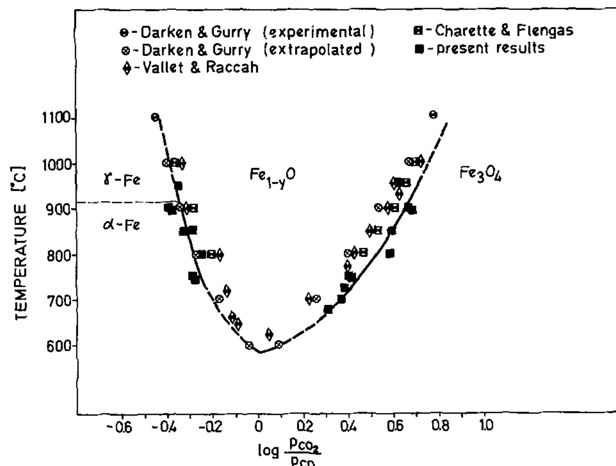

Fig. 5. Experimental data for the wustite phase diagram plotted in temperature *vs.* logarithm of the CO_2/CO ratio.

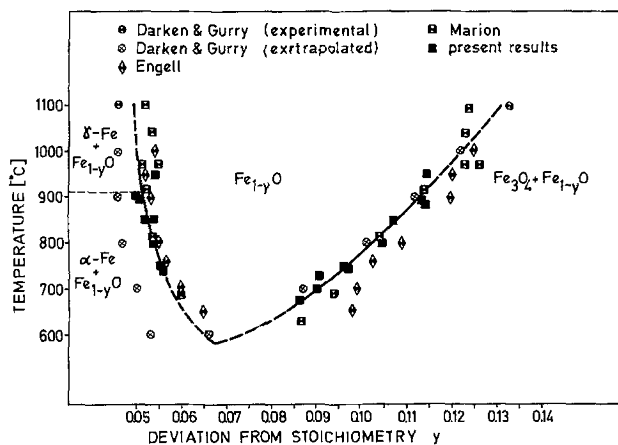

Fig. 6. Experimental data for the wustite phase diagram plotted in temperature vs. oxide composition.

2. The work function data do not confirm the earlier postulated p- to n-type transition for the wustite phase (3-6).

3. The work function is very sensitive to crystalline structure and thus may be used to determine the partial pressure of oxygen corresponding to the thermodynamic equilibrium state between the two phases. A surprising agreement between the presently obtained data from the work function measurements and the literature data concerning phase boundaries of the wustite phase indicates that this typical surface sensitive method is capable of giving information relevant to the bulk when the investigated system is well equilibrated.

4. The phase boundaries of the wustite phase determined from the work function measurements agree well with other literature data (31-33).

5. The hypothesis of Vallet and Raccah (15), Kleman (16), and Fender and Riley (17) concerning different structural domains in the wustite phase was not confirmed in the present investigations.

ABSTRACT

Water rinse of aluminum metallized integrated circuits must be carefully monitored because the Al can oxidize rapidly under certain conditions. Al oxidation in 10 MΩ deionized water was therefore studied using Auger spectroscopy, and transmission and scanning electron microscopies, to investigate the oxide growth as a function of water temperature and rinse time, use of photolithography, and Cu-doping of the Al. Al oxide thicknesses were 20-30Å before any treatment and were 35, 70, and ≅3000Å after 5 min rinses in 40°, 60°, and 80°C water, respectively. Photolithography and Cu doping induced no large effects. In 40°C water, little oxidation occurred for 20 min and rapid oxidation began after 40 min, especially at nucleation sites with C and Si contamination. The oxide grown in water has a porous structure, is nearly amorphous, and contains gamma-alumina and hydrated oxides. Near 80°C, several thousand angstroms of oxide can grow in minutes.

Oxidation of Al metallization in integrated circuits (IC's) can significantly affect device yield by increasing the contact resistance. This is especially true with beam leaded (1) devices to which contacts are established without any physical means of breaking the oxide barrier over the Al. Even with wire bonded devices, excessive oxide growth is obviously undesirable. Because deionized (DI) water rinsing of Al is an integral part of IC processing, the growth of Al oxide in DI water was investigated in this work.

Experimental

Sample preparation.—The samples studied are listed in Table I together with the relevant final treatments. Abbreviated descriptions of the processing steps are given in Table II; the water rinse step, No. 4, is the critical operation of interest here. The Cu-doped Al films of Table I were 1.5 μm thick, with 0.5 atom percent (a/o) Cu deposited at either ≅40°C or at 300°C by e-gun evaporation, and the undoped films were similarly deposited at 40°C. The column labeled "EG-BHF" refers to a 30 sec dip in 1:1:1 ethyleneglycol:buffered-HF:H_2O etch, and "450°C anneal" refers to a 30 min anneal in 1 atm H_2. The EG-BHF treatment removes Al oxide as well as some Si-nitride and SiO_2, with only a minimal attack of the Al and therefore its value as a cleaning etch for the entire Al metallized IC wafer was examined. In Table I, all "Testers" are full-surface Al films (on oxidized Si) unless photolithography is indicated. The device samples 18 to 21 were pulled from device lots, after the processing steps indicated; these steps are listed in Table II. The DI water entering the overflow rinse bath had a resistivity over 10 MΩ and was heated in a stainless steel tube just prior to admission into the bath.

Analysis methods.—Instances of extensive Al oxidation could be detected under the optical microscope, by a halo type of feature along the edges of patterned Al. After 450°C anneal, the oxide layer sometimes developed cracks and the oxide could be removed with adhesive tape, as demonstrated in Fig. 1. A scanning electron microscope (SEM) was used in this work for rapidly evaluating the effect of a particular water rinse and to scan many different areas of a chip. Typical SEM micrographs are displayed in Fig. 2. Surface oxide films >100Å thick appeared to quickly degrade the SEM spatial resolution. Auger electron spectroscopy (AES) was used for chemical analysis and for measuring oxide thicknesses <100Å. Details of this technique, which utilizes the chemically shifted Auger peak of Al in the oxide, is described in Ref. (2); the technique requires no ion milling and has high rela-

tive accuracy (several angstroms) and spatial resolution (<10 μm). Thicknesses >100Å were estimated approximately using the ion-mill Auger technique, assuming the ion milling rate for SiO_2. This estimate is obviously inaccurate and was used only to demonstrate that the oxide grown was very thick. Final detailed information was obtained using the transmission electron microscope (TEM) by examining thin cross sections of the regions of interest. This last technique has been described elsewhere (3).

Results

Preliminary identification of Al oxidation problem.—An optically visible film formed on Al by rinsing in 80°C water (device sample 18) was determined by AES to be essentially pure Al oxide. On this sample, a halo visible optically and by the SEM on SiO_2 areas more than 20 μm away from patterned Al was also found by AES to be Al oxide; evidently, this oxide spreads beyond Al areas. Optical examination after Al etch and before photoresist strip had revealed no Al on these SiO_2 areas so that this oxide is not formed from unetched Al residues. These initial results clearly established the importance of Al oxidation during device processing.

Auger studies.—Testers 1-17 of Table I were then prepared and AES experiments were performed to answer four questions:

1. What are typical Al-oxide thicknesses after various treatments?
2. What is the critical DI water temperature below which oxidation rate becomes negligible?
3. Does oxidation depend on Cu doping?
4. Does oxidation proceed in pure water, free of photoresist and/or A30 carry-over?

Results are as follows: Samples 1, 16A, and 17A established the typical air-formed oxide thickness (20-30Å) on as-deposited Al (Cu doped and undoped). We have not compared the initial oxide growth rates of Cu doped and undoped Al in detail. Typically, oxide thicknesses were about 20Å within 2 hr after deposition, about 30Å after several weeks, and about 35Å after several months of air exposure for both types of Al. Samples 1-15 were taken from many different deposition runs and received varying times of air exposure prior to experimental treatments and analyses. Therefore, their initial surface oxides varied somewhat and these variations may have masked the smaller effects; the experiments using these samples were intended to reveal only the stronger effects. This defect is rectified for samples 16A-17D, as explained below.

Samples 2, 4, and 5 showed that the surface oxide thickness does not increase appreciably up to 20 min at 40°C (35Å maximum). The statistical accuracy of the Auger data is demonstrated with sample 5, for which the average oxide thickness and standard deviation of one measurement each from five different areas within about 3 mm of each other were 31.2 ±0.4Å. Thus in principle, measured differences between samples of 3% (1Å at 30Å) could be significant; in practice, it has been demonstrated (2) that differences of 10% (3Å) are meaningful.

Samples 3 and 6 showed that photolithography does not affect the oxide thickness after 40°C rinse for Cu doped and undoped Al, respectively.

Sample 7 showed that the EG-BHF etch leaves a surface oxide of about 42Å.

Sample 8 revealed that the H_2 anneal, preceded by the EG-BHF treatment, increases the oxide thickness by about 30Å, to about 65Å. It might appear surprising at first that oxide growth occurs in a reducing (H_2) ambient. However, we have reproduced this result many times (not listed in Table I) and it is in fact consistent with the following two observations. (*i*) H_2 anneal has not been found to decrease the oxide thick-

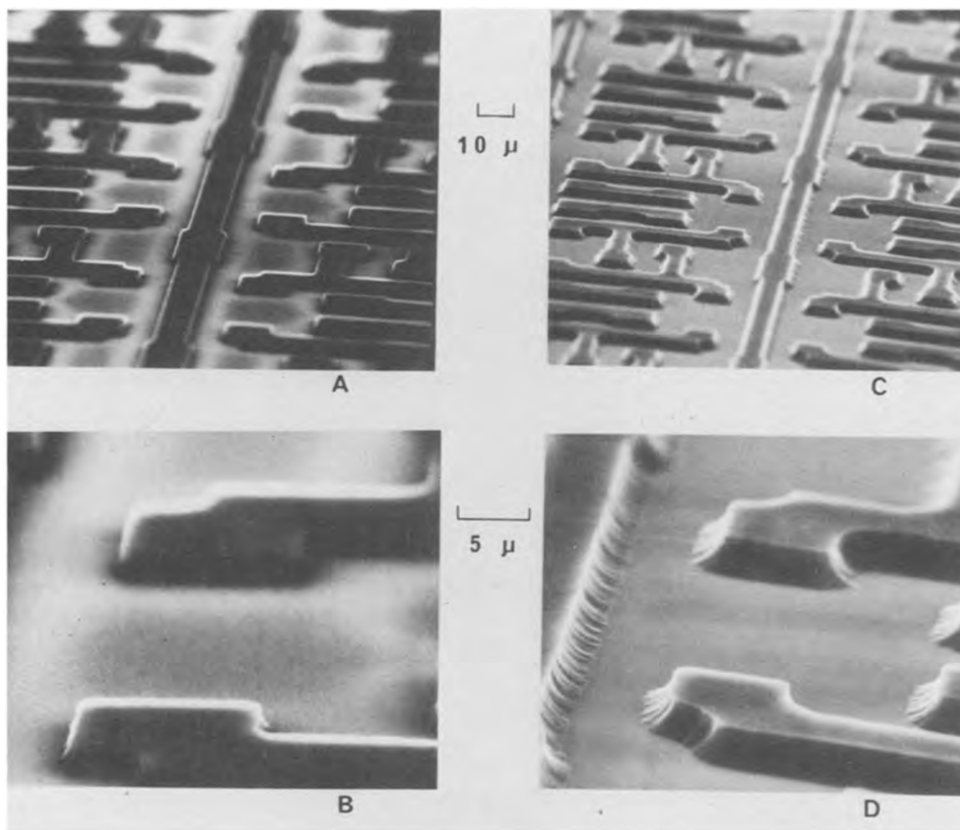

Fig. 2. SEM micrographs of the halo feature due to thick oxide growth. (A), (B) taken at two magnifications using sample 15 with thick surface film. The halo is the light contrast surrounding Al features; note the poor spatial resolution caused by the presence of an insulating film. (C), (D) from sample 3 with thin oxide (35Å); there is no halo, and spatial resolution is greatly improved.

ness in any of the present experiments, and (*ii*) it is obviously not possible to remove all contaminants during the anneal. We propose that small amounts of contaminants, either from the furnace or the wafers themselves, cause the Al to oxidize; once formed, the oxide is apparently stable in H_2 at 450°C.

Samples 9, 10, and 11 demonstrated that the oxide thickness begins to increase at 50°-60°C, to 60-70Å. Photolithography and Cu doping did not produce large effects.

Samples 12-15 showed the rapid oxide growth (to approximately 3000Å) at 80°C, which is fairly independent of photolithography and Cu doping. The 3000Å estimate does not take into account the porosity factor; for example, if the porosity factor (defined as the percentage of total film thickness occupied by pore space) is 75%, the actual oxide thickness could be 1.2 µm. The oxide thickness on sample 15 was estimated

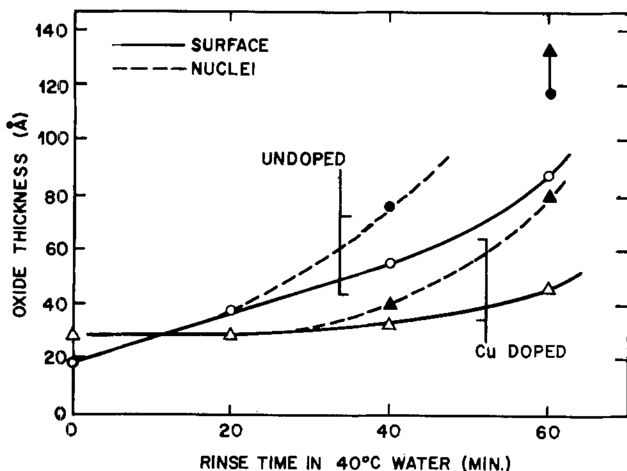

Fig. 3. Oxidation rate of Cu-doped (triangles) and undoped (circles) Al in 40°C water, samples 16 and 17. Filled points are data from the contaminated nucleation centers. The arrow on the filled circle at 116Å indicates that the oxide was thicker than 116Å.

from SEM photographs of cleaved specimens to be at least several thousand angstroms.

For samples 1-15, wafers from several Al deposition runs were used, so that the initial oxide thickness before treatment probably varied from wafer to wafer. To ensure identical starting conditions, samples 16 and 17 (Cu doped and undoped, respectively) were cleaved into 4 quarters each. These were then treated in 40°C water for 0, 20, 40, and 60 min, and the resultant surface oxide thicknesses were measured and are shown in Fig. 3. When viewed in the SEM mode of the Auger apparatus, the untreated surfaces 16A and 17A appeared featureless, and the Auger spectra revealed only slight C and S contamination. The inability to detect Si indicated that the cleaving operation for separating each wafer into samples A-D resulted in no serious Si contamination. After 20 min rinse, a faint, uneven texture was visible on both samples 16B and 17B, when viewed in the SEM mode of the Auger apparatus. After 40 min treatment, these features appeared clearly as nucleation centers that were sufficiently large (>10 µm) for Auger analysis. They were found to be oxide nuclei which grew even larger after 60 min treatment; the Auger data from these areas are also included in Fig. 3. The arrow on the data point at 116Å indicates that the oxide was >116Å thick.

No Si was detectable (<0.1%) on 16A and 17A, but about 2% Si was found on all B, C, and D samples. Since similar amounts of Si were found on surfaces of unbroken wafers after 40°C rinse, this contaminant was not unique to these cleaved samples. Although the significance of this surface Si is not clear, the nucleation centers contained higher Si and C contamination, suggesting that the more rapid oxidation at these centers is related to the contaminants. Possible sources of these contaminants are the wafer itself for Si and the original C contamination on the Al surface. This result points out the importance of removing all photoresist residues during IC processing. The data of Fig. 3 lead to the following conclusions (applies to 40°C rinse):

1. Cu-doped Al oxidized more slowly than undoped Al. However, it is not known whether the slower oxi-

dation rate of the doped film was due to its thicker initial passivating oxide, or to a difference in some other property of films deposited in different machines.

2. Oxidation rate is slow for the first approximately 20 min and becomes rapid after about 40 min.

3. Oxidation is more rapid at nucleation sites. These sites were more contaminated with C and Si than the rest of the surface.

For sample 18, a device wafer after 80°C rinse, the total oxide thickness was not measured, but was determined by Auger analysis to be >>100Å, in agreement with the above.

For sample 19, the oxide growth caused by 80°C rinse was measured following the processing to step 4 of Table II. The oxide thickness was estimated from TEM micrographs to be 6000-9000Å.

Sample 20 was processed to step 10 and the oxide thickness was estimated using Auger analysis by ion milling through the Ti-Pt layer and into the Al at a contact window. The oxide thicknesses of $\lesssim$ 6000 and 1600Å for samples 19 and 20, respectively, verify the rapid oxide growth for a device configuration, and comparison of samples 19 and 20 suggests that large amounts of oxide are removed by the brief EG-BHF etch.

Finally, sample 21 demonstrated that devices can be processed using 40°C water rinse with oxide growth limited to 43Å. This oxide thickness, which further increases upon H_2 anneal, is uncomfortably close to the limit of 55Å beyond which electrical contact problems after subsequent Ti deposition are expected, as established in a separate report (4); this point is further amplified in the Discussion.

AES indicated that after photolithography and 40°C water rinse, the amount of surface C was <0.5 atom layer (<1Å) and the Al surface is therefore sufficiently clean for the next processing step. The only other contaminants detected were about 0.05 atom layer of Si and S and much smaller quantities of Cl and F, and the dopant Cu in Cu-doped Al.

Attempts were made in this work to check the Auger measurements, d(Auger), of Al-oxide thickness by comparison with ellipsometric measurements, d(ellip.), for the full surface testers. Values of d(ellip.) were usually in reasonable agreement with d(Auger) but they sometimes differed by over a factor of 3, with d(ellip.) always larger. When the electrical breakdown voltages of these oxides were measured, the breakdown voltage was linear with d(Auger) but not related in any obvious manner to some of the d(ellip.) values (4). Therefore, we conclude that ellipsometric measurements may be sensitive to the contaminants and precise structure of the oxide and cannot be used except under certain controlled conditions. Values of d(Auger) have also been checked using a gravimetric method (in which the oxide film is weighed) and were in agreement with the resulting d(grav.) (4). Thus in addition to a fairly sound theoretical basis (2), there is experimental evidence that the Auger method of oxide thickness measurement gives probably the most reliable results available at present.

TEM analyses.—TEM of cleaved edges of sample 12 revealed the oxide to be about 5000Å thick and to have a porous, filamentary structure; typical micrographs are exhibited in Fig. 4. The oxide thickness estimates from TEM are often over a factor of two larger than from ion-mill Auger analysis. This disagreement is due at least in part to the film porosity. Cleaved samples were investigated in addition to sectioned samples (following paragraph) because of the avoidance of sectioning and ion-milling artifacts (sectioned samples are ion milled during the final stages of preparation). Avoidance of these artifacts is particularly important for obtaining reliable diffraction patterns (discussed below). Although the cleavage method is simple and fast, the cleavage geometry is not precisely known for the oxide, and details of the Al film are difficult to study because of the uneven cleavage geometry and because the Al probably deforms during breakage. Therefore, some samples were also sectioned and examined.

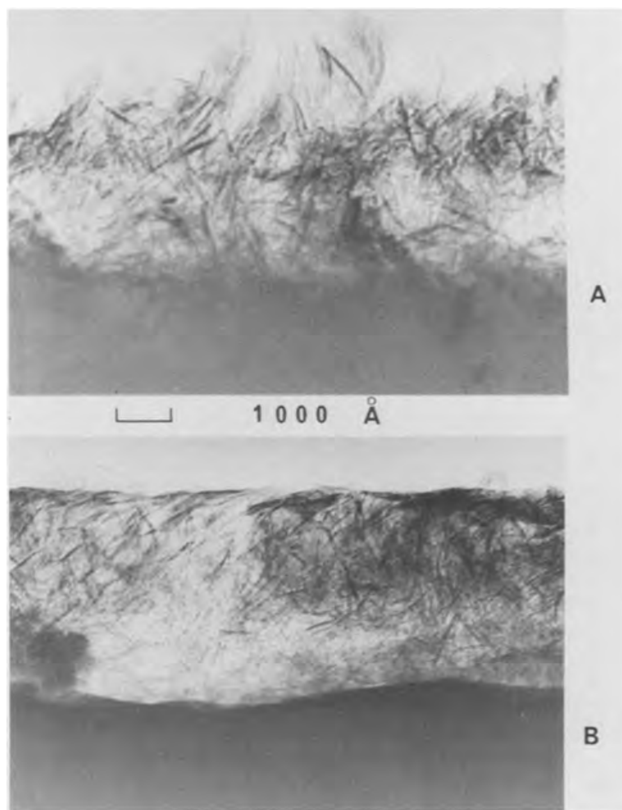

Fig. 4. TEM micrographs from a cleaved edge of sample 12, (80°C water rinse), taken from two areas. The filamentary material is Al oxide; the featureless region below the oxide is Al. The plane of the Al surface is tilted about 45°C from the electron beam axis.

TEM micrographs of cross sections of device wafer 19 are shown in Fig. 5 and 6. The appearance of the Al oxide is similar to that of sample 12 in Fig. 4, although the method of sample preparation for TEM was entirely different (simple cleaving *vs.* sectioning). In Fig. 5, a "hairline crack" can be seen running the entire width of the photograph from left to right just above the oxide-Al interface. This crack may be responsible for the lifting of the oxide as seen in Fig. 1. There is no preferential oxidation of the Al grain boundaries. Figure 6 was taken from an area tens of microns away from an Al runner that was found to the far right, out of the photograph. The horizontal line running across the photograph near center is the surface of the substrate Si, and the wavy features below this surface are mostly diffraction contrast from ion milling artifacts such as thickness variations. The cantilevered object entering from the left is a poly-Si gate (left edge) which ascends the (45°) tapered field oxide to a poly-Si runner (center). Material surrounding the poly-Si is SiO_2; close scrutiny reveals faint outlines of the various layers of thermal and deposited SiO_2. The Al oxide (filamentary material) is seen to migrate onto the SiO_2 surface and its thickness decreases toward the left, away from the Al source to the right (out of the picture).

Electron diffraction analysis of sample 12 indicated a nearly amorphous phase of gamma-alumina; the electron diffraction data are presented in Table III, under the "Measured" column, and compared to the expected values for gamma-alumina, boehmite, and bayerite. Relative intensities (x-ray) are also given in parentheses. The best match is with gamma-alumina; there is a possible presence of the monohydrate, boehmite, and no indication of the presence of the trihydrate, bayerite. This does not mean that bayerite is absent, as it may be in a more amorphous state

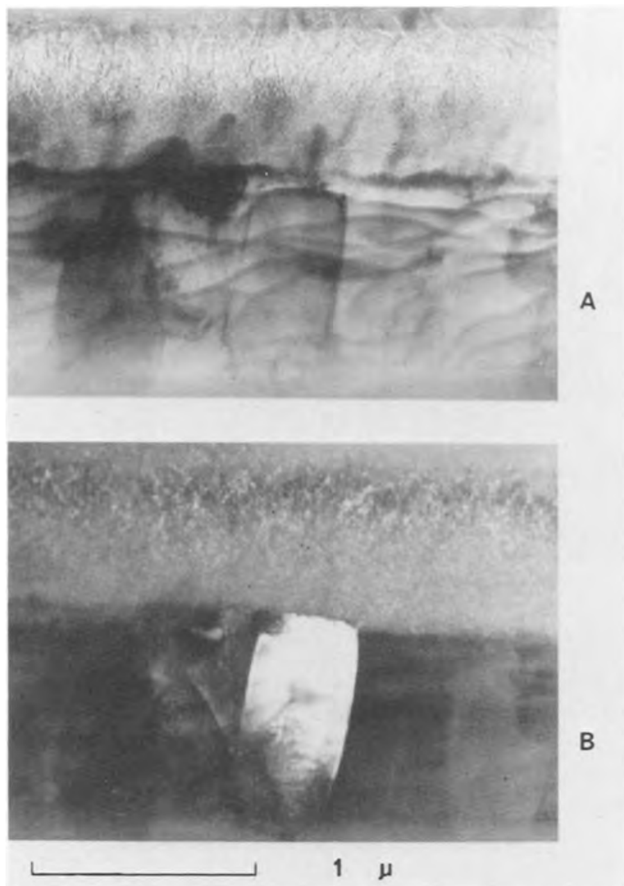

Fig. 5. TEM of thin cross sections of sample 19 taken perpendicular to the plane of the chip; the Al surface normal points up in the photograph. (A) Bright field picture showing the Al oxide (upper half) and the polycrystalline Al (lower half of photograph). (B) Dark field picture of the same area; revealing the precise location of the oxide-Al interface and the presence of small crystallites in the oxide.

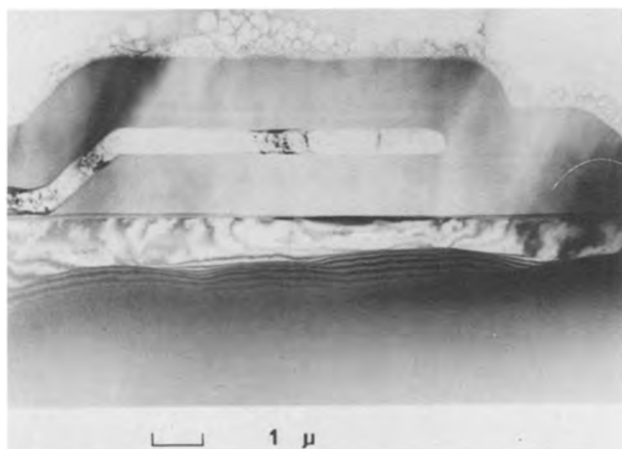

Fig. 6. SiO_2 area of sample 19, tens of microns away from an Al runner located to the far right (out of the picture). The identity of each feature is explained in the text. The filamentary material on the SiO_2 surface is Al oxide. The bubbles seen above the Al oxide are artifacts in the epoxy used to embed the specimen to facilitate handling. The Al oxide is thinner toward the left, away from the Al runner, suggesting that the runner is the source of the oxide.

than the others. All three compounds have been previously identified in diffraction patterns from Al oxidized in hot water (5, 6) (to a much greater extent than attempted here). The absence of the strong lines at d = 4.56, 2.80, 2.28, and 1.52Å for gamma-alumina and 6.11Å for boehmite in our diffraction data might

be due to the difference in atomic scattering factor between x-ray and electron diffraction, and to diffraction effects from extremely small crystallites with anisotropic growth habits.

The relatively thick oxide film on sample 12 (3000Å) could not be detected using x-ray diffraction and we attribute this result to its nearly amorphous nature. In agreement with this conclusion, no individual crystallites could be resolved with TEM. For the more extensively oxidized device wafer of Fig. 5 with an oxide 6000-9000Å thick, small particles, about 50Å in diameter, were visible in the dark field micrographs (Fig. 5B).

Discussion

The most significant new results of this work are the accurate quantitative measurements of the first <100Å of oxide growth in 10 MΩ DI water, under conditions actually experienced in IC processing. The fact that Al oxidizes in hot water is well documented (5-11). Our results are in qualitative agreement with literature; namely, that oxidation becomes rapid above 60°C and that the initial thin oxide is essentially amorphous. Although alloying of the Al and contaminants in the water certainly produce large effects (5, 9, 12) all the workers agree that the purest Al in the purest water available to them has resulted in oxidation (5-12).

The mechanism of Al oxidation in water has been described in some detail (6, 8). Oxidation proceeds in two major steps. In the first, Al and water react and release hydrogen, forming gamma-alumina. In the second, this oxide is hydrated and also redeposited. Thus the role played by any initial passivating oxide in delaying the onset of this oxidation is obviously important.

More generally, Al corrosion occurs in polar liquids, such as water and methanol (12). It is in polar liquids that nonneutral *p*H is readily attained, and the dependence on *p*H of the oxidation rate of Al in hot water has been clearly demonstrated (6, 8). This means, for example, that replacement of water with nonaqueous solutions will not necessarily eliminate the oxidation problem, since many nonaqueous solutions, such as methanol, are polar. Our finding that a low level of Cu doping retards oxidation slightly is of interest because, at high levels (≅4%), Cu has been reported to increase the corrosion activity (5, 9). However, our result is in qualitative agreement with the fact that anodization rate decreases with Cu doping (10). Investigation of Si-doped Al may also be interesting, because it has been reported (7) that Si doping retards Al oxidation in water. This last point is

interesting because Si is always present in Si IC processing and Si was one of the contaminants found on the Al in this work.

The usefulness of the above results to IC processing is obvious. Although DI water rinse is most effective at higher temperatures, we have established that above 50°C, oxide growth rate becomes too fast and the allowed thickness limit (4) of about 55Å can be exceeded in a matter of minutes. This limit is the sum of the amount of oxide that is effectively nullified by subsequent Ti deposition (45Å) and the electron tunneling distance (12Å), as determined by electrical breakdown measurements. The EG-BHF etch was shown here to be very effective for removing thick Al oxide. However, it leaves a relatively thick residual oxide (about 40Å) which further increases in thickness upon H_2 anneal (to about 65Å). A different etch based on a mixture of CrO_3 and H_3PO_4 has been shown (4) to leave a much thinner residual oxide (about 30Å) and may be preferable for reducing oxide thickness.

The rapid oxidation property of Al is not always undesirable and can be exploited to useful purpose. For example, even a mild treatment in hot water may be sufficient to passivate exposed Al areas of an IC chip. If an entire device is coated with Al, a passivating layer can be grown by completely oxidizing the Al. It should be kept in mind, however, that during oxidation, hydrated oxides will migrate and redeposit on adjacent areas that are tens of microns away from the Al. Since many materials are stable in hot water, they can be used as mask material for selective oxidation of thin Al films.

Conclusions

1. 40°C is a "safe" temperature for DI water rinse of Al (up to about 20 min); 50°-60°C is the "danger point" beyond which excessive oxidation will occur. The Al surface is quite clean (<1Å of C) after a 5 min, 40°C rinse following photolithography.
2. Al-oxide growth occurs in pure water; (HR100) photolithography, (H_3PO_4-based) Al etch, (A30) resist stripping, and Cu doping ($\cong$0.5 a/o), do not significantly affect the oxidation rate.
3. This oxide is porous and contains nearly amorphous gamma-alumina and probably some hydrated oxides.
4. The Al oxide is able to spread >20 μm from the Al to adjacent areas; this probably occurs by dissolution of gamma-alumina and redeposition of the hydrated oxides (6, 8).
5. This oxide is loosely adherent to Al, especially after 450°C H_2 anneal, and causes poor adhesion of subsequent metals deposited over the Al.

Silicon-on-Sapphire Crystalline Perfection and MOS Transistor Mobility

C. E. Weitzel* and R. T. Smith

RCA Corporation, RCA Laboratories, Princeton, New Jesrey 08540

ABSTRACT

Experimental data show that there is a correlation between the crystalline perfection of a (100) silicon-on-sapphire epitaxial film and the magnitude and direction of misorientation of the sapphire substrate from the $\{1\bar{1}02\}$ normal. The perfection is ascertained by measuring the half-width of Si {400} θ:2θ x-ray diffraction profiles. Data obtained from SOS/MOS transistors show a direct relationship between epitaxial perfection and FET mobility. Other factors which influence the perfection of the SOS film are growth temperature and film thickness.

For many years considerable effort has been expended in optimizing the quality of the epitaxial silicon films grown on sapphire substrates. In the earliest work (1-3), the optimization was achieved by selecting the appropriate Al_2O_3 planes which allow single crystal silicon growth and by using silane rather than silicon tetrachloride as the source gas. To achieve higher quality SOS films later workers (4-11) found it necessary to optimize other parameters: type of sapphire, substrate polishing and cleaning, predeposition firing, growth rate and temperature, and postdeposition annealing. Additional work (12-18) was directed toward understanding and optimizing changes in the SOS films which resulted from MOS transistor fabrication. More recently a vast array of sophisti-

cated analysis techniques have been used by numerous workers (19-35) whose goal is to understand and optimize the Si-Al_2O_3 system.

Despite all of this work on optimizing (100) SOS films, there is no mention of the possible dependence of SOS film quality on the sapphire substrate misorientation from the {1$\bar{1}$02} plane. Recently we presented data (36) that were obtained from wafers cut from EFG (edge defined film fed growth) sapphire ribbons that were polished using techniques that subsequently have been improved. These data indicate that small misorientations of the substrate away from the {$\bar{1}$102} affect the SOS film perfection, and as a result the transistor mobility. More importantly the data show that the most perfect (100) SOS films are not obtained on the {$\bar{1}$102} sapphire plane but rather off this plane. The data presented here are corroborating observations obtained using state-of-the-art Czochralski substrates. The relative crystalline perfection of SOS films is determined by x-ray diffraction profiles and is shown to correlate with SOS/MOS transistor mobility. The data from the Czochralski substrates also indicate that the most perfect SOS films are grown on substrates which are off the {1$\bar{1}$02} plane. Since the same results were obtained for both sources of sapphire and both polishing techniques we must conclude that the optimum substrate orientation is independent of these parameters. The transistor mobility and film perfection are also shown to be directly related for SOS films grown at different temperatures and of different thicknesses.

Experimental Techniques

The 1½ in. diam sapphire substrates used in this investigation were cut from Czochralski sapphire boules and polished by Union Carbide using state-of-the-art techniques. Since a systematic investigation of substrate misorientation was planned, the misorientation of a large number of substrates was measured using x-ray Laue and diffractometry techniques. Each wafer had a fiducial flat ground at 45° to an Al_2O_3 "a" axis lying in the plane of the wafer face. The projection of the Al_2O_3 "c" axis in the polished side of the wafer was determined relative to the ground fiducial flat by the back-reflection Laue method. Components of misorientation of the face of the wafers from the {1$\bar{1}$02} were thus measured in orthogonal directions perpendicular and parallel to the projection of the "c" axis. The orthogonal components of misorientation were measured on a Siemens diffractometer equipped with a Siemans single crystal orienter and using a Cu $K\alpha_1$ {1$\bar{1}$02} reflection. Components of misorientation were read directly to an accuracy of ±0.02°.

From this pool of substrates four groups of five substrates were selected to be processed together. In selecting the substrates for each group, care was taken to select substrates with widely varying misorientation so that any difference in transistor parameters would be obvious. Figure 1 shows the misorientation components of 20 of the substrates which were studied. A perfectly oriented wafer would be located at the origin of this graph. Figure 1 also shows how the wafers are divided into four processing lots and the processing lot number. At the time the wafers were purchased, the orientation specification was 2.0° in any direction from {1$\bar{1}$02}. Only three of the 20 wafers were outside of this specification.

After the components of misorientation of the substrates were measured, the substrates were fired in H_2 at 1200°C for 30 min. The epitaxial silicon films were grown on five substrates at a time in a five-sided barrel reactor by the pyrolysis of SiH_4 at 970°C pyrometer. The films were doped 1 × $10^{15}/cm^3$ n-type during growth. Nominally 0.6 μm films were grown in 20 sec. Following epitaxial silicon growth, diffraction profiles were obtained from both the Al_2O_3 {2$\bar{2}$04} and Si {400} in the rocking curve (ω-scan) and θ:2θ

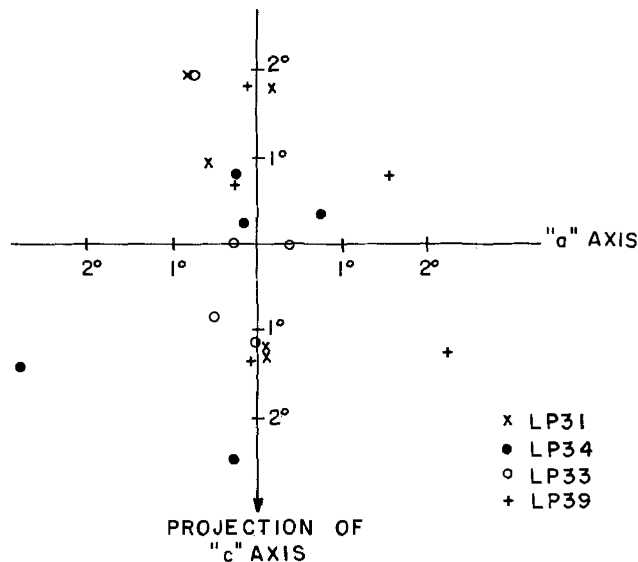

Fig. 1. Misorientation components of 20 Czochralski {1102} sapphire substrates.

modes. These diffraction profiles were obtained from a rectangular area about 1 cm × 1 mm near the center of each wafer. A Siemans ω-drive diffractometer with Cu Kα radiation was used to record the peak profiles. The smallest entrance and receiving slits (0.125 and 0.05 mm, respectively) were used to minimize the instrumental broadening. Scanning speeds were 1/8°/min in the θ:2θ mode and 1/4°/min in the ω-mode. The crystal scanning-chart speed coupling gave a strip chart recording sensitivity of 0.03125°/cm and 0.0625°/cm in the θ:2θ and ω-modes, respectively. In the θ:2θ mode, one samples only from a set of parallel planes, and the broadening over instrumental may be caused by a crystalline defect causing nonuniformity in the d-spacing of these planes or small crystallite size effects or both. In the ω-mode the detector is set at a fixed position centered within an angular range of 0.02° about the maximum diffracted intensity setting; hence any plane having a d-spacing characteristic of the angular setting of the detector may be sampled as the crystal alone is rotated through its diffracting range. Broadening in this mode may be caused by relative misorientation of crystallites or sample curvature or both. Each sample was oriented such that its diffraction normal was in the plane of the diffractometer. This was accomplished by incrementally rotating the sample about its face normal and successively readjusting the crystal ω setting and detector 2θ setting to maximize the diffracted intensity. The correct setting is attained when ω reaches a maximum or minimum value.

Following characterization of the epitaxial silicon film, SOS/MOS transistors were fabricated using the P+ polysilicon gate deep depletion process (37). Briefly the processing steps are: silicon island definition and etching, growth of 1200Å of channel oxide, polysilicon deposition, doping and etching, channel oxide self-aligned etch, doping of sources and drains from doped oxides, contacts, metallization and overcoat. The process results in the fabrication of an n-channel deep depletion transistor and a p-channel enhancement mode transistor. The average FET mobility for a wafer is determined by averaging the mobilities measured at five points on each wafer, one point at the center of the wafer and four points equally spaced around the perimeter of the wafer within ¼ in. of the wafer edge. The mobility of each point is arrived at by plotting the drain current *vs.* gate voltage with V_D = 0.1V. The transconductance is determined from the linear part of this curve where the g_m is maximum. The FET mobility is then calculated using the physical dimensions of the transistor (38).

Experimental Results

Substrate misorientation and silicon epitaxial perfection.—Of the four diffraction profiles obtained from each sample, the Si $\theta:2\theta$ half-widths were found to have the greatest correlation to device performance. The Si ω-scan half-widths paralleled those of the $\theta:2\theta$ with some exceptions. It is thought that these exceptions are due to the dependence of the ω-scan half-width on the direction of scan. Since each crystal was oriented so that it was scanned in the direction of misorientation and the orientation of each was different, a common scanning direction did not exist. Since the $\theta:2\theta$ half-widths are a valid qualitative comparison of relative crystalline quality or perfection, we have chosen to compare device performance characteristics with the crystalline quality as obtained from $\theta:2\theta$ scan half-widths.

The half-widths obtained from $\{2\bar{2}04\}$ $\theta:2\theta$ scans of all the Al_2O_3 substrates were found to have a mean value of 0.0413° ± 0.0029°. Although the Al_2O_3 half-widths showed very little variation, the {400} $\theta:2\theta$ half-widths of Si deposited on these substrates ranged from 0.117° to 0.157° as shown in Table I. The half-width of a {400} Cu $K\alpha_1$ reflection of bulk Si obtained with the same instrumental conditions was found to be 0.0500°. Thus it appears that the method was insensitive to any variations in the quality of the Al_2O_3 substrate, if present; while, the $\theta:2\theta$ half-widths of the epi Si were from 2.3 to 3.1 times as large as those of bulk Si. Repeated half-width measurements of the same SOS sample indicated that the measured half-widths are reproducible to within ±3.0%. The diffraction profiles of the {400} Si reflection were similar to those reported earlier (36).

The half-widths obtained from each of the 20 wafers are shown in Table I. The wafers in each processing lot are listed in order of increasing $\theta:2\theta$ half-width. Therefore, the SOS film having the smallest half-width is listed first in each group of five wafers, and the one with the largest half-width is listed last. An examination of the components of misorientation of each wafer revealed a correlation between the component of misorientation parallel to the mirror plane and the $\theta:2\theta$ half-width as shown in Table I. The wafers, whose component of misorientation parallel to the mirror plane is positive, have the smallest half-widths; whereas, the wafers whose component of misorientation is negative have the largest. Therefore, wafers misoriented in the top half plane of Fig. 1 consistently have smaller half-widths than those in the bottom half plane. This correlation is obvious for all of the lots except LP33. Possible causes of this lack of correlation in lot LP33 are discussed later. No correlation was found between the components of misorientation parallel to the "a" axis and the $\theta:2\theta$ half-widths. This is not surprising since most of the wafers are only slightly displaced from the mirror plane, Fig. 1.

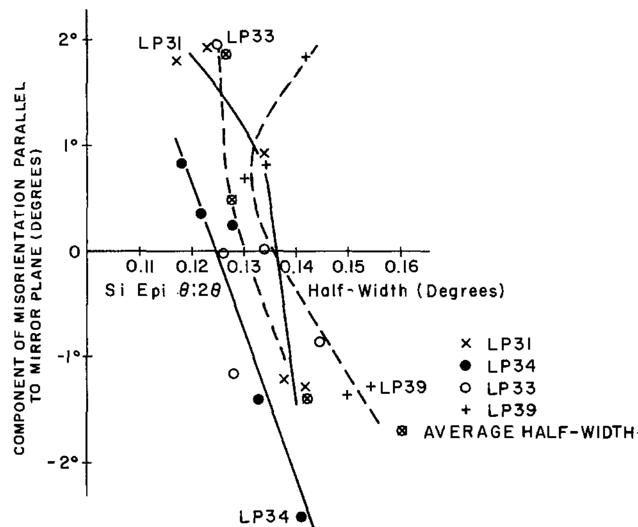

Fig. 2. Silicon {400} $\theta:2\theta$ half-widths vs. component of misorientation parallel to the mirror plane.

The data from the first two columns of Table I are shown graphically in Fig. 2. The ordinate in Fig. 2 is the component of misorientation parallel to the mirror plane and the abscissa is the $\theta:2\theta$ half-width. The lines are drawn to approximately fit the experimental data points. Three of the lines show a monotonic decrease in $\theta:2\theta$ half-width as the component of misorientation changes from negative to positive; whereas, the fourth line, for processing lot LP39, shows a decrease followed by an increase for the most positive component of misorientation. The 20 points plotted in Fig. 2 could be gathered together into three groups: those with components of misorientation parallel to the mirror plane of about −1°, those with components between 0° and +1°, and those with components around +2°. The average half-widths of these three groups are 0.140°, 0.128°, and 0.127°, respectively. These averages also reflect the correlation with substrate orientation. The average half-width and misorientation component of these three groups is plotted in Fig. 2 by the circled X.

Silicon $\theta:2\theta$ half-width and SOS/MOS transistor mobility.—Since the $\theta:2\theta$ diffraction profile is a measure of the quality of the epitaxial film, such a parameter should also correlate with the electrical properties of the film that are also affected by film quality. Since the mobility of charge carriers is limited by scattering events, the mobility of carriers in a more highly defected material would necessarily have to be smaller than in a more defect-free material. This correlation is shown by the transistor mobility data in Table I. The maximum, minimum, and average mobilities of both n-channel and p-channel transistors on each wafer are shown. With the exception of data for lot LP33, the average mobility decreases as the $\theta:2\theta$ half-width increases. The maximum and minimum mobilities for each wafer also show this trend. For most of the wafers the maximum and minimum mobilities differ from the average mobility by less than 5%. For a few wafers, however, the difference is as great as 10%.

This correlation between crystalline perfection and FET mobility is shown graphically in Fig. 3. The FET mobility for n-channel deep depletion transistors and p-channel enhancement transistors from lot LP34 is plotted *vs.* the $\theta:2\theta$ half-width of the silicon epitaxial film. The spread in mobility above and below

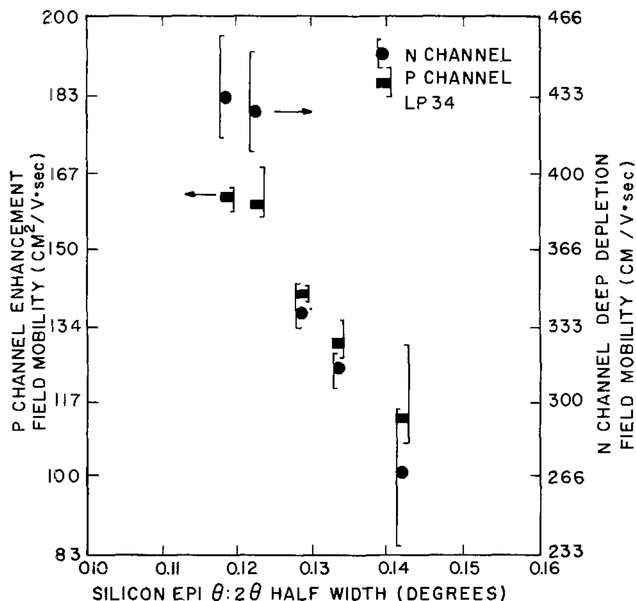

Fig. 3. FET mobility of n-channel deep depletion and p-channel enhancement transistors vs. θ:2θ half-width of silicon epitaxial film for wafers in lot LP34.

the average is shown by the vertical bar. The data show that the mobility in the accumulation layer of the n-channel device is reduced from 432 cm^2/V sec for a half-width of 0.118° to 268 cm^2/V sec for a half-width of 0.141°. The average mobility in the inversion layer of the p-channel device decreases from 162 to 114 cm^2/V sec. For a 3.32° change in substrate orientation, the mobility is reduced to 70% of its maximum value. The average mobilities for the devices on wafers in the three groups previously discussed in reference to Fig. 2 also show the same effect. The average n-channel mobility for the three groups is 380, 450, and 443 cm^2/V sec, respectively, and the average p-channel mobility for the groups is 164, 183, and 197 cm^2/V sec, respectively.

Since the crystalline perfection correlates with misorientation direction and also with the FET mobility, the mobility must also correlate with misorientation direction. This correlation is shown in Fig. 4 for processing lot LP31. In Fig. 4 the misorientation components for each substrate are plotted on a graph similar to Fig. 1. Next to each point is given the average n-channel and p-channel FET mobility. Devices fabricated on substrates which are above the origin, which in Fig. 2 have been shown to have lower

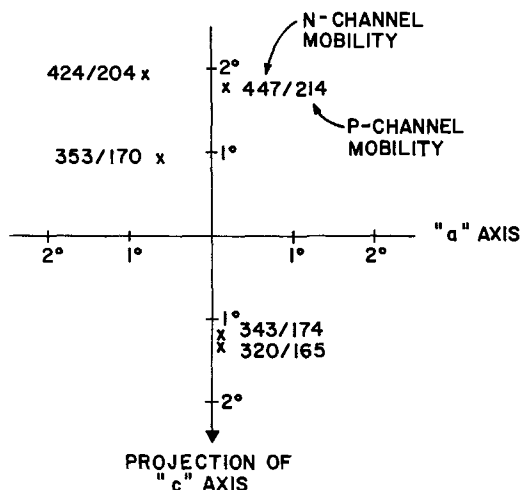

Fig. 4. FET mobility of n-channel deep depletion and p-channel enhancement transistors vs. components of substrate misorientation for wafers in lot LP31.

defect concentrations, have higher FET mobilities than devices fabricated on substrates which are located below the origin which have been shown to have higher defect concentrations.

Other parameters affecting SOS epitaxial perfection.—The correlation between substrate misorientation, silicon θ:2θ half-width, and SOS/MOS transistor mobility is quite obvious when the data from the five wafers which were processed together are compared. However, the correlation becomes less obvious when all 20 wafers are grouped together for analysis. In addition, the lack of correlation for the data from lot LP33 is unexpected in light of the data from the other lots. These facts indicate that, in addition to substrate misorientation, there are other factors which affect SOS epitaxial quality. If other parameters were not important, all of the lines connecting the data points in Fig. 2 would cross the zero degree axis at the same point. Instead, there is a 0.0115° variation in half-width on this axis. This variation exists in spite of the fact that the wafers were processed as identically as is presently possible.

The factors that are not totally controlled are probably those that affect the substrate polishing and cleaning and the silicon growth. Until recently no technique for quantitatively measuring the perfection of a polished sapphire surface has been available. The infrared work by Duffy and Zanzucchi (31) is a step in this direction. An important factor to control with regard to the silicon growth is the temperature. This is usually done with an optical pyrometer. Since the pyrometer measures the temperature through the wall of the growth reactor any deposit that accumulates on the inside wall of the reactor will cause an error in the temperature at which the film is grown. The sensitivity of the quality of the SOS film to growth temperature is shown by the data in Fig. 5. To eliminate the effect of the accumulating deposit the bell jar was thoroughly cleaned prior to growing the SOS films for this experiment. In addition after each deposition run the bell jar was cleaned again. These precautions were taken so that the susceptor temperature could be measured accurately. The FET mobility of n-channel deep depletion transistors is plotted on the ordinate and the growth temperature, as measured by an optical pyrometer, is plotted on the abscissa. The vertical bars indicate the spread in mobility across each 1½ in. diam wafer. The misorientation components of all of the wafers are the same to within 0.100°. As the deposition temperature is increased from 930° to 1000°C, the average FET mobility increases from 260 cm^2/V sec to a high of 445 cm^2/V sec and back down to 258 cm^2/V sec. The spread in mobility across a wafer is smallest for films grown near the optimum temperature. The films grown at 930° and 1000°C had

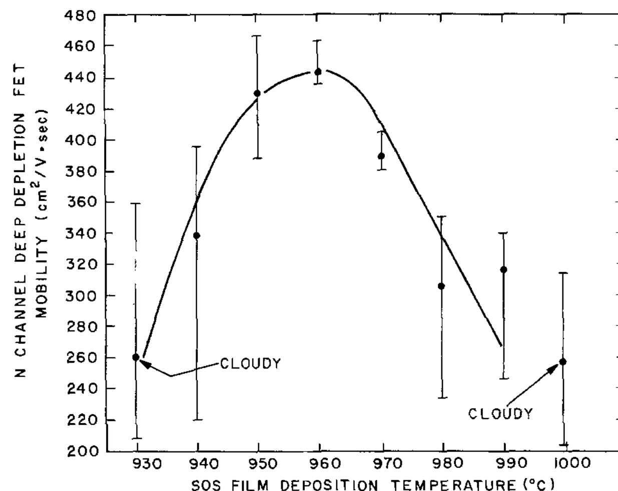

Fig. 5. N-channel FET mobility vs. SOS film growth temperature

a cloudy or milky appearance when viewed with intense low-angle lighting. In all probability there are degrees of cloudiness not discernible to the human eye for some of the other lower mobility wafers. The crystalline structure of the cloudy films is presently being studied. The θ:2θ half-width of cloudy films is larger than that of noncloudy films for identically oriented wafers. The data indicate that temperature control to within ±5.0° of the optimum temperature is desirable. However, it is still not that simple, because the temperature across the surface of the growth susceptor varies. In addition, the temperature variation across a warped wafer will be different from that across a flat wafer.

Talysurf measurements indicate that occasionally the films on one or more wafers in a deposition run are thicker or thinner than expected. Again as with temperature, this can have a measurable effect on FET mobility and θ:2θ half-width, as shown in Fig. 6. The misorientation components of all of the wafers are the same within 0.100°. The mobility for n-channel deep depletion transistors is plotted on the left-hand ordinate, and θ:2θ half-width is plotted on the right-hand ordinate. Again the vertical bar indicates the spread in mobility across the wafer. The preprocessed film thickness is plotted on the abscissa. Approximately 700Å of silicon is consumed during oxidation in the process. As the film thickness decreases the mobility first decreases slowly and then rapidly below 3000Å. This mobility decrease is mirrored by an increase in θ:2θ half-widths. These mobility data are consistent with those of other workers (39-41). These data indicate that the defect density of an SOS film increases as the Si-Al_2O_3 interface is approached. Cross-section transmission electron micrographs also show this dependence of defect density on film thickness (24).

The high temperature processing steps that the film undergoes during the fabrication of MOS devices also have a significant effect on the defect density of the SOS epitaxial film, as shown by the data in Fig. 7. These data were taken by measuring the θ:2θ half-width of as grown 0.6μ thick films. Then a thermal SiO_2 layer is grown in HCl steam on each of the films, as would be done in normal processing. A different oxidation temperature and time was used for the two films. Normally the SiO_2 is used as an etch mask for the silicon film. However, in this experiment the oxide is merely removed before the θ:2θ half-widths are re-measured. The results are shown in Fig. 7. It is interesting to note that the film with the larger half-width that was oxidized at the higher temperature for the longer time had the smaller half-width following the oxidation. Next the films were oxidized as if the channel oxide were being grown. The oxide was removed, and the half-widths remeasured. This process was repeated after each of the anneals at 1050°C

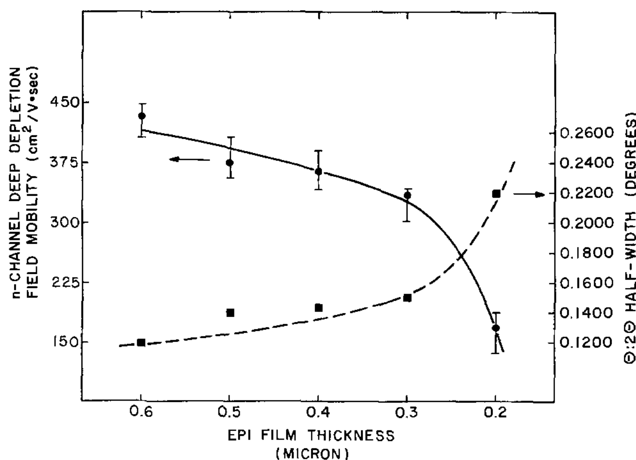

Fig. 6. N-channel FET mobility and θ:2θ half-width vs. SOS film thickness.

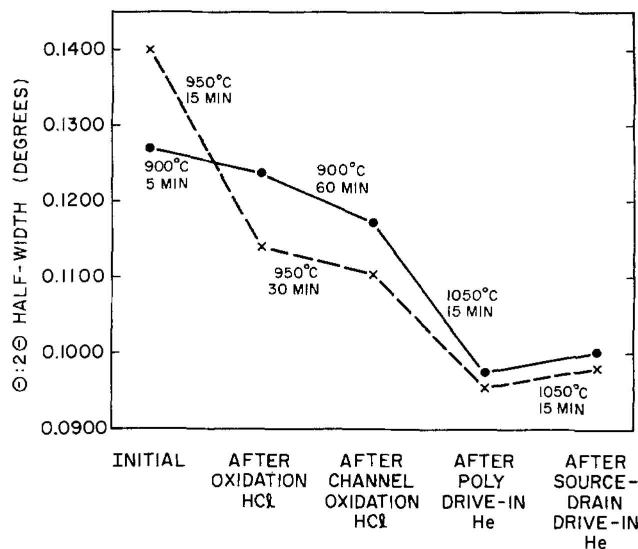

Fig. 7. Effect of high temperature processing steps on silicon {400} θ:2θ half-widths.

in helium for 15 min. The data clearly show that the high temperature processing steps cause a decrease in the θ:2θ half-width. This is indicative of an annealing out of some of the defects in the SOS film. That the more defective film had less defects at the end of the processing shows the importance of the time and temperature for improving the perfection of the film. Finally the data show that continued annealing does not reduce the SOS, θ:2θ half-width to that observed for bulk silicon, 0.0500 degrees. Rather the half-width decrease saturates at a value between 0.0900 and 0.1000 degrees. These results were confirmed by other experiments in which SOS films were annealed in inert ambients for periods of hours or days. In all cases the half-widths decreased; and in many cases following saturation, the half-widths increased with further annealing, as did the data in Fig. 7. The smallest half-width measured for an annealed 0.6μ SOS film was 0.0844 degrees, and only one other film out of about 30 had a measured half-width of below 0.0900 degrees.

Discussion

The experimental data presented here is additional evidence for the correlation between sapphire substrate misorientation, silicon θ:2θ half-width, and SOS/MOS transistor mobility. In the earlier work (36) this correlation was found using wafers cut from EFG sapphire ribbons that were polished using techniques that have subsequently been improved. As a result there was concern that the source of the sapphire and polishing techniques might have contributed to the effect. The present observations, however, were obtained using substrates cut from Czochralski boules. These wafers were fabricated using state-of-the-art techniques which included a final polish using colloidal-silica type polishing agents. Since the same behavior was found for both sources of sapphire and both polishing techniques, we must conclude that one factor that determines the qualtity of the SOS film is the substrate misorientation. In addition the data show that the highest quality SOS films are not grown on the {1$\bar{1}$02} plane, as was formerly supposed, but rather off this plane by an, as yet, undetermined amount. This optimum orientation is presently being sought.

Although most of the experimental data clearly shows the correlation between substrate misorientation, SOS film perfection, and FET mobility, anomalous results are occasionally found. In this work the data from lot LP33 is clearly anomalous when compared with the data from the other lots. In addition the wafer with the component of misorientation parallel to the mirror plane of +1.85 degrees in lot LP39 is

also somewhat anomalous. One possible explanation of this behavior is that factors other than substrate misorientation are affecting the film quality. The data in Fig. 5 and 6 show that growth temperature and film thickness are two other factors which affect film perfection. The growth temperature could be different for wafers in the same deposition run if the faces of the susceptor are at different temperatures or if there is poor thermal contact between the wafer and susceptor which could be caused by wafer warpage. The data in Fig. 5 clearly show that a deviation of only 10°C from the optimum growth temperature can cause a signficant decrease in transistor mobility. A limited study of film thickness variation for wafers grown at identical conditions revealed that although the thickness of 90% of the films was within ±10% of the average thickness of all the SOS films, the thickness of the films on the other 10% of the wafers differed by as much as ±25%. This translates to a film thickness variation of ±1500Å. The data in Fig. 6 show that a variation in thickness of this magnitude would also have a significant effect on $\theta:2\theta$ half-width and transistor mobility.

The data in Table I show that for the anomalous wafer in lot LP39 not only is the mobility lower than expected, but the half-width is also greater than would be expected for a wafer with this misorientation. Therefore, the correlation between mobility and half-width still holds; whereas the correlation with misorientation is violated. This type of behavior would be expected if the film were too thin or if the growth temperature were not optimum.

In light of the correlation between misorientation, half-width, and mobility for the data from the other three lots, the data for lot LP33 is most disconcerting. The data for lot LP33 in Table I show very little correlation between any of the measured parameters. If the half-width data correlated with the mobility data, but not the misorientation the arguments used for the wafer in lot LP39 with regard to growth temperature and film thickness could be applied here. However, the data for LP33 in Table I do not show this correlation. Therefore, the only explanation for the lack of correlation is that either the wafers became mixed up or that there are other factors which can affect the film mobility but not the half-width.

The data which show the decrease in half-width following various processing steps points out an important fact about SOS films. The fundamental properties of SOS films are not unaffected by the processing steps required for transistor fabrication. On the contrary SOS films are very sensitive to processing parameters. These x-ray diffraction techniques are merely another tool that can be used to acquire a better understanding of the dynamics of the $Si-Al_2O_3$ system. The ultimate goal of all this work is the optimization of SOS transistor performance.

Summary

Experimental data obtained from state-of-the-art Czochralski sapphire substrates were presented which show a correlation between substrate misorientation, SOS film perfection, as measured by x-ray diffraction techniques, and SOS/MOS transistor mobility. The correlation is identical to that obtained in earlier work (36) in which EFG ribbon wafers were used. The data indicate that the optimum substrate orientation is not the $\{1\bar{1}02\}$ plane but rather off this plane. Growth temperature and film thickness are also shown to have a large effect on film perfection and transistor performance.

Optical Monitoring of the Etching of SiO_2 and Si_3N_4 on Si by the Use of Grating Test Patterns

H. P. Kleinknecht and H. Meier

Laboratories RCA Limited, CH-8048 Zurich, Switzerland

ABSTRACT

An optical technique is described which monitors both the etch depth and the amount of lateral underetching during the etching process. This technique applies to wet chemical etching as well as to plasma etching. For this purpose a test pattern containing one or more diffraction gratings is included on the mask, which is used to define the particular etching step. During the etching process a laser beam is aimed at this test pattern on the Si wafer and the reflected first-order diffraction intensities are monitored. As the etching progresses and the grating profile deepens, the diffracted intensity goes through oscillations which give an in-process indication of etch depth and etch rate. In the wet process the complete underetching underneath the photoresist bars of the grating is signaled by a drastic drop in the diffraction intensity. The simultaneous monitoring of a number of gratings with different bar widths permits one to follow the underetching in fine steps.

In silicon devices and integrated circuits fabrication many processing steps involve etching of SiO_2 and Si_3N_4 layers on Si through photoresist patterns. The lateral dimensions and the profiles of the patterns etched into the layers depend to some degree on the amount of underetching or undercutting in lateral direction underneath the photoresist mask. In many cases this undercutting is undesirable because it reduces the edge definition. In other cases a certain amount of undercutting is desirable for a sloped, rounded edge of the layer which is required in order to ensure continuity of the metallization stripes at the edge. In any case it is necessary to have control over the amount of underetching, and it is desirable to have in-process control over this parameter.

One technique, which reduces undercutting, is plasma etching (1). Unfortunately, in contrast to wet etching, the plasma-etching process does not stop completely when the SiO_2 has been removed, but it continues to etch into the silicon. This problem has been addressed by Heinecke (2), who has obtained a ratio of etch rates of 10:1 in favor of SiO_2. However, with etch rates being very much dependent on rf power, temperature, flow rate, and pressure (3, 4), one still would like to monitor the etch depth *in situ*.

Poulsen and Smith (5) have described an endpoint detection system which operates on the change of the spectral emission from the plasma during the plasma etching process. Konnerth and Dill (6) have used a computed-controlled spectrophotometer for measuring the thickness of glass and SiO_2 layers during etching and of photoresist during development. Van der Meulen and Hien (7) have constructed an automated ellipsometer for *in situ* measurement of dielectric layers at high temperature.

This paper describes a technique for in-process monitoring of the etching which is probably cheaper and more flexible than the systems quoted above and which has been shown to work for wet chemical etching as well as for plasma etching of SiO_2 and Si_3N_4 layers on Si wafers. In addition to the etch depth, this technique also monitors the amount of underetching which, to the knowledge of the authors, has not been done before. The new method uses test patterns in the form of diffraction gratings which can be arranged in a "knock-out" area on the normal photomask used for the delineation of the particular etching step to be controlled. Such gratings can be monitored during the etching process by reflection of a laser beam which results in a diffraction pattern. The intensities of the diffraction orders can give information about the profile of the grating, in particular on the etch depth, etch rate, and undercutting.

Figure 1 shows in a schematic way what can be expected to happen if, for instance, a SiO_2 layer is etched in HF through a fine photoresist grating pattern: As the etching progresses, the thickness, h, of the SiO_2 layer will decrease. This will cause the phase difference of the light reflected from the photoresist bars and from the SiO_2 to change. As a result the diffracted intensity will oscillate. This oscillation will stop when the etch has reached the SiO_2-Si interface. At the same time the etching will progress laterally. As soon as this lateral underetching has gone as far as half the width of the photoresist bars ($u \geq a/2$), the grating bars will start to shift and finally fall off. This will destroy the periodicity of the grating, and as a consequence the diffraction pattern, *e.g.*, the first order, will decrease in intensity.

Exploratory Tests with Wet Etching

In order to test this, a number of polished silicon wafers were covered with a SiO_2 layer of 0.94 μm thickness (as measured by ellipsometry), coated with photoresist and exposed through a mask containing 1.5×3 mm^2 areas with a grating-like parallel bar pattern of a periodicity of 10.2 μm and a width of the bars of $a = 3.0$ μm.

Key words: wet etching, plasma etching, etch depth, etch rate, underetching.

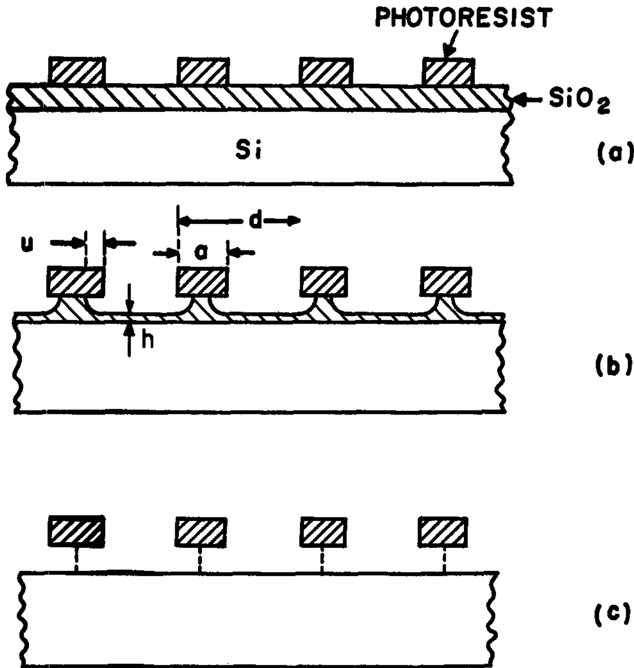

Fig. 1. Etching of a grating test pattern

Samples cleaved from these wafers were mounted on a Teflon holder which could be immersed into a Teflon etch container provided with a window of transparent acrylic sheet. The optical setup is described in Fig. 2. The beam of a He-Ne laser ($\lambda = 6328$Å) is chopped and aimed approximately perpendicular at the grating area of the sample. During the etching, which was done in buffered HF, the intensity, I_1, of the first-order diffraction beam was measured with a silicon PIN diode and a lock-in amplifier.

Figure 3 shows the recorder curves for three consecutive experiments. One observes the expected oscillations which stop after 5.5 min, indicating that the etching has reached the $Si\text{-}SiO_2$ interface. After about 7 min there is the sharp decrease which indicates an undercutting of $u = a/2 = 1.5$ μm. This interpretation was confirmed by microscopic inspection of the samples after the etching cycle.

Analysis of the Diffraction Intensity

For a quantitative interpretation of the oscillations of the diffracted intensity *vs.* time one has to use diffraction theory, which is relatively simple for the Fraunhofer regime only. The diffracted intensities of the 10 μm grating were measured for up to 12 orders with the incident beam polarized parallel and perpendicular to the grating lines. No significant difference was observed, which was taken as a justification to use the Fraunhofer integral (8). One can write the diffracted amplitude, U, for the case of a square aperture as

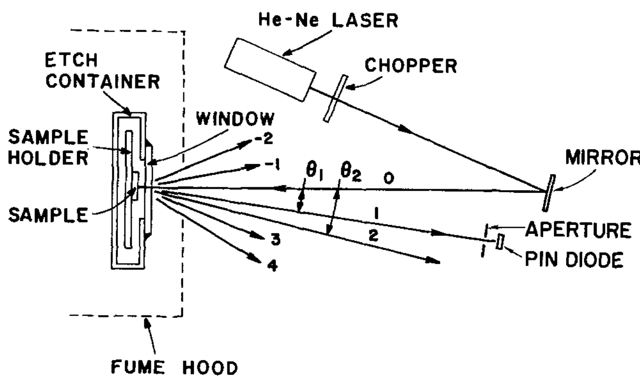

Fig. 2. First experimental set-up

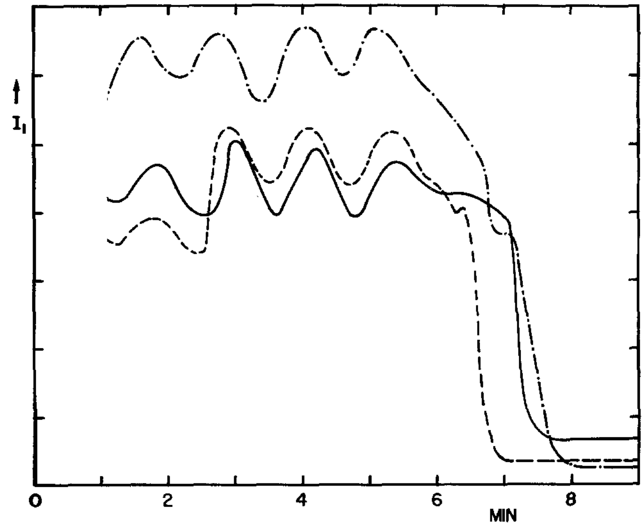

Fig. 3. First-order intensities vs. time of three samples with 10 μm gratings measured during wet etching.

$$U(\zeta) \propto \frac{e^{i\zeta N} - 1}{e^{i\zeta} - 1} \int_0^d r(x) e^{-i\zeta \frac{x}{d}} dx \quad [1]$$

Here N is the total number of grating lines, d the grating constant, and

$$\zeta \equiv \frac{2\pi}{\lambda} d \sin \theta \quad [2]$$

θ is the angle of diffraction (see Fig. 2). $r(x)$ is the complex reflectivity as a function of the coordinate x running perpendicular to the grating bars in the plane of the grating. The analysis will be restricted to a rectangular grating profile as shown in Fig. 4. Fortunately, as will be shown below, this will be good enough for our purpose. For this case the reflectivity, $r(x)$, can be taken to be constant across the grating bars ($= r_a$) and across the spaces in between ($= r_b$). If ϕ is the phase difference between the two reflectivities, one has

$$r(x) = \begin{cases} r_a \equiv |r_a| & i(o < x < a) \\ r_b \equiv |r_b| \exp(i\phi); & (a < x < d) \end{cases} \quad [3]$$

where $|r_a|$, $|r_b|$ and ϕ are independent of x.

On inserting Eq. [3] into Eq. [1] the intensity $I(\zeta) = |U|^2$ can be calculated. $I(\zeta)$ is large for $\zeta = m \cdot 2\pi$ only, *i.e.*, for the directions of the diffraction orders (order number m), namely

$$I(m) \propto \frac{\sin^2\left(m\pi \frac{a}{d}\right)}{m^2} [|r_a|^2 + |r_b|^2 - 2|r_a||r_b| \cos \phi] \quad [4]$$

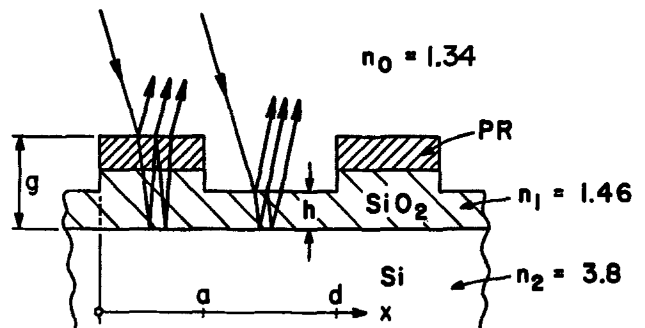

Fig. 4. Rectangular grating profile used for calculating diffraction intensities.

Note that the bracket does not contain the order number, m. In order to test the validity of the rectangular profile approximation, the intensities of the first 10 diffraction orders were measured quantitatively on several samples and plotted as a function of the order number, m. Figure 5 gives such a plot. The curve is a computer fit to the measured points according to Eq. [4]. As can be seen, the rectangular approximation is justified for the first three orders which is good enough for the present work since only the first-order intensities are used.

The reflectivities r_a and r_b in Eq. [4] depend on the refractive indexes and the thicknesses of the four media: etching solution, photoresist, SiO_2, and Si. For monitoring the SiO_2 thickness, h, in the region $a < x < d$ during etching, one only needs an expression for r as a function of h. Since in the practical case the photoresist is not etched, r_a can be considered to be constant. Using, for instance, Ref. (9) one gets for normal incidence

$$r_b = \frac{r_1 + r_2 \exp(i2\beta)}{1 + r_1 r_2 \exp(i2\beta)} \exp(i2\gamma) \qquad [5]$$

with

$$r_1 = \frac{n_0 - n_1}{n_0 + n_1}; \quad r_2 = \frac{n_1 - n_2}{n_1 + n_2} \qquad [6]$$

and

$$\beta = \frac{2\pi}{\lambda} n_1 h; \quad \gamma = \frac{2\pi}{\lambda} n_0 (g - h) \qquad [7]$$

n_0 is the refractive index of the etching solution (buffered HF), which we measured to be 1.34; $n_1 = 1.46$ for SiO_2; $n_2 = 3.8$ for Si at $\lambda = 6328Å$. The factor $\exp(i2\gamma)$ in Eq. [5] is due to profile depth, $g - h$ (see Fig. 4). From this one can calculate $|r_b|$, ϕ, and the bracket of Eq. [4], which is proportional to the intensity. The result is plotted in Fig. 6 for three photoresist thicknesses, *i.e.*, three different values of r_a. As can be seen, the main oscillations are the same for all three curves, having a period of about $\Delta h = 0.22$ μm.

Knowing this period, one can by comparison of Fig. 3 and 6 assign to each point in time an oxide thickness, h. We notice that within 5.5 min we go through a total of 4.5 periods of 0.22 μm each, which gives a layer thickness of 0.99 μm in good agreement with the ellipsometric value of 0.94 μm and an etch rate of 0.18 μm/min.

Plasma Etching of SiO_2 Layers

The technique of monitoring the etch depth and the etch rate described above was also tried out with plasma etching. The etching apparatus used was a commercial system: Model "PDE/PDS-301" built by the LFE Corporation. The etching chamber of this system has a plane front window which is suitable for the optical tests. The samples and the optical equipment were the same as described above.

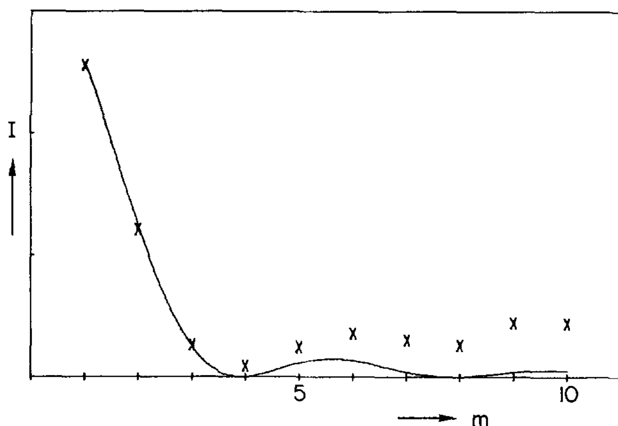

Fig. 5. Intensity vs. order number of a sample containing a 10 μm photoresist grating on Si + SiO_2. The curve is a fit to Eq. [4].

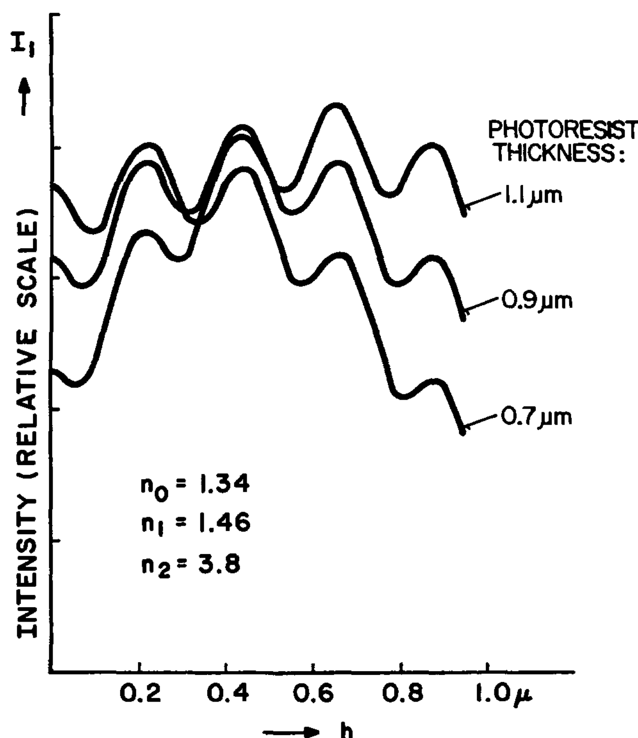

Fig. 6. Calculated first-order intensity as a function of the SiO_2 thickness, h, for three different photoresist thicknesses.

Figure 7 gives recordings of the first-order intensities for three runs with different flow rates of the reactive gas. Aside from the shoulders and small maxima in the top curve, which are very likely due to sputter abrasion of the photoresist, one can see that the spacing of the maxima decreases, *i.e.*, the etch rate increases, with increasing gas flow. In addition, the spacing of the maxima decreases, as the etching goes on; very likely an increase of etch rate due to heating (3).

It has to be pointed out that similar reflectivity oscillations can be obtained by interference in specular

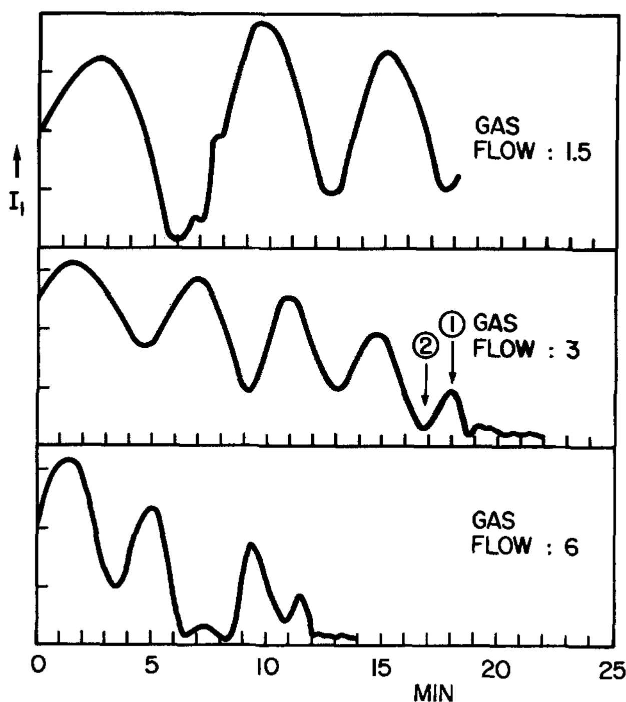

Fig. 7. First-order intensities vs. time of three samples measured during plasma etching.

reflection on uniform SiO_2 layers without gratings. However, the practical disadvantage of the specular reflection for monitoring IC processing is that it requires a uniform area on the sample which is as large as the laser beam. If a large part of the beam is reflected from other areas of the structure containing photoresist, other oxides, etc., this reflection will largely go in the same specular direction and distort or bury the wanted signal. The grating gives the possibility to use test areas on the wafer, which can be smaller than the laser beam. The detector properly positioned as in Fig. 2 will receive nearly no other signal but the one coming from the grating. All light reflected, diffracted, and scattered from other structures on the wafer will go mostly in other directions.

For a quantitative evaluation one again has to go through the analysis which was indicated above for wet etching with the only difference that now the refractive index of the surrounding medium is $n_0 = 1$ instead of 1.34. The results of these calculations are strong oscillations in I_1 with a period of 0.217 μm.

The middle and bottom curves in Fig. 7 show 5 maxima. The last maximum occurs after 4.4 periods giving a total oxide thickness of $4.4 \times 0.217 = 0.95$ μm in good agreement with the ellipsometric thickness measurement. After the 5th maximum the intensity drops to a low constant value. Microscopic inspection after that showed that the spaces not covered by photoresist were heavily pitted and showed a mat silvery gray color characteristic of bare Si.

In several etching experiments the process was interrupted at the top of the 5th maximum (arrow 1 in Fig. 7). The microscope then showed that the Si was bare and very little pitting was present. For other samples etching was stopped at the 4th minimum (arrow 2 in Fig. 7) leaving a residual SiO_2 layer of uniform blue color indicating a thickness of 700-800Å. These experiments prove that satisfactory control can be achieved by the monitoring process with the possibility to stop the etching at a given etch depth regardless of the etch rate, *i.e.*, independent of the particular conditions.

Nevertheless, this technique permits very rapid and simple measurement of the etch rates as the process goes on. As a demonstration of this we summarize in Fig. 8 these preliminary plasma etch data in terms of the etch rates in SiO_2 as a function of gas flow for two rf power levels. The etch rate at the beginning of the process (initial) is lower than the final value because of heating.

Plasma Etching of Si_3N_4 and SiO_2

The problem of defining patterns and etching windows into Si_3N_4-SiO_2 double layers is particularly suited for plasma etching. In this case wet chemical etching is rather complicated and troublesome. Therefore the optical monitoring technique was tried out for this case too, using samples with 1000Å of Si_3N_4 on top of 1 μm of SiO_2. Figure 9 gives one of the I_1 *vs* t curves taken during the process. In the first 5 min a rather irregular pattern is seen which is interpreted as the etching through Si_3N_4 indicating an etch rate of 200 Å/min. After that the curve looks similar to the other SiO_2 etching curves. The etch rates obtained from the curve fit quite well with the other SiO_2 etch rate data. They are included in Fig. 8 with the points marked "N".

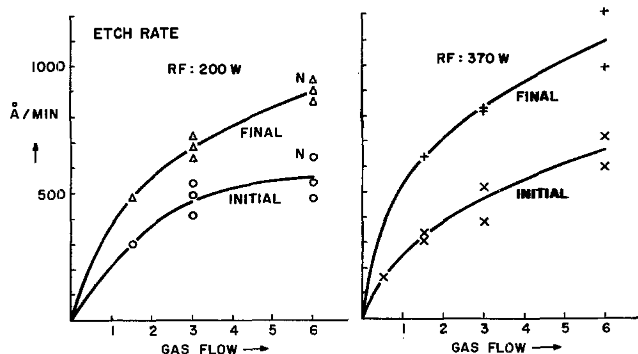

Fig. 8. Etch rates vs. gas flow in plasma etching

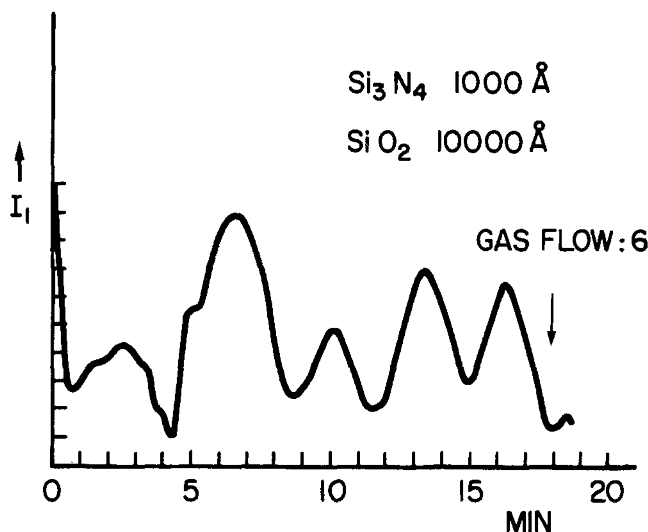

Fig. 9. First-order intensity vs. time during plasma etching of a Si_3N_4-SiO_2 double layer.

With the particular sample in Fig. 9 the etching was terminated after the 5th oxide maximum as shown. The microscope showed bare Si and pitting. In another run with a similar sample the etching was interrupted at the 4th minimum (arrow in Fig. 9). This left a blue, uniform 700Å thick SiO_2 layer. This thin SiO_2 layer can now easily be removed with dilute HF without the danger of undercutting.

Refinement of the Technique for Wet Etching

Encouraged by these exploratory experiments, we have proceeded to refine the technique to bring it closer to usefulness in the factory. In order to obtain a finer measure for the degree of underetching a test pattern containing 4 gratings with 4 different periodicities, $d = 10$, 6, 4, and 3 μm, and bar width $a \sim d/2$, was designed, which is sketched at the top of Fig. 10. The dimension, 1×1 mm, is small enough to fit into a "knock-out" area of the wafer. The four gratings are rotated by 45° with respect to one another. This results in 4 diffraction patterns which also are rotated by 45°, making the separation of the 4 signals easier. The bottom part of Fig. 10 shows the diffraction reflexes as they appear on a screen if the laser beam strikes the test pattern with normal incidence.

By positioning four Si detectors at the locations of the four first orders, one can simultaneously monitor the underetching of the 4 gratings. With $a = d/2$ one will expect the fall-off of the 4 signals for a lateral underetching, u, equal to 0.75, 1.0, 1.5, and 2.5 μm, respectively.

Figure 11 gives the traces of the signal from 3 of those 4 gratings recorded simultaneously during one etch run. One sees the oscillations, simultaneous in all 3 traces, and the fall-off successively for the 3, 4, and 6 μm gratings.

A large number of etching runs in buffered hydrofluoric acid were made. No special care was taken to keep the etch rate constant by temperature control or by always using fresh solutions, etc. This was not done, because the objective of the optical test is to obtain the right amount of etching in the presence of changing etch rates. In spite of these changes the characteristic behavior of the four first-order diffraction intensities of the 10, 6, 4, and 3 μm gratings as shown on the recorder were always the same. Another example of

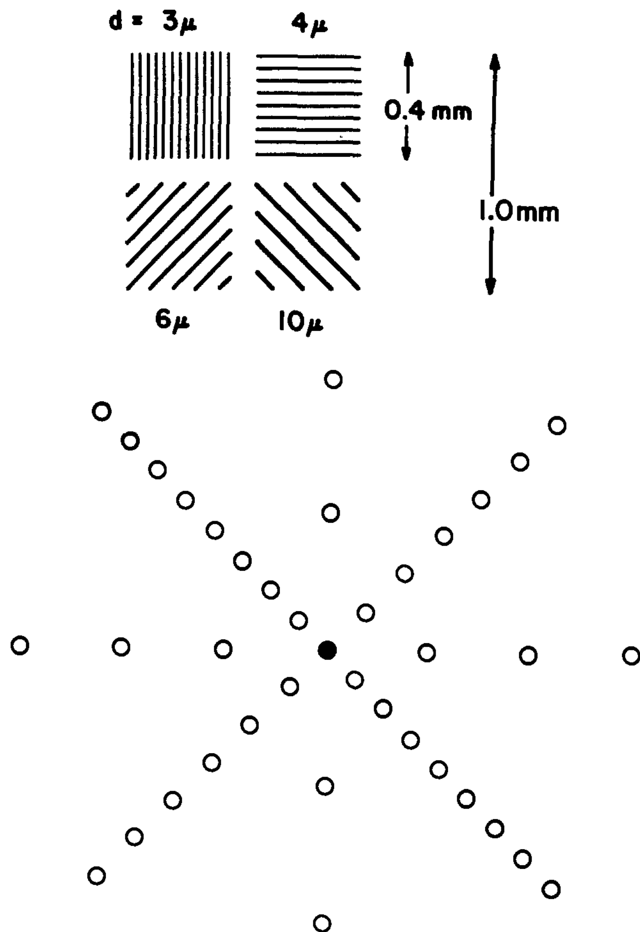

Fig. 10. Schematic drawing of the 4 grating test pattern (top) and the corresponding diffraction pattern.

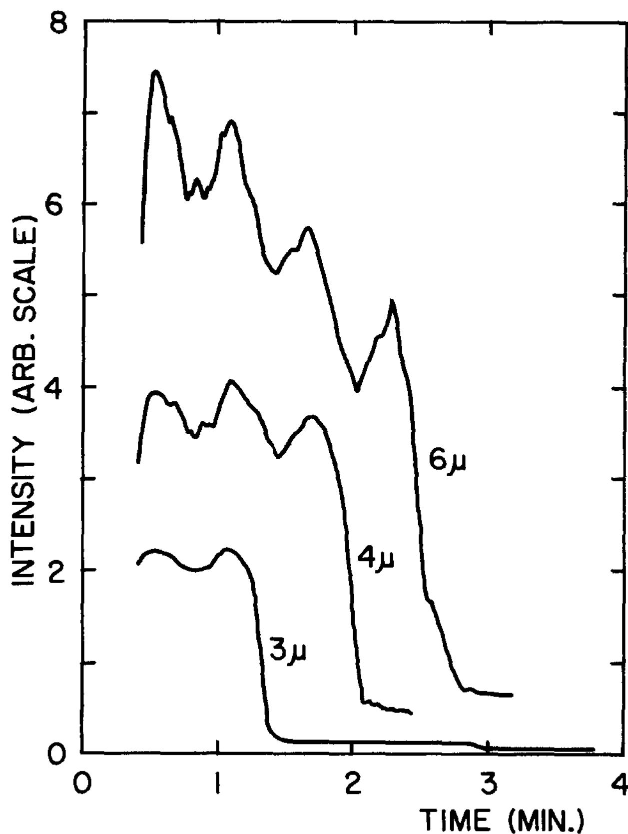

Fig. 11. Recorder trace of an etch run with first-order intensities for 3 gratings simultaneously.

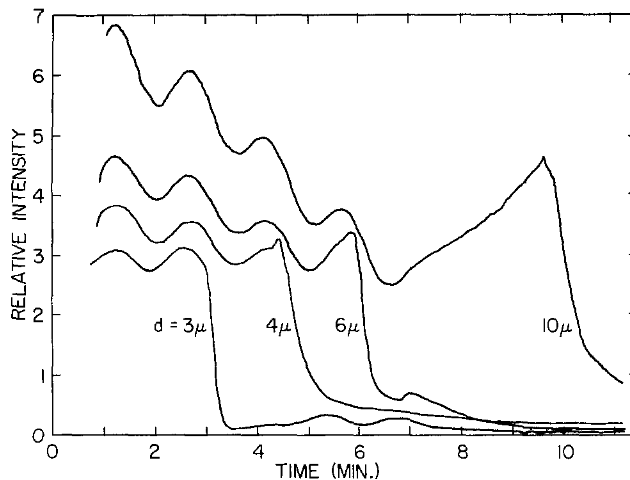

Fig. 12. Recorder trace of a typical etch run: first-order intensities of the four gratings (d = 3, 4, 6, and 10 µm) vs. time.

such a recorder trace for all 4 gratings is shown in Fig. 12. Again, all four signals oscillate in synchronism, each period corresponding to a decrease in h of about 0.22 µm. After about 2.2 periods, *i.e.*, after 0.48 µm of normal etching, the 3 µm grating starts to fall off. This indicates that in this case lateral undercutting has penetrated somewhat faster (0.75 µm) than the normal etching. After 3.3 periods (0.7 µm of normal etching) the 4 µm grating starts to fall off, indicating an undercutting of 1.0 µm, and after 4.1 periods (0.9 µm) the fall-off of the 6 µm grating starts, signaling an undercutting of 1.5 µm. The oscillations of the signal from the 10 µm grating stop after about 5 periods corresponding to the SiO_2 thickness of 1.1 µm. From then on the 10 µm signal rises smoothly until it shows a fall-off after 16 min, at which point the lateral etching has reached about 2.5 µm.

As can be seen from this plot, the normal etch rate is rather uniformly 0.16 µm/min and the lateral undercutting is about 1.5 times as fast as the normal etching for all four gratings. These figures may be different for other etch conditions. However, in any case a recording of the type of Fig. 12 gives the etch rate, and most important, signals the exact time at which the lateral underetching has reached a certain extent, namely, for the test pattern used here, 0.75, 1.0, 1.5, and 2.5 µm.

Finally Fig. 13 shows the equipment used for these last experiments. The test sample, T, is placed in a suitable etch container in the fume hood, H. This sample can be the end wafer of a whole lot of wafers being etched together. The beam of the laser, L, (λ = 0.6328 µm, 1 mW) goes through the chopper, C, and is di-

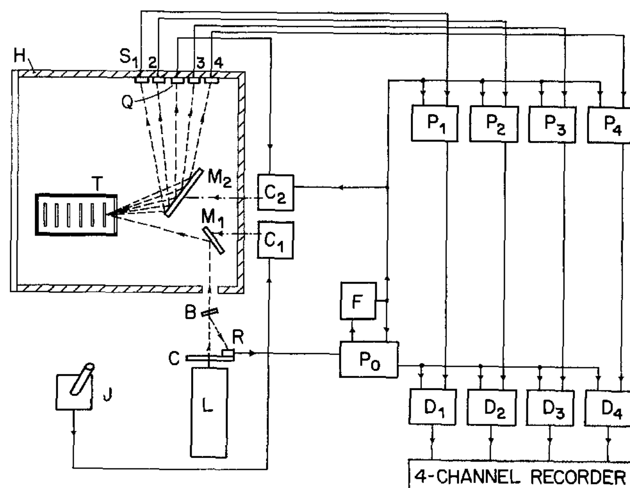

Fig. 13. Block diagram of the test set

rected by the mirror, M_1, at the test pattern on the sample. The mirror, M_2, directs the reflected diffraction pattern at the four silicon solar cells, S_1, S_2, S_3, and S_4, which are connected to the four phase-sensitive amplifiers P_1, P_2, P_3, and P_4. The signal coming from the reference detector, R, is amplified in P_0 and processed in F to be used as a frequency reference. The amplifiers P_1-P_4 are sample-and-hold type operational amplifiers, which make the system insensitive to room light. In order to be independent of any changes in the incident laser intensity, the reference signal is fed together with the signals from P_1 to P_4 into the divider circuits D_1, D_2, D_3, and D_4.

During the first experiments it was recognized that it was desirable to adjust the mirror, M_1, very quickly and conveniently in order to "find" the test pattern on the wafer during a few seconds after immersion into the etch bath. For this reason, the mirror, M_1, was equipped with servo motors for remote control of the two tilt angles, which are operated from the joy stick, J, via the servo circuit, C_1.

The mirror, M_2, is equipped with a similar servo system in order to make sure that, regardless of the orientation of M_1 and of the sample, the diffraction pattern always strikes the solar cells S_1-S_4. This servo system is controlled by the signal of a quadrant sensor, Q, which senses the position of zero-order diffracted beam.

Conclusion

Test patterns in the form of diffraction gratings offer a simple technique for the in-process control of the etching of patterns into SiO_2 through photoresist masks both for wet etching as well as for plasma etching. In the case of the wet etching the time at which the undercutting has reached a given amount can be determined by a pronounced drop of the diffraction signal. A test pattern containing several gratings of different line widths appears to be promising for the tailoring of a desired amount of undercutting. In plasma etching the grating technique gives reliable control of the etch depth even if the SiO_2 is covered with a Si_3N_4 layer.

The theory of this process as well as detailed information about the equipment has been given.

Oxidation of Copper in CO_2 at 800°-1000°C

W. J. Tomlinson and J. Yates[1]

Department of Applied Sciences, Lanchester Polytechnic, Eastlands, Rugby, United Kingdom

ABSTRACT

The oxidation of spectrographically pure copper in carbon dioxide has been studied at 800°-1000°C. An initial linear oxidation rate changed gradually to a second, lower, linear oxidation rate. During the first linear stage the surface was covered with a feathery pattern of small dendrites of unknown structure which were replaced progressively with more massive crystallites of Cu_2O associated with the second linear stage. The thickness of the Cu_2O layer at 1000°C when the surface was fully covered was 14 μm. Surface finish, preannealing, and gas flow rate in the range 0.1-2.0 cm sec^{-1} had no effect on the reaction. It is reasoned that the rate-controlling process was the decomposition of CO_2 to form chemisorbed oxygen which was influenced by a change of catalytic activity on the surfaces of the structures associated with the two linear kinetic curves.

Oxidation is a multistep process. The early stages involve oxygen dissolution in the metal and nucleation and growth of the oxide. Once the surface is covered with a continuous layer of oxide, for oxidation to continue the following steps for the reactants must occur: (*i*) transport within the gas, (*ii*) reaction at the gas/

[1] Chester Education Department, Chester, United Kingdom.
Key words: linear kinetics, nucleation, Cu_2O.

oxide interface, (*iii*) transport within the oxide, and (*iv*) reaction at the metal/oxide interface. One step is usually rate controlling, and the reaction is reflected in the kinetics. Parabolic oxidation kinetics typically indicates that diffusion within the oxide layer is rate controlling. Linear kinetics are relatively uncommon and imply that the slow step is a phase boundary reaction; provided the reaction products form a uniform dense layer they frequently change to a parabolic form as the amount of oxidation increases.

Linear oxidation in CO_2 or CO_2-CO mixtures has been observed with Fe by Hauffe and Pfeiffer (1) and other workers (2-5), with Co (6), Mn (7), Ni (8), and with Cu (9, 10). Hauffe and Pfeiffer found that the linear oxidation rate of Fe in CO_2/CO mixtures is proportional to $(P_{CO_2}/P_{CO})^{2/3}$, and the rate depended solely on the decomposition of CO_2 to form chemisorbed oxygen. Smeltzer (2) interpreted his linear oxidation rates of Fe in CO_2 as incorporation of chemisorbed oxygen into FeO at temperatures below 910°C and both dissociation of CO_2 and incorporation into FeO above 910°C. C. Wagner (11) derived a formula which indicated that the linear oxidation rate should depend not only on the CO_2/CO ratio but also on the sum of the partial pressures of CO_2 and CO. This was confirmed by Pettit *et al.* (4). Swaroop and J. B. Wagner studied the oxidation of Cu in CO_2/CO mixtures at 1000°C (10). Two linear curves were observed with a distinct change occurring at an oxide thickness of 0.4-0.6 μm. From the pressure dependence of the first linear rate constant, it was inferred that the reaction mechanism did not involve chemisorption.

The present work investigates the oxidation of Cu in CO_2 at 800°-1000°C. The equilibrium pressures of oxygen with CO_2, Cu_2O, and CuO are shown in Table I. From these data CuO is not expected to form on Cu oxidized in CO_2, and it is seen that the P_{O_2} from dissociation of CO_2 is only slightly greater than that from dissociation of Cu_2O. However, these data are for bulk substances at equilibrium, and during oxidation the interfacial energies and dynamic flow conditions will alter the thermodynamic data and possibly the catalytic effects due to the electronic/atomic defect equilibria being altered. The early stages of oxidation are usually very sensitive to surface structure and cleanliness, and so the purity of the Cu and CO_2, and the surface finish are important. Transport in the gas may also have an influence because of the low pressure of oxygen in CO_2.

Experimental

The Cu was spectrographically pure with maximum impurities (ppm): Ag 10, Pb 2, Si 1, Ca < 1, Mg < 1, Fe < 1. It was supplied by Johnson Matthey and Company Limited as 0.25 mm thick cold-worked sheet and cut into coupons about 4 cm² surface area with a hole for a Pt suspension wire. Four surface finishes were used. In the as-received condition the specimen was simply degreased in acetone before exposure. Mechanical polishing consisted of polishing to 6/0 grade paper then washing in turn with distilled water and acetone. The bath used for chemical polishing (12) consisted of 55 v/o HNO_3 (density 1.75), 25 v/o glacial acetic acid, and 20 v/o H_3PO_4 (density 1.40), and the specimen was immersed for 1-2 min at 55°C and then washed as above. The bath for electrochemical polishing was 33 cm³ HNO_3 and 67 cm³ CH_3OH cooled to 0°C and operated at 3V and 1 A cm^{-2} for 30 sec. After polishing the specimen was washed as above.

The quartz-spring thermobalance was similar to one used previously (13). The main difference was a magnetic winch which allowed insertion and removal of a specimen to and from the hot zone while under vacuum or CO_2. Temperature control was within ± 2°C and the weight gain could be measured to within ± 0.03 mg cm^{-2}. The operating procedure was as used previously (13), but in addition the oxidized specimen could be quickly quenched in cool CO_2.

Special analytical grade CO_2 supplied by Distillers Company Limited was used. It had maximum impurities : residual gases (non-KOH soluble) < 25 ppm (by volume), water < 50 ppm (by weight), and other gases < 5 ppm (by volume). The water content was further reduced by passing through silica gel and then phosphorus pentoxide. Gas flow was measured by a rotameter. Gas pressure was 1 atm.

Standard x-ray diffraction techniques were used to examine the surface products.

Table I. Equilibrium pressures of oxygen at 1000°C [Ref. (10)]

Reaction	P_{O_2} (atm)
$CO_2 = CO + \frac{1}{2} O_2$	1.2×10^{-6}
$Cu_2O = 2Cu + \frac{1}{2} O_2$	5.6×10^{-7}
$2CuO = Cu_2O + \frac{1}{2} O_2$	1.4×10^{-1}

Results

Figure 1 shows the rate curves for the oxidation of chemically polished Cu in CO_2 flowing at 0.2 cm sec^{-1}. At 900° and 1000°C there were two linear curves with the gradient of the first curve greater than that of the second, and an intermediate region which is shown dashed. At 800°C there was only one linear curve. The amount of oxidation was small, and in such cases surface finish, gas speed, and preannealing might be particularly important so oxidation data were obtained under the following conditions: (*i*) Cu chemically, mechanically, and electrolytically polished, and in the as-received condition, was oxidized at 800°-1000° in CO_2 flowing at 0.2 cm sec^{-1}; (*ii*) chemically polished Cu was oxidized at 1000°C in CO_2 flowing at 0.1-2.0 cm sec^{-1}; and (*iii*) Cu was preannealed at 1000°C and 10^{-5} mm Hg, chemically or electrolytically polished, then oxidized at 1000°C in CO_2 flowing at 0.2 cm sec^{-1}. In all cases the results were of the same form as Fig. 1. All these data are summarized in Tables II, III, and IV.

In Fig. 1 the points in the dashed region could belong to either curve. This represents a gradual transition from the first linear curve to that of the second. The extrapolated intersection coordinates of the lines were used to characterize the change, and these are reported with the other kinetic data in Tables II, III, and IV. It is seen that at 900° and 1000°C the transition

occurs at a critical weight gain of 0.6-0.7 mg cm^{-2} but at 800°C the total amount of oxidation was only 0.3 mg cm^{-2} so the transition was absent. An unexpected feature of the kinetic data is its insensitivity to changes in surface finish, preannealing, and gas speed in the range 0.1-0.2 cm sec^{-1}. Because of this insensitivity, all the data have been analyzed together, and the results are reported in Table V. The Arrhenius function of the first linear curve is shown in Fig. 2.

Specimens oxidized 72 hr at 900° and 1000°C were examined by x-ray diffraction powder techniques, and in back reflection after 40 and 72 hr at 1000 C and 72 hr at 800° and 900°C. The amount of reaction product at 800°C was too small to be detected. Cu_2O was observed in all other cases but no CuO was detected.

The surface was examined after oxidation at various times at 800°, 900°, and 1000°C. Figure 3 shows typical oxidized surfaces. There were two types of surface structures, one small, feathery, and acicular, and the other much larger, thicker, and more rounded. For convenience in this paper they will be called dendrites and crystallites, respectively. The crystallites were identified as Cu_2O, but the structure of the dendrites is uncertain. The formation of the surface products always followed the sequence: dendrites were nucleated

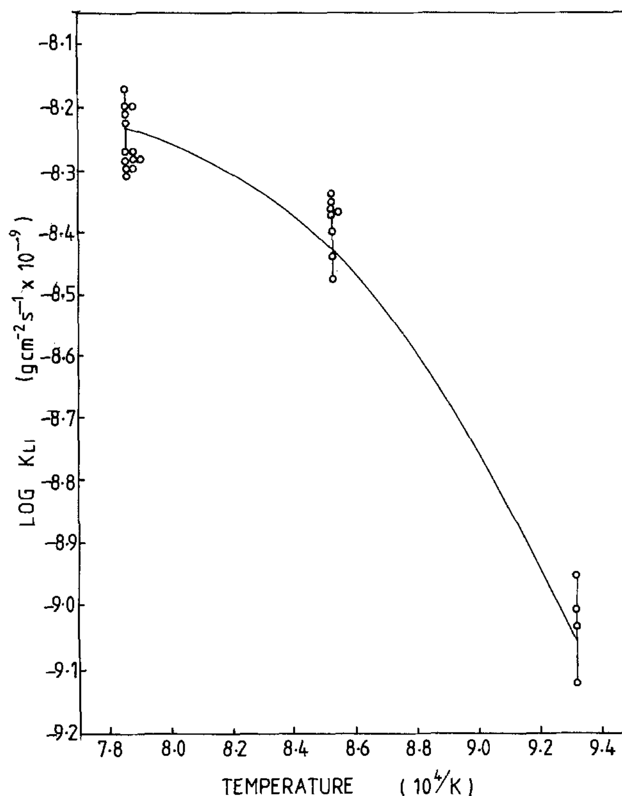

Fig. 2. The Arrhenius function of the first linear rate constant

(Fig. 3a) and spread rapidly over the whole surface (Fig. 3b), crystallites then nucleated on the dendrites, and further oxidation resulted in the growth of the crystallites (Fig. 3c) until the whole surface was covered (Fig. 3d). In Fig. 3 note that (a) is for oxidation at 800°C and the others for specimens oxidized at 1000°C. The reaction at 1000°C was so fast that it was not possible to record at 1000°C the stage shown in Fig. 3a for oxidation at 800°C. The times the structures appeared at each temperature are shown in Table VI where it is seen that the structures always appeared in the same sequence, but after longer times as the temperature was lowered. No detailed topographical studies were carried out but the crystal heights were estimated using the depth-of-focus of a microscope. Using a fine adjustment with a drum calibrated in micrometers, under oil immersion it was observed that for a given oxidation the crystallites were approximately the same height, and that at 1000°C their height was nearly the same for crystallites on specimens oxidized for 20 and 40 hr. The height of the dendrites was always very much less than the height of the crystallites. Figure 4 shows the cross section of the dendrites and crystallites formed on a specimen oxidized for 24 hr at 1000°C. The concave Cu surface clearly reflects the Cu used in the nucleation and growth of the oxide. The maximum thickness of the dendrites and crystallites shown are about 1-2 and 10 μm, respectively. Cu_2O has a density of 6.0 g cm^{-3} (14), so at 1000°C the Cu_2O film was about 14 μm thick when the surface was covered.

Discussion

The kinetic data summarized in Table V indicates good reproducibility for the rate constants in the two linear kinetic stages over the temperature range 800°-1000°C. Swaroop and Wagner (10) also observed at 1000°C two linear curves and the first one had rate constants in the range 6.1 to 8.93 × 10^{-9} g cm^{-2} sec^{-1}. This agrees well with the present, lower, values of 5.00-6.83 × 10^{-9} g cm^{-2} sec.$^{-1}$. However, the two linear curves of Swaroop and Wagner appear to make a sharp transition whereas in the present work the change was gradual over a large weight gain range.

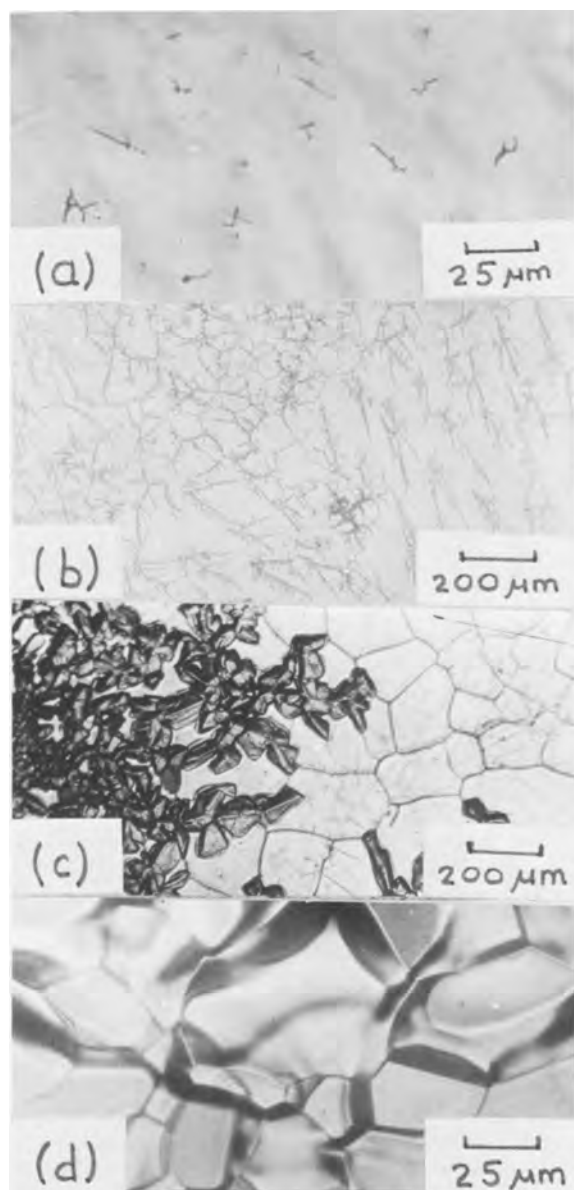

Fig. 3. Surface morphology of chemically polished Cu oxidized in CO_2. (a) 800°C, 72 hr; dendrites nucleated. (b) 1000°C, 10 min; dendrites cover the surface, a crystallite nucleating. (c) 1000°C, 20 hr; dendrites and crystallites. (d) 1000°C, 72 hr; surface covered with crystallites.

There is a direct relation between the kinetics and surface morphology. The kinetic transition co-ordinates are shown in Tables II, III, and IV, where it is seen that the change occurs at a critical amount of oxidation of 0.6-0.7 mg cm^{-2}, and in the time range 30-38 hr at 1000°C and 36-51 hr at 900°C. When compared with the surface morphologies, it is seen that the first linear kinetic curve occurs when mainly den-

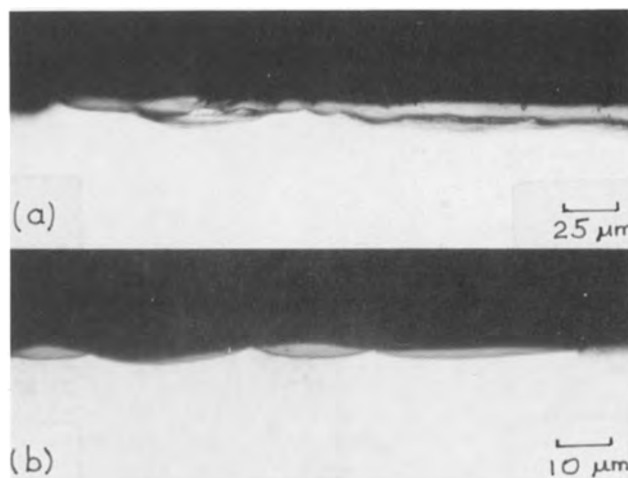

Fig. 4. Chemically polished Cu oxidized in CO_2 for 24 hr at 1000°C. Unetched. Cu at bottom. (a) Cross section of a crystallite about 10 μm thick. Note the concave Cu surface due to removal of Cu into the preexisting dendrites and separate crystallites before lateral growth formed the uniformly thick massive crystallite. (b) Cross section of dendrites in the intercrystalline regions. Note the concave Cu surface containing the oxide dendrites with a maximum thickness of 1-2 μm.

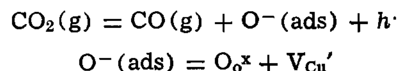
drites cover the surface, and the second linear curve is associated with the crystallites, and the gradual change in kinetics reflects the change in structure as the crystallites grow to cover the surface. Because the two gradients are so close, scatter in the data tends to mask the transition and so the change in kinetics cannot be defined precisely. A more appropriate equation describing the apparent dependence of the rate constant on surface features would be

$$\text{rate} = K_{L1}(1 - f) + K_{L2}f$$

where f is the fraction of the surface that is covered with crystallites.

Linear oxidation kinetics reflect a phase boundary reaction, or a constant rate of supply of gas from the interior of the gas across a boundary layer of constant thickness. In the present case gas supply is not the rate-controlling process since the thickness of the boundary layer, and so the flux of gas reaching the surface, is a function of gas speed, and no effect of gas speed on the oxidation rate was detected. Moreover, if the gas supply was rate controlling, then there would be only one linear reaction rate corresponding to the gas supply, whereas two linear kinetic curves were observed. The insensitivity of the kinetics to surface finish and preannealing indicates that the rate-controlling process is also not at the metal/oxide interface. It appears from these considerations that reaction control is at the oxide/gas interface where the possible reactions are chemisorption and incorporation represented by the equations



$$CO_2(g) = CO(g) + O^-(ads) + h^{\cdot}$$

$$O^-(ads) = O_o^x + V_{Cu}'$$

with similar equations for O(ads) and O^{2-}(ads). Here the defect chemistry notation of Kröger and Vink (15) is used. The average activation energies of the first linear curve (Fig. 2) are of the order $E_{800\text{-}900} = 170$ kJ mol^{-1} and $E_{900\text{-}1000} = 50$ kJ mol^{-1} and while these have no detailed diagnostic value it is clear that they are within those typical of adsorption processes, and also they become less as the temperature is increased. Hauffe and Pfeiffer (1) have shown that the rate-controlling process during the oxidation of Fe in CO_2/CO mixtures is the decomposition of CO_2 on the surface to form chemisorbed O^-. Also Kobayashi and Wagner

have shown (16) that the catalytic activity of a surface depends not only on the composition of the gas phase, but also on the composition of the solid phase, in particular the concentration of electronic defects.

During the second linear stage the catalytic surface is clearly Cu_2O crystallites but during the first linear stage the surface structure is uncertain. While spread over the whole surface, the dendrites represent only a small fraction of the area. The Cu atoms in Cu_2O form a fcc lattice with oxygen atoms occupying one quarter of the tetrahedral sites (17). The linear misfit in the Cu_2O/Cu system is 18% (18), and it is probable that the dendrites are a distorted epitaxial form of Cu_2O. Considerable effort has been made in nucleation studies to identify the surface structures in between the nuclei but its nature is still largely conjectural. Rhead (19) assumed on the basis of known data that a thin layer exists which is intermediate between a chemisorbed layer and an oxide layer which is formed by place exchange, and the mixed character of such an adsorbed layer has been shown by recent emission microscopical research where molecules made up of a nucleus of three or four metal atoms around an oxygen atom have been identified (20).

With Cu_2O the equation of nonstoichiometry is

$$\frac{1}{2}\, O_2(g) = O_o^x + V_{Cu}'' + 2\, h^{\cdot}$$

and there is a relation between the concentrations of atomic and electronic defects. Since the energies of the intermediate layer/metastable Cu_2O and Cu_2O are different they will have different concentrations of atomic defects and so by the above, different concentrations of $h^{\cdot}$, *i.e.*, the two surfaces will have similar but slightly different catalytic activities. The two linear rate constants are similar in magnitude and so could reflect the different rates of catalytic decomposition of CO_2 to form adsorbed oxygen on the two similar surfaces. Moreover, the higher linear rate constant is associated with the intermediate surface structures which would be expected to have a higher catalytic activity. Also a nonlinear activation energy as observed for the first linear rate (Fig. 2) is not inconsistent with these ideas. Dissociation of defect complexes and/or ionization of defects may occur (21, 22) as the temperature is raised, and these would alter the concentrations of atomic and electronic defects and so affect the catalytic activity of the surface. A complication with oxidation in CO_2 is that there will be additional oxygen at higher temperatures owing to the greater degree of dissociation of CO_2. However, in the present case there is a lower than expected oxidation rate at higher temperatures and this would indicate that the rate of oxidation is less sensitive to the extra oxygen present than it is to the reduced catalytic activity of the surface. A possible cause of such a reduced catalytic activity as the temperature is raised is that the intermediate structure of the catalytic surface may move towards a lower energy and so less active structure. A similar mechanism to decomposition of CO_2 has been observed with the decomposition of N_2O on Cu_2O and the simultaneous oxidation of Cu, where the catalytic decomposition depended on the concentration of $h^{\cdot}$ (23).

Swaroop and Wagner (10) found that the first linear rate constant for Cu oxidized in CO_2/Ar mixtures obeyed an empirical equation of the form

$$K_{L1} = CP^{n}_{CO_2}$$

where C and n are constants, and found values of $n =$ 1.3 and 1.5. For oxidation of Ni in CO_2/CO mixtures $n = 1$ and for Fe in CO_2/CO mixtures $n = 0.33$ while Fe in low pressure oxygen $n = 0.7$ (10). It is stated (10) that for $n > 1$ the oxidation mechanism is not due to chemisorption but the basis of this statement is not clear. Moreover, Swaroop and Wagner have taken their surface oxide in the first linear stage to be Cu_2O and have assumed it forms a uniform layer, whereas in the present work the first linear kinetics is associated with an intermediate surface structure whose area is changing, and it may be that the cause of the unusual (if indeed they are) n values for Cu is the changing areas during nucleation and growth available for a catalytic chemisorption reaction.

Conclusions

Copper oxidized in CO_2 at 800°-1000°C follows an initial linear kinetic law which changes gradually to a second, lower, linear law. At any temperature small feathery-patterned unstable dendrites formed. Later crystallites of Cu_2O formed on the dendrites and grew to cover the whole surface. The first linear curve was associated with a surface covered with dendrites and the second linear curve with the Cu_2O crystallites. Surface finish, preannealing, and gas flow rate in the range 0.1-2.0 cm sec^{-1} have no effect on the oxidation rate. It is considered that the rate-controlling process is the catalytic decomposition of CO_2 on the surface to form chemisorbed oxygen.

Manuscript submitted Oct. 27, 1976; revised manuscript received Nov. 18, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Thermodynamic Properties of Metal-Water Systems at Elevated Temperatures

Dale F. Taylor

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The advent of commercial nuclear power generation has created an increased need for thermodynamic data on metal-water systems at temperatures up to 350°C. The entropy correspondence principle discovered by Criss and Cobble [*J. Am. Chem. Soc.*, **86**, 5385 and 5391 (1964)] provides an excellent means of estimating high-temperature partial molar ionic entropies and hence high-temperature heat capacities, from entropy values at 25°C. It is therefore often possible to calculate both equilibrium constants and standard electrode potentials with surprising accuracy for elevated temperatures. Unfortunately, different conventions have been used by several authors in publishing calculated numerical data. One purpose of the present paper is to clarify these differences. In addition, a means of simplifying the calculations is described. This new approach permits rapid modification or augmentation of existing values when more accurate data become available, or when information at other temperatures is required. Values of K_w, the ionization product of water, and $E^\circ_{AgX/Ag}$, the standard electrode potentials of silver-silver halide electrodes, are calculated as examples for temperatures up to 300°C, and these values are compared with available experimental data.

The advent of commercial nuclear power generation has created an increased need for thermodynamic data on metal-water systems at temperatures up to 350°C. An understanding of the corrosion processes which can facilitate the transport of radioactive contaminants or cause cracking of structural materials is particularly important, and with faster reaction rates at higher temperatures, thermodynamic properties play an increasingly important role in controlling the chemistry of dissolved species.

Unfortunately the entropy, heat capacity, and volume data required for calculating the relevant values of ΔG°, and hence the equilibrium constants and standard cell potentials, for conditions other than 25°C and 1 atm pressure are not presently available for many species of interest. However, the entropy correspondence principle discovered by Criss and Cobble (1) provides an excellent means of estimating high-temperature partial molar ionic entropies, and hence high-temperature heat capacities, from entropy values at 25°C. It is therefore often possible to calculate both equilibrium constants and standard electrode potentials with surprising accuracy for elevated temperatures. For example, at temperatures up to 250°C, most predicted values of K_w, the ionization product of water, and $E^\circ_{AgX/Ag}$, the standard electrode potentials of silver-silver halide electrodes, agree with available measured values within the quoted experimental uncertainty. Beyond 250°C, the contribution of pressure to changes in free energy starts to become important, and systematic deviations occur. Calculations involving temperatures above 300°C are probably only semiquantitatively correct.

Robins *et al.* (2), Townsend (3), Cowan and Staehle (4), MacDonald *et al.* (5-7), and Cobble and Murray (8) among others, have used this approach to predict the thermodynamic behavior of several elements and their oxidation products in high-temperature aqueous systems. Some confusion may arise, however, because different conventions have been used in listing numerical data. One purpose of the present paper is to clarify these differences.

In addition, a means of simplifying the calculations is described. This new approach permits rapid modification or augmentation of existing values when more accurate data become available, or when information at other temperatures is required.

Key words: electrolyte, chemical potential, heat capacity, entropy, equilibrium constant, standard hydrogen electrode (SHE), electrode potential.

Free Energy Changes at Elevated Temperatures

For a reaction which goes to completion at temperature T and pressure P, the change in free energy is given by

$$\Delta G = \sum_p \alpha_p \mu_p - \sum_r \alpha_r \mu_r \qquad [1]$$

where α_p and α_r are the stoichiometric coefficients of the products and reactants, respectively, and $\mu(T, P)$ is the chemical potential: the molar free energy for pure substances and the partial molar free energy for species in solution.

Since the activity of system component i, a_i, is defined by

$$\mu_i(T, P) = \mu_i^\circ + RT \ln a_i \qquad [2]$$

where μ_i° is the chemical potential of component i in some conveniently specified standard state at temperature T, the value of μ_i° depends on the units chosen to express a_i, and on the choice of standard state. The standard state for gases is the hypothetical pure ideal gas at unit pressure, usually 1 atm. The standard chemical potential μ°_{gas} thus depends only on temperature. The standard state for a liquid or solid element or compound is its stable state of aggregation as a pure substance at equilibrium, and therefore μ°_{solid} and μ°_{liquid} depend on both the temperature and pressure. This is the usual choice of standard state for the solvent in an electrolyte solution, but it is not convenient for the solute. The standard state for electrolyte solutions is that of a hypothetical ideal solution at unit concentration, most often unit molality to avoid complications from density changes, and μ°_{solute} is dependent on both temperature and pressure.

If the chemical potential of any component in its standard state is known at 25°C, 1 atm (298.15°K, 1.01325×10^5 Pa), integration of the relationships

$$\left(\frac{\partial \mu_i}{\partial T}\right)_P = -\bar{S}_i, \quad \left(\frac{\partial \mu_i}{\partial P}\right)_T = \bar{V}_i \qquad [3]$$

with the definition

$$\left(\frac{\partial \bar{S}_i}{\partial T}\right)_P \equiv \frac{\bar{C}_{P_i}}{T} \qquad [4]$$

yields the chemical potential of this component in its

standard state at any temperature (or pressure for condensed phases and electrolyte solutions)

$$\mu_i^\circ(T,P) = \mu_i^\circ(25^\circ C, 1\ \text{atm}) + \int_{1\ \text{atm}}^{P} \overline{V}_i^\circ dP'$$
$$+ \int_{298.15}^{T} \overline{C}_{Pi}^\circ dT' - T\int_{298.15}^{T} \overline{C}_{Pi}^\circ d\ln T'$$
$$- (T - 298.15)\overline{S}_i^\circ(25^\circ C, 1\ \text{atm}) \quad [5]$$

where the superscript ° denotes the standard state and unit activity, V, S, and C_P have their usual thermodynamic meanings, and the superscript $^-$ denotes $(\partial/\partial n_i)_{P,T,n_j}$: the molar value for pure substances and the partial molar value for components in solution.

$\Delta\mu_i^\circ$ is independent of the integration path, but since $\overline{V}_i^\circ$ and $\overline{C}_{Pi}^\circ$ are each functions of both T and P, the order of integration is important. $\overline{C}_{Pi}^\circ$ is generally available as a function of temperature for a pressure of 1 atm. $\overline{V}_i^\circ$ is then required as a function of P at temperature T.

$\mu_i^\circ(25^\circ C, 1\ \text{atm})$ for ions in solution and pure compounds is defined as the molar Gibbs free energy of formation by Eq. [1] and the convention which assigns a chemical potential of zero to H^+_{aq} and the elements in their standard states at the arbitrary reference point of 25°C and 1 atm. Thus the values of $\mu_i^\circ(T, P)$ calculated from [5] are not correct on an absolute scale, but the value of $\Delta G^\circ(T,P)$ calculated from [1] for any reaction is correct because a change is being evaluated and the arbitrary zero cancels out. This approach to calculating $\Delta G^\circ(T,P)$ is particularly convenient when a number of reactions with several common reactants and products are being considered. MacDonald was the first to adopt the procedure, but added an unnecessary complication by extending the Gibbs energy of formation terminology to temperatures and pressures other than 25°C and 1 atm (5, 9, 10).[1]

Cobble anticipated minor effects from changes in partial molar volumes at temperatures up to 300°C, and suggested that the pressure term could be ignored, especially since very little is known about the partial molar volumes of ions (11). It will be shown that this approximation is a good one.

Accurate molar heat capacity data is available for many pure substances in a readily integrable power series of the form (12, 13)

$$\overline{C}_{Pi}^\circ(T) = A_i + B_iT + C_iT^{-2} \quad [6]$$

but ionic partial molar heat capacities are generally not available.

Criss and Cobble (1) developed a technique for evaluating $\overline{S}_i^\circ(T)$ for ions, and their results suggest a very simple new approach to calculating $\overline{C}_{Pi}^\circ$, one which is both more accurate at higher temperatures than the average value they proposed, and conveniently consistent with [6].

[1] Cobble and Murray (8) have chosen to list values of the free energy function (FEF) based on a reference temperature of 25°C

$$\text{FEF}_i(T) \equiv \frac{\mu_i^\circ(T) - \overline{H}_i^\circ(25^\circ C)}{T} = \frac{\overline{H}_i^\circ(T) - \overline{H}_i^\circ(25^\circ C)}{T} - \overline{S}_i^\circ(T)$$

Thus, since

$$\text{FEF}_i(T) = \frac{1}{T}\int_{298.15}^{T} \overline{C}_{P_i}^\circ(T')dT' - \int_{298.15}^{T} \overline{C}_{P_i}^\circ(T')d\ln T' - \overline{S}_i^\circ(25^\circ C)$$

$$\mu_i^\circ(T) = \mu_i^\circ(25^\circ C) + T[\text{FEF}_i(T)] - 298.15[\text{FEF}_i(25^\circ C)]$$

This modification of the direct approach requires separate specification of μ_i° (25°C) values and some additional computation. However, the value of $\overline{S}_i^\circ$ (25°C) is immediately available as—FEF_i (25°C), and the slow variation of the free energy function with temperature permits interpolation between calculated values.

Criss and Cobble observed that "a standard state can be chosen at every temperature such that the partial molar entropies of one class of ions at that temperature are linearly related to the corresponding entropies at some reference temperature." The zero for ionic entropies at each temperature was defined by the value of $\overline{\overline{S}}{}^\circ_{H^+}(T)$, the partial molar ionic entropy of the hydrogen ion which resulted in the best linear fit of experimental data. The reference temperature was chosen to be 25°C. Thus for a given class of ion (simple cations, simple anions, oxy-anions, acid oxy-anions)

$$\overline{\overline{S}}{}_i^\circ(T) = a(T) + b(T)\overline{\overline{S}}{}_i^\circ(25^\circ C) \quad [7]$$

where $\overline{\overline{S}}$ denotes a partial molar entropy not referred to the conventional scale which sets $\overline{S}^\circ_{H^+}(T) \equiv 0$.

In fact, the $\overline{\overline{S}}{}_i^\circ$ values defined in this manner appear to be absolute or "third law" entropies. $\overline{\overline{S}}{}^\circ_{H^+}$ (25°C) is −5.0 calories mole^{-1} degree^{-1}, in relatively good agreement with the value of −4.48 calories mole^{-1} degree^{-1} deduced by deBethune *et al.* for the standard ionic entropy of electrochemical transport of hydrogen ions at 25°C (14), and the value of −5.5 calories mole^{-1} degree^{-1} obtained by Laidler and Pegis for the standard entropy of hydration of hydrogen ions (15).

Entropies on the conventional scale are related to the absolute scale at any temperature by the equation

$$\overline{\overline{S}}{}_i^\circ(T) = \overline{S}_i^\circ(T) + z\overline{\overline{S}}{}^\circ_{H^+}(T) \quad [8]$$

where z is the charge on the ion (with sign). At 25°C, this becomes

$$\overline{\overline{S}}{}_i^\circ(25^\circ C) = \overline{S}_i^\circ(25^\circ C) - 5.0z \quad [9]$$

Criss and Cobble noted that up to 150°C the parameters $a(T)$ and $b(T)$ in Eq. [7] varied approximately linearly with temperature, with most of the deviation occurring near 60°C. On this basis they extrapolated their results to 300°C. Thus for a given class of ion, the tabulated values can be reproduced quite accurately by relationships of the form

$$a = a_1 + a_2T, \quad b = b_1 + b_2T \quad [10]$$

and by substituting from Eq. [7] and [10] into [4]

$$\overline{C}_{Pi}^\circ(T) = [a_2 + b_2\overline{\overline{S}}{}_i^\circ(25^\circ C)]T \equiv B_iT \quad [11]$$

Equation [11] will be referred to as the linear ionic heat capacity approximation (LIHCA). This relationship makes computer or calculator programs based on Eq. [5] and [6] directly applicable to ionic species with $A_i = C_i = 0$, and μ_i° can be calculated in one step for any temperature in the range where the constant pressure approximation is valid. Note that the choice of $\overline{S}_i^\circ(25^\circ C)$ or $\overline{\overline{S}}{}_i^\circ(25C^\circ)$ in Eq. [5] does not affect the value of ΔG° obtained from [3] provided that the same choice is made for calculations of all μ_i°. Since absolute values must be used in [11], there is less confusion if they are used throughout. In either case, the choice of convention must be clearly stated.

The apparent linearity of partial molar ionic heat capacities with temperature was noted first in studies of weak acids (16, 17), and the work of Criss and Cobble (1) seems to confirm its generality. Naumov *et al.* (18) also list partial molar ionic heat capacities in this form. A reasonable estimate of high-temperature partial molar ionic heat capacities can thus be obtained easily when the values at 25°C are available.

Electrode Potentials at Elevated Temperatures

The change in free energy for the generalized reduction in an aqueous system

$$aA + hH^+ + ne^- = bB + wH_2O \quad [12]$$

is not experimentally accessible, but the tendency for any such reduction to occur can be measured relative

to a standard reduction, usually chosen to be the standard hydrogen electrode (SHE) reaction

$$H^+(a_{H^+} = 1) + e^- = 1/2\, H_2(a_{H_2} = 1) \quad [13]$$

in aqueous systems. Thus for constant n, the values of $\Delta G°_{A/B}$ at any temperature for the complete reactions represented by

$$aA + (h - n)H^+ + \frac{n}{2} H_2 = bB + wH_2O \quad [14]$$

are one basis for comparing the relative tendencies of the reductions represented by [12] to occur at that temperature.

Since

$$\Delta G = - n\mathbf{F}E \quad [15]$$

where E is a measurable cell potential and $\mathbf{F}$ is the Faraday, it is logical to define a "standard electrode potential" for [12]

$$E°_{A/B} \equiv -\Delta G°_{A/B}/n\mathbf{F} \quad [16]$$

The standard electrode potential for [12] at any temperature can therefore be obtained by determining $\Delta G°_{A/B}$ through Eq. [1] and [5]. It follows as a natural consequence of [16] that

$$E°_{H^+/H_2} = 0 \quad [17]$$

at all temperatures since $\Delta G°_{A/B}$ is identically zero when Eq. [12] represents the SHE reaction.

The definition of the standard electrode potential can be generalized to include activities other than unity for the reactants and products in [12] through Eq. [1] and [2]. Since the activities of H_2 and H^+ contributed from [13] are unity by definition

$$E_{A/B} = E°_{A/B} - \frac{RT}{n\mathbf{F}} \ln \left[\frac{a_B{}^b a_{H_2O}{}^w}{a_A{}^a a_{H^+}{}^h} \right] \quad [18]$$

The electrode potential, or "potential *vs.* SHE at the same temperature" provides a very convenient basis for comparison among all the reactions which are possible in the system at a given temperature.

The concept of the electrode potential is by definition independent of the convention which sets $\mu°_{H_2}$ and $\mu°_{H^+}$ equal to 0 at 25°C, and does not require, as suggested by Van Rysselberghe (19), that

$$\tfrac{1}{2}\mu°_{H_2} = \mu°_{H^+} \quad [19]$$

This relationship is true only at the temperature for which $\mu°_{H_2}$ and $\mu°_{H^+}$ are defined to be zero.

The variation of $E_{A/B}$ with temperature defines the "isothermal" temperature coefficient of the electrode potential since $E_{A/B}$ is referred to the SHE at the same temperature. Another alternative for describing the effect of temperature on reaction [12] is to measure the tendency for this reaction to occur at temperature T relative to the same reaction at a fixed reference temperature, normally 25°C. This is satisfying from an experimental point of view since any two identical electrodes at different temperatures in the same cell will develop a potential difference which is independent of metallic thermocouple effects and the thermal liquid junction potential (14).

For two hydrogen electrodes, this thermal cell reaction is

$$H^+(T) + \tfrac{1}{2} H_2(25°C) = \tfrac{1}{2} H_2(T) + H^+(25°C) \quad [20]$$

and

$$\Delta G°^*_{H^+/H_2}(T) = \tfrac{1}{2}\mu°_{H_2}(T) - \mu°_{H^+}(T) \quad [21]$$

where * denotes the 25°C "thermal" convention. In a manner analogous to that used in defining $E°$, a standard "thermal" electrode potential can be defined for the SHE

$$E°^*_{H^+/H_2}(T) = - \Delta G°^*_{H^+/H_2}(T)/\mathbf{F} \quad [22]$$

It is important to note that absolute ionic entropies must be used in Eq. [5] to obtain standard thermal electrode potentials. The use of absolute entropies for all calculations therefore seems advisable.

Comparison of the Linear Ionic Heat Capacity Approximation with Experimental Data

Very accurate values for the ionic dissociation constant of water, K_w (20), and the standard electrode potentials (*vs.* SHE at the same temperature) of the silver/silver halide electrodes (21-23) are available for comparison with predicted values over a wide temperature range. Both comparisons have been made previously on a limited or graphical basis using the multiparameter Criss-Cobble approximation (4, 6, 11). These studies provide an excellent source of calculated data. In addition, the measurements of Fales and Mudge (24) are available for verifying predictions of thermal hydrogen electrode potentials up to 60°C.

Table I contains the thermodynamic data used in all the calculations of $\mu_i°$ values. The parameters for water are not included since $\mu°_{H_2O}$ values were taken directly from the data of Helgeson and Kirkham (25) and these are listed in Table II. $\mu°_{OH^-}(25°C)$ was calculated by [1] using the value of $\Delta G°_w(25°C)$ determined by Sweeton, Mesmer, and Baes (20)

$$H_2O = H^+ + OH^- \quad [23]$$

$$\Delta G°_w = - RT \ln K_w = \mu°_{H^+} + \mu°_{OH^-} - \mu°_{H_2O} \quad [24]$$

B_i values (for $\overline{C}_{Pi}°$) were calculated from Eq. [4] for H^+ and Eq. [11] for the other ions. A linear fit of the Criss-Cobble entropy parameters to 300°C, excluding the values at 60°C, resulted in the following values for H^+, and simple anions

$$(\partial \overline{\overline{S}}°_{H^+}/\partial T)_P = 9.35 \times 10^{-2} \text{ cal mole}^{-1} \text{ deg}^{-2}$$
$$a_2 = -1.77 \times 10^{-1} \text{ cal mole}^{-1} \text{ deg}^{-2}$$
$$b_2 = -1.12 \times 10^{-4} \text{ deg}^{-1}$$

Table II summarizes the results from calculations of $\Delta G°_w$ and pK_w using the linear ionic heat capacity approximation (LIHCA). The number of significant figures is not warranted by the accuracy of the original

data, but all $\mu_i°$ and $\Delta G°$ values were calculated to the nearest calorie for direct comparison with the results published by other authors. Six of the calculated pK_w values are within ±0.1% of the experimental values, and all ten of the values up to 250°C deviate less than ±0.25%. The deviation at 275°C is −0.43%, and at 300°C, −1%.

This systematic error escalation above 250°C probably results from contributions to $\Delta G°$ by the rapidly increasing vapor pressure of water. Sweeton *et al.* indicated that the effects of density changes on the partial molar volumes of ions are not well understood in this temperature region (20). Extrapolation of the constant pressure approximation to temperatures above 300°C is a questionable procedure, especially since no experimental data are available for comparison.

The accuracy below 300°C is quite remarkable. MacDonald and Butler (6, 9) assumed all discrepancies in K_w were the result of inaccuracies in $\mu°_{H^+}$ and recalculated "corrected" values of this parameter for application to other systems. However, since Criss and Cobble obtained $\bar{\bar{S}}°_{H^+}$ by fitting all available ionic entropy data (1), $\mu°_{H^+}$ is probably more accurate than the other calculated values, and further comparison with experimental observations seems to bear this out.

Table III lists the results from calculations of $\mu_i°$ for components of the hydrogen and silver-silver halide electrodes, again using the linear ionic heat capacity approximation.

Corresponding standard potentials (*vs.* SHE at the same temperature) appear in Table IV, along with values calculated from MacDonald and Butler's results (6) and observed values (21-23). Equation [14] takes the form

$$AgX + \tfrac{1}{2} H_2 = Ag + H^+ + X^- \quad [25]$$

and hence

$$E°_{AgX/Ag} = (\mu°_{AgX} + \tfrac{1}{2}\mu°_{H_2} - \mu°_{Ag} - \mu°_{H^+} - \mu°_{X^-})/\mathbf{F} \quad [26]$$

A value of 23060.9 calories V^{-1} equivalent^{-1} was used for **F**.

Once again, the calculated results are quite accurate. The agreement for Ag/AgCl is almost perfect. The very systematic error of ~+4 mV for Ag/AgBr can be eliminated by a change of +90 cal in the $\mu°_{Br^-}$(25°C) value. The Ag/AgI results do not agree nearly as well, and no simple adjustment of parameters can bring them more closely into line. However, the linear ionic heat capacity approximation with no special adjustment of parameters duplicates the MacDonald-Butler results at lower temperatures, and yields consistently better results at higher temperatures.

The excellent agreement with experimental results obtained for K_w and the silver-silver chloride and

[1] Experimental.
[2] Smoothed/extrapolated.

bromide standard potentials undoubtedly reflects the fact that these or similar experimental results were used to determine values for the parameters of the correspondence principle in the first place. This in no way detracts from the demonstrated general internal consistency of the approach, but suggests that the silver-silver iodide results may be a better indication of the accuracy to be expected. It should also be noted, however, that silver iodide undergoes a phase transition at 144.6°C (23), and it is possible that at least part of the discrepancy arises from the failure to account for this in the calculations.

The value of a_2 for simple anions used in these calculations was obtained from the parameters of the linear correspondence principle as they appeared in Criss and Cobble's original publication (1). The value of a_2 calculated after correcting for an apparent typographical error which was first noticed by Tremaine *et al.* (a for simple anions at 300°C should be -47.2 instead of -49.2) (28) is -1.72×10^{-1} calories mole^{-1} degree^{-2}. This "corrected" value actually causes a slight deterioration in the agreement between all calculated and observed values, with the original value fortuitously producing a fit which does not benefit significantly from optimization.

Even at 60°C, where the linear ionic heat capacity approximation should be least accurate, it compares well with experimental data from thermal electrode measurements. From [21] and [22], and the data in Table III,

$$E^{\circ *}_{H^+/H_2}(60^\circ C, \text{LIHCA}) = 0.029\text{V} \quad [27]$$

From the data of Fales and Mudge (24), deBethune *et al.* calculated an expression for the thermal potential of the hydrogen electrode (Pt/H_2 ($f = 1$), 0.1M HCl/sat'd KCl) which gives $E^*_{H^+(0.1m)/H_2}(60^\circ C)$ as 0.022V (14). The standard thermal potential at 60°C can be calculated from [28], an equation obtained by generalizing Eq. [21] and [22] to include activities other than unity

$$E^{\circ *}_{H^+/H_2}(60^\circ C) = E^*_{H^+(0.1m)/H_2}(60^\circ C) + \left[\frac{RT}{\mathbf{F}} \ln a_{H^+}\right]_{25^\circ C} - \left[\frac{RT}{\mathbf{F}} \ln a_{H^+}\right]_{60^\circ C} \quad [28]$$

where $a_{H^+} = 0.1\ \gamma_\pm(\text{HCl})$. The values obtained by Greeley *et al.* (29) for $\gamma_\pm(\text{HCl}, 0.1m)$, 0.7972 at 25°C and 0.776 at 60°C, yield

$$E^{\circ *}_{H^+/H_2}(60^\circ C, \text{OBS.}) = 0.030\text{V} \quad [29]$$

It is interesting to note that [22] predicts that the temperature coefficient of the thermal SHE potential, $\partial E^{\circ *}_{H^+/H_2}/\partial T$, decreases significantly as the temperature increases, contrary to the behavior first assumed by MacDonald (9). Using the values in Tables I and III, the temperature coefficient is 0.893 mV deg^{-1} at 25°C, passing through zero and changing sign at a temperature of about 265°C. This result differs slightly from MacDonald's later calculation (10) because of his "corrected" $\mu^\circ_{H^+}$ values.

Conclusions

1. The Criss-Cobble entropy correspondence principle makes possible surprisingly accurate predictions of thermodynamic properties in aqueous systems at temperatures up to *ca.* 300°C.

2. The linear ionic heat capacity approximation (LIHCA) reduces the number of parameters required, simplifies the calculations, and makes possible a one-step computation while improving over-all accuracy.

3. Extrapolation of the constant pressure approximation to temperatures above 300°C may involve considerable error.

4. It is important to state the $\mu_i^\circ(25^\circ C)$ and $\overline{S}_i^\circ(25^\circ C)$ values used in calculations on any system. Separate $\mu_i^\circ(T)$ values are the most useful parameters for subsequent applications of the data.

Boron in Near-Intrinsic $\langle 100 \rangle$ and $\langle 111 \rangle$ Silicon under Inert and Oxidizing Ambients—Diffusion and Segregation

Dimitri A. Antoniadis,* Adalberto G. Gonzalez, and Robert W. Dutton

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

The diffusivity of boron in <100> and <111> silicon is experimentally determined under both inert and oxidizing (dry O_2) ambient conditions in the range of temperatures 850°-1200°C. The boron is implanted at moderate dose (1.3×10^{14} cm^{-2}) and energy (70 keV) and subsequently activated by a moderate temperature anneal. The resulting profile ensures near-intrinsic silicon at the processing temperatures and serves as initial condition for subsequent processing. Diffusivities and segregation coefficients are calculated as fitting parameters in numerical solution of the experiments. A systematic fitting procedure is used and the target experimental parameters are sheet resistances and junction depths. Inert ambient diffusivities agree well with previous measurements, thus demonstrating the integrity of newly published mobility data used in the simulations. Diffusivities in oxidizing ambient are enhanced, more so in <100> than in <111> silicon. The enhancement increases with decreasing temperature, being about 10 for <100> at 850°C. It is demonstrated that there is good agreement between the observed diffusivity enhancement and growth of oxidation stacking faults if an interstitialcy mechanism is invoked to explain both phenomena. Observed segregation coefficients are different for the two silicon orientations but they obey the same activation energy over the temperature range.

Boron is the dominant p-type dopant for silicon technology. For this reason a great amount of effort has been expended during the last two decades for the determination of physical properties of boron in silicon at fabrication conditions. Since the device electrical characteristics depend strongly on the final impurity distributions, a detailed understanding of boron impurity diffusivity in silicon and its partition (segregation) in the silicon-silicon oxide interface is essential.

It is presently established that boron diffuses at least partly by means of charged-defect interactions (1, 2). For this reason the diffusivity of boron is affected by substitutional impurities in silicon present at sufficient levels to cause the crystal to become extrinsic at the fabrication temperatures. The terms intrinsic and extrinsic in this paper refer to the condition of the silicon at the process temperature. Boron diffusivity in absence of oxidation is uniform, *i.e.*, independent of impurity concentration provided this concentration is lower than that of intrinsic carriers at the process temperature. We refer to this as "intrinsic boron diffusivity." Boron diffusivity under extrinsic conditions becomes a function of Fermi level position increasing as the Fermi level approaches the valence band and decreasing as the Fermi level approaches the conduction band. The results of this effect are to a large degree responsible for the abundance of conflicting values of boron diffusion coefficients. Reviews on this matter have been presented by Kendall and DeVries (4) and Fair (5).

It has also been established that the diffusivity of boron in silicon is enhanced by the growth of silicon dioxide at the surface (6-9). The degree of enhancement is greater in <100> crystal orientation than in <111>. Again a number of mostly conflicting diffusion coefficients have been reported mainly because of the coexistence, in most experiments, of high concentration effects, oxidation effects, and redistribution of boron at the moving silicon-silicon oxide boundary (10).

The redistribution of boron during oxidation is, to a large degree, controlled by the segregation (or partition) process at the moving silicon-oxide interface (3). This physical process gives rise to a nonunity segregation coefficient defined as $m = C_{si}/C_{ox}$, where C_{si} and C_{ox} are the impurity concentrations at the two sides of the interface. The only direct measurements of the ratio m for boron as a function of temperature and crystal orientation have been presented by Colby and Katz (11). Most of the other values appearing in the literature have been indirectly calculated from redistribution models under various degrees of approximations and thus do not present a consistent picture of the physical process (10).

In the present paper we report the results of a study of boron diffusivity in near intrinsic <100> and <111> silicon under inert (N_2) and oxidizing (dry O_2) ambients at various temperatures. For the oxidation cases we also calculate the effective segregation coefficients, which we define as the constant ratios, m_{eff}, that best fit the experimental data over the entire time of each experiment.

The initial distribution of boron for all experiments was established by means of an ion-implantation and annealing process that insures the complete boron electrical activation and the intrinsic silicon requirements at the temperatures of the experiments. Diffusivities and segregation coefficients have been calculated using a new IC process simulator (12) together with an automatic optimizer program that seeks the best-fit parameters compatible with the measured data. For the determination of diffusivities in inert atmosphere the only measured data were the initial and final sheet resistance for each experiment. For the simultaneous determination of diffusivity and segregation coefficients in the oxidation experiments, the additional information of junction depths was used. Recently reported hole mobilities were used (13, 14) for the calculation of sheet resistances resulting from the simulation. The reliability of the technique and the integrity of the mobility data is demonstrated by the excellent fit of the diffusivity in inert ambient by a single activation energy and the agreement with other reliable data (15).

In dry O_2, diffusivity enhancement has been observed, more so in <100> than in <111>. This is in

* Electrochemical Society Active Member.

Key words: boron, oxidation, diffusivity, enhancement, segregation.

qualitative agreement with previously reported data (9, 11). For both orientations the observed enhancement increases as the temperature is decreased and the results cannot be characterized by a single activation energy. We demonstrate that this behavior is predicted by the self-interstitial supersaturation model proposed by Hu (16) to explain the growth of stacking faults and the diffusivity enhancement during silicon oxidation. In this context we show that the diffusivity data obtained here are compatible with the stacking fault growth data obtained by Hu (17, 18).

The segregation coefficients determined here are generally higher than those measured by Colby and Katz.[1] Also in all cases the calculated segregation coefficient is higher in <100> than in <111> silicon, but their difference is not as large as that reported by the above workers.

Experiment

The substrate materials used were low dislocation density ($\leq 100/cm^2$), Czochralski-grown, phosphorus-doped, <111> and <100> crystal orientation silicon wafers, with an initial resistivity of 5-10 Ω-cm. Clean wafers were oxidized at 1000°C for 60 min in dry oxygen, growing about 510Å of SiO_2 for <100> material and about 615Å of SiO_2 for <111> material. Subsequently the wafers were implanted with B^{11+} at a dose of 1.33×10^{14} atoms/cm², at an energy of 70 keV, and at 7° misalignment to minimize channeling. The oxide layer was used to minimize silicon damage at the surface during implantation and to prevent evaporation of impurities during subsequent nitrogen drive-ins. Such a static oxide film does not affect the diffusion of boron (6). Although it is possible to have oxygen knock-ons into the silicon during implantation (19), it was assumed that the amount of oxygen present in the lattice would not seriously affect the diffusion of boron (less than 10^{12} atoms/cm² get knocked on to a maximum depth of 1000Å in the worst case). After implantation, the wafers were annealed in an N_2 atmosphere at 900°C for 35 min. The implantation and the annealing conditions were chosen in order to give the initial distribution of substitutional boron that has been experimentally determined by Hofker *et al.* (20), using secondary ion mass spectroscopy (SIMS) and electrical profiling techniques. This distribution is shown in Fig. 1. The only difference between the present process and that of Hofker *et al.* was the presence of the thin capping oxide, in which a maximum of 6% of the implanted dose is retained. The importance of excluding the implant annealing phase from the diffusion experiments cannot be overemphasized. Transient diffusion phenomena (20, 21) occurring during the electrical activation of the implant can easily lead to overestimation of the normal (thermal) diffusivity, particularly at the lower temperatures (20). Also, since initial sheet resistances are needed with our method, the implant had to be fully electrically activated prior to subsequent processing. Each as-annealed wafer was cut into quarters and one quarter was retained as a reference, while the other three were used for experiments at the same temperature and ambient. Since the peak concentration of the as-annealed boron profile was below 4×10^{18} atoms/cm³ and the intrinsic carrier concentration even at the lowest temperature considered here (850°C) is about 5×10^{18} carriers/cm³ (22), the silicon substrate was near intrinsic under all conditions of our experiments and thus extrinsic diffusivity effects have been avoided.

For inert ambient experiments, <100> and <111> quarter wafers were subjected to nitrogen atmosphere drive-ins for different times and temperatures. For oxidizing ambient experiments, the quarter wafers were previously stripped of capping dioxide in 5:1 H_2O/HF solution until hydrophobic, and then subjected to 100% dry O_2 atmosphere drive-ins for different times and temperatures. In most cases diffusion of <100> and <111> wafers was performed simultaneously in the same furnace to guarantee the same processing conditions.

After processing, junction depths were measured using angle lapping and electrical probing with a high precision spreading resistance two-point probe (23). The mechanical reliability of the probe yields junction depths with a resolution of ± 500Å for deep junctions (2-5 μm), and ± 250Å for shallow ones (0.5-2 μm). Some of the deeper junction depths were verified using groove and stain techniques and a sodium light dual-beam interferometer. Sheet resistances were measured using a light (45g) and a heavy pressure (180g) linear four-point probe array. Agreement between the measured values had a relative deviation no greater than 3%. Oxide thicknesses were measured with an ellipsometer at various points on the wafer, observing a fluctuation no greater than 2%. Good agreement was observed between the experimental thicknesses and those reported recently (24), except for the experiments at 900°C where thicknesses were consistently lower.

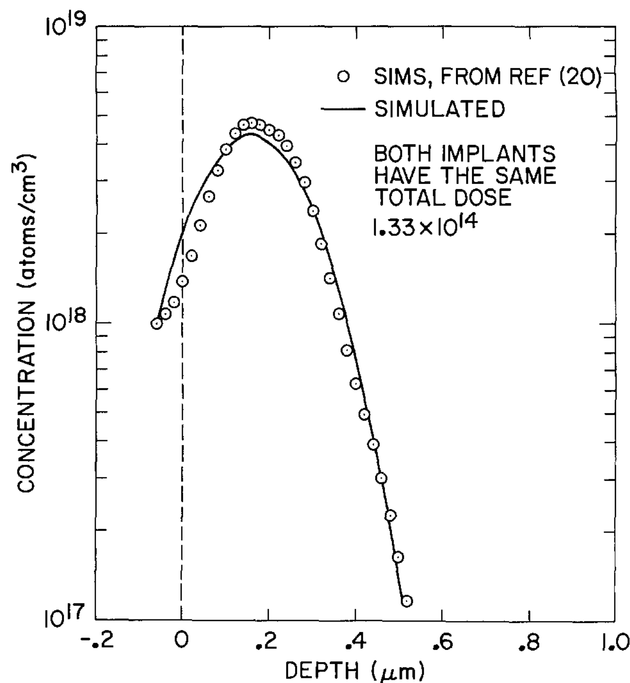

Fig. 1. Boron implant, 1.33×10^{14} ions/cm² dose, 70 keV, annealed at 900°C for 35 min.

Analysis

The process simulator SUPREM (12) was used to model the impurity distribution of boron, on a computer, for every one of the different experimental processing schedules. In each case, the simulated profile characteristics were matched to the corresponding measured values. The diffusion and segregation coefficients were thus obtained as a result of the fitting process. In the simulation of oxidation, minor adjustments were made to the linear and parabolic oxide growth rates (25) in order to simulate the proper experimental oxide thicknesses.

The simulated junction depths and sheet resistances were compared with the corresponding measurements of these quantities. In each case, the initial estimates of diffusion and segregation coefficients were iteratively adjusted until agreement (within less than 1%) between measured and simulated values was established. The iterative adjustment was carried out by the built-in SUPREM optimizer (26). The optimizer

[1] The definition of the segregation coefficient here follows that of Grove *et al.* (19), and is the inverse of the one used by Colby and Katz. Since boron generally prefers the oxide, "higher" segregation coefficient, in this paper, means a smaller boron concentration in the oxide side of the interface for a given concentration in silicon.

is operated as a nonlinear equation solver in which the unknown diffusion coefficient in the case of inert ambient drive-ins is found by fitting the measured sheet resistance. In the case of oxidizing ambient drive-ins the diffusion and segregation coefficients are found by fitting both the measured sheet resistances and junction depths.

Optimized parameter extraction is a systematic way of obtaining model-dependent parameters from measured data, even under conditions where parameters interact strongly. This method proves most useful when two or more parameters are to be fitted simultaneously as in the case of oxidizing ambient diffusion, where the boron diffusivity tends to increase the junction depth and lower sheet resistance, whereas segregation and the moving boundary tend to raise sheet resistance and decrease junction depth. It is important to note that in this work both diffusion and segregation coefficients were extracted simultaneously.

The simulated sheet resistance computed by SUPREM is a strong function of the hole mobility. Recently available information (13, 14) has been used to achieve substantially better agreement with actual measured values than was possible using older references (27, 28). The new mobility data as well as a smooth function fitted to them are shown in Fig. 2. Details on the fitting function are given in the Appendix. In order to minimize the effect of small process variations and measuring equipment condition in the observed values of sheet resistance, a constant ratio technique was employed. Each time sheet resistance was measured on a processed wafer, the corresponding control wafer was also monitored. Thus the goal of the fitting process was to match the observed and simulated ratios of processed-to-unprocessed sheet resistances rather than exact absolute values. Since the control wafers reflect the state of the common initial impurity distributions, small variations in the process up to this step tend to cancel out. Also, by measuring process and control wafers at the same time, probe conditioning variations tend to cancel out.

Results and Discussion

Diffusion.—Figure 3 is an Arrhenius plot of boron diffusivity obtained in inert ambients. An activation energy of 3.42 eV with an intercept factor of 0.55 cm^2/sec (often called preexponential factor), is found to describe boron diffusivity in <111> and <100> crystal orientation silicon, in the range of 900°-1200°C. For comparison, the diffusivity obtained by Kurtz and Yee under near intrinsic conditions (15) is also plotted. The agreement of our results with those generally accepted data supports the reliability of our fitting approach, namely, using only sheet resistance data. As a further confirmation we also performed junction depth measurements in selected nonoxidized samples, and the agreement with simulation was found to be satisfactory.

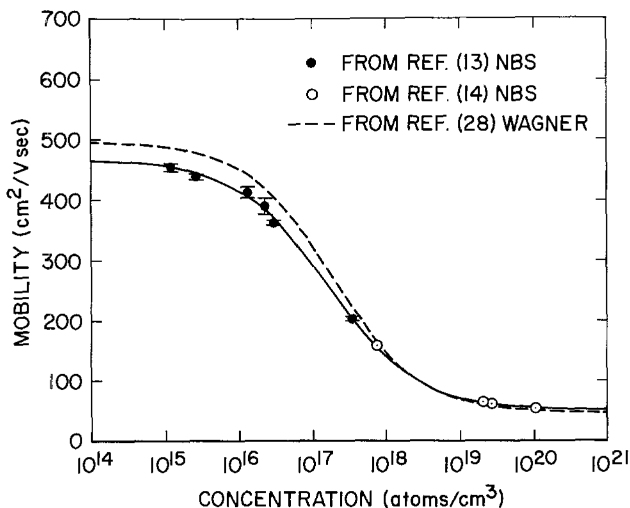

Fig. 2. Hole mobility in boron-doped silicon

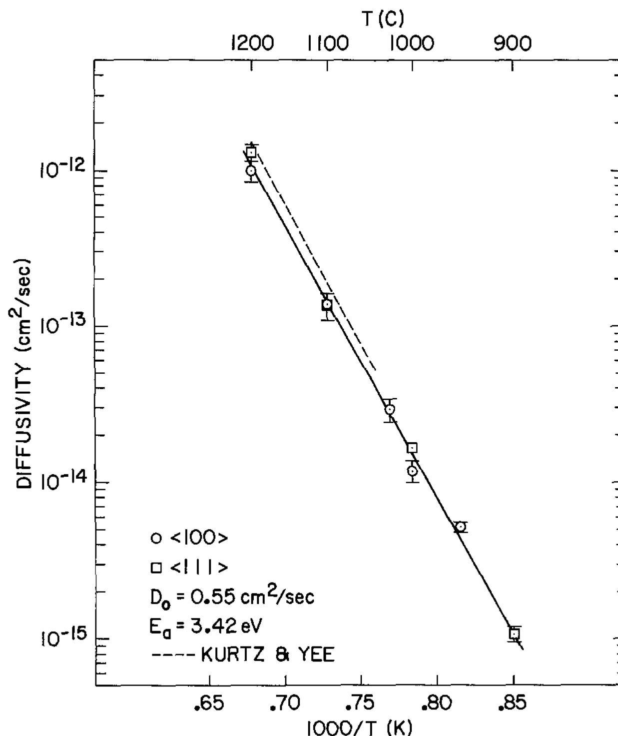

Fig. 3. Boron diffusivity in intrinsic silicon in nonoxidizing ambient

Having established the integrity of the sheet resistance approach we have been able to confidently use the additional information of junction depth for the simultaneous determination of diffusivity and effective segregation coefficient in the oxidation experiments. The results are shown in Fig. 4. As a reference, the inert ambient diffusivity is also plotted. Diffusivity enhancement has been obtained for the <100> orientations in practically all temperatures investigated. However, for the <111> orientation, enhancement was observed only at 900° and 850°C. Although other investigators have also reported absence of enhancement (6, 7) or reduced <111> enhancement (9) at the higher temperatures, we do recognize the fact that our data may be slightly underestimating the diffusivity because the spreading resistance method often tends to underestimate junction depth.

A remarkable feature of the data presented here is the multifold increase of boron diffusivity at the lower temperatures. For <100> silicon there exist enhancements of order 2, 5, and 10 at 1000°, 900°, and 850°C, respectively. For <111> silicon the enhancement order is 2 at 900°C and 5 at 850°C. It is clear that for both orientations the enhancement increases with decreasing temperature. An attempt to fit the data by a single activation energy over the entire range of the present experiments would be misleading.

An extensive set of boron diffusivities in <100>, <110>, and <111> silicon has recently been published by Masetti *et al.* (9). However, since they have used chemical predeposition the silicon was not intrinsic at least for part of the process duration. Furthermore, their numerical scheme cannot take concentration dependence into account. For dry O_2 in the range from 950° to 1200°C they have reported data fitted by single activation energies. Enhancement for <111> is small (about 1.2 over the whole range), but larger for <100>, increasing with decreasing temperature. Qualitatively these data are similar to ours but there is significant quantitative disagreement in the <100> case, particularly at 1000-1100°C. In general it

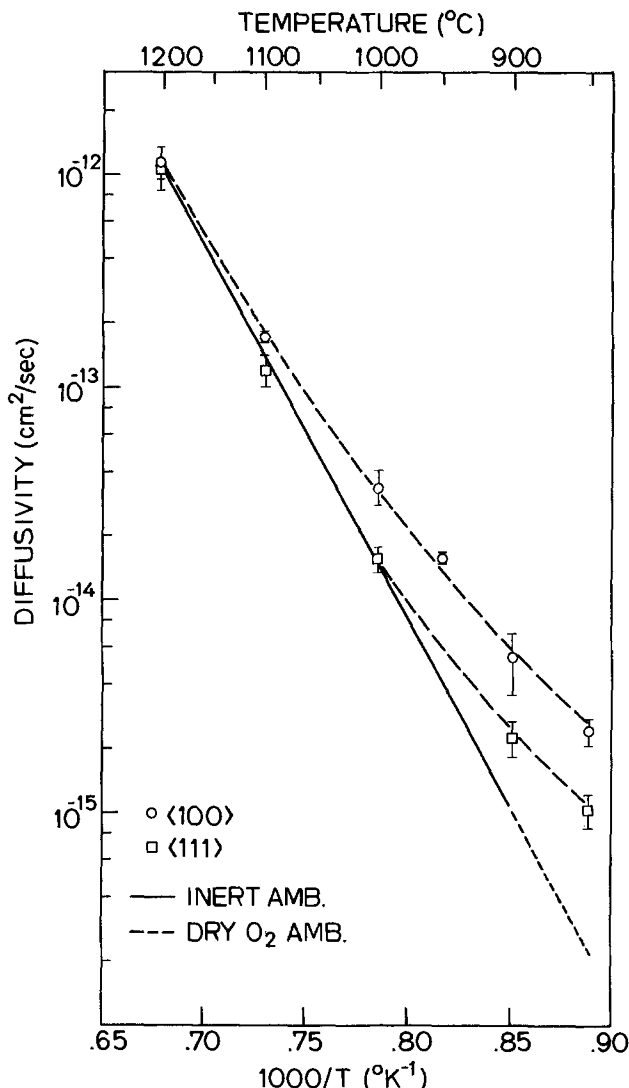

Fig. 4. Boron diffusivity in silicon in an oxidizing ambient

is difficult to compare our oxidation results to previously published data mainly because of differences in experimental conditions and in some instances, methods of data analysis. For this reason we will not pursue a comparative survey of the literature at this point.

Concentrating on the data presented in this paper, an explanation of the temperature-dependent behavior of the diffusivity enhancement will now be presented based on the model proposed by Hu (16) to explain the formation of stacking faults and enhanced diffusion during oxidation of silicon. Briefly, this model envisages a supersaturation of the silicon lattice by excess self-interstitials at concentrations dependent on the oxide growth rate and silicon orientation. These interstitials are thus responsible for the growth of stacking faults and, by invoking a dominant interstitialcy diffusion mechanism for boron, also responsible for diffusion enhancement. Assuming a fractional interstitialcy mechanism, f_A, it is straightforward to show that the effective diffusivity $<D>$ of boron in an oxidation process of duration t, is given by

$$<D> = \frac{1}{t}\int_0^t D dt$$

$$= D^* + \frac{D^*}{tC_i^*} f_A \int_0^t (C_i - C_i^*) dt \quad [1]$$

where D^* is the intrinsic diffusivity of boron and C_i^* and C_i the intrinsic and the extrinsic concentrations of silicon self-interstitials, respectively. Using Hu's theory (16), the above equation allows one to relate the effective diffusivity to the size of oxidation stacking faults. Indeed, from Eq. [13] of Ref. (16) the length, r, of stacking faults as a function of the process duration, t, can be expressed as

$$r = \pi\alpha_0^2 D_i \int_0^t (C_i - C_i^*) dt \quad [2]$$

where α_0 is the capture distance of interstitials by the faults and D_i the silicon interstitial diffusivity. Thus the ratio $<D>/D^*$ can be expressed by

$$\frac{<D>}{D^*} = 1 + f_A \frac{r}{\pi\alpha_0^2 D_i C_i^* t} \quad [3]$$

Assuming further that the diffusivity of silicon is partly due to an interstitialcy mechanism (29, 30), we may write

$$D_i C_i^* = f_s D_s C_s \quad [4]$$

where f_s is the fractional interstitialcy mechanism, and D_s and C_s the intrinsic diffusivity and lattice concentration of silicon. Thus Eq. [3] becomes

$$\frac{<D>}{D^*} - 1 = \frac{f_A}{f_s} \frac{r}{\pi\alpha_0^2 D_s C_s t} \quad [5]$$

Recently Hu (17, 18), published an empirical relationship for r based on his experiments

$$r = (Ae^{-Q_f/kT}) t^{0.8} \quad [6]$$

where T is the absolute temperature, k is Boltzmann's constant, and for both wet and dry oxygen $Q_f = 2.3$ eV while the values of A for dry oxygen are $A = 326$ cm sec$^{-0.8}$ for $<100>$, and $A = 156$ sec$^{-0.8}$ for $<111>$ silicon. Finally, it is well known that at least within limited temperature ranges the self-diffusivity of silicon can be expressed in terms of a single activation energy, Q_s (4, 5, 31)

$$D_s = D_{os} \exp\left(-\frac{Q_s}{kT}\right) \quad [7]$$

Hence using Eq. [6] and [7] in Eq. [5] we have

$$\left(\frac{<D>}{D^*} - 1\right) t^{0.2} = \frac{f_A}{f_s} \frac{A}{\pi\alpha_0^2 D_{os} C_s} \exp\left(\frac{Q_s - Q_f}{kT}\right) \quad [8]$$

In the above expression all factors are experimentally determinable with the exception of the ratio f_A/f_s.

Figure 5 is a plot of the quantity $(<D>/D^* - 1)t^{0.2}$ obtained from our $<100>$ experiments. It can be seen that this quantity exhibits a negative activation energy of -1.8 eV at the temperatures below 1000°C while over-all an activation energy of about -2 eV may be fitted. Assuming the experimentally determined values $Q_f = 2.3$ eV (17, 18) and $Q_s = 4.4$ eV (an average of values in literature for the low temperature end), the activation energy expected from Eq. [8] is -2.1 eV. Thus, there is at least good qualitative agreement between theory and experiments. This agreement is even better if the value $Q_s = 4.1$ eV recently obtained by Sanders and Dobson (31), near the lower temperatures of our experiments is used.

A quantitative comparison between theory and experiments is not directly feasible. The reason is mainly the presence of the term f_A/f_s. Accepting the Sanders and Dobson data (31), as representative of lower temperatures (5), and $\alpha_0 = 3.85 \times 10^{-8}$ cm, we obtain the following relationship from Eq. [8]

$$\frac{f_s}{f_A}\left(\frac{<D>}{D^*} - 1\right) t^{0.2} = B \exp(1.8/kT) \quad [9]$$

where $B = 2.4 \times 10^{-7}$ for boron in $<100>$ silicon and $B = 1.1 \times 10^{-7}$ for boron in $<111>$ silicon. Table I summarizes the observed $(<D>/D^* - 1)t^{0.2}$ results

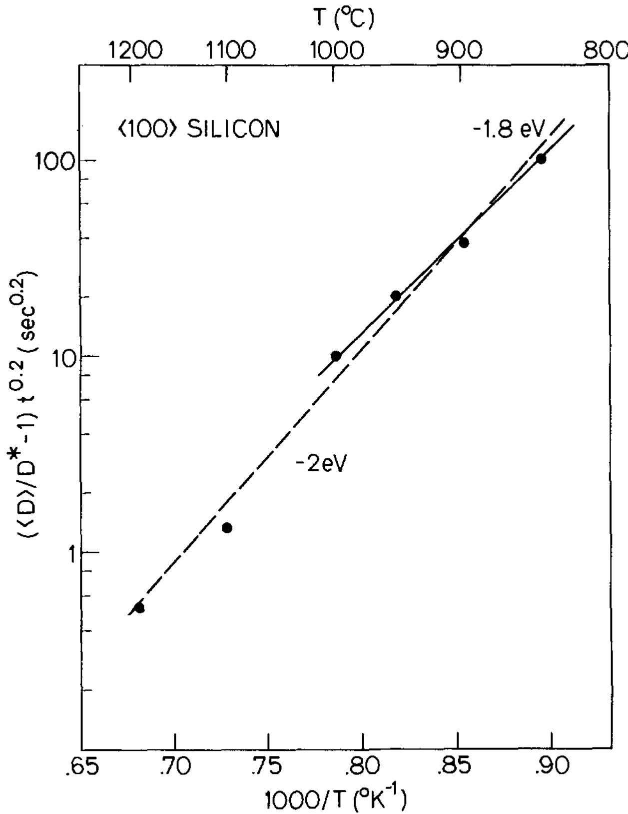

Fig. 5. The boron diffusivity enhancement factor in <100> silicon as a function of temperature.

and the calculated values of f_A/f_S from Eq. [9]. It is clear that a value of about 3 would be expected from the presented theory. The meaning of this is that the fractional interstitialcy mechanism for boron diffusion in silicon is about three times larger than that for silicon self-diffusion. Although this conclusion cannot be supported from independent data we do feel that it is quite plausible.

It is clear from Eq. [8] that the presented theory together with the experimentally determined growth of stacking faults predict a slight inverse time dependence ($\sim t^{-0.2}$) of the diffusivity enhancement. Due to the magnitude of experimental errors we have not attempted to accurately establish this time dependence. However, we have indeed observed a consistent time dependence suggesting at t^{-a} relation and although the exact value of "a" is not clear, there is conclusive evidence that it is smaller than 0.5.

In conclusion it should be mentioned that an inherent assumption in the present theory is that the concentration of excess silicon interstitials is not affected by the density of stacking faults. This assumption is quite valid since only a small fraction of the excess interstitials is expected to participate in the fault growth. Thus, although the density of oxidation stacking faults may vary significantly in accordance to the density of available nucleation sites that, in turn, depends on sample preparation, the length of the faults is only dependent on oxidation conditions and surface orientation (16, 7, 32). Thus, we do not expect that the introduction of boron by ion implantation

Table I. f_A/f_S from data and theory

T (°C)	From experiments ($\langle D\rangle/D^* - 1$) $t^{0.2}$ (sec.$^{0.2}$)		f_A/f_s	
	<100>	<111>	<100>	<111>
850	104	42	3.6	3.2
900	38	14	2.9	2.3
950	21	—	3.3	—
1000	10	—	3.1	—

(which increases strain sites) may have affected the diffusion enhancement mechanism. In addition, transient phenomena such as excess point defect concentration due to the ion implantation do not affect our results because, as already mentioned, all samples received annealing prior to the diffusion experiments.

Segregation.—Under conditions of thermal equilibrium the chemical potential as seen by an impurity species such as B, As, or P must be continuous across the Si/SiO_2 boundary. Thus, generally the concentration of impurities across the boundary are not equal, giving rise to a nonunity equilibrium segregation coefficient, m_{eq}. Theoretical calculations only bracket the value of m_{eq} within several orders of magnitude. It is not clear whether during thermal oxidation of silicon the segregation process is actually in equilibrium. It thus follows that the actual impurity ratio may not be either equal to m_{eq} or even constant throughout an oxidation process step. In the present work we have assumed that at a given temperature, the segregation process can be characterized by a constant (effective) segregation coefficient. The segregation coefficients thus obtained are plotted as a function of temperature and silicon orientation in Fig. 6. For comparison, the data presented by Colby and Katz (11), Prince and Schwettmann (33), and Murarka (34) are also shown. As can be seen, our data can be fitted by a single activation energy over the entire range of temperature of the experiments. However, there is a disagreement with the other three sets of data. Although no explanation can be given at present, the difference in experimental methods between the various works needs to be outlined. (*i*) Colby and Katz have obtained their data by direct measurement of boron concentrations across the interface using SIMS. As in the present work they have used dry O_2 oxidation. However, unlike our case the silicon crystal was not intrinsic, but rather it was uniformly doped at relatively high concentration (2×10^{19} cm^{-3}). (*ii*) Prince and Schwettmann have obtained their data by a fitting technique similar to ours. However, their oxidation process was performed in steam ambient. (*iii*) Finally, Murarka (34) has also used a fitting technique similar to ours and in addition his experiments were at low dose and in dry O_2 ambient. Thus, the experimental and fitting procedures

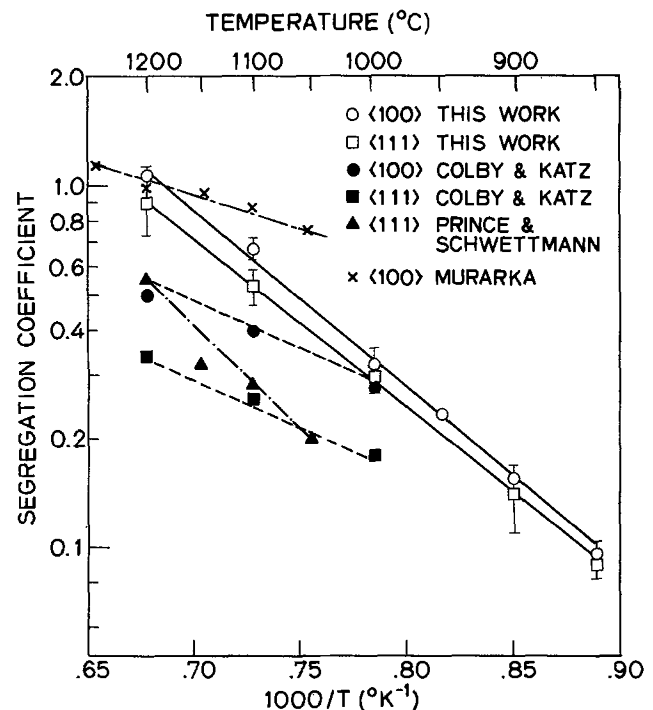

Fig. 6. Boron effective segregation coefficient in <100> and <111> silicon.

are similar with only two but possibly important differences. First, Murarka's samples were not annealed prior to the oxidation experiments, and second the mobility data he used was after Caughey and Thomas (27). If a fast-transient diffusivity exists at the beginning of the oxidation, the effect would be to preserve more boron in the silicon, thus appearing as a lower effective segregation coefficient. This effect would be more pronounced at lower temperatures (29), with a resulting decrease in the activation energy of the segregation coefficient.

Conclusions

The diffusivity of ion-implanted boron in <100> and <111> near-intrinsic silicon has been studied experimentally under inert (N_2) and oxidizing ambients (dry O_2). The method has consisted of fitting computer-simulated process results to observations by means of an automatic zero-in algorithm. As-annealed rather than as-implanted initial profiles were used to avoid the regime of transient diffusion during initial annealing and to ensure full implant activation. The initial profile was assumed similar to that experimentally determined (by SIMS) in another work (20) under almost identical conditions. For inert ambient experiments the only measured data were the initial and final sheet resistance. The determined intrinsic diffusivity agrees well with previously reported data (15) and thus it may be concluded that the recent mobility data used in the present simulation are quite realistic. Previously accepted mobility data (27, 28) would give different results.

In the oxidation experiments both sheet resistance and junction depth were measured. The fitting process has thus yielded the effective segregation and diffusion coefficients. Diffusivity enhancement has been observed in both orientations. In qualitative agreement with previous works more enhancement was observed in <100> than in <111>. Also this enhancement was found to increase with decreasing temperature. Quantitative differences do exist between this and the only comparable published work (9), which, however, was carried out using chemical deposition.

The determined effective segregation coefficients are in the general range of previously reported ones and obey a single activation energy. There is, however, a small difference between <100> and <111> orientations. Such an effect has been previously observed (11).

We have demonstrated that there is reasonable agreement between experimentally determined oxidation enhanced diffusion and growth of stacking faults, if one accepts the interstitialcy oversaturation model proposed by Hu (16). Within the context of this model it is necessary to assume at least a fractional interstitialcy diffusion mechanism for boron. Also, in order to bring the two sets of data to quantitative agreement, a fractional interstitial self-diffusion mechanism must be assumed for silicon, approximately three times smaller than for boron. The model readily predicts the observed increase of enhancement with decreasing temperature. It also predicts a slight time dependence of the diffusivity enhancement. At present the experimental errors of our method have not allowed verification of this dependence.

APPENDIX

From the work of Caughey and Thomas (27), mobility can be expressed in the following functional form

$$\mu(C) = \mu_{min} + \frac{(\mu_{max} - \mu_{min})}{1 + (C/C_{ref})^{\beta}} \quad [A-1]$$

where μ_{min} and μ_{max} are the minimum and maximum mobility values expected, C_{ref} a reference concentration value, and β an exponential factor that controls the slope around $C = C_{ref}$. From Ref. (13) and (14), the following values were obtained for this work

p-type	μ_{min}	μ_{max}	C_{ref}	β
Ref. (26)	47.7	495	6.3 E16	0.76
Ref. (27)	47.7	495	1.9 E17	0.76
This work	49.705	467.729	1.606 E17	0.700

n-type	μ_{min}	μ_{max}	C_{ref}	β
Ref. (26)	65	1330	8.5 E16	0.72
This work	55.24	1388.157	1.072 E17	0.733

The use of these new mobility function values resulted in excellent fit between measured and simulated sheet resistance values.

Preparation and Some Properties of Chemically Vapor-Deposited Si-Rich SiO_2 and Si_3N_4 Films

D. Dong,* E. A. Irene,* and D. R. Young

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Films of SiO_2 and Si_3N_4 containing excess Si were prepared by chemical vapor deposition at 700°C by the reaction of gaseous SiH_4 and N_2O for the Si-rich SiO_2 and NH_3 for the Si-rich Si_3N_4. By adjusting the gas-phase ratio of the reactants it was possible to vary the amount of Si in the films. Transmission electron microscopy studies revealed that the films contain two amorphous phases. One phase is amorphous Si while the other is SiO_2 or Si_3N_4. The Si content of the films was measured by electron microprobe analysis. Ellipsometry measurements on the films were made at several angles of incidence in order to measure the film absorption coefficients which were found to increase with increasing Si content. The d-c conduction characteristic for the Si-rich films was found to be nonohmic. The resistivity at any given field was found to decrease with an increase of the Si content.

Films of silicon dioxide (SiO_2) and silicon nitride (Si_3N_4) prepared by chemical vapor deposition (CVD) have received considerable study. These films are used as gate dielectrics and for a variety of masking procedures within the MOS technology. Typically, the films are prepared in an open-tube CVD reactor at temperatures greater than 500°C by the reaction of a volatile silicon compound such as SiH_4 with a gaseous oxidant such as O_2, CO_2, H_2O, N_2O, etc. for SiO_2 films and SiH_4 with NH_3 for Si_3N_4 films. The films are usually amorphous and if the SiH_4 is maintained at about 10% or less of the reactive gas mixture, the film compositions are stoichiometric SiO_2 or Si_3N_4. It has been reported (1-4) that the Si content of Si_3N_4 films can be increased for CVD films. In these previous studies, the Si content of the films was inferred from refractive index changes, etch rate measurements, and electrical behavior. For Si-rich SiO_2 films, several articles (5-8) demonstrate the preparation of these films by sputtering, glow discharge, and evaporation techniques except for a recent paper (9), in which Si-rich SiO_2 was prepared by CVD using a SiH_4-N_2O-N_2 mixture. The Si-rich films exhibited higher conductivity (3, 4, 9) than the stoichiometric analogs, and the conductivity increased with Si content. Use was made of this variable conductivity property to controllably limit reverse current for a pn-junction diode (9).

The goals of the present study were to determine the CVD parameters which yield Si-rich SiO_2 and Si_3N_4 with a desired amount of Si; to identify the relationships between gas phase mixtures, solid phase composition, resistivity, and refractive index; and to determine whether the films are homogeneous or phase separated. Presently, there exists controversy (5, 7) whether Si-rich SiO_2 is composed of a mixture of Si-Si_4 and Si-SiO_4 tetrahedra or simply separate Si and SiO_2 phases. Therefore, transmission electron microscopy (TEM) was performed on the films prepared in this study to elucidate the morphology.

Experimental Procedures

CVD.—The CVD apparatus was the same resistance-heated system previously described (10). The Si-rich films were deposited on cleaned <100> oriented, chem-mechanically polished, 2 Ω-cm p-type Si wafers (3.2 cm diam). The cleaning procedure for the Si substrates was also previously reported (11). A temperature of 700°C was used for all depositions. This temperature was chosen to be low enough to preclude extensive decomposition of the SiH_4 prior to injection into the reaction zone of the furnace. Although higher temperatures can be used to prepare Si-rich films, the amount of SiH_4 used for the preparations becomes excessively large.

The Si-rich SiO_2 films were prepared by the reaction of gaseous N_2O and SiH_4; for Si-rich Si_3N_4, NH_3 and SiH_4 were the reactants. In both cases the reactants were diluted with a N_2 carrier. The total flow into the CVD reactor (at 20°C, 1 atm) was maintained at 15 liters/min (~13 cm/sec linear gas stream velocity) of which the reactant gases were always less than 0.5 liters/min. In order to alter the Si content of the films, the gas phase reactant ratios, R_O (N_2O/SiH_4), for Si-rich SiO_2 and R_N (NH_3/SiH_4) for Si-rich Si_3N_4 was varied.

The elemental composition of the films was obtained from electron microprobe analyses on films several thousands of angstroms thick. Film thickness, index of refraction, and optical adsorption were measured by ellipsometry. Electrodes for electrical measurements

were evaporated Al dots (0.8 mm diam) on the film side of the samples and gallium-indium paste was used for the Si side electrical contact.

Ellipsometry.—Excess Si in the films causes optical absorption. The absorption needs to be characterized in order to perform accurate ellipsometric measurements of the film thickness. For this purpose, a special procedure was used (12) in which ellipsometry was performed at multiple angles of incidence. The procedure is outlined as follows: (*i*) Two zone ellipsometric measurements were made on a particular sample at constant wavelength (5461Å) but at several angles of incidence, ϕ, ranging between 60° and 80° in 5° intervals. (*ii*) A range of values for adsorption, κ, was arbitrarily chosen. The film thickness, D, and the real part of the film refractive index, N, were calculated for each κ and at each ϕ. The relationship between κ, N in the complex refractive index, N is given by the equation

$$\overline{N} = N(1 - i\kappa)$$

(*iii*) For each value of ϕ a line in κ, N, and D space was obtained. The sets of lines for various ϕ were plotted together on a three coordinate axes graph. In principle, all the lines should intersect yielding one value for N, κ, and D. However, due to experimental uncertainties (12), a zone of convergence is realized. From the zone of convergence, an average value for N, κ, and D can be obtained. An example of the convergence is given in Fig. 1a. Figure 1b shows a cut of Fig. 1a showing the κ and N planes. Such projections were used to obtain the numerical values reported later.

Electrical measurements.—The resistivity, ρ, was measured with the 2 Ω-cm p-type silicon substrates in accumulation. Heavily doped substrates were not used in order to preclude possible dopant effects in the films. Capacitance-voltage measurements at 1 MHz were made to determine whether the films stored charge or whether they lost the injected charge as anticipated by considering the measured values of ρ.

In order to compare the results for films with different Si content, films of approximately the same thickness (700 ± 100Å) were measured. The applied voltage ramp speed and amplitude were kept constant and the films were ramped first from depletion to accumulation, and then in reverse. The hysteresis in the C-V curve measured on the voltage near flatband (called ΔV) is proportional to the amount of charge, assumed to be near the Si surface, stored by the films.

Transmission electron microscopy (TEM).—The samples for TEM studies were prepared as previously described (13). Starting with films ~500Å on an Si substrate, the substrate was etched with HF-HNO_3 mixtures. The etch mixtures vigorously attacked the Si-rich SiO_2 and stoichiometric SiO_2 films. The etchant moderately attacked Si-rich Si_3N_4 films and only slightly attacked stoichiometric Si_3N_4 films. The qualitative difference in the etch rates observed and the resultant morphologies lead to the results to be reported.

Results

Film composition.—The solid-phase compositions as a function of gas phase reactant ratios, R_O and R_N, are shown in Fig. 2a for Si-SiO_2 films and in Fig. 2b for Si-Si_3N_4 films. For the higher gas phase ratios, the films approach stoichiometric SiO_2 and Si_3N_4. For R_O < 50 and R_N < 25, there is Si enrichment of the oxide

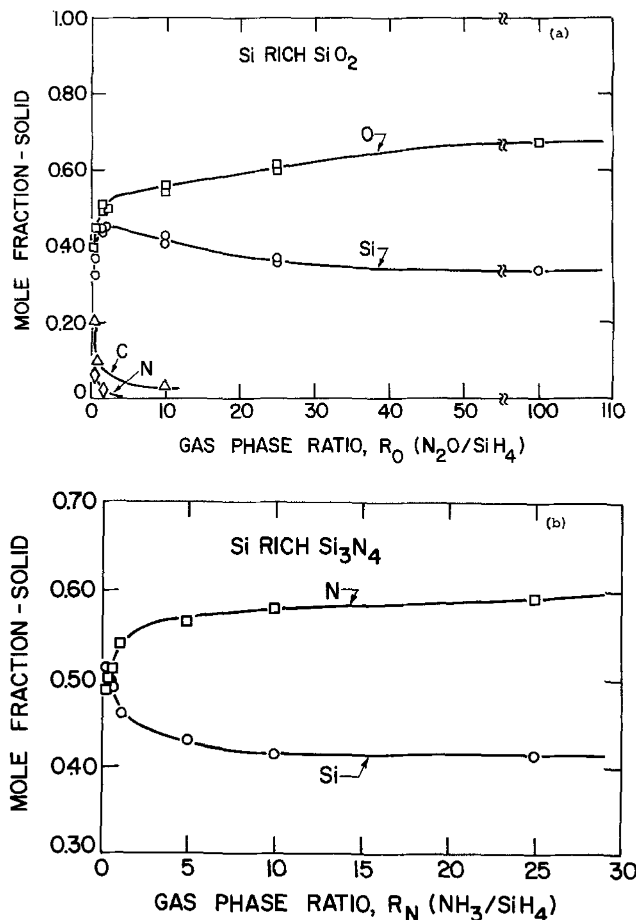

Fig. 2. a, Electron microprobe analyses of Si-rich SiO_2 vs. the gas-phase ratio; b, the same relationship for Si-rich Si_3N_4.

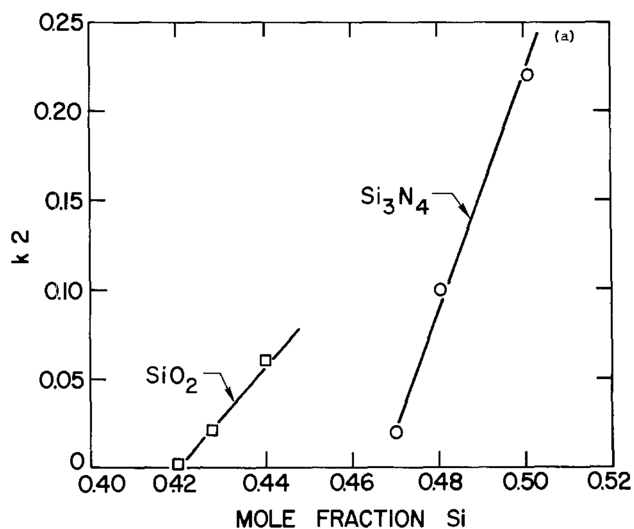
and nitride films. For the Si-rich Si_3N_4 films, the Si content increases smoothly with decreasing R_N for the entire range studied ($0.6 < R_N < 25$), and the Si content varies from 42 to 51% in this R_N range. Similarly, for R_O values between 100 and ~ 3, the Si content for the oxide films varies from 33 to 45%. However, for $R_O < 3$, both the Si and O content drop sharply while significant amounts of N and C appear. Later-reported resistivity values are also sensitive to this anomalous drop in Si content. Although not experimentally verified in this study, we believe that silicon oxynitride and/or oxycarbide type compounds were formed due to carbon impurities in the N_2O and the large amount of N_2 that was present.

Refractive index.—The optical absorption of these Si-rich films was characterized by the previously outlined ellipsometry procedures. The measured absorption coefficient values are shown in Fig. 3. The values of κ are seen to be small for the Si range studied, and if κ is assumed to be zero, less than 10% error in thickness is made for film thicknesses in the first ellipsometric period. Figure 3a shows that the absorption increases nearly linearly with Si content. Figure 3b shows that Si content for Si-rich SiO_2 films does not increase smoothly for low R_O values. In fact, as observed in Fig. 2a, the Si content drops for low R_O values while N and C levels increase. Therefore, κ is a sensitive measure of the Si content for these films.

Electrical measurements.—Figure 4 summarizes the resistivity measurements. The d-c behavior is seen to be nonohmic and ρ decreases as the Si content increases. Therefore, from Fig. 4a and 4b, films with desired values of ρ can be grown if the value for the operating field, E, across the film is specified. As mentioned previously for the Si-rich SiO_2 films at low values of R_O, the Si content drops anomalously. As seen in Fig. 4a, the curve for $R_O = 1$ shows larger values for ρ at any field studied than for the $R_O = 3$ curve. Therefore, the ρ value for a specified E is also



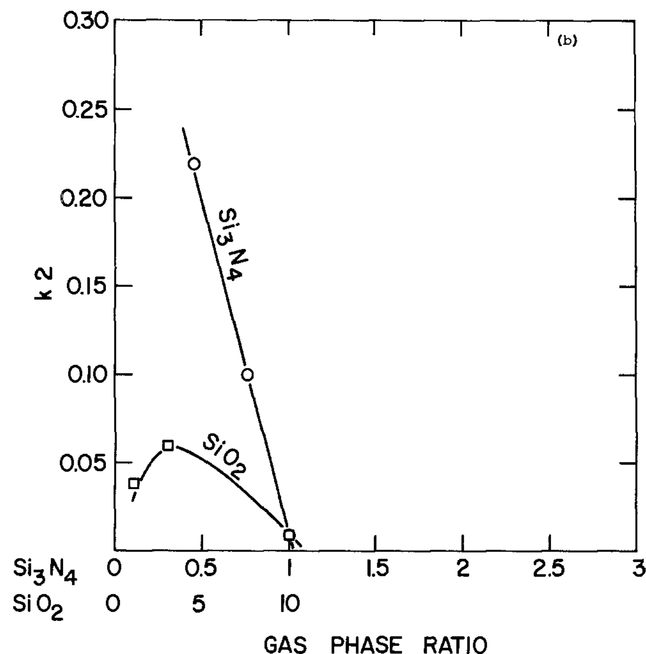


Fig. 3. a, The absorption coefficient, $K2$, vs. the Si content for both Si-rich SiO_2 and Si_3N_4 films; b, $K2$ vs. the gas-phase ratios R_O and R_N.

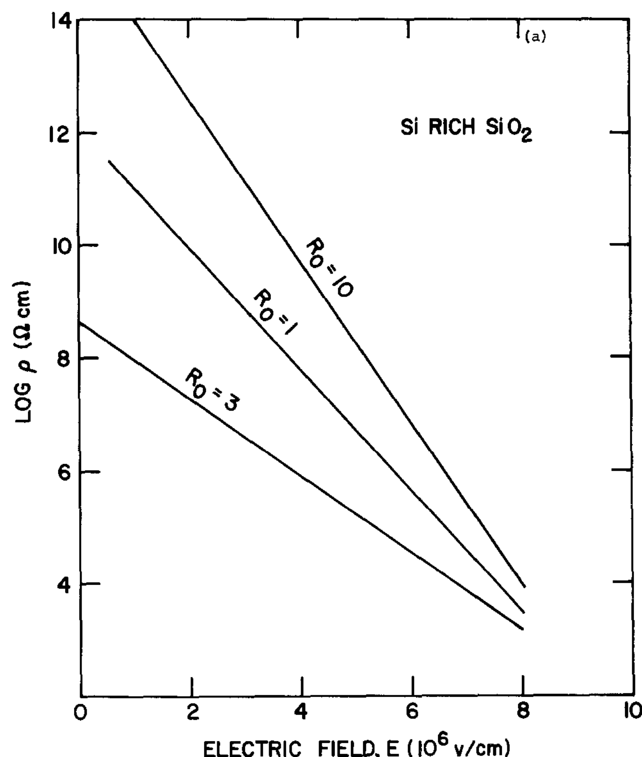

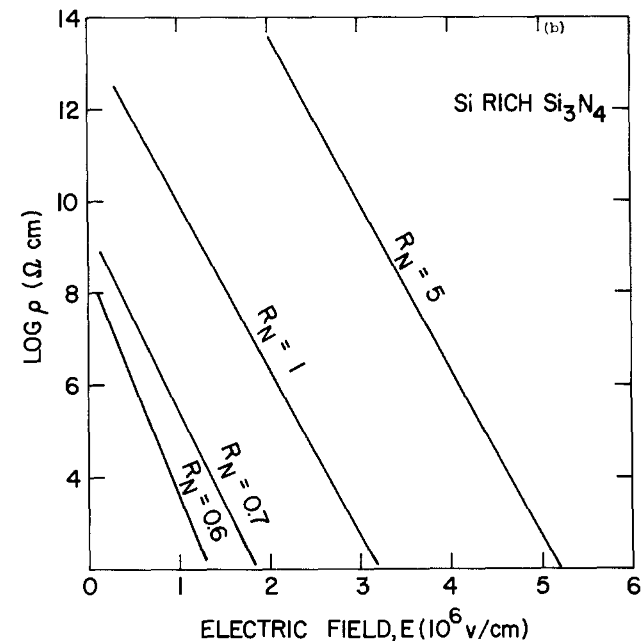

Fig. 4. a, The plot of $\log_{10} \rho$ vs. the applied electric field, E, for Si-SiO_2 with various gas phase ratios, R_O; b, the same as Fig. 4a for Si-Si_3N_4 for various R_N.

a sensitive indicator of the Si content of the film. For the Si-rich Si_3N_4 film, the Si content increased smoothly with decreasing R_N in the range studied, and the ρ values decreased for decreasing R_N.

The capacitance-voltage, *C-V* measurements are summarized in Fig. 5. Figure 5a shows that for Si-Si_3N_4 films the amount of stored charge, as measured by the hysteresis in the *C-V* curves, decreases with increasing Si content. This is to be expected inasmuch as with decreasing ρ the time constant for the storage of charge should also decrease. However, Fig. 5b for Si-SiO_2 shows an enhancement of charge storage with increasing Si content. This may be due to a thin thermal oxide being formed at the Si surface in the ambient containing N_2O. When the thin thermal oxide is coated with the Si-rich SiO_2, a metal, insulator, SiO_2, silicon (MIOS), charge storage structure is formed.

Transmission electron microscopy.—The TEM results are summarized by Fig. 6. The photographs are interpreted by remembering that the etchant used to prepare the samples attacks Si very vigorously, SiO_2 vigorously, and only very mildly attacks Si_3N_4. Figure 6a shows the TEM results for stoichiometric Si_3N_4. With the exception of some particulate in the films, the micrographs are featureless indicating uniform etching. Figure 6b, however, shows the result from the etchant attacking the Si-rich Si_3N_4. The bright areas are regions where Si has been preferentially attacked by etchant. Both photographs show only diffuse diffraction halos indicative of amorphous material. The Si-rich material shows randomly distributed Si areas having a rather connective appearance. Figure 6c and 6d show a comparison for stoichiometric and Si-rich SiO_2 films. Although the effect is not as definitive as for the Si_3N_4 films, it is clear that some regions of the

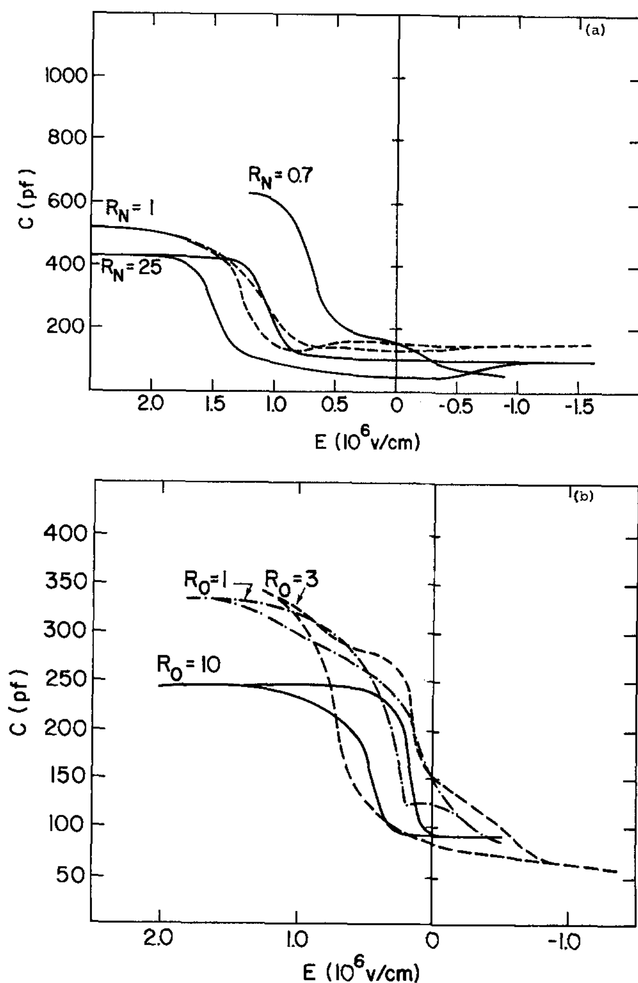

Fig. 5. a, *C-V* curves for Si-Si_3N_4 with various R_N; b, *C-V* curves for Si-SiO_2 with various R_O.

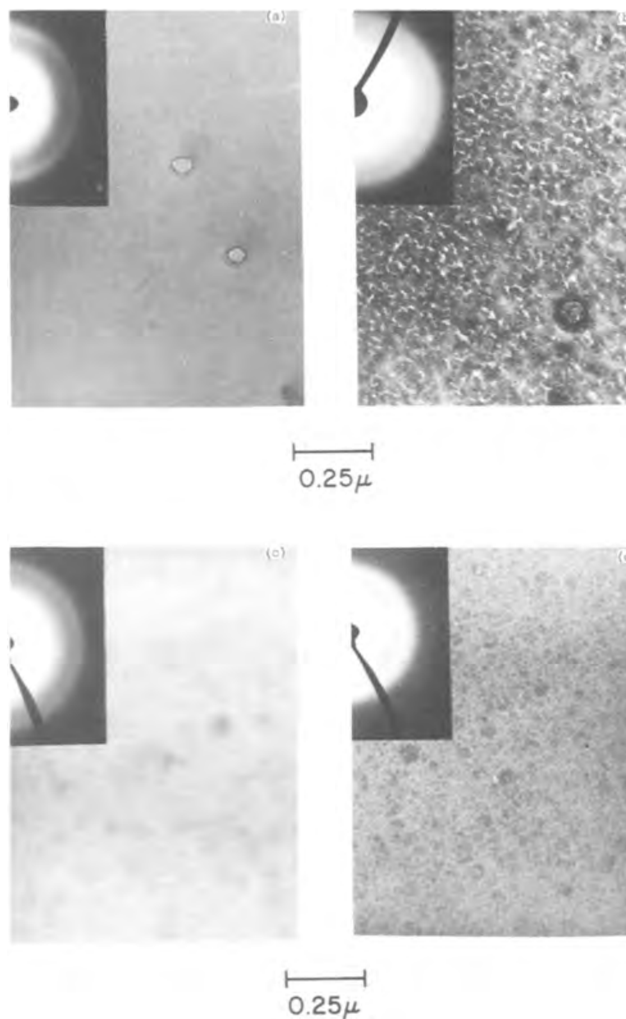

Fig. 6. TEM micrographs and diffraction patterns for stoichiometric and Si-rich Si_3N_4 and SiO_2. a, stoichiometric Si_3N_4, $R_N = 25$; b, Si-rich Si_3N_4, $R_N = 0.5$; c, stoichiometric SiO_2, $R_O = 100$; d, Si-rich SiO_2, $R_O = 1$.

Si-rich SiO_2 shown in Fig. 6d are attacked more vigorously than others while by comparison Fig. 6c shows uniform etching characteristics. Since SiO_2 and Si are attacked by the etchant, this result for Si-rich SiO_2 is expected. Both 6b and 6d reveal that the etched phase is connective rather than spherical.

Based on the morphologies discovered by TEM, it is concluded that these Si-rich materials are composed of two amorphous phases: a silicon phase and either a SiO_2 or Si_3N_4 phase.

Summary

It has been shown that films of SiO_2 and Si_3N_4 can be prepared with a controllable excess of Si by chemical vapor deposition by adjusting the gas phase reactant ratios. The excess Si forms a rather connective secondary phase under the conditions of the present study. The resistivity and optical absorption are both sensitive to the Si content of the films. The d-c conductive behavior for the Si-rich films is nonohmic but for any given field the resistivity decreases with increasing Si content.

Technical Notes

Protective Glassy Layers Passivating Copper at 500°C

B. J. Mulder

Philips Research Laboratories, Eindhoven, Netherlands

Copper objects of complicated shape have been coated with a protective glassy layer consisting mainly of SiO_2 with a thickness of a few tenths of a micron. The coating offers protection against oxidation in air at temperatures up to 500°C. The coating is applied by chemical vapor deposition in sealed ampuls using a technique worked out by Chu and Gruber (1) for coating semiconductor materials. The reactive gases (HF and H_2O) were not, however, introduced as such, but generated *in situ* from copper difluoridehydrate (2). Glass is transported from the walls of the ampul in a cooler zone onto the copper in a hotter zone.

The arrangement for the coating reaction is shown in Fig. 1. Ampuls were made of borosilicate glass. Larger ampuls were sprung open at A for loading. The ampuls contained: (*i*) Copper difluoridehydrate, preferably in a separate glass container with the powder not in direct sight of the copper substrate. The water content of the fluoride[1] was apparently not critical: the mono and the dihydrate served equally well. Normally a technical-grade monohydrate was used in amounts corresponding to 1-2 mg per milliliter of ampul volume; (*ii*) The carefully cleaned and degreased copper objects. The copper was normally pretreated with a polishing etch; (*iii*) A glass heat shield, protecting the copper against oxidation when the ampul was repaired (in a vertical position) at A. The ampul was pumped with a rotary pump and sealed at B. It was then heated without delay in a furnace with two temperature zones, one at 550°C (just below the softening point of the glass) where the copper was placed, and one at 500°C for the fluoride. Heating up took about 5-10 min; after another 30 min the ampul was taken out of the furnace and cooled. We froze the bottom end of the ampul in liquid nitrogen to prevent reverse transport reactions and also to avoid condensation of vapor on the copper.

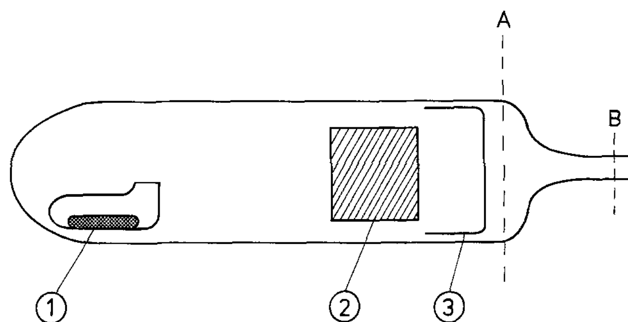

Fig. 1. Arrangement for chemical vapor deposition of glass onto copper in sealed borosilicate ampuls. Ampuls were used with diameters ranging from 10 to 60 mm and a length of about 250 mm.

The layers had a very uniform and smooth appearance, which was preserved when the copper was heated in air up to temperatures of 500°C. This suggests that the layers are essentially pinhole free.

The thickness of the layers was determined from measurements of their x-ray fluorescence.[2] With 500°C for the temperature of the source region and 550°C for the substrate the layers attained their final thickness of a few tenths of a micron in about 30 min. The thickness increased with the amount of copper di-

Key words: chemical vapor deposition, copper, passivation, SiO_2, glass.

[1] The water content of a hydrate was determined by slowly heating in air to 600°C and weighing the residue of CuO.

[2] The intensity of the characteristic fluorescence of silicon was referred to standard layers prepared by bias sputtering fused quartz on copper foil. The intensity was almost proportional to the thickness of the standards up to 0.4 μm. Since the sample layers consisted almost entirely of SiO_2, intensities were converted into thickness using data for fused quartz.

fluoride weighed into the ampul: for a tenfold increase in copper-difluoride (from 0.7 to 7 mg per ml volume of the ampul) the thickness approximately doubled from 0.15 to 0.3 μm SiO_2. The composition of the layer was studied qualitatively by secondary ion mass spectrometry (SIMS), revealing F, B, and OH as minor contaminants of the SiO_2. The F/Si ratio was determined quantitatively by electron-excited x-ray spectrometry[3] and was found to correspond to $x = 0.005$ in the composition formula $SiO_{2-x}F_{2x}$. Heating in air for 16 hr at 450°C approximately halved the fluorine content of the layers without affecting their integrity.

[3] Thin standard layers with a known Si/F ratio were prepared by mixing polyvinylidenefluoride, $[(-CH_2CF_2)_n]$ dissolved in hot cyclohexanone, and heavy silicone oil $[(-Si(CH_3)_2O)_n]$ dissolved in hot toluene, spraying the hot mixture onto warm copper foil and evaporating the solvents. The correction required for the difference between the mass absorption coefficients of standards and samples turned out to be quite small.

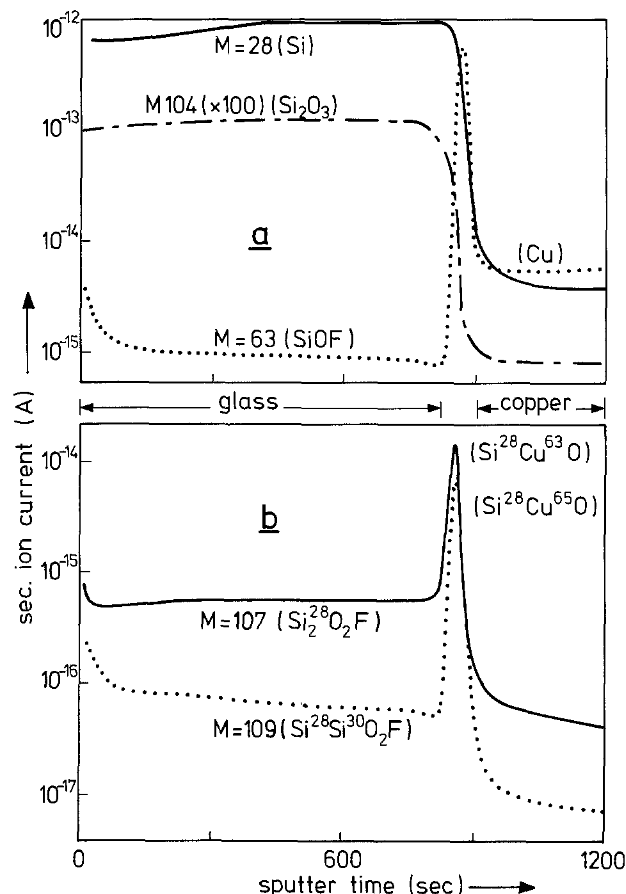

Fig. 2. Depth profiles obtained by SIMS for a 2000Å thick glass coating on copper.

An in-depth analysis with SIMS revealed the existence of an interlayer between glass and copper, characterized by the production of CuSiO clusters. Depth profiles of a typical coating are shown in Fig. 2. The curves were traced while scanning an area of 1 mm^2 with a primary beam of oxygen ions. Positive ions with a fixed mass and originating from the central 50 × 50 μm^2 region of the erosion crater were detected. The presence of an interlayer of ~ 200Å thick is evident from the peak in the curves traced for mass numbers 107 and 109 (Fig. 2b). In the peak the intensity ratio for the two mass numbers is equal to the abundance ratio of Cu^{63} and Cu^{65} (2.23), showing the peak to be associated with the production of CuSiO clusters. "Mixed" clusters (Cu and Si) are not observed in SIMS when scanning an abrupt junction (3) and are therefore indicative of the presence of an interlayer. To the left of the peak the intensity ratio in Fig. 2b is close to the ratio expected for Si^{28} and Si^{30} containing clusters (~14). Other noticeable features of the curves are the very efficient production of copper ions (see curve for M = 63) from the interlayer and the relatively high production of fluorine containing clusters from the surface region of the coating.

The interlayer may arise from the diffusion of copper into the defective SiO_2 at the temperature of the coating reaction. An in-depth inhomogeneity was also suggested by measurements of the electrically insulating properties of the layers, using a mercury drop as one of the electrodes. Layers thicker than about 0.1 μm behaved normally in that they withstood voltages corresponding to field strengths of several times 10^6 V/cm, whereas thinner layers usually broke down at voltages corresponding to only 10^4-10^5 V/cm.

Acknowledgments

The x-ray radiation of the layers was measured by E. W. J. M. van Meijl. SIMS was performed by H. A. M. de Grefte.

Anodization of Layered Semiconductors: A Method to Count the Number of Layers

A. Moritani, H. Kubo, and J. Nakai

Department of Electronics, Faculty of Engineering, Osaka University, Suita, Osaka, 565, Japan

In the anodization process of metals and semiconductors, it has been known that there exist nonpassive (or active) states and passive states, depending on the surface potential of the anode materials. We define the nonpassive state as the state in which the anodic dissolution is in process or a nonpassive film is growing with little increase of the anode potential on the surface of the anode material when anodization is performed under constant current condition. In this paper we demonstrate that anodization provides a new and simple method to count the number of layers

Key words: semiconductor, anode, ellipsometry, passivity.

in some layered semiconductors by utilizing the property of the nonpassive-passive transition which has been widely observed in the fundamental anodic process in metals and semiconductors (1, 2).

The layered semiconductors have been a recent topic in both experimental and theoretical studies (3). The micalike layer structures are characterized by strong covalent bonds within each layer and by weak van der Waals forces between layers, so that there exist high and fairly wide potential barriers and the crystals are easily cleaved at the layer boundary which we may consider to be another surface. Therefore, it is reasonable to expect that if a layered semiconductor is anodized in the direction normal to the cleaved surface, the nonpassive-passive transition will repeat at the nth layer boundary (n = 1, 2, 3, . . .). Thus, a periodically varying structure reflecting the layered structure with the monolayer thickness of ~10Å is expected to be observed in the cell voltage *vs.* time (V_c-*vs.*-t) characteristic curve when anodization is performed under a proper constant current condition with the use of a proper electrolyte. These observations will enable us to count the number of layers in the layered semiconductors: we can count the number of layers by this method after some experiments with the layered semiconductor of interest are over.

The electrolytic cell-system used in this study consists of a platinum cathode, the semiconductor anode, a simple quartz beaker, a magnetic stirrer, and a solution of sodium borate in ethylene glycol as the electrolyte. The cell voltage is measured and recorded through a buffer amplifier with high input impedance. The second derivatives of the V_c-*vs.*-t characteristics are recorded simultaneously in order to clarify the periodic structure and make it easier to count the number. P-type Bi_2Te_3 and p-type GaTe with carrier concentrations of 1-5 $\times$ 10^{19} cm^{-3} and 0.5-2 $\times$ 10^{16} cm^{-3} at room temperature were used as the semiconductor samples. The samples were cleaved in laboratory air, and edges and ohmic contact of the samples were covered for insulation by an epoxy paint.

Periodically increasing cell voltages are observed in Fig. 1 and 2 for Bi_2Te_3 and GaTe, respectively, as expected. It is seen in these figures that these periodic structures are formed by repetition of the unit-line-shape shown in the insert of Fig. 1, where τ_n represents the duration time of the nonpassive state and V_{cn} represents the cell voltage increase in the passive state for the nth layer.

For the purpose of confirming that the unit line-shape really results from anodization of the monolayer, we have performed ellipsometric measurements on the anodic films grown by anodization of more than 20 layers and obtained the anodized film thickness of 16 ± 1Å for monolayer anodization. The ratio of this value to the monolayer thickness of Bi_2Te_3, *i.e.*, 10.16Å (4) is 1.57 which is in close agreement with the theoretically expected value.[1]

Another experiment was done as in what follows to confirm that the region indicated by τ_n in the unit lineshape is really in the nonpassive state. The experimental result of τ_n *vs.* current density J_d (τ_n-*vs.*-J_d) characteristics are shown in Fig. 3 where the solid and broken curves were obtained with the use of the electrolytes which were prepared by dissolving 100 and 200g of sodium borate in one liter of ethylene glycol, respectively. It is observed in Fig. 3 that τ_n increases as J_d decreases and is dependent upon the electrolyte: the slope of the τ_n-*vs.*-J_d characteristic lines in log-log plot is found in the range of −1−−2, depending upon the electrolyte. These observations may be sufficient for the verification that the region indicated by τ_n is in the nonpassive state.

[1] The theoretical ratio of the oxide thickness to the monolayer thickness of Bi_2Te_3 (so-called Pilling-Bedworth ratio) was evaluated to be 1.54 ± 0.02 under the assumption that the growth film consists of trioxides, *i.e.*, Bi_2O_3 and TeO_3 which seem to be the most probable products of oxides from Bi_2Te_3; see Ref. (10).

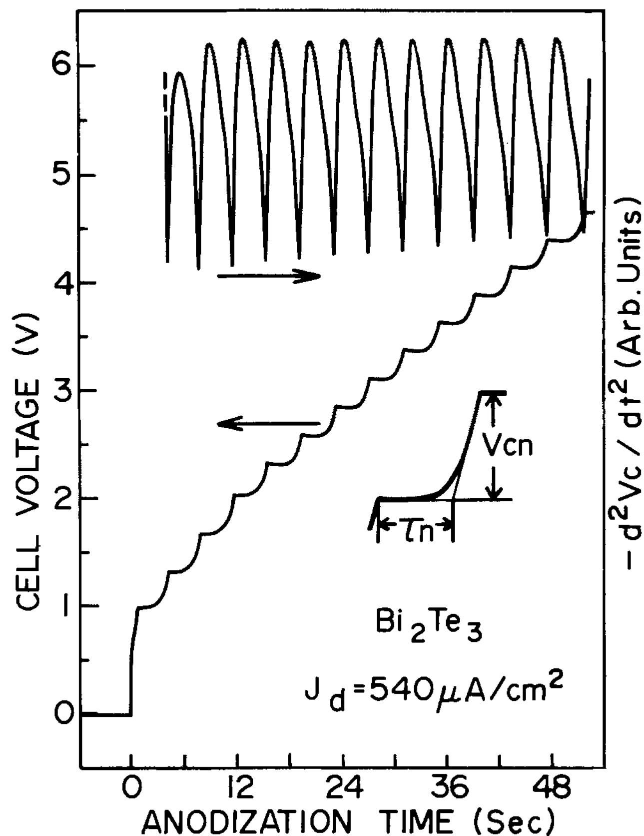

Fig. 1. The V_c-*vs.*-t characteristic and the second derivative of the V_c-*vs.*-t characteristic in Bi_2Te_3. Anodization was performed under constant current density J_d = 540 $\mu A/cm^2$. The initial voltage drop induces large transient output in the second derivative circuit, so that the initial part of the second derivative is not recorded in this figure. The inserted figure shows the unit line-shape from which the V_c-*vs.*-t characteristic curve is constructed.

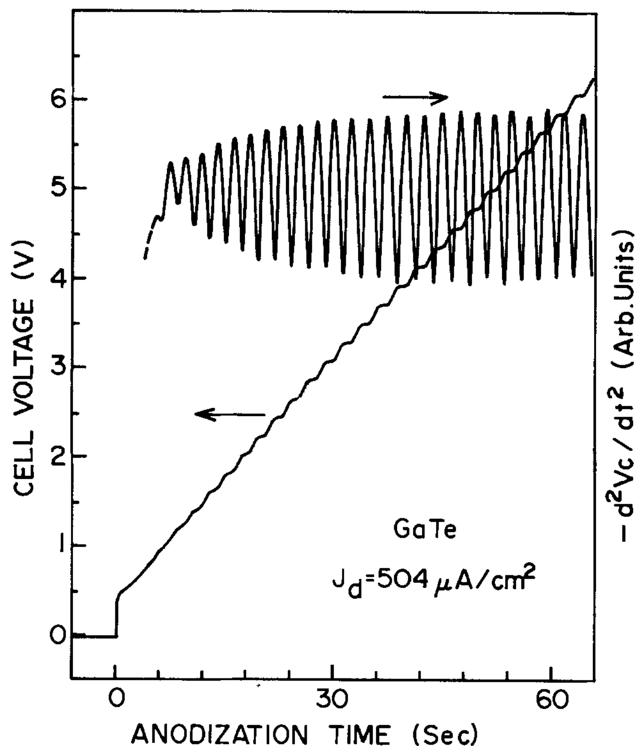

Fig. 2. The V_c-*vs.*-t characteristic and the second derivative of the V_c-*vs.*-t characteristic in GaTe. Anodization was performed with constant current density J_d = 504 $\mu A/cm^2$. The initial voltage drop induces large transient output in the second derivative circuit, so that the initial part of the second derivative is not recorded in this figure.

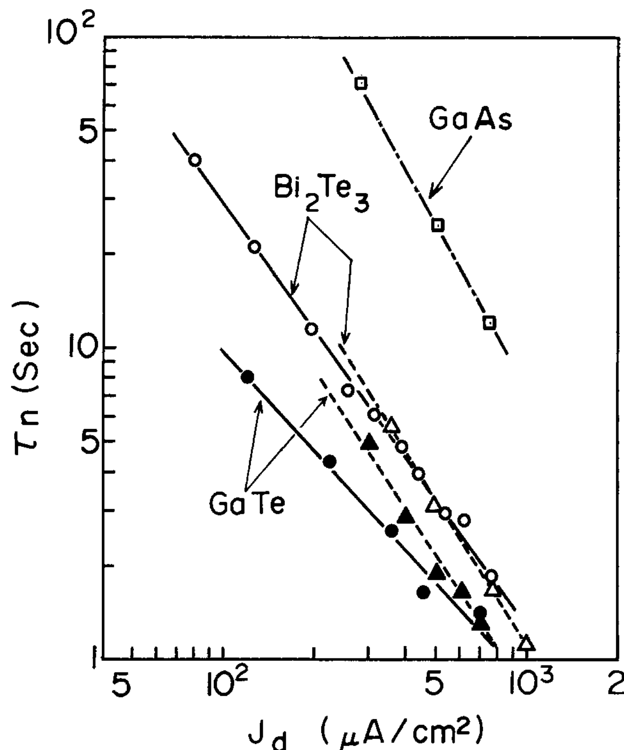

Fig. 3. The τ_n-vs.-J_d characteristics. The solid and broken lines were obtained with the use of electrolytes of sodium borate in ethylene glycol (100 g/liter) and (200 g/liter), respectively. The τ-vs.-t characteristic obtained in GaAs is shown for reference.

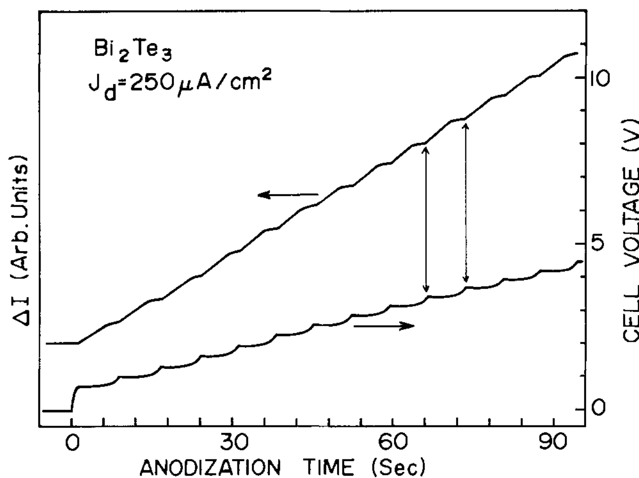

Fig. 4. The off-null signal of *in situ* ellipsometry (ΔI) and the corresponding V_c-vs.-t characteristic during constant current anodization with $J_d = 250\ \mu A/cm^2$ in Bi_2Te_3.

For reference, the τ-*vs.*-t characteristic observed in GaAs (5) is shown in Fig. 3, where τ is the duration time in the nonpassive region.

We have observed the periodic structure optically too in *in situ* ellipsometric measurements.[2] In Fig. 4, the *in situ* ellipsometry signal with initial null setting is shown together with V_c-*vs.*-t characteristic for Bi_2Te_3. ΔI is the increase of photomultiplier intensity due to the anodic film growth which causes the offset from the null setting. It is noted that ΔI shows rapid increase in the nonpassive region and little increase in the passive region. This observation strongly suggests that a conductive nonpassive film grows in the nonpassive state and transforms into a passive film in the passive state. These phenomena have been found in the anodic processes of iron and indium (6):[3] the initial film on iron in slightly alkaline solution at potentials $V < V_p$ is $Fe(OH)_2$, which transforms completely into Fe_2O_3 at higher potentials $V > V_p$, where V_p is a critical anode potential.

Thus, we have come to the stage that the unit lineshape represents anodization of the monolayer and it is possible to count the number of layers with extremely thin monolayer, *i.e.*, 7.45Å in GaTe (7) and 10.16Å in Bi_2Te_3 (4). In Fig. 1 and 2 are shown the second derivatives of the V_c-*vs.*-t characteristics which enable us to count more clearly the number, especially of the initial several layers in GaTe. We have counted the number up to 115 for Bi_2Te_3 and 95 $\pm$ 2 for GaTe in one anodization procedure.[4]

It should be noted that the nonpassive region for the first layer of Bi_2Te_3 was not observed in many cases, in other words, $\tau_1 \approx 0$. This experimental result for the first layer in Bi_2Te_3 may be corresponding to the observation in the anodization of GaAs by Harvey and Kruger (8). They have shown that, in the nonpassive region, no change in ellipsometric parameters attributable to a film forming on an initially clean anode was observed, but nonpassive anodic film was grown with virtually no change in potential when a vestige of a previously formed passive film presumably remained. In the present case, it is reasonable to consider that the passive film of the first layer can possibly be the nucleus for the nonpassive film growth of the second layer and this process repeats in the nth layer ($n \geqq 2$).

It should be also noted that in Bi_2Te_3 the steady state in the anodization process is built up in the region $n \leqq 5$ in many cases

$$V_{cn} \gtrsim V_{c(n+1)}; \quad (n = 1, 2, 3, 4),$$

$$V_{cn} = V_{c(n+1)}; \quad (n \geqq 5)$$

On the other hand, a quite different feature from Bi_2Te_3 is observed before the steady state in anodization of GaTe: not little increase of cell voltage in the nonpassive (?) regions is observed in Fig. 2, which causes uncertainty in counting the number of initial few layers, and more layer numbers are required to realize the steady-state anodization than in Bi_2Te_3. The electrochemical mechanism which induces different values of V_{cn} or amplitude of the second derivative between, before, and under the steady state in both cases is not understood at present. However, it is a realistic idea that materials with different quality will be produced in different situations: one anodization proceeds adjacent to the electrolyte and the other at a distance from the electrolyte through the buffer layer of previously anodized film.

We have obtained very similar results in Bi_2Se_3 and GaSe to those in Bi_2Te_3 and GaTe. The anodized films of these semiconductors are easily removed by most acids and alkalis, so that successive anodization and removal of the films will enable us to count the number in thick semiconductor samples.

It is of great interest to investigate the structure and electrical property of the anodized films or to apply the present method to the intercalation study in the layered transition metal dichalcogenides (9).

Acknowledgments

The authors would like to thank Prof. C. Hamaguchi and Dr. T. Shirakawa for kindly providing the second derivative circuit and for useful discussions. They would also like to thank Professor H. Yoneyama for helpful and stimulating discussions. This work is partially supported by the Grant-in-Aid for Scientific Re-

[2] The details of the present experimental setup will be reported elsewhere. The readers should refer to Ref. (8) for details in the *in situ* ellipsometry.

[3] We have also obtained the experimental results which suggests the formation of the nonpassive film on GaAs which probably transforms into the passive film; see Ref. (5).

[4] The error limit is due to the uncertainty in counting the number of initial few anodized-layers of GaTe; it does not include miscount which would result if atomic layers of more than those contained within the monolayer are consumed in the anodic dissolution process before the onset of passivation in the initial stage of anodization.

Etching Characteristics of Phosphorus Containing Polycrystalline Silicon in a CF_4 Plasma

Kiyokatsu Jinno,[1] Hiroshi Kinoshita,[1] and Yasuo Matsumoto[1]

Tokyo Shibaura Electric Company, Limited, Toshiba Research and Development Center, Kawasaki 210, Japan

The use of a rf-generated plasma for the etching of dielectric and other films and for the removal of photoresists has become a viable alternative to the conventional wet chemical etching used in the fabrication of semiconductor devices since the plasma process is simpler and more economical (1-9). Using a CF_4 plasma for poly-Si etching eliminates the additional oxidation and associated process steps since photoresists can be used as a masking material in the plasma.

From a device fabrication viewpoint, it is important to investigate the plasma etching of phosphorus containing poly-Si which is widely used to reduce the resistivity of the interconnections and gate electrodes in MOS LSI's. In our experiments, phosphorus was introduced into the poly-Si films by two methods; doping with PH_3 during the chemical vapor deposition of the poly-Si films at 550°C in an Ar ambient (doped poly-Si method) and diffusion from a phosphosilicate glass (PSG) film after the deposition of an undoped poly-Si film by the decomposition of SiH_4 at 800°C in an N_2 ambient (diffused poly-Si method). The films were about 5000Å thick. Plasma etching was carried out in the IPC 2005-1813SC plasma etcher with an 8 in. diam quartz reactor with aluminum shield. The etching gas was a CF_4, the gas pressure was maintained at 0.6 Torr, and the rf power was kept at 150W. Film thicknesses were measured by using a Talystep.

The phosphorus concentration of the poly-Si films was varied by changing the flow rate ratio of PH_3 to SiH_4 and keeping the diffusion time at 1000°C. It was estimated by the Auger electron analysis.

In Fig. 1, the relative etch rates (defined as the etch rate of the doped poly-Si film to that of the undoped poly-Si film) of the poly-Si film formed by the two doping methods are shown as a function of phosphorus concentration. The two methods give almost the same results. It is apparent that the etch rate of phosphorus containing poly-Si films in a CF_4 plasma is independent of the doping methods and only depends on the phosphorus concentration in those films. This fact is clearly seen in Fig. 2 which shows the scanning electron micrographs of the cross section of a 4 μm wide line. The etch rate is high

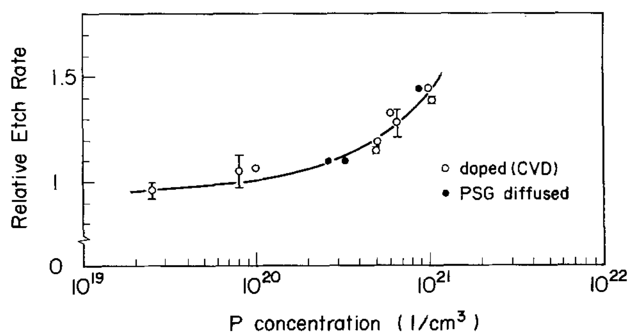

Fig. 1. Relative etch rate of the poly-Si films vs. phosphorus concentration.

at the surface of the diffused poly-Si film due to the high phosphorus concentration measured by the Auger electron analysis. From Auger electron analysis data, high phosphorus concentration regions exist to 800Å in depth from the diffused poly-Si film surface, whereas below the regions the phosphorus concentration takes a constant value and increases with increasing diffusion time. Meanwhile, the phosphorus-doped poly-Si film has an isotropical edge due to the uniform concentration of phosphorus measured by the Auger electron analysis. The etched profile of an undoped poly-Si film has also isotropical edge and is shown in Fig. 2 for a comparison.

In a CF_4 plasma etching, a gas plasma is generated in the reaction chamber by the rf power and silicon compound films begin to react with an activated fluorine species. A large plasma etch rate is obtained for elements which produce fluorides with high volatility. Therefore, phosphorus doping effect in a CF_4 plasma etching can be interpreted by high volatility of PH_3 (bp = 101.5°C at 760 mm Hg) compared to SiF_4 (bp = 94.8°C at 760 mm Hg) (10).

As a conclusion, the plasma etch rate of phosphorus containing poly-Si films is dependent on the phosphorus concentration, and the etched profile of those films depends on the phosphorus concentration distribution in depth direction.

Acknowledgment

End Point Determination of Aluminum CCl_4 Plasma Etching by Optical Emission Spectroscopy

B. J. Curtis and H. J. Brunner

Laboratories RCA Limited, Zurich, Switzerland

The use of optical emission spectra for end point detection has been reported for the CF_4 plasma etching of Si (1, 2) and for the O_2 plasma stripping of photoresist (3, 5). This note reports the application of the method to the CCl_4 plasma etching of aluminium

Etching experiments were carried out in a parallel plate reactor consisting of a pyrex glass cylinder 30 cm in diameter and 35 cm high with ports to accommodate a silica window and a quadrupole mass-spectrometer; the end plates were made of stainless steel. The water-cooled electrodes, made of polished nickel-plated copper, were 20 cm in diameter and, for these experiments, were spaced 40 mm apart. CCl_4 was introduced through the centre of the upper electrode which was connected to a 13.56 MHz rf generator. The substrates were placed on the lower, grounded electrode. Optical emission spectra were taken on a Heathkit EUE-700 Monochromator using an RCA photomultiplier type IP28, a Keithley 601 electrometer as an amplifier and a chart recorder. The distance between the monochromator entrance slit and the plasma was 30 cm; the emission was viewed through the silica window without focussing.

Fig. 1 (upper) shows the spectrum of a CCl_4 plasma at a pressure of 7 Pa and 500 Watts power; the CCl_4 flowrate was 20 scc per minute. An unequivocal assignment (4) of all of the peaks has so far not been possible, even though the species present in the gas phase are known from mass-spectrometric measurements. However, bands due to CCl can be identified with maxima at 255.8 nm, 277.7 nm, 278.6 nm, 305.5 nm and 460 nm. Free chlorine is known to be present in the system and bands at 257.0 nm and 307.0 nm overlap with those due to CCl. The peaks at 199.1 nm, 297.2 nm and 312.7 nm are also probably due to reactive, chlorine containing species since during etching, their intensity is very much reduced (see Fig. 1 (lower)). The peaks at

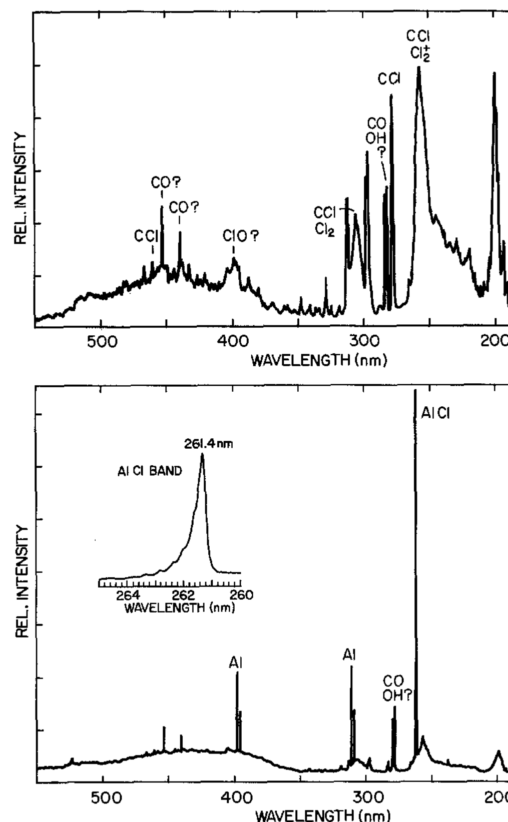

Fig. 1 (upper) Emission spectrum of CCl_4 plasma and 500 Watts, 7 Pa and 20 scc per minute flow rate. Scan rate 30 nm per minute. (Lower) Emission spectrum during CCl_4 plasma etching of aluminium under the same conditions as (upper). Spectrometer sensitivity one third of that used in (upper).

282.3 nm and 282.8 nm probably result from CO and OH; their intensity is unchanged during etching (Fig. 1 (lower)). The assignment of the peaks at 398.2 nm (possibly ClO) and at 438.7 nm and 452.8 nm (both possibly CO) is not certain.

Fig. 1 (lower) shows the spectrum obtained during the etching of an aluminium

plate of the same size as the grounded electrode. It should be noted that due to the high intensity of the peak at 261.4 nm, the sensitivity of the detection system was reduced by a factor of three compared to Fig. 1 (upper). The intensity of the CCl and Cl_2 lines is drastically reduced together with those at 199.1 nm, 297.2 nm and 312.7 nm which indicates that these too are probably due to a reactive chlorine containing species. A number of new peaks appear which can be identified as being due to AlCl (261.4 nm) and atomic Al (308.2 nm, 309.3 nm, 394.4 nm and 396.2 nm). In the inset, the AlCl band is shown at higher resolution.

For end point detection purposes, the AlCl band at 261.4 nm is more sensitive than the atomic Al lines which are not always detected from a small area substrate. Fig. 2 shows the course of etching a 3x3 cm substrate consisting of a 1300 nm thick Al layer evaporated onto a glass substrate. A photoresist grating with lines 200 um wide and a spacing of 200 um was defined on the Al layer. The CCl_4 plasma was ignited (500 Watts, 7 Pa, flow rate 20 scc per minute) and after an induction period of several minutes, etching began as indicated by the rapid build-up of the intensity of the 261.4 nm band. The decay of intensity at the end of etching was not so rapid but could possibly be influenced by geometrical factors. In this instance the etch rate was 185 nm per minute.

Etching can also be followed by the intensity of the lines resulting from CCl and/or Cl_2. For instance, the intensities of the peaks at 199.1 nm, 297.2 nm, 305.5 nm and 312.7 nm all decrease when etching begins and increase again at the end point.

In conclusion it can be said that the 261.4 nm emission band of AlCl is a sensitive indicator of aluminium etching in a CCl_4 plasma and should prove to be useful in further studies on this system and other halogen containing species. Furthermore, the CCl and/or Cl_2 peaks at 199.1 nm, 297.2 nm, 305.5 nm and 312.7 nm are also very effective end point indicators and merit further study.

$CuInS_2$ Liquid Junction Solar Cells

M. Robbins, K. J. Bachmann,* V. G. Lambrecht, F. A. Thiel, J. Thomson, Jr., R. G. Vadimsky, S. Menezes, A. Heller,* and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

We report that single crystal and pressure sintered polycrystalline electrodes of n-$CuInS_2$ in the cells n-$CuInS_2$/1-2 F Na_2S, 1-3 F S°, 0-2 F NaOH/C exhibit good quantum efficiency under short circuit and respectable voltage at open circuit with irradiation at and above solar intensities. The output stability of the system at steady illumination appears particularly promising.

Samples of single crystal $CuInS_2$ were grown by the gradient freeze technique and were annealed in cadmium vapor at 700°C for 100 hours in sealed, evacuated silica tubes to convert the material into n-type of low resistivity. Polycrystalline $CuInS_2$ was prepared from ultrapure CuO and In_2O_3 (Alfa Research Chemicals). Appropriate mixtures of the oxides were heated in flowing H_2S at 800°C for 4 hours and cooled. The resulting $CuInS_2$ powder was pressure sintered at 700°C and 10,000 psi for 2 hrs. to yield pellets with 99.5 to 99.9% of single crystal density. The pellets were annealed in Cd vapor as above.

The experimental techniques for current-voltage curves, photospectra, and stability measurement have been earlier described (1,2). Studies of the temperature dependence of the current-voltage behavior were made with a jacketed cell equipped with a bottom optical flat and a semiconductor electrode of an approximately circular slice, indium back-contacted, and mounted on a steel shaft in a rotating disk configuration. A sequence of a 30 sec. immersion in 4:1 HCl-HNO_3, H_2O rinse, 30 sec 10% KCN immersion, and H_2O rinse was used to etch the semiconductor surface.

Current-voltage curves for n-$CuInS_2$ crystal electrodes in the jacketed cell exposed to constant tungsten-halogen illumination as a function of temperature are shown in Figure 1. The maximum power output vs. temperature is presented in the figure insert. At 60-75 mw/cm^2 insolation levels, cells with different n-$CuInS_2$ specimens delivered, at ambient temperatures, maximum power outputs corresponding to power conversion efficiencies of 3.5 - 4.3%. The temperature data at light intensities equivalent to up to three times AM2 show a 50% increase from 26 to 70°C. The corresponding fill factor improves from 0.23 to 0.31. Fill factors up to 0.45 have been measured at lower current density in 2F Na_2S - 3F S solution. The low fill factor reflects poor behavior at the foot of the voltammetric curve. Correcting the short circuit current to AM2 insolation (75 mw/cm^2) in the sunlight experiments, the quantum efficiency, calculated using the 21 ma/cm^2 theoretical value (3) for a 1.53 e.v. band gap (4), ranges from 50-60%.

Extended runs of $CuInS_2$ photoanodes (to 2 x 10^4 coul/cm^2 charge passage) produce no detectable weight loss or visible alteration in these cells, i.e. no evidence of photocorrosion. Additionally, the current output at short circuit or resistive load has been essentially constant for this same level of charge passage throughout test periods approximating 1.5 months of 8 hr./day sun.

*Electrochemical Society Active Member.

The n-$CuInS_2$ electrode is so far notable for its stability in operation in its anion-element redox couple. It resembles, in this respect, n-CdS which has a 2.4 e.v. band gap and thus a poorer overlap with the solar spectrum. Common anion cells avoid the ion exchange problem. Even for the weight-stable photoanode of n-CdSe in sulfide-polysulfide cells (2) such surface exchange processes appear implicated in output stability deterioration (5).

In view of the close to optimum band gap (6) for solar conversion of $CuInS_2$, these photoelectrochemical cells have considerable possibility for improvement in efficiency. If the fill factor can be increased to take advantage of the good limiting open circuit and short circuit parameters, the n-$CuInS_2$ based cell may be a useful entrant in the field of liquid junction solar cell systems.

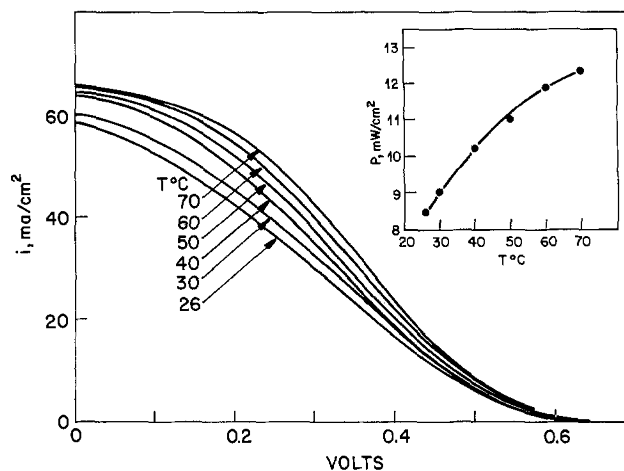

Fig. 1 Current-voltage curves for the cell n-$CuInS_2$/2F Na_2S, 3F S, 2F NaOH/C with constant tungsten-halogen illumination at different cell temperatures without stirring. The insert shows the maximum power plotted vs. temperature.

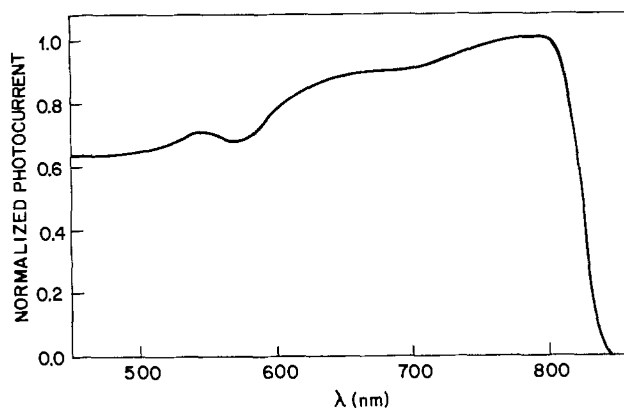

Fig. 2 Photocurrent spectrum at short circuit to a carbon electrode of a n-$CuInS_2$ electrode in 1F Na_2S-1F NaOH.

Resin-Bonded Cellulose Separators: An Overview with Prognoses

James R. Dafler*,[1]

ESB Incorporated Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

Resin-bonded cellulose separators are very widely used in the starting, lighting, and ignition battery industry. Since their appearance and maturity, they have undergone systematic improvements, but their basic shortcomings have remained. Separator development is reviewed here, and the pertinent structure and chemistry of the cellulose substrate is discussed. The current literature, which indicates that improvements in substrate character and acid resistance can be made, is also reviewed.

In 1917, almost the beginning of the modern starting, lighting, and ignition battery industry, Brooks pointed out the lead-accumulator was unexcelled in portable service applications (1). Separators at that time were wood veneer and were superior to anything in use despite the stringent requirements of their manufacture. At that time, only treated wood possessed good wicking action and reasonable conductivity and held active material in place against vibration and the eroding action of hydrogen generated on overcharge. Other materials had been tried, but until the microporous hard rubber separator appeared, wood veneers and combinations of wood and other materials dominated separator practice. Eyanson developed an unglazed porcelain membrane with incorporated lead spacers (2), but this product undoubtedly gave a cell of high internal resistance. Sperry developed a perforated, corrugated, hard rubber sheet that was really a simple, open spacer (3). The earliest hard rubber separators, used as adjuncts to wood, were approximately 30% porous. Batteries in which they were used were poor for cranking purposes (4).

Hardy and Hungerbuhler (5) experimented with artificial stone for making separator membranes. They compressed and then baked silicates, feldspars, bone, and lime to form refractory porous sheets. Rodman (6, 7) experimented with techniques to make porous glass separators, developing membranes of sand or fine glass powder fritted together.

In 1910, Flanders described an untreated wood veneer separator using a well-defined rib structure (8), and after this a number of wood/hard rubber combinations were developed. Carpenter (9) coated thin wood sheets with vulcanized rubber, and Chamberlain described a process to produce wood veneers machined so that the ribs were integral to the separator structure (10). Gould's patent, describing the use of hard rubber and wood laminated together, appeared in 1916 (11).

Many battery researchers applied themselves to the separator problem between Brooks's time and the period during which the resin-bonded paper separator appeared, then matured. One of the more interesting inventions was Bliss's (12) ingenious attempt to make a porous phenol-formaldehyde sheet. He mixed asbestos and zinc with resin, polymerized it, and removed the zinc with acid. A number of other inventions included a separator of chopped bird feathers and sodium sulfite (13), bitumen-impregnated felts (14), roofing felt with extruded hard rubber ribs (15), and Willard's novel combination of fiber cables and wood strips bonded into sheets with a latex (16).

The search for the correct material to allow ionic transport and still provide a useful, robust separator later followed several newer lines of inquiry. Ekisler described a separator made of layers of drawn glass fibers and bound with rubber latex or a phenolic resin (17), and Lunn used rubber cements to fix flexible rubber separators directly to plates (18). Slayter made a separator of crossed felts and wools (19) to realize a gradient of pore sizes normal to the separator; he also developed a braided fiberglass structure for tubular lead-acid batteries (20). The Chloride Electrical Storage Company, Limited patented a separator formulation that used diatomaceous earths or other fillers with rubber latexes or thermoplastic resins (21). Fuller and Sudlow anticipated the envelope separator concept as early as 1939 in their patent describing an electrolyte-retaining separator matrix (22).

In 1943, Slayter patented a process for making porous, fibrous glass sheets (23), and Vinal later (1950) experimented with complex laminates of glass wool and thermoplastics such as polystyrene (24). He developed pores in the plastic by using leachable salts such as potassium sulfate or magnesium sulfate. During this period, Szper developed an electrolyte-retaining separator matrix by mixing kieselguhr, sulfur, soluble alginates, and rubber, then pasting the slurry onto glass wool sheets (25). This was followed by several attempts to use diatomaceous earths and various resins. Walker (26) used neoprene and diatomaceous earth, while Phillips (27) used glass fibers matted with diatomaceous earth and styrene-butadiene copolymer laminated to phenolic-bonded glass mat. With this technique, he hoped to realize a selected, one-sided microporosity.

Wood separator technology was pioneered much earlier and by 1917 was relatively mature, represent-

Key words: cellulose, hydrolysis, heterogeneous, lead acid battery, polymerization.

ing a large patent and process-patent literature. The 1911 patents of Dodge (28) and Taylor (29) describe processes to manufacture separators using complex, serial treatments of the wood veneers in acids and alkali. Skinner (30) used hot sulfite solutions (100°-175°C) and pressurized washing and drying to make separator sheets, while Morrison (31) cooked wood sheets in hot paraffins to remove the volatile matter. The finished product was produced by solvent extraction. Later, Skinner (32) boiled his wood veneers in solutions of sodium sulfide or, more simply, plain water, but retained pressurized drying and washing.

Wright (33) used a process he referred to as electrical osmosis in his process for making separators of bass and cherrywood. Morrison attempted to alleviate lead-tree formation by precipitating barium sulfate or strontium sulfate in the pores of his wooden matrixes (34). The 1916 Shimazu patents describe a complex procedure for making thin wood separators (35). Shimazu specified acid sulfite treatment, alkali carbonate washes, and even alkali peroxide treatments in his processes.

After 1917, wood technology continued to be elaborated as shown by Lunn's development of integral grooves and ribs (36), Norris's combination of wood, hard rubber, and celluloid (37), and several combinations of wood with glass-matt (38) and other spacers and protectors (39-41). The bulk of wood used was treated by one or another complex aqueous treatments (28-35). The most novel preparation of wood veneers seems to be that of Steerup (42), who opened the pores by steaming, followed by treatment with ammonia. The ammonia and ammoniacal compounds were then volatilized with steam at 125°-130°C.

The drain on the supply of Port Orford Cedar, the wood separator of choice up to that time, led to definitive research and development on other coniferous woods. The paper by Peakes, Lloyd, Barnes, Berry, and Ritter (43) represents the most complete study of wood preparation in the nonpatent literature. It was a seminal effort that came, unfortunately, at the end of the period of dominance by wood in separator practice.

Schidrowitz and Goldsbrough were, apparently, the first developers of porous, spongy rubber sheet materials (44). Their original patent of 1914 (45) used a rubber latex, sulfur, and substances that decomposed during the cure to develop porosity during vulcanization.

Willard appears the first to use hard rubber in a battery separator development (46). His development consisted of cloth fibers and other filaments embedded in hardened or vulcanized rubber. Separators were made by cutting thin sheets of the composite normal to the direction of the embedded filaments. Willard's later patents were also embodiments, albeit different ones, of the same general idea (47).

By the mid-1930's, hard rubber separators were made commercially by a number of different techniques such as Beckmann's molded latex sheet with ribs (48) and Martindell's hard rubber separator with specially positioned ribs (49). In 1937, Greenup and Olcott (50, 51) demonstrated the over-all chemical stability of vulcanized natural latex separators. By that time, hard rubber separators gave long life and improved cranking performance (in automotive applications).

Hard rubber separators are widely used for industrial batteries (forklift truck, telephone substations, etc.) and a lesser extent for the manufacture of automotive and truck cranking batteries. However, as Palmer (52) points out, resin-bonded paper is the basic separator in use today in the starting, lighting, and ignition (SLI) battery industry. It appears, historically, as a natural follow-up to cedar and other wood veneer separator materials. The good-to-excellent resistivity and integrity of wood veneers suggest that impregnated cellulose (as in wood cell-wall coverings) should make a good, porous matrix suitable for SLI applications. Resin-bonded paper and wood veneer separators have similar total porosities, quite different pore size distributions (53), and different chemical stabilities in the acid environment of SLI batteries. Like wood, resin-bonded paper separators have good stiffness and burst strength properties (53, 54).

Cellulosic separators—evolution.—Resin-bonded paper separators entered the SLI battery field with considerable impact in the 1950's. Commercial manufacture by paper and fiber specialties manufacturing firms has resulted in a separator that possesses a considerable cost-effective advantage over hard rubber and other polymer materials and currently occupies a dominant position in SLI battery assembly (52).

Cellulose appeared as early as 1922 when Wood and Smith brought out a complex matrix of hard rubber, wool, and cotton fibers (55). This was to be a separator that developed increased pore volume as the cotton linters were digested in the acidic medium. The future use of paper separators may have been forecast by Benner *et al.* in their 1930 development, a matrix which consisted of cellulose fibers and tough, noncorroding spacers bonded into a composite sheet (56).

Dillehay developed a paper polymerized with furfuryl alcohol (57) that consisted of approximately 85% cellulose. Later, Lehmberg processed a felt of Vinyon (a vinyl acetate-polyvinyl chloride copolymer) and cotton (58), asserting that hydrolysis of the cotton, by increasing the porosity, relieved "leading-through."

Uber's 1951 patent (59) represents the modern resin-bonded cellulose (RBC) separator. His matrix was impregnated with phenolic resins and is still used in present-day separator practice. There was a rush to develop similar matrixes but with refinements and minor improvements. Wilson patented (60) phenolic-impregnated papers, sometimes with complex refinements, as was the patent awarded Merrill in 1954 (61). Uhlig *et al.* (62) embellished the basic concept by adding pinewood resins—for reasons not clear to this reader. Merrill and Mears pulped glass fibers with the basic cellulose slurry. In Merrill's development (63) furfural- and urea-formaldehyde resins were used as impregnating agents. Mear's use of glass fibers (64) was more complex: he hoped to develop a matrix so that the separator was rich in glass fibers on one side and rich in cellulose content on the other.

During this period a number of patents appeared dealing with standard phenolic-impregnated matrixes reinforced with sprays or coatings of other additional resins. Raphael and Schweitzer (65) and Beckvold and Hartman (66) treated regular RBC-separators with sprays of other thermosetting resins. Raphael and Schweitzer endorsed the use of suspended, acid-resistant fibrous material in the sprays; they suggested polyvinyl chloride, polyethylene, polystyrene, butadiene-styrene copolymers, and many others, including polymers and copolymers of isobutylene.

Dowse and his colleagues (67) developed rather complex cellulose separators employing special folds at the edges of grids and plates, and Stickel (68) brought out a simple two-faced die used to crimp a permanent rib into partially cured phenolic-impregnated paper. Later, Little (69) and Hall (70) made simple improvements in the rib used on typical paper separators.

After this period of activity, most new developments in these separator areas appear to be more visionary than practical. Mills's (71) and Vedovelli's (72) developments are rather complicated, involving special impregnations or various kinds of duplex laminates of plastics bonded to paper. Zenczak's development (73), a separator using phenolics as impregnates but starting with a lignocellulose paper base, is rather interesting in view of the frequent and profitable use of lignins in expander technology.

Antimonial alloy grids—A complication.—Several authors have pointed out the strengths and weaknesses of RBC separators. For automotive end use, Lander (74) has indicated, given current element design, that economics or cost effectiveness is the principal factor considered for separator selection. Sundberg (75) showed an increasing awareness of the role that pores play in the failure of SLI batteries related, apparently, to antimony migration and diffusion.

Antimony transfer from the positive grid alloy to the negative grid has been recognized as a major system problem for some time (76). Crennell and Milligan (77) investigated the hydrogen overpotential of aged cells with antimonial positive grids to explain the steady, irreversible sulfation of negative electrodes. Antimony migration and its effects—self-discharge of the negative on stand, reduced charging efficiency and sulfation of the negative, and stibine evolution on overcharge (78)—remain a complex problem. The lowering of end-of-charge voltage (ECV) may be the result of extensive antimony transfer or the result of high resistance short circuits built up in the separator by deposition, solution, and crystallization of lead dioxide or other semiconducting lead salts (perforation failure).

Some investigators believe lead trees are responsible for failures similar to short circuits, and there remains in separator practice a "leading through" measurement to test a separator's resistance to lead "dendrite" growth. Wranglen has demonstrated which conditions are necessary for well-characterized lead dendrite growth in electrocrystallization systems (79). Unfortunately, he reported no work in sulfuric acid media.

Lead dendrites are propagated from asperities in high current-density environments and represent a diffusion-controlled phenomenon. In low current density environments, nondendritic growth layers may form on exposed planes. This mode is quite slow, compared with dendritic growth, resulting in plates and mosaics. In the transition region of current density, layered growth can also occur at surface asperities.

The isolation of separator failure effects in batteries having antimony-lead alloys is a complex problem that can be settled only by direct physical examination of suspect elements. The charge history of deeply discharged automotive batteries will show gradual lowering of the ECV due, no doubt, to antimony transfer. This may be the cause of element failure if there is no direct evidence of short-circuit failure. In the presence of very low ECV's and physical evidence of shorting, then the latter must be assumed the preponderant cause of failure.

Resin-Bonded Cellulose Separators

Corrosion in SLI battery electrolyte.—In mineral acids, cellulose is highly reactive and hydrolyzes rapidly. For RBC separators to be useful in sulfuric acid (H_2SO_4) media ranging from 3.3*N* (sp gr approximately 1.1) to 10.7*N* (sp gr approximately 1.3), they must resist their native tendency to hydrolyze. The currently used impregnation, a two-stage, water-borne phenolic resin, accomplishes considerable protection, but RBC separators lose up to 15% of their weight if stored in battery grade acid (approximately 9.2*N* H_2SO_4) at 52°C. In actual battery practice, the loss has been seen to be greater (52).

Straightforward corrosion experiments were done in this laboratory. A very large number of carefully cut and preweighed pieces of RBC separator were placed in 9.18*N* H_2SO_4 (1.256 sp gr) and stored at 52°C for an extensive period. Samples taken over periods up to 2400 hr suffered considerable weight loss and continuous darkening of the materials, as shown in Fig. 1. These are two separate but related phenomena. When we applied regression analysis to our isothermal corrosion data, we found that weight loss, based on the percent cellulose in the composite, fit a logarithmic relationship

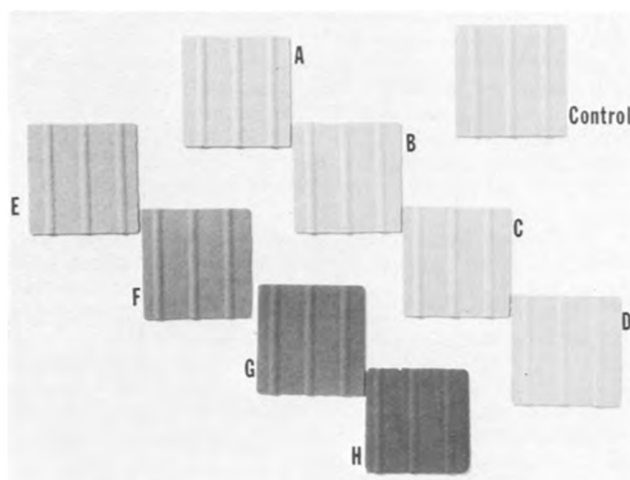

Fig. 1. Color change in sulfuric-acid treated RBC separators. Separator pieces were stored in 9.2*N* H_2SO_4, at 52°C for: A, 19 hr; B, 43 hr; C, 230 hr; D, 530 hr; E, 840 hr; F, 1200 hr; G, 1500 hr; and H, 2400 hr.

$$P(\%\ \text{wt loss in } 9.18N\ H_2SO_4) = 2.058 \log_{10}{}^2 t + 0.30176 \quad [1]$$

where t is expressed in hours.

The degradation of cellulose by mineral acids has been studied in very great detail since 1844 (80). De Carolles found a spectrum of what he called "wood sulfuric acids" when wood cellulose was treated with strong H_2SO_4. Addition compounds were found (81) when very concentrated H_2SO_4 was used. These compounds were of the form $(C_6H_{10}O_5 \cdot 4H_2O \cdot H_2SO_4)_n$.

Freudenberg and colleagues (82) studied the degradation of cellulose in 51% H_2SO_4 at 18°C. They presumed the H_2SO_4 to be instrumental in the reaction—the process was not ordinary hydrogen ion catalyzed hydrolysis. Freudenberg assumed the hydrolysis unimolecular, with the velocity constant a function of the fraction of reacted glucose linkages.

The cellulose in RBC separators is significantly protected, but is not protected well enough, and separators taken from very old cells or from batteries cycled for very long periods are usually extremely frangible. They seem, almost, a lacy network of phenolics unsupported by the original cellulose. This is not the case, however, and weight measurements show that, even in this brittle condition, much of the original cellulose remains.

The probable key to better RBC separators, with respect to hydrolysis, lies in a better resin impregnation technique. Other resins have been used (57, 58, 63, 66), but the phenolic impregnation scheme remains the most common current practice. For the relatively undemanding applications in SLI batteries, RBC separators are the most cost effective (74).

Phenolics of the same kind used in RBC separators are used in other kinds of lead-acid battery systems. In tubular plate cells which are used for industrial and stationary applications, the tubes are frequently braided fiberglass bundles with a phenolic binder. After considerable cycle life, the resin bonding on the fiberglass tubes is found to be completely eroded. The tubes then lose their rigidity, and considerable active material loss is possible, with an associated loss of battery performance.

The phenolics associated with RBC separators are known to discolor and react in battery electrolyte after extensive exposure (Fig. 1). They do not, however, erode completely, indicating that their long life is, in part, due to the association with the cellulose substrate.

An obvious conclusion is that the cellulose and phenolic resin binders copolymerize to form a matrix that resists corrosion in this environment. The evidence for copolymerization is quite strong: a combination of structural evidence of inter- and intramolecular hydrogen bonds (83), labile hydroxyl groups (84, 85), and differences seen in the ability of dry alpha cellulose to reorganize in the presence of water vapor (86). Much of the evidence has been assembled in a recent paper (87).

It is essentially the corrosion of the substrate cellulose that brings about the degradation of RBC separators. The currently used phenolic impregnation system is effective in delaying the loss of material, but not as well as battery manufacturers could wish for. The hope for better RBC separators, therefore, lies in improving the current process of impregnation, or in a new or modified process that will produce a more corrosion-resistant matrix that still retains most of the desired cost effectiveness of paper.

A note on cellulose structure.—Cellulose, derived from whatever source, is a highly crystalline material that yields definite x-ray diffraction patterns. This was, apparently, first discovered by Nishikawa and Ono (88). X-ray investigation was intensified, and several cellulose modifications were determined (Cellulose I, II, III, and IV). Alpha cellulose, the main raw material from cotton and many woods, is principally Cellulose I, referred to as native cellulose. A monoclinic unit cell structure possessing two screw axes was proffered by Meyer and Misch (89) and has retained its essential usefulness for several decades, in spite of many modifications. The Meyer and Misch unit cell is a refinement of earlier predictions (90) and has withstood a fairly steady current of refinement.

Considered to be made up of crystalline regions imbedded in an amorphous matrix, cellulose structure was for a long period described as two phased, or micellar, a description that culminated in the fringed-micelle model (91-94) now questioned by many investigators. Cellulose is a polymer of beta-cellobiose, and its structure is determined, in extension, by the nature of the monomer and the character of the chain linkages (95, 96). Beta-cellobiose is a Beta-linked dimer of glucose and in Haworth's (97) nomenclature is represented by the structure shown in Fig. 2.

The unit cell for cellulose is still not generally determined to everyone's satisfaction, but many reasonably satisfactory models exist (89, 90, 98). It is generally agreed that the pyranose rings assume the less-strained *trans*- or chair-form. Transitions to the *cis*-form which occur in excess energy environments are suggested by Reeves (99) as a possible cause for differences in physical structure and reactivity. This suggestion has been supported by work done by Bjornhaug, Ellefsen, and Tonnesen (100).

The cellulose structural element attains a rod-like stiffness due to stability imparted by intermolecular and intramolecular hydrogen bonding. Liang and Marchessault, in a series of infrared spectroscopic analyses, obtained extensive evidence for the existence of these bonds (83). The hydrogen bonds restrict the anhydroglucose units to a limited region of movement about the acetal linkage. The net result of hydrogen bonding is a spectrum of activity for the hydroxyls associated with the ring carbons. Recently, Røwland, Roberts, and Bose (84) measured the relative reactivities of the carbons associated with intramolecular hydrogen bonds and with intermolecular bonds. Using a hydrocellulose, they found the C-2 hydroxyl (Fig. 2) to be stable, with the C-6 and C-3 hydroxyls approximately 54% and 29%, respectively, as available for reaction. For fibrous cotton, the relative availabilities were approximately 77 and 32%, respectively, the difference being due, presumably, to the greater relative order and crystallinity of the regenerated cellulose (hydrocellulose).

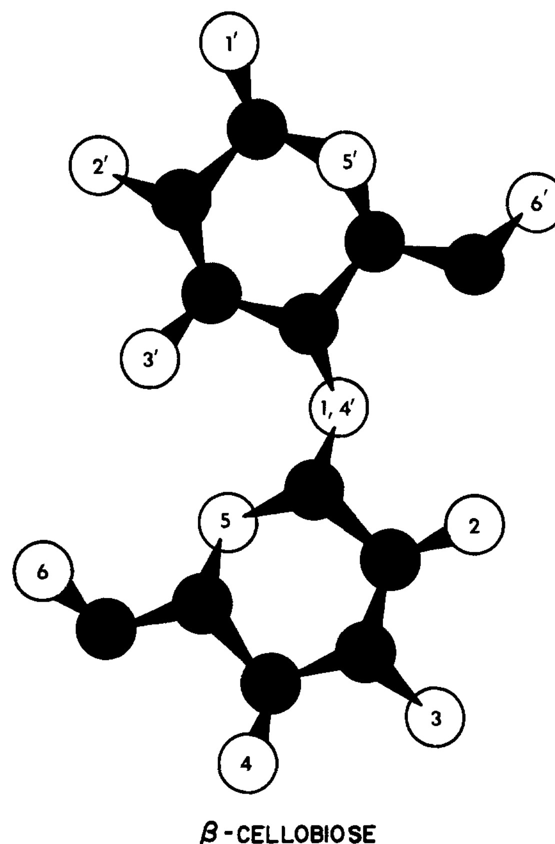

Fig. 2. The structure of α cellobiose. Open circles are oxygen, closed circles carbon. The associated hydrogens are not shown.

St. John Manley argues that we should consider cellulose from the molecular point of view, and he shows how the reactivity and puzzling retention of apparent crystallinity can be explained using his protofibril model (101). The protofibril model explains how the index of crystallinity of hydrocellulose and cotton fibers appears the same, in spite of the great difference in their physical properties. It also obviates the group-theoretical work of Jones (102), who was unable to correlate the x-ray intensities and derived structure factors for cellulose I and II to any conventional space group.

The St. J. Manley model says, essentially, that the protofibril is completely crystalline and the properties and reactivity of cellulose may best be understood by studying the processes into which protofibrils enter. Accessibility and the properties of other cellulose structures are, in this construction, only reflections of the manner in which the protofibrils form larger superstructures (Cellulose I, Cellulose II, etc.).

The protofibril model, incorporating as it does an orderly pleating and folding of supermolecular structures, uses a natural, flattened helix and encompasses the persistently proffered hypothesis of screw dislocations and spiral structures first adumbrated by Balls in 1923 (103). The small but finite regions that are essentially the physical zones between ribbons and folds give rise to the amorphous halo of typical Debye-Scherrer x-ray diffraction patterns.

The spirally wound protofibril model is not uniquely St. John Manley's. R. Mark *et al.*, to explain the high elastic modulus of cellulose, formulated an extended (nonfolded) chain model that is very like a coiled bedspring (104).

Later structure investigation by electron diffraction and newer calculations on existing x-ray diffraction data still lead to diverging hypotheses. Kulshreshthwa

and Dweltz (105) give reasons for abandoning the notion of degree of crystallinity entirely, and they discredit the fringed-micelle (two-phase) model, pointing out that crystallinity as currently understood indicates only a difference between the molecular order of a sample and that of a crystalline standard. Hebert and Muller (106), using electron diffraction, have partially substantiated Jones's conclusions (102) about the unit cell and its space group. The Meyer-Misch unit cell requires it to be of space-group symmetry $P2_1$, which requires the absence of x-ray or electron diffraction lines, corresponding to [0*k*0] indexing (*k* an odd integer, only). Because these lines are present in both x-ray and electron diffraction, the Meyer-Misch unit cell clearly fails to correlate all the available data.

X-ray diffraction experiments have long been a primary means to investigate the structure and the chemical stability of cellulose (107). It has been used in a limited way to study the corrosion of RBC separators in battery grade acids (108). The x-ray diffraction spectrum of RBC separators is a characteristic that is sensitive to the condition of the matrix (87, 108) and can be used, in conjunction with density and weight-loss measurements, to index the quality of the retained cellulose in samples that have been hydrolyzed.

The impregnation of cellulose with phenolics in the paper-making and polymer-curing processes leads to an x-ray diffraction spectrum only qualitatively different from the spectrum of alpha cellulose as shown in Fig. 3. However, the reaction of RBC separator matrixes to water is quite different, and water vapor actually lowers the order of the separator matrix while having a definite ordering effect on untreated alpha cellulose (86, 87, 109, 110).

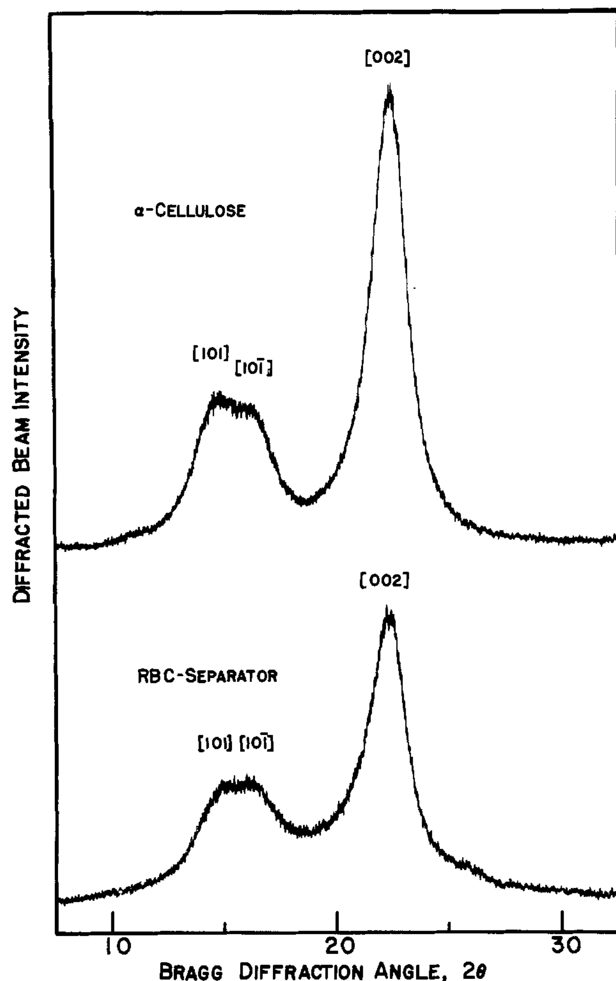

Fig. 3. The x-ray diffraction spectra of α cellulose compared to RBC separator. Conditions of the analysis (field and beam current) were unchanged.

It should be noted that cellulose, as in all highly crystalline materials, can be decrystallized physically (107c) and chemically (111), but it can also be reordered or annealed by heat-treatment (112) and a water-plasticization process (109, 113). The structure and properties of this matrix, alpha cellulose with a reactive polymer impregnate is still not fully understood and characterized. Enough, however, is known to make careful, qualified prognoses on the future of this matrix for separator applications. This writer, unlike Palmer (52), is convinced cellulose can be the primary substrate for a much improved SLI-separator matrix.

Some relevant chemistry.—The two-phase hypothetical description of cellulose—the amorphous/crystalline model (fringed micelle)—was very useful for correlating data from a great number of early studies on hydrolysis in acid media. Meller (114) investigated the acid hydrolysis of what he called the "easily accessible fraction" in two papers published in 1949 and 1953. He measured activation energies for hydrolysis that indicated the rate of weight loss to be controlled by an "activated diffusion" process. Meller suggested that reactivity could be used to measure the crystalline/amorphous ratio.

Nickerson and Haberle had already assumed that the attainment of a constant reaction rate meant much the same thing for the retained crystalline fraction in hydrolyzing cellulose (115). They also assumed the crystalline/amorphous ratio could be determined by hydrolysis measurements. Sharples (116) demonstrated that certain linkages were more acid sensitive than others in the cellulose chains of Egyptian cotton. Sharples, however, did this work on chemically modified cotton samples, and it is not clear whether the chemical preparation altered the reactivity, because Sharples found differences in acid-sensitive linkages in regenerated cottons from different sources.

Ant-Wuorinen and Visapaa concluded from extensive hydrolysis experiments, coupled with x-ray diffraction measurements, that changes in the "index of crystallinity" indicated little about amorphous/crystalline ratios but indicated, rather, the degree of lateral order (117). These workers used the crystalline/amorphous concept to deal with hydrolysis data, assuming that the micellar, crystalline bodies are fundamentally more stable to hydrolysis. The difficulty with their lateral order hypothesis is pronounced for extensively hydrolyzed cellulose such as Nickerson's hydrocellulose (115). These are materials without extensive lateral order (in a micro sense) but with very high indexes of crystallinity.

In this laboratory, alpha cellulose (Cellulose I) was hydrolyzed in 1.40 sp gr H_2SO_4 for 36 hr at 52°C. The liquor was black to dark brown and the cellulose slabs completely degraded. The solid particulate matter was washed in distilled water until free of $(SO_4^{=})$. The resulting material was white and formed a viscous dispersion in water. A small hand sheet was made by filtration and dried in vacuo; the result, a brittle horny material, was analyzed by x-ray diffraction. The x-ray spectrum was compared directly with the spectrum of raw material cellulose (87). The spectra are almost identical, and the crystallinity indexes, in the sense of Segal (107b) or Hermans and Weidinger (107a), are virtually the same. This indicates that the crystallinity index is dependent, mainly, on structural elements much smaller than regular fiber bodies (118a). The degree of polymerization of alpha cellulose is on the order of 10^3-10^4, while that of extensively treated hydrocellulose is approximately 10^2 (118b).

As pointed out, the crystallinity of separators is somewhat lower for finished separators than for native cellulose (87, 108), however, the crystallinity index is not greatly decreased by storage in battery electro-

lytes. Physical examination of separator pieces stored for hundreds of hours in SLI electrolyte indicated corroded edges and other signs of weight loss, but x-ray examination indicated a practically unchanged degree of crystallinity (87).

The discoloration of the separators (Fig. 1) during long periods of acid storage and cycling is not easy to explain. Many battery researchers assume that it is a charlike, darkened, hydrolyzed product of cellulose or glucose degradation. For this explanation to hold, we must assume these dark species are labile, reacted parts of the fibrous network, and somehow bound by the polymer resins used to protect the cellulose; however, hydrocelluloses made by acid hydrolysis are clean and white (115). The dark products, being water- or acid-soluble, are not trapped in the fiber matrix that remains after hydrolysis and cannot account for the darkening.

The possibility that the darkening is due to degradation of the phenolformaldehyde resins must be examined. Resins of this type are cured at temperatures on the order of 195°C (119). The resins used in separator manufacture are treated at approximately 210°C in a continuous process, and the "cure" may be incomplete; thus there are likely to be labile moeities in the finished separators. It is known that sulfonation of phenol-formaldehyde resins has been used to produce ion-exchange resins (120), generally reddish-brown in color. Though the acid medium in batteries is dilute compared with sulfonation media, exposure is extensive, and the presence of partially cured resins may make this speculation palatable.

The dark color taken on by H_2SO_4-treated separators may also be the result of acidic oxidation of labile phenol moeities and of acid-catalyzed formation of phenolic and aldehydic condensation products. The acid undoubtedly catalyzes a certain amount of "curing" in the resins present, but prolonged H_2SO_4 exposure will certainly catalyze condensation reactions, which are known to be pH sensitive. Phenol alcohols condense rapidly on contact with sulfuric acid (121).

The bulk of experimentation concerned with the hydrolysis of cellulose itself has been done in hydrochloric acid (HCl) media (114-116, 118b, 122-125), and weight changes in HCl are used to define the character of alpha cellulose used as a raw material in various polymer processes (126). An extensive and continuous research into the properties of cellulose in H_2SO_4 media has been done in Finland by Ant-Wuorinen and colleagues (117, 127-130) at the State Institute for Technical Research at Helsinki.

Ant-Wuorinen's hydrolysis data (130) for bleached sulfite pulp is shown plotted in Fig. 4. Bleached sulfite pulp is the basic raw material of RBC separators, and to the present, these are some of the best developed H_2SO_4-hydrolysis data available. In this scheme, the investigators were interested, mainly, in reaction velocity (as a function of H_2SO_4 concentration) and the

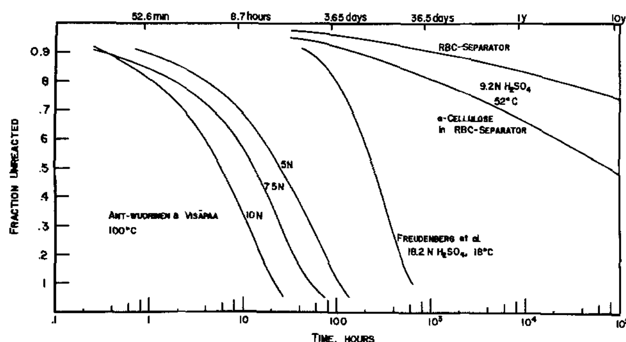

Fig. 4. Hydrolysis data for cellulose I. The data of several investigators are compared here, with all data plotted as the normalized unreacted fraction vs. time of hydrolysis.

reaction half-lives. Also plotted in Fig. 4 are data generated by regression analysis of RBC separator weight loss (Fig. 1). We have also plotted the Freudenberg *et al.* data (82) to indicate the complex relationship that exists between acid concentration, temperature, and time (131, 132). What is clear is that the cellulose in RBC separators reacts almost typically with sulfuric acid, though at a much lower rate. Inherent in this is the obvious suggestion that better impregnation can be performed or that an improved resin (more sulfuric-acid-resistant) will yield a separator capable of longer life in a typical battery environment.

Prognoses: Toward a Better Separator

Phenolic-bonded cellulose matrixes are the most widely used kind of separators in the SLI industry (52) for reasons of cost effectiveness (74), but a cursory perusal of the patent and the specialized literature clearly shows that this very mature product has not been significantly improved in years. Its dominance in the automotive battery industry, that most numerous and profit stimulating of lead-acid batteries, has inadvertently placed it in a limbo from which it promises never to come forth. Recent work in separator technology (87, 133) indicates that the problem of RBC separator failure is a complex problem associated with the fundamental paper matrix and with the nature of the impregnation.

The paper matrix—Pore size distribution.—Palmer (52), Sundberg (75), and others (133) argue effectively that pore size distribution in the separator is the principal variable in considering failure, whether due to antimony transfer or so-called perforation failure. It has been shown (133) that large pore separators most frequently fail by the perforation mechanism and offer an excellent matrix for capture and growth of suspended and dissolved lead species, and Sundberg (75) has argued that large pore matrixes permit greater transport of antimony from the positive grid to the negative, placing the blame on antimony diffusion. Diffusive transfer should be practically the same whatever the separator or barrier; however, the electrolyte in a cycling cell is subject to a great deal of stirring during charge and overcharge. The transfer is in part convective, but it ought to be noted the pores in RBC separators are so large that convective mixing can take place within them (134), so that transport of antimony through these separators is more likely than through microporous separators (135).

A water-laid paper (fourdrinier) can be made so that the pore size distribution is much smaller. Filter paper manufacturers have sold papers with pore sizes in the 1-5μ range for many years (136). Figure 5 shows the pore size distribution (PSD) of three matrixes: wood, fine filter paper, and coarse filter paper (137). The PSD of the coarse filter is very similar to the PSD found for RBC separators (75, 133). Wood veneer is known to be a superior separator for lead-acid applications, so these data suggest that an impregnated fine-pore paper matrix will approach wood in performance. As Sundberg has shown (75), such a matrix would slow the transfer of antimony and yield a lower hydrogen evolution test datum than a typical RBC separator.

In manufacturing a paper matrix with smaller pores and a PSD shifted to smaller values, there would, undoubtedly, be a premium to pay. The paper could be made with knife-milled fibers to produce a more dense, less porous matrix. It would also be possible to formulate with microcrystalline cellulose to selectively fill pores and reduce net porosity and average pore size. Formulation of a new, small-pore matrix should result in (*i*) higher density, (*ii*) lowered wettability, and (*iii*) increased frangibility. There will be a resistivity penalty to pay, and the use of additional synthetic fibers may be necessary to retain required breaking strength. Such a matrix, however, should be lighter by

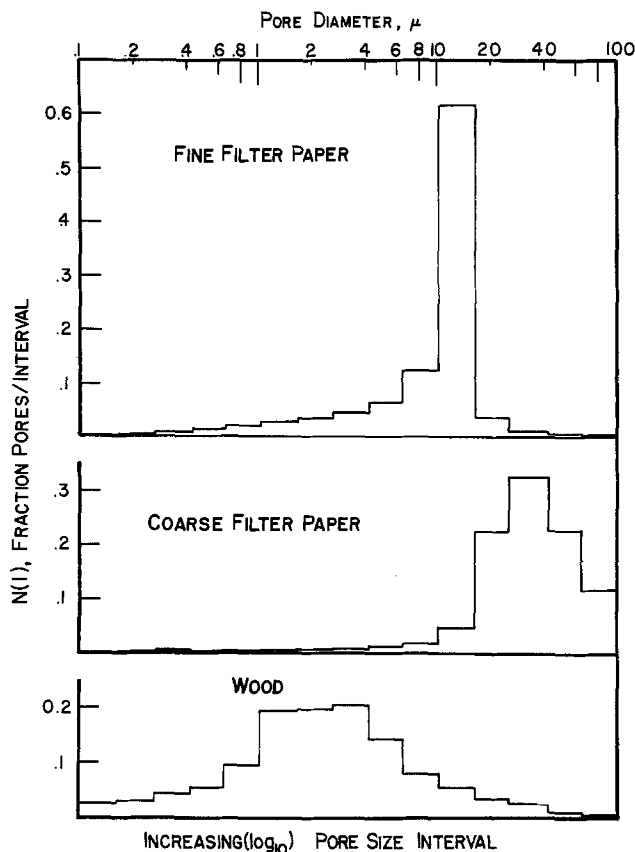

Fig. 5. Pore size distributions for paper and wood matrixes compared. Data from Ref. (137).

virtue of requiring a thinner back-web. There will be increased expense due to the use of processed cellulose, but this will be minimized by thinner separators and longer life.

There should be considerable incentive for developing such a matrix. The RBC separator now holds an almost 2:1 price advantage over the widely used microporous separator matrixes. The dollar incentive therefore is great, and the clear-cut attractiveness of a better RBC separator and its probable penetration into deep-cycling lead-acid battery markets is indisputable.

Impregnation—Key to stability.—The RBC separator using phenolic resin impregnation has proved to be reasonably stable in H_2SO_4 media, but clearly the labile hydroxyls and acetal linkages in the substrate are not completely involved in the curing scheme which gives acid resistance to the matrix. Whether the paper matrix can be made receptive to more complete sorption and penetration of the uncured resin is a complex question. Thode, Swanson, and Becker (138) measured the BET specific surface area of swelled alpha cellulose and found a high value (100 sq m/g). They showed that beating increases the BET area and the cumulative pore volume in the range of 44-800Å.

Ruzicka and Kudlacek (139) used argon and did very careful solvent-exchange drying to develop a more detailed picture of the surface area and pore volume dependence on fiber treatment. For native cellulose, they found a specific area of about 30 sq m/g but showed that chemical treatment tended to produce "swelled" fibers with areas of approximately 225 sq m/g, and the swelled condition was maintained if azeotropic drying was used to prepare the sample.

The sorption by cellulose of polymeric materials was shown by Luce and Robertson to depend strongly on the degree of swelling (140) that took place, either prior to or during polymer sorption. The equilibrium sorption of polyvinyl alcohol (with a molecular weight of about 10^5) was very strongly affected by the nature of the polymer carrier. If a "swelling" carrier such as water is used, the sorbed quantity is far greater than if a "non-swelling" solvent is used. Preswelled fibers also took up greater quantities of PVA, in direct proportion to the degree of swelling produced by the swelling agent. Luce and Robertson also found that more polymer was sorbed if the temperature rose, with the higher molecular weight fractions of polymer being sorbed more strongly.

These sorption data point to the necessity of optimizing the resin treatment procedures currently used to make separators. We know, for example, that there is a great degree of swelling that takes place during the original pulping of the alpha cellulose, the subsequent beating, and the blending with synthetic fibers. The basic matrix is then made by typical paper-forming techniques. Currently, the absorption of protective resins is a continuous process, indicating that a real equilibrium among the fiber matrix, the polymer, and the swelling agent is not likely to be reached.

In SEM examination of resin-bonded separators, globules are found. These can only be explained as excesses of resin that cured in place before they could be evaporated. Other effects that we have interpreted as due to an excess of liquid-phase resins on the fiber surfaces have been seen in SEM photos: dimplelike surface artifacts. These are shown in Fig. 6, which also shows the globules of excess resin that are sometimes seen.

Both phenomena indicate that RBC separators are frequently formulated with a large excess of resin. In one case, the excess is so large that liquid (midcure) resins coalesce into relatively large globules (Fig. 6a and 6b). In the other case, the liquid excess is confined to fiber surfaces but does not effectively penetrate. As the resin cures and the liquid layer contracts, it undergoes normal surface-free energy minimization (141), resulting in the circular dimples seen in Fig. 6c and 6d.

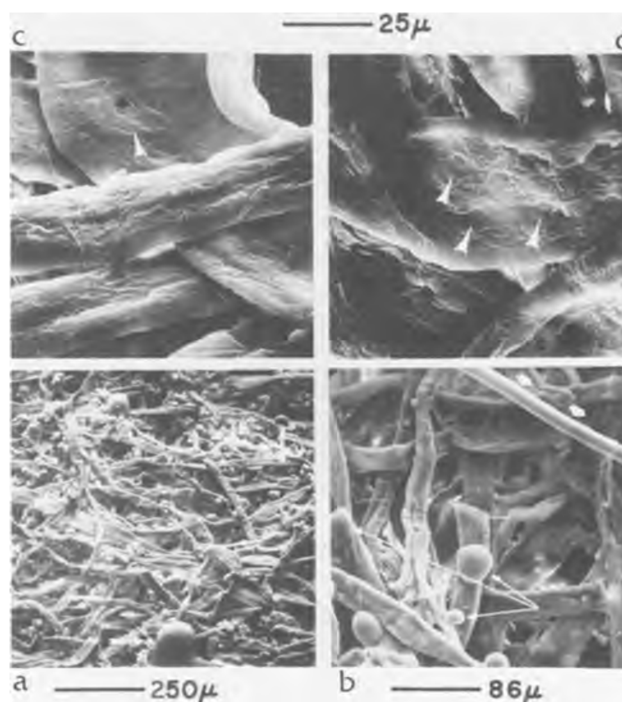

Fig. 6. Scanning electron micrographs of RBC separator matrixes. The evidence for nonequilibrated sorption is indicated. a and b show large liquid excesses of impregnate, as indicated by the globules (narrow arrows). The broad arrows (b) indicate the synthetic resins used to give breaking strength to the sheets. c and d indicate zones where normal surface free energy minimization has created dimplelike structures in the curing liquid film on the fiber surface.

The specific reactivities of the —OH present on the cellulose chains are different, and the accessibility of the sites is different, some being distant from the reactive interface (84) and requiring, therefore, special swelling techniques to allow more complete access to the reactive sites. The spectrum of accessibilities is associated with the highly structured nature of alpha cellulose, and the annealing work of Attala and Nagel (112) and Basch and Lewin (113) shows that the basic structural units can be opened to reactive and reorganizing influences. Morosoff's work on rewetting and drying indicates much the same conclusions (109).

Another interesting suggestion is that of formulating the substrate paper with mechanically decrystallized cellulose. Amorphous cellulose is more reactive than crystalline material, and a paper formulated of a large proportion of this more reactive species should absorb the impregnating resins more fully and therefore be better protected. In-process methods of decrystallization may also be possible. Tsuji, Hirai, and Hosono (142) decrystallized fabrics chemically, using a sodium hydroxide/acrylonitrile treatment, and realized very high accessibilities with only small changes in fabric properties. Using a wide variety of pretreatments, they produced highly decrystallized cellulose with very high specific reactivities. Treatments such as these may be the key to providing a more completely prereacted (impregnated) separator matrix. The usefulness of simple mechanical decrystallization is reduced by the tendency of amorphous cellulose to recrystallize when immersed in water (143).

Graft copolymerization—A new fiber.—A second development route to a new, more efficient separator matrix may lie in generating what is basically a new fiber. This can be done by graft copolymerization of newer or better impregnates onto the cellulosic backbone. Mino and Kaizermann (144) found that ceric ion redox systems gave high yields of copolymer, because the free-radical sites were generated mainly on the trunk polymer. Richards described, in 1961, several interesting approaches to grafting, using the ceric ion (145) and also diazonium cellulose derivatives (146) as initiators. He was able to graft acrylonitrile onto cellulose in this way. Similarly, styrene-cellulose copolymers have been made, using hydroxyl radicals (147) as initiators or catalysts. Irradiation from gamma sources has been successfully used to graft ethyl acrylate onto cellulose (148). Other energetic radiation schemes are expected to be efficient as initiating methods.

The number of monomers studied to date has been large (149), and the dominant initiator technique has utilized ceric salts or other strong oxidizers (150) to create reactive sites on the cellulose backbone. This technique has been popular because it has resulted in low yields of homopolymer, apparently because (144) initiation (free-radical production) is restricted to the trunk molecule. Ide and Takayama found low yields of polymethyl-methacrylate (PMMA) when grafting MMA onto cellulose, using $Ce(NO_3)_3 \cdot 2NH_4NO_3$ as initiator (151). When he grafted vinyl acetates onto cellulose (152), Ide found somewhat higher homopolymer yields, indicating that initiation also takes place on the monomer in this case. Ide also found the homopolymer yield higher with acrylonitrile (153). Ogiwara and Kubota (154) found that the yield of homopolymer, in the case of MMA/cellulose grafts, might depend on the order of addition of initiator (in this case, ceric ion). They found grafting more efficient if ceric-ion initiator was added to an aqueous suspension of cellulose and MMA, but in this scheme, the homopolymer yield folowed graft efficiency.

The graft copolymerization of monomers onto cellulose has been pursued most actively using methyl methacrylates and related monomers (126, 148, 150, 151, 153-155). Styrene has been studied (146, 156), as has vinylpyridine (157) and methylvinylpyridine (158). The latter is a very interesting prospect for separator applications, because Kryazhev and Rogovin found large ion exchange capacities (3-4 mequiv. HCl/g) for the cellulose-methylvinylpyridine copolymer (158).

Most grafts decrease the hydrophilic character of the copolymer, though Hui and Lepoutre made copolymers with quite enhanced water absorbency (159). They used a cationic monomer of poly(2-dimethylaminoethyl-methacrylate). These water absorbency properties should appear very interesting to those working in the lead-acid battery industry. Lepoutre *et al.* studied the effect of grafted vinyl monomer on the water sorption kinetics of alpha cellulose (160). Grafted styrene was studied, in particular, and it was found that the degree of swelling during grafting played a large part in determining final properties. They found that nonpolar grafts decreased equilibrium water content but increased the diffusivity of water. Polar monomers, such as ethyl acrylate, acrylonitrile, and acrylic acid had the opposite effect, showing that side-chain configuration was instrumental in determining properties.

Grigoryan and Rogovin grafted poly(2,3-dichlorobutadiene) onto cellulose and found decreased hydrophilic character and increased resistance to mineral acids (161). It is expected that resistance to mineral acids will be dependent on the acid resistance of the grafted monomer.

Ogiwara, Kubota, Murayama, and Sakamoto studied the physical and chemical stability of papers made from copolymers of MMA, acrylonitrile, vinyl acetate, and styrene (162). They found the papers generally weak, with dimensional stability a function of water retention, becoming lower as water content increased. The papers were all made from grafted material, indicating the feasibility of such processes. Goynes and Harris (163) studied the character of cotton onto which acrylonitrile or butyl methacrylate was grafted. Up to grafts of approximately 60%, the fiber surfaces appeared almost normal. Higher fractions of graft caused flaking and shredding. Abrasion testing and flex abrasion tests indicated the resistance to tearing, and abrasion decreased as the fraction of graft increased. In cross-sectional microscopic analyses, the fibers were seen to be grafted throughout their bodies, with apparent uniformity a direct function of graft percentage.

Manuscript submitted Aug. 8, 1977; revised manuscript received Dec. 29, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by ESB Incorporated.

The Characterization of Internal Power Losses in Pacemaker Batteries by Calorimetry

L. D. Hansen

Thermochemical Institute and Department of Chemistry, Brigham Young University, Provo, Utah 84602

and R. M. Hart

Tronac, Incorporated, Orem, Utah 84057

ABSTRACT

A calorimeter for measuring heat output from batteries is described. The calorimeter has a peak-to-peak noise level of 0.3 μW. A thermodynamic analysis of battery processes is given and a method of using the calorimetric data to study and define parasitic processes is illustrated with data on several batteries.

One of the limits on the operational life of pacemakers is the battery which is used as a power source. All batteries are subject to internal self-discharge which, in turn, limits or shortens the life of the batteries. This self-discharge can result from three processes: (*i*) migration and direct chemical combination of anode or cathode substances; (*ii*) spontaneous decomposition of the anode or cathode; and (*iii*) reaction of the anode or cathode with contaminant gases or some battery component that was supposedly inert. The rates of these self-discharge processes can be dependent on or independent of the current being drawn from the battery. Since self-discharge is essentially a chemical reaction occurring inside the battery, it can be measured and studied by determining the rate of heat production of the battery in a calorimeter (1-5). The possibility also exists for developing the calorimetric method into a nondestructive quality control test to eliminate batteries with abnormally high self-discharge rates.

The purposes of this paper are: (*i*) to describe a calorimeter which was designed specifically for studying pacemaker batteries; (*ii*) to give a thermodynamic basis for determining the dependence of the rate of self-discharge on electrical current in the battery; and (*iii*) to present some of the results which have been obtained on various types of batteries.

Key words: thermodynamics, lithium, silver, mercury, zinc.

Calorimeter

The calorimeter used in this study is commercially available and is a twin-cell differential heat flow instrument as shown in Fig. 1. The calorimeter has a peak-to-peak noise level of less than 0.3 μW and a precision better than 1 μW on a battery measurement.

The calorimeter consists of an aluminum block 15 cm wide, 17 cm high, and 30 cm long with a tapered channel 10 cm wide, 10 cm deep, and 25 cm long cut into it, four wedges of 2.5 cm thick aluminum which were placed in the channel, and four thermoelectric measuring devices (Cambion Model 1052) which are mounted on the aluminum wedges together with two battery holders made of thin aluminum. The large aluminum block assembly was suspended by four 0.25 in. bolts in the center of a watertight box which was then submerged in a Tronac Model 405 water bath controlled to

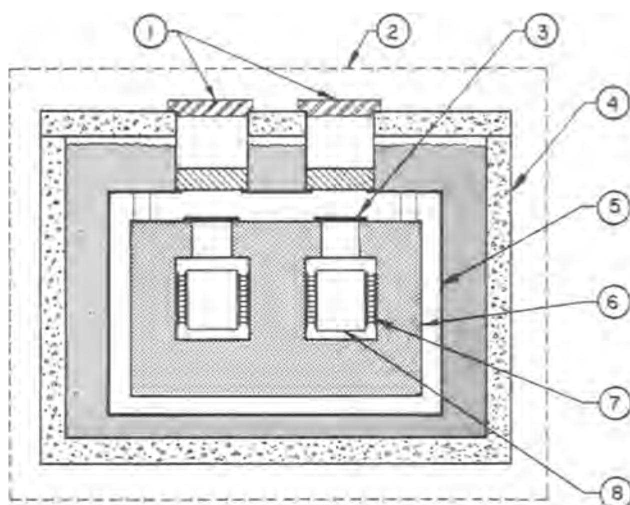

Fig. 1. Schematic of Tronac battery calorimeter. 1, access tubes and covers; 2, temperature-controlled air bath with electronics inside; 3, covers on block compartments; 4, temperature-controlled water bath; 5, water-tight stainless steel box; 6, aluminum heat sink block; 7, thermoelectric sensors; 8, battery holder.

$\pm$ 0.0002°C. Two pipes, sealed around holes in the box cover, give access through the water bath to the battery holders. During a measurement, the holes in the box cover and the battery holders are covered with aluminum plates to prevent heat transfer by air currents.

The outputs from the two sets of thermoelectric devices were connected with opposing polarities so that the effects of any temperature fluctuations in the block would be canceled in the output. The difference in the output voltages of the two compartments, which is proportional to the difference in the rates of heat production in the two compartments, was filtered with a simple R-C filter (time constant = 6 min), amplified by a Keithley Model 150B amplifier, and recorded on a strip chart recorder. Typically the recorder was run at 5 cm/hr and 100 mV full scale and the amplifier at a gain of 3×10^4. A 5½-digit digital voltmeter and printer were connected in parallel with the recorder for some runs in which the recorder dead band was a significant limitation. Peak-to-peak baseline noise was found to be about ± 0.1 μW if the heat capacity of the compartment used as a reference was carefully adjusted by an aluminum block to be the same as the compartment containing a battery.

Calibrations were done in two ways. In most cases, a 1 kΩ resistor mounted in the battery holder was used to provide a known rate of heat to the cell. In one case, a 1 kΩ resistor was mounted directly on a battery. There was no significant difference in the results. Calibrations were done at heater powers of 20, 27, 137, and 184 μW. Again, there was no significant difference in the output voltage/μW of heat input. The calibration constant is believed to be accurate to ~2% on the lowest heater power and to ~1% on the higher ones. A Tronac 450EC board was used to supply power to the heater. Heater and standard resistor voltages were measured with a Data Precision Model 3500, 5½ digit DVM. The results from a sample set of calibration runs are given in Table I.

Measurements of open-circuit heat dissipation of batteries were made by equilibrating the batteries for 8-12 hr in the space above the measurement compartment, placing a battery in a compartment, waiting until any heat stored in the battery because of a temperature difference was dissipated totally as shown by a flat baseline (usually about 1 hr) and then removing the battery. The difference in the measured rate of heat output from a given compartment before and after removal of the battery is then the heat output of the battery. Tests using an aluminum block in place of

a battery showed that the reproducibility of this procedure was better than $\pm$ 1 μW.

Measurements of heat dissipation in batteries under discharge were made by electrically connecting the battery to a resistor outside the calorimeter with two No. 40AWG wires. The wires were placed in good thermal contact with the calorimeter block to prevent thermal leakage from outside the calorimeter. All measurements were made at 37°C.

Theory

For an experiment on an ideal battery where the battery is in a calorimeter and connected electrically to a load resistor outside the calorimeter

$$Q = \text{heat produced in the calorimeter} \quad [1]$$

$$W = I^2Rt = \text{electrical energy dissipated in the resistor if the battery is sealed so that } \Delta PV \text{ work is zero} \quad [2]$$

and

$$W = I^2Rt + P\Delta V \text{ if the battery is open to the atmosphere} \quad [3]$$

The first law of thermodynamics states that

$$\Delta E = Q - W \quad [4]$$

Substituting Eq. [2] into Eq. [4] and taking the derivative with respect to time, we have Eq. [5]

$$\frac{d\Delta E_1}{dt} = \frac{I\Delta E_1}{\mathbf{F}} = q - I^2R \quad [5]$$

where I is the current in the resistor, $\mathbf{F}$ is the Faraday, ΔE_1 is the total energy change per equivalent of current producing reaction under the conditions extant in the battery, q is the rate of heat production in the battery, and R is the load resistance value. For a real battery with more than one reaction occurring and less than 100% current producing efficiency of the main reaction, it is necessary to add a term to the left side of Eq. [5] for each extra reaction and for that part of the main reaction that does not produce current.

$$\frac{I\Delta E_1}{\mathbf{F}} + \frac{d\Delta E_2}{dt} + \frac{d\Delta E_3}{dt} + \ldots = q - I^2R \quad [6]$$

Equation [6] applies exactly only if the battery is sealed so that ΔPV work is zero. If the battery is open to the atmosphere so that P is constant

$$\Delta E = \Delta H - P\Delta V \quad [7]$$

and [8] can be obtained by substituting [7] and [3] into [4], taking the time derivative, and adding the terms for the extra reactions

$$\frac{I\Delta H_1}{\mathbf{F}} + \frac{d\Delta H_2}{dt} + \frac{d\Delta H_3}{dt} + \ldots = q - I^2R \quad [8]$$

Since the extended life batteries studied here were sealed, Eq. [6] will be used in the remainder of this paper although it should be obvious that H may be substituted for E in any of the following equations.

Rearranging Eq. [6] so that all known terms are on the right side gives Eq. [9], where P_{internal} is the sum of the unknown derivative terms. The

$$P_{\text{internal}} = q - I^2R - \frac{I\Delta E_1}{\mathbf{F}} \quad [9]$$

behavior of P_{internal} as a function of the current can tell much about the nature of the unknown processes in a battery as is shown in the discussion.

Results and Discussion

Table II gives the results obtained for a series of open-circuit ($I = 0$) heat dissipation measurements on batteries of various kinds, shapes, and sizes. These results clearly show the capabilities of the calorimeter as well as the reproducibility of open-circuit heat dissipation in a set of supposedly identical batteries.

Calorimetric measurements of open-circuit heat dissipation of batteries may not accurately reflect that a primary chemical reaction is occurring in the battery with a consequent loss in amp-hours available. Any process, such as crystal growth, evaporation of liquids, curing of plastics and cements, and mechanical strain release can produce a change in the total energy content of the battery and, hence, an output signal to the calorimeter. These changes are usually not significant in determining battery life, although they can lead to mechanical failure of some battery component. Calorimetric experiments can be done to determine the magnitude and source of most of these effects by measuring the heat output of each of the battery components separately. Open-circuit heat dissipation is also typically a function of age as shown in Fig. 2, and this must be taken into account in interpreting these kinds of data.

Table III gives representative results of measurements of heat dissipation for three different types of batteries under discharge. The data from Table III were used to calculate values of P_{internal} (Eq. [9]) which were then plotted as shown in Fig. 3.

Since P_{internal} represents the chemical or stored energy dissipated as heat by all reactions that do not produce current, a line with a slope equal to zero, as in the Li/I_2 system, shows that all such processes are independent of the current. The slope of zero also proves that all of the current producing reactions have been accounted for properly by the one assumed reaction with a current efficiency of 100% in the Li/I_2 battery. The nonzero intercept is thus probably due to processes as mentioned above which do not cause a loss in total available current.

The AgO/Zn battery becomes slightly more efficient in the use of total stored energy as the current increases while the HgO/Zn battery apparently rapidly loses energy efficiency as the current increases (Fig. 3). Both of the latter effects are probably due to changes in current producing reactions since intermediate oxidation states are possible for the Hg and Ag. Further evidence that more than one current producing reaction is involved in the AgO/Zn battery was observed in the calorimetric data produced during the transient from zero to 156 μA of discharge as shown in Fig. 4. The shoulder on the curve clearly shows that an additional reaction occurs at the higher current after depletion of some intermediate component.

The linearity of the curve for the HgO/Zn battery at the higher currents suggests that either the ΔE_1 value is in error by about 4%, which is unreasonable for these substances, or that we have not fully accounted for the battery reactions which produce current.

In summary, data plotted as shown in Fig. 3 can be used to show that all current dependent battery proc-

* Values given in this column are the actual measured differences between the rate of heat production with the external load resistor circuit closed and open. To get the total heat production rate for calculation of P_{internal}, 5, 7, or 6 μW from the independent measurement of the open-circuit heat-production rate without wires attached to the battery must be added for the Li/I_2, AgO/Zn, and HgO/Zn battery, respectively.

** This value is significantly in doubt because the battery did not reach a steady-state heat production rate for several hours and the return to the baseline after opening the circuit was also extremely slow.

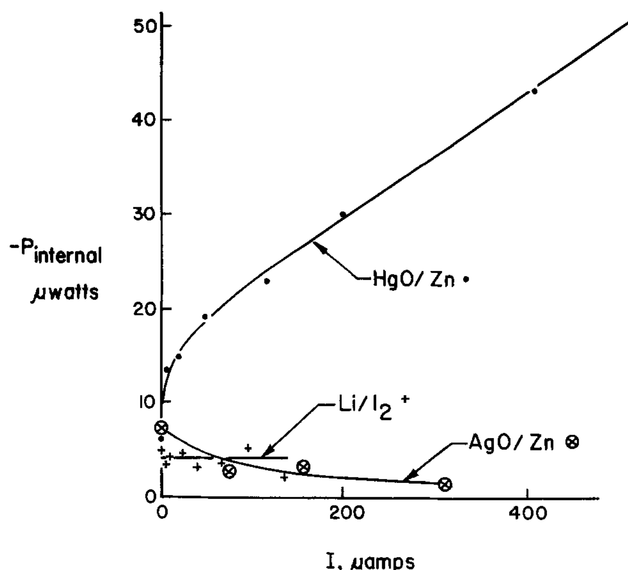

Fig. 3. Plots of $P_{internal}$ against current being drawn from the battery. (See text Eq. [9].)

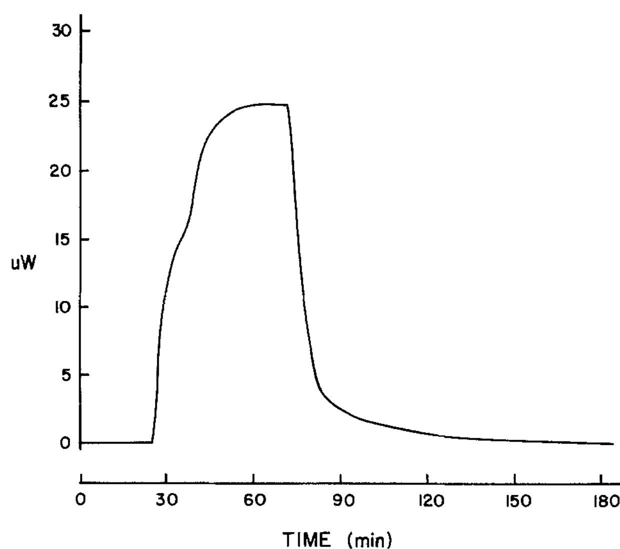

Fig. 4. Actual calorimeter output for a AgO/Zn battery. From 0 to 28 min the battery circuit was open. At 28 min a 10 kΩ resistor was connected across the battery. The circuit was opened at 70 min. Power dissipation is relative to the baseline with the battery in the calorimeter with wires attached but with the circuit open.

esses have been correctly described (slope = zero) or that they have not. In the latter case, the form of the curve suggests the nature of the remaining processes.

Anodic Behavior of Lithium in Aqueous Electrolytes

III. Influence of Flow Velocity, Contact Pressure, and Concentration

E. L. Littauer,* K. C. Tsai,* and R. P. Hollandsworth

Lockheed Palo Alto Research Laboratory, Palo Alto, California 94304

ABSTRACT

The influence of electrolyte flow velocity, concentration, and contact pressure on the anodic behavior of lithium at constant temperatures in LiOH was studied. The experimental results reveal that, under constant load polarization, a steady-state *i-E* curve is obtained consisting of resistance and concentration polarization components. A method to accurately determine the film thickness was devised. It was found that the oxide film at the anode surface is quite thick, *ca.* 10^{-2} cm, and its thickness remained constant irrespective of polarization level at constant electrolyte concentration, flow rate, and anode-cathode contact pressure. The effective diffusion layer at the Li active surface is thin, *ca.* 10^{-3} cm. The fraction of active surface area was found to change significantly with LiOH concentration (ranging from 0.05 in 4.84M to 0.39 in 2.96M), but it was virtually independent of flow velocity and contact pressure. Likewise, electrolyte concentration has far greater influence on film resistance than flow rate or contact pressure. Electrolyte flow velocity variation is, however, an effective means to alter power output from the cell.

The oxide/hydroxide film which forms on Li anodes in aqueous, strongly alkaline electrolytes has some unusual properties. For example, even though it is fairly thick (*ca.* 5×10^{-2} cm) it will support high flux rates with very low polarization and yet have sufficient strength to tolerate the counterelectrode being pressed against it without shorting at pressures up to 30×10^4 Pa. In high rate Li-H_2O cells, the counterelectrode comprises a ribbed backplate overlaid by a metallic mesh screen active surface. It is the

* Electrochemical Society Active Member.

Key words: lithium, lithium hydroxide, concentration polarization, limiting current, diffusion layer.

screen which presses against the anode surface and the electrolyte passes behind and around the mesh.

The performance of the cell is controlled by the nature of the anodic film. This film moderates the normally rapid corrosion reaction of the metal with aqueous electrolytes and, provided the OH^- concentration is sufficient, the Li will discharge with good coulombic efficiency if it is polarized by about 300 mV from its OCV ($E_o' = -2.78V$ *vs.* NHE). In other words, the direct corrosion reaction of Li with H_2O (the parasitic reaction) can be effectively inhibited. An unexpected phenomenon is observed with Li, namely, a highly characteristic transient passivation which occurs at $-2.66V$ *vs.* NHE. This phenomenon was examined in detail in a previous paper (1), where specifics of the cell and its operational features were also described.

It has been found that the rates of the electrochemical and parasitic reactions respond very reproducibly to the following factors: (*i*) anode-cathode contact pressure, (*ii*) velocity of electrolyte flow across the anode surface, (*iii*) electrolyte temperature, and (*iv*) OH^- concentration. Increasing contact pressure and flow result in enhanced cell power output without decrement in faradaic efficiency. Significant temperature increase (to $< 40°C$) or decrease of OH^- concentration ($<$ 3M LiOH) increase cell power substantially but generally at some sacrifice in efficiency.

The above-listed factors *i-iv* influence the properties of the LiOH protective layer and these properties control the functioning of the cell. In normal operation the film is in a state of quasi-equilibrium dissolving at the film/electrolyte interface at the same rate as the metal is oxidized. The higher the hydroxyl ion concentration over the range 2-5M, the slower is the dissolution rate and the more protective is the film. This paper examines quantitatively and diagnostically the influence of electrolyte flow velocity, concentration, and anode-cathode contact pressure on the anodic behavior of Li in LiOH solution at constant temperature. Polarization behavior and *in situ* film thickness measurements are reported.

Experimental

Polarization experiments.—The test arrangements and procedures have been detailed previously (1). The *i-E* curves were obtained using the constant load (resistive) polarization technique. A custom electronic load capable of maintaining $\pm$ 0.01V was employed. Electrolyte concentrations ranged from 2.96 to 4.84M and the temperature was maintained at 298° $\pm$ 0.1°K. In the electrolyte flow velocity study, the anode-cathode contact pressure was held at 6.2×10^4 Pa (630 g/cm^2). The solution flow velocity which refers to the average inlet velocity was controlled to within 5%. The velocities studied ranged from 0.064 to 0.42 m/sec. The experimental conditions used in this investigation correlated with actual Li-H_2O battery operation. Generally, a steady-state *i-E* reading was achieved within 1 sec for a given load at any flow velocity. Fresh 99.9% Li anodes were used for each run. In the contact pressure study, a single flow rate of 0.18 m/sec was used. Experiments were performed with the anode-cathode contact pressure controlled to within 5% of 4.1, 6.2, 10.3, and 20.7×10^4 Pa by using an air pressure cylinder linked to the anode push rod. Hydraulic pressure on the electrode which would normally be created by the circulating solution was eliminated by a thrust balance cylinder connected to the inlet and outlet lines of the cell. Polarization runs were performed in triplicate. Reproducibility was such that the experimental curves could be exactly superimposed.

Film thickness determinations.—For these experiments a modified test cell was used. Alterations were made to the cathode compartment to equip it with a solenoid-actuated needlepoint penetrometer. The needle was platinum-plated 4130 steel. The probe was positioned so that on activation it could pass through the cathode matrix and subsequently penetrate the anode surface. Details of the assembly are given in Fig. 1. A Hewlett-Packard 4815A rf impedance meter set at 500 kHz was connected to the anode and to the needle probe. The distance traveled by the probe was monitored by a G. L. Collins Corporation linear motion transducer which had a voltage output directly proportional to position. The outputs of the impedance meter and the linear motion transducer were recorded with a Honeywell Model 1858 CRT visicorder. The probe position could be measured with an accuracy of about 10^{-3} cm. To confirm the sensitivity of the technique, a penetrometer test was performed in a dry room on a lightly oxidized Li specimen. The film thickness result was then compared with precise microscopic measurements of cross sections of the same specimen. The penetrometer gave an average thickness of 6.1×10^{-3} cm and by microscope measurement it was found to be 5.3×10^{-3} cm.

Film thickness was determined as a function of solution flow rate at 0.10, 0.16, 0.23, 0.32, and 0.39 m/sec in 3.2 to 4.7M LiOH. The measurements were taken at six polarization points from OCV to $E_H = -1.0V$. Similarly, film thickness was determined at five anode-cathode contact pressures; 3.5, 7.0, 14.0, 21.0, and 28.0×10^4 Pa over the same polarization range in 4M LiOH. A typical visicorder plot is shown in Fig. 2. Here curve Z represents the impedance between the probe and the anode. It was observed that the resistance within the film was slightly higher than within the electrolyte. After activation, the penetrometer probe plunged through the electrolyte at *ca.* 0.7 m/sec contacted the film, slowed down, and contin-

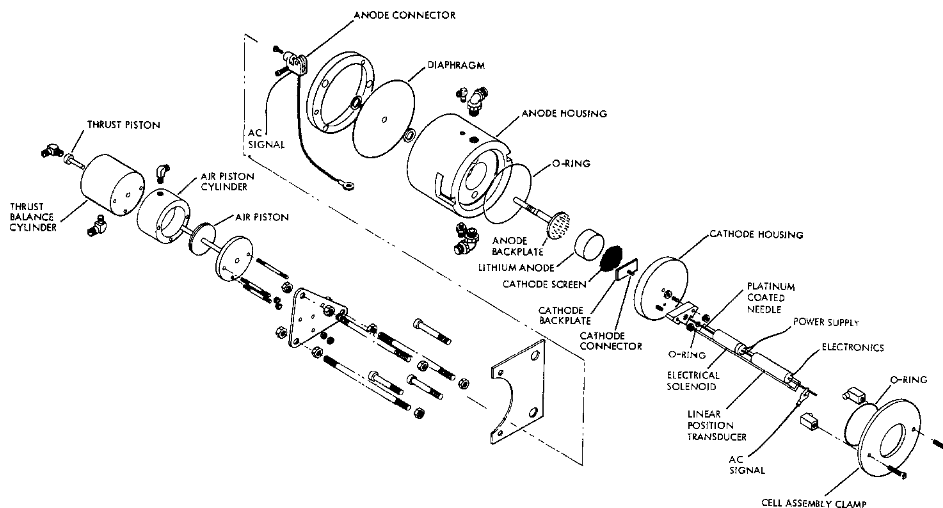

Fig. 1. Exploded view of 1.14 $\times$ 10^{-3} m^2 lithium test cell for film thickness measurement.

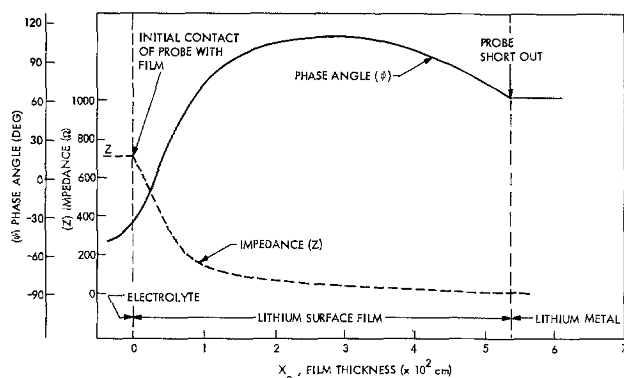

Fig. 2. Visicorder trace of film thickness measurement

ued through the film into the underlying Li. The total time spent by the probe in the film was about 2 sec. The initial point of this measurement was obtained from the instance of film-probe contact where an abrupt change in impedance (curve Z) was observed. The end point of this film thickness measurement was obtained when the probe made direct contact with the Li and the circuit shorted. But, because the measuring system possessed a residual impedance, the exact location of the end point was difficult to determine. It was found that if, in addition to the impedance measurement, the phase angle was also recorded the end point was more clearly indicated. Curve ψ depicts a trace of phase angle output between the probe and the anode from $-45°$ to $+110°$. A change in slope of the phase angle scan at short-out was clearly indicated in all the experiments.

Potential decay experiment.—The thickness of the diffusion layer at the limiting current is an important factor in the development of the theoretical model. To determine its value under typical test conditions at the polarization level characteristic of the limiting current [which has been arbitrarily selected as $\eta = 2.87V$, $E_H = 0(V)$], a potential decay experiment was designed. Knowing the time of the potential decay transient, the diffusion layer thickness may be calculated. For this experiment, a special cell was constructed. It was identical to the 1.14×10^{-3} m^2 unit used for the polarization experiments except that it accommodated a smaller 1×10^{-4} m^2 anode. With this reduced surface area, a Princeton Applied Research Model 173 potentiostat/galvanostat could be utilized and this in conjunction with a Tektronix Model 549 storage oscilloscope provided the necessary instrumentation. The Li was polarized potentiostatically to $E_H = 0(V)$ in 4M LiOH at a flow rate of 0.2 m/sec and a contact pressure of 6.2×10^4 Pa. A Hg/HgO reference electrode was used. When the current was interrupted, the potential decay was measured as the anode reverted to its OCV. The experiment was run in triplicate, reproducibility was to within 10%.

Results

Flow velocity experiments.—Figure 3 shows the effect of flow velocity, v, on the anodic polarization in 4M LiOH at 25°C. The polarization curves possess two distinct regions. The initial portion of the curve depicted as a-c is linear. It represents *IR* across an essentially invariant protective layer. The curved, highly polarized portion c-l, has a configuration which is often characterized by a limiting current situation. [It should be noted here that the transient passivation phenomenon described previously (1) was observed at low flow rates. Since it does not occur at the higher rates and is not significant to the present investigation, it has not been shown in Fig. 3.]

In the region a-c it is assumed that the anodic film formation rate is balanced by the film dissolution rate. At constant anode-cathode contact pressure, in-

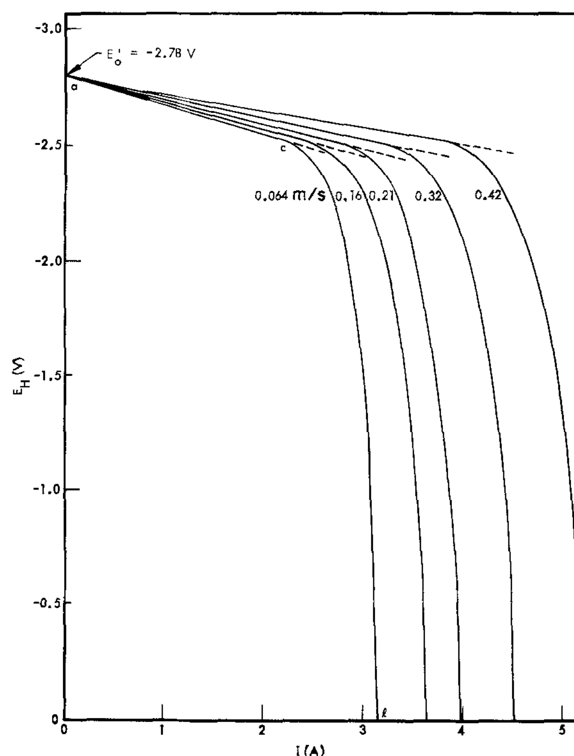

Fig. 3. Effect of flow velocity on the anodic polarization of lithium in 4M LiOH at 298°K. Anode-cathode contact pressure = 6.2×10^4 Pa, $A = 1.14 \times 10^{-3}$ m^2.

crease in flow velocity decreases the film's resistance. It is also observed that the maximum current density depicted as i_l increases substantially with increasing flow.

From the slopes of the resistive polarization sections of the curves in Fig. 3, a plot may be drawn of film resistance *vs.* velocity. This is shown in Fig. 4, as curve A. In Fig. 5 is shown the relationship between film thickness and polarization level at fixed anode-cathode contact pressure and flow velocity. It will be observed that the thickness remains virtually constant under the polarization conditions studied in this work. For comparison purposes, the results of the film thickness *vs.* flow velocity experiments are also plotted in Fig. 4. These appear as curve B.

Anode-cathode contact pressure experiments.—Figure 6 shows a filmed Li anode after operation at a contact pressure of 7×10^4 Pa in 4M LiOH at 2.3

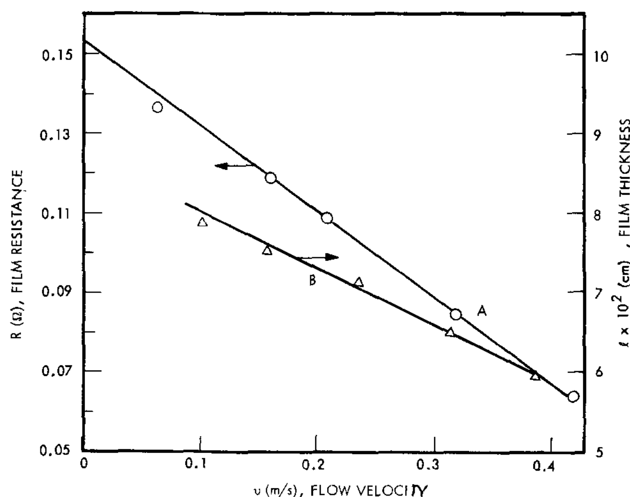

Fig. 4. Effect of flow velocity on anode film resistance and film thickness in 4M LiOH at $P = 6.2 \times 10^4$ Pa, $T = 298°$K.

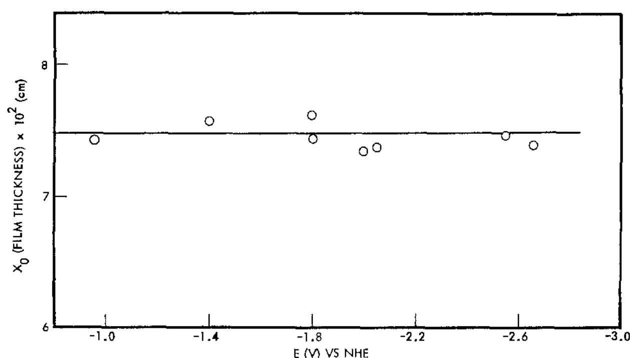

Fig. 5. Invariant dependence of film thickness on anodic polarization at $v = 0.16$ m/sec, $P = 6.2 \times 10^4$ Pa in 4M LiOH.

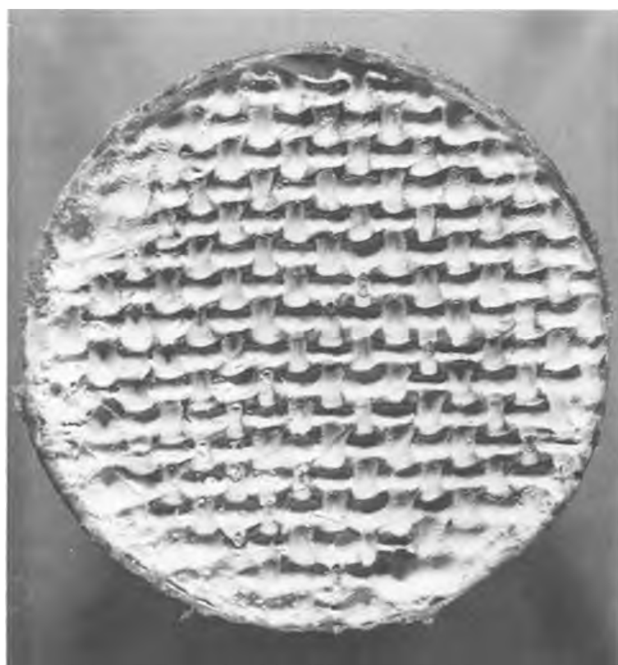

Fig. 6. Imprint of cathode screen on the anode surface

kA/m^2. The imprint of the cathode screen due to electrolyte flow is clearly evidenced. It was found that at up to 28×10^4 Pa (the limit of the experimental apparatus) no short-circuiting occurred. This remarkable property of the anode film is of course the key to the successul operation of the cell without the need for a separator.

The influence of contact pressure on the anodic polarization is shown in Fig. 7. The slope of the ohmic polarization region a-c is plotted against contact pressure in Fig. 8. Curve A represents the derived film resistance and curve B represents the measured film thickness as a function of contact pressure.

The influence of electrolyte concentration on anode film resistance and film thickness is given in Fig. 9. Unlike the situation with contact pressure and electrolyte flow velocity, the film resistance is not linearly related to electrolyte concentration.

Table I lists the limiting current (I_l), the critical current (I_c), film thickness (x_o), and film resistance (R) values obtained in the experiments where the flow rate was 0.16 m/sec at a contact pressure of 6.2×10^4 Pa. Also included in this table are literature data for LiOH mean activity $a_\pm$, conductivity k, and LiOH mean diffusion coefficient D_o.

Potential decay experiment.—The average value measured for the potential decay transient τ at the limiting current I_l in 4M LiOH was 3.5×10^{-3} sec. It has been shown (2) that when a metal is potentio-

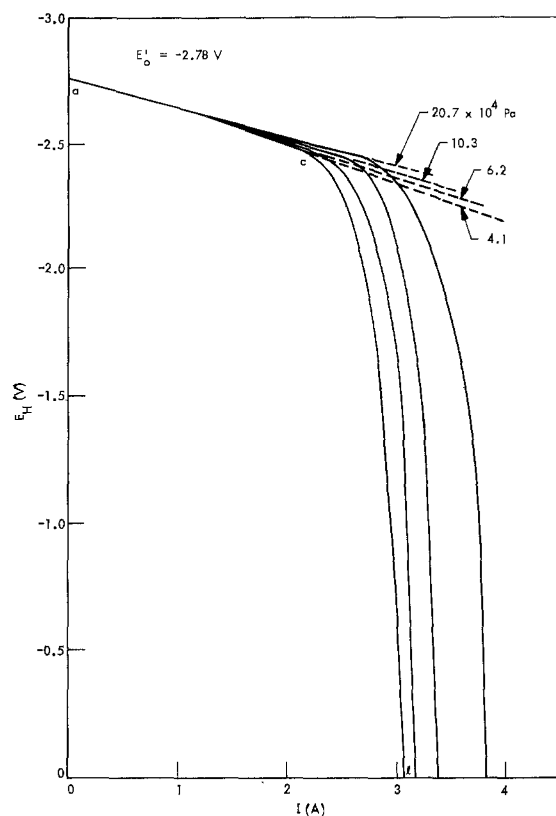

Fig. 7. Effect of contact pressure on the anodic polarization of Li in 4M LiOH at 298°K, $v = 0.064$ m/sec, $A = 1.14 \times 10^{-3}$ m^2.

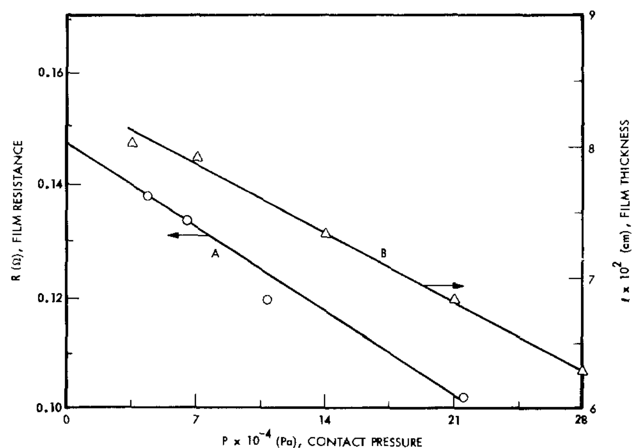

Fig. 8. Effect of contact pressure on anode film resistance and film thickness at 298°K, $v = 0.064$ m/sec.

statically polarized, the diffusion layer thickness may be calculated using the equation

$$\delta = \sqrt{\pi D \tau} \quad [1]$$

where D is the diffusion coefficient of the current limiting species. In this system where LiOH is the only electrolyte solute, it is appropriate to use the mean diffusion coefficient rather than the coefficient for the hydroxyl ion (3). D_o for 4M LiOH is 5.3×10^{-6} cm^2 sec^{-1} and thus δ computes to 2.4×10^{-4} cm.

Discussion

The dissolution of Li in strongly alkaline solutions appears either as an electron-producing electrochemical reaction, or as a direct corrosion (parasitic) reaction.

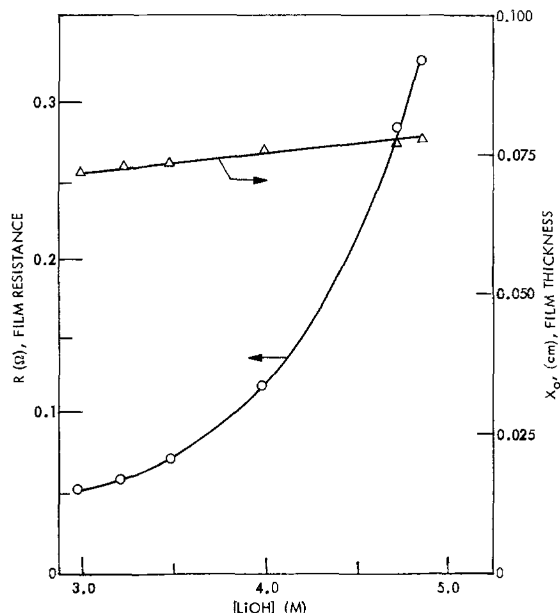

Fig. 9. Influence of electrolyte concentration on anode film resistance and film thickness at 298°K, $P = 6.2 \times 10^4$ Pa, $v = 0.16$ m/sec.

In the electron-producing reaction, a number of steps presumably occur in the process of producing a Li^+ aquocation. However, it is generally accepted that in an anodic oxidation such as this the resulting charge transfer reaction may be expressed (4)

$$Li + OH^- \rightleftarrows LiOH + e \quad [2]$$

(Then, by dissociation $LiOH \rightleftarrows Li^+ + OH^-$) .

The corrosion reaction on the other hand is simply represented by the over-all reaction

$$Li + H_2O \rightleftarrows LiOH + 1/2\, H_2 \quad [3]$$

(The over-all corrosion reaction [3] is of course a coupling of [2] with the cathodic reduction of H_2O at adjacent sites on the corroding surface.)

In situ stereozoom microscope observation of the anode surface indicates that the Li is always evenly covered by an oxide layer, and SEM examination of a filmed anode reveals a porous structure. The significance of this observation must be taken with caution because the observed porosity could have resulted from reaction of electrolyte with the Li after removal of the specimen from the electrolyte.

However, even though pores in the film have not actually been seen during polarization experiments (the highest magnification available with the existing experimental setup is only 80×), there exists sufficient diagnostic data to support the hypothesis that the protective film is, in fact, porous (5).

The anodic polarization curves, Fig. 3 and 7, can be described in terms of an active resistive polarization region depicted as a-c and a highly polarized region shown as c-l. As will be indicated subsequently, the electrochemical controlling mechanisms are different in these two regions so, for convenience, this discussion considers each separately.

Polarization region a-c.—Over the span of the active polarization region, steady-state conditions are observed. It is believed that in this region a quasi-equilibrium state exists between active and inactive sites. The slope of the curve dE/Adi represents the effective resistance across the film. This resistance R may be tied to the tortuosity of the film by the relationship (5)

$$R = \frac{Tx_o}{kA\,(1 - \theta_o)} \quad [4]$$

where x_o is the film thickness, k is the average specific conductivity of electrolyte permeating the film, A is the projected surface area, T is the tortuosity, and θ_o is the surface coverage by the oxide film.

Inspection of Fig. 9 shows that x_o/R and therefore θ_o change significantly with concentration, especially above 4M LiOH, whereas from Fig. 4 and 8 it can be seen that, in the cases of the other variables, *i.e.*, flow rate and contact pressure, the ratio of x_o/R and therefore θ_o do not change greatly over the ranges studied. This effect serves to explain why the anodic polarization of Li is very strongly influenced by OH^- concentration especially at high molarities, and electrolyte flow rate and contact pressure have been observed to be of secondary importance in cell operation.

Accurate assessment of the surface coverage requires knowledge of the tortuosity factor but this cannot be measured directly. For the present discussion, T is assumed to be 1. Errors arising from this if T is in fact somewhat greater than 1 will be reflected in an incorrect value of $1 - \theta_o$. However, of importance in this paper is not the absolute magnitude of the surface coverage, but merely a knowledge of significant changes in surface coverage as the experimental conditions are varied. From the film thickness *vs.* film resistance data of Fig. 9, $1 - \theta_o$ may be determined as a function of electrolyte concentration. Values of the surface coverage (assuming $T = 1$) are given in Table II and are plotted in Fig. 10. Inspection of this figure shows how sensitive the surface coverage is to varying electrolyte concentrations. In Li-H_2O battery operation, the LiOH concentration is maintained between 3.5 and 5M if good coulombic efficiency is to be expected. It will also be seen that over the range 3.5-5M LiOH the active surface area decreases from *ca.*

25 to 8%, and, in the active polarization region, the coverage is almost independent of flow rate, contact pressure, and polarization potential. In this region a steady-state polarization is established almost immediately; it may be assumed that the concentration of Li^+ at the active surface equals the initial concentration. The rate of removal of Li^+ by diffusion is equal to the total Li^+ flux and no concentration buildup occurs at the surface. It has been established [Ref. (6), Eq. 12] that the current density, i_c, defined by polarization point c, may be expressed by the equation

$$i_c = (n\mathbf{F}D_o\rho)C_o \qquad [5]$$

where C_o is the Li^+ or OH^- concentration at the Li surface at OCV. **F** is the Faraday and n is the equivalents per mole. It has also been shown [Ref. (6), Eq. 6] that the concentration C_o is related to the bulk concentration C_b by the relationship

$$C_b = C_o \exp(-\rho\delta) \qquad [6]$$

where ρ is a constant.

As will be shown later, δ and x_o are each related linearly to flow rate and therefore x_o may be expressed in terms of δ, viz., $x_o = \rho/\rho'\ \delta$ where ρ' is also a constant. Then Eq. [6] becomes

$$C_b = C_o \exp(-\rho' x_o) \qquad [7]$$

The magnitude of i_c is strongly influenced by flow velocity and by contact pressure. Of interest is the relationship between i_c and film resistance or film thickness. This can be obtained theoretically from Eq. [4], [5], and [7] viz.

$$\ln i_c = K + \gamma R \qquad [8]$$

where K and γ are constants at any given electrolyte concentration and temperature. Here

$$K = \ln(n\mathbf{F}D_o\rho)C_b \qquad [9]$$

and

$$\gamma = \rho' kA(1-\theta_o)T \qquad [10]$$

Figure 11 displays a plot of film resistance R *vs.* ln i_c. The data to construct this plot were obtained from Fig. 3 and 7 (i_c values) and Fig. 4 and 8 (R values). It is consistent with Eq. [8] and, at the same time, it shows how diffusion of Li^+ away from the active surface or OH^- to the active surface through the oxide film are the key processes governing the inner working of the Li-H_2O cell.

Determination of the current density depicted as i_c is critical to the operation of the cell. It is at this point that the Li anode can be discharged with high current efficiency (*i.e.,* 90%) (7). Also the concentration gradient within the diffusion layer remains constant. This is important and it indicates that to maximize cell efficiency at a specified operating point, the bulk concentration must be held constant.

Transition potential c.—Though contact pressure and electrolyte flow velocity significantly influence the magnitude of i_c they have very small effect on the observed polarization potential $\eta_c = E_c - E_o'$. Over the experimental conditions reported here, η_c was found to range from 240 to 300 mV.

Polarization η_c can be expressed in terms of the resistance across the film R and the transition current $I_c^\dagger$ at electrode potential E_c, *i.e.*, $\eta_c = I_c^\dagger R$. η_c may be calculated from a relationship which combines Eq. [4], [5], and [7]

$$\eta_c = m\frac{x_o}{\exp(\rho' x_o)} \qquad [11]$$

Since $\rho' x_o = \rho\delta$, and $m = [n\mathbf{F}D_o\rho TC_b]/[k(1-\theta_o)]$, then by selecting an η_c from Fig. 3 and a corresponding x_o (film thickness) from Fig. 4, and the other parameters from Tables I and II, the constants ρ and ρ' may be obtained.

In the resistance polarization region (a-c) in Fig. 3 and 7, $C_b \simeq C_o$ and it then follows from Eq. [7] that $\rho' x_o << 1$. Thus Eq. [11] can be approximated

$$\eta_c^o \simeq m\frac{x_o^o}{\exp(\rho' x_o^o)} \qquad [12]$$

where x_o^o is the film thickness at $v = 0$ and $P = 0$ and η_c^o is the maximum polarization at point c. Extrapolation of the curves of Fig. 4 and 8, *i.e.*, film thickness as a function of electrolyte flow or contact pressure shows that in 4M LiOH at 298°K, x_o^o is 8.8 $\times 10^{-2}$ cm. Calculation from this makes $\eta_c^o = 300$ mV. In actual practice, increasing flow velocity or contact pressure reduces this polarization slightly but increases i_c significantly.

It has been found that η_c's calculated using Eq. [11] are very close to the polarization levels observed in actual Li-H_2O battery discharges. As has been mentioned previously and is repeated here for emphasis, the knowledge of η_c's under various experimental conditions is important for optimizing control of the Li-H_2O battery.

Polarization region c-l.—At first inspection, the rapid polarization in this region seems to be due to a passivation phenomena. In the Li-H_2O system, mechanical passivation is indeed observed especially under forced flux, *i.e.*, under galvanostatic polarization (6). In a subsequent paper which is in preparation, we show that under constant load polarization, characteristic anodic passivation curves are observed when the OH^- concentration is significantly greater than 5M (accomplished by adding KOH or NaOH to the electrolyte). By characteristic passivation curves, we mean the response observed as the potential becomes more noble and the current increases until it passes through an initial maximum. Subsequently the current decreases to a greater or lesser extent reflecting surface blockage. At even more noble potentials the current increases again as transpassivity occurs. This passivation in strong $[OH^-]$ takes place when the overvoltage is *ca.* 400 mV. The point we wish to make here is the fact that under constant load polarization in the LiOH solutions of the present work, no decrease in current is observed; not even when the electrode is polarized by as much as 2.8-3V. Further, we have observed in studies in strong $[OH^-]$ solution that once the anode has passivated, it requires a minimum of half a minute for the potential to revert to OCV when the load is removed. This is to be expected since dissolution of pore plugging crystallites to reestablish a specific equilibrium point generally requires considerable time for consummation. The delay accounts for the hysteresis usually observed when metals are passivated by thick films. In the work reported in this paper, OCV was reattained within milliseconds of removing the load. In the light of these factors, it was decided that a passivation phenomenon could not satisfactorily explain the configuration of the polarization curves or the extremely rapid potential recovery on removing the load. It is proposed that a better explanation is tied to a solution mass transport phenomenon in which concentration polarization becomes dominant.

Concentration polarization.—Under constant load (resistance polarization), the Li^+ surface concentration remains constant at any specific polarization level and passivation does therefore not occur because the surface concentration of LiOH does not normally exceed saturation in this electrolyte. Under galvanostatic polarization, on the other hand, at potentials more noble than point c of Fig. 3 and 7, there is a subtle but important difference in the mass transport. Here, the Li^+ flux is held constant and supersaturation of LiOH and precipitation of crystallites occurs in pores and interstices in the LiOH film (6). The behavior of Li in LiOH solution is in certain ways analogous to electropolishing. In studies of this topic (8), it has been shown that the change from concentration polarization to passivation polarization is due mainly to whether the reaction products can be dissolved and transported away from the interface fast enough to prevent precipitation of the products on the surface. To better understand the processes occurring at a Li anode under resistance polarization, it should be realized that neither the flux at the interface, *i.e.*, $(\partial C/\partial x)_{x\to o}$, nor the surface concentration C_o are held constant. Figure 12 has been constructed to show schematically the concentration gradient for Li^+, or OH^- within the effective diffusion layer, δ. In the schematic it is assumed that a linear diffusion model holds. Electroneutrality requires that, in this 1.1 binary electrolyte, the concentration of Li^+ always equals that of OH^-. Thus, the slope of each curve represents the flux of LiOH (or Li^+) diffusing away from the active metal surface which has a LiOH surface concentration, C_o. At I_l, C_o attains its maximum, *i.e.*, $C_o = C_s$.

In the context of concentration polarization, it is of interest to note that the effective diffusion layer thickness, δ, calculated from the potential decay experi-

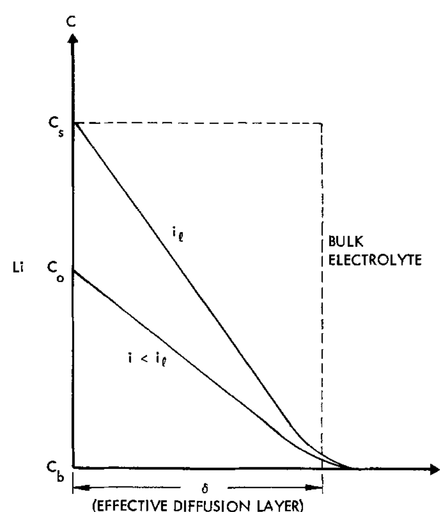

Fig. 12. Concentration distribution within the effective diffusion layer of thickness δ (idealized). C_b = bulk LiOH concentration, C_s = saturated concentration, C_o = LiOH concentration at the active surface where the flux $i < i_l$ (limiting current density).

ment, *i.e.*, 2.4×10^{-4} cm, is of the same order as the value 7.8×10^{-4} cm obtained from the limiting current and film thickness experimental results. Details of this calculation are given in the next section under limiting current.

Limiting current.—From the previous discussion, the concentration polarization region c-l should be dealt with as a resistance polarization due to the current-dependent resistance of the diffusion layer within the porous lithium electrode (9). In this case, the removal of the reaction product, Li^+, is rate determining when current flows. Under steady-state condition, the surface concentration, C_o, at any polarization point beyond c is constant but is greater than C_b. At c no concentration polarization is observed, but only ohmic polarization. At l concentration polarization is predominant whereby the surface concentration of the reaction product reaches its saturation, *e.g.*, $C_o = C_s$. It is obvious that when the concentration at the electrode surface gets closer to saturation, it is more difficult to remove the reaction product via diffusion and thus a higher overpotential is observed. It has been shown previously (6) that the limiting current flowing at the electrode surface is related to its surface concentration by

$$i_l - i_c = \frac{n\mathbf{F}D_o}{\delta}(C_s - C_b) = \frac{I_l - I_c}{A(1-\theta_o)} \quad [13]$$

Eq. [4] and [13] yield

$$I_l - I_c = \frac{n\mathbf{F}D_o T x_o}{\delta k R}(C_s - C_b) \quad [14]$$

Figure 13 which has been obtained from Fig. 3 shows that a linear relationship exists in this system between I_l and v. This relationship, which presumably comes about because of the unusual mass transport occurring across the anode film when the cathode screen is pressed against it, is quite different from the classical flat plate approximations of Lévéque (10) where $I_l \alpha v^{1/3}$. Taking experimental I_l's and the parameters of Table I, the effective diffusion layer δ can be obtained from Eq. [14]. The results of this calculation are plotted in Fig. 14. The δ's so calculated are smaller than would normally be expected. Generally in the case of a tranquil solution, $\delta = 3 \times 10^{-2}$ cm, or at a flat plate under laminar flow $\delta = 10^{-2}$ cm or less. It seems therefore that the cathode

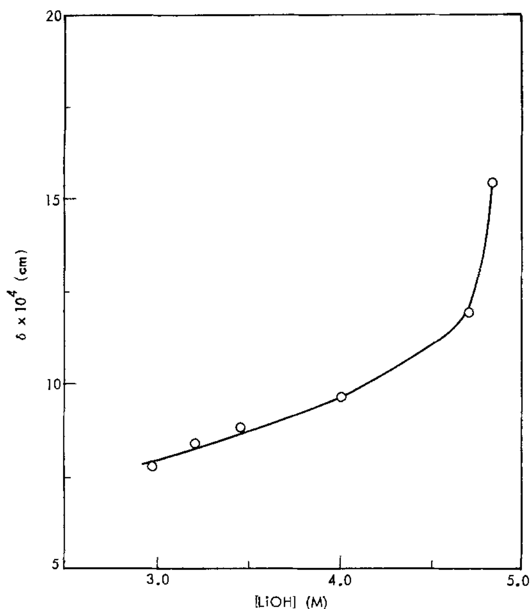

Fig. 13. Influence of electrolyte flow velocity on limiting current in 4M LiOH at 298°K, $P = 6.2 \times 10^4$ Pa, $A = 1.14 \times 10^{-3}$ m^2.

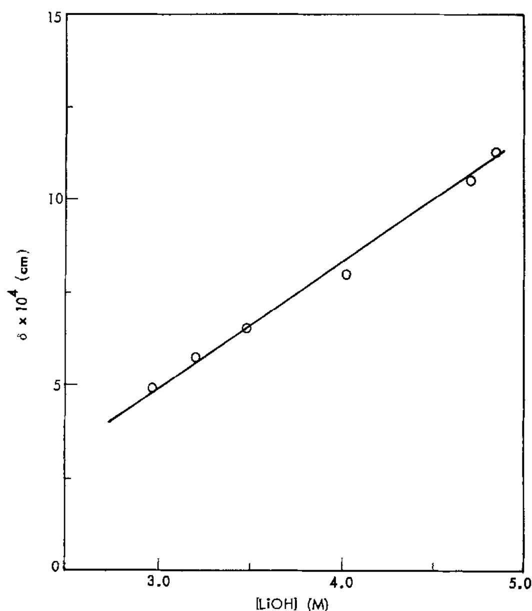

Fig. 14. Concentration dependence of the effective diffusion layer in LiOH.

screen geometry has a major impact on the hydrodynamics within the interelectrode flow channel. The reduced dimensions of δ can be explained by the existence of a substantial electrolyte flow component perpendicular to the anode surface. This component arises from the fluid passing around the metal screen elements.

Finally, the actual limiting current density based on the true active surface area, *i.e.*, $A(1 - \theta_o)$ rather than the projected surface area A can be calculated from Eq. [13], Table I, and Fig. 13 and the results are given in Table II. It is of interest to note that the limiting current densities obtained here are generally high (*i.e.*, > 10 kA/m^2) in this highly alkaline solution. An unusual situation is observed in this system, namely, as is seen in column 4 of Table II, the limiting current density decreases with increasing concentration. This anomaly is readily understood by further inspection of Eq. [13]; when C_b increases D_o and $C_s - C_b$ decrease while δ increases. The end result of these interdependent factors is the reverse trend of the limiting currents.

Conclusions

This study has confirmed that a Li anode in LiOH electrolyte is almost completely covered with a protective film. The active surface area amounts to a small percentage of the projected area and at a fixed LiOH concentration it does not change over a polarization span of ~ 3V from OCV. Also of significance is the fact that the film thickness changes only slightly with electrolyte concentration, polarization level, anode-cathode contact pressure, and electrolyte flow velocity. The paper has shown how electrolyte concentration because of its effect on surface coverage has such major impact on the operation of the cell. Variations in electrolyte flow rate have a nominal influence on the transition current density, which corresponds to the polarization level at which the cell operates most efficiently, and thus changing the flow rate is a convenient way to adjust cell power while maintaining good efficiency. Electrolyte concentration remains, however, the critical control parameter.

Of interest is the observation that the diffusion layer thickness is about 1/50 the thickness of the anodic oxide film and is far thinner than that normally observed on metals at which an electrochemical reaction is proceeding. This suggests that a major electrolyte flow component must exist perpendicular to the electrode surface. It confirms the important role which the cathode screen element plays and shows how vital it is to place this element very close to or have it touching the anode surface. By doing this the electrolyte flow is presumably perturbed into the desired direction. Quantitatively, this concept has not been resolved as yet. Work is proceeding at this time to model the mass transport in the interelectrode cavity. A convective component term on the same coordinate as the diffusion direction now appears to the authors to be a significant factor.

Acknowledgment

The authors wish to thank Professor E. Gileadi, of Tel Aviv University, for many stimulating discussions concerning this paper. This work was supported in its entirety by Lockheed Missiles & Space Company, Incorporated.

Electrodissolution Kinetics of Iron in Chloride Solutions

VI. Concentrated Acidic Solutions

H. C. Kuo and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Anodic iron dissolution in acidic chloride solutions (constant ionic strength of 4.5M) over a wide range of H^+ and Cl^- concentrations has been investigated. Anodic dissolution in low $[H^+]$-concentrated chloride solutions is accelerated by both Cl^- and OH^- with Tafel slopes of 0.075 V/decade at low polarization and accelerated by only OH^- with Tafel slopes of 0.04 V/decade at high polarization. On the other hand, anodic dissolution in highly acidic-concentrated chloride solutions is accelerated by both H^+ and Cl^- with Tafel slopes of 0.11 V/decade and first-order dependence on both H^+ and Cl^-. For low Cl^- concentrations in either dilute or concentrated acidic solutions, anodic dissolution is inhibited by Cl^-. The experimental results indicate that anodic iron dissolution in acidic chloride solutions proceeds by simultaneous parallel reactions. Mechanisms which are consistent with the empirical rate expressions have been developed.

The OH^--accelerated mechanisms of anodic iron dissolution in acidic solutions proposed by Heusler (1) and Bockris *et al.* (2) have stimulated considerable activity in fundamental metal electrodissolution kinetic studies. There is a voluminous literature on iron studies alone confirming the acceleration of its anodic dissolution by hydroxyl ions in acidic solutions.

Recently, McCafferty and Hackerman (3) reported that in highly acidic and concentrated chloride solutions, anodic dissolution of iron is accelerated by both hydrogen and chloride ions. Shortly thereafter, Lorenz and co-workers (4) also reported such phenomena. On the other hand, both groups found that at lower acid concentrations, the rate of iron electrodissolution is decreased by increases in both Cl^- and H^+ concentrations. There were significant differences in some of the kinetic parameters (anodic Tafel slopes and reaction orders) reported by the two groups. At about the same time, Chin (5) reported that in acidic solutions of $[Cl^-] \leq 1.9M$ and $[H^+] \leq 1M$ anodic dissolution of iron is accelerated by both chloride and hydroxyl ions. This result appears to contradict the chloride-inhibited results of McCafferty and Hackerman (3) and Lorenz (4) at low acid concentrations. All three papers provide reviews of the literature on anodic dissolution of iron in acidic chloride solutions.

The purpose of the present work is to determine more precisely the conditions under which iron electrodissolution occurs by either an OH^- or H^+-accelerated mechanism and by either a chloride-accelerated or chloride-inhibited mechanism. The kinetics of the anodic dissolution of iron in acidic solutions is investigated by the rotating-disk electrode technique over a wide range of chloride and hydrogen ion concentrations with all solutions maintained at a constant ionic strength of 4.5M.

Experimental

The description of the rotating-disk electrode apparatus and instrumentation, the electrochemical cell, and the experimental procedure are given elsewhere (6).

The test electrodes were made from a 1.27 cm (½ in.) diam rod of Ferrovac E iron. The rod was first turned down and polished on a lathe to a diameter of 1.257 cm. It was then cut into 1.27 cm lengths using an Al_2O_3 abrasive wheel. During the cutting process, water was used to cool the iron rod. Both faces of the electrodes were polished with waterproof alumina paper of various grit (No. 240, No. 400, and No. 600). After polishing, the electrodes were washed and rinsed in distilled water, degreased with hot benzene in a Soxhlet column for 4 hr, and then annealed under vacuum ($<10^{-4}$ mm Hg) at 700°C for 1 hr and cooled down slowly to room temperature.

The reference electrode was a saturated calomel electrode (SCE). All potentials reported in this study were referred to this electrode. The reference electrode was housed in a small glass reservoir and connected to the Luggin capillary through a glass tube. In those experiments in which perchlorate ions were present in the electrolyte, a fiber junction salt bridge (double junction) was inserted between the saturated calomel electrode and electrolyte to preclude precipitation of potassium perchlorate within the fiber junction of the calomel electrode. This bridge was filled with 4.2M NaCl solution.

A dual-function Princeton Applied Research potentiostat/galvanostat (Model 173) with a current-voltage converter plug in (PAR Model 176) was used to control the potential between the test and reference electrode (potentiostat mode) or to supply constant current through the electrochemical cell (galvanostat mode). The potential of the test electrode was measured with a Keithley electrometer (Model 602 B). The current through the cell was measured either by the built-in panel meter on the potentiostat/galvanostat or by a Simpson ammeter (Model 269) connected to the circuit. A dual-channel Moseley strip chart recorder (Model 1700A) was used to monitor the potential and current. An Exact function generator (Model 255) was connected to the potentiostat in order to supply the triggering pulse to switch the applied potential/current from one setting to another during polarization. In the pulse polarization or transient studies the current transients were recorded on a Tektronix storage oscilloscope (Type 564).

All solutions were prepared from Analytical Reagent Grade chemicals and deionized water which was subsequently distilled. The electrolyte was continuously deoxygenated with prepurified nitrogen gas which was first passed through a heated (480°C) copper column to remove the residual oxygen. The electrode was immersed in the electrolyte about 12 hr after the deoxygenation was started. Before immersion the electrode was activated in 5N HCl solution for 20 min, fol-

Key words: anodic, corrosion, dissolution, mechanisms.

lowed by thorough rinsing in a stream of distilled water. The corrosion potential of the working electrode was continuously monitored and recorded after immersion in the electrolyte. The corrosion potential usually attained a steady-state value within 2 hr. Polarization was started after about 3 hr immersion. In all of the polarization experiments, the rotation rate was fixed at 1000 rpm; however, a few experiments were performed by varying the rotation rate to check for mass transfer effects.

The H^+ effects were studied in (*i*) xNaCl + yHCl ($x + y = 4.5M$) solutions. The Cl^- effects were studied in (*ii*) solutions of pH = 1.1, xNaCl + $y$$NaClO_4$ + 0.01M $HClO_4$ ($x + y = 4.49M$), and (*iii*) solutions of 4.5M H^+, xHCl + $y$$HClO_4$ ($x + y = 4.5M$). In the last two series, the concentration of chloride ions was varied from 0 to 4.5M. The solutions were maintained at room temperature ($\approx$ 23°C).

All the potential values have been corrected for the ohmic overpotentials. The potential values have also been corrected for the liquid junction potentials which have been estimated by calculations given elsewhere (6).

Results

Effect of H^+ in 4.5M Cl^- (xNaCl + yHCl, $x + y = 4.5M$).—Table I presents the corrosion potentials at various H^+ concentrations. Anodic Tafel plots for $[H^+] \leq 0.5M$ solutions are shown in Fig. 1. With the exception of the $[H^+] = 0.5M$ plot, 2 linear Tafel regions are observed (*i.e.*, for $[H^+] \leq 0.1M$ plots). Slopes of correlating anodic Tafel lines are as follows

at low polarization, $b_a = 0.075$ V/decade, $[H^+] \leq 0.1M$

and

at high polarization, $b_a = 0.040$ V/decade, $[H^+] \leq 0.1M$

Only the higher Tafel slope is obtained for $[H^+] = 0.5M$ over the potential range shown in Fig. 1.

For both Tafel regions, the rate of anodic dissolution increases with decrease in H^+ concentrations. Electrochemical reaction order plots are presented in Fig. 2 and shows that

for the low polarization region,

$$\left(\frac{\partial \log i_a}{\partial pH}\right)_{\phi_a = -0.50V} = 0.6, \quad [H^+] \leq 0.1M$$

and

for the high polarization region,

$$\left(\frac{\partial \log i_a}{\partial pH}\right)_{\phi_a = -0.40V} = 1.1, \quad [H^+] \leq 0.1M$$

The low polarization data are in accord with the results of Chin (5), while the high polarization data with the OH^--accelerated mechanism proposed by Bockris *et al.* (2).

Figure 3 shows the results for more highly acidic solutions ($[H^+] \geq 1M$) with the data for $[H^+] = 0.5M$ included for comparison. For solutions of $1M \leq [H^+] \leq 4.5M$ the corelating anodic Tafel line of slope

$$b_a = 0.110 \text{ V/decade}, \quad [H^+] \geq 1M$$

The results in Fig. 3 show that for 4.5M Cl^- solutions in which $[H^+] \geq 1M$, the rate of anodic dissolution increases with increase in H^+ concentrations, which is directly opposite to that observed at lower acidic solutions ($[H^+] \leq 0.5M$). These results confirm those reported previously by McCafferty and Hackerman (3), and Lorenz and co-workers (4) that H^+ accelerates the anodic dissolution of iron in highly acidic, concentrated chloride solutions.

Figure 4 gives the reaction order plot for $[H^+] \geq 1M$ and shows that

$$\left(\frac{\partial \log i_a}{\partial \log [H^+]}\right)_{\phi_a = -0.30V} = 1.0, \quad [H^+] \geq 1M$$

The first-order dependence on $[H^+]$ is in accord with

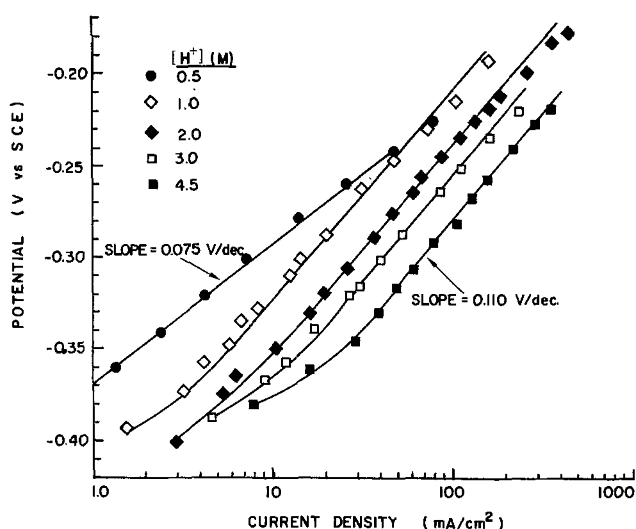

Fig. 3. Effect of H^+ on anodic iron dissolution in xNaCl + yHCl ($x + y = 4.5$M). $[H^+] \geqq 0.5$M.

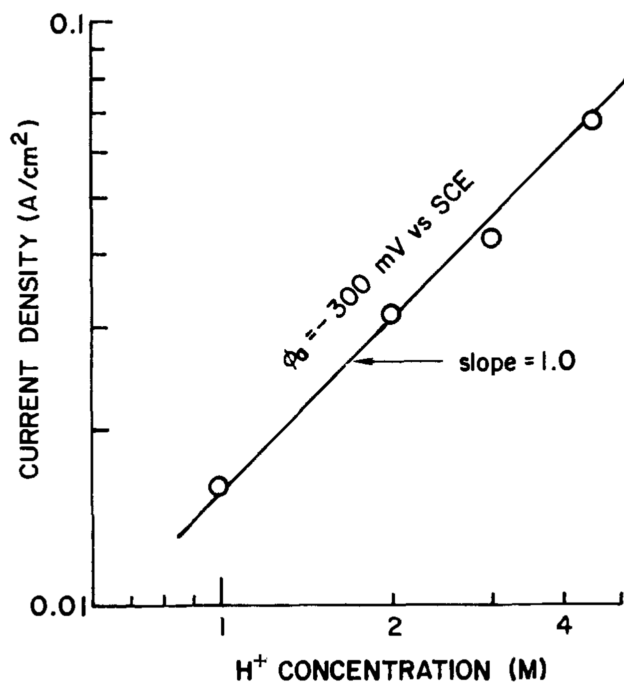

Fig. 4. Reaction order plot of anodic iron dissolution in xNaCl + yHCl ($x + y = 4.5$M) with respect to H^+. $[H^+] \geqq 1$M.

the work of Lorenz and co-workers (4), but not with the results of McCafferty and Hackerman (3) who reported a second-order dependence on $[H^+]$.

Effect of Cl^- in pH = 1.1 solutions (0.01M $HClO_4$- + xNaCl + yNaClO$_4$, $x + y = 4.49$M).—Table II gives the corrosion potentials at various Cl^- concentrations.

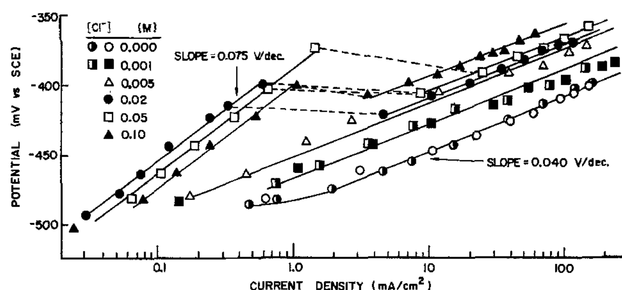

Fig. 5. Effect of Cl^- on anodic iron dissolution in 0.01M $HClO_4$ + xNaCl + yNaClO$_4$ ($x + y = 4.49$M). pH = 1.1 and $[Cl^-] \leqq 0.10$. Half-filled points represent galvanostatic data. Open and closed points represent potentiostatic data.

Anodic Tafel plots for $[Cl^-] \leqq 0.1$M are shown in Fig. 5. Linear Tafel lines of slope = 0.04 V/decade are obtained for $[Cl^-] \leqq 0.005$M. In this range, anodic dissolution of iron is inhibited by chloride ions. For $[Cl^-] > 0.005$M, anodic Tafel slopes are 0.075 V/decade at low polarization. In this region, Cl^- accelerates anodic dissolution. Above -0.425V, pseudosteady-state currents, which followed the Tafel lines with the higher slope, are observed but subsequently increase to much higher steady-state values (dashed lines). These latter values followed the Tafel lines with the lower slope. Since potentiostatic control is maintained throughout the transition period, the corrected potential of the iron electrode is decreased as the current is increased in the shift from the higher Tafel slope region to the lower Tafel slope region. This is due to the larger *IR* drop correction for the potential at the higher current value.

A typical current transient ($[Cl^-] = 0.01$M), which exhibits the above phenomenon is shown in Fig. 6. For $\phi_a = -0.48$V (Fig. 6a) the current quickly reaches steady state (A) in about 2 sec. The actual transient was followed for about 10 min with no discernible change in this steady-state value. For $\phi_a = -0.40$V (Fig. 6b), the current remains steady (A) for the time period between 2-12 sec. After about 12 sec, the current increases and, at about 40 sec, attains a new much higher steady-state value (B). For $\phi_a = -0.38$V (Fig. 6c) and above the current quickly reaches a minimum (A) and then rapidly increases to the final steady value (B). The duration of the pseudosteady state (A) decreases rapidly with increase in the applied potential. The time rate of increase of the current transient from the pseudosteady state (A) to the final steady state (B) increases rapidly with increasing applied potential. For applied potentials higher than -0.37V, the final steady state (B) is attained within a few milliseconds.

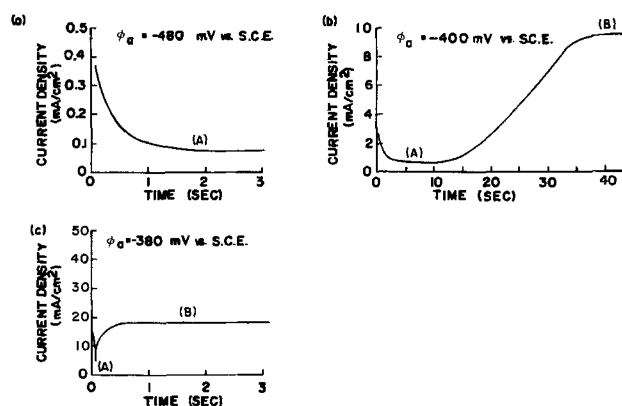

Fig. 6. Current transient during anodic potential pulse polarization of iron in 0.01M $HClO_4$ + 0.01M NaCl + 4.48M NaClO$_4$. pH = 1.1.

4.473M $HClO_4$ + 0.027M HCl	−353 ± 5	90	0.30
4.45M $HClO_4$ + 0.05M HCl	−364 ± 6	95	0.14
4.4M $HClO_4$ + 0.1M HCl	−375 ± 6	95	0.09
4.3M $HClO_4$ + 0.2M HCl	−387 ± 6	95	0.14
4.1M $HClO_4$ + 0.4M HCl	−390 ± 10	105	0.31
3.5M $HClO_4$ + 1.0M HCl	−381 ± 5	105	1.4
2.5M $HClO_4$ + 2.0M HCl	−375 ± 6	105	3.0
1.5M $HClO_4$ + 3.0M HCl	−382 ± 10	105	4.7
0.5M $HClO_4$ + 4.0M HCl	−390 ± 9	105	5.3

The above transient behavior occurs in the intermediate potential region of the Tafel plots for $0.01 \leq [Cl^-] \leq 0.1M$. Current values (A) fall on the Tafel lines with slope of 0.075 V/decade and current values (B) fall on the Tafel lines with slope of 0.04 V/decade. In addition to significantly different anodic Tafel slopes, the effect of Cl^- on anodic dissolution is directly opposite in the two cases. Anodic dissolution of iron represented by Tafel lines with the higher slope is accelerated by Cl^- while anodic dissolution is inhibited by Cl^- for the other case.

For $[Cl^-] \geq 0.2M$, Tafel lines of slope = 0.075 V/decade are obtained at low polarization and anodic dissolution is accelerated by chloride ions (Fig. 7). At higher polarization, the Tafel lines have slope of 0.04 V/decade and appear independent of Cl^-. That is

at high polarization,

$$\left(\frac{\partial \log i_a}{\partial \log [Cl^-]}\right)_{\phi=-0.33V} = 0, \quad [Cl^-] \geq 0.2M$$

On the other hand, Fig. 8 shows that

at low polarization,

$$\left(\frac{\partial \log i_a}{\partial \log [Cl^-]}\right)_{\phi=-0.45V} = 0.4, \quad [Cl^-] \geq 0.2M$$

Effect of Cl^- in 4.5M H^+ ($xHCl + yHClO_4$, $x + y$ = 4.5M).—For $[Cl^-] \leq 0.05M$, anodic Tafel plots are given in Fig. 9. In pure perchloric acid, an anodic Tafel slope of 0.044 V/decade is observed. With increasing chloride concentration up to 0.05M, the anodic Tafel slope monotonically increases to about 0.095 V/decade. It is observed that Cl^- inhibited the anodic dissolution of iron in this concentration region.

For $[Cl^-] \geq 0.1M$, Fig. 10 shows that Cl^- accelerates anodic dissolution and, except for 0.1 and 0.2M Cl^-, which had anodic Tafel slopes of 0.095 V/decade, slopes of 0.11 V/decade are obtained for the correlating Tafel lines ($[Cl^-] \geq 0.4M$).

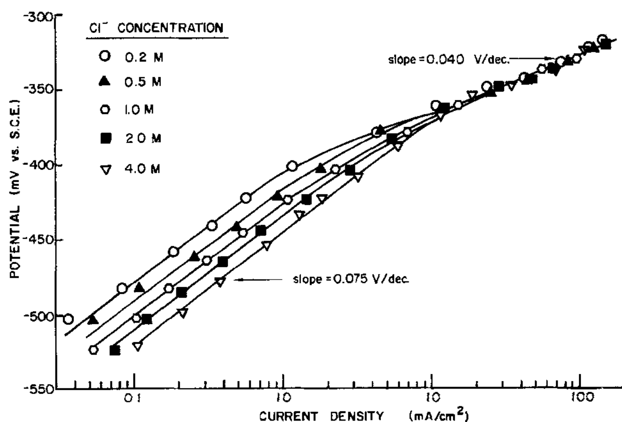

Fig. 7. Effect of Cl^- on anodic iron dissolution in 0.01M $HClO_4$ + $xNaCl$ + $yNaClO_4$ ($x + y$ = 4.49M). pH = 1.1 and 0.2M ≤ $[Cl^-]$ ≤ 4.0M.

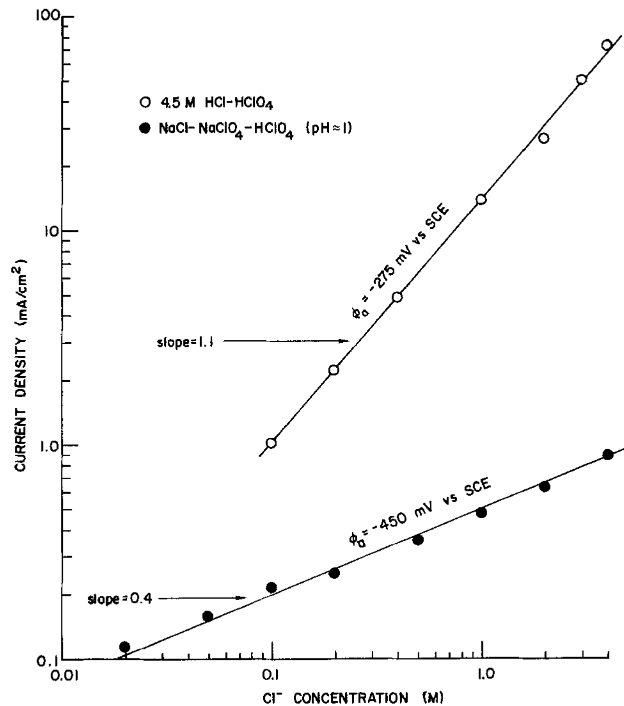

Fig. 8. Chloride reaction order plots of anodic iron dissolution. pH = 1.1 and $[H^+]$ = 4.5M solutions.

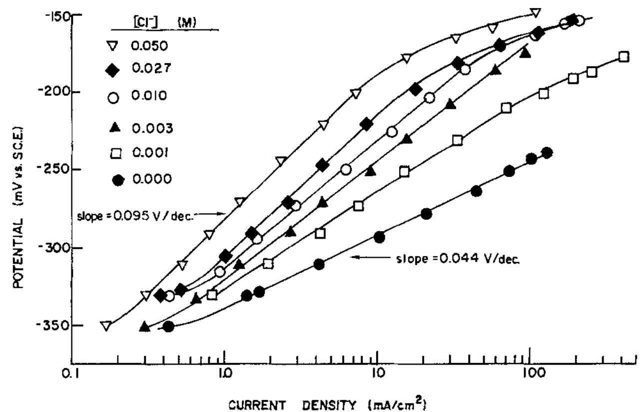

Fig. 9. Effect of Cl^- on anodic iron dissolution in $xHCl$ + $yHClO_4$ ($x + y$ = 4.5M). $[H^+]$ = 4.5M and 0 ≤ $[Cl^-]$ ≤ 0.050M.

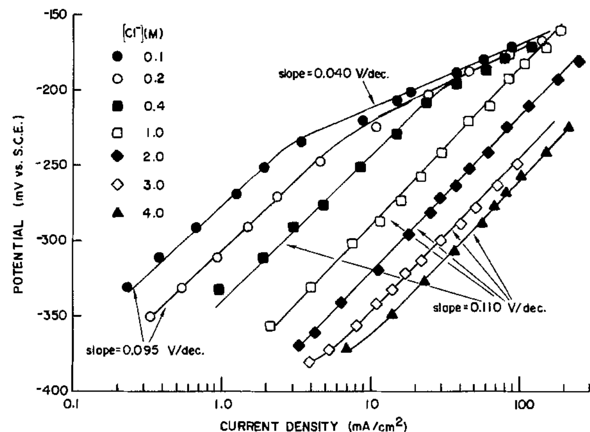

Fig. 10. Effect of Cl^- on anodic iron dissolution in $xHCl$ + $yHClO_4$ ($x + y$ = 4.5M). $[H^+]$ = 4.5M and 0.1M ≤ $[Cl^-]$ ≤ 4.0M.

The reaction order plot of the data obtained in Fig. 8, show that

$$\left(\frac{\partial \log i_a}{\partial \log [Cl^-]}\right)_{\phi_a=-0.275V} = 1.1, \ [Cl^-] \geq 0.1M$$

Empirical rate expressions for anodic dissolution of iron.—On the basis of the experimental polarization data, the kinetics of iron electrodissolution in acidic chloride solutions, ionic strength of 4.5M, can be expressed as follows

For low $[H^+]$, concentrated Cl^-

$$i_a = k_a[Cl^-]^{0.4}[OH^-]^{0.6} \exp\left(\frac{4}{5}\frac{F\phi}{RT}\right), \quad \text{at low polarization} \quad [1]$$

$$i'_a = k'_a[OH^-] \exp\left(\frac{3}{2}\frac{F\phi}{RT}\right), \text{ at high polarization} \quad [2]$$

For high $[H^+]$, concentrated Cl^-

$$i_a = k''_a [H^+][Cl^-]^{1.1} \exp\left(\frac{F\phi}{2RT}\right) \quad [3]$$

Equation [1] is in accord with the previous results, at lower chloride concentrations, of Chin (5). Equations [1] and [2] indicate, as suggested earlier by Chin (5), that the electrodissolution of iron in dilute acidic chloride solutions proceeds by two coupled parallel reactions as represented by the Cl^--accelerated mechanism (5) and the OH^--accelerated mechanism (2). In a series of papers, Bech-Nielsen [*e.g.*, see Ref. (7-9)] has discussed the idea of 2 distinctly different parallel anodic dissolution processes of iron in acidic solutions.

Plots of the potential (ϕ_t) and current (i_t) coordinates of the intersection of the two Tafel lines, as shown in Fig. 1, *vs.* pH are presented in Fig. 11. Equations [1] and [2] give the pH dependence of these intersection coordinates as

$$\frac{\partial \phi_t}{\partial pH} = -34 \text{ mV}/pH \quad [4]$$

and

$$\frac{\partial \log i_t}{\partial pH} = 0.14 \quad [5]$$

These values compare well with the experimental plots in Fig. 11 which give −40 mV/pH and 0.15, respectively.

Equation [3], which represents anodic iron dissolution in highly acidic concentrated chloride solutions, is in accord with the work of Lorenz and co-workers (4) except for the chloride reaction order which they report as 0.6. On the other hand McCafferty and Hackerman (3) reported a much lower anodic Tafel slope of about 60 mV/decade, an H^+ reaction order of 2 compared to first order in this work and a chloride reaction order between the first order obtained in the work and the value reported by Lorenz (4).

Discussion

Low H^+ concentrations.—In low $[H^+]$ and concentrated chloride solutions the results of anodic iron dissolution of this work are compared with those of McCafferty and Hackerman (3) and Lorenz and co-workers (4, 10) below:

In this work

$$i_a = k_a[Cl^-]^{0.4}[OH^-]^{0.6} \exp\left(\frac{4}{5}\frac{F\phi}{RT}\right), \quad \text{at low polarization} \quad [1]$$

and

$$i'_a = k'_a[OH^-] \exp\left(\frac{3}{2}\frac{F\phi}{RT}\right), \text{ at high polarization} \quad [2]$$

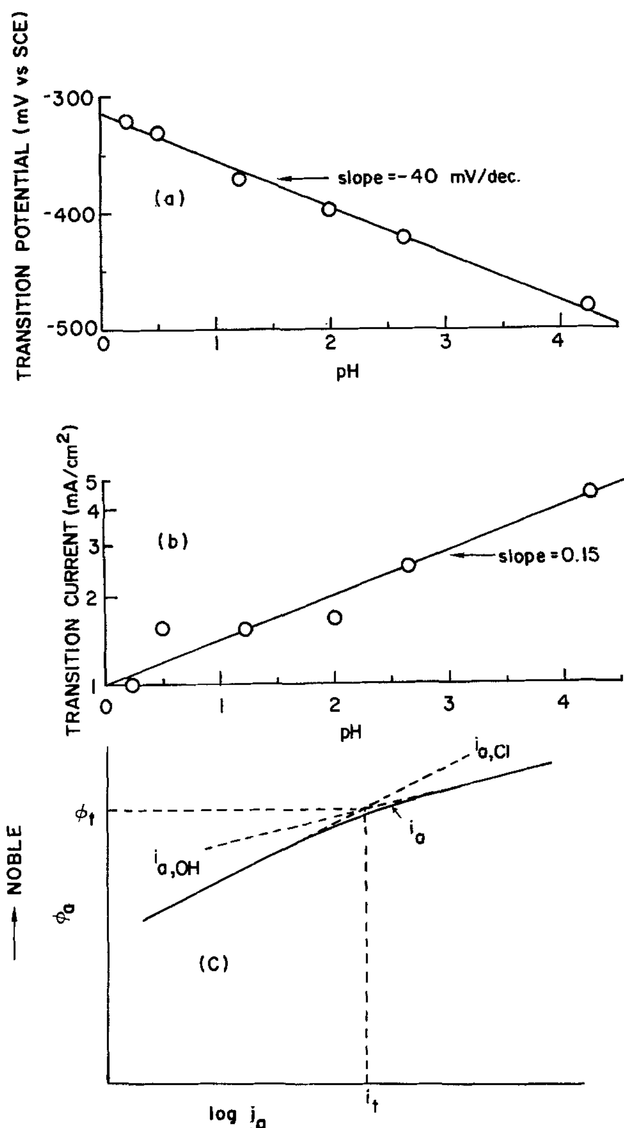

Fig. 11. (a) Transition potential (ϕ_t) *vs.* pH; (b) Transition current (i_t) *vs.* pH; (c) Schematic diagram of coupled, parallel OH^--accelerated and Cl^--accelerated anodic iron dissolution in acidic chloride solution.

McCafferty and Hackerman (3) found

$$i_a = k_a[Cl^-]^{-0.9}[OH^-]^{0.9} \exp\left(\frac{4}{5}\frac{F\phi}{RT}\right) \quad [1a]$$

and Lorenz and co-workers (4, 10) obtained

$$i_a = k_a[Cl^-]^{-0.7}[OH^-]^{0.7} \exp\left(\frac{F\phi}{RT}\right) \quad [1b]$$

The results of the latter two groups indicate that at low $[H^+]$, chloride ions inhibit anodic iron dissolution in contrast to Chin's (5) and this work which show that chloride ions accelerate anodic dissolution.

The experimental results of this work can be interpreted in terms of coupled parallel reactions as represented by the Cl^--accelerated mechanism (5) and the OH^--accelerated mechanism (2, 11) given below:

Cl^--accelerated mechanism

$$Fe \cdot H_2O + Cl^- = FeClOH^-_{ads} + H^+ + e \quad [a]$$

$$FeClOH^-_{ads} \xrightarrow{\text{rds}} FeClOH + e \quad [b]$$

$$FeClOH + H^+ = Fe^{++} + Cl^- + H_2O \quad [c]$$

OH^--accelerated mechanism

$$Fe \cdot H_2O = FeOH_{ads} + H^+ + e \qquad [a']$$

$$FeOH_{ads} \xrightarrow{rds} FeOH^+ + e \qquad [b']$$

$$FeOH^+ + H^+ = Fe^{++} + H_2O \qquad [c']$$

The surface coverage of $FeClOH^-$ is assumed to range between 0.2 -0.8 and to follow Temkin adsorption behavior. On the other hand, the surface coverage of FeOH is assumed to be very small, *i.e.*, $\theta_{FeOH} \rightarrow 0$. By following the derivation given previously (5), the anodic iron dissolution rate equation for the Cl^- accelerated mechanism can be obtained

$$i_{a,Cl} = k_{a,Cl} [Cl^-]^{0.5} [OH^-]^{0.5} \exp\left(\frac{\mathbf{F}\phi}{RT}\right) \qquad [6]$$

The charge-transfer (β) and adsorption (γ) symmetry factors are assumed to be 0.5, *i.e.*, $\beta = \gamma = 0.5$.

Since $\theta_{FeOH} \rightarrow 0$ and the standard free energy of adsorption of FeOH should be much larger than that of $FeClOH^-$, ΔG°_{FeOH} should remain essentially constant and FeOH should follow Langmuir adsorption behavior. The rate equation for the OH^--accelerated mechanism can be derived as

$$i_{a,OH} = k_{a,OH} [OH^-] \exp\left(\frac{3}{2}\frac{\mathbf{F}}{RT}\right) \qquad [7]$$

Both Eq. [6] and [7] are in good agreement with the empirical relationships, Eq. [1] and [2], respectively. By considering the two equations as representing parallel anodic dissolution reactions, the total rate of anodic iron dissolution in solutions of low $[H^+]$ and concentrated Cl^- can be expressed as

$$i_{a,total} = i_{a,Cl} + i_{a,OH} \qquad [8]$$

At lower anodic potentials,

$$i_{a,Cl} >> i_{a,OH}$$

and

$$i_{a,total} \approx i_{a,Cl} \qquad [8a]$$

At higher anodic potentials,

$$i_{a,Cl} << i_{a,OH}$$

and

$$i_{a,total} \approx i_{a,OH} \qquad [8b]$$

A schematic diagram of Eq. [8], the continuous line, and Eq. [8a] and [8b] is shown in Fig. 11c. At the transition point (ϕ_t, i_t)

$$i_t = i_{a,Cl} = i_{a,OH} \qquad [9]$$

As discussed above, Eq. [4] and [5] give the *p*H dependence of the transition coordinates and compares well with the experimental results shown in Fig. 11.

For low $[H^+]$ (*p*H = 1.1) and $[Cl^-] \leq 0.005M$ (Fig. 5), the surface area accessible for anodic iron dissolution by the OH^--accelerated mechanism is decreased with increase in Cl^- concentrations due to increases in both θ_{FeOHCl^-} (for low $[Cl^-]$, $\theta_{FeOHCl^-} << 1$), and surface adsorption of Cl^-. This leads to the apparent inhibition effect of Cl^- on anodic iron dissolution.

For low $[H^+]$ (*p*H = 1.1) and $0.01M \leq [Cl^-] \leq 0.10M$, $FeOHCl^-$ attains intermediate surface coverage and, at low polarization, anodic iron dissolution proceeds by the Cl^- accelerated mechanism. At higher potentials, the OH^--accelerated mechanism becomes dominant. In the Cl^- concentration range, 0.01M-0.10M, adsorption of Cl^- and the surface coverage of $FeOHCl^-$ continues to increase with increase in Cl^- concentration. The consequent decrease in accessible surface area for OH^--accelerated anodic dissolution leads to further decreases in the apparent rate, $i_{a,OH}$. For $[Cl^-] \geq 0.2M$, and low $[H^+]$ (*p*H = 1.1), the surface area accessible for OH^--accelerated anodic dissolution remains essentially constant, and the total anodic dissolution rate, at high polarization, is independent of further increases in Cl^- concentration.

High H^+ concentrations.—In highly acidic and concentrated chloride solutions, anodic iron dissolution is accelerated by both chloride and hydrogen ions and follows the rate expression

$$i_{a,H} = k_{a,H} [H^+][Cl^-]^{1.1} \exp\left(\frac{\mathbf{F}\phi}{2RT}\right) \qquad [10]$$

This empirical rate expression is consistent with the following H^+-accelerated mechanism

$$Fe \cdot H_2O + Cl^- = FeCl_{ads} + H_2O + e \qquad [a'']$$

$$FeCl_{ads} + H^+ = FeClH^+ \qquad [b'']$$

$$FeClH^+ + Cl^- \xrightarrow{rds} FeCl_2 + H^+ + e \qquad [c'']$$

$$FeCl_2 = Fe^{++} + 2Cl^- \qquad [d'']$$

It is assumed that $\theta_{FeCl} \rightarrow 1$ and $\theta_{FeClH^+} \rightarrow 0$ so that both adsorbed species follow Langmuir adsorption behavior. The rate of step [c''] is expressed as

$$i_{[c'']} = k_{a,[c'']} \theta_{FeClH^+} [Cl^-] \exp\left(\frac{\beta_{[c'']}\mathbf{F}\phi}{RT}\right) \qquad [11]$$

If step [b''] is assumed to be in quasiequilibrium

$$\theta_{FeClH^+} = K_{[b'']} \theta_{FeCl} [H^+] \qquad [12]$$

$$= K_{[b'']} [H^+], \text{ since } \theta_{FeCl} \rightarrow 1 \qquad [13]$$

Equations [11] and [13], then, give

$$i_{[c'']} = k_{a,[c'']} K_{[b'']} [H^+][Cl^-] \exp\left(\frac{\beta\mathbf{F}\phi}{RT}\right) \qquad [14]$$

If $\beta = 0.5$, the rate of anodic dissolution is

$$i_{a,H} = k_{a,H} [H^+][Cl^-] \exp\left(\frac{\mathbf{F}\phi}{2RT}\right) \qquad [15]$$

Equation [15], which is derived from the proposed mechanism, is in accord with Eq. [10] which is a representation of the experimental results.

Steps [a'']-[d''] are a modification of the steps proposed by Lorenz and co-workers (4). However, in the mechanism proposed by the latter group, Temkin adsorption behavior of the adsorbed species, FeCl, was assumed in contrast to Langmuirian behavior of FeCl and $FeClH^+$ as proposed in the mechanism in this work.

Figure 10 shows that for $[Cl^-]$ = 0.1, 0.2, and 0.4M, the anodic Tafel lines (with slopes of approximately 0.1 V/decade), which shifted to higher anodic dissolution rates with the increase in Cl^- concentration, changed to an anodic Tafel line with a slope of 0.04 V/decade at high polarization. Anodic dissolution, in the latter region, appeared to be independent of Cl^- concentration. This observation suggests, although the experimental data is not, by any means, extensive, that anodic iron dissolution in highly acidic and concentrated chloride solutions may also occur by parallel reactions as represented by the H^+-accelerated mechanism and the OH^--accelerated mechanism, *i.e.*

$$i_{a,total} = i_{a,H} + i_{a,OH} \qquad [16]$$

The former ($i_{a,H}$) is dominant at lower polarization and the latter ($i_{a,OH}$) at higher polarization. More extensive anodic polarization studies at higher potentials than those examined in this work are required to verify this point. At much higher potentials, limiting diffusion currents have recently been observed in studies of high anodic iron dissolution rates in concentrated acidic and neutral chloride solutions (12, 13).

The results in Fig. 10 for Cl^- concentrations of 0.1, 0.2, and 0.4M at higher polarization also suggest that

anodic iron dissolution in chloride-free concentrated perchloric acid follows the OH^--accelerated mechanism even at low polarization. Some preliminary results of anodic iron dissolution in chloride-free acidic perchlorate solutions ($x HClO_4 + y NaClO_4$, $x + y =$ 6M), as shown in Fig. 12, indicate that anodic dissolution is, indeed, decreased with increase in H^+ concentration over the entire potential range examined.

In highly acidic ($[H^+] = 4.5M$) and dilute chloride ($[Cl^-] \leq 0.05M$) solutions, the anodic dissolution rate is decreased and the anodic Tafel slope is increased with increase in concentration of chloride ions. The increase in anodic Tafel slope from 0.04 to 0.095 V/decade, when Cl^- is increased from 0.000 to 0.050M indicates that the mechanism of anodic iron dissolution is changing in this concentration range. On the other hand, at low H^+ (pH = 1.1) and low Cl^- concentrations, as discussed above, Cl^- also inhibits anodic dissolution, but the anodic Tafel slope (0.04 V/decade) remains constant, indicating no change in the mechanism.

The OH^--accelerated mechanism is dominant for highly acidic and very dilute chloride solutions. If $\theta_{FeCl} \rightarrow 0$ and $\theta_{FeCl} >> \theta_{FeOH} + \theta_{FeClH^+}$ (exclusive of adsorbed water molecules), the rate of anodic iron dissolution can be expressed as

$$i_a = k_{a,OH}(1 - \theta_{FeCl})[OH^-] \exp\left(\frac{3}{2}\frac{\mathbf{F}\phi}{RT}\right) \quad [17]$$

For Langmuir adsorption and step [a″] in quasiequilibrium

$$k_{[a'']}[Cl^-](1 - \theta_{FeCl}) \exp\frac{\beta \mathbf{F}\phi}{RT} = k_{-[a'']}\theta_{FeCl} \exp - \frac{(1-\beta)\mathbf{F}\phi}{RT} \quad [18]$$

An expression for θ_{FeCl} in terms of the potential and Cl^- concentration is obtained from Eq. [18]

$$\theta_{FeCl} = \frac{k_{[a'']}[Cl^-]\exp\left(\frac{\mathbf{F}\phi}{RT}\right)}{k_{[a'']}[Cl^-]\exp\left(\frac{\mathbf{F}\phi}{RT}\right) + k_{[-a'']}} \quad [19]$$

Also

$$(1 - \theta_{FeCl}) = \frac{1}{K_{[a'']}[Cl^-]\exp\left(\frac{\mathbf{F}\phi}{RT}\right) + 1} \quad [20]$$

where

$$K_{[a']} = \frac{k_{[a'']}}{k_{[-a'']}}$$

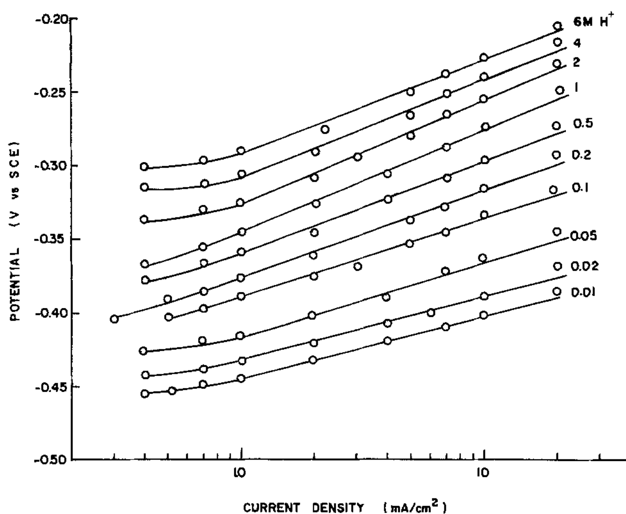

Fig. 12. Effect of H^+ on anodic iron dissolution in chloride-free acidic perchlorate solutions ($xHClO_4 + yNaClO_4$, $x + y = 6M$).

With the expression for $(1 - \theta_{FeCl})$ given in Eq. [20], Eq. [17] becomes

$$i_a = k_{a,OH}[OH^-] \frac{\exp\left(\frac{3}{2}\frac{\mathbf{F}\phi}{RT}\right)}{K_{[a'']}[Cl^-]\exp\left(\frac{\mathbf{F}\phi}{RT}\right) + 1} \quad [21]$$

For chloride-free solutions, Eq. [21] becomes

$$i_a = k_{a,OH}[OH^-] \exp\left(\frac{3}{2}\frac{\mathbf{F}\phi}{RT}\right)$$

which is the rate expression for the OH^--accelerated mechanism. For dilute concentrations of Cl^- in which $K_{[a'']}[Cl^-] \exp(\mathbf{F}\phi/RT) >> 1$, Eq. [21] gives

$$i_a = k_{a,OH}K^{-1}_{[a'']}[Cl^-]^{-1}[OH^-] \exp\left(\frac{\mathbf{F}\phi}{2RT}\right) \quad [22]$$

For the dilute concentrations, $[Cl^-] \leq 0.05M$, the rate expression for anodic dissolution is assumed to be between the latter two limiting cases, and Eq. [20] is given a power law form

$$(1 - \theta_{FeCl}) \approx K_{[a'']}^{-\delta}[Cl^-]^{-\delta} \exp\left(-\frac{\delta \mathbf{F}\phi}{RT}\right) \quad [23]$$

where $0 \leq \delta \leq 1$. δ changes from 0 to 1 with increase in $[Cl^-]$. Then Eq. [23] and [17] give

$$i_a \approx k_{a,OH}K_{[a'']}^{-\delta}[Cl^-]^{-\delta}[OH^-] \exp\left[\frac{\left(\frac{3}{2} - \delta\right)\mathbf{F}\phi}{RT}\right] \quad [24]$$

As δ increases from zero to values approaching one as $[Cl^-]$ increases from zero to some finite dilute concentration of Cl^-, Eq. [24] shows the inhibition effect of Cl^- and the increase in the anodic Tafel slope from 0.04 V/decade to values approaching 0.12 V/decade with increase in Cl^- concentration. Therefore, Eq. [24] predicts anodic iron dissolution behavior for $[H^+] =$ 4.5M and $0.000M \leq [Cl^-] \leq 0.050M$ as shown in Fig. 9. For $[Cl^-] \geq 0.1M$ and $H^+ = 4.5M$, the anodic behavior follows the H^+ and Cl^--accelerated mechanism.

General comments.—The results obtained in this work indicate that anodic iron dissolution behavior in acidic chloride solutions depends strongly on both the H^+ and Cl^- concentrations. Electrodissolution appears to proceed by parallel anodic reactions in both dilute and concentrated acidic chloride solutions. Proposed mechanisms which have been developed to interpret the experimental electrode kinetic data, involve several chloro-iron complexes as adsorbed reaction intermediates. Similar complexes have also been proposed in other mechanisms (*e.g.*, see Ref. (3, 4, 10, 14, 15). A good review of work indicating the importance of halo-iron complexes in iron corrosion is given by Foley (16, 17).

Hysteresis effects in the anodic polarization of iron in HCl have been ascribed by Foroulis (18) to complexation. The results shown in Fig. 5 and 6 of this work are not only consistent with this speculation, but, in addition, provide the further information which indicates that this phenomenon is due to the simultaneous occurrence of two parallel anodic dissolution reactions, one involving a chloro-iron complex and the other which does not.

The relevance of these parallel anodic dissolution reactions (depending on both H^+ and Cl^- concentrations) to localized corrosion and to the efficiency and efficacy of electrochemical machining processes is indicated since both of the latter are are so strongly dependent on the type of anions present in the electrolyte. However, much more detailed kinetic studies

on the effect of anions on anodic metal dissolution in both the active and transpassive regions are required for a fuller understanding. The importance of such further work to the prevention or control of localized corrosion and to optimization of electrochemical machining is evident.

Electrochemical Aspects of the Beveling of Sputtered Permalloy Films

J. J. Kelly and G. J. Koel

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

For the production of thin film magnetic heads, beveled steps in sputtered Permalloy films have been made using a duplex layer chemical etching technique. In this work, special attention was paid to galvanic interaction between the Permalloy base layer and the top layer metal, titanium. By changing the HF concentration of the $H_2SO_4/H_2O_2/HF$ etchant, the beveling angle α could be varied between 6° and 40°. The fact that (*i*) the rest potential of the bimetallic system lies in a region of the anodic polarization curve for titanium, in which the metal dissolution rate is almost completely independent of potential but strongly dependent on HF concentration, and (*ii*) the etch rate of Permalloy is insensitive to HF concentration, is important in this application. Values of α calculated on the basis of electrochemical measurements agree favorably with values found in chemical etching experiments. Factors that influence the beveling process when, as in the present case, a metal is used as the top layer to etch another metal are discussed.

In two recent reviews (1, 2) attention has been drawn to the fact that, while chemical etching of metals is widely used for pattern definition in semiconductor technology, relatively little study has been devoted to the specific electrochemistry of practical etching systems. In many cases a purely empirical approach is adopted when choosing an etchant for a particular application. In some recent publications (3-6) it has been shown that certain problems relating to metal etching for device fabrication could be solved by making use of the insight gained from electrochemical measurements.

In this paper we report on an electrochemical study of the bevel-etching of sputtered Permalloy, which is used in thin film magnetic heads. Figure 1 shows a SEM photograph of such a head, containing 6 turns. The lay-out and fabrication process have been described elsewhere (7, 8). One of the main problems in making this head was failure due to open metallization; electrical breaks were found in conductors crossing silica-covered steps in the Permalloy pattern. This results from incomplete coverage of the sharp Permalloy profiles normally obtained by chemical etching. Similar effects have been observed in integrated circuit technology (9). The problem can be avoided by beveling the steps using a duplex layer chemical etching technique (2, 10, 11). In the present paper we focus attention on the specific electrochemical problems involved when a metal or alloy, such as Permalloy, is bevel-etched in this way.

Key words: metal, transducer, polarization, etching.

Beveling of Metal Films

In previous publications (10, 11) it was shown that, by using a duplex layer chemical etching technique, beveling of thin films could be achieved. The method depends on the fact that, while both layers dissolve in the chemical etchant, the etch rate of the top layer is greater than that of the underlying layer (Fig. 2). The beveling angle α is given by the equation (10)[1]

$$\sin \alpha = \frac{\text{etch rate base layer}}{\text{etch rate top layer}} \quad [1]$$

[1] In Ref. (10), sin α is given by the ratio of the base layer and lateral etch rates, u_B and u_L, respectively. However, $u_L = u_T$, the etch rate of the top layer, if $u_T t >> d$, where t is the etching time for the system and d is the top layer thickness. This can easily be shown to hold in the present case.

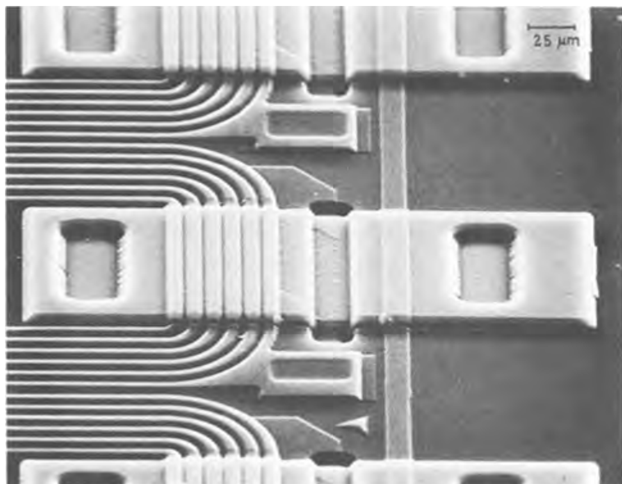

Fig. 1. SEM photograph of a six-turn thin-film magnetic head. Various crossovers and feed-through hole steps are obvious.

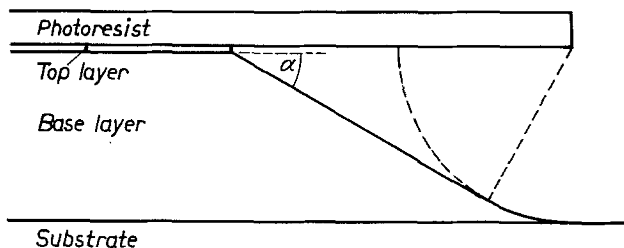

Fig. 2. Theoretical undercutting profile in a base layer with a faster etching top layer. The circular dashed line shows the etch profile expected for isotropic dissolution of the base layer when the top layer is not present.

Good agreement between experimental and theoretical values of α has been obtained for sputtered silica layers (12).

Difficulties may be encountered when a metal is used as top layer in order to bevel-etch another metal. As a result of the electrical contact between the two metals in the etching electrolyte, a galvanic element is formed; a potential is established which may be different from the rest potentials of the individual metals in the etchant. This means that the chemical etch rate of each metal of the bimetallic system may be modified. The direction and magnitude of these changes in etch rate depend on the current density-potential characteristics of the metals in the particular etchant and on the relative surface areas of the metals exposed to the etching solution (2, 3).

During bevel-etching, the exposed area of the top layer is much smaller than that of the base layer and the potential of the bimetallic system is essentially determined by the underlying metal. The resulting potential shift experienced by the top layer metal will be in the anodic direction if this metal is less noble than the underlying metal, and in the cathodic direction if it is more noble. In many cases the etch rate of a metal depends exponentially on its potential (1). The potential shift resulting from the bimetallic contact may therefore lead to a considerable increase or decrease in the etch rate of the top layer (2, 3).

In order to prevent extreme acceleration or deceleration of this etch rate, careful consideration must be given to the choice of top layer metal and etchant. In an attempt to avoid such problems, we used a metal which was less noble than the underlying metal but which had a potential-independent anodic partial current in the region of the rest potential of the bimetallic system (3, 13).

The electrochemical concept involved will be illustrated in this paper for the bevel-etching of sputtered Permalloy, using a sputtered titanium film as top layer. Titanium can be passivated in sulfuric acid solution (14). A characteristic active/passive peak is observed, followed by a potential region in which the anodic current (passive current) is very low and constant. Addition of fluoride ions to the solution increases the current both in the peak and in the passive regions (15, 16). Permalloy can be readily dissolved in a H_2SO_4/HF solution containing a suitable oxidizing agent. In the present study, hydrogen peroxide was mainly used. Some experiments were also carried out with other oxidizing agents.

The experimental results are presented in three sections. The first section describes beveling of Permalloy using various H_2SO_4/HF etchants and Ti as top layer. In the two subsequent sections electrochemical results for titanium and Permalloy are given. Finally the relevance of these results to the bevel-etching of Permalloy is discussed.

In order to avoid galvanic effects during dissolution of Permalloy films it is also possible to use an insulating top layer instead of a metal. In this way beveled steps in Permalloy films can be made by applying a sputtered silica top layer. However, our experience has shown that the etch rates of such oxide layers depend strongly on their composition, *i.e.*, on sputtering conditions such as oxygen pressure and rf power density. On the other hand, the results obtained with Ti layers were much less sensitive to such factors and reproducible steps of varying angle could be easily achieved.

Experimental

Beveling experiments.—Permalloy films, containing 79 weight percent (w/o) Ni, 16 w/o Fe, and 5 w/o Mo, were deposited on oxidized silicon slices by sputtering bulk alloy at an argon pressure of 5-10 mTorr, an rf power density of 0.6-1.2 W/cm^2, and a substrate temperature of 320°C. The deposition rate, which depended on the sputtering conditions, was between 0.6 and 0.8 μm/hr. Titanium films were sputtered at an rf power density of 0.6 W/cm^2 and an argon pressure of 10 mTorr. The deposition rate was approximately 100 Å/min. For beveling experiments, 0.05-0.10 μm thick Ti layers were deposited on 3 μm thick Permalloy layers.

Shipley AZ 1350H photoresist was applied on the Ti top layer by spinning at 3000 rpm. The photoresist was exposed for 20-25 sec in a Kulica Soffa exposure unit and developed for 1 min in an AZ 1350H developer. The resist was then baked out at 140°C for 1 hr. The metal was etched through the windows of the pattern.

When a 2 μm thick Ti film was etched using a photoresist pattern, applied as described above, beveling of the Ti film was not observed. This indicates that photoresist lift from the Ti top layer does not play a role in the Permalloy beveling process.

Beveling angles were calculated from the thickness of the Permalloy layer and the length of the beveled slope. The layer thickness was determined by using a Talystep or a Leitz interferometer. The length of the slope was measured by normal optical microscopy. These results were checked against beveling angles found using SEM photos.

Electrochemical measurements.—Because it was inconvenient to sputter very thick films and because thin film electrodes could only be used for a rather limited period, electrochemical measurements were also made with bulk metal electrodes. For these experiments the metal, in the form of a cylinder with a face area of between 0.5 and 1.0 cm^2, was tightly imbedded in a Teflon holder. Electrode surfaces were mechanically polished before use. For Ti electrodes, 99.95% pure metal, supplied by Imperial Metal Industries, England, in the form of 10 mm diam rods was used. Permalloy electrodes were machined from pellets which were made by casting the melt obtained using an argon arc onto a water-cooled copper surface. The composition of the bulk alloy was nominally the same

as that of the thin films. In both cases 99.99% pure Ni, Fe, and Mo were used for making the Permalloy.

Film electrodes were made by sputtering approximately 5 μm of the metal or alloy onto the respective bulk electrode under conditions similar to those described above. The substrate was first sputter-etched in order to remove surface oxide.

For certain experiments the electrodes were rotated in order to investigate the influence of stirring on the dissolution reaction. The experimental arrangement has been previously described (3).

Steady-state polarization curves were measured using a Wenking 70 TS 1 potentiostat controlled by a Wenking stepping-motor potentiometer, Model SMP 72. A glass-free cell and measuring system was used with either a saturated calomel electrode (SCE) or a mercury/mercury sulfate electrode as reference. All potentials are given with respect to SCE. Polarization curves were reproducible to within 5%.

Other experimental conditions.—The temperature of the beveling and electrochemical experiments was 23° ± 2°C. All chemicals used were of reagent grade, supplied by Merck. The fluoride concentration of the solutions was measured using an Orion fluoride electrode Type 96-09.

Results

Beveling of Permalloy films.—The hydrogen peroxide etchant used to bevel sputtered Permalloy films with Ti as top layer contained 3.9M H_2SO_4, 1.12M H_2O_2, and a variable HF concentration of between 0.4 and 4.0M. Gas evolution was observed during etching. In Fig. 3 a SEM photo of a beveled step is shown. The beveling angle α could be varied between 6° and 40° by changing the HF concentration, as shown in Fig. 4.

Beveled steps in Permalloy films were also made using H_2SO_4/HF etchants in which hydrogen peroxide was replaced by other oxidizing agents, *e.g.*, ferric ammonium sulfate or potassium dichromate. Gas evolution was not observed in these cases. The dissolution rates of the metals, and consequently the beveling angles, were found to be dependent on the hydrodynamic conditions maintained during etching.

Electrochemical results for titanium.—Previous work (15-17) on the influence of fluoride ions on the anodic behavior of Ti in H_2SO_4 solution has been confined to lower concentrations (≤0.1M NaF or HF). In order to achieve practicable etch rates it was necessary to increase the fluoride concentration considerably.

Figure 5 shows the steady-state anodic polarization curve for a Ti rotating disk electrode (RDE) in a solution containing 0.75M HF, 3.9M H_2SO_4 at 23°C and 500 rpm. The general form of this curve is similar to that observed for lower fluoride concentrations (15, 16), but in the present case the current in both the active and passive regions is much larger. The rest potential of Ti in this solution is approximately −0.9V. For potentials higher than 0V, the current is almost completely independent of potential. In this region the current changes by less than 10% when the H_2SO_4 concentration is reduced by a factor of 2. The passive current increases markedly, however, with increasing HF concentration, as is clear from Fig. 5.

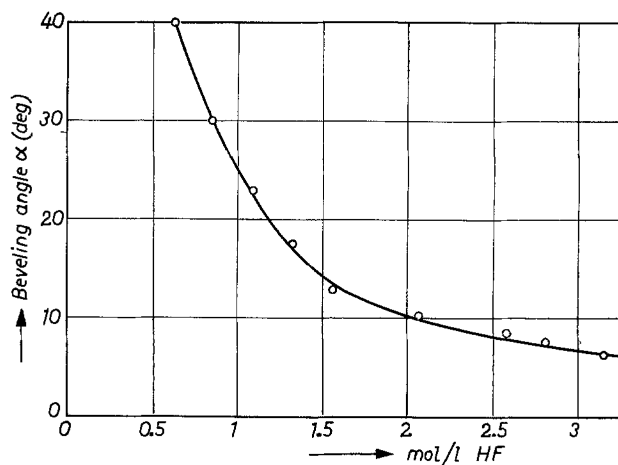

Fig. 4. Dependence of the beveling angle α on the HF concentration of the H_2SO_4 (3.9M)/H_2O_2 (1.12M)/HF etchant.

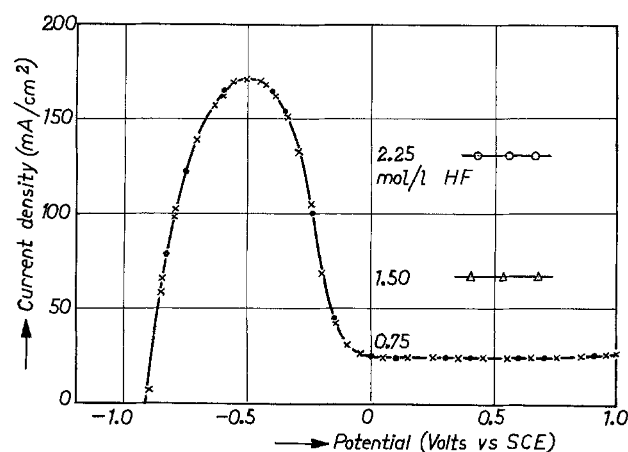

Fig. 5. Anodic polarization curve for a Ti RDE in 3.9M H_2SO_4, 0.75M HF at 23°C and 500 rpm. Passive current densities are also shown for 1.50 and 2.25M HF.

Similar results were found for sputtered Ti film electrodes. In the peak region, the curves differed somewhat from those measured with bulk metal electrodes. The passive current, however, was the same for both cases. This agrees with the observations of Caprani (16) who showed that for low fluoride concentrations the polarization behavior in the rising part of the peak depended on the origin of the Ti samples. On the other hand, in the descending part of the peak and in the passive region the curves were practically independent of the sample.

The passive current depends on the rotation rate ω of the electrode as shown in Fig. 6. Between 0 and 150 rpm the current is almost doubled. At higher rotation rates the current increases more slowly and practically levels off.

Reduction of H_2O_2 on Ti is negligible in the passive region, as can be seen from curve b of Fig. 7. Curve a was measured using the same HF/H_2SO_4 solution but without H_2O_2. A measurable contribution from H_2O_2 reduction is only found for potentials in the peak region (<0V). On the other hand, considerable reduc-

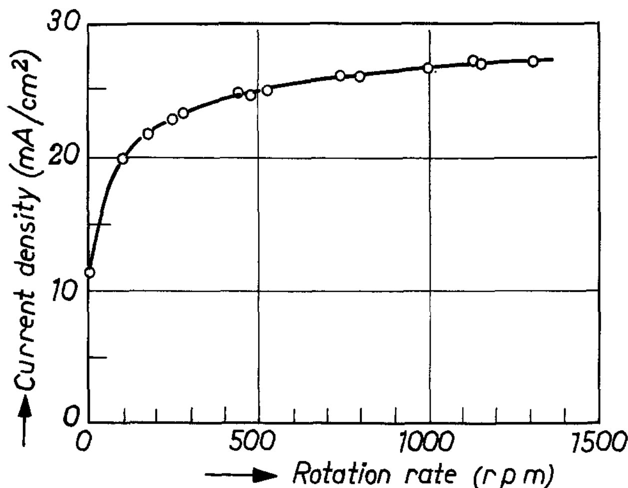

Fig. 6. The influence of the rotation rate on the passive current density of a Ti RDE at 23°C in 3.9M H_2SO_4, 0.75M HF.

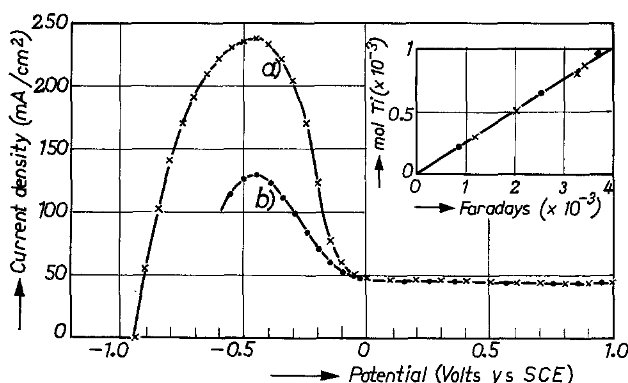

Fig. 7. Anodic polarization curves for a Ti RDE at 23°C, 500 rpm in a 3.9M H_2SO_4, 1.0M HF solution: curve a without H_2O_2, curve b with 1.12M H_2O_2. The insert shows the number of moles of Ti dissolved as a function of the charge passed at 0.40V (SCE) for the conditions used to measure curves a and b.

tion of H_2O_2 on Pt is observed at much higher potentials in this solution. Other oxidizing agents such as ferric salts show a similar behavior, being appreciably reduced only at lower potentials. Oxygen evolution is not observed for potentials up to 3V.

From weight-loss experiments it was shown that, in the passive region, Ti dissolves in the tetravalent state. An example of results is shown in the insert of Fig. 7. It is clear that four faradays are required to dissolve 1 mole Ti and this result is not affected by the presence of H_2O_2 in the electrolyte.

Dissolution of Ti in the passive region is partly controlled by mass transport in the solution. At higher rotation rates the current becomes almost independent of ω and a value close to that expected for $\omega = \infty$ is found. In this case, steady-state, potential step, and impedance measurements have indicated (17) that dissolution of Ti is primarily determined by ionic transport through a surface film on the metal. Since the film thickness is directly proportional to the applied potential, dissolution of the metal occurs under the influence of an almost constant electric field across the surface film. This accounts for the potential-independent anodic current. The steady-state film thickness decreases with increasing fluoride concentration; the electric field across the film increases and consequently the anodic current increases. That the reduction of oxidizing agents present in the solution is negligible in the passive region can be ascribed to the poor electronic conductivity of the passivating layer (18).

Electrochemical results for Permalloy.—The chemical etch rate of sputtered Permalloy films in 3.9M H_2SO_4, 1.12M H_2O_2 solution is practically independent of the HF concentration in the range 0.2-4.0M, as shown in Fig. 8. A similar result was found for the bulk alloy. The presence of a small quantity of HF in the etchant is necessary to ensure dissolution.

Figure 9 shows the influence of HF concentraion on the polarization curves for Permalloy in this solution. In each case a straight line is observed over a region of approximately 50 mV on either side of the rest potential. A slight shift in rest potential is found for increasing HF concentrations. This amounts to 35 mV for an increase from 0.25 to 1.25M. The slope of all curves is the same. It is not clear why the polarization curves for Permalloy in this electrolyte are linear over a potential range of approximately 100 mV. It is also strange that, while the rest potential of Permalloy in the solution changes as a function of the HF concentration, the chemical dissolution rate of the alloy remains constant. The anodic behavior of alloys can, of course, be quite complex (19) and, in Fig. 9, we are considering the dissolution of a three-component alloy together with the reduction of hydrogen peroxide.

Passive behavior is observed if HF is not present in the electrolyte: At potentials noble to the rest potential (approximately 0.5V), a very small anodic current is observed; at more cathodic potentials H_2O_2 reduction occurs.

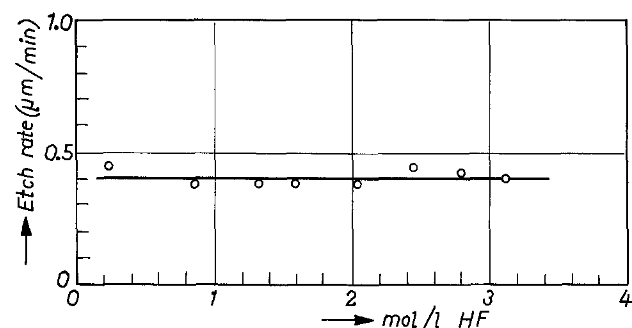

Fig. 8. The chemical etch rate of sputtered Permalloy films as a function of the HF concentration of the chemical etchant.

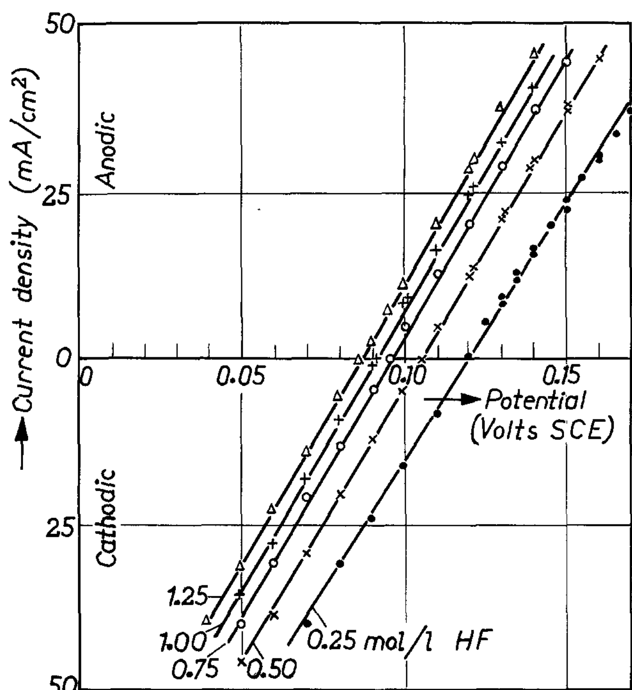

Fig. 9. Polarization curves for a Permalloy RDE at 24°C, 500 rpm in 3.9M H_2SO_4, 1.12M H_2O_2, and HF concentrations as indicated on the curves.

Considerable oxygen evolution is observed at the surface of the Permalloy during its chemical dissolution in this $H_2SO_4/H_2O_2/HF$ medium. Electrochemical oxidation of H_2O_2 on the alloy seems unlikely at the low value of the rest potential. Oxygen evolution may be due to catalytic decomposition of H_2O_2.

Figure 10 shows the steady-state polarization curve for a stationary Permalloy electrode in 2.0M H_2SO_4, 0.9M HF solution, containing 0.5M $NH_4Fe(SO_4)_2$. At potentials lower than the rest potential a cathodic current plateau is observed, and this results from diffusion-controlled reduction of ferric ions. As expected, the current density in this region depends on the ferric concentration and on the stirring conditions at the electrode.

Discussion

As was shown in Fig. 4, the beveling angle α can be varied between 6° and 40° by changing the HF concentration of the etchant. The chemical etch rate of sputtered Permalloy films does not depend significantly on this concentration (Fig. 8). This indicates that the beveling process is controlled by the Ti dissolution rate, which in turn is determined by the HF concentration of the etchant. Using the data for beveled steps given in Fig. 4, an experimental etch rate for Ti can be obtained from Eq. [1]. Results are shown as circles in Fig. 11.

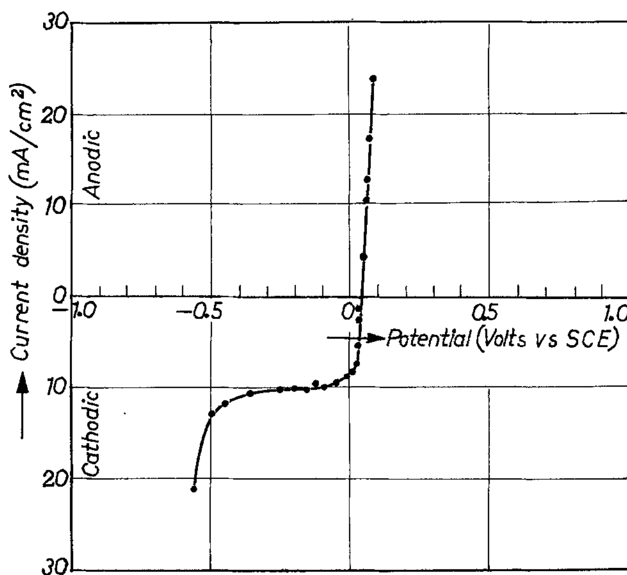

Fig. 10. Polarization curve for a stationary Permalloy electrode at 24°C in 2.0M H_2SO_4, 0.9M HF, and 0.5M $NH_4Fe(SO_4)_2$ solution.

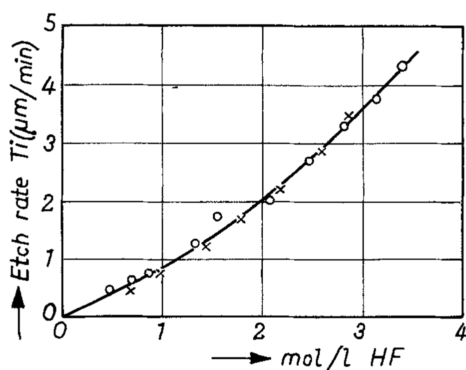

Fig. 11. The etch rate of Ti as a function of the HF concentration of the etchant: ○, values calculated from Eq. [1] and Fig. 4; ×, values calculated from the current density at the rest potential of the bimetallic system.

The electrochemical measurements have shown that the rest potential of the bimetallic system, determined by the Permalloy, lies in the constant current region for Ti (compare Fig. 5 and 9). In this region the dissolution rate of Ti is not sensitive to shifts in potential of up to 100 mV. It is therefore not affected by the change in rest potential caused by the increase in HF content of the etchant (Fig. 9). The etch rate of Ti can, however, be varied over orders of magnitude by changing the HF concentration of the solution. If these electrochemical results reflect the conditions which exist for the bimetallic system during beveling, then the current in the plateau region of the polarization curve for Ti should be a measure of the etch rate of this metal. Since considerable gas evolution occurs during dissolution of Permalloy in this $H_2SO_4/H_2O_2/HF$ medium, stirring conditions are created at the dissolving Ti surface. The effect of stirring can be simulated by the rotating disk experiments. We have arbitrarily assumed that gas evolution is equivalent to a rotation rate of 500 rpm. A decrease of this value to 200 rpm or an increase to 1500 rpm gives a change of less than 12% in the passive current (Fig. 6). Values for the etch rate of Ti, calculated from the passive current at 500 rpm and assuming that the metal dissolves as tetravalent ions, are shown as crosses in Fig. 11. The agreement between the etch rates of Ti as obtained from the beveling experiments and the results calculated from the electrochemical measurements is reasonably good (Fig. 11). This suggests that the proposed electrochemical approach to bevel-etching in bimetallic systems is justified.

Chemical dissolution of Permalloy in H_2SO_4/HF solution containing $NH_4Fe(SO_4)_2$ is determined by the diffusion-controlled cathodic reaction (Fig. 10). This means that the dissolution rate of the alloy depends on the concentration of the oxidizing agent and on the hydrodynamic conditions at the electrode. This is probably also the case for the dichromate solutions. The absence of gas evolution during etching with ferric or dichromate etchants may be an advantage for certain applications since gas bubbles, adhering to the metal surface, may locally inhibit dissolution (2). However, beveling systems based on the above etchants are sensitive to changes in the stirring conditions during etching. Reproducibility can be ensured by rotating the substrates at a fixed rate.

A peculiarity of this particular beveling system is the fact that Ti is dissolved at a potential (approximately 0.1V in the case of the H_2O_2 etchant) at which chemical dissolution of the metal itself should not be possible since reduction of the oxidizing agent of the etchant does not occur, to any appreciable extent, at potentials in the passive region. The metal dissolves because it is in galvanic contact with Permalloy, and the cathodic reaction, *e.g.*, reduction of H_2O_2, occurs exclusively on the alloy.

Conclusions

When a metal is employed as top layer in order to bevel-etch another metal using the duplex layer chemical etching technique, certain precautions are essential. Under unfavorable conditions, quite disastrous undercutting can occur as a result of galvanic effects (2, 3).

In the present study involving sputtered Permalloy, satisfactory results were obtained by using a suitable combination of top layer metal and etchant. These results suggest that, for a reliable etching process, the anodic partial current-potential curve of the top layer metal in the etchant should be relatively flat in the region of the rest potential of the bimetallic couple, *i.e.*, the metal should show passivating or polishing behavior.

Unsteady Mass Transfer in the Boundary Layer on a Continuous Moving Sheet Electrode

Rama Subba Reddy Gorla

Department of Mechanical Engineering, Cleveland State University, Cleveland, Ohio 44115

ABSTRACT

An analysis is presented to investigate the transient mass transfer in the boundary layer on a continuous moving sheet electrode. The unsteady mass flux and details of the concentration field are obtained and have been presented graphically. The asymptotic approach of the transient surface mass flux toward the final steady state has been described. The range of Schmidt numbers investigated was from 0.01 to 1000.

The study of mass transfer on a continuous flat surface moving at high speed is of considerable practical interest. Such systems are used in the electrotinning of steel sheets and copper wires, paper drying, glass sheet and steel plate cooling, etc.

Sakiadis (1) was probably the first to examine the laminar and turbulent boundary layers on a continuous moving belt. The corresponding problem involving cylindrical surfaces has been studied by Koldenhof (2). Tsou *et al.* (3) developed a method for creating the continuous surface, using a rotating drum of large diameter. The heat-transfer coefficients and data related to transition from laminar to turbulent flow have been obtained by them experimentally. References (4-6) include numerical solutions and experimental data related to the study of heat transfer from a continuous moving belt. More recently, Chin (7) presented an asymptotic solution valid for large Schmidt numbers for mass transfer to a continuous moving flat sheet under laminar conditions.

The present work is undertaken in order to study the unsteady mass transfer to a continuous moving sheet electrode. The transient surface response behavior and the details of the transient concentration fields for the case of a step change in surface concentration are obtained for various Schmidt numbers. The step function result serves as a fundamental solution, since by a superposition technique it can be generalized to apply for arbitrary time variations in the wall concentration.

Key words: mass transport, transients, electrodeposition.

Analysis

Let us consider a continuous flat-sheet electrode moving with a constant velocity U_w through a stationary electrochemical cell. The sheet enters the cell through a slot at one end of the cell and leaves the cell at the opposite side through another slot. A model of the flow with the coordinate system has been shown in Fig. 1. We assume the flow to be steady and the bulk concentration of the diffusing ion to be constant at C_∞. Initially the concentration of the diffusing ion at the electrode surface is C_∞ and at time $t = 0$ a step change in surface concentration is applied.

The appropriate governing equations within boundary layer approximation may be written as

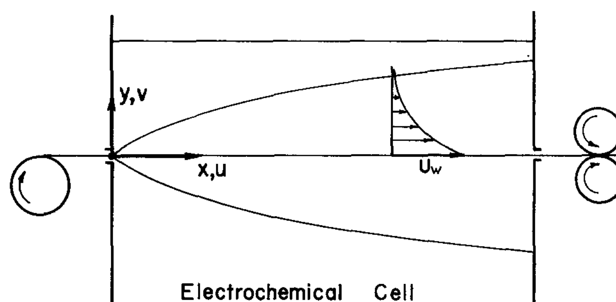

Fig. 1. Coordinate system and flow development

Mass

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad [1]$$

Momentum

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = \nu \cdot \frac{\partial^2 u}{\partial y^2} \quad [2]$$

Diffusion

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} + v\frac{\partial C}{\partial y} = D \cdot \frac{\partial^2 C}{\partial y^2} \quad [3]$$

The boundary conditions for the velocity field are

$$u(x,0) = U_w,\ v(x,0) = 0, \text{ and } u(x,\infty) = 0 \quad [4]$$

The initial and boundary conditions for the concentration field are

$$C(x,y,0) = C_\infty,\ C(x,0,t) = C_\infty + (C_w - C_\infty)\cdot 1(t), \text{ and } C(x,\infty,t) = C_\infty \quad [5]$$

Proceeding with the analysis, we define

$$\eta = y\sqrt{\frac{U_w}{\nu x}}$$

$$u = U_w \cdot f'(\eta)$$

$$v = \frac{1}{2}\sqrt{\frac{\nu U_w}{x}}\,[\eta f'(\eta) - f(\eta)] \quad [6]$$

The primes above designate differentiation with respect to η only. It may be verified that the continuity equation is automatically satisfied and the momentum equation becomes

$$f''' + \frac{ff''}{2} = 0 \quad [7]$$

The transformed boundary conditions for the velocity field are

$$f'(0) = 1,\ f(0) = 0, \text{ and } f'(\infty) = 0 \quad [8]$$

A numerical solution of Eq. [7] and [8] yields the velocity profile.

To transform the diffusion equation, we define

$$\theta = \frac{C - C_\infty}{C_w - C_\infty}$$

$$\tau = \frac{U_w t}{x} \quad [9]$$

Equation [3] then becomes

$$\mathrm{Sc}\{1 - f'\tau\}\frac{\delta\theta}{\delta\tau} = \frac{\delta^2\theta}{\delta\eta^2} + \frac{Scf}{2}\cdot\frac{\delta\theta}{\delta\eta} \quad [10]$$

with initial and boundary conditions

$$\theta(\eta,0) = 0,\ \theta(0,\tau) = 1(\tau), \text{ and } \theta(\infty,\tau) = 0 \quad [11]$$

Defining the Laplace transform of θ as

$$\bar\theta(\eta,p) = \int_0^\infty e^{-p\tau}\cdot\theta(\eta,\tau)\,d\tau$$

and applying the Laplace transformation to Eq. [10] and [11], we have

$$\bar\theta'' + \frac{\mathrm{Sc}f}{2}\bar\theta' = \mathrm{Sc}\left\{p\bar\theta + f'\frac{\delta p\bar\theta}{\delta p}\right\} \quad [12]$$

with boundary conditions

$$\bar\theta(0) = \frac{1}{p} \text{ and } \bar\theta(\infty) = 0 \quad [13]$$

We now seek a series solution of the form

$$\bar\theta(\eta,p) = \frac{1}{p}\cdot\exp\left\{-\frac{\mathrm{Sc}I}{2} - [\mathrm{Sc}(p+\lambda)]^{1/2}\eta + \frac{\mathrm{Sc}\eta f}{4}\right\}\cdot\sum_{n=0}^{\infty} u_n(\eta)\cdot[\mathrm{Sc}(p+\lambda)]^{-n/2} \quad [14]$$

where

$$I = \int_0^\eta f\,d\eta \quad [15]$$

and λ is a function of η which is still unknown.

From an inspection of Eq. [14] we see that $\theta(\infty) = 0$ is satisfied. Substituting Eq. [14] into [12] and equating the coefficients of similar powers of $(p + \lambda)$, there results a set of second-order ordinary differential equations from which one can deduce

$$u_0(\eta) = 1$$

$$u_1(\eta) = \frac{\mathrm{Sc}\cdot\lambda\eta}{2} + \frac{\mathrm{Sc}}{8}(\eta f' - f) + \frac{\mathrm{Sc}^2}{32}\int_0^\eta[(\eta f')^2 - f^2]\,d\eta$$

$$u_2(\eta) = \frac{\mathrm{Sc}^2}{8}\eta^2\lambda^2 + \frac{\mathrm{Sc}\eta\lambda}{2}\chi_1 + \chi_2$$

where

$$\chi_1 = \frac{\mathrm{Sc}}{8}(\eta f' - f) + \frac{\mathrm{Sc}^2}{32}\int_0^\eta[(\eta f')^2 - f^2]\,d\eta$$

$$\chi_2 = \frac{1}{2}(\chi_1^2 + \chi_1') + \frac{\mathrm{Sc}}{4}\left[f\chi_1 + \int_0^\eta(\eta f' - f)\chi_1'\,d\eta\right]$$

etc.

It has been found that first five terms in the series provide satisfactory convergence.

Taking the inverse of Eq. [14], we obtain an expression for the concentration field as

$$\theta(\eta,\tau) = \exp\left\{-\frac{\mathrm{Sc}}{2}\left(I - \frac{\eta f}{2}\right) - (\mathrm{Sc}\lambda)^{1/2}\eta\right\}\cdot\sum_{n=0}^{\infty}u_n(\eta)\,(\mathrm{Sc}\lambda)^{-n/2}\cdot H_n \quad [16]$$

where

$$H_0 = h_1 + h_2$$

$$H_1 = h_1 - h_2$$

$$H_2 = H_0 - h_3$$

$$H_3 = H_1 + (\mathrm{Sc}\lambda)^{1/2}\eta h_3 - h_4$$

$$H_4 = H_0 - \left(1 + \lambda\tau + \frac{\mathrm{Sc}\lambda\eta^2}{2}\right)h_3 + \frac{1}{2}(\mathrm{Sc}\lambda)^{1/2}\cdot\eta h_4$$

etc.

and

$$h_1 = \frac{1}{2}\,\mathrm{erfc}\,[\mathrm{Sc}^{1/2}(4\tau)^{-1/2}\eta - (\lambda\tau)^{1/2}]$$

$$h_2 = \frac{1}{2}\exp[2(\mathrm{Sc}\lambda)^{1/2}\eta]\cdot\mathrm{erfc}\,[\mathrm{Sc}^{1/2}(4\tau)^{-1/2}\eta + (\lambda\tau)^{1/2}]$$

$$h_3 = \exp[(\mathrm{Sc}\lambda)^{1/2}\eta - \lambda\tau]\cdot\mathrm{erfc}\,[\mathrm{Sc}^{1/2}(4\tau)^{-1/2}\eta]$$

$$h_4 = 2\pi^{-1/2}(\lambda\tau)^{1/2}\exp - [\mathrm{Sc}^{1/2}(4\tau)^{-1/2}\eta - (\lambda\tau)^{1/2}]^2 \quad [17]$$

One can notice that H_n varies from 0 to 1 as τ varies from 0 to ∞ and also as η varies from 0 to ∞. For all values of η, as $\tau \to \infty$, $H_n \to 1$.

The steady-state temperature distribution is obtained by letting $\tau \to \infty$ in Eq. [16]. For steady state, we have

$$\theta_S(\eta) = \exp\left\{-\frac{Sc}{2}\left(I - \frac{\eta f}{2}\right) - (Sc\lambda)^{1/2}\eta\right\} \cdot \sum_{n=0}^{\infty} u_n(\eta) \cdot (Sc\lambda)^{-n/2} \quad [18]$$

Differentiating Eq. [18] with respect to η and setting $\eta = 0$, one obtains for the steady-state value for the wall concentration gradient

$$\theta_S'(0) = -(Sc\lambda_w)^{1/2} + \sum_{n=1}^{\infty} u_n'(0)\,[Sc\lambda_w]^{-n/2} \quad [19]$$

To evaluate λ, it becomes necessary to find the steady-state solution. θ_S satisfies the second-order differential equation

$$\theta_S'' + \left(\frac{Scf}{2}\right)\theta_S' = 0 \quad [20]$$

with boundary conditions

$$\theta_S(0) = 1 \text{ and } \theta_S(\infty) = 0$$

Equation [20] is solved by using a fourth-order Runge Kutta method of numerical integration. Since the value of $\theta_S(0)$ is known, a search for $\theta_S(0)$ was made so that the resulting solution yields $\theta_S(\infty) = 0$. This was accomplished numerically by means of an iterative computer program. The present results for $\theta_S'(0)$ are shown in Table I and a comparison with the results reported in literature reveals a good agreement for the whole range of Schmidt numbers. The numerical solution thus generated for $\theta_S(\eta)$ was used to determine $\lambda(\eta)$ from Eq. [18]. For $\eta = 0$, the series in Eq. [18] becomes identically unity and so use of Eq. [20] was made to evaluate λ_w. An iterative computer program was devised to evaluate $\lambda(\eta)$ numerically. Figure 2 shows the distribution of λ for Sc ranging from 0.01 to 1000. The numerical results for λ_w are tabulated in Table II for the same range of Schmidt numbers.

After obtaining the numerical results for $\lambda(\eta)$, it is now possible to evaluate the transient concentration distribution and the mass flux at the electrode surface. Equation [16] was used to get the former. Equations [16] and [19] were used to evaluate $\theta'(0,\tau)/\theta_S'(0)$ which is same as the ratio of the instantaneous to steady-state Sherwood numbers. Figures 3, 4, and 5 illustrate the growth of the concentration layer with time, for Sc = 0.01, 1, and 1000, respectively. For the sake of brevity, data for other Schmidt numbers are not included.

The local mass flux at the electrode surface is related to the concentration gradient by

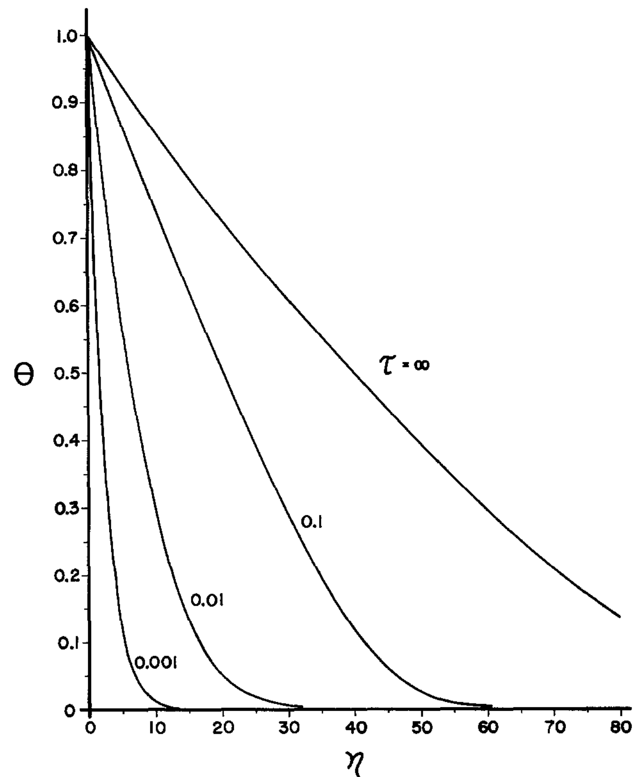

Fig. 3. Transient concentration profiles for Sc = 0.01

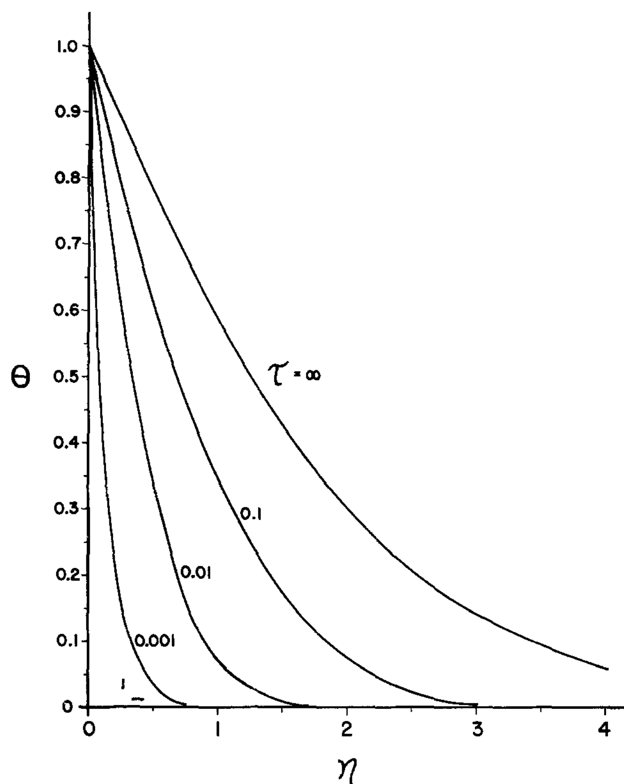

Fig. 4. Transient concentration profiles for Sc = 1

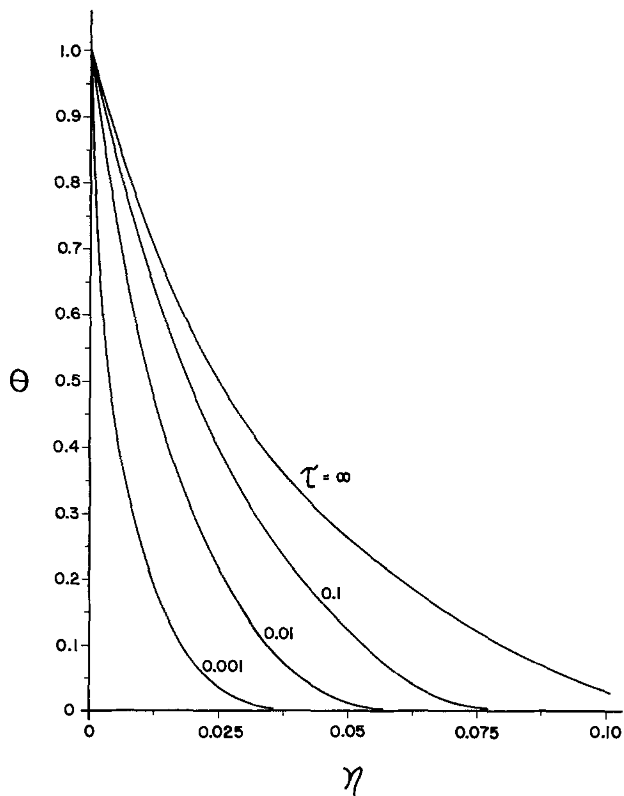

Fig. 5. Transient concentration profiles for Sc = 1000

$$j_w = -D\left(\frac{\partial C}{\partial y}\right)_{y=0} = k(C_w - C_\infty) \quad [21]$$

where k is the local mass transfer coefficient. The local Sherwood number Sh_x can be written as

$$Sh_x = \frac{kx}{D} = -Re_x^{1/2} \cdot \theta'(0,\tau) \quad [22]$$

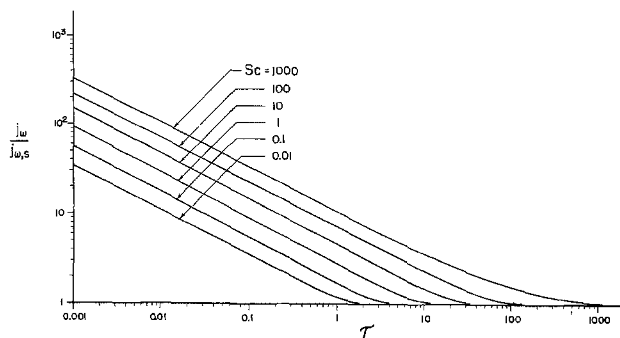

Fig. 6. $(j_w/j_{w,s})$ vs. τ for Sc = 0.01-1000

A quantity of practical interest is the ratio of the instantaneous to steady-state values of the mass flux rates. We have then

$$\frac{j_w}{j_{ws}} = \frac{Sh}{Sh_s} = \frac{\theta'(0,\tau)}{\theta_s'(0)} \quad [23]$$

The above can be deduced from Eq. [16] and [19] for any value of time and Schmidt number. Figure 6 shows such results for Sc ranging from 0.01 to 1000. It may be observed that the surface mass transfer approaches the steady-state conditions asymptotically.

Concluding Remarks

The problem of transient mass transfer in the boundary layer on a continuous sheet electrode has been solved analytically for the case of step change in surface concentration. The results for the case of arbitrary surface concentration variation can be deduced from the present results by numerical superposition methods. The problem corresponding to the step change in surface mass flux is presently under investigation and these results will be reported at a later date.

Electrochemical Parametric Pumping

Y. Oren and A. Soffer*

Atomic Energy Commission, Nuclear Research Centre-Negev, Beer-Sheva, Israel

ABSTRACT

An electrochemical column consisting of two high surface porous carbon electrodes and a thin separator, was operated in four-action electrochemical parametric pumping cycles at the double layer potential range. A significant concentration profile was built up along the column indicating that several theoretical plates were attained. The separative properties of a single theoretical plate was derived. The method seems promising for industrial water processing.

Many solid-fluid phase systems could adequately serve in multistage separation columns, as they exhibit a high separation factor α, where $\alpha = K_A/K_B$, where K_A and K_B are, respectively, the partition coefficients of the two constituents to be separated, A and B. However, if the solid phase is used as stationary packing, the concentration profile will escape from the column, as in the case of chromatography. This renders chromatography unsuitable for large scale separation, although its analytical value is of no doubt.

Various separation modes have been suggested, which engage the entire active solid phase of the column length. For example, a chromatographic column can be fed by several pulses prior to elution of the first pulse (1) or the solid phase can be mobilized in order to imitate the fluid-fluid countercurrent process (2). The disadvantages of this last mode are mechanical problems associated with the solid mobilization.

Another approach (3) is cyclic variations of the intensive variable which rule the partition coefficients, while the fluid in the column is moved according to a predetermined routine. The thermodynamic intensive variables employed experimentally were pressure (4), concentration (5), temperature (6-8), and electrical potential (9). Pressure change does not allow multistage operation of the column, because the expansion due to pressure reduction would cause appreciable mixing of the column contents. The concentration parameter can be varied either by dilution or by addition of a competing material. Both these modes do not allow efficient multistage operation.

Unlike the other variables, temperature changes can be applied more easily and independent of the axial flow. On the other hand, the temperature parameter involves considerable energy dissipation because part of the heat is transferred to the bulk of the column contents.

The electrical potential as a variable intensive parameter can be immediately and speedily applied to the system without disturbing the axial flow. Also the associated energy per cycle is close to the heat of adsorption. This implies that, unlike heat transfer, electrical energy is transferred as a whole to the solution-electrode interface, thereby influencing the material transfer from the solid electrode phase to the solution.

Single cycles of electrodeposition and dissolution of heavy metal ions were used by several authors for batch separations (10-12). These processes are noncontinuous and can be classified with chromatographic concepts rather than with the continuously operated cyclic system. They, however, all differ from ordinary electrochemical cells by the very high material hold-up of the electrode.

Among the cyclic modes applied to stationary solid adsorbent columns, parametric pumping received major consideration. Parametric pumping was introduced in 1966 (6) and is still studied (7). The striking feature of this method is its multistage separation property, *i.e.*, very large concentration differences can be formed along the column (8).

The Electrochemical Parametric Pumping Concept

The present work demonstrates the experimental and few of the theoretical aspects of the electrochemical parametric pump which combines the high separation capability of the parametric pumping method and the electrochemical properties of high surface porous carbon electrodes. We use the separation of NaCl from water (desalination) as a process model for introducing this concept. Blair and Murphy (13) and Johonson and Newman (14) discussed extensively the use of a two high surface porous carbon electrodes set up for desalting water by means of electroadsorption and electrodesorption cycles in a batch process. It was shown by Johonson and Newman and by Soffer and Folman (15) that ionic adsorption in the double layer (dl) region of these electrodes was the actual mechanism of the desalination process. This adsorption is quantitative due to the high charging capacity caused by the high specific surface area of the carbon electrodes.

* Electrochemical Society Active Member.

Key words: porous carbon electrodes, parametric pumping, separation, desalination.

It is, however, possible to predict the properties of such a cell by the study of a single porous carbon electrode being the working electrode in the usual three electrode system (working, auxiliary, and reference) (15, 16). Relying on the experimental results of the porous carbon-Ag/AgCl cell, it was shown (16) that anion and cation adsorption efficiencies[1] as high as 83 and 85%, respectively, can be achieved when the carbon electrode is in the potential ranges 0.2-0.4V and −0.2 to −0.4V *vs.* SCE. Adsorption efficiency was also discussed by Johonson and Newman (14) who used the terms "cation and anion responsive electrodes" for the more negative and the more positive electrodes, respectively.

The electrochemical parametric pumping column for the separation of NaCl from water consist in principle of two identical high surface carbon electrodes separated by an inert separator and filled with the appropriate solution. Each electrochemical parametric pumping cycle consists of four consecutive operations (Fig. 1): A. Adsorption, which, in a generalized sense is a step of transfer of g moles of the material to be separated from the solution to the electrode phase. This transfer is induced by changing the potential difference (as the intensive parameter) across the electrodes. F. Forward axial pumping of the solution during which the g moles which are bound to the solid electrode, remain stationary. D. Desorption, which is also an electrically induced step and causes a back transfer of the g moles from the electrode to the solution phase. B. Backward axial pumping of the solution where the g moles are free to move.

The separation capability of the electrochemical parapump can be readily understood through the fact that the component to be separated is differently adsorbed by the electrode (say, component "a" is preferred). Averaging on a cycle, a stream moving forward (F) is poorer, and a stream moving backward (B) is richer in component "a." This resembles the countercurrent separation processes, while the F and B streams are in complete analogy with the two fluid phases.

Experimental

The experimental setup was composed of the electrochemical column and its accessories. They included a control system for automatic parametric pumping operation, electrochemical instrumentation, pumping equipment, an air thermostat, and a solution deaeration arrangement. The assembly operated almost fully automatically.

The electrochemical column.—The electrode material was Carbopack B, supplied by Supelco Incorporated. This is a graphitized carbon black, similar to that referred to as "Graphon." According to the manufacturers specifications, it has a specific surface area of 100 m^2/g. This was verified by us by BET measurements. Like other blacks, it should be composed of almost spherical particles of average diameter 25 μm. The particles are stacked as granules of 60/80 mesh. A bed of such material should therefore exhibit two distinct pore ranges: the interparticle range of 20-30 mμ (mesopores) and the 10^5 fold intergranular range of 0.1-0.3 mm (macropores). The column design is shown in Fig. 2. Each carbon electrode bed is 1 mm thick, 10 mm wide, and 96 cm long. The separator thickness is 0.35 mm. It was made of three layers in order to prevent electrode particles making short circuits between the electrodes along the column. The weight of each carbon electrode was 3.1g and the free volume of the column was 16.1 cm^3.

The pumping equipment.—The pumping flow diagram is shown in Fig. 3. Forward and backward pumping cycles at total reflux are induced by the ΔV pump. When the product is withdrawn, valve V_2 is open and the σ pump and the solenoid valve are operated parallel to the ΔV pump in synchronous cycles. The product may be either returned to the inlet vessel or sampled through valve V_1. As the volume of the solution in the inlet vessel was very large (4 liters), compared to the free column volume, its concentration remained prac-

[1] Adsorption efficiency is determined as $F(\partial\Gamma_+/\partial q)_\mu$ for cations and $F(\partial\Gamma_-/\partial q)_\mu$ for anions. F is the Faraday number, q is the dl charge, μ is the salt chemical potential, and Γ is the amount of ions adsorbed.

tically constant during each run. The volume of the lower head consists mainly of the connecting lines. This volume was minimized to 3.3 cm^3 to shorten the time of approach to steady state.

For cyclic pumping of the solution we used Metrohm EA 412 Microdosimat automatic titrators, remote controlled and modified for parametric pumping operation. They were equipped with upper and lower limit switches for the piston displacement, and an output of 1000 volumetric pulses for the full interchangeable piston stroke. Their original relay control systems were modified to enable forward or backward piston movement or arrest, after accepting suitable pulses from the control system.

The control system (Fig. 4).—This system consisted of six self-contained units for controlling electrochemical parapump functions: charge, discharge, forward ΔV pumping, backward ΔV pumping, product sampling, and withdrawal. Each function is started by an input signal applied to the control unit and terminates after an internal preset reference is reached.

Termination is followed by an output signal which can activate any other control unit. The termination reference potentials of the charge and discharge functions are preset by two voltage comparators, CVC and DVC, and compared with the column electrode potentials. Termination of the forward movement and product withdrawal functions is induced by upper limit switches of the ΔV and the product pumps. For backward movement and product sampling, the termination reference is preset on a counter, which is fed by the output pulses of the pumps. Charging and discharging are performed at constant current.

The temperature controlling system.—Temperature control was necessary to prevent solution conductivity variations due to temperature changes. An air thermostat was preferred because of the large dimensions of the setup. A fast response proportional controller (local production) enabled thermostating at 25° ± 0.1°C.

Conductivity, pH, and voltage measurements.—The conductivity was measured with a Wayne Kerr autobalance universal bridge, Model B 642. The pH in the lower and upper heads of the column was recorded continuously during each run; usually it was 6-8, indicating the conductance is due solely to NaCl. The two types of potential differences recorded were: (*i*) the potential difference between the electrodes, E, for continuous information about electrode capacity and *IR* drop; and (*ii*) the potential drop along the electrodes, e_1 and e_2, to verify the homogeneity of column packing.

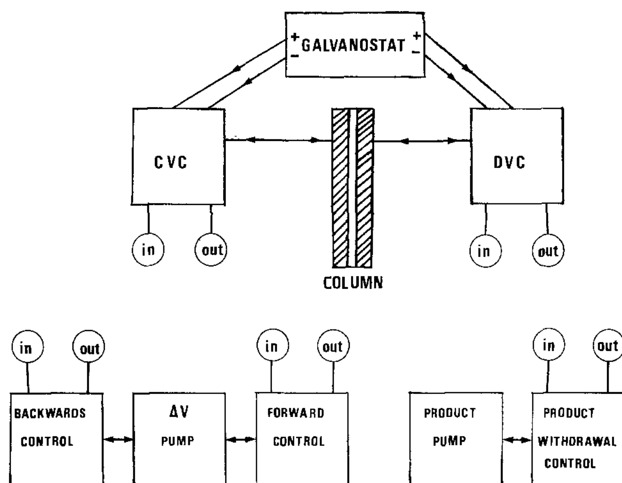

Fig. 4. Control system with pulse signal connections for electrochemical parametric pumping.

For solution deaeration, an inert gas was bubbled through the solution in the inlet vessel before and during each experiment. The gas was purified from O_2 by passing it over a copper bed at 450°C, then prewetted by bubbling through water to prevent evaporation of the solution. All experiments were carried out with 0.01*N* NaCl at the upper head.

Results and Discussion

The differential capacitance of the electrode material.—The dl capacity and charging rate of the electrode material were determined before packing the column. These two properties rule the column performance regarding the amount of salt holdup, *m*, moles per gram carbon, and cycle time. The transient behavior of the macropore (diameter > 100 μm) (17) was insufficient for evaluating the cycle time, since there was strong evidence that the solution conductivity within the interparticle mesopores is considerably lower than the corresponding free solution (18) or the solution in the macropores. A cyclic voltamogram of the Carbopack carbon is given in Fig. 5. The differential capacitance, *Cd*, can be calculated according to

$$Cd = \frac{i}{dv/dt} \qquad [1]$$

which corresponds to an equilibrated dl (19) and has the value of 4.3 $\mu F/cm^2$ at zero potential difference. The slow current reversal after the inversion of the voltage sweep gives the characteristic charging time of 15 sec for Carbopack. The charge and discharge times of the column were chosen considerably larger than this characteristic time.

Analysis of the chronopotentiogram.—A typical experimental plot of a single parametric pumping cycle is given in Fig. 6. The plot is composed of three main components repeated several times during the cycle: a vertical *IR* drop section, V_{IR}, a curved transient section, V_T, and a linear part. This behavior is readily understood considering the equivalent electrical circuit of a cross section of the electrode, sketched in Fig. 7. This is a serial combination of two equivalent circuits, each corresponding to the cell: porous electrode dl |solution| reference electrode. A detailed analysis for a galvanostatic charging mode is given in a previous report (17). The *IR* drop is due to the solution within the separator, the transient is due to the R.C. character of the porous electrode and the linear

part is practically the charge *vs.* potential curve which emerges after the decay of the transient. The equilibrium value of the average integral dl capacity for two identical electrodes is evaluated by

$$C = \frac{2i\Delta t}{(E_C - E_D)GS} \qquad [2]$$

where Δt is the charging or discharging time (seconds), G is the mass of a single electrode (grams), S is the specific BET surface area (square centimeter/gram), and i is the charging or discharging current. E_C and E_D are shown in Fig. 6.

The value obtained for Fig. 6 is 4.1 μF/cm^2 and is within the values of the differential capacity obtained for the single electrode voltamogram of Fig. 5.

The following restrictions are made in order to obtain optimal operating conditions for the electrochemical parametric pump: the potential difference $V_{max} - (V_{min} + V_{IR})$ is limited to slightly less than 1.23V to prevent gas evolution; V_{min} is chosen to be within the potential difference range which causes a charge efficiency slightly higher than zero (see discussion below). The pumping time during steps F and B (Fig. 6) was long enough to enable a sufficient decay of the transient.

Charge distribution along the column.—The longitudinal equivalent circuit of the column is given in Fig. 8 together with two modes of the power supply connections and the voltage difference along the electrodes. Since these modes are virtually identical, the same e *vs.* time plots should be obtained. However, differences may arise if the column packing is longitudinally inhomogeneous, or a concentration gradient develops. Typical e plots are given in Fig. 9 for a case where no concentration gradient exists. The initial in-

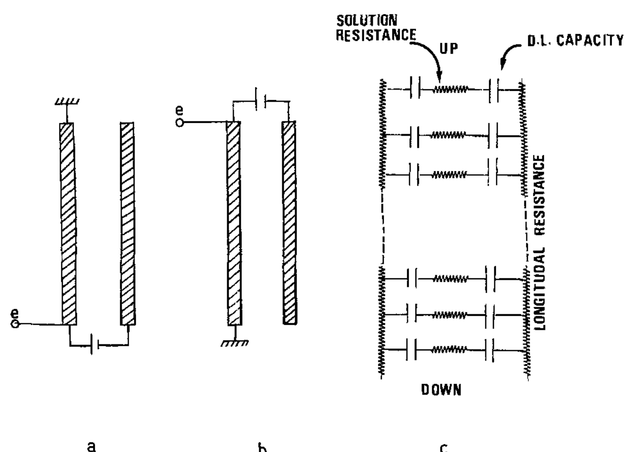

Fig. 8. a. Lower mode of power supply connection. b. Upper mode of power supply connection. c. Longitudinal equivalent circuit of column packing.

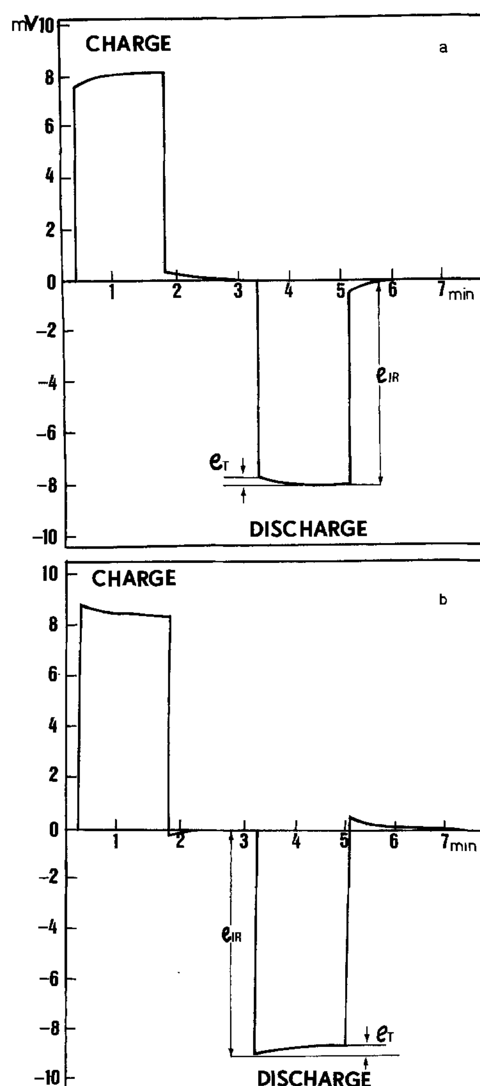

Fig. 9. The variation of the longitudinal potential during a cycle. a. With lower mode of power supply connection. b. With upper mode of power supply connection.

crease, e_{IR}, is immediate since no potential gradient is applied on the capacitors (Fig. 8) at $t = 0$. The (distributed) capacitors close to the current source are charged faster, as they encounter nonlongitudinal electrode resistivity. The initial longitudinal current path is therefore shorter and extends afterward to charge the farther capacitors. This results in an increasing transient, e_t, as shown in Fig. 9a. The decreasing transient of Fig. 9 contradicts, therefore, the expected trend and shows that the lower capacitors are preferentially charged. This clearly indicates that the lower part of the column is more densely packed, *i.e.*, the distributed capacitance is larger. The noticeable decrease of the transient, e_t, in the presence of a concentration profile confirms these arguments, since in this case the lower solution resistivity enables faster dl charging at the lower parts of the column.

Column separation capacity and charge efficiency.—The column separation capacity is defined as the net number of moles adsorbed per carbon weight unit. It can be calculated according to

$$C_p = \frac{(C_o - C_{\Delta E}) V_o}{G} \quad [3]$$

where C_o and $C_{\Delta E}$ are, respectively, solution concentration before and after charging the electrodes, V_o is the solution free volume in the column, and G is the total weight of carbon in the column.

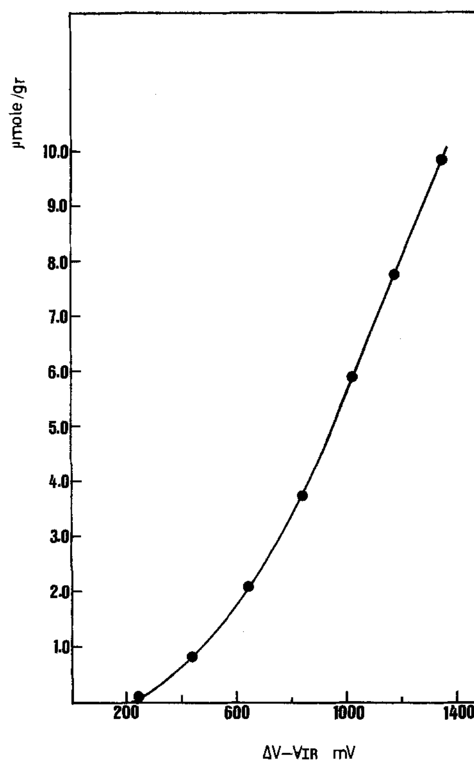
The separation capacity is a function of the potential difference between the two carbon electrodes and, as expected (16), it increases as the potential difference increases (Fig. 10a). Figure 10b shows the differential charge efficiency of the column as a function of the potential difference. The differential charge efficiency at any potential difference is determined from the slope of separation capacity *vs.* electrode charge curve. It is clear from Fig. 10b that over a wide range at high potential differences there are no side reactions (water decomposition) at the dl and almost all the charge investment is directed to change NaCl concentration in the column. It is expected that the differential charge efficiency will decrease on going to higher potential differences as a result of a marked effect of side reactions.

The two curves described in addition to the electrochemical properties already discussed, give a complete description of the basic characteristics of the column.

Concentration profile buildup.—Figure 11 gives the results of an electrochemical parametric pumping run which was accomplished according to the mode shown in Fig. 3 (F and B pathways). It is, in principle, a total reflux mode because no product is withdrawn from the system. However, it differs from the common total reflux mode in that in each cycle, the top of the column is being washed with a solution volume equal to the displacement volume and having the initial concentration.

According to the operation scheme shown in Fig. 1, one should expect an increase of the concentration in the bottom of the column until reaching steady-state value. As shown in Fig. 11, the approach to steady state is faster and the steady-state concentration is lower when the displacement volume ratio is larger.

The unit batch process and the theoretical plate.—The equivalent height of a theoretical plate (EHTP) of a separation column is a fundamental property defining the length of the column required for accomplishing the basic and maximum separation. By knowing the separation power and the length of the theoretical plate of a given column, one could predict the separation properties of the whole column of steady state. We propose, in this section, a simple model by which it is possible to estimate the properties of the theoretical plate of an electrochemical parametric



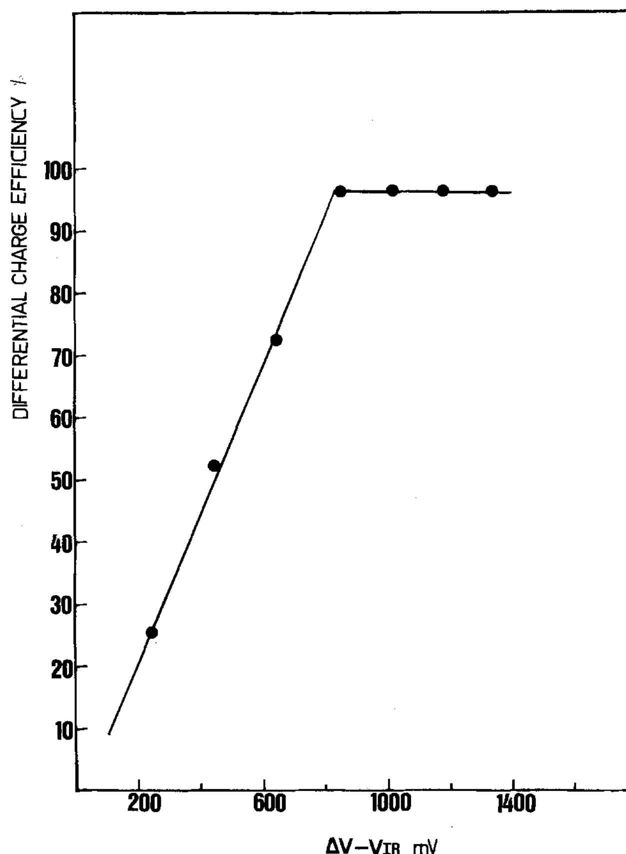


Fig. 10. a (top). Separation capacity of the column *vs.* potential difference. b (bottom). Differential charge efficiency of the column *vs.* potential difference. $C_o = 0.01N$, $I = 50$ mA.

pumping column. According to the model, the theoretical plate is assumed to be a batch unit active cell composed of two carbon electrodes of G grams total weight and solution free volume, V_t. The cell is connected to an upper and a lower imaginary reservoir, each with a total volume at least equal to the displacement volume, ΔV (Fig. 12).

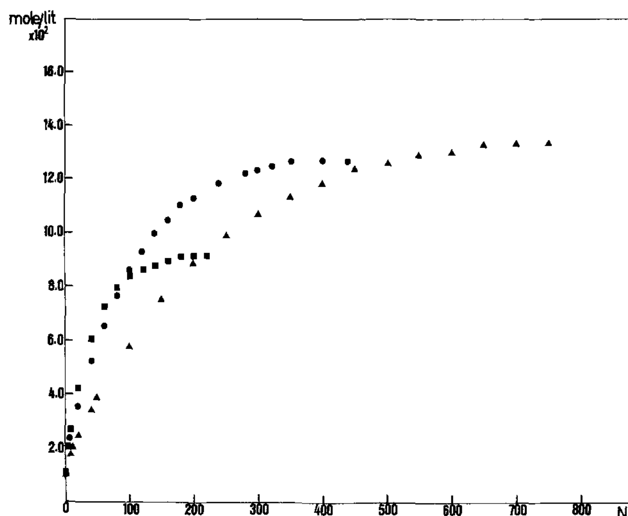

Fig. 11. Concentration at total reflux in the bottom head of the column vs. cycle number. The concentration in the upper head is kept constant. E_D = 360 mV, E_C = 1280 mV, C_o = 0.01N, I = 50 mA. Constant pumping rate. $\Delta V/V_t$: 0.5, ■; 0.25, ●; 0.125, ▲.

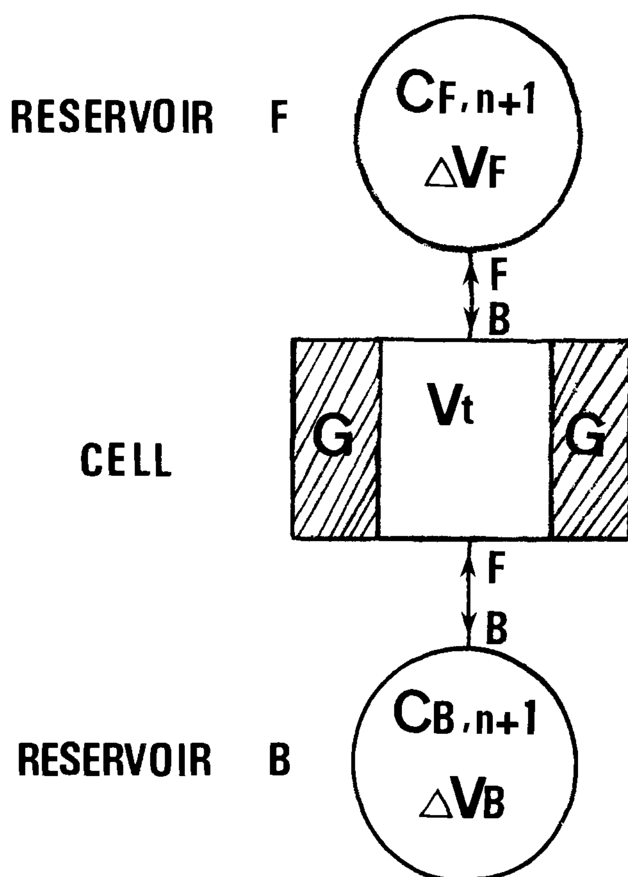

Fig. 12. Diagram of a unit batch process

The composition of the solutions in the reservoirs does not change after steady state has been reached. In this sense, it is equivalent to the steady-state behavior of any three adjacent theoretical plates in the column.

A second assumption of the model is the existence of a stationary fraction, f, of the solution volume, V_t, of the active unit cell. This stationary fraction may exist, since the plane of shear is located in the solution far from the interface. In the present case, the stationary solution may include the mesopore volume of the carbon granules. The displacement volume ΔV is therefore

$$\Delta V = (1 - f)V_t \qquad [4]$$

Each cycle n terminates with the backward step which empties the upper reservoir. In the following we give the material balance equations of the four steps: C, F, D, and B, of the subsequent cycle $n + 1$. Let C_Fn C_Bn, and C_Cn be, respectively, the concentration of the upper and lower reservoirs and of the active cell. For the charge step

$$V_tC^C_{C,n+1} = V_tC^B_{C,n} - mG \qquad [5]$$

The superscripts C and B stand for the charge and the backward steps, respectively. The amount of salt absorbed at the charge step is m moles per gram of carbon and G is the carbon electrode weight.

For the forward step, in the upper reservoir

$$C_{F,n+1} = C^C_{C,n+1} \qquad [6]$$

Forward step in active unit

$$V_tC^F_{C,n+1} = V_tfC^C_{C,n+1} + V_t(1-f)C_{B,n} \qquad [7]$$

For the discharge step in the active unit

$$V_tC^D_{C,n+1} = V_tC^F_{C,n+1} + mG \qquad [8]$$

Backward step in the lower reservoir

$$C_{B,n+1} = C^D_{C,n+1} \qquad [9]$$

Backward step in the active unit

$$V_tC^B_{C,n+1} = V_tfC^D_{C,n+1} + V_t(1-f)C_{F,n+1} \qquad [10]$$

At steady state, the concentration does not change with the cycle number, therefore

$$C^B_{C,n} = C^B_{C,n+1} \qquad [11]$$

and

$$C_{B,n} = C_{B,n+1} \qquad [12]$$

From these two conditions, together with the material balance equations, Eq. [5]-[10], the expression

$$C_{B,n+1} - C_{F,n+1} = \frac{mG}{fV_t} = \frac{\Delta C}{f} \qquad [13]$$

is obtained as a basic property of the theoretical plate.

The second equality is obtained using Eq. [5] and recognizing that ΔC is

$$\Delta C = C^B_{C,n} - C^C_{C,n+1} \qquad [14]$$

Thus a single batch unit is able to multiply the basic concentration difference, C, by the ultimate factor $1/f$ ($f < 1$).

The number of theoretical plates, N, in the column can be expressed in several ways

$$N = \frac{L}{\Delta 1} = \frac{C_f - C_o}{C_{B,n+1} - C_{F,n+1}} = \frac{V_o}{V_t} \qquad [15a]$$

$$\frac{L}{\Delta 1} = \frac{f(C_f - C_o)}{\Delta C} = \frac{V_o(1-f)}{\Delta V} \qquad [15b]$$

where L is the length of the column, V_o its total solution volume (free volume), C_f and C_o the steady-state concentrations at the lower and upper heads of the column, respectively, and $\Delta 1$ is the EHTP.

In order to obtain Eq. [15b], Eq. [14] and [13] were used. The last expression is arranged to obtain the stationary volume fraction as

$$f = \frac{V_o\Delta C}{\Delta V(C_f - C_o) + V_o\Delta C} \qquad [16]$$

Substituting in Eq. [13]

$$C_{B,n+1} - C_{F,n+1} = 1/V_o[\Delta V(C_f - C_o) + V_o\Delta C] \qquad [17]$$

The EHTP is given, using Eq. [15] and [16], by

$$\Delta 1 = \frac{L[\Delta V(C_f - C_o) + V_o\Delta C]}{(C_f - C_o)V_o} \qquad [18]$$

Since the theoretical plate multiplies the effect, ΔC, another theoretical plate length Δz may be defined

$$\Delta z = \frac{L \Delta C}{C_f - C_o} \qquad [19]$$

The magnitudes of some of the parameters in Eq. [16]-[19] are summarized in Table I for the parametric pumping experiments which approach steady state (Fig. 11).

Conclusion

The electrochemical parametric pump enables the use of the selectivity of electrode processes for multistage separating columns. The electrical energy acts only on the electrode/solution interface, *i.e.*, on the active part of the separating column. This is unlike thermal parametric pumping where heat is acquired by the passive matter, such as the bulk of the adsorbent, the solution, and the column walls. The separative power of the unit batch process at steady state exceeds the single cycle effect by $1/f$ and can thus attain very high values.

It seems, therefore, that electrochemical parametric pumping operated in multistage columns will have a high separation power for desalination. This seems promising for industrial water processing.

The Standard Potential of the Mercury-Mercuric Iodate Electrode

Charles P. Nash

Department of Chemistry, University of California, Davis, California 95616

ABSTRACT

Electrochemical cells of the type $Hg(l)|Hg_2(IO_3)_2(s)|KIO_3(aq,M)$-$|Hg(IO_3)_2(s)|Hg(l)$ have been used to determine the standard potential of the half-reaction $Hg(IO_3)_2(s) + 2e = Hg(l) + 2IO_3^-(aq)$ to be $\mathcal{E}^\circ = 0.4601 \pm 0.0007V$ at 298.2°K. For mercuric iodate $\Delta G^\circ_f = -167.2 \pm 0.3$ kJ · mole^{-1} at 298.2°K, and around room temperature $S^\circ \approx 159$ J · mole^{-1} · K^{-1}. The entropy of mercuric iodate is anomalously small, so that for the reaction $Hg(l) + Hg(IO_3)_2(s) = Hg_2(IO_3)_2(s)$ near room temperature $\Delta S^\circ \approx +33$ J · mole^{-1} · K^{-1}.

In the course of a brief survey aimed at comparing the reported thermodynamic properties of solid mercuric and mercurous compounds, it was found that the literature concerning mercuric iodate is confusing. Latimer (1) cited identical standard potentials of +0.394V for the two-electron reductions of both mercuric and mercurous iodates, but he also tabulated Gibbs energies of formation for these two compounds that imply that the mercurous salt is stable with respect to disproportionation by some 23.4 kJ·mole^{-1}. Milazzo (2) also lists the mercurous iodate potential as 0.394V and he reports the mercuric iodate potential to be 0.40V, but no basis is given for this figure.

Key words: thermodynamics, entropy, cell, metals.

There is no doubt that mercurous iodate is thermodynamically stable. The detailed studies of Haring and Zapponi (3) have established that the mercury-mercurous iodate electrode is both reproducible and reversible. Hills and Ives (4) have revised the value of the standard potential reported by Haring and Zapponi to account for subsequent changes in the accepted value of the potential of the calomel electrode, and for the half-reaction $Hg_2(IO_3)_2(s) + 2e = 2Hg(l) + 2IO_3^-(aq)$ cite $\mathcal{E}^\circ_{Hg_2(IO_3)_2} = 0.3944 \pm 0.0004V$ at

298.2°K. Haring and Zapponi (3) also mentioned that they made an approximate determination of the potential of the mercuric iodate electrode, and found it to be "5 to 6 centivolts higher than that of the mercurous iodate electrode."

The present paper reports measurements of the potentials of the cells of the type

Experimental

Preliminary experiments established that at room temperature type [I] cells exhibited stable potentials for about three days. At about the same time that the cell potentials became erratic, the solid phase in the mercuric iodate electrode compartment turned distinctly gray in color, and a positive test for mercurous ion resulted when the gray solid was treated with concentrated ammonia. The general behavior of an old type [I] cell was similar to that of a cell that contained deliberately premixed mercuric and mercurous iodates (*vide infra*).

Deionized water was used throughout. All chemicals were Mallinckrodt Analytical Reagent Grade except for the mercury, which was Ballard's C. P. Triple Distilled, supplied by Quicksilver Products, Incorporated.

Mercurous iodate was prepared by adding 20 ml of $0.1M$ mercurous nitrate in $0.01M$ nitric acid to 20 ml of $0.2M$ potassium iodate over a 2 hr period with continuous stirring. Stirring was continued for 1 hr; then the precipitate was allowed to settle and the supernatant liquid was decanted. The precipitate was washed with vigorous stirring; five times with water, then five times with the potassium iodate solution that was to be used as the electrolyte in the cell of interest. The washed precipitate was also stored under the appropriate potassium iodate solution. Mercuric iodate was prepared in the same fashion by mixing stoichiometric amounts of mercuric nitrate and potassium iodate solutions, and similar washing and storage methods were also employed.

The cell was constructed by inserting the vertical side-arms of three single electrode half-cells (of local construction but similar to Sargent No. 30505) into a rubber stopper. The stopper was then sealed with wax into a 32 mm ID filter tube (Corning No. 9840). Moist mercurous iodate paste and mercury were placed in one half-cell, mercuric iodate paste alone was placed in the second, and a commercial saturated calomel electrode (Sargent No. 30490 or Beckman No. 39170) inserted in a rubber stopper was sealed into the third. The iodate electrode compartments were fitted with homemade platinum point electrodes held in place with rubber stoppers.

The potassium iodate electrolyte solution was sucked into each half-cell compartment through the filter tube, at the end of which operation the filled filter tube was capped with a dropper top. The assembled cell was equilibrated for at least 12 hr at the temperature of interest, either 25.00° ± 0.05°C or 0.00° ± 0.01°C. Then thermostated mercury was injected into the mercuric iodate electrode compartment, and the potentials of the three possible cell combinations were determined over a period of two days. At the end of each series of measurements at both temperatures the potential of the calomel working electrode was compared to that of a thermodynamic saturated calomel electrode prepared by the method of Hills and Ives (5). All cell potentials were measured with a Beckman Research pH meter.

Results and Discussion

The results of these experiments are summarized in Table I. The type [I] cell has already been diagrammed. Cell type [II] is

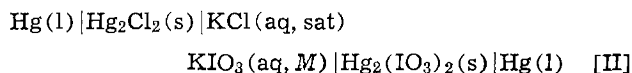

Table I. Measured cell potentials

Cell type	Temp (°C)	M	E_{obs} (volts)
I	25	0.05	0.0658 ± 0.0006
II	25	0.05	0.2357 ± 0.0006*
III	25	0.05	0.3015 ± 0.0006*

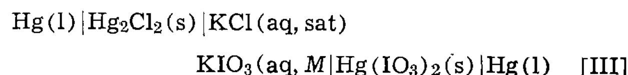
* Referenced to a Hills and Ives type saturated calomel electrode (5) at the temperature of interest.

and cell type [III] is



Each entry in Table I is a result of twenty determinations. Two cell assemblies were constructed for each concentration of the electrolyte, and ten sets of measurements were made on each assembly.

We note first that the measured potentials at 25°C of the three type [I] cells having different concentrations of potassium iodate electrolyte are in excellent agreement with each other. In every instance the cell potential stabilized within the first hour, and during its useful lifetime the cell was quite insensitive to mechanical vibration. This behavior is in marked contrast to that of a similar cell in which the solid phase in the right-hand electrode compartment was a mixture of 85% mercuric ioodate with 15% mercurous iodate, and the electrolyte was $0.05M$ potassium iodate. Here the potential of the undisturbed cell fluctuated erratically for the first 4 hr, but a relatively constant value of 58 mV was finally achieved. In the subsequent two-day period during which observations were made, the slightest tapping of the mixed-solid cell compartment caused the measured potential of the cell to vary unsystematically between the limits of 52 and 59 mV. On the basis of these observations it is highly probable that only a single solid phase is present in the mercuric iodate compartments of our stable type [I] or type [III] cells.

We find also that in the two instances where comparisons can be made, the measured potentials of the type [II] cells at 25°C are in reasonable agreement with the values that would be expected for them on the basis of the accepted potentials of the saturated calomel and mercurous iodate electrodes.

The emf of a type [II] cell is given by

$$\mathcal{E}_{II} = \mathcal{E}^{\circ}_{Hg_2(IO_3)_2} - \mathcal{E}_{sat.\ cal.} - \frac{RT}{2F} \ln (M_{KIO_3}\gamma_{\pm KIO_3})^2 + \mathcal{E}_{LJ} \quad [1]$$

where $\mathcal{E}_{LJ}$ is the liquid junction potential. When we use the values $\mathcal{E}^{\circ}_{Hg_2(IO_3)_2} = 0.3944V$ (4), $\mathcal{E}_{sat.\ cal.} = 0.2412V$ (6), and mean ion activity coefficients of 0.765 and 0.692 for 0.05 and $0.1M$ potassium iodate solutions (7), respectively, we calculate that in the absence of a liquid junction potential one should observe emf's for the type [II] cells at 25°C of 0.2369V for the cell containing $0.05M$ electrolyte and 0.2217V for the cell containing $0.1M$ electrolyte. According to the Henderson equation (8), the sign of the liquid junction potential in a type [II] cell is negative, and it is slightly more negative for the cell containing the more concentrated potassium iodate solution.

The emf of a type [I] cell is given by

$$\mathcal{E}^{\circ}_{I} = \mathcal{E}^{\circ}_{Hg(IO_3)_2} - \mathcal{E}^{\circ}_{Hg_2(IO_3)_2} \quad [2]$$

where $\mathcal{E}^{\circ}_{Hg(IO_3)_2}$ symbolizes the standard potential for

the half-reaction $Hg(IO_3)_2(s) + 2e = Hg(l) + 2IO_3^-(aq)$. We find $\mathcal{E}^\circ_{Hg(IO_3)_2} = 0.4601 \pm 0.0007V$ at 298.2°K. We also find that in the neighborhood of room temperature

$$\left(\frac{\partial \mathcal{E}^\circ_I}{\partial T}\right)_P \approx \left(\frac{\Delta \mathcal{E}^\circ_I}{\Delta T}\right)_P = (1.7 \pm 0.2) \times 10^{-4}\,V \cdot K^{-1}$$

The chemical reaction consistent with a type [I] cell is

$$Hg(l) + Hg(IO_3)_2(s) = Hg_2(IO_3)_2(s) \quad [3]$$

for which $\Delta G^\circ_{298} = -2\mathbf{F}\mathcal{E}^\circ_I = -12{,}700 \pm 100$ J·mole^{-1}, and $\Delta S^\circ = 2\mathbf{F}(\partial \mathcal{E}^\circ_I/\partial T)_P \approx 33 \pm 4$ J·mole^{-1}·K^{-1}.

When the value for $\mathcal{E}^\circ_{Hg(IO_3)_2}$ is combined with the standard Gibbs energy of formation for $IO_3^-(aq)$ of -128.0 kJ·mole^{-1} given by Wagman *et al.* (9), we find $\Delta G^\circ_{f,Hg(IO_3)_2} = -167.2 \pm 0.3$ kJ·mole^{-1} at 298.2°K.

It is a remarkable finding that reaction [3] is accompanied by an increase in entropy. According to the data compiled by Wagman *et al.* (10), the corresponding reactions involving the mercurous and mercuric chlorides, bromides, and iodides all proceed with entropy decreases. The present results can be used to estimate the entropies of both mercurous and mercuric iodate, and thus find the origin of this unusual result.

If one takes the temperature derivative of Eq. [1], ignoring the temperature dependence of the activity coefficient of KIO_3, and also uses the experimental temperature dependence of what Hills and Ives (6) have termed $\mathcal{E}''$ to represent the behavior of the saturated calomel electrode together with the liquid junction potential, he obtains

$$\left(\frac{\partial \mathcal{E}^\circ_{Hg_2(IO_3)_2}}{\partial T}\right)_P \approx \frac{\Delta \mathcal{E}^\circ_{Hg_2(IO_3)_2}}{\Delta T} \approx \frac{\Delta \mathcal{E}_{II}}{\Delta T} + \frac{\Delta \mathcal{E}''}{\Delta T} + \frac{\mathbf{R}}{\mathbf{F}} \ln (M_{KIO_3}\gamma_{\pm KIO_3})$$

$$\frac{\Delta \mathcal{E}^\circ_{Hg_2(IO_3)_2}}{\Delta T} \approx (8.1 \pm 0.2) \times 10^{-4} - 6.3 \times 10^{-4} - 2.3 \times 10^{-4} = (-5 \pm 2) \times 10^{-5}\,V \cdot K^{-1} \quad [4]$$

Hence, for the reaction

$$Hg_2(IO_3)_2(s) + H_2(g, p = 1) = 2Hg(l) + 2HIO_3(aq, a = 1) \quad [5]$$

$\Delta S^\circ \approx -10 \pm 4$ J·mole^{-1}·K^{-1} around room temperature. From this result and the known entropies of the other species at 298°K, namely, $S^\circ_{H_2} = 130$, $S^\circ_{HIO_3} = S^\circ_{IO_3^-} = 118$, $S^\circ_{Hg} = 76$ J·mole^{-1}·K^{-1} (9, 10), we find $S^\circ_{Hg_2(IO_3)_2} \approx 268$ J·mole^{-1}·K^{-1}. Since ΔS° for reaction [3] is about 33 J·mole^{-1}·K^{-1}, we then conclude that the standard entropy of mercuric iodate is approximately 159 J·mole^{-1}·K^{-1}.

Latimer (11) has published a tabular summary of ionic entropy contributions that suggests that, as an estimate, the entropy of the iodate salt of a divalent cation should exceed that of the corresponding chloride salt by about 117 J·mole^{-1}·K^{-1}. Given that the entropies of mercurous chloride and mercuric chloride are 192 J·mole^{-1}·K^{-1} and 146 J·mole^{-1}·K^{-1}, respectively, it is obvious that while both the iodates have entropies that are smaller than Latimer's group contributions would predict, the discrepancy is strikingly large for mercuric iodate.

At present, the crystal structures of the mercuric and mercurous iodates are both unknown. From the infrared spectra of the two solids, however, Dasent and Waddington (12) have concluded that in each case there is covalent bonding between the cation and the iodate ion. Moreover, the work of Belcher and Goulden (13), who measured the solubilities of mercuric and mercurous iodates in water, may be combined with the present results to provide some evidence that the mercuric ion interacts more strongly with iodate than does the mercurous ion.

Belcher and Goulden (13) found total iodate concentrations in saturated solutions of the mercuric and mercurous iodates of 1.6×10^{-4} and $6.4 \times 10^{-5}M$, respectively. The standard electrode potentials for these compounds lead to solubility products of 5.6×10^{-14} for mercuric iodate and 2.7×10^{-14} for mercurous iodate, from which it follows that the free iodate-ion concentrations in the corresponding saturated solutions are 4.8×10^{-5} and $3.8 \times 10^{-5}M$. If the difference between our calculated iodate ion concentrations and the measured total iodate content of the saturated solutions is attributed to the formation of aggregates in solution, it is apparent that of the two cations the mercuric ion has the greater iodate binding capacity. It is, of course, impossible to determine either the stoichiometries of the aggregates or their formation constants from the limited data available.

Conclusions

The mercury-mercuric iodate electrode is reproducible and reversible, provided that measurements are made before the spontaneous reaction between the electrode components has produced significant amounts of mercurous iodate. The standard potential of the half-reaction $Hg(IO_3)_2(s) + 2e = Hg(l) + 2IO_3^-(aq)$ is $\mathcal{E}^\circ = 0.4601 \pm 0.0007V$ at 298.2°K. For mercuric iodate at 298.2°K, $\Delta G^\circ_f = -167.2 \pm 0.3$ kJ·mole^{-1}, and around room temperature $S^\circ \approx 159$ J·mole^{-1}·K^{-1}. For mercurous iodate around room temperature $S^\circ \approx 268$ J·mole^{-1}·K^{-1}. The entropy of mercuric iodate is so small that the reaction $Hg(l) + Hg(IO_3)_2(s) = Hg_2(IO_3)_2(s)$ proceeds with an entropy increase of 33 J·mole^{-1}·K^{-1}.

The Reduction of Oxygen on Teflon-Bonded Perovskite Oxide Electrodes

K. L. K. Yeung* and A. C. C. Tseung*

Department of Chemistry, The City University, London, England

ABSTRACT

The electrochemical reduction of oxygen on Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$ electrodes in 45% KOH was studied as a function of temperature and oxygen partial pressure. The activation energy was 10.75 kcal/mole and the relationship between i and P_{O_2} obeys the relationship $d \ln i / d \ln P_{O_2} = ½$, suggesting that the rate of oxygen chemisorption is the rate-controlling step, Galvanostatic oxygen stripping showed that the surface coverage of oxygen was only 1% for both Sr-doped $LaCoO_3$ and $NdCoO_3$, and that the coverage was independent of temperature in the range 25°-80°C.

Earlier work by Tseung and Bevan (1) shows that Sr-doped $LaCoO_3$ exhibits reversible behavior toward oxygen reduction in 45% KOH solution at room temperature. The performance at room temperature is low ~2 mA/cm², 500 mV *vs.* DHE (Dynamic Hydrogen Electrode) but it increases linearly with temperature and surpasses that of platinum black at 170°C (250 mA/cm² as compared to 180 mA/cm² for Pt black, 75% KOH, 900 mV *vs.* DHE). It is suggested that the performance is controlled by the number of Co^{3+}/Co^{4+} couples free to interact with the oxygen molecule and that the numbers of such couples are low at 25°C but increase in number as the temperature rises. Studies by Kudo *et al.* (2, 3) on $La_{1-x}Sr_xCoO_3$ and $Nd_{1-x}Sr_xCoO_3$ ($x = 0.5$) suggest that the electrochemical reduction of O_2 on these oxides proceed via two parallel routes

$$½\, O_2 + H_2O + 2e = 2\, OH^- \quad [1]$$

$$O\ (\text{lattice}) + H_2O = 2e + 2\, OH^- \quad [2]$$

They also suggest that the relatively low performance at room temperature is due to the slow rate of oxygen ion diffusion in the lattice. They reach this conclusion mainly from cyclic voltammetric studies on Teflon-bonded $La_{0.5}Sr_{0.5}CoO_3$ electrodes. When the potential is swept from an anodic potential more positive than the reversible oxygen electrode potential to the cathodic region, the cathodic current increases almost linearly with decreasing potential until an overvoltage of 400 mV is reached. Thereafter, the cathodic current decreases and in the reverse sweep the cathodic current is markedly lower. They claim that this shows that oxide is being reduced and that the limiting step is the rate of oxygen ion diffusion in the oxide lattice. This paper presents further cyclic voltammetric and pulse measuremnts on the reduction of oxygen on perovskite oxides.

Experimental

$La_{0.5}Sr_{0.5}CoO_3$ and $Nd_{0.5}Sr_{0.5}CoO_3$ were prepared by freeze drying of the mixed nitrate solutions (1), followed by vacuum decomposition at 250°C for 5 hr. The powders were then heated in air at 600°C for 5 hr. The formation of the perovskite phase was confirmed by x-ray powder diffraction, though it is not certain whether all the material had fully reacted since the lower limit for x-ray detection is only about 5%. The BET surface area for $La_{0.5}Sr_{0.5}CoO_3$ was 17 M²/g and $Nd_{0.5}Sr_{0.5}CoO_3$ was 20 M²/g. The powders were fabricated into Teflon-bonded electrodes on 100 mesh Pt screens (5). The catalyst: Teflon ratio was fixed at 10:3. The electrodes were tested in floating half-cells (6) using a dynamic hydrogen reference electrode (DHE). A piece of gold foil was used as the counter-electrode. The potential of the test electrode was controlled by a Chemical Electronics 3A Potentiostat. The KOH electrolyte solution was prepared by dissolving Analar grade KOH in distilled, deionized water. The impurities in the solution were preadsorbed (4) at 0.1V *vs.* RHE for 3 days. A Chemical Electronics Linear Sweep Generator was used in the cyclic voltammetric studies. Potentiostatic and galvanostatic pulse studies were performed with the aid of a Chemical Electronics pulse generator and the signals were recorded by a storage oscilloscope.

Results and Discussion

Cyclic voltammetric studies.—Figure 1 shows the cyclic voltammograms of a "floating" Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$ electrode. The electrode was swept initially from the open-circuit potential to 1.5V. The subsequent cathodic current increases almost linearly with decreasing potential until 950 mV is reached.

Thereafter, the cathodic current decreases and on the reverse sweep, the cathodic current is markedly lower. The results are similar to those obtained by Kudo *et al.* (2). Kudo *et al.* suggest that this shows that the oxide ion is reduced and that the limiting step is the rate of oxygen ion diffusion in the oxide lattice. Their anomalous results, however, can be better explained by taking into account the presence of high pressure oxygen generated and stored inside the pores of the electrocatalyst (7). However, if the electrode is taken to 1.5V for 15 min and then purged with N_2 at the open-circuit potential for different periods of time, the anomalous behavior gradually disappears at longer

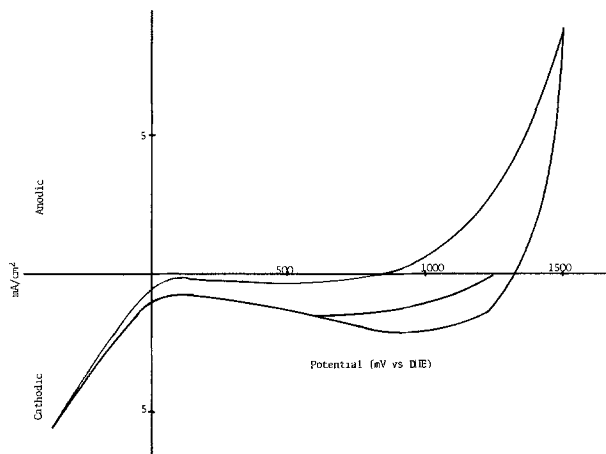

Fig. 1. The cyclic voltammogram of a Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$ electrode. 45% KOH, O_2, 25°C; catalyst loading = 17 mg; catalyst/Teflon = 10/3; scan rate 50 mV/sec.

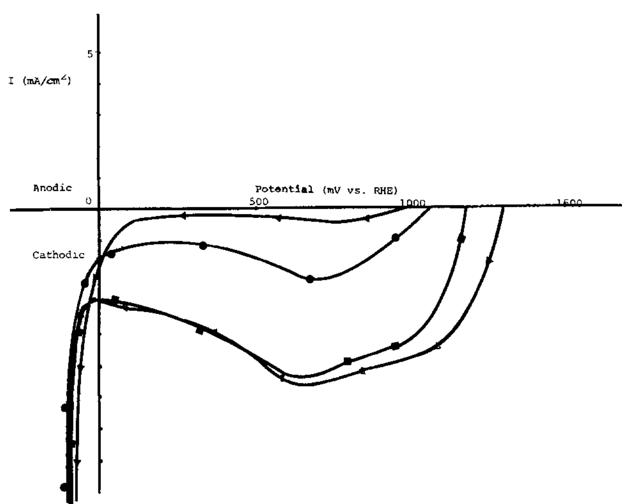

Fig. 2. The cathodic curves for a Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$ electrode after holding at 1.5V for 15 min and subsequently purged with N_2 for different time. Scan rate = 50 mV/sec; N purging time (min). △, 10; ■, 30; ●, 90; ▲, 240.

purging times, as shown in Fig. 2. When the electrode is swept from the open-circuit potential to more cathodic potentials under N_2, the current is very low; these results indicate that the anomalous behavior is associated with the high pressure oxygen inside the pores and not due to the reduction of the oxide.

Steady-state performance of $Nd_{0.5}Sr_{0.5}CoO_3$.—Figure 3 shows the performance of $Nd_{0.5}Sr_{0.5}CoO_3$ at 25°, 40°, 60°, and 80°C. The open-circuit voltage of the electrode at 25°C was 1.20V, very close to the oxygen electrode potential (1.22V *vs.* RHE at 25°C, 45% KOH). The attainment of reversible oxygen electrode potential suggests that oxygen is dissociatively chemisorbed (1). Therefore, for every oxygen molecule chemisorbed "side-on," there will be two electron-transfer sites. Thus the current should be directly proportional to the square root of O_2 partial pressure, *i.e.*

$$I = k(P_{O_2})^{0.5}$$

By plotting log I at constant electrode voltage *vs.* RHE against log P_{O_2}, the value of the index in the general relation $I = kP^n$ can be ascertained. Results for tests at different oxygen partial pressures and temperatures show that the value of n is between 0.45 and 0.53 (Fig. 4). A plot of $1/T$ *vs.* ln i (Fig. 5) shows that the performance increases linearly with temperature and the activation energy for the oxygen reduction is 10.75 kcal/mole.

Potentiostatic pulse studies.—In order to get more precise kinetic information on the oxygen reduction process on Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$, it is necessary to eliminate mass transfer effects as much as possible. In principle, the potentiostatic pulse method is ideally suited for this type of investigation (8, 9). The

transient behavior of an electrode under "mass transfer free" conditions at zero time can be displayed on an oscilloscope screen. However, it is not possible to make measurements at exactly zero time due to double layer charging effects; every electrode behaves as a "leaky" condenser and at the instant of applying a potential or current, a very short but finite time is required to charge the electrode. This time interval depends on the capacity of the electrode double layer and therefore the electrode surface area. An approximate method is to take measurements at the shortest time interval after which double layer charging is complete and accept a small amount of concentration polarization.

The double layer charging time can be measured from the potential transients in the absence of reactants. This approach was adopted in the present study.

Figure 6 compares the steady-state performance of a $Nd_{0.5}Sr_{0.5}CoO_3$ with its potentiostatic pulse performance (after 1 msec) at 25°C, 45% KOH. At 500 mV, the steady-state performance was only 7.5 mA/cm², whereas over 85 mA/cm² was obtained by potentiostatic pulse measurements. Since Teflon-bonded electrodes do not show appreciable mass transfer limitations except at very high current densities, the differences in performance could not be attributed to mass transfer limitations alone. Figure 7 shows that there is only a small difference between the steady-state and potentiostatic pulse performance for a Teflon-bonded Pt electrode operating under similar conditions.

As shown in Fig. 8 a plot of ln i (i, current density at 200 mV overpotential) against $1/T$ for the potentiostatic pulse results gave a straight plot, but the calculated activation energy was only 2.26 kcal/mole; significantly lower than the results obtained earlier from the steady-state results (10.75 kcal/mole). The very low activation energy for results obtained by

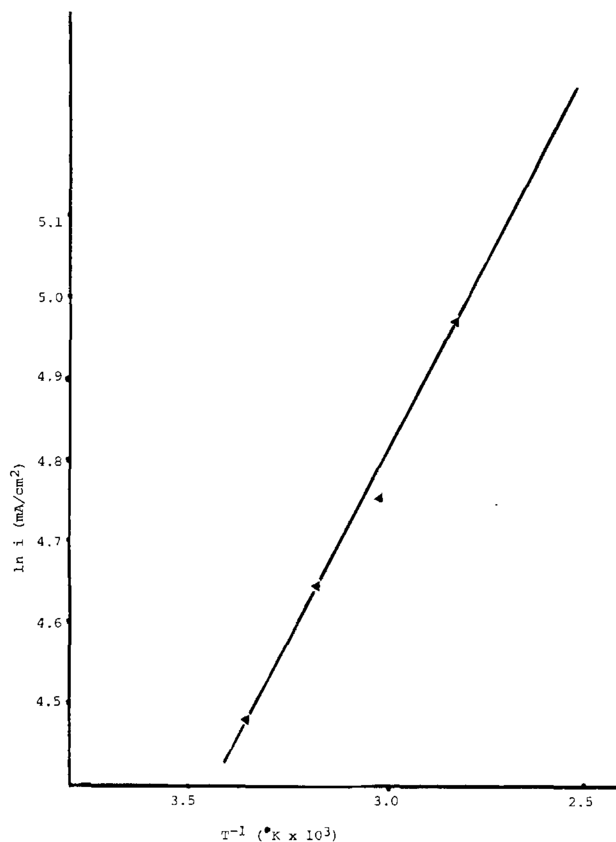

Fig. 8. ln i vs. $1/T$ for a Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$ electrode (potentiostatic pulse measurement).

potentiostatic pulse suggest that under transient conditions the rate of reaction is not controlled by the rate of oxygen chemisorption, since before each pulse the oxygen molecules have already been adsorbed on the electrode surface.

Measurement of oxygen coverage.—The galvanostatic "oxygen" stripping method (10) was used to determine the electrochemical surface area for oxygen reduction. Oxygen was bubbled through the test cell until a steady open-circuit voltage was reached. The electrode was then potentiostatically held at this potential and a stream of deoxygenated white spot N_2 was used to purge dissolved oxygen in the electrolyte for 15 min. A cathodic, galvanostatic pulse was then used to reduce the oxygen chemisorbed on the electrode surface. The potential was recorded on a storage oscilloscope. A mercury relay switching circuit was used to switch the potentiostatic circuit to the galvanostatic circuit. Figure 8 shows a typical potential time curve for a $Nd_{0.5}Sr_{0.5}CoO_3$ electrode. Most of the oxygen reduction reaction was completed within 900-400 mV. Table I gives the oxygen coverage on $Nd_{0.5}Sr_{0.5}CoO_3$ and $La_{0.5}Sr_{0.5}CoO_3$ as a function of temperature. The electrochemically active surface area was based on the galvanostatic results for oxygen reduction, assuming that the oxygen molecule to be chemisorbed "side-on" (cross section area of oxygen atom 1.72°A²). The total surface area of the electrode

Tablel I. O_2 surface coverage

$$\left(\frac{\text{electrochemical area}}{\text{BET area}}\right)$$

Temperature (°C)	Pt (%)	$Nd_{0.5}Sr_{0.5}CoO_3$ (%)	$La_{0.5}Sr_{0.5}CoO_3$ (%)
25	100	1.08	1.06
40	—	1.08	1.06
60	—	1.08	1.06
80	—	1.08	1.06

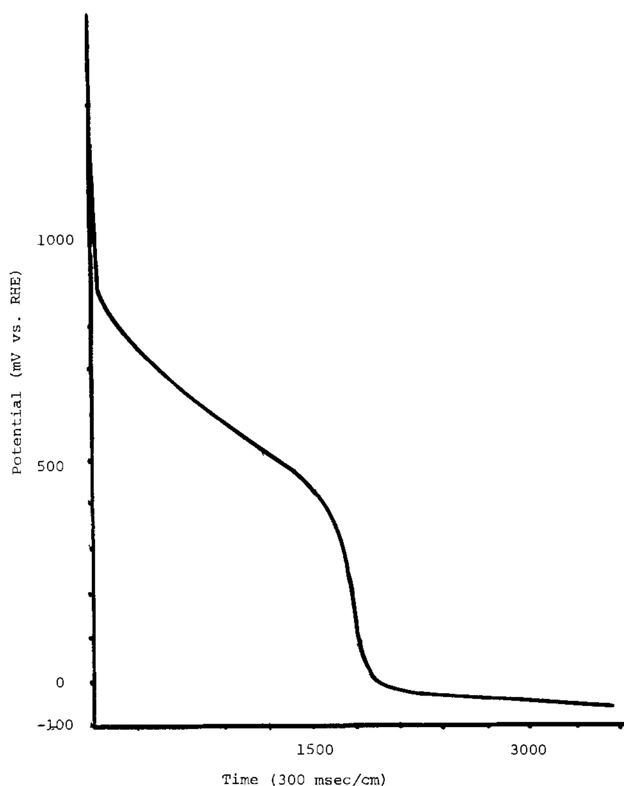

Fig. 9. The voltage-time relationship for O_2 stripping from a Teflon-bonded $Nd_{0.5}Sr_{0.5}CoO_3$ electrode at 45°C in 45% KOH.

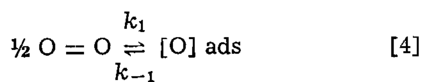
was calculated from the catalyst loading and the BET surface area of the catalyst. The result for a Pt electrode is also included for reference.

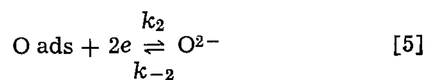
The results show that the oxygen coverage is very low in both Sr-doped $NdCoO_3$ and $LaCoO_3$ electrodes, and the surface coverage is independent of temperature. The degree of surface coverage is almost the same in both cases. This is to be expected since Sr doping levels are the same in both cases. The fact that there is no change in surface coverage with temperature suggests that the improvement in performance with temperature is not due to the increase in the number of active sites as suggested previously by Tseung and Bevan (1).

General discussion.—Recent homomolecular studies by Hibbert and Tseung (11) have shown that the activation energy for the dissociative oxygen chemisorption on $La_{0.5}Sr_{0.5}CoO_3$ is 15 kcal/mole, similar to the activation energy for oxygen reduction under steady-state conditions, 13 kcal/mole, suggesting that the rate of dissociative oxygen chemisorption is the rate-limiting step. The present electrochemical studies are also in accord with the above findings.

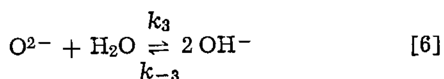
If the rate of oxygen chemisorption is the rate-determining step, then we can derive the mathematical relationship between the current density and oxygen partial pressure. When O_2 is dissociative chemisorbed, the reaction mechanism can be expressed as



$$\tfrac{1}{2}\,O = O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [O] \text{ ads} \qquad [4]$$



$$O \text{ ads} + 2e \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} O^{2-} \qquad [5]$$



$$O^{2-} + H_2O \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} 2\,OH^- \qquad [6]$$

Let p be the partial pressure of O_2 in contact with the electrode and θ be the fraction of energetically and geometrically suitable sites covered by [O] ads at given current i. At steady state, this fraction remains constant. The fraction of the surface covered at p is then found by setting $d\theta/dt$ equal to zero, since the surface coverage is low (1%), the Langmuir adsorption equation can be applied to this case

$$\frac{d\theta}{dt} = k_1 p^{1/2}(1-\theta) - k_{-1}\theta - k_2\theta = 0 \qquad [7]$$

$$\therefore\ \theta = \frac{k_1 p^{1/2}}{k_{-1} + k_2 + k_1 p^{1/2}} \qquad [8]$$

If the chemisorption is the rds, then the current i is given by $2\mathbf{F}k_2\theta$, thus

$$i = \frac{2\mathbf{F}k_1 k_2 p^{1/2}}{k_{-1} + k_2 + k_1 p^{1/2}} \qquad [9]$$

However, the rate constant (k_2) for the ionization [O] ads is dependent on the electrode potential

$$k_2 = k \exp\left[(1-\alpha)\mathbf{F}\eta/RT\right] \qquad [10]$$

Substitute Eq. [10] into Eq. [9]

$$i = \frac{2\mathbf{F}k_1 k p^{1/2} \exp\left[(1-\alpha)\mathbf{F}\eta/RT\right]}{k_{-1} + k\exp\left[(1-\alpha)\mathbf{F}\eta/RT\right] + k_1 p^{1/2}} \qquad [11]$$

If the reaction is controlled by the rate of chemisorption, k_1 and $k_1 p^{1/2}$ should be small. Under heavy cathodic polarization, the denominator of Eq. [11] is determined mainly by the exponential term. Hence the current is given approximately by

$$i = \frac{K p^{1/2} \exp\left[(1-\alpha)\mathbf{F}\eta/RT\right]}{k_{-1} + k\exp\left[(1-\alpha)\mathbf{F}\eta/RT\right]} \qquad [12]$$

where $K = 2\mathbf{F}k_1 k$.

Taking logarithms on both sides, we have

$$\ln i = \ln A + \tfrac{1}{2}\ln P \qquad [13]$$

where

$$A = \frac{K_2 \exp\left[(1-\alpha)\mathbf{F}\eta/RT\right]}{k_{-1} + k\exp\left[(1-\alpha)\mathbf{F}\eta/RT\right]}$$

therefore

$$\frac{d\ln i}{d\ln p} = \frac{1}{2} \qquad [14]$$

Since both $La_{0.5}Sr_{0.5}CoO_3$ (1) and $Nd_{0.5}Sr_{0.5}CoO_3$ obey Eq. [14], it is suggested that the rate-limiting process is the rate of dissociative oxygen chemisorption on the electrode surface.

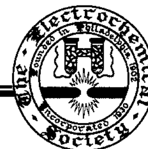
Technical Note



Epitaxial Layers of Cu_2S Grown from Liquid Solution and Investigated by RHEED

O. J. Cain
IBM General Technology Division, Essex Junction, Vermont 05452

and R. W. Vook
Department of Chemical Engineering and Material Science, Syracuse University, Syracuse, New York 13210

A study of epitaxial overgrowths of Cu_2S obtained by reacting copper films with sulfur vapor was reported earlier (1). Similar reaction overgrowths can be accomplished in liquid solutions; however, the solvent must not react with the metal, and the solubility of the solute (reactive species) should be low so the growth proceeds slowly. Methanol was found to work well as a solvent with sulfur. The purpose of this work was to determine if sulfide layers formed by a liquid solution technique would grow epitaxially, to study the overgrowth structure and morphology, and to compare it with similar overgrowths formed by a vapor-growth technique.

Experimental Approach

Single crystal copper film substrates were prepared by evaporating copper onto muscovite at 400°C to a thickness of 1200Å. Details of the substrate preparation were discussed earlier (1). The copper/mica sample was mounted on a RHEED specimen mount with silver paint and the oxide on the copper was removed by a 1-3 sec etch in dilute nitric acid (3:1, H_2O:70% HNO_3). The specimens were then rinsed sequentially with deionized water and methanol and finally dried in a stream of nitrogen. Reflection high energy electron diffraction (RHEED) patterns from these etched copper films showed only copper lines (with a small amount of polycrystalline structure shown by the faint ring pattern) (see Fig. 1). Also, the shortened streaks show that the surface is now somewhat rougher than before the etch. The diffraction patterns exhibited oxide lines if the copper films were etched before and not after mounting. Nitric acid is a strong oxidant and may be expected to leave oxide on the copper film. However, RHEED and Transmission Electron Diffraction (TED) patterns did not reveal any oxide overgrowth. Nevertheless, a very thin oxide layer may be present and not detected. Although the RHEED pat-

Key words: RHEED investigation, Cu_2S epitaxial layers, liquid solution.

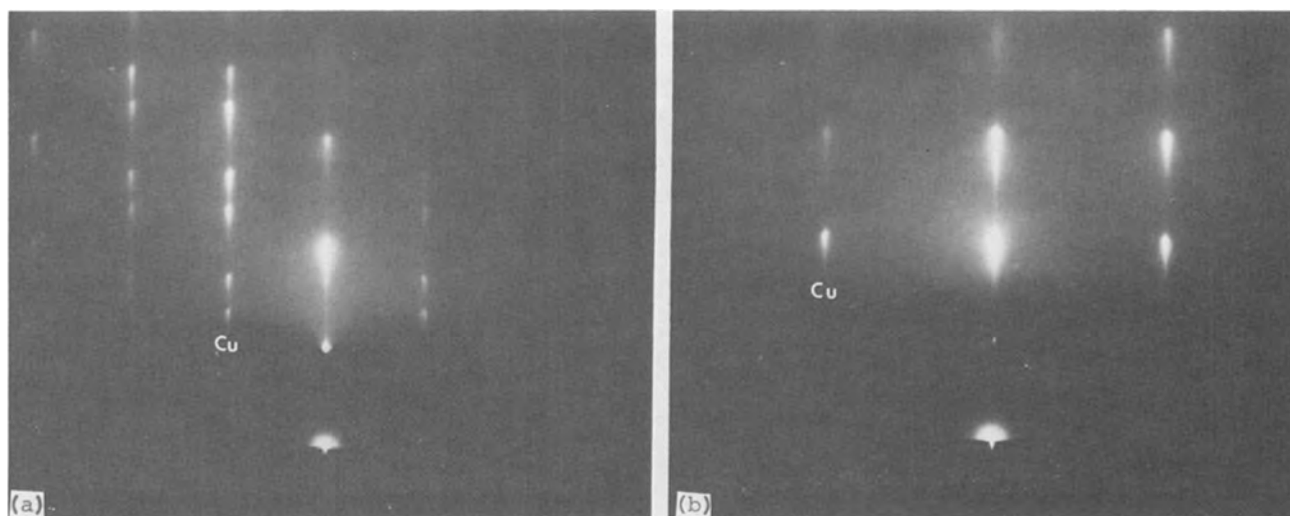


Fig. 1. RHEED patterns from (111) Cu etched in dilute nitric acid. (a) $[1\bar{1}0]$ azimuth; (b) $[2\bar{1}\bar{1}]$ azimuth

terns indicate some roughening, the surface was not grossly faceted by the acid etch as shown by the SEM prints in Fig. 2.

The sulfur/methanol solution was prepared by placing a small quantity of sulfur in the methanol and letting it stand for about 100 hr to reach saturation.

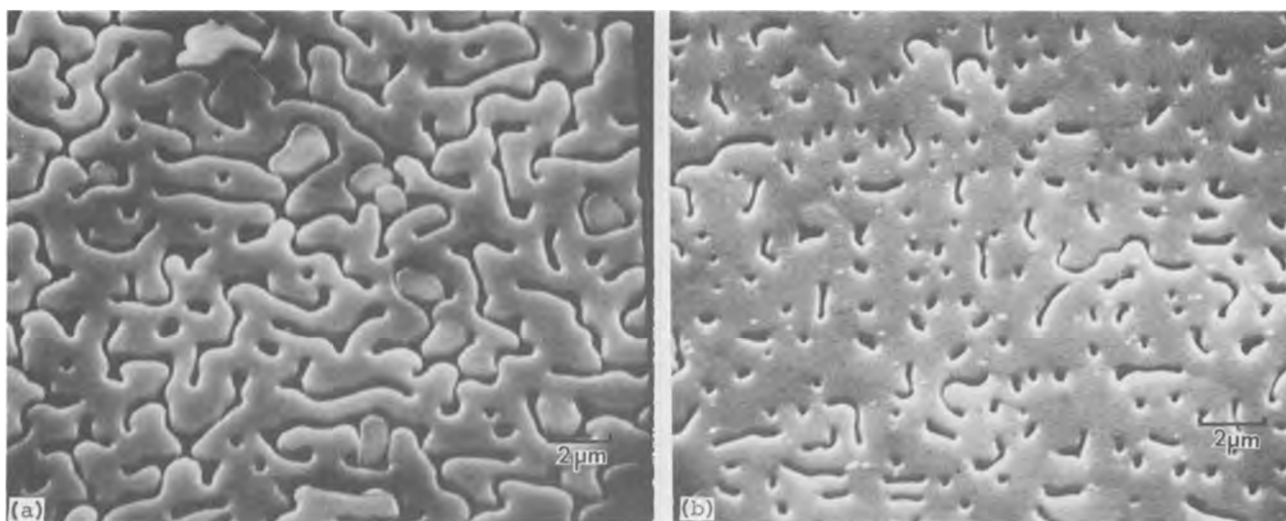

Fig. 2. Scanning electron micrographs of (111) Cu films. The films are in the channel-growth stage. Therefore, the black areas are holes in the film. (a) Before etching with HNO_3; (b) after etching with HNO_3.

Fig. 3. RHEED patterns (00.1) Cu_2S overgrowths on (111) Cu (a) [1$\bar{1}$0] Cu azimuth showing a weak [12.0] pattern from (00.1) Cu_2S; (b) [2$\bar{1}\bar{1}$] Cu azimuth showing a weak [10.0] pattern from (00.1) Cu_2S; (c) and (d) similar patterns as in (a) and (b), respectively, for overgrowths but only for Cu_2S. These patterns also contain orthorhombic and double diffraction effects.

The concentration of sulfur in saturated methanol was measured at 0.27 g/liter at room temperature. This concentration was determined by filtering the solution through filter paper to remove undissoved sulfur, sampling the solution to a specific volume of 4.5 cm^3 and placing thin, clean silver disks in the sampling solution serially until no tarnish was observed on the disks after a 2 day soak. The amount of sulfur on the disks was then measured electrometrically (2). The accuracy of the tarnish film thickness measurement under the present constraints is probably only within a factor of 2.

Copper films were immersed in the sulfur-saturated solution of methanol for various times immediately after the etch-rinse-dry sequence. The films were then studied by RHEED and SEM.

Results

The (111) copper films developed a visible tarnish after 1 sec of exposure in sulfur-saturated methanol at room temperature. The RHEED patterns indicate a hexagonal Cu_2S overgrowth in the earliest stages (*i.e.*, for a 1 sec exposure) and a progression to orthorhombic structures for the thicker films. There was no indication that the overgrowths started out as cubic Cu_2S as in the vapor-grown case (1).

The hexagonal overgrowths yielded RHEED patterns shown in Fig. 3. These patterns show that the orientation relation is {00.1} Cu_2S || {111} Cu with <10.0> Cu_2S || <211> of Cu. This epitaxial relationship shows the same 30° rotation between the sulfide and copper as the most prominent one produced in both the cubic and hexagonal vapor-grown sulfide layers reported elsewhere (1). The 30° rotation between the overgrowth and substrate reduces the misfit from 0.377 in the case of a "parallel" growth to 0.0796 for the rotated growth. The interfacial energy is then reduced significantly in the case of the rotated overgrowth.

Patterns from thicker overgrowths contained additional spots (Fig. 3c and 3d) identified as orthorhombic Cu_2S as well as some that can be explained by double diffraction between a "parallel" hexagonal growth and one rotated by 30°. When the thickness of the overgrowths prevented observation of the substrate diffraction pattern (Fig. 3c and 3d) the substrate azimuth could still be determined in RHEED by means of the strong Kikuchi bands from the copper showing on the projector screen. The Kikuchi bands seldom show up in the prints because short exposure times were used to get optimum spot resolution.

The RHEED patterns produced by the liquid solution-grown layers are not as sharp as those from vapor grown layers. The more diffused pattern indicates a lower quality epitaxial layer. Also, in the thicker overgrowths there is some arcing of the spots and even some rings in the patterns, indicating some polycrystalline growth. Poorer quality epitaxial growth obtained by the liquid solution method is not surprising, considering that the growth rates in this case were at least three orders of magnitude larger (based on the relative exposure times and size of the island growths) than for the vapor grown layers.

The morphology of growth in the liquid solution method is shown in the scanning electron micrograph in Fig. 4. The growth resulted in three-dimensional islands.

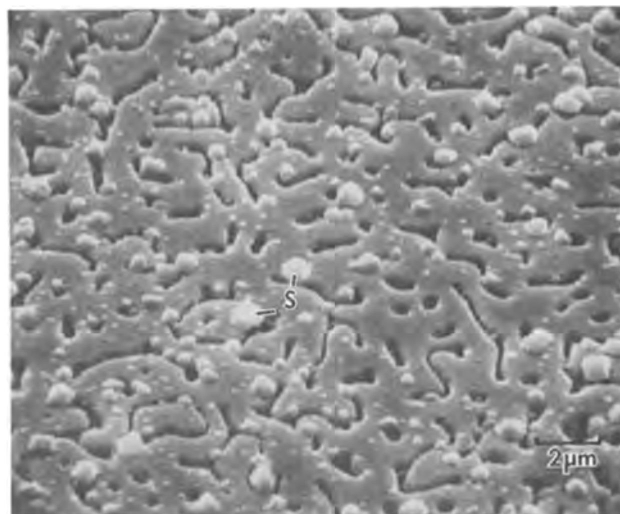

Fig. 4. Scanning electron micrograph print of Cu_2S growth, S, on noncontinuous film of (111) Cu.

Discussion

There is very little published work closely related to the present study. Two papers (3, 4) have dealt with tarnish layers produced by exposing copper to sulfur containing organic compounds. Wolynec (3) used 0.008 and 0.22M aqueous solutions of thiourea for exposure times of 210-360 min. The tarnish films consisted of an orthorhombic phase of Cu_2S or $Cu_{1.96}S$. The present study used solutions of approximately the same concentration of sulfur as Wolynec's (0.26 g/liter), but for much shorter exposure time. Wolynec's work with K poly S also showed orthorhombic Cu_2S for his shortest exposures. However, he also obtained other sulfur species together with oxides of copper. Labor (4) grew sulfide layers on copper in solutions of sulfur in organic solvents, CS_2 (high sulfur solubility), and C_6H_6 (low solubility). He found a quadratic metastable phase $Cu_{1.97}S$, orthorhombic and cubic $Cu_{(2-x)}S$, and eventually CuS.

The present work with low exposure levels resulted in thin epitaxial overgrowths of Cu_2S. No evidence for other sulfides or oxides was found from RHEED or TED results. The previous work (3, 4) involved high exposures that resulted in thick polycrystalline films and tended to produce sulfide phases containing more than 33 atom percent sulfur as well as oxides.

In summary, epitaxial overgrowths of hexagonal Cu_2S were produced on (111) copper substrates reacted with a solution of sulfur in methanol. The orthorhombic phase of Cu_2S was found in the thicker overgrowths. The orientation characteristics were similar to those of layers grown by the vapor technique (1).

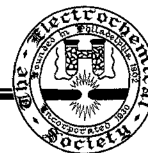
Brief Communications



The Photogalvanic Effect in a Modified Iron Thionine System

H. Ti Tien and James M. Mountz

Department of Biophysics, Michigan State University, East Lansing, Michigan 48824

Photoelectrochemical cells have been proposed for the direct conversion of solar energy to electricity or chemical fuel (1). These cells, on the basis of two well-established photoeffects, can be classified as either photovoltaic or photogalvanic. The operation of a photovoltaic cell depends on the generation of an electromotive force as a result of the absorption of light, whereas the operation of a photogalvanic cell relies on the excitation by light of photoactive species in solution which induces a faradaic process at the electrode. The best-known example of photogalvanic cells is the iron-thionine system studied extensively by Rabinowitch (2) and others (3-7), in which the photoinduced reduction of thionine by ferrous ions takes place in the bulk solution.

In the course of our attempt in developing a new type of photoelectrochemical cell (8), the operation of which would be based on the combined principles of the two photoelectric effects, we have observed the photogalvanic effect in a modified thionine iron solution which should be of interest in the development of a practical photogalvanic device.

The usual photogalvanic effect is observed by immersing two identical platinum electrodes into the iron thionine solution and shielding one in the dark while the other is illuminated. The usual solution consists of 10^{-4}M thionine, 10^{-2}M $FeSO_4$, 4 × 10^{-4}M $(Fe)_2(SO_4)_3$, and 10^{-2}M H_2SO_4 (see Table I). This solution was prepared and placed in a glass chamber which was illuminated with a light intensity of 800 W/m^2 from a tungsten halogen projection lamp. A heat filter was installed and the system was shielded from spurious light. Upon illumination we observed a photoresponse of 112 mV as shown in Fig. 1(A). Using a 0.1M H_2SO_4 solution did not improve the photoresponse.

We found that by changing the electrolyte solution to 10^{-4}M thionine, 10^{-2}M $FeCl_2$, 10^{-4}M $FeCl_3$, and 0.1M sodium acetate at *p*H 4 a photoresponse of more than 200 mV could be observed in the identical experimental setup. This response is shown in Fig. 1(B). The magnitude of the response had an interesting dependence on the *p*H of the solution and thus was further investigated.

The results of our study of the effect of *p*H on the maximum light-induced potential are shown in Fig. 2. Below *p*H 3, the photopotential behaves in a complex manner. Above *p*H 3.5 the photopotential varies linearly with *p*H, with a slope of 60 mV following the Nernst equation. The maximum change is obtained at a *p*H equal to 3.4.

Following the suggestions by Rabinowitch (2) and others (9), we can write the following for the potential-determining reaction of the illuminated electrode

$$\cdot TH_2^+ \rightarrow TH^+ + H^+ + e \qquad [1]$$

Key words: photocell, solar energy, photoelectrochemical cell.

Table I. Photopotentials of some thionine-iron systems

Solution (M)	*p*H	Photopotential (mV)	Reference
Thionine (1.5×10^{-5}) Fe^{3+} (5×10^{-5}) Fe^{2+} (1×10^{-2})	2.5	185	(3)
Thionine (4×10^{-5}) Fe^{2+} (1×10^{-2})	2.5	111	(4)
Thionine (10^{-5}-10^{-3}) Fe^{3+} (10^{-5}-10^{-3}) Fe^{2+} (10^{-2})	1-2	200	(5)
Thionine (10^{-3}) Fe^{3+} (5×10^{-4}) Fe^{2+} (10^{-2}) H_2SO_4 (10^{-2}) in 5% acetonitrile	2	175	(6)
Thionine (10^{-4}) Fe^{3+} (10^{-4}) Fe^{2+} (10^{-2}) in 0.1M sodium acetate	3.4	230	This work

where $\cdot TH_2^+$ and TH^+ are the semiquinoid form and oxidized form of the dye thionine, respectively. The photopotential (E^*) can then be given by

$$E^* = E^\circ + \frac{RT}{\mathbf{F}} \ln \frac{[TH^+][H^+]}{[\cdot TH_2^+]} \qquad [2]$$

where E° denotes the standard redox potential for $\cdot TH_2^+$ to TH^+. Equation [2] predicts a decreasing photopotential for the cell with increasing *p*H. This has been found to be the case at *p*H higher than 3.5 (Fig. 2).

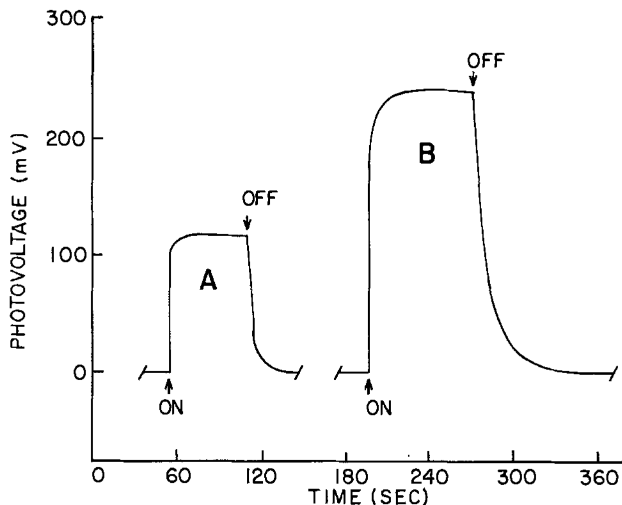


Fig. 1. Open-circuit photoresponses of the photogalvanic cell against time. The cell was illuminated by a 250W tungsten-halogen projector lamp (EHJ-Sylvania). ↑, light on; ↓, light off. A, the conventional iron-thionine solution; B, the modified iron-thionine solution described in this report.

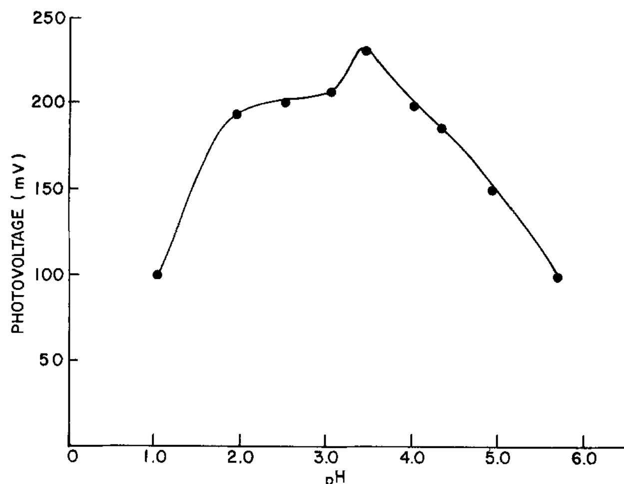

Fig. 2. The dependence of the photogalvanic response for the solution as a function of pH.

As to why the maximum photopotential should occur around pH 3.4, we have no ready answer, for this phenomenon has not been studied. However, it appears that, since the species $\cdot TH_2^+$ is generated by light, it is evident from Eq. [1] that the observed photopotential should depend on the stability of the entity at the electrode surface. Conceivably the acetate ion acting as a ligand can somehow either alter the redox potential of the system or increase the rate of interfacial electron transfer. Additional experiments using a variety of ligands are of obvious interest.

Summarizing, we have shown that the photoresponse of the conventional iron thionine system can be enhanced with a slight modification of the solution. In addition, an interesting pH dependence was observed. The finding presented here merits further exploration.

Electrochemical Oxidation and Reduction of Thin Films of Prussian Blue

Vernon D. Neff

Department of Chemistry, Kent State University, Kent, Ohio 44242

We would like to communicate some interesting preliminary results concerning the electrochemical behavior of thin films of Prussian blue. There are actually two well-characterized forms of Prussian blue (PB) which have the formulas $KFe^{III}Fe^{II}(CN)_6$ and $Fe^{III}_4[Fe^{II}(CN)_6]_3$ (1). The latter compound is prepared from a solution containing a large excess of ferric ion. In addition to PB itself, two additional, closely related compounds are of interest. These are Everitt's salt $K_2Fe^{II}Fe^{II}(CN)_6$, which is colorless, and Berlin Green $Fe^{III}Fe^{III}(CN)_6$ (2). All three compounds have the same basic cubic crystal structure consisting of iron ions bridged by the cyanide groups, although subtle structural modifications may occur, depending on the stoichiometry (3, 4). The physical and chemical properties of these compounds have been reviewed by Robin and Day (5).

We have discovered a method for preparing thin adherent films of PB on various metal and semiconductor substrates. The particular experiment we wish to discuss is concerned with a thin PB film on a platinum foil electrode. The film is obtained from a solution containing equimolar amounts of ferric chloride and potassium ferricyanide. A one-to-one complex between ferric ion and ferricyanide ions forms in such solutions (6). The solution must be freshly prepared because the complex will slowly polymerize and eventually a colloidal precipitate of insoluble Berlin green is formed (7).

Key words: electrochemical oxidation, electrochemical reduction, Prussian blue films.

A fresh solution 0.01M in reagent grade $FeCl_3 \cdot 6H_2O$ and 0.01M in reagent grade $K_3Fe(CN)_6$ was prepared in triply distilled water. A 1 cm^2 platinum foil electrode, with platinum lead encased in Teflon, was cathodized for 1 hr at 1 mA in a 1M HCl solution. The electrode was placed in the ferric ferricyanide solution and, after several minutes a blue film was formed on the surface. The electrode was removed from the solution and rinsed thoroughly with distilled water.

A cyclic voltammogram of the PB electrode in quiet 1M KCl solution is shown in Fig. 1. The voltammogram was obtained with a PAR Model 173 potentiostat equipped with a Model 175 voltage programmer. The interesting feature of this voltammogram is that on the anodic side of the sweep (0.6V *vs.* SCE) the electrode is bright blue, whereas on the cathodic side (0.0V *vs.* SCE) it is colorless. Furthermore it is possible to switch rapidly between the blue and colorless states with the selecting switch on the potentiostat. The electrode reaction evidently occurs in the film itself and corresponds to the ultimate reduction of PB to the colorless "Everitt's salt."

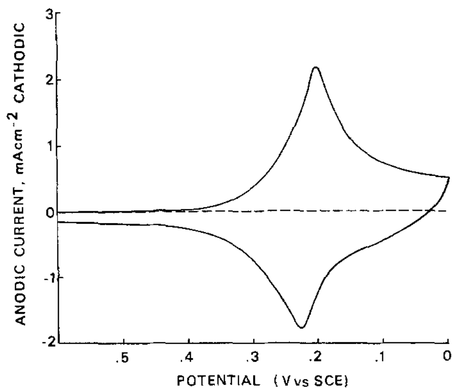

Fig. 1. Single sweep voltammogram of a thin film of Prussian blue on platinum foil in 0.1M KCl solution. The scan rate is 10 mV/sec.

A second observation is concerned with the oxidation of the PB film at more anodic potentials. At a potential of approximately 1.0V *vs.* SCE the film becomes green. In this case the film has apparently been oxidized to Berlin green. Again the color can be switched rapidly between blue and green but the film begins to deteriorate after several cycles presumably because of the simultaneous oxidation of chloride ion and the formation of surface oxide on the platinum.

The details of these electrochemical reactions are currently under investigation.

Manuscript submitted Sept. 29 1977; revised manuscript received Dec. 1, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by Kent State University.

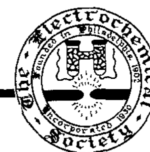
DISCUSSION SECTION



This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 124, No. 7, 9, and 12, July, September, and December 1977.

Fabricating Patterns in Tin Oxide Film by Electrochemical Reaction

B. J. Baliga and S. K. Ghandhi
(pp. 1059-1060, Vol. 124, No. 7)

I. F. Chang:[1] The technique of fabricating patterns of tin oxide films by electrochemiceal reaction has also been developed in our laboratory.[2] We have found that the over-all etching rate of tin oxide film is not significantly dependent on the concentration of HCl in water as shown by Baliga *et al.*[3] However, we would like to point out an important fact concerning the selection of a critical HCl concentration.

Since the over-all etching process consists of two consecutive steps: (*i*) electrochemical reduction of tin oxide to tin (the dark coloration of metal tin can be directly observed during the etching and analyzed by interrupting the etching process); and (*ii*) etching of tin by HCl, it is necesary to select the electrolyte composition such that the reduction rate of tin oxide (step *i*) is higher than the etching rate of tin metal (step *ii*). This selection guarantees that all the detail patterns to be etched are etched away with no electrically isolated oxide regions formed on the glass substrate. We have found that, for achieving best etching results, the concentration of HCl in water should be approximately 7%. An etched pattern with resolution on the order of 20 μm is shown in Fig. 1.

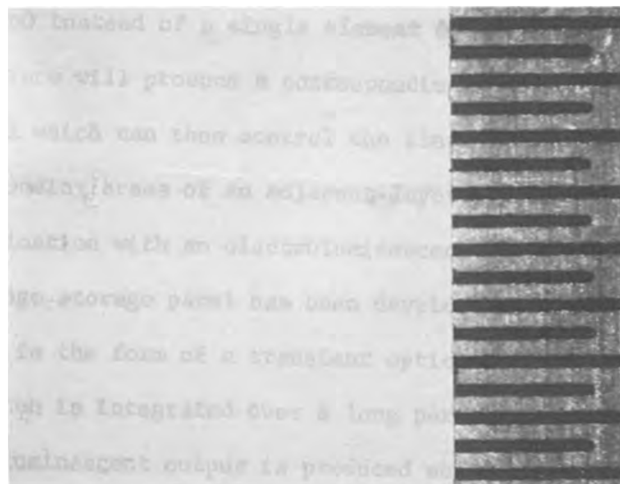


Fig. 1. Etched pattern in tin oxide film on glass substrate by electrochemical reaction technique (the ruler indicates 0.05 mm per division).

During the course of our work, we have also discovered some prior art in the patent literature[4,5] describing general metal oxide etching by electrochemical reaction.

B. J. Baliga and S. K. Ghandhi:[6] We agree with Chang that better etching can be achieved by ensuring

that the reduction rate of the tin oxide is higher than the etching rate of tin metal. However, we disagree that it is necessary to select the electrolyte composition from this consideration. Our work has shown that the above requirement can instead be satisfied by controlling the current density, as was stated in the paper. We, therefore, prefer to choose the electrolyte composition in the range where the etch rate is independent of the HCl concentration (see Fig. 1) in order to obtain good control and reproducibility during etching. We also wish to point out that we have been able to achieve a pattern resolution of 6 μm, which is the limit of our present photolithographic equipment, and can expect even better results with this technique.

We apologize for not providing a reference to the authors prior publication. Unfortunately, we (and the reader) only have ready access to the professional literature in which we found no mention of this work.

The Hydrogen Electrode in Molten Carbonate

W. M. Vogel and C. D. Iacorangelo
(pp. 1305-1309, Vol. 124, No. 9)

A. Borucka:[7] This paper offers a comparison between experimental measurements of the "open-circuit" potentials and calculations of the theoretical equilibrium potential values based on consideration of four possible over-all electrochemical reactions, three of which, however, have not as yet been demonstrated to occur practically.

At this stage of progress of the scientific studies of the anodic gas reactions in molten carbonates, it is almost more important to point out the necessity of better design of the experimental apparatus than to question the assumptions upon which the calculations are based.

The apparatus presented by the authors (Fig. 1 in the paper under discussion) does not ensure accurate or stable melt composition because of the indicated purging with pure nitrogen (which may also have upset the accuracy of the gas compositions studied). Purging of an alkali carbonate melt at 650°C with any pure gas (other than CO_2) must, necessarily, lead to unstable and ill-defined melt and gas compositions, as was pointed out twenty years ago by Broers[7a] and later demonstrated experimentally by others.[9-11]

Of the many possible over-all electrochemical and chemical reactions at fuel gas electrodes in molten carbonates (as noted by Broers[7a]), only two were so far confirmed by accurate experimental evidence:[10]

$$CO + CO_3^{=} \rightleftarrows 2CO_2 + 2e^-$$

and

$$2CO \rightleftarrows C + CO_2$$

On the other hand, the H_2/CO_2 gas electrode (which should be more properly regarded as a more complex $H_2/H_2O/CO_2/CO$ gas system) has not been to this date properly evaluated. Nevertheless, earlier studies[8,12] stress the presence of carbon monoxide even when only a dry H_2/CO_2 gas mixture is supplied to the carbonate electrolyte.

In view of the similarity of the theoretical equilibrium potentials (at 1000°K)[8] for the four reactions considered by the authors (*i.e.*, Eq. [7]-[10] in the paper under discussion) the analytical results of the Russian scientists,[12] and the prior work on dry CO/CO_2 gas anodes,[10] future more rigorous work on the $H_2/CO_2/CO_3^{=}$ system is indicated

W. M. Vogel and C. D. Iacorangelo:[11] The discussion by A. Borucka of our paper appears to center on two points, *i.e.*, which of the many reactions do actually take place at the H_2/H_2O electrode in molten carbonate, and the possibility that the melt used in this study was altered by purging with N_2.

In equilibrium all individual electrochemical reactions have the same potential. However it is not an easy task to supply the electrode with a gas which is in equilibrium under operating conditions. Ordinarily, one makes a gas mixture at room temperature. In the process of heating such a mixture to operating temperature the composition changes. The problem then is to determine the actual gas composition at the electrode from that of the feed gas. We have shown that, except under specified experimental conditions, the assumption of simultaneous shift and methane equilibria yields the observed OCP. It does not matter whether we use the Nernst equation for the H_2/H_2O, CO_2 reaction or some other reaction such as, *e.g.*, the CO/CO_2 electrode. The results are the same. The agreement of such values with the OCP does not allow one to make any statement about the rates of the various reactions, but it would appear to justify our conclusion that there are no unexplained differences between OCP and equilibrium potential as we find, *e.g.*, for the low temperature O_2 electrode.

It is somewhat misleading to say that the melt was purged with N_2. Only that melt which served as salt bridge between the various electrodes was purged with a slow stream of N_2 to keep air from entering. The working and reference electrodes were contained in individual compartments connected to the melt bridge via small holes. In addition, these electrode metals (wires) were immersed only a few mm in the melt. Because of these precautions only that melt was important, aside from possible liquid junction potentials, which surrounded the tips of these two electrodes, *i.e.*, essentially at the three-phase boundary melt/gas/electrode metal. Wiggling the electrode wires had no effect on the observed potentials as one should expect to see if there had been significant gradients of the $O^{=}$ concentration away from the three-phase boundary line.

The Pb/Pb^{2+} Exchange Reaction in Perchlorate Acidic Solutions

A. S. Gioda, M. C. Giordano, and V. A. Macagno
(pp. 1324-1329, Vol. 124, No. 9)

S. D. Kapusta:[12] The i *vs.* t relationship for a plane electrode having a large i_o and undergoing anodic dissolution at a constant potential is like that shown in Fig. 1.

The theoretical situation can be adequately described by solving the differential equations of semi-

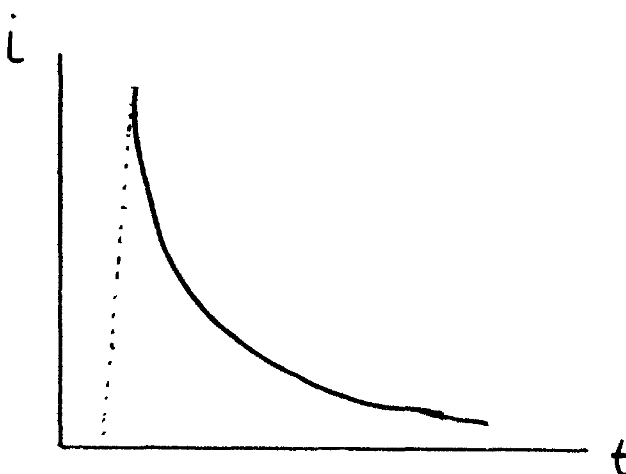

Fig. 1.

infinite lineal diffusion. Using the appropriate boundary conditions

$$i = n\mathbf{F}AC_r(D/\pi t)^{1/2}[1 - \exp(nf\eta)] \quad [1]$$

for long times or, for short times

$$i = i_a A \left(\frac{1 - 2\lambda t^{1/2}}{\pi^{1/2}} \right) \quad [2]$$

The symbols have their usual meaning. i_a is a current controlled only by activation.

Equation [1] represents an anodic current under diffusion control, while Eq. [2] represents one under mixed activated and diffusion control. Figures 2 and 3 describe these equations graphically.

Using a potential-step technique, we can obtain the current controlled only by activation by extrapolating the straight line of Fig. 3 to $t = 0$.

The authors used a potential-step technique for their steady-state polarization curve. Currents were read at a given time (*e.g.*, 1 min), so Eq. [1] holds. Under such circumstances, a Tafel-like behavior is obtained, with a slope

$$\partial\eta/\partial \ln i = 1/nf = 30 \text{ mV} \quad \text{since} \quad n = 2$$

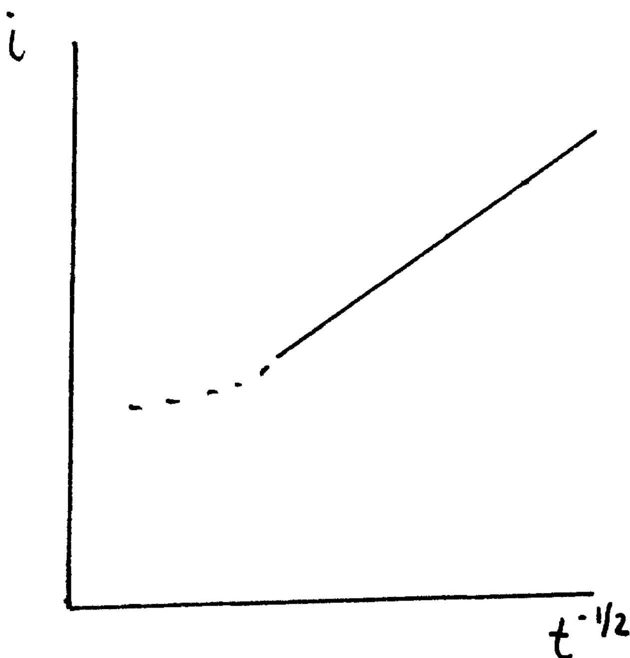

Fig. 2.

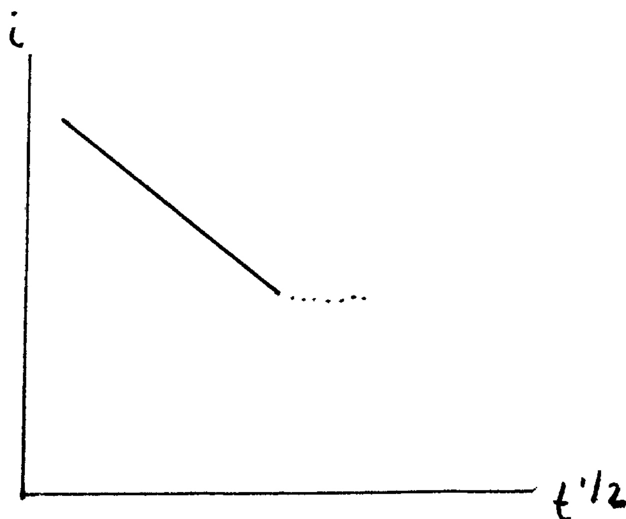

Fig. 3.

As is well known kinetic parameters cannot be obtained from diffusion data. Accordingly, the rate-determining step and the whole mechanism could be different, as previously proposed.[13]

A. S. Gioda, M. C. Giordano, and V. A. Macagno:[14] We thoroughly agree with the statement that kinetic parameters cannot be obtained from diffusion data.

The complete $I - \eta$ equation[15] for the potential-step method contains several terms to account for both charge transfer and diffusion control.

If there is not mass transfer polarization, I is a constant independent of t. Besides, as the correction term for mass transfer polarization becomes more pronounced with time, theoretically $I \to 0$ as $t \to \infty$ if diffusion is the sole mode of mass transfer.

The I *vs.* t curves under potentiostatic conditions performed by us[16] for the reaction under discussion show a constant current value within a few seconds following the potential step in unstirred solutions. The necessary time to reach a steady state becomes shorter (less than 1 sec) when the same experiment is performed at the rotating-disk electrode, but the value of the steady-state current is almost independent of the electrode rotation speed, w (see also the reference in footnote[17]).

This could be taken as an indication that the reaction is not under diffusion control. Moreover, the Tafel slope and reaction orders obtained by the potential-step method at $t = 0$ agree with our previous published values.

Furthermore, some experiments performed at low overpotentials[18] should indicate that "surface" diffusion could play an important role in the over-all process.

Standard Free Energy of Formation of Alumina

D. Ghosh and D. A. R. Kay
(pp. 1836-1845, Vol. 124, No. 12)

H. Byker and R. A. Howald:[19] Ten years ago the suggestion of Ghosh and Kay[20] that the accepted value for the standard heat of formation of corundum (-400.5 ± 0.3 kcal mole^{-1})[21] was in error by about 7 kcal mole^{-1} would have been welcomed, because at that time there was a serious discrepancy in the thermodynamic properties of Al(III) compounds between measured enthalpies and equilibrium measurements. Groups at the Geophysical Laboratory[22] and the Bureau of Mines[23] had extensive measurements on heats of solution in HF and NaOH solutions which provided good relative enthalpies for most Al(III) compounds, but corundum is not soluble to an appreciable extent at an appreciable rate in either of these solvents. However, with the introduction of high temperature oxide calorimetry by Kleppa *et al.*[24] there are good values for the enthalpies relative to corundum. Also in the meantime it has been clearly established that there had been errors in the heat of formation of

secondary standards like gamma alumina,[24] gibbsite,[25] and aluminum chloride.[26] With new values for these enthalpies the discrepancies between enthalpy and equilibrium measurements have disappeared. If the enthalpy of corundum is to be adjusted now, the enthalpies of all Al(III) compounds will have to be shifted by an equivalent amount. The suggestion of Ghosh and Kay[20] does not conflict simply with oxygen bomb calorimetry of aluminum,[27-31] but also with careful determination of the heats of formation of AlF_3,[21,32] $Al(OH)_3$,[25] and $AlCl_3$.[21,26]

Even if one were comparing only the emf measurements with oxygen bomb calorimetry[27-31] the direction of the discrepancy suggests an error in the emf work. The most likely substantial errors in bomb calorimetry are incomplete combustion and unstable products, both of which lead to a less negative heat of formation. This kind of error easily accounts for the low values cited by Ghosh and Kay from the literature before 1940. In potentiometric work most errors will give a potential lower than the thermodynamic equilibrium value, and Ghosh and Kay have done very well to come within 50 mV of the calculated potential in this system. We suspect that the problem lies in the electronic conductance of solid Al_2O_3, which means that one is measuring in part oxygen or aluminum activities on both sides of an Al_2O_3 tube, or alternatively that a steady current is flowing through the Al_2O_3 in an attempt to bring the activities of Al and O_2 to equality on opposite sides of the tube.

We had hoped that data on the vaporization equilibria of corundum would settle the question decisively. The vaporization studies Drowart *et al.*,[33] and Rao and Motzfeldt[34] are in excellent agreement with the current JANAF[21] values for Al_2O_3 and $Al_2O(g)$, however the uncertainties are such that a heat of formation for Al_2O_3 of -393 kcal $mole^{-1}$ is not quite excluded. Similarly Farber *et al.*[35] report a heat of formation from vaporization to Al of -399 ± 10 in better agreement with the JANAF value but including -393 kcal $mole^{-1}$.

The difficulties with Knudsen cell materials at these temperatures are so serious that the best data are apparently those for free evaporation from a liquid surface[36] at the melting point. Burns[37] values for the pressures of Al and O over the liquid at the melting point give $P_{Al}P_O^{1.5} = 2.00 \times 10^{-15}$ $atm^{5/2}$, which can be compared to calculated equilibrium constants at the latest JANAF melting point[37] (2327°K) of 1.531×10^{-15} and 3.350×10^{-15} $atm^{5/2}$ for $H°_{298.15} = -400.5$ and -393.0 kcal $mole^{-1}$, respectively. If the liquid is actually 5° or 10° above the melting point due to its higher emissivity (and higher absorptivity), as suggested by the work of Paule,[38] the comparison will favor $H°_{298.15}$ (Al_2O_3, *c*, corundum) $= -400.5$ kcal $mole^{-1}$ even more.

D. Ghosh and D. A. R. Kay:[39] The contribution of Byker and Howald, which discusses our paper on the electrochemical determination of the high temperature standard free energy of formation of corundum in relation to mineralogical studies in aluminosilicate systems and mass spectrometric studies in the Al-O system, is most welcome.

In undertaking the high temperature electrochemical work it was hoped that a value of $\Delta G°_f(\alpha\text{-}Al_2O_3)$, which was consistent with related data in the literature, would be established unequivocally. Clearly, this is not the case.

The conflict between the values of $\Delta H°_{298}$ (α-Al_2O_3) as determined by oxygen bomb calorimetry and those derived from high temperature electrochemical measurements is well defined and there can be no argument with the comments of Byker and Howald on the direction of expected errors in both techniques. However, the authors have had difficulty in establishing incontrovertible evidence in support of either value, *i.e.*, a $\Delta H°_{298}$ (α-Al_2O_3) of -400.5 or -392.6 kcal/mole, from related work in the literature.

As implied in the discussion, the accuracy of studies in the Al-O system using Knudsen cell techniques is such that they could be consistent with either value, even when an alumina effusion cell is used.[40] The results of the surface evaporation studies of Burns[41] again cannot distinguish unambiguously between the two values when the effect of inaccuracies in the partial pressures are considered. An aluminum partial pressure of $1.25 \pm 0.25 \times 10^{-6}$ atm at 2318°K, for example, is quoted in this work.

The rationalization of a discrepancy between the thermodynamic properties of Al(III) compounds derived from thermochemical measurements and those derived from reversed hydrothermal equilibrium studies is much more complex. The suggestion of Zen,[42,43] who used the results of the high temperature oxide calorimetry of Holm and Kleppa[44] in his calculations, was that an error of about 7 kcal/mole in the presently accepted value of $\Delta H°_{298}$ (α-Al_2O_3) would eliminate the discrepancy, a suggestion consistent with the results of the electrochemical work. However, in 1974, Thompson[45] did recalculate the standard enthalpies of the aluminous minerals on the basis of a reported revised value for the standard enthalpy of formation of gibbsite. These recalculations resulted in a set of standard enthalpy and free-energy values for the aluminous minerals which were consistent with $\Delta H°_{298}$ (α-Al_2O_3) $= -400.5$ kcal/mole. Regressed Gibbs energy difference functions derived from reversed experimental equilibrium data were also used to generate a set of free-energy data for the aluminous minerals with a forced consistency with $\Delta H°_{298}$ (α-Al_2O_3) $=$ -400.5 kcal/mole.

The key question to be asked is whether the data used directly and indirectly by Thompson is his recalculations are now of sufficient accuracy to preclude a value of $\Delta H°_{298}$ (α-Al_2O_3) of -392.6 kcal/mole, bearing in mind the double-edged consideration that the maximum error quoted in all the work involving the determination of $\Delta H°_{298}$ (α-Al_2O_3) by oxygen bomb calorimetry is only $\pm$ 0.5 kcal/mole. If the answer is affirmative, then clearly there is a systematic error in the electrochemical work and the cells cannot be used to determine alumina activities in metallurgical slags, which was the original intention. If the answer is negative, then the problem has yet to be resolved.

temperature thermochemistry. The significance of the conclusions notwithstanding, the clarity of presentation makes this a commendable study paper for research students. It is remiss, however, in two aspects.

First, the authors do not indicate that they determined the crystal structure of the Al_2O_3 participating in the cell reaction. Kubaschewski *et al.*[47] discuss this point in detail with reference to bomb calorimetry, citing the work of Schneider[48] as an example in which the reaction product, thought to be α-Al_2O_3, was in fact δ-Al_2O_3. The "Fisher Scientific, Certified" status of the authors' alumina documents only its purity and not its crystal structure. Clearly, the conclusions reached in this study would be strengthened if the authors established that the alumina used was, indeed, α-Al_2O_3.

Second, the authors' Fig. 1, purportedly a binary phase diagram, contains a thermodynamically impossible three-phase region. This point is clarified by Mitchel and Burel,[49] who note that "CaF_2" is actually CaF_2 + 1.5-2.0 w/o CaO. Figure 1 is, thus, a vertical section through a ternary phase diagram, a nontrivial distinction worthy of passing mention in the paper. Also on this point, it is pertinent to note that Mitchell and Burel attributed the difference between published binary phase diagrams for the (*i.e.*, "CaF_2"-Al_2O_3) system to variations in the Al_2O_3-$CaO \cdot (Al_2O_3)_6$ ratio, *i.e.*, to position along the CaO axis of the ternary diagram.

D. Ghosh and D. A. R. Kay:[50] We would like to thank Professor Devereux for his interest and comments on our recent paper.

With regard to his first point, the room temperature crystallographic form of the alumina starting material is thought to be relatively unimportant in view of the presence of α-Al_2O_3 refractories in the high temperature slag system. However, routine x-ray powder diffraction analysis of "Fisher Scientific, Certified" alumina produced a pattern which matched that of ASTM No. 10-173 for α-Al_2O_3.

The second point regarding the "CaF_2"-Al_2O_3 phase diagram, is important in its own right and the fact that it is indeed a section of the CaF_2-CaO-Al_2O_3 ternary diagram was not emphasized in our paper. X-ray powder diffraction analysis of the "CaF_2"-Al_2O_3 electrolyte used in our experiments confirmed the presence of α-Al_2O_3, CaF_2, and $CaO \cdot (Al_2O_3)_6$ as determined originally by Mitchell and Burel. As indicated by these authors, the high temperature reactions

$$(CaF_2) + H_2O_{(g)} = 2HF_{(g)} + (CaO) \quad [1]$$

and

$$3(CaF_2) + (Al_2O_3) = 2AlF_{3(g)} + 3(CaO) \quad [2]$$

can lead to indeterminate quantities of CaO in high temperature "CaF_2"-Al_2O_3 slag systems. Whether or not the differences between published phase diagrams of the "CaF_2"-Al_2O_3 system can be attributed to the presence of varying amounts of CaO, must remain a matter for conjecture.

Thermal Oxidation of Phosphorus-Doped Polycrystalline Silicon in Wet Oxygen

Hideo Sunami

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Oxidation characteristics of heavily phosphorus-doped polycrystalline silicon films and single crystal silicon substrates are investigated in a wet oxygen ambient over the temperature range 700°-850°C based on the linear-parabolic rate law. Polysilicon, undoped or uniformly doped with phosphorus of 1.1×10^{19}-2.2×10^{21} cm^{-3} by diffusion drive-in or ion implantation, is studied in comparison with lightly doped or heavily doped (100), (110), and (111) faces of silicon substrates. Phosphorus concentrations greater than 1×10^{20} cm^{-3} cause a significant increase in oxidation rates. Above 1×10^{21} cm^{-3}, however, oxidation rates tend to become saturated. A very rapid oxidation in the initial stage of oxidation is observed. This initial oxide does not fit the linear-parabolic rate law. The resistivity of the phosphorus-doped polysilicon is minimized at 5×10^{-4} Ω-cm for a phosphorus concentration of around 6×10^{20} cm^{-3}. The initial resistivity remains almost constant after reduction of the polysilicon thickness by oxidation. In addition, no evidence of enhanced oxidation along the grain boundaries is observed.

The thermal oxidation kinetics of silicon have been extensively investigated over the past twenty years. One result was the introduction of the linear-parabolic rate law (1) which successfully characterizes experimental results. The activation energies for the rate constants derived from the linear-parabolic model are found in the literature to vary between 0.4 and 2.3 eV (2). Discrepancies in activation energies have been validly attributed to the fact that thermal oxidation of silicon is highly influenced by sodium contamination (2) and/or water traces in the ambient (3, 4). In addition, thermal oxidation of silicon is also influenced by silicon dopant concentrations greater than 1×10^{20} cm^{-3} (5, 6). The dopant concentration dependence of rate constants was previously reported for dry oxidation (7). Although concentration dependent oxidation (CDO) is most pronounced in wet oxygen (5), the kinetics of CDO have not been thoroughly analyzed yet.

The use of polysilicon films has become increasingly important, since silicon gate technology is presently used for many MOS integrated circuits. Consequently several studies were reported on the thermal oxidation of polysilicon films particularly for the crystallinity effect (8) and some CDO effects (9). Recently, silicon dioxide films grown on polysilicon gates have been employed as intermediate insulators for double or higher level polysilicon devices for large scale charge coupled devices (10) and random access memories (11). The quality of the oxide grown on the polysilicon gates is expected to effect the reliability of these devices.

This work characterizes the thermal oxidation of polysilicon films in comparison with various silicon substrate faces with emphasis on heavy doping effects. Undoped polysilicon samples, phosphorus-diffused, and phosphorus-implanted films and single crystal silicon samples of both lightly doped crystals and phosphorus-diffused surfaces were examined. This work also discusses the resistivity of phosphorus-doped polysilicon films and the grain boundary effect on thermal oxidation of polysilicon films deposited on oxidized silicon substrates. Oxidation processes were carried out in wet oxygen (90°C H_2O) in the 700°-850°C range, and CDO was accomplished primarily at 750°C.

Key words: ion implantation, diffusion drive-in, resistivity, grain.

Experimental

In this study, polysilicon films were deposited on thermally oxidized silicon substrates by the thermal decomposition of silane at 625°C in the thickness range 350-500 nm. Grain size of as-deposited films was measured to be around 50 nm by transmission electron microscopy. Phosphorus doping was carried out by the conventional predeposition technique at 1000°C using $POCl_3$ source or ion implantation at 50 keV with doses of 1×10^{15}-1×10^{17} cm^{-2}. Subsequent annealing was realized in a dry oxygen ambient at 1000°C for 20 min in order to provide a uniform concentration across the film and to clean the surface for the implanted samples. Thin oxides formed on the film by the annealing in oxygen were removed with an HF aqueous solution prior to CDO. The annealing also gave rise to grain growth of the film, of which sizes were measured to be 80 and around 1000 nm for phosphorus concentrations of 1.1×10^{20} and 1.1×10^{21} cm^{-3}, respectively. Film resistivity was measured by four-point probe measurement after removal of the oxide.

Silicon substrates having (100), (110), and (111) faces were used in the form of circular slices, 76 mm in diameter, cut from Czochralski crystals, and mirror polished to 400 μm. Impurity concentrations of these substrates were 1×10^{15} cm^{-3} (boron), 1×10^{15} cm^{-3} (boron), and 3×10^{14} cm^{-3} (phosphorus), respectively. Phosphorus-doped surfaces on (100) substrates were obtained by the same predeposition mentioned above. Sheet resistivity and junction depth of the phosphorus-doped layer were 8.5 Ω/□ and about 1 μm, respectively. The carrier concentration of the surface was found to be 7×10^{20} cm^{-3} by incremental removal of the surface and subsequent four-point probe measurement.

A three-zone, resistance-heated furnace with a high purity alumina liner was used for this study. The oxidation chamber was a single wall, fused silica tube. The tube was thoroughly degreased and bathed in aqua regia and then bathed in a mixture of HF and H_2O and thoroughly rinsed in deionized water. Oxygen flow rate was 3 liters/min for this 11 cm ID tube. The resulting partial pressure of water vapor in oxygen was estimated to be 470 mm Hg. This value was obtained from the volume consumption of water supplied from a reservoir which kept the surface level of water in the bubbler constant. As vapor pressure is 524 mm Hg under equilibrium conditions at 90°C, the oxygen was almost completely saturated with water vapor in this experiment. Oxidation temperature was controlled to ± 1°C over the range of 700°-850°C. Cleaning procedures prior to CDO included rinses both in an organic solvent and aqua regia, and light etching of the surface layer, particularly for single crystal silicon with the exception of phosphorus-diffused surfaces.

Oxide thicknesses were determined using an ellipsometer for oxides on single crystal silicon or a Talystep meter for those on polysilicon films. Talystep measurements were calibrated by the ellipsometer for oxides on single crystal silicon, and both methods coincided to within 5%.

Results

Experimental oxidation data were taken to illustrate the following points:

1. The effect of phosphorus doping from 10^{19} to above 10^{21} cm^{-3} and rate constants and activation energies were calculated therefrom.
2. A comparison of the power law exponent (12), n, from the equation

$$x^n = kt$$

showing different behavior for an initial oxidation regime as compared with thicker oxides.

3. A comparison of polysilicon data with data taken on lightly doped single crystal silicon with (100), (110), and (111) faces.
4. The effect of oxidation on a resistivity change and a grain growth for the films.

Plots of the logarithm of oxide thickness *vs.* that of phosphorus chemical concentration for various oxidation times in the case of oxidation in wet oxygen (90°C H_2O) at 750°C are shown in Fig. 1. Oxidation rates increased sharply for concentrations greater than 1×10^{20} cm^{-3}. Almost the same concentration dependence was observed at both 700° and 800°C except absolute values of oxidation rates. These data in the form of the logarithm of oxide thickness *vs.* the logarithm of oxidation time at various concentrations are plotted in Fig. 2. Values indicated at the end of the curves correspond to the exponent n in the empirical power law dependence, $x^n = kt$, where x, k, and t are oxide thickness, rate constant, and oxidation time, respectively (12). Normally, n ranges from 1 for thinner oxides to 2 for thicker oxides. However, n exceeds 2 for two curves of 1.1×10^{21} and 2.2×10^{21} cm^{-3}. Their values of n are around 2.4. This anomalous phenomenon can be explained by the assumption that very rapid oxidation occurs at an early stage of oxidation resulting in an initial oxide which seems to exist analytically prior to CDO. This is discussed in detail in the next section.

Oxidation characteristics of heavily doped and non-doped polysilicon films are plotted in Fig. 3 for 700°, 750°, 800°, and 850°C. Phosphorus doping was accomplished by the conventional predeposition technique at 1000°C for 20 min. The resulting phosphorus concentration was indirectly estimated to be 3×10^{20} cm^{-3} by fitting the oxide thickness values in Fig. 3 to the plots in Fig. 1 for 750°C oxidation.

Similarly, the oxidation of heavily phosphorus-doped (100) surfaces and lightly doped substrates are shown in Fig. 4 for the same temperatures as in Fig. 3. Phosphorus doping of substrates was performed under the same conditions as described above. However, the phosphorus concentration was found to be 7×10^{20} cm^{-3} by incremental removal and four-point probe measurement in reference to Irvin's results (13). This difference between 3×10^{20} cm^{-3} for polysilicon and 7×10^{20} cm^{-3} for (100) silicon even with a simultaneous predeposition has not been explained yet.

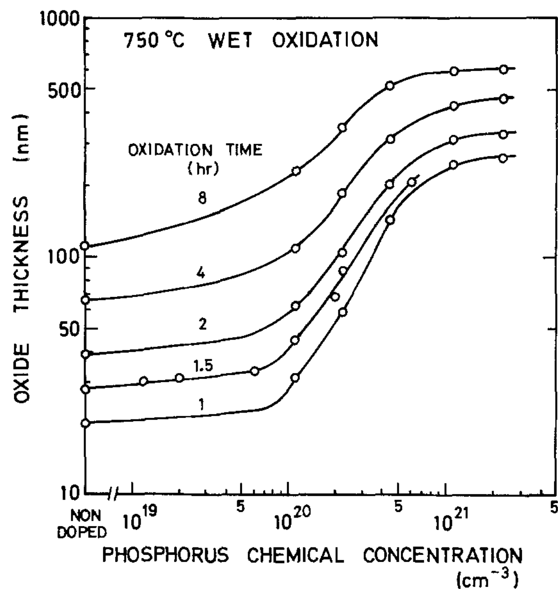

Fig. 1. Oxidation of heavily doped polysilicon films with phosphorus in wet oxygen (90°C H_2O). Polysilicon films were deposited on oxidized silicon substrates, 450-500 nm in thickness and doped through ion implantation. Annealing at 1000°C in dry oxygen was performed prior to oxidation.

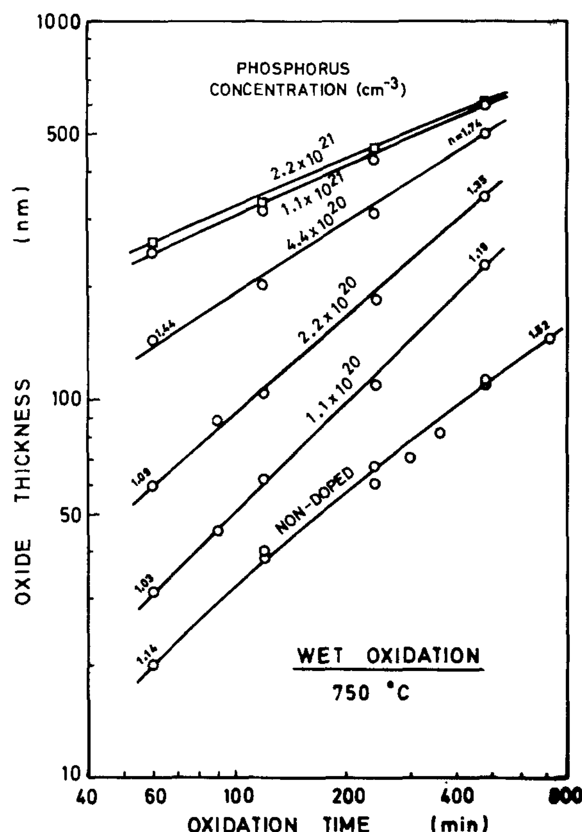

Fig. 2. Oxidation of heavily doped polysilicon films with phosphorus in wet oxygen (90°C H_2O). The plots employ the same data as shown in Fig. 1. Values indicated at the limit of each curve correspond to the exponent n in the power law dependence, $x^n = kt$.

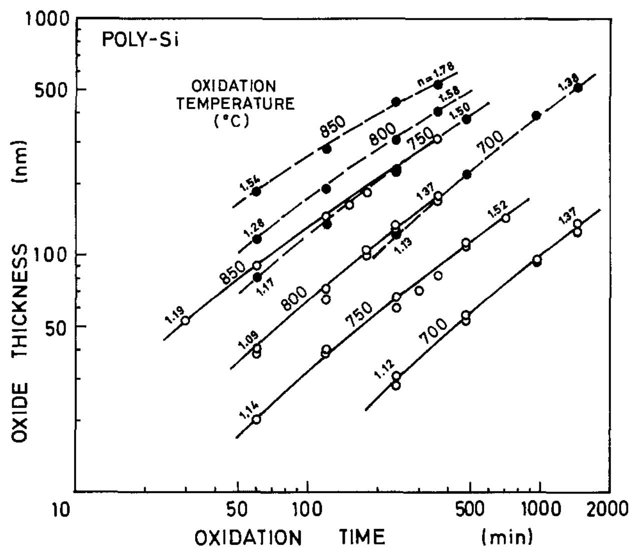

Fig. 3. Oxidation of phosphorus-doped and nondoped polysilicon films in wet oxygen (90°C H_2O): ●, phosphorus doped (3 × 10^{20} cm^{-3}); ○, nondoped.

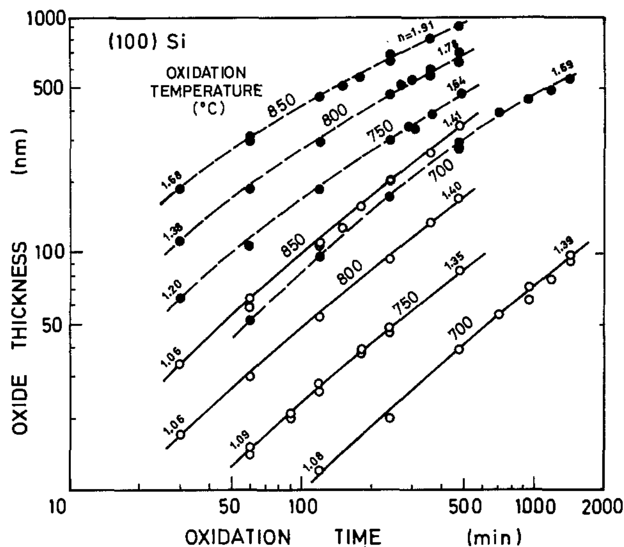

Fig. 4. Oxidation of phosphorus-doped (100) surfaces and lightly doped (100) substrates in wet oxygen (90°C H_2O): ●, phosphorus doped (7 × 10^{20} cm^{-3}); ○, uniformly boron doped (1 × 10^{15} cm^{-3}).

Wet oxidation of nondoped polysilicon in comparison with (100), (110), and (111) faces of single silicon substrates is shown in Fig. 5 for 700° and 750°C. It is seen that at both temperatures the polysilicon rate was between (110) and (111).

The resistivities obtained for phosphorus-doped polysilicon films are shown as a function of chemical concentration in Fig. 6. Resistivity was evaluated from the product of oxide thickness and sheet resistivity using four-point probe measurement. The existence of a resistivity minimum of 5 × 10^{-4} Ω-cm is clearly distinguished for a concentration of around 6 × 10^{20} cm^{-3}. As have been mentioned in the Experimental section, grain sizes of the films were found to be 80 and around 1000 nm for the concentrations of 1.1 × 10^{20} and 1.1 × 10^{21} cm^{-3}, respectively (14).

Resistivity changes in polysilicon films doped with phosphorus (3 × 10^{20} cm^{-3}) associated with wet oxidation are shown in Fig. 7. The abscissa denotes residual polysilicon thickness after oxidation. Solid symbols designate the initial values of resistivity and thickness. The resistivity of as-oxidized films increased to a great extent for 700°C because most phosphorus

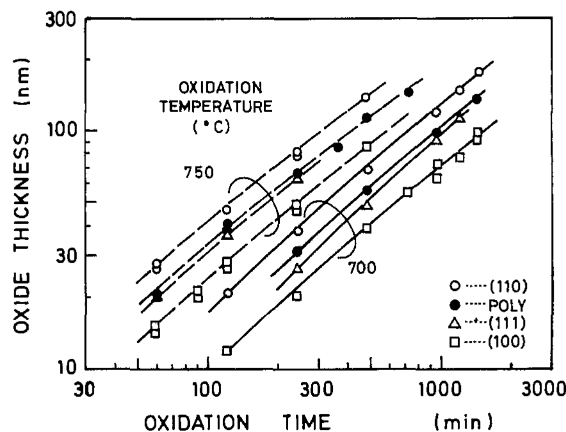

Fig. 5. Crystal orientation and crystallinity dependences of oxidation in wet oxygen (90°C H_2O) at 700° and 750°C. Impurity concentrations of (100), (110), and (111) faces are 1 × 10^{15} (boron), 1 × 10^{15} (boron), and 3 × 10^{14} cm^{-3} (phosphorus), respectively. The polysilicon films are not intentionally doped.

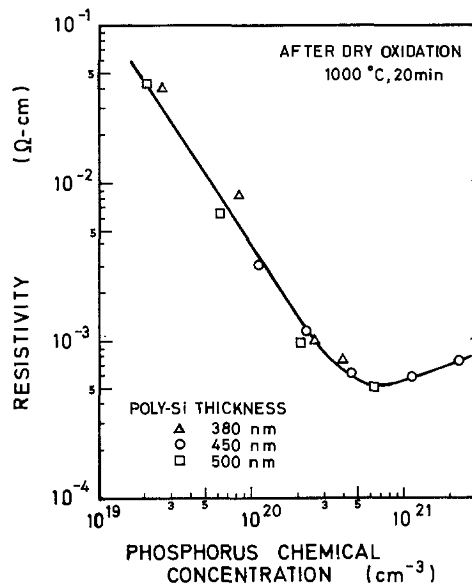

Fig. 6. Resistivity of phosphorus-implanted polysilicon films, 380-500 nm thick, deposited on oxidized silicon substrates. The films were annealed in dry oxygen at 1000°C for 20 min prior to resistivity measurements.

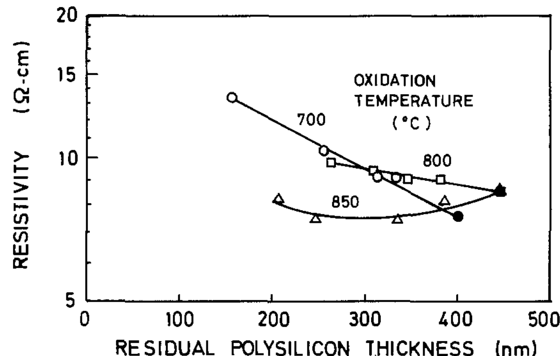

Fig. 7. Resistivity changes of polysilicon films doped with phosphorus (3 × 10^{20} cm^{-3}) associated with the wet oxidation (90°C H_2O). Solid symbols denote the initial conditions of polysilicon doped with phosphorus prior to the oxidation. Annealing at 1000°C for 5 min in nitrogen was added prior to resistivity measurement only in the case of 700°C.

atoms become segregated and electrically inactive. Therefore, annealing of 1000°C for 5 min in nitrogen ambient was introduced prior to resistivity measure-

ment in order to make the atoms electrically active, only in the case of 700°C.

Discussion

The effect of heavy doping on the initial oxide kinetics.—The linear rate constant B/A and the parabolic rate constant B were evaluated based on the general relationship for thermal oxidation of silicon (1). First, oxide thickness x was plotted *vs.* the value of oxidation time t divided by x. Then, the plots yielded a straight line with an intercept equal to $-A$, and slope equal to B by the least squares fitting technique. Two lines corresponding to phosphorus concentrations of 1.1×10^{21} and 2.2×10^{21} cm^{-3} yielded negative values of A contrary to the observations by Deal and Grove for wet oxidation (1). This result suggests the generation of an "initial oxide" which does not obey linear-parabolic kinetics for some cases of thermal oxidation with heavily doped silicon even for wet oxidation. The existence of an initial oxide gives rise to not only the negative values of A but also values of n greater than 2 previously mentioned.

To evaluate initial oxide thickness x_i, a plot of x^2 *vs.* t is made and shown in Fig. 8. The lines corresponding to phosphorus concentrations of 1.1×10^{21} and 2.2×10^{21} cm^{-3} show an almost true linear slope and yielded x_i^2 at $t = 0$ and initial oxidation time t_i at $x^2 = 0$. This initial oxidation regime was shown in Yeh's experimental data in the case of steam oxidation of phosphorus-doped (111) substrates (15). However, Deal and Sklar (5) concluded that this correspondence was attributed not to the concept of initial oxide but to an initial porous oxide present on the phosphorus-diffused surface. Values of x_i obtained are shown in Table I for the present work in comparison to Yeh's experiments.

The linear rate constant B/A and the parabolic rate constant B were evaluated for wet oxidation of phosphorus-doped polysilicon films at 750°C. These rate constants are shown in Fig. 8 considering initial oxidation regime for phosphorus concentrations of 1.1×10^{21} and 2.2×10^{21} cm^{-3}. With increasing phosphorus concentrations greater than 1×10^{20} cm^{-3}, B/A increases sharply. Besides, B increases only by a factor of 10 and then becomes saturated.

CDO can be divided into two regimes. One regime is derived from the enhancement of diffusion of oxidizing species due to phosphorus atoms incorporated in the oxide. The other is derived from the enhancement of surface reactions due to the catalytic behavior of phosphorus atoms. The results obtained shown in Fig. 9 indicate that the catalytic reaction becomes relatively

* Calculated from Yeh's (15) values of oxide thicknesses as a function of oxidation time.

dominant compared to the saturated parabolic rate constant especially in the region of higher phosphorus concentrations.

It is speculated that very rapid oxidation, giving rise to an initial oxide, may originate from the formation of P_2O_5 glass due to accelerated outward diffusion of phosphorus atoms in the very early stages of oxidation. Furthermore, an excess of phosphorus atoms implanted into polysilicon films greater than the solid solubility may take part in the P_2O_5 formation. Preliminary ion-probe microanalysis showed that the highest phosphorus concentration was located at the surface of the oxide exposed to the oxidation ambient and thus may support the above speculation. The "initial oxide," which forms during dry oxidation, has similar characteristics to initial oxide found in the present study, although they are derived from different mechanisms.

Effects of impurity redistribution and crystallinity.—It is well known that phosphorus atoms pile up at the silicon surface during thermal oxidation, resulting in higher surface concentrations. This "pile-up" is most pronounced in wet oxygen and/or at lower oxidation temperatures (15, 16). In wet oxidation of single crystal silicon at 750°C, the ratio of the phosphorus concentration in silicon near the oxide-silicon interface to the bulk concentration (C_s/C_B) is estimated to be greater than 10 assuming that the segregation coefficient and the diffusivity of phosphorus still hold. In addition, diffusivity increases significantly at higher concentrations and especially in polysilicon (17). Since the diffusivity of phosphorus in polysilicon is several times greater than that in single crystal silicon, the value of C_s/C_B for polysilicon is expected to be far less than that for single crystal silicon. The re-

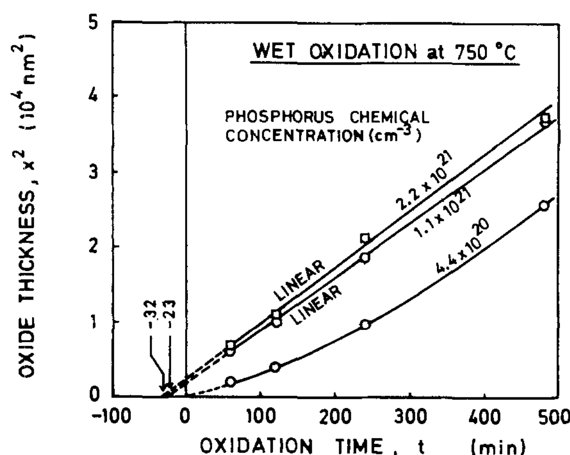

Fig. 8. Evaluation of initial oxide thickness x_i for thermal oxidation of phosphorus-doped polysilicon in wet oxygen (90°C H_2O) at 750°C. The lines for concentrations of 1.1×10^{21} and 2.2×10^{21} cm^{-3} show almost true linear slopes and yield values of x_i^2 at $t = 0$ and values of t_i at $x^2 = 0$.

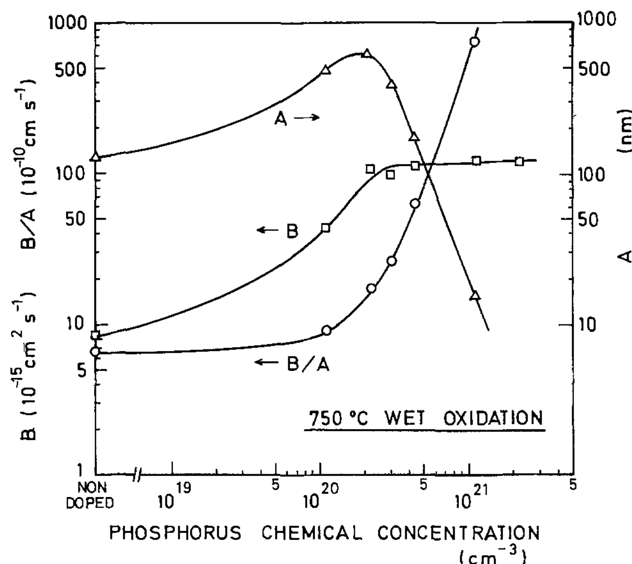

Fig. 9. Phosphorus concentration dependences of the linear rate constant B/A and the parabolic rate constant B for wet oxidation (90°C H_2O) of polysilicon films at 750°C.

sistivity changes obtained for phosphorus-doped polysilicon associated with the wet oxidation were very small as shown in Fig. 7. This was not expected from the value of C_S/C_B for single crystal silicon. Resistivity should decrease significantly following thickness reduction if the pile-up occurs for polysilicon similar to the predicted redistribution for single crystal silicon. Consequently the impurity redistribution in phosphorus-doped polysilicon associated with the wet oxidation may be relatively negligible compared to single crystal silicon.

Rate constants evaluated for different faces of single crystal silicon and polysilicon are shown in Table II for 750°C wet oxidation. The linear rate constant increases in the order (100), (111), polysilicon, and (110). The linear rate constant values obtained, shown in Table II, agree qualitatively with the relative order of the surface density of silicon bonds which are available to the water molecules (18, 19). Crystal orientation of the majority of grains in polysilicon films is highly affected by the film deposition technique (20). From transmission electron microscopy, the orientations of the majority of the grains were found to be <111> and <110>. This fact is consistent with the order of the rate constants for polysilicon and (111) and (110) faces of single crystal silicon.

The thermal oxidation of polysilicon in wet oxygen is similar to that of single crystal silicon considering that the resistivity changes of phosphorus-doped polysilicon and the crystal orientation effect on oxidation. In addition, neither penetration of oxide along grain boundaries nor grain growth were found associated with the wet oxidation with scanning electron microscope observations for cleaved surfaces of the film.

Oxide quality in this work.—Temperature dependence of the linear and the parabolic rate constants evaluated from the data plotted in Fig. 3 and 4 are shown in Fig. 10 and 11, respectively, over the temperature range from 700° to 850°C. Wet oxidation characteristics using a water bubbler in this work are compared with previous works (1, 2), particularly for a contamination effect. Concerning the contamination effect, Revesz and Evans (2) concluded that Na atoms increased the parabolic and linear preexponential factors and activation energies in the temperature range of 920°-1200°C (2, 21). The E_a of the parabolic rate constant B was observed to be 2.30 eV for lightly doped (100) silicon. This value is quite close to 2.29 eV for Na contaminated (111) silicon obtained in Ref. (2). Moreover, the E_a of the linear rate constant B/A for lightly doped (100) silicon was evaluated to be 1.52 eV, slightly less than the reported values of 1.92 eV (1) and 1.91 eV (2). Phosphorus atoms play the important role of Na-getters and presumably reduce the effect of Na on enhanced diffusion of oxidizing species, thus resulting in slower oxidation rates. In this sense it appears consistent that the E_a of B/A increases from 1.52 to 1.86 eV and E_a of B decreases from 2.30 to 1.03 eV due to phosphorus doping of 7×10^{20} cm^{-3}. From the above discussion, it is probable that these oxides in this study may be contaminated with Na to some extent. However, BT stress measurements gave mobile ion (almost Na) densities in the oxides of around 1×10^{11} cm^{-2} (10^{16} cm^{-3} for 100 nm thick oxide). This value obtained is far smaller than that of 10^{20}

cm^{-3} in the previous experiment where Na atoms were intentionally doped (2).

While most Na atoms incorporated into the oxide remain inactive (22), Na concentration of 10^{20} cm^{-3} (10^{15} cm^{-2} for 100 nm thick oxide) yielded such enhanced oxidation. As the BT stress measurement can detect only active ions, the result of BT stress measurement is not necessarily inconsistent with the previous results (2). Further investigation should be focused on this point.

Conclusions

It has been shown that thermal oxidation rates of heavily doped polysilicon films (phosphorus concentrations greater than 1×10^{20} cm^{-3}) in wet oxygen at 750°C depend on the phosphorus concentration in the film. The parabolic rate constant saturates at concentrations greater than 2×10^{20} cm^{-3}, while the linear rate constant increases are progressively accelerated.

Above phosphorus concentrations of 1×10^{21} cm^{-3}, very rapid oxidation takes place at the beginning of the oxidation period resulting in "initial oxide" formation. Thicknesses of the initial oxide are observed to be 123 and 156 nm for 1.1×10^{21} and 2.2×10^{21} cm^{-3}, respectively. It is speculated that the initial oxide may originate not from the space charge enhanced oxidation (1) but from growth of P_2O_5 glass which results from the phosphorus atoms exceeding solid solubility at the oxidation temperature.

The resistivity of phosphorus-implanted polysilicon films has a minimum value of 5×10^{-4} Ω-cm for doping concentrations of around 6×10^{20} cm^{-3} after annealing at 1000°C. After the annealing initial grain size of 50 nm was enlarged to 80 and around 1000 nm for concentrations of 1.1×10^{20} and 1.1×10^{21} cm^{-3}, respectively. After wet oxidation film resistivity remains fundamentally stable and neither penetration of oxide along grain boundaries nor additional grain growth were observed.

The oxidation rate of lightly doped silicon and nondoped polysilicon increases (100), (111), polysilicon, and (110), in this order. This is consistent with the observation that polysilicon films are oriented between <111> and <110> directions according to transmission electron microscopy.

The activation energies of linear and parabolic rate constants obtained for (100) silicon are 1.52 and 2.30 eV, respectively. The former increases and the latter decreases with phosphorus doping of 7×10^{20} cm^{-3}. These characteristics may lead to speculation that the wet oxidation in this work is possibly contaminated by Na atoms despite the fact that *BT* stress measurement, which can detect only active ions, gave mobile ion densities of around 1×10^{11} cm^{-2}.

Acknowledgments

The author is indebted to Y. Wada for valuable discussions regarding grain growth as well as to N. Hashimoto for his constant encouragement and discussions concerning ion microprobe analysis. The author also wishes to thank S. Nishimatsu and Y. Kamigaki for technical discussions generally concerning thermal oxidation of silicon and H. Usui for performing the ion implantation procedures used in this study.

Oxidation Kinetics of Cobalt Diffusing out of High Current Density (HCD) Plated Gold

J. H. Thomas, III[1]

Bell Telephone, Columbus, Ohio 43213

ABSTRACT

Auger electron spectroscopy and Auger depth profiling techniques have been used to study the growth kinetics of cobalt oxide films which form on thermally aged HCD-plated hard gold in dry laboratory air. Films were observed to grow according to parabolic growth kinetics. At temperatures of 150° and 180°C, a large amount of potassium is observed on the film surface and may be associated with the observed recrystallization in hard gold electroplates. Film growth appears to saturate at 180°C for times greater than 48 hr. A general model was developed for film growth on dilute two-component noble metal alloys exposed to a single reacting gas specie, assuming conservation of the reacting specie (flux continuity at the metal-film interface) and parabolic film growth. The conditions necessary for the film growth to be controlled by diffusion from the alloy are given in terms of the material constants. For this specific case, the general solution reduces to that of an infinite sink and the diffusion constant can simply be computed from the parabolic growth rate constant. The diffusion coefficients for Co in Au were calculated between 100° and 180°C. An activation energy of 1.83 eV was obtained for this process.

With the increased usage of high current density plated gold (HCD) in the electronics industry, it has become necessary to understand and characterize processes by which gold alloy electroplates thermally degrade (1). It has been shown that hard golds exhibit increases in contact resistance (2) presumably due to the diffusion and subsequent oxidation of cobalt (which is used as a hardener) on the gold surface (3). Thermal aging studies in dry air have shown cobalt to oxidize to what appears to be CoO (4). The diffusion coefficients for cobalt diffusing out of hard gold have been determined for HCD gold and LCD (low current density) gold using a model which requires that the controlling process for oxide growth is diffusion (3). The kinetics of oxide formation on noble metal alloys has been studied experimentally by a number of investigators [see Ref. (5) for references], and has been theoretically studied by Wagner (6).

In this paper, the kinetics of CoO growth on HCD-plated hard gold has been studied at temperatures ranging from 75°-180°C. Film growth kinetics have been analyzed using a model for film growth on a dilute noble metal alloy, and film growth rates and the diffusion coefficients for cobalt diffusion out of HCD hard gold have been computed using this model. As a result of model calculations, a more general method of computing corrosion rates due to reactions in a single component gas system and diffusion coefficients in a two component alloy from concentration profiles has been developed.

Experimental

Film thickness measurements and surface analysis of cobalt-hardened HCD gold were analyzed with a Physical Electronics Industries scanning Auger system. This system is equipped with a single pass cylindrical mirror analyzer (CMA), coaxial electron gun, and Varian rastered ion gun. Depth profiles reported in this paper were performed at a pressure of 5×10^{-5} Torr argon at a beam energy of 1 keV. The sputter rate of gold under these conditions was measured as 6.3 Å/min (7). All Auger spectra were obtained at a beam energy of 3 keV and an emission current of 1.8 mA.

Hard gold plating was performed in a production plater. All samples were processed by initially depositing a nickel layer (~2.5 μm) followed by a gold flash. Nominally, 7.3 μm of hard gold from a proprietary Engelhard phosphate plating bath was deposited at current densities of 150-225 mA/cm^2 (depending on sample geometry) on the gold flash. The cobalt concentration as determined by atomic absorption spectroscopy was found to be 0.25-0.26 weight percent (w/o) and was confirmed by quantitative AES. The gold plating thickness was measured by cross-sectioning techniques and was found to range from 6.6 to 8.2 μm. All samples were fabricated on CDA 725 rolled stock which was cleaned prior to electroplating. 1 × 1 in. samples were cut from the 1 in. wide continuous strip for study.

Prior to thermally aging the samples, all samples were cleaned in a trichloroethane vapor degreaser and subsequently in boiling 10% H_2O_2 solution for 3 min. Samples were then thoroughly rinsed in DI water and placed in chemically cleaned petri dishes to protect them from accidental contamination. Thermal treatments were performed for 50, 150, 250, 500, and 1000 hr at 75°, 100°, 125°, and 140°C, respectively, and 6, 24, 48, and 100 hr at 180°C. Samples were stored in a dessicator prior to performing AES measurements. One sample was measured at each time and temperature giving a total of 24 samples. Oven temperatures were stabilized to the desired set point and were found to vary within ±2°C of that set point. All aging was performed in laboratory air.

Results

Typical spectra for 75°/1000 hr, 140°/1000 hr, and 180°/100 hr are shown in Fig. 1 for comparison purposes. The primary contaminants which are characteristic of samples aged at temperatures less than 100°C for 1000 hr are carbon, oxygen, chlorine, and traces of copper and cobalt. The small amount of copper (at 75° and 100°C) may be due to the residue left from a reaction of the copper-based substrate material (CDA 725) with the peroxide cleaning solution. The largest signals are typically carbon and chlorine. During sputter depth profiling, these contaminants are removed within the first few minutes of sputtering. At higher temperatures, 140°C, the main signals observed are due to oxygen and cobalt with some carbon, chlorine, and a trace of potassium (in order of decreasing amplitude). Potassium is not observed at times and temperatures less than 140°C/1000

[1] Present address: RCA David Sarnoff Research Center, Princeton, New Jersey 08540.

Key words: alloy, diffusion, oxidation.

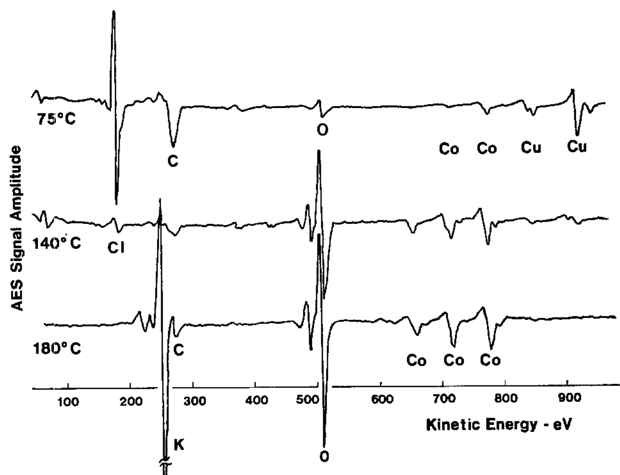

Fig. 1. Auger electron spectra are shown for HCD gold electroplate aged 75°C/1000 hr, 140°C/1000 hr. and 180°C/100 hr.

hr for these samples. With the exception of potassium and signal amplitude, this spectrum is similar to other spectra in the range 100°-140°C. At 180°C, potassium is the strongest Auger signal observed. Large oxygen and cobalt signals are also observed. Potassium is known to be incorporated in gold which is deposited from cyanide gold baths (8). The evolution of potassium from the gold deposit is characteristic of aging at higher temperatures (~140°C). Since Co and O appearing in the 100°-180°C temperature range are the primary surface species (except K at 180°C), the kinetics of CoO formation on the hard-gold surface have been studied in detail.

Figure 2 shows typical depth profiles for gold aged at 100°C and 140°C for 1000 hr and 180°C for 48 hr. At 100°C, contamination (film formation) appears to be limited to the surface region. However, Co is clearly observed. At times and temperatures less than this, cobalt is only observed in trace amounts. In the 140°C depth profile, cobalt and oxygen are observed to track in signal amplitude as has been observed by other investigators (3, 4). At 180°C, the potassium signal tracks the oxygen signal. Thus, it is likely that potassium is chemically involved in the film. Consequently, these films are not simply oxide films as observed from 100° to 140°C. At times less than 48 hr, at 180°C the films are similar to those in the range 100°-140°C. In all the data shown it is significant that the substrate materials (copper and nickel) are conspicuously absent. This indicates that for the times and temperatures studied, substrate diffusion is not an important mechanism.

To study film growth kinetics, the film thickness was measured as the sputtering time required for the cobalt Auger signal amplitude to reach ½ its peak signal amplitude. This method of film thickness determination was used consistently for each sample. Sputter times (at ½ the peak Co signal amplitude) were converted to film thickness by assuming the sputter rate for Co to apply to CoO. The sputter rate for Co relative to Au is 0.5 (9). Figure 3 summarizes the film thickness, determined in this way, for 100°, 125°, 140°, and 180°C data as a function of time. A CoO film is assumed for 180°C, 48 and 100 hr films. At 100°C, a marginally measurable CoO film is observed. Therefore, only one point is shown (5Å thickness at 1000 hr) and represents the detectability limits of the system. At 180°C, a scale change (2) is indicated. The CoO film thickness is observed to increase with time and temperature with what appears to be a parabolic dependence on time. At 180°C, after 48 hr, the film thickness (~200Å) does not appear to increase with time. If all the cobalt is assumed to diffuse to the gold surface and oxidize, a film thickness of ~750Å would be obtained (for 0.26 w/o Co). These data in-

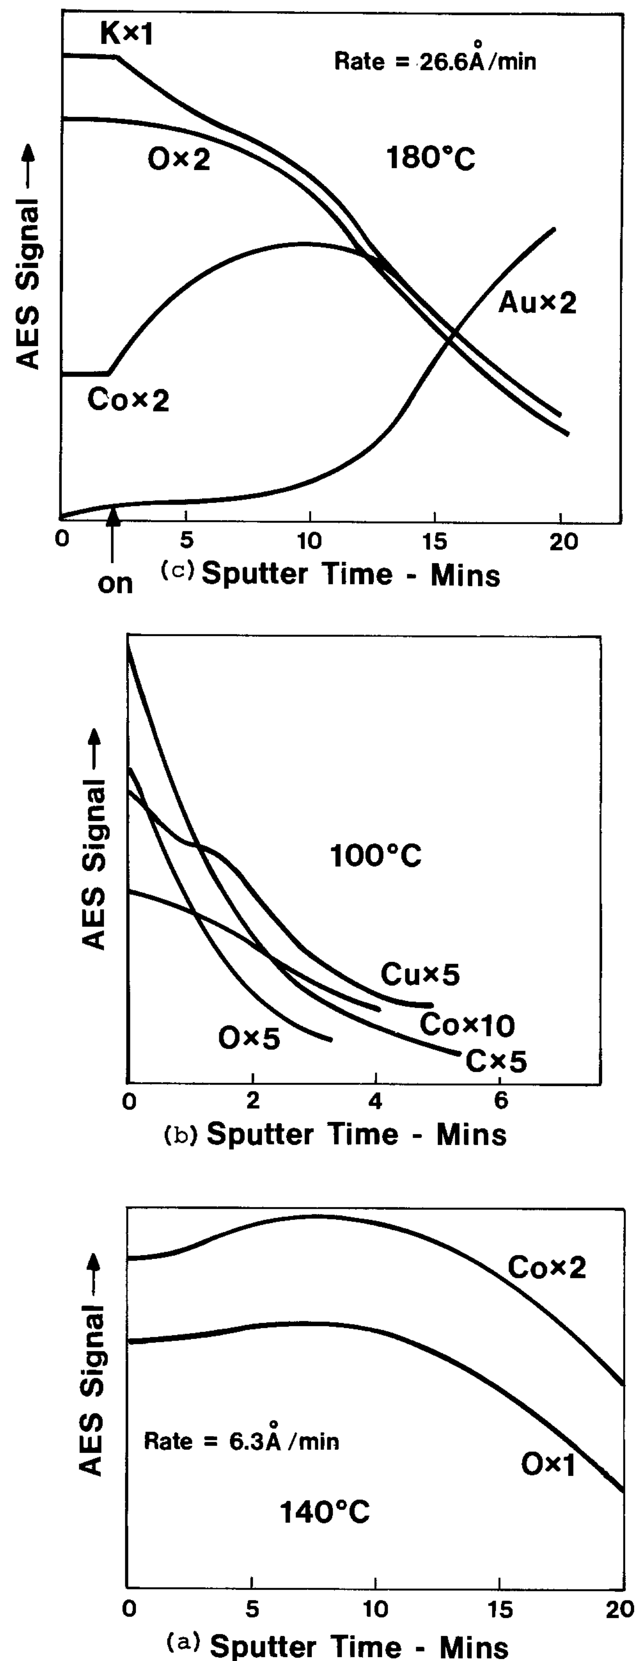

Fig. 2. Depth profiles are shown for 100°C/1000 hr, 140°C/1000 hr, and 180°C/100 hr. Auger signal amplitude is plotted as a function of film thickness using gold as a reference and correcting the rate to that of cobalt metal (as an approximation). (A) and (B) were sputtered at 6.3 Å/min. (C) was sputtered at 26.6 Å/min.

dicate that 27% of the total amount of cobalt has actually been oxidized. It is likely that the oxide observed on the gold surface is due to the oxidation of cobalt which diffuses to the surface easily (probably

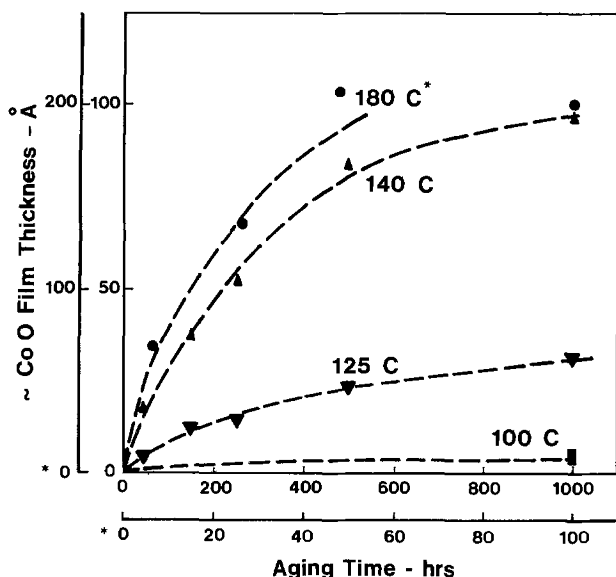

Fig. 3. Film thickness is plotted as a function of time with thermal aging temperature as a parameter. CoO thickness is determined from the sputter time required to reduce the Co signal to 1/2 its peak amplitude.

from grain boundaries). The remaining cobalt is probably in the gold metal lattice and thus would diffuse at a slower rate.

Model

To analyze the data presented in Fig. 3, a model has been developed for film growth on dilute noble metal alloys which incorporates the film growth rate of a reacting species (B) from the alloy. A sketch of the model is shown in Fig. 4 where the two-component alloy (A,B) is contained in the left-hand plane, that is, the alloy is assumed infinite in extent. The oxidized species concentration, $C(x,t)$, is shown as a function of x, the depth into the alloy. The alloy surface is assumed to be fixed at $x = 0$. After a time, t, an oxide $x_f(t)$ in thickness grows which contains C_o mole fraction of the oxidized species, B. C_o is assumed to be constant, that is, the oxide is assumed to grow stoichiometrically from $t = 0$. Fick's second law

$$D\frac{\partial^2 C(x,t)}{\partial x^2} = \frac{\partial C}{\partial t}, \quad x \leq 0 \qquad [1]$$

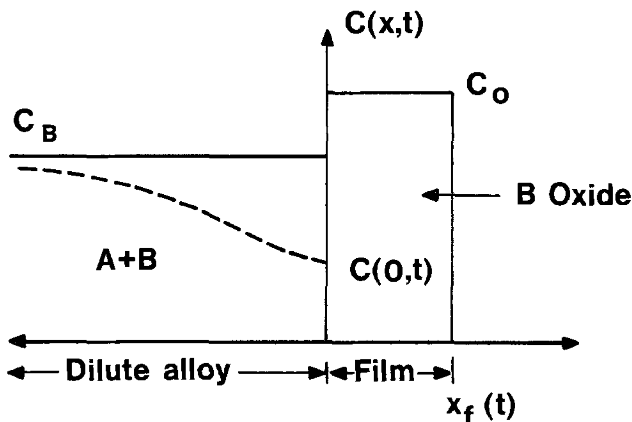

Fig. 4. A semi-infinite model is shown for noble metal alloy oxidation which contains a reactive specie. Fick's second law was solved using the boundary conditions as shown for the concentration of the reactive specie $C(x, t)$ for $x \leq 0$. C_B = bulk concentration of B in A; C_o = concentration of B in oxide (or film); x_f = film thickness. Solve Fick's second law with the initial condition that $C(x, 0) = C_B$ and the boundary conditions that $C(x, t) = C_B$, $x = -\infty$ and $D\, \partial C/\partial x_{x=0} = C_o\, dx/dt$.

is solved for the initial condition $C(x,0) = C_B$, where C_B is the bulk concentration of the oxidized species, D is the diffusion coefficient of the species in the alloy, and C is the concentration. One boundary condition is that at $x = -\infty$, $C(-\infty, t) = C_B$, that is, the concentration at $x = -\infty$ is fixed. The second boundary condition is derived from the conservation of the oxidized species [see Ref. (10)] for films which form according to parabolic growth kinetics (5), that is

$$x_f^2 = k_c t \qquad [2]$$

where k_c is the parabolic growth constant (cm²/sec). The boundary condition reduces to a condition relating the flux of B at the interface to the time dependence of the film growth on the surface (10)

$$D\frac{\partial C}{\partial x}\bigg|_{x=0^-} = C_o\frac{dx_f}{dt} = C_o\frac{k_c}{2x_f} \qquad [3]$$

Fick's second law for this problem is solvedThetaking the Laplace transform in time and applying the above initial condition and boundary conditions (11, 12). The solution in the Laplace variable, p, is

$$C(x,p) = -C_o\sqrt{\frac{p}{D}}\tilde{x}_f(p)\exp\left[x\sqrt{\frac{p}{D}}\right] + \frac{C_B}{p} \qquad [4]$$

where $\tilde{x}_f$ is the Laplace transform of $x_f(t)$. For the parabolic case of film growth, $x_f^2 = k_c t$, the Laplace transform is

$$\tilde{x}_f(p) = \sqrt{\frac{k_c \pi}{4}}\, p^{-3/2} \qquad [5]$$

The solution $C(x, t)$ is readily obtained by taking the inverse transform of Eq. [4] with Eq. [5] and is

$$C(x,t) = -C_o\sqrt{\frac{\pi k_c}{4D}}\,\mathrm{erfc}\left[-\frac{x}{2\sqrt{Dt}}\right] + C_B \quad x \leq 0 \qquad [6]$$

This solution is similar to Wagner's solution (6) for alloy oxidation when he assumes a nonmoving metal-oxide boundary.

Of particular interest is the concentration $C(0, t)$ at the alloy film interface. Equation [6] reduces, for $x = 0$, to

$$C(0,t) = C_B - C_o\sqrt{\frac{\pi k_c}{4D}} \qquad [7]$$

Thus, for a given set of material properties, k_c, D, C_o, and C_B the concentration, $C(0, t)$, is fixed. If $C(0, t)$ can be measured, since C_o and C_B are known, the ratio of k_c/D can be determined from Eq. [7]. Now consider two cases for Eq. [7]

$$C(0,t) > 0 \qquad [8]$$

and

$$C(0,t) \leq 0 \qquad [9]$$

When $C(0, t)$ is greater than zero, the concentration is dependent on both k and D. Therefore, the oxidation rate does, in part, control the film growth rate (simply the case of a finite sink). When $C(0, t)$ is less than zero, (which is physically impossible), the film should cease to grow until more material diffuses to the surface. Therefore, the limiting case for film growth is $C(0, t) = 0$. This is the case of the infinite sink (3), that is, all the material which diffuses out is immediately oxidized. In this situation, the concentration is solely dependent on the diffusion of specie B in the alloy. It can easily be shown that Eq. [6] reduces to a function of D only when $C(0, t) = 0$. C_B is then related to C_o, k_c, and D by Eq. (7). The film growth equation is then rewritten as

$$x_f^2 = \frac{4}{\pi}\left[\frac{C_B}{C_o}\right]^2 Dt \qquad [10]$$

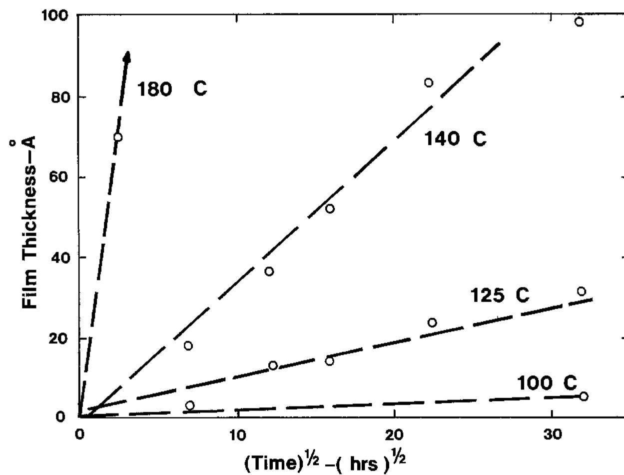

Fig. 5. Parabolic model $x = K_0 t$ data shown in Fig. 3 are replotted on x_f vs. $t^{1/2}$ coordinates, where x_f = film thickness and t = time.

x_f is simply a function of $\sqrt{Dt}$ for an infinite sink situation and k_c is $4/\pi \times (C_B/C_o)^2 D$. This model reduces to the case studied by Wagner (6) and more recently by Tompkins (3) in the limit of a diffusion-controlled process.

Analysis

The film thickness data shown in Fig. 3 can be used to compute both the corrosion rate constant, k_c, and the diffusion coefficient, D, for Co in Au as a function of temperature. If the film grows according to parabolic kinetics (Eq. [2]), the data should plot linearly on x_f vs. $t^{1/2}$ coordinates. Data of Fig. 3 are replotted in Fig. 5. Points have been least squares fitted to straight lines which are shown as dashed lines. Since the 100°C data consists of only one point, a line was drawn through this point. These data fit a straight line rather well. The slopes of the straight lines give directly the corrosion rate constant k_c as a function of temperature. This is summarized in Table I. Along with these data, Gulbransen and Andrew's (13) corrosion rates for cobalt metal, obtained by extrapolating their data to 100°C, have been included for comparison.

To obtain the diffusion coefficient for Co in Au from these data, k_c must be multiplied by the factor $\pi/4\ (C_o/C_B)^2$. This constant for 0.25-0.26 w/o Co in gold and CoO formation is 3500. An accurate determination of $C(0, t)$ was not performed in this study. However, experimentally $C(0, t)$ is observed to decrease, that is, the Co Auger signal decreases at what appears to be the film-alloy interface. It is assumed that this model for $C(0, t) = 0$ can be used to approximate the real system. In that case, D is directly obtained and is summarized in Table I.

To demonstrate the usefulness and validity of this model, D was also computed using Tompkins' model which was developed for an infinite sink assumption. Using his empirical relationship between film thickness and Dt, D was computed for each time and temperature. D was then arithmetically averaged at each temperature and is listed in Table I. Comparing D obtained from the corrosion rate constants or the slope of x_c vs. $t^{1/2}$ with values of D computed using Tompkins' empirical equation (3) shows excellent agreement. D ranges from 0.9×10^{-13} cm²/sec at 180°C to 2.4×10^{-18} cm²/sec at 100°C.

Finally, since D is activated, that is, $D \propto \exp(E_A/kT)$, the activation energy for the diffusion of cobalt out of HCD gold can be determined from an Arrhenius plot. Figure 6 shows D plotted as a function of $1/T$ (in °K)$^{-1}$. A straight line can be drawn through these points and the activation energy was computed from the slope of this line as 1.83 eV. This value is much higher than the value of 1.24 eV obtained by Tompkins (3) for LCD-plated cobalt-hardened gold. This determination is independent of an absolute measure of film thickness, that is, these values are only dependent on the slope of x_f vs. $t^{1/2}$.

Activation energy for diffusion can be computed accurately from a knowledge of the relative film thickness. Absolute values of D, however, require an accurate measurement of film thickness and when using Auger depth profiling for this purpose, an accurate measurement of the relative sputter rate of CoO with respect to gold is needed.

Table I

Temperature (°C)	Corrosion rate constant (k_c (cm²/sec))	Gulbransen-Andrew (k_c on Co)	Diffusion coefficient* (D_{Co-Au} (cm²/sec))	Diffusion coefficient** (Tompkins model) (cm²/sec)
100	7.0×10^{-22}	3.8×10^{-20}	2.4×10^{-18}	5.7×10^{-18}
125	5.4×10^{-20}	1.3×10^{-19}	1.9×10^{-16}	2.1×10^{-16}
140	3.2×10^{-19}	2.5×10^{-19}	1.1×10^{-15}	$2\ 3 \times 10^{-15}$

Conclusions

Auger electron spectroscopy has been employed to study thermally aged HCD hard-gold electrodeposits. At temperatures below 100°C, little film forms on the surface of the gold plate as measured by AES depth profiling. Typical surface contaminants observed by Auger are carbon, chlorine, oxygen, and traces of cobalt and copper. It is possible that small amounts of copper come from the H_2O_2 cleaning process. At 100°C/1000 hr and at higher temperatures cobalt and oxygen are observed to be the major surface species as observed in previous thermal aging studies. At 140°C/1000 hr and 180°C, potassium is observed to evolve.

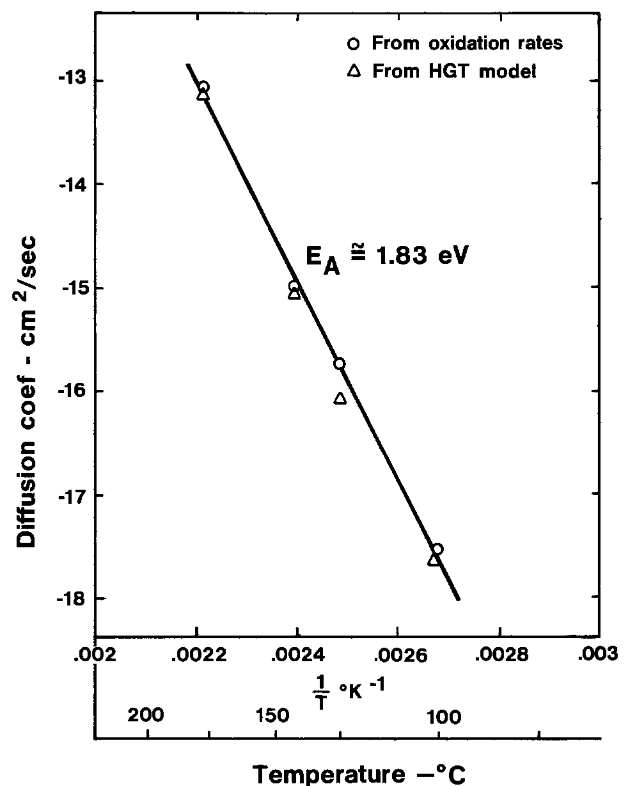

Fig. 6. The computed diffusion coefficient, D, for cobalt diffusion in hard gold is shown as a function of (temperature)$^{-1}$. From the slope of this data, the activation energy for D is 1.83 eV.

Kinetics of this process are presently being studied. It is likely that the potassium evolution which forms a substantial film with cobalt and oxygen, may be related to recrystallization around 150°C (14). It was also observed that only part of the available cobalt is oxidized at temperatures below 180°C. This is possibly due to the release and subsequent oxidation of an inter-granular cobalt species (14).

A model has been developed to analyze the kinetics of CoO film formation on the cobalt-hardened gold electroplate. Fick's second law was employed to derive a model for parabolic film growth on a dilute two-component noble metal alloy. Solutions of this equation show that the infinite sink model (that is, when all the oxidized species is oxidized as soon as it arrives at the surface or when $C = 0$ at the interface) is a special case of this more general model. In general, film growth is found to depend on both the diffusion of cobalt out of hard gold and the oxidation rate of cobalt. This model allows one to compute k_c/D if $C(0, t)$, C_B, and C_0 are known by experimental measurements.

Kinetic data for CoO formation on hard gold were analyzed using this model in the limit of $C = 0$ at the interface (infinite sink) for a parabolic film growth model. Data were shown to fit the parabolic growth model and, using this model, the diffusion coefficient of Co in Au was calculated. D ranges from $\sim 1 \times 10^{-13}$ to $\sim 3 \times 10^{-18}$ cm²/sec for 180° to 100°C, respectively. The activation energy for cobalt diffusion out of gold was calculated to be 1.83 eV. This calculation was made by using the slopes of the x_f *vs.* $t^{1/2}$ data, and hence, is independent of an absolute knowledge of film thickness. A finite model is presently being developed by S. P. Sharma and the author (15). D was also computed using Tompkin's empirical equation and was shown to agree closely with this model.

Acknowledgments

The author is indebted to Mr. G. Pigg for supplying the hard-gold samples used in this study. He also wishes to thank E. T. Ratliff, and especially L. L. Hines, for their technical assistance and F. E. Bader for his comments regarding this manuscript. The efforts of and numerous enlightening discussions with S. P. Sharma concerning the development of the model are most gratefully acknowledged.

Manuscript submitted Oct. 14, 1977; revised manuscript received Jan. 3, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by Bell Laboratories.

Properties of Al_2O_3 Films Deposited from the $AlCl_3$, CO_2, and H_2 System

V. J. Silvestri,* C. M. Osburn,* and D. W. Ormond*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Films of aluminum oxide (Al_2O_3) have been deposited in a hot-walled chemical vapor deposition reactor using $AlCl_3$, CO_2, and H_2 gas. The deposition rate and film properties such as structure, composition, index of refraction, dielectric strength, and electrical conductivity were evaluated as a function of deposition temperature and gas input rates. Although the dielectric strength increased with decreasing grain size, the electrical conductivity was better correlated to deposition temperature than to grain size. Conditions were determined to optimize the dielectric strength of films grown in the temperature range 700°-900°C. Depending on the exact conditions, the deposition rate could be limited by either the $AlCl_3$ or the CO_2 input rate.

The initial use of gas phase hydrolysis of $SiCl_4$ with a mixture of H_2 and CO_2 gases to form SiO_2 was demonstrated by Steinmaier and Bloem (1) and Tung and Caffrey (2). Following this and using $AlCl_3$ instead of $SiCl_4$, polycrystalline films of Al_2O_3 have been deposited by a number of investigators (3-6). The most recent and extensive of these studies is that of Iida and Tsujide (6) and Kamoshida *et al.* (7-9) who studied films over a temperature range of 400°-1000°C. The dielectric properties of films using this process have also been reported (10-13). In general electrical properties were evaluated for films deposited using a fixed gas composition. This present study has made an effort to: (*i*) characterize deposition rates over a large range of system parameter changes (temperature, CO_2 and $AlCl_3$ input partial pressures); (*ii*) evaluate

* Electrochemical Society Active Member.
Key words: insulator, current, ellipsometry, CVD.

how these process variables can alter film properties such as structure, composition, index of refraction, dielectric strength, and electrical conductivity; and (*iii*) correlate the observed electrical properties with the structure of the films.

Experimental

The Al_2O_3 films were grown by chemical vapor deposition employing gas mixtures of $AlCl_3$, H_2, and CO_2 in a nitrogen carrier gas. The deposition took place in a resistance-heated, double-wall quartz tube. The inner tube was 100 cm in length and 5 cm in diameter. The $AlCl_3$-N_2 and H_2-CO_2-N_2 gas mixtures were introduced through separate lines into the reaction tube. There they could mix over a heated furnace length of 53.3 cm prior to the deposition zone. The Al_2O_3 was generally deposited on 2 Ω-cm, p-type Si wafers oriented in the <100>. Characteristically six 3.2 cm diam Si substrates were loaded horizontally along a holder for a film deposition. Details of the experimental systems have been reported elsewhere (14). In the present investigation the experimental parameters varied and their ranges were: substrate temperature (T_S), 730°-915°C; $AlCl_3$ input rate in moles per minute (n_{AlCl_3}/min) from 2.4×10^{-4} to 1.1×10^{-3}; and CO_2 input rate in moles per minute (n_{CO_2}/min) from 3.9×10^{-4} to 6.2×10^{-2}. The $AlCl_3$ input rates were varied by changing the temperature of the $AlCl_3$ evaporator over the range of 115°-130°C. The mole per minute input rate for CO_2 represents a range of flow of from 10-1500 cm^3/min. The nitrogen main carrier gas flow (f_{N_2}) was maintained at 15.2 liters/min for all experiments, and the flow of hydrogen (f_{H_2}) was kept at 3.8 liters/min. The average linear gas stream velocity for a typical flow rate of 21.5 liters/min corresponded to 18.3 cm/sec calculated at room temperature.

The deposition rate data were taken for a fixed substrate holder position and were monitored by ellipsometrically measuring thickness for a fixed set of conditions. The best thickness uniformity, for the six wafers along the substrate holder, was obtained when the temperature gradient was such that there was a 4°C increase from the center of the first wafer on the upstream side to the center of the last wafer, a distance of 15.2 cm. With such a gradient and a flow rate of 21.5 liters/min, film thicknesses could be kept to within ± 3% over 80% of the area of all six wafers. These results were reproducible to within ± 2% from run to run. If over a series of runs (40-50) the total change (decrease in growth rate) approached 8%, the $AlCl_3$ source was replenished.

Since the $AlCl_3$ source was not always at equilibrium at the carrier gas flows used here, separate experiments were carried out to determine the $AlCl_3$ output in moles per minute for the temperatures and evaporator flows most commonly used. The $AlCl_3$ output was gravimetrically measured by trapping the effluent $AlCl_3$ in a series of cold traps at Dry Ice temperatures for each flow and evaporator temperature of interest.

Several other samples were prepared in separate experiments by Zirinsky (15) of our laboratory using an $AlBr_3$ source with NO and H_2 to deposit films on substrates heated with an rf susceptor.

Film thickness and index of refraction were measured using ellipsometry (14, 16). Film structure was evaluated using transmission electron microscopy (TEM) and low angle x-ray diffraction as described earlier (17, 18). Composition data came from microprobe analysis (14).

The dielectric strength of the films was measured on aluminum-Al_2O_3-Si capacitor structures; typically the capacitor area was 5×10^{-3} cm^2. A linearly varying voltage ramp was applied to a capacitor and the current monitored with an electrometer. The breakdown voltage was recorded when the current jumped to a very high level signifying a shorted capacitor. Since defects (pinholes or particulate inclusions) can lower the breakdown voltage, many capacitors (typically 25) were broken down and the maximum breakdown voltage was taken to be the dielectric strength of a defect free film. Because this dielectric strength varies with the ramp rate, a uniform rate of 0.1 mV/cm-sec was chosen for all measurements.

Results and Discussion

Deposition rate.—Deposition rate was found to be independent of deposition time for all experimental conditions employed and was evaluated as a function of substrate temperature (Fig. 1), CO_2 input rate (Fig. 2), $AlCl_3$ input rate (Fig. 3), and CO_2/$AlCl_3$ ratio (Fig. 4). In Fig. 1 a logarithmic plot of the deposition rate *vs.* $10/T$ (°K) results in a straight line relationship. Also plotted are the data of Doo and Tsang (5) and Iida and Tsujide (6) showing higher deposition rates. Presumably the differences between the present system hot-wall furnace and nitrogen carrier gas and the systems used earlier (rf heated susceptors and hydrogen carrier gas) contribute to the observed growth rate differences. Nevertheless, the activation energy for deposition, −22.8 kcal/mole, is in good agreement with that found by Doo and Tsang (5). The growth rate dependence on temperature is not believed to be associated with a surface rate limitation. Deposition rate data (not included here) show that growth rate is a linear function of flow rate$^{1/2}$. This data supports a mass transport model.

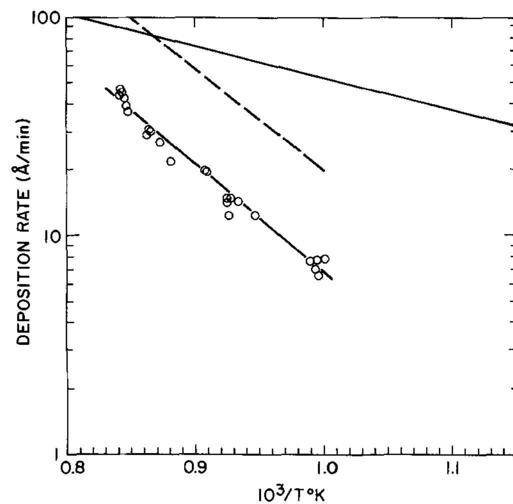

Fig. 1. Deposition rate as a function of substrate temperature, — Iida and Tsujide (6); -- Doo and Tsang (5); ○, present work, n_{AlCl_3}/min = 2.5×10^{-4}, n_{CO_2}/min = 3.85×10^{-3}, n_{H_2}/min = 0.17.

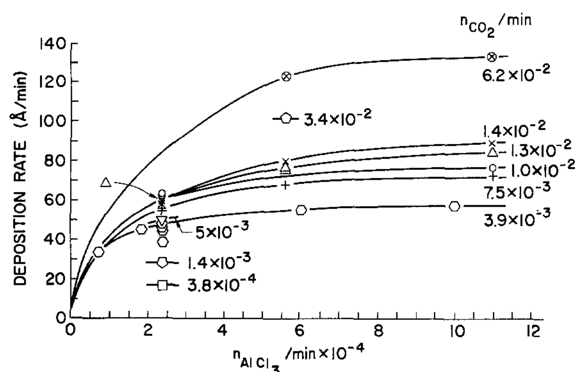

Fig. 3. Deposition rate at 914°C as a function of $AlCl_3$ input rate (in moles per minute) for various n_{CO_2}/min rates from the data taken from Fig. 2. Curve at $n_{CO_2} = 3.9 \times 10^{-3}$ is data obtained from experiments separate from Fig. 2.

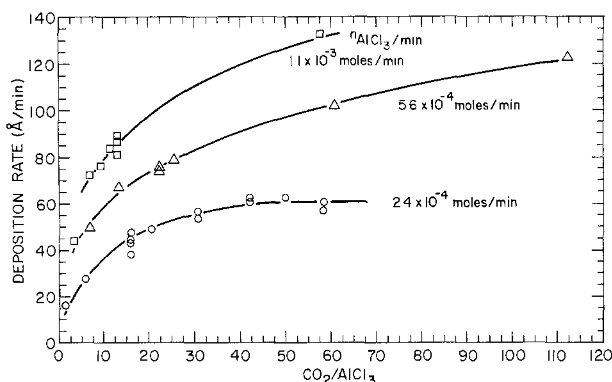

Fig. 4. Deposition rate vs. n_{CO_2}/n_{AlCl_3} ratio derived from Fig. 2

As plotted in Fig. 2 and 3 deposition rate at 914°C appears to be limited by either CO_2 or $AlCl_3$ input rates. In Fig. 2, the growth rate is independent of $AlCl_3$ input but increases steeply as the CO_2 input increases from 0-5 $\times$ 10^{-3} moles/min. When copious amounts of CO_2 are admitted, on the other hand, the deposition rate approaches a constant value determined by the $AlCl_3$ concentration. Similarly in Fig. 3 the data show that the growth rate increases steeply as $AlCl_3$ is admitted to the system but approaches a limit at high $AlCl_3$ flow rates. The data in Fig. 2 and 3 can also be plotted as a function of CO_2 and $AlCl_3$ mole fraction on log-log plots. Deposition rates for such plots show an increase as a function of increasing mole fraction on log-log plots. Deposition rates for $AlCl_3$, respectively. This would indicate a complex chemical system with more than a single rate-limiting step.

In a hot-wall system growth rate is very sensitive to position dependence and flow rate. It has been shown in previous work (14) that a characteristic decrease in growth rate is seen on substrates further

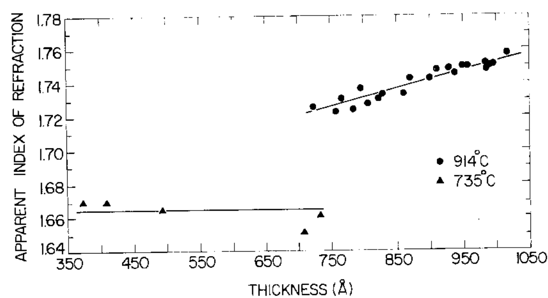

Fig. 5. Apparent index of refraction vs. thickness for films deposited at various temperatures.

downstream. The typical flow for the present experiments ~21.5 liters/min was chosen to keep this observed reduction in growth rate to a minimum over a considerable length (15.2 cm).

The reaction

$$H_2(g) + CO_2(g) = H_2O(g) + CO(g) \quad [1]$$

and the reaction.

$$2AlCl_3(g) + 3H_2O(g) = Al_2O_3(s) + 6HCl(g) \quad [2]$$

are believed to be operative. From thermodynamic

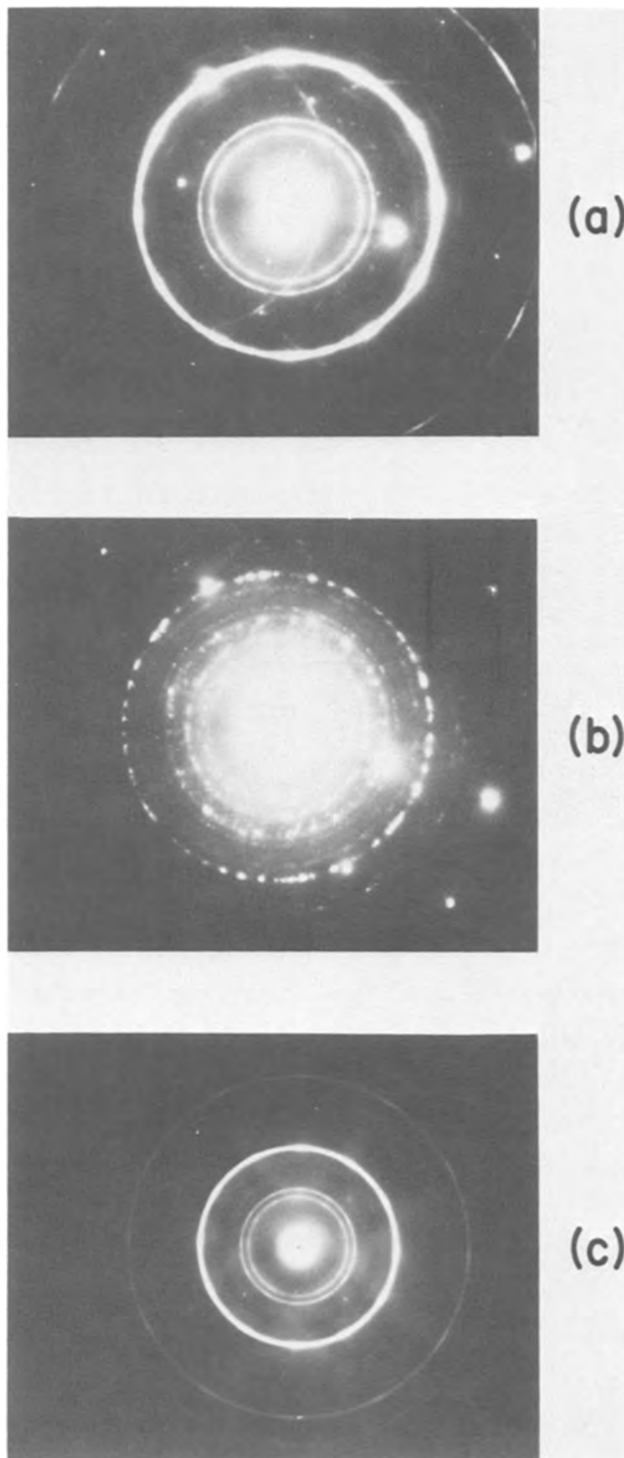

Fig. 6. Electron diffraction patterns: (a) film deposited at 915°C for conditions listed in Fig. 1; (b) film deposited at 808°C for conditions listed in Fig. 1; (c) film deposited at 914°C for n_{AlCl_3}/min $= 1 \times 10^{-3}$ and $CO_2/AlCl_3 = 10$ where maximum dielectric breakdown voltage was observed.

considerations alone, one can say that both reactions [1] and [2] would proceed to the right at 914°C. However, this argument would predict that the deposition rate at constant $AlCl_3$ input would saturate at CO_2/$AlCl_3$ ≈ 1.5. Considerably higher amounts of CO_2 are needed to saturate the reaction (see Fig. 4).

Index of refraction.—If the index of refraction was measured ellipsometrically assuming no absorption, the apparent index was observed to vary with film thickness at high substrate deposition temperatures (Fig 5). The films deposited at low temperature (~700°C) were transparent (*i.e.*, exhibited no haze when viewed with incident light and had an index of 1.665), whereas the high temperature films all exhibited haze to varying degrees and were most likely absorptive. Films grown at lower temperatures (735°C) have been shown to be amorphous by TEM (13) and low angle x-ray diffraction (14), while those grown at higher temperature (914°C) were polycrystalline. The apparent variations of index of refraction with thickness would thus appear to be associated with absorption of light by the polycrystalline films.

Composition.—An assessment of chlorine in films grown at temperatures from 730°-915°C was made using the electron microprobe. The chlorine content of films deposited at 805° and 732°C was 0.0015 and 0.008 weight fractions, respectively, and in agreement with earlier work (6). For films deposited above 900°C, the chlorine was below the detection limit of 0.0008 weight fraction. Carbon was not detected by microprobe analysis having a lower detection limit of 0.01 weight fraction.

Film structure.—The diffraction patterns for Al_2O_3 films grown under various conditions are shown in Fig. 6. Irene *et al.* (17) found the diffraction pattern to correspond most closely to the KI alumina phase described in Ref. (19, 20). Torkar and Krischner (20) attribute this phase to the presence of OH in the Al_2O_3 structure. Since these Al_2O_3 films are prepared in H_2O-rich ambients, the KI phase is most likely; however, it is not possible to unambiguously rule out α-alumina or γ-alumina. Using low angle diffraction techniques, Light *et al.* (18) characterized the films grown at 915°C as polycrystalline and probably γ-alumina having preferred orientation in the <111> direction when deposited on <100> Si surfaces.

Figure 7 shows the TEM grain structures of Al_2O_3 films deposited at different temperatures as well as under conditions giving the maximum dielectric breakdown voltage for the high temperature films. Films grown at low deposition temperatures (735°C) were found to be amorphous. The grain size of the film grown at 808°C appeared in general to be smaller that that found in the 915°C film, however, grain boundaries are not as clearly defined in the low temperature film. The grains in the 915°C film are in the range of 300-500Å.

Electrical properties.—The maximum dielectric strength of the Al_2O_3 films is given as a function of film deposition temperature in Fig. 8 where it can be seen that dielectric strength improves significantly with reduced temperature of growth. The data of Carnes and Duffy (21) and Zirinsky (15) are included for comparison. It is also of interest to note that the conductivity of the films varies with deposition temperature (Fig. 9). At a constant field, films grown at 735°C had 2-2.5 decades higher current density. Also shown in Fig. 8-9 are data from films deposited at 900°C by Zirinsky in a system employing an rf susceptor (cold-wall system) using H_2-NO-$AlBr_3$ gases. Even though the NO-$AlBr_3$, cold-wall sample had superior break-

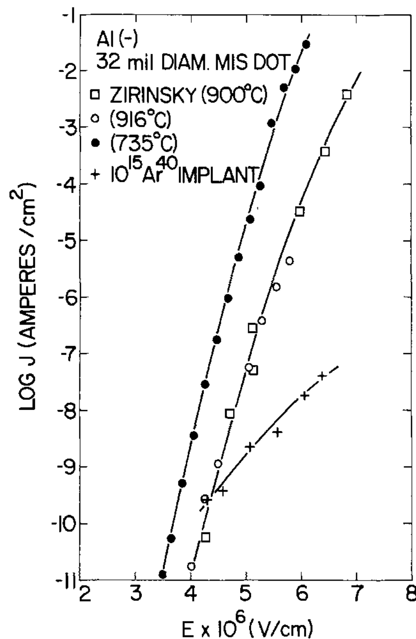

Fig. 9. Conductivity data for film grown under conditions in Fig. 1 compared to films grown using NO and $AlBr_3$, Zirinsky (15).

down strength (Fig. 8), it had the same conductivity. This improved breakdown for low temperature films could be related to the increased amorphous character of the films with reduced deposition temperature. Likewise, the improved breakdown observed for the 900°C sample grown using the NO-$AlBr_3$ process is believed to be related to reduced crystallite size since low angle x-ray techniques indicated that the NO grown films appear to have a similar grain size and more amorphous character than those films grown by the CO_2-$AlCl_3$ process at 808°C. For similar temperatures apparently, the cold-wall NO process tends to produce films having smaller grains and with more amorphous character in comparison to the hot-wall, CO_2 process.

The statistical distribution of breakdown voltage was found to be very dependent on wafer position on the susceptor (Fig. 10) and on the film thickness (Fig. 11). The second substrate in the series of six consistently had the highest breakdown strength (normalized to thickness) and tightest distribution of breakdown voltages. This same film was usually thicker than the preceding or following films. As Fig. 11 shows, thick films (>1000Å) had very tight distributions, while thin films (200Å) showed a bimodal breakdown distribution. While it could be speculated that this behavior is a result of breakdown at grain boundaries, direct substantiation is lacking.

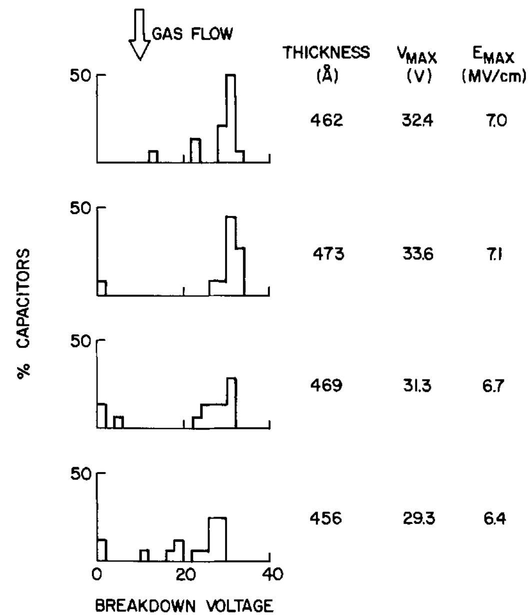

Fig. 10. Statistical distribution of breakdown voltage for different substrate positions in gas stream.

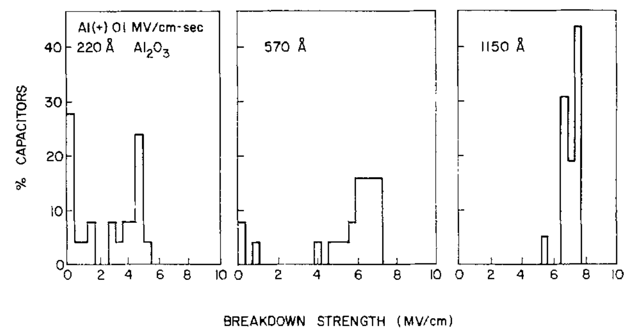

Fig. 11. Statistical distribution of breakdown voltage for different film thickness.

From Fig. 12 dielectric strength is found to be dependent on the ratio of CO_2 to $AlCl_3$ for each $AlCl_3$ source temperature. The optimization, however, does not relate to maximum growth rate (Fig. 4 and 13) but does occur at about 75 Å/min. Figures 7a and d compare the grain structure of two films grown at 915°C. The film in Fig. 7a was grown at $CO_2/AlCl_3$ = 16, had a 400Å grain size, and broke down at 6.5 mV/cm; the Fig. 7d film had 300Å grains, 7 mV/cm breakdown strength, and was deposited at 75 Å/min at $CO/AlCl_3$ of 10.

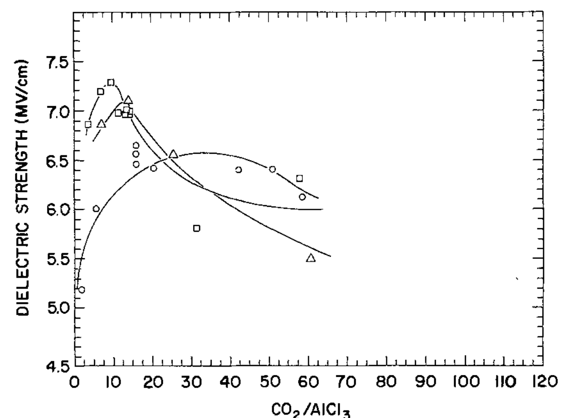

Fig. 12. Dielectric strength vs. $CO_2/AlCl_3$ for the films deposited under conditions in Fig. 2.

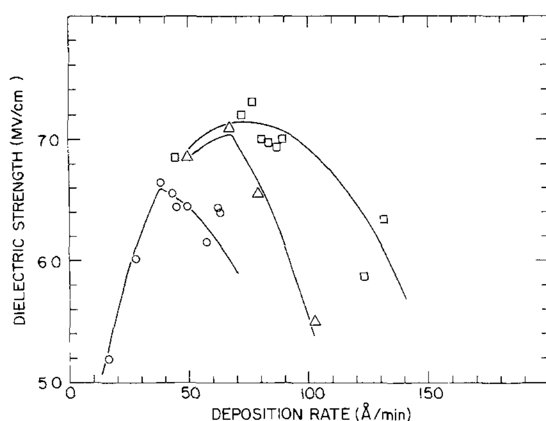

Fig. 13. Dielectric strength vs. deposition rate for the films in Fig. 2.

The general trend from the electrical-structure correlation studies is that films exhibit higher breakdown strengths with decreasing crystallite size. A comparison of these results with electrical properties and grain size observed for the AlN phase in the Al-O-N system (17) is also of interest. The data of Irene *et al.* (17) is summarized in Table I where it was also noted that dielectric breakdown increases with decrease in grain size. The maximum breakdown was observed at what was characterized as an amorphous film (<100Å grains). This finding is consistent with the present data found for Al_2O_3 (Fig. 8). The measured current density for the AlN case, however, decreases with decreasing grain size which is contrary to what is observed for Al_2O_3. It would appear that the conductivity of Al_2O_3 is more dependent on deposition temperature than on grain size possibly because of impurity content or stoichiometry.

In an attempt to make the structure more amorphous and thus improve the breakdown strength, Al_2O_3 films were implanted with argon or oxygen at 30 keV in doses 1-3 $\times$ $10^{15}/cm^2$. Although a profound decrease in conductivity resulted (Fig. 9), the breakdown voltage distribution was actually degraded.

Summary

A wide range of deposition conditions have been described for depositing Al_2O_3 films by the hydrolysis of $AlCl_3$ in the presence of CO_2 and H_2 using N_2 as a carrier gas. Deposition rate could be increased with increases of reactant partial pressures as well as temperature. Properties of the films such as index of refraction, impurity content, and crystallinity vary as these system parameters are changed. Films were decidedly polycrystalline at high deposition temperatures (~900°C) but were more amorphous with progressively lower deposition temperatures. Films deposited at lower temperature contained substantial Cl. Observed changes in electrical properties (dielectric breakdown and conductivity) have been correlated with both the gas composition used in depositing the films and the crystallinity of the films. The breakdown strength increased with decreasing grain size and deposition temperature but could be optimized at each temperature by proper choice of the deposition parameters.

Table I. Electrical properties and grain size for AlN phase (17)

Deposition temp (°C)	O content (atom %)	Grain size (A)	Dielectric breakdown (mV/cm)	Current (J) (A/cm^2) (2 mV/cm)
770	0	500	2.5	1×10^{-2}
770	8	250	3.2-6	1×10^{-6}
900	0	300	4.2	2×10^{-4}
900	20	<100*	8.0	1×10^{-8}

* Considered amorphous.

The Effect of Electrostriction on the Anodic Oxidation of Tungsten

J. L. Ord,* J. C. Clayton,[1] and K. Brudzewski[2]

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

Ellipsometry is used to measure the strain induced in the oxide film by the electric field during the anodic oxidation of tungsten. The strain is found to vary as the 5/3 power of the field and to equal 1% at a field of 5.25×10^6 V/cm under galvanostatic oxidation at 200 μA/cm^2. Open-circuit transient analysis is used to determine the dependence of the current density and the dielectric constant on the field in the oxide film. The current is found to be limited by an effective field proportional to the product of the field and the dielectric constant. The dielectric constant is found to vary linearly with field, decreasing by 45% between zero field and the oxidation field. The Clausius-Mossotti relation is used to relate the variation in the dielectric constant to the strain in the film, and the results of the open-circuit transient analysis are found to be in very good agreement with the ellipsometric measurements of strain. It is concluded that field-induced strain in the oxide film has a strong effect on its dielectric constant, and through it on the effective field which controls the anodic oxidation process.

In a previous paper (1), we reported a field dependence of the dielectric constant during the anodic oxidation of tantalum, niobium, and tungsten, and used an effective-field model to relate it to the field dependence of the ionic current density. Ellipsometry was used to measure the strains induced in the oxide films by changes in field, and the associated changes in the low and high frequency dielectric constants were found to agree reasonably well with values predicted using the Clausius-Mossotti relation between dielectric constant and density. By assuming log (i) proportional to an effective field, we found that the field dependence of the dielectric constant could account fairly well for the curvature in the dependence of log (i) on E for the anodic oxidation of tantalum (2) and niobium (3). We were unable to test an effective field model for tungsten because no attempt had been made to measure log (i)-E curvature. We have now developed a technique for determining log (i)-E curvature from the analysis of open-circuit transients (4), and we apply this technique here to the anodic oxidation of tungsten.

More recently, Young and co-workers found that the field induces anisotropy in the anodic oxides of tantalum (5) and niobium (6), and carried out an anisotropic analysis of their optical data. Their values for the sign and magnitude of the strains and index changes agreed reasonably well with the results of our earlier work which used isotropic optical analysis. They varied the field over a wider range than we had used and found a quadratic field dependence instead of the linear dependence we had reported. More recent work in our laboratory (7) confirms the optical anisotropy of the anodic oxide of niobium, but not the quadratic field dependence, and concludes that relaxation processes complicate attempts to determine the field dependence. Studies on tantalum film capacitors (8, 9) found a complicated field dependence in that system also and reported a dependence of the results on the history of the sample, thus confirming the important role of relaxation processes.

Although tungsten oxide exhibits larger field-induced strains than do the oxides of tantalum and niobium, it is a more difficult system to study in sulfuric acid electrolyte because breakdown occurs at a relatively low potential, restricting the thickness range available for optical analysis, and film dissolution tends to mask field-induced thickness changes. In this study we use both sulfuric acid and the acetic acid electrolyte used by Keil and Salomon (10) to study the anodization of vanadium. Tungsten oxide does not dissolve in this electrolyte, and a wide range of film thickness can be studied, but one must be alert to the possibility of undesirable side effects. In some systems, organic electrolyte inclusions modify the dielectric properties of the outer portion of the oxide film, and effects of this type have been used (7, 11) as evidence to support an effective field model for ionic conduction in oxide films. In the case of tungsten oxide, the extensive work on electrochromism has shown the properties of the film to be highly sensitive to variations in its composition and structure (12). It has been claimed, on the basis of ellipsometric measurements (13), that even the anodic oxide formed on tungsten in dilute sulfuric acid is made up of two layers of approximately equal thickness but with refractive indexes which differ by 5%.

Experimental

The self-nulling ellipsometer used for the optical measurements has been described in detail elsewhere (14, 15). It uses a helium-neon laser for a light source, and the refractive index values we report here are for the helium-neon laser wavelength, 6328Å. In the configuration used for this study, the instrument has a resolution of 0.01°, and under favorable optical conditions its nulling time is less than 1 sec. A hollow equilateral glass prism is used as a cell and requires that the angle of incidence be set at 60°. The cell has standard-taper joints for mounting the electrode holder, a platinum counterelectrode, a mercurous sulfate reference electrode, and a gas dispersion tube used for saturating the electrolyte with argon. All measurements were made at room temperature, 22°C, and values given for the potential of the tungsten working electrode are relative to the reference electrode. In the experiments in acetic acid electrolyte, the mercurous sulfate reference electrode is replaced by a platinum wire. This has some effect on the potential values, but the resistance of the acetic acid electrolyte has a much greater effect. With our cell geometry, the correction for electrolyte resistance may be as large as 3V.

Key words: electrostriction, ellipsometry, tungsten, oxidation, oxide film, Tafel slope.

The tungsten working electrode is a cylindrical single crystal with a flat on one side for optical measurements. It is clamped between Teflon washers in the electrode holder and is mounted in the cell with its axis vertical, exposing an area of 1.25 cm^2 to the electrolyte. The optical surface is prepared by several stages of diamond polishing followed by an electropolish in sodium hydroxide. For all of the experiments reported here, the final surface preparation consists of immersion in dilute sodium hydroxide to dissolve the oxide film formed in a previous experiment. The sample is repolished only after oxidation to high potential in acetic acid electrolyte, and after polishing it is cycled several times before use in another experiment. The sulfuric acid electrolyte is 0.1M, and the acetic acid electrolyte is 2.0M in water, and 0.02M in sodium borate.

The circuitry used with the cell is operated by a HP 2114B minicomputer through D/A and A/D converters which enable currents to be set and potentials to be read under program control. At one second intervals the computer records time, potential, current density, and the null settings of the polarizer and analyzer prisms of the ellipsometer, and at 20 sec intervals it writes the accumulated data onto magnetic tape. In extended experiments, the time interval between readings is usually lengthened in order to reduce the total number of data points recorded. The computer can also apply and record open-circuit transients at specified intervals under program control. The way in which this is done is described in detail elsewhere (4).

Results

Ellipsometric measurements.—The first experiments were designed to see whether the range of oxide film thickness could be extended by using acetic acid electrolyte in place of sulfuric acid electrolyte. The results of one such experiment, performed at a current density of 200 $\mu A/cm^2$, are plotted in Fig. 1. Potential is plotted *vs.* time in the lower portion of the figure, and the null settings of the polarizer and analyzer prisms of the ellipsometer, *P* and *A*, are plotted one *vs.* the other in the upper portion of the figure. Initially potential rises linearly with time, and the optical data fall on the closed loop in the *P-A* plane. This result is similar to the result obtained in sulfuric acid, and the film grown in this region has the same refractive index as the film grown in sulfuric acid. At the end of the linear region, the film thickness is little different from the film thickness at breakdown in sulfuric acid.

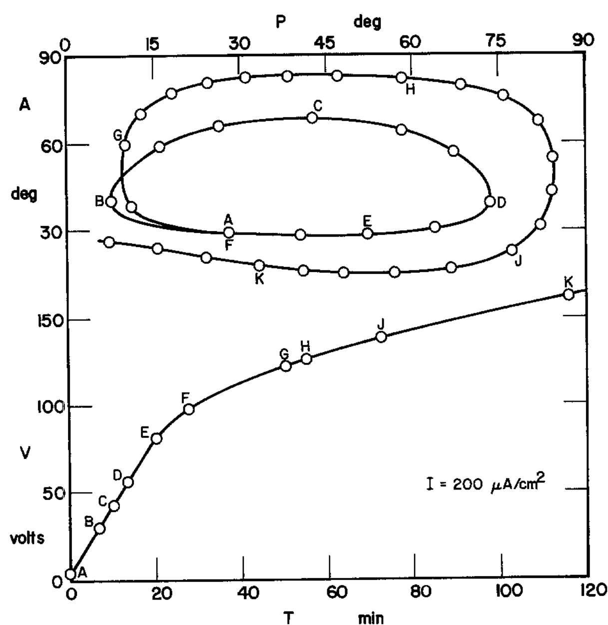

Fig. 1. Anodic oxidation of tungsten in acetic acid electrolyte at 200 $\mu A/cm^2$. Corresponding points are labeled A through K on the potential-time plot in the lower portion of the figure, and on the *P-A* plot of the optical data in the upper portion.

Under continued oxidation, the increase in potential becomes progressively slower, and the optical data begin to spiral outward in the *P-A* plane. In addition, the surface begins to scatter light diffusely as if it were roughening on a very fine scale, and the potential transients observed on changing the current density exhibit greatly enhanced overshoot. Scanning electron microscopy detects the formation of shallow pits on the order of 1 μm in diameter in this region, but Auger spectroscopy finds no sign of the electrolyte inclusion expected in a porous oxide or a duplex film. Clearly, both the film growth process and the structure of the film itself are different in this region, and hence optical measurements which extend into this region will be of no help in analyzing the anisotropy of the film grown in the initial region. We must, therefore, make an assumption about the degree of anisotropy of the oxide film in order to carry out our optical analysis. Wang (7) found that changes in the refractive index in the field direction were twice as large as those transverse to the field for niobium oxide, and we will assume that this is the case for tungsten oxide also.

Analysis of the first loop optical data in Fig. 1 using this assumption gives $n_z = 2.1144$ in the field direction, and $n_x = n_y = 2.1450$ transverse to the field with the oxidation field applied. At zero field the film is isotropic with a refractive index of $n = 2.1756$. The layer grows on a substrate of index $4.280 - 3.0781$ in a medium of index 1.375, and the initial film thickness is 16.5Å. Up to a potential of 65V, the field in the film at a current density of 200 $\mu A/cm^2$ is 5.25×10^6 V/cm, and when the first optical loop closes at point F, the oxide film is 1800Å thick. The results of this analysis differ little from the results of our earlier work which used isotropic analysis to calculate an index of 2.145 and a field of 5.2×10^6 V/cm at a current density of 200 $\mu A/cm^2$ in sulfuric acid electrolyte. Our results do not agree with the recent ellipsometric measurements of Sarakinos and Spyridelis performed at an angle of incidence of 60° and a wavelength of 5461Å in a medium of refractive index 1.333 (13). Under their optical conditions, they expect their first loop to close at a thickness of under 1500Å, but they find that their experimental data fall somewhat outside the loop at this point, then swing in toward the loop but do not cross it before breakdown. They analyze this behavior in detail and conclude that the anodic film is made up of two component layers of approximately equal thickness but with refractive indexes which differ by 5%. We often obtain optical data of this type as we condition a diamond-polished optical surface for electrochemical measurements by alternate anodic oxidation and oxide film dissolution. We follow the oxidation cycles optically and use closure of the first optical loop (at 1800Å under our conditions) as an indicator that the surface is ready for electrochemical measurements. We do not think that the suggestion that a duplex film forms on tungsten in sulfuric acid electrolyte merits serious consideration.

Although the useful range of oxide film thickness is no greater in acetic acid than in sulfuric acid, the oxide film does not dissolve in acetic acid, and this simplifies considerably the analysis of optical data in field-switching experiments. The results of a typical field-switching experiment performed in sulfuric acid electrolyte are plotted in Fig. 2, the potential-time plot in the lower portion of the figure and corresponding *P-A* plot in the upper portion. The algorithm which applies the transient reduces the overpotential at 60 sec intervals by 7/32nds of its initial value, and does this four times before reversing the stepping direction, then finally reapplying the original oxidation

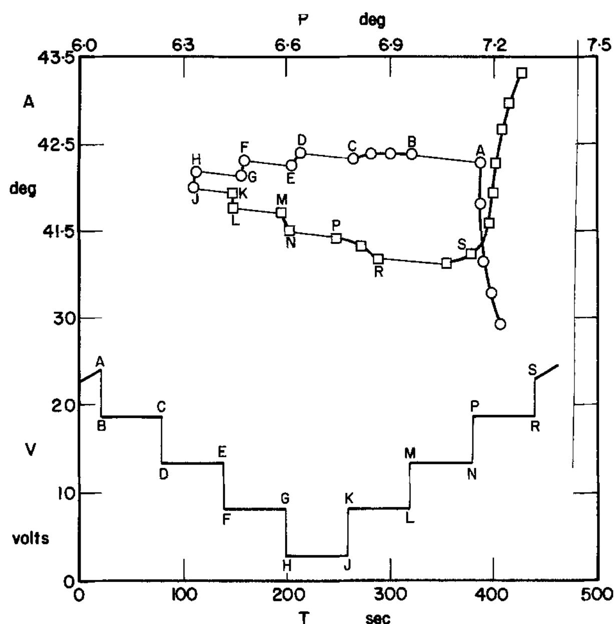

Fig. 2. Field switching experiment during the anodic oxidation of tungsten in sulfuric acid electrolyte at 200 $\mu A/cm^2$. The optical data fall in the region of point B in Fig. 1.

current density at point S. In sulfuric acid electrolyte this switching sequence provides optical data at the same set of electric field values independent of the initial potential or film thickness, but in acetic acid the resistive voltage drop in the electrolyte complicates matters somewhat. Ideally, one would like to perform this switching sequence at points B, C, and D based on the assumption that $\Delta n_z/\Delta n_x = 2$. The experiment plotted in Fig. 2 was performed in the region of point B in Fig. 1, and the scales used to plot the optical data in the upper portion of the figure are greatly expanded over the scales used in Fig. 1. The pattern traced out by the optical data, although somewhat complicated, shows up clearly in this figure because the layer dissolution which occurs in sulfuric acid displaces the data recorded on switching the field back up so that they do not overlap the data recorded on switching the field down. As the data recorded before and after the switching transient indicate, film growth at constant index displaces the optical data almost vertically upward in the figure, and the extent of film dissolution during the switching transient can be calculated from the amount that point S lies below point A. Interpretation of the lateral displacements in the optical data which occur when the potential is switched is more difficult because although vertical displacements are due to changes in film thickness only, lateral displacements involve changes both in film index and in film thickness. At the three lowest field values, the switching produces a sudden lateral shift which involves a change in film index and in film thickness, followed by a slow downward shift as the film dissolves at essentially zero applied current density. In regions BC and PR, a slow lateral shift continues after the rapid shift observed on changing the field. The lateral shifts from A to B and from R to S are consistent with what one would extrapolate from the rest of the data, but the additional lateral displacements from B to C and from P to R appear to be due to a relaxation process which requires charge transport. Regions BC and PR differ from the other constant potential regions in that they are the only ones during which there is appreciable current flow. It is likely that the relaxation process observed here is the same one which is responsible for the overshoot in the potential when the current density is changed suddenly from one value to another. Since our aim in this paper is to study field-dependent processes rather than relaxation processes, we base our analysis on data taken either at low current density or at times short compared to the relaxation time.

The data used in the quantitative optical analysis of the field dependence were obtained in acetic acid electrolyte by applying the field switching sequence from Fig. 2 at points B, C, and D at the extremes of the first optical loop in Fig. 1. The results obtained from the field-switching sequence applied at point C at the top of the optical loop are plotted in Fig. 3 using the same lettering scheme for the switching sequence as was used in Fig. 2. Theoretical curves for an anisotropic analysis based on a zero field isotropic index of 2.1756 and a $\Delta n_z/\Delta n_x$ ratio of 2 are superimposed on the data. Although the experiment was performed in a different optical region, the data exhibit the same general characteristics as the optical data in Fig. 2, except that there is no evidence of film dissolution, and the relaxation process appears more pronounced along BC and less so along PR than in Fig. 2. (The apparent difference in the relaxation process is largely due to an increase in the field in region BC in acetic acid due to a change in the resistive voltage drop in the electrolyte and to an increase in the field in region PR in sulfuric acid due to film dissolution.)

The data obtained as the field is switched down from C to H and back up from J to P fall on a single line on the P-A plot in Fig. 3. The fact that the line is inclined to both the constant index and constant thickness theoretical curves shows that both thickness and index change with field. The thickness change, a full 5Å, can be read directly in the figure. The constant index curves intermediate between the isotropic $n = 2.1756$ curve and the $n_z = 2.1154$ curve are fitted to the average of the down and up switching data at each field step, and correspond to n_z values of 2.1743, 2.1674, 2.1589, and 2.1548 reading from top to bottom in the figure. The form of the field dependence can be determined by plotting the change in n_z from its isotropic values as a function of field, and this is done in Fig. 4. The curve in the figure is a power law, E^p, fitted to the first four points. The best fit is obtained with this form of field dependence for $p = 1.67$. The deviation of the fifth point from the curve fitted to the first four is due to the optical shift associated with the relaxation process, and the fact that the field increment between the fourth and fifth points is smaller than the other increments is due to the voltage drop in the electrolyte at a current density of 200 $\mu A/cm^2$. The value used in Fig. 3 for the isotropic index at zero

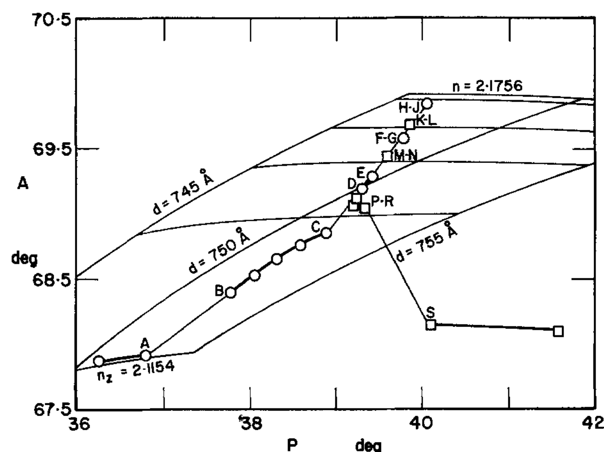

Fig. 3. Field switching experiment during the anodic oxidation of tungsten in acetic acid electrolyte at 200 $\mu A/cm^2$. The field-switching sequence from Fig. 2 was applied in the region of point C in Fig. 1. The theoretical thickness and index curves are for a film which is isotropic at zero field and whose index changes twice as much in the field direction as in the transverse direction when the field is applied.

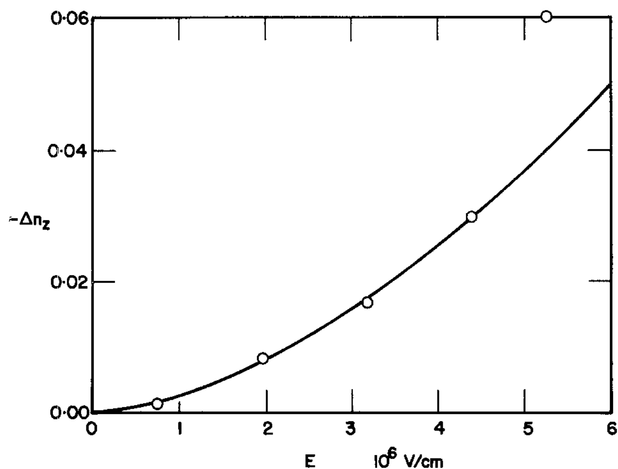

Fig. 4. The field dependence of Δn_z determined from the experiment plotted in Fig. 3. The plotted points correspond to the constant index curves in Fig. 3. The first 4 points fit a 5/3-power dependence on field, and the 5th point shows an offset due to a relaxation process (BC in Fig. 3).

field was obtained by extrapolating the field dependence plotted in Fig. 4 to zero field.

The optical analysis shown in Fig. 3 is consistent with the optical analysis of a switching experiment performed at point B in Fig. 1. When we say the analyses are consistent, we mean that all refractive index values agree and that thickness changes exhibit the proportionality to film thickness required to give a relation between field and strain which is independent of film thickness. The left end of the optical loop is probably the best place to perform field-switching experiments because the angle between constant-index curves and constant-thickness curves is greatest in this region, and although the over-all magnitude of the shift in the optical data is less than at the top of the loop, the null sensitivity is considerably better. At the right end of the first optical loop where the sensitivity to thickness and index changes is not as good, we do not get a consistent analysis, but we do not know whether this is due to the low sensitivity, or whether is is an early indication of breakdown.

Open-circuit transient measurements.—Open-circuit transients can be used to determine the dependence of current density on potential during anodic oxidation. We will only outline the steps involved in the analysis here, and we refer the reader elsewhere (4) for a detailed description of the experimental technique, methods of analysis, and effects of log (i)-E curvature. In the high overpotential region, the relation between current density and potential for an activation-controlled process can be written

$$i = i_o \exp((V - V^*)/V_o) \qquad [1]$$

where V^* is the zero of overpotential, i_o is the exchange current density, and V_o is the Tafel slope defined in terms of natural logarithms. If the applied current to the electrode is interrupted, the decay of overpotential across the oxide film will be governed by the relation

$$C\,dV/dt = -\,i_o \exp((V - V^*)/V_o) \qquad [2]$$

provided that the capacitance of the oxide film, C, is constant over the transient. This equation may be integrated under the condition that $i = i_1$ and $V = V_1$ when the circuit is opened at $t = 0$, to give

$$V = V_1 - V_o \ln(1 + t/T) \qquad [3]$$

where $T = CV_o/i_1$. Equation [3] can be fitted to V-t data by varying T to minimize the standard deviation in V given by least squares analysis. V_o and $1/C$ are determined directly by this analysis, and i_o and V^* can be determined from measurements at different film thicknesses if the current density is limited by the electric field in the oxide film.

The analysis of a transient produced by opening the circuit at a potential of 18V during the anodic oxidation of tungsten in sulfuric acid electrolyte at a current density of 200 μA/cm^2 is shown is shown in Fig. 5. In the lower portion of the figure the V-t data are plotted along with the least squares fitted line for $T = 4.3$ msec, the value which minimizes the standard deviation in V. The least squares analysis gives $V_o = 1.728$V and $1/C = 2.01$ cm^2/μF. In the upper portion of Fig. 5 we plot the deviation of the data from the fitted line on a 20 times expanded scale. This plot shows that the 33 mV standard deviation is systematic rather than random, and that the data exhibit very little real scatter.

Figure 6 shows the V_o and $1/C$ data obtained by analysis of sequences of open-circuit transients ap-

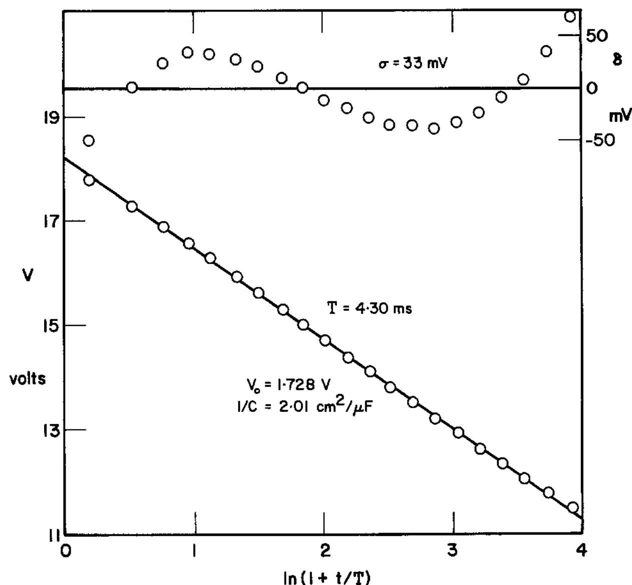

Fig. 5. Analysis of an open-circuit transient applied at a potential of 18V during the anodic oxidation of tungsten in sulfuric acid at a current density of 200 μA/cm^2. The deviation of the data from the least squares fitted line is shown on a 20-times expanded scale in the upper portion of the figure.

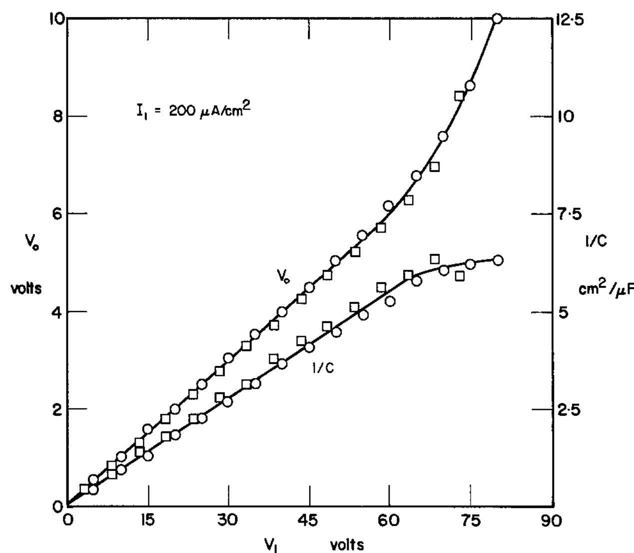

Fig. 6. Values of V_o and 1/C determined by the analysis of open-circuit transients applied at a sequence of potentials during the anodic oxidation of tungsten in acetic acid (squares) and sulfuric acid (circles) at a current density of 200 μA/cm^2.

plied during the anodic oxidation of tungsten at 200 $\mu A/cm^2$ in sulfuric and acetic acid electrolytes plotted as a function of V_1, the potential at which the transient was applied. In order to make the data obtained in the two electrolytes more readily comparable, the V_1 values in acetic acid were corrected for the iR drop in the electrolyte (approximately 2V), but not for the pH difference between the electrolytes. This plot can be used in many ways: It enables us to compare the electrochemical characteristics of oxide films formed in the two electrolytes, to determine whether or not the conduction process is controlled by the field in the film, to detect points at which the nature of the conduction process changes, and to determine the parameters i_o and V^* which cannot be determined by the analysis of a single transient.

There appears to be no significant difference in the electrochemical characteristics of the films formed in the two electrolytes. The small differences between $1/C$ values may be due to analysis problems associated with the iR correction in acetic acid, or, because capacitance is an area-dependent parameter, a difference in the roughness of the sample surface between the two runs. From the fact that the films have the same refractive index and the same electrochemical characteristics, we conclude that the same oxide film forms in the two electrolytes. The lower solubility of the oxide film in acetic acid makes it the preferred electrolyte for sensitive optical measurements, but the lower electrolyte resistance makes sulfuric acid the preferred electrolyte for second-order analysis of open-circuit transients.

The linear dependences of V_o and $1/C$ on V_1 below 60V are characteristic of a process controlled by the electric field in the oxide film. This could be demonstrated equally well by plotting V_o and $1/C$ *vs.* the oxide film thickness determined by ellipsometry, but the form of plot used in Fig. 6 has the advantage that V^*, the zero of overpotential, appears as a point on the graph, and the potential at which the conduction process begins to change can be read directly. For an ideal field-limited process, V^* is given by the common V_o and $1/C$ intercepts on the V_1 axis. For the sulfuric acid data in Fig. 6, the V_1 intercepts of least squares lines fitted to the V_o and $1/C$ data, -0.335 and -0.633V, respectively, are in close agreement. The curvature in the V_o and $1/C$ data above 60V in both electrolytes indicates a change in the conduction process, and we interpret this change as the earliest indicator of film breakdown. This result supports the conclusion we drew from the optical data that although the postbreakdown film-growth processes may differ, the film breaks down at the same potential in the two electrolytes. The restricted potential range available for study poses no problem for open-circuit transient measurements, so we restrict our second-order analysis to transients with V_1 values below 20V to be well clear of any breakdown effects.

The second-order analysis is based on three postulates: (*i*) The logarithm of the ionic current density is linearly dependent on the effective field in the oxide film, (*ii*) the effective field is proportional to the product of the applied field and the dielectric constant of the film, and (*iii*) the dielectric constant of the film depends on the electric field in the film. Under these postulates, the differential equation of a transient can be put into the same form as Eq. [2] by transforming to the variable U defined by

$$U = (V - V^*)K/K_1 \qquad [4]$$

where K is the dielectric constant of the oxide film, and K_1 is its value at the oxidation field, 5.25×10^6 V/cm. The differential equation of the transient is then

$$C_1\, dU/dt = -\, i_o \exp (U/V_o) \qquad [5]$$

where C_1 is the value of the capacitance at the oxidation field. The procedure for fitting a transient is similar to the first-order procedure except that an additional step is required to specify the field-dependence of the dielectric constant. In this study we assume a power-law dependence of K on E which, written in terms of potential, has the form

$$K = K_o(1 - \gamma_n((V - V^*)/(V_1 - V^*))^n) \qquad [6]$$

where K_o is the zero-field value of K, and γ_n is the fraction by which the dielectric constant decreases on going from zero field to the oxidation field. This form has the computational advantage that γ_n is dimensionless, but the value of γ_n does depend on the oxidation field. In fitting transients, we set n equal to 1 or 2, choose a value for γ_n, fit the transient by the first-order procedure, then repeat the process for other values of γ_n. We then test the effectiveness of the second-order analysis and find the best-fit value for γ_n by plotting σ, the standard deviation of the potential data from the fitted line, as a function of γ_n. This is done in Fig. 7 for second-order analysis of the transient plotted in Fig. 5. Standard deviation curves are shown for assumed linear and quadratic dependences of K on E, both of which intersect the σ-axis at the first-order value, 33 mV. The quadratic dependence gives a simple minimum at $\gamma_2 = 0.238$, but the linear dependence gives a relative minimum just below the very sharp absolute minimum at $\gamma_1 = 0.441$. At $\gamma_2 = 0.238$, σ is reduced by a factor of 6 from its first-order value, whereas at $\gamma_1 = 0.441$ the reduction factor is 25. The 1.3 mV standard deviation at $\gamma_1 = 0.441$ is really quite remarkable in view of the fact that the A/D converter has a least-significant bit of 5 mV. Our recording technique makes it theoretically possible to achieve such low values of σ provided the signal is noise-free, the A/D converter is highly linear, and the functional dependence of V on t is known precisely, but it is very unusual to meet all of these conditions in practice. When studying the anodic oxidation of tantalum (4) we did not achieve such low values of σ, and we were unable to discriminate between a linear and a quadratic dependence of K on E. Here we conclude that a linear dependence of dielectric constant on field fits the data very well across the field region spanned by the open-circuit transient.

The expressions determined by first- and second-order analysis for the dependence of the current density on the field are displayed graphically on a plot of log (i) *vs.* E in Fig. 8. The first-order expression is a line which intersects the i-axis at $i_o = 4.18 \times 10^{-3}$ $\mu A/cm^2$, and the second-order expression is a curve

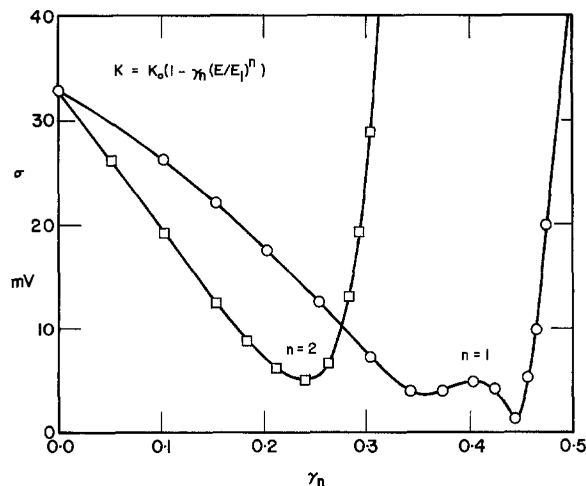

Fig. 7. Plot of σ, the standard deviation in V given by least squares analysis, as a function of γ_n, the field coefficient of the dielectric constant, for second-order analysis of the open-circuit transient from Fig. 5. At $\gamma_2 = 0.238$, $\sigma = 5.15$ mV, and at $\gamma_1 = 0.441$, $\sigma = 1.30$ mV.

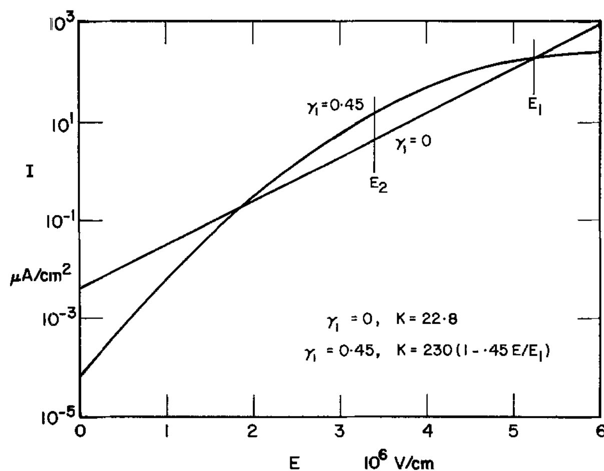

Fig. 8. Dependences of log (*i*) and *K* on field determined by first- and second-order open-circuit transient analysis. The expressions describe how log (*i*) and *K* respond as the field changes from an initial value of 5.25 × 10^6 V/cm under conditions where no relaxation takes place.

which intersects the i-axis at $i_o = 6.68 \times 10^{-5}$ μA/cm², and crosses the first-order line once at the oxidation field and again at lower field. (The value 0.45 for γ_1 comes from the analysis of a sequence of 10 transients, the final one of which is the transient with $\gamma_1 = 0.441$ plotted in Fig. 5.) The field region over which the open-circuit analysis was carried out is shown in the figure, and the plotted relations are seen to have substantially different average Tafel slopes across this region.

The first-order analysis gives a value of 22.8 for *K* independent of field, whereas the second-order analysis gives a value of 230 for *K* at zero field, decreasing to 127 at the oxidation field. The full order-of magnitude difference between the first- and second-order zero-field values for *K* may appear unreasonably large, but it is a direct consequence of the assumption that *K* depends on *E*. The capacitive discharge current involves two terms in second order

$$CdV/dt + (V - V^*)dC/dt = C_o(1 - 2\gamma_1)dV/dt \quad [7]$$

where C_o is the value of the capacitance at zero field. This equation predicts a value of $(1 - 2\gamma_1)$ for the ratio between the first- and second-order *K* values at zero field, and for $\gamma_1 = 0.45$ this is precisely an order of magnitude.

Discussion

The optical and open-circuit measurements give quite different results for the form and strength of the dependence of the dielectric constant on the field. Although the difference in the strength of the field dependence is not surprising in view of the difference in frequency, the difference in the form of the dependence does appear to be inconsistent. We can test the consistency of the two results if we assume that the changes in dielectric constant result from changes in density produced by field-induced strain in the film. This enables us to express the results of the two measurements in terms of a frequency-independent quantity, the strain in the film, but it does introduce one further assumption. In the case of the ellipsometric measurements, no assumption is needed to express the result in terms of strain: The analysis in Fig. 3 and 4 gives the field-dependence of the strain directly

$$\epsilon = 1.00 \times 10^{-2}(E/E_1)^{1.67} \quad [8]$$

where ϵ is the strain in the film and E_1 is the oxidation field, 5.25 × 10^6 V/cm.

The open-circuit result can be expressed in terms of strain if we use the Clausius-Mossotti relation to express the dependence of the dielectric constant on density

$$(K - 1)/(K + 2) = B\rho \quad [9]$$

where ρ is the density of the film and *B* is a constant. Although the applicability of the Clausius-Mossotti relation to anisotropic electrostrictive systems is certainly open to question, a recent series of papers suggests that Clausius-Mossotti theory can be extended to deal with the photoelastic behavior of anisotropic materials (16-19) If we attempt to test the applicability of the Clausius-Mossotti relation in our anisotropic optical analysis by using it to predict the change in refractive index which should result from the observed density change, we get a value which agrees well with the observed changes in n_x and n_y.

The Clausius-Mossotti relation predicts a much stronger effect of strain on the dielectric constant at low frequencies where the dielectric constant has a higher value. The form of the relation is such that the left side of Eq. [9] approaches a limiting value of 1 for large values of *K*. Near this limit, small variations in density can cause large fractional changes in *K*, and the relation between *K* and ϵ becomes nonlinear. It is this property of the Clausius-Mossotti relation which removes the apparent inconsistency between the results of the optical and open-circuit measurements. If we use the values $K_o = 230.67$ and $\gamma_1 = 0.4411$ which come from the second-order minimization plotted in Fig. 8, and use the Clausius-Mossotti relation to calculate the strain necessary to produce the field dependence of the dielectric constant, we obtain the relation

$$\epsilon = 5.71 \times 10^{-3}/(E_1/E - 0.437) \quad [10]$$

Equations [8] and [10] certainly use different functional forms to express the dependence of strain on field, but it must be remembered that the functional dependences are simply convenient ways of representing smooth curves through experimental results in a particular field region. Figure 9 shows a plot of the two functions *vs.* field. The optical data points are shown in the figure, as is the field region over which open-circuit transients are fitted.

The agreement between the two curves, particularly in the region where their fitting ranges overlap, is extraordinarily good; so good, in fact, that one hardly knows what to say about it. There are many steps involved in obtaining the curve in Fig. 9 from the initial table of 21 *V-t* values recorded during an open-circuit transient and it would be very easy to explain

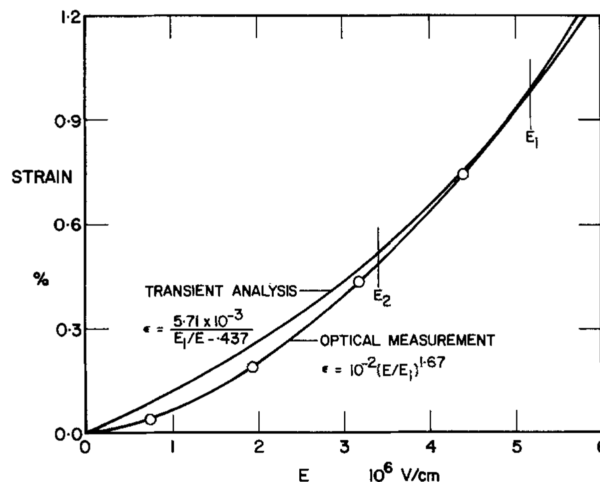

Fig. 9. The field dependence of the strain in the oxide film as determined by ellipsometry and as required by the Clausius-Mossotti relation to fit the dependence of *K* on *E* determined by second-order analysis of open-circuit transients. The curves become tangent near E_1 but do not cross.

away a discrepancy between the open-circuit and the optical results. The converse problem of what one can say about the many steps when there is no discrepancy in the final results is a challenging problem in inference. We regard Fig. 9 as a pivotal result which establishes the "physical" model as a quantitative theory which provides new insight into many of the phenomena associated with anodic oxidation. Fortunately the new insight suggests a wide variety of further experiments whose outcome will ultimately decide the fate of the theory.

There are two points which should be kept in mind when assessing the significance of Fig. 9. The first is the fact that the open-circuit analysis is primarily a technique for studying conductivity, not capacitance. This is true in second order as well as in first. Although the field dependence of the dielectric constant enters into both the capacitive discharge term on the left of Eq. [5] and the conductivity term on the right, the exponential dependence in the conductivity term dominates. Numerical integration of the equation shows that the capacitive term gives a second-order effect which is an order of magnitude smaller than that of the conductivity term and of the opposite sign. Hence the field dependence of the dielectric constant determined by the open-circuit measurements comes from the analysis of the conductivity, and the assumption that the conduction process is limited by an effective field KE is essential to the analysis.

It is also important to note that the curves in Fig. 9 describe the relation between field and strain in the absence of relaxation processes. The optical curve is fitted to data obtained at fields which are low enough that there is insufficient current to drive the relaxation process, and the open-circuit analysis is carried out over times short compared to the relaxation time. The plot of log (i) *vs.* E in Fig. 8 is subject to the same restriction: it describes the way log (i) responds when E is changed from an initial value of E_1 under conditions where no relaxation takes place. In the physical model, the relaxation process is a relaxation of stress in the film. Under steady growth at constant field, the continuous atomic rearrangement asociated with the ionic conduction and film growth processes makes it impossible for the film to support a shear stress. When the field is changed, stress is induced in the film, but this stress relaxes as the ionic current continues to flow. Unfortunately this mechanism does not allow for relaxation at zero field, and this greatly complicates the analysis of the system by the methods of continuum mechanics. It is our view that this is the reason we do not observe the quadratic dependence of strain on field predicted for electrostrictive systems in which the stress is zero at zero field.

Examination of Aluminum-Copper Films during the Galvanostatic Formation of Anodic Oxide

II. Rutherford Backscattering and Depth Profiling

H.-H. Strehblow,[1] C. M. Melliar-Smith,* and W. M. Augustyniak

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The anodization of evaporated aluminum/copper alloy films has been investigated using Rutherford backscattering. It has been shown that the copper, initially distributed uniformly through the aluminum film, is not incorporated in the anodic oxide but accumulated at the metal oxide interface. At high potentials this interface becomes rougher due to copper-rich inclusions which finally cause local film breakdown. An excess copper accumulation of about 1 atomic percent above average is distributed over 650Å of the metal phase and moves inward as the anodic oxide grows. This transport is explained by an enhanced diffusion of the copper through a disordered metal layer caused by the formation of the anodic oxide.

Rutherford backscattering is one of the best methods to obtain information about the elemental depth distribution near the surface of a material to a depth of about 1 μm. Studies have been made of anodic oxides on metals (1), the mobility of different implanted tracers in the high electric field of anodic films (2, 3), and their transfer from the metal to the oxide phase (4). This technique has been used to obtain additional information about the composition of vapor-deposited aluminum-copper films and their passivating oxides formed under galvanostatic conditions. The results have been used to explain some of the corrosion properties of these films.

Experimental

The anodization conditions and the electrochemical corrosion properties of the films have been already described in detail (5), and are only briefly described here. The aluminum/copper alloy films were deposited by electron beam evaporation and subsequently anodized in one of three buffer solutions: phthalate buffer, pH 5.0, 0.023M KHPhth + 0.027M K_2Phth; citrate buffer, pH 6.0, 0.1M; and borax buffer, pH 9.2, 0.1M. The as-deposited films showed a grain size of approximately 1000Å by transmission electron microscopy (5). Due to the small solid solubility of copper in aluminum (6), the copper is present as the θ-phase $CuAl_2$ and this phase could be detected by x-ray diffraction if the copper concentration exceeds 1 atomic percent (a/o) (7). The metal films were examined before and after galvanostatic anodization using Rutherford backscattering (8) from a 1.9 or 1.7 Me $_4He^+$ ion beam. The energy resolution of the detector was about 10 keV corresponding to an approximate 200Å depth resolution. The backscattered ions were collected by a solid-state detector at an angle of $\theta = 175°$ measured against the forward direction of the incident beam. Ion beam currents of 10 nA were used for the measurements.

Results

Figure 1 shows a spectrum for an Al-1.0% Cu (all copper concentrations are referred to as atomic percent) film on a quartz substrate before and after anodization in citrate buffer (pH = 6.0) with a current density of 1 mA/cm² to 100V. The parts of the spectra corresponding to scattering from the copper, aluminum, and oxygen in the film and oxygen in the quartz substrate are well resolved. The peaks at channel 160 for the anodized and at 180 for the original film are caused by the overlap of the energies of backscattered particles from the trailing edge of the aluminum film and the leading edge of the silicon in the quartz substrate. The overlap arises because the silicon atoms have only slightly higher mass than the aluminum atoms. This effect was not observed when sapphire was used as the substrate material. The position of the copper and aluminum high energy edges of the as-deposited films demonstrates that both metals are present at the surface. This was confirmed by taking the spectra of pure copper and pure aluminum specimens whose leading edges fall at these same energies.

The relative heights of the copper and aluminum plateaus in the spectra can be used to calculate values for the composition of the metal film. Taking the heights of the plateaus H_{Cu} and H_{Al} at the same energy separation from the leading edge one gets

$$\text{Cu}\ \% = \frac{H_{Cu}/(29)^2}{H_{Cu}/(29)^2 + H_{Al}/(13)^2} \qquad [1]$$

the relation containing a compensation for the fact that the Rutherford backscattering cross section of an element is approximately proportional to the square of its atomic number. In this work the plateau heights were measured 12 channels below the energy of the half-height at the leading edges at which point the rising portion of the leading edge is complete. The re-

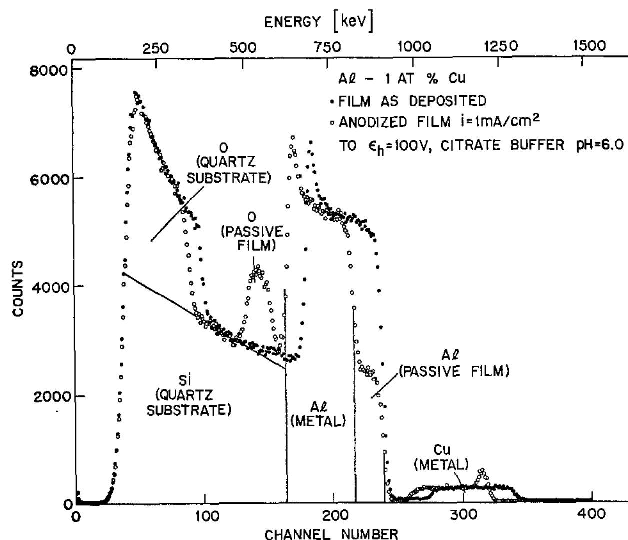

Fig. 1. Rutherford backscattering spectrum of an Al/1 a/o Cu film on quartz before and after anodization with $i = 1$ mA/cm² to $E_h = 100$V in 0.1M citrate buffer, pH = 6.0.

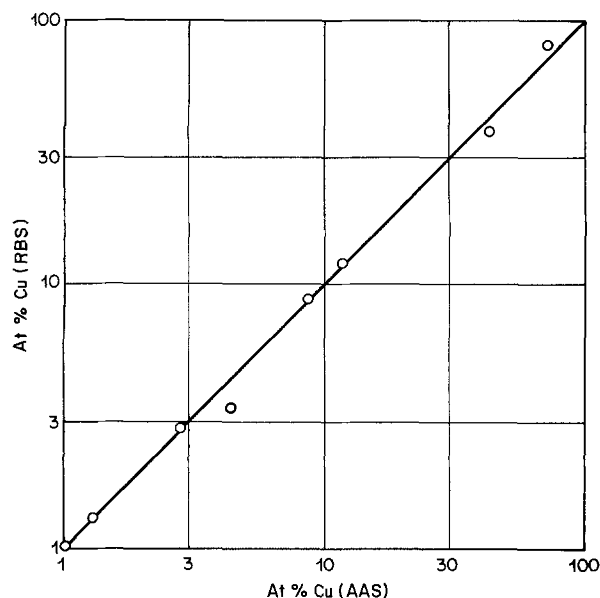

Fig. 2. Composition of vapor-deposited films determined by Rutherford backscattering and atomic absorption spectroscopy.

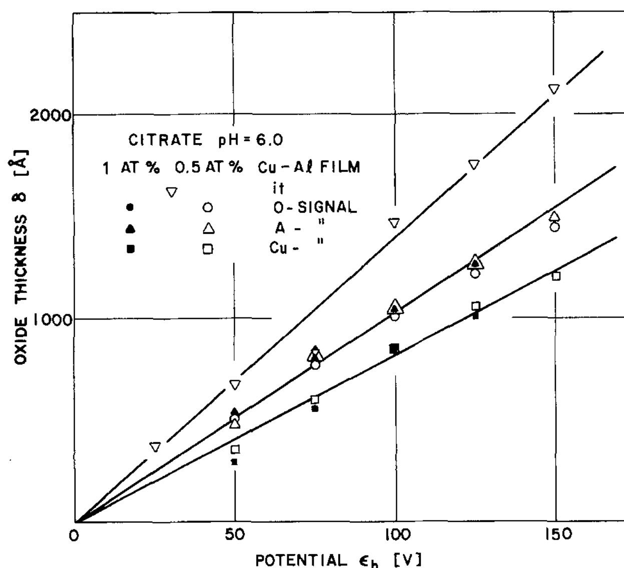

Fig. 3. Thickness of anodic oxide δ on Al/l a/o Cu films on sapphire formed with constant current to different potentials E_h, i = 1 mA/cm², 0.1M citrate, pH = 6.0, deduced from anodic charge and the changes of the O, Al, and Cu signals.

sults are shown in Fig. 2 as a function of the values for the averaged bulk composition obtained by atomic absorption spectroscopy. The films do not have any appreciable depth gradient of copper as can be seen by the nearly flat top of the copper plateau shown in Fig. 1 and 5. The small increase with decreasing energy E is due to the proportionality of the backscattering yield to E^{-2}. The copper concentration with depth is constant to about 2%.

The spectrum of the anodized film shows some significant changes. The leading edge of the copper signal is shifted by 22 channels. Similarly there is a step of 23 channels on the aluminum signal, although its leading edge has not changed position, and an oxygen peak with a width of 20 channels appears on top of the silicon signal of the substrate. These spectral changes are consistent with the formation of an anodic oxide on the surface of the metal film, with the shift in the leading edge of the copper peak showing that this constituent is not incorporated in the oxide, but rather lies beneath it.

The oxygen peak was integrated to determine the amount of oxide present. Background corrections were made for the contribution of the supporting material (Si or Al) by extrapolating their peaks to higher energies. The oxygen content of the passive film was found to increase linearly with the anodization charge and potential giving additional support that the passive oxide is nonporous and increases in thickness linearly with time at constant current. From the width of the step in the aluminum signal the oxide thickness was obtained.

The shift in the leading edge of the copper signal can also be used to calculate the amount of aluminum oxide on top of the copper. The layer thickness is obtained by the following relation (9)

$$'N = \Delta E[K^2(\epsilon(\text{in}) + |\sec\theta|\epsilon(\text{out}))]^{-1} \qquad [2]$$

$'N$ = at./cm², ΔE = energy width of plateau [keV between half-heights], θ = 175° (angle of detection), K^2 = backscattering kinematic factor, ϵ(in) = ^{4}He—stopping cross section [eV/10^{15} at./cm²] for E_o, ϵ(out) = for KE_o, and E_o = energy of incident ion beam (1.9 or 1.7 MeV). The stopping cross sections ϵ(in) and ϵ(out) for Al_2O_3 were calculated by applying Braggs rule from the values of the pure elements

$$\epsilon = 0.4\epsilon_{Al} + 0.6\epsilon_O$$

The values for ϵ were taken from Ref. (9). $'N$ was transformed into a thickness by dividing by the density of atoms in corundum. However, as the anodic film presumably has a somewhat lower density, this should be seen as a lower limit of the thickness.

Figure 3 shows the thickness (δ) of anodic oxides formed on Al/1% Cu and Al/0.5% Cu films to different potentials (citrate buffer, i = 1 mA/cm²). δ is calculated from the changes of the oxygen, aluminum, and copper signals in the Rutherford spectra.

The thickness values calculated from the oxygen peak and the aluminum peak, respectively, are very close to each other. The thickness calculated from the charge is significantly greater and it is apparent that some dissolution of the aluminum occurs during anodization, as previously observed by radioactive tracer methods (10). In contrast, the thickness calculated from the shift in the copper peak is somewhat less. This is probably due to a roughening of the metal/oxide interface or that some residual copper remains in the oxide close to the interface.

Within the major part of the oxide (~80%) no copper can be detected within the limits of detection (0.1%). Figure 4 shows a magnification of the copper signals of Fig. 1. Integration of the copper peak before and after the anodization shows no loss of this metal during anodization in either 0.1M borax (pH=9.2) or citrate (pH=6.0) solutions.

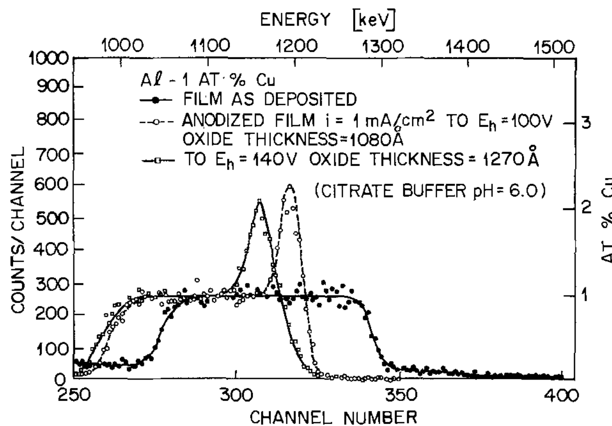

Fig. 4. Copper signals of an Al/l a/o Cu film as deposited and anodized to 100 and 140 V_H, in 0.1M citrate buffer, pH = 6.0, i = 1 mA/cm².

A pronounced enrichment of copper was detected at the metal oxide interface for aluminum films containing about 1% copper. The Rutherford spectrum shows that this enrichment is equivalent to an additional 1 a/o during anodization up to 80V, corresponding to about 800Å of oxide (Fig. 5a). This peak has a half-width of 33 keV corresponding to an enriched copper layer of about 650Å. The copper enrichment moves into the metal film thus retreating from the advancing, newly formed oxide, because it is not transferred into the oxide phase. Once the copper concentration rises above 2% no further enrichment occurs but rather the leading edge of the peak gets less steep (Fig. 4 and 5a). Galvanostatic anodization with 1 mA/cm² to 140V leads to an additional 400Å oxide (22 keV) surrounding local areas of copper-rich metal. Once the enrichment peak has reached its maximum height no change in the shape of its tailing edge can be detected even when the potential for local film damage is reached (Fig. 4 and 5a). This indicates that the transport mechanism of copper into the metal phase does not change during the different stages of oxide formation. Figure 5b shows the increasing accumulation of copper at the metal oxide interface for an Al/0.5% Cu film anodized to different potentials up to 150V, at which point a steady-state accumulation still has not been reached.

In some cases the specimen was tilted by 60° so that the beam was incident at 30° to the specimen's surface. Figure 6 demonstrates the change in the spectrum. The peaks of the surface atoms would not be expected to move; however, the remainder of the film will be broadened by the factor of $1/\cos \Delta\Phi = 2$. This broadening was observed for the copper peaks and demonstrates that the copper enrichment is distributed over a depth of several hundred angstroms and that the results were not caused by the depth resolution of the analytical technique. The broadening of the copper peak and its increase with sample tilting has been observed for specimens with 0.2-1.3% copper after anodization to different potentials. For $E_h < 75$V the effects of tilting are less marked as the accumulation of copper occurs over a small distance, approaching the depth resolution of the analysis. At $E_h = 25$V the copper enrichment is too small to be measured (Fig. 5b). The distribution of the copper enrichment was determined from the distance of the half-heights of the leading edge of the copper signal and the tailing edge of the copper enrichment peak. Applying relation [2], the copper accumulation layer is calculated to be 650Å thick.

Thin Al/1% Cu films of about 1500Å thickness have been anodized completely. In this case the copper moves to the substrate oxide interface as indicated by its peak shift equivalent to the 1400Å anodic oxide layer (Fig. 7). After this complete anodization the specimens are transparent. The interface is also

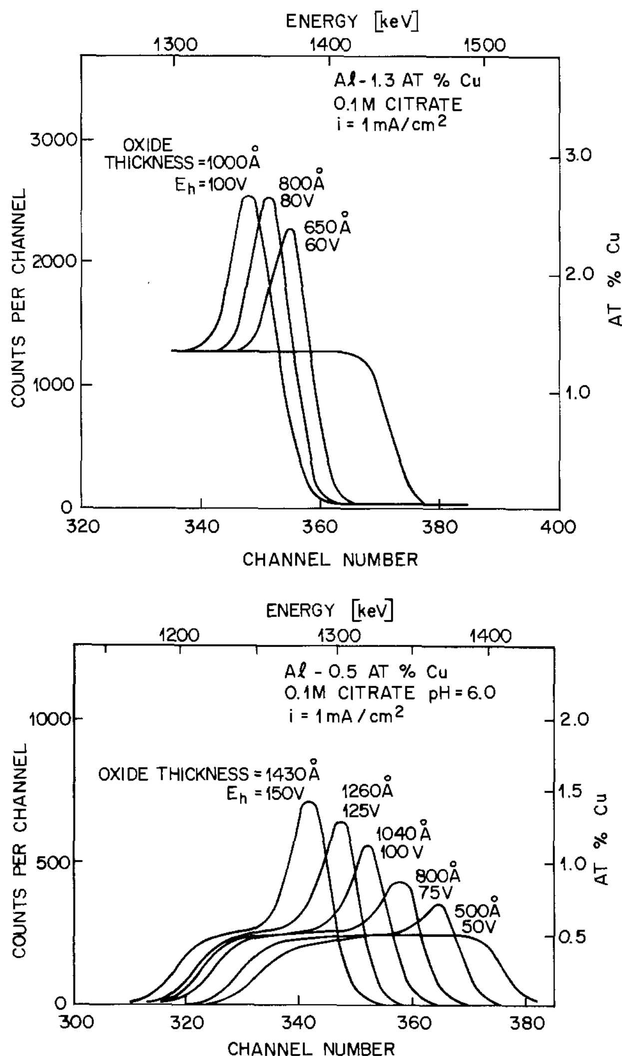

Fig. 5. Copper signal of an (a, upper) Al/1.3 a/o Cu and (b, lower) 0.5 a/o Cu film anodized to different potentials, $i = 1$ mA/cm², 0.1M citrate buffer, pH = 6.0.

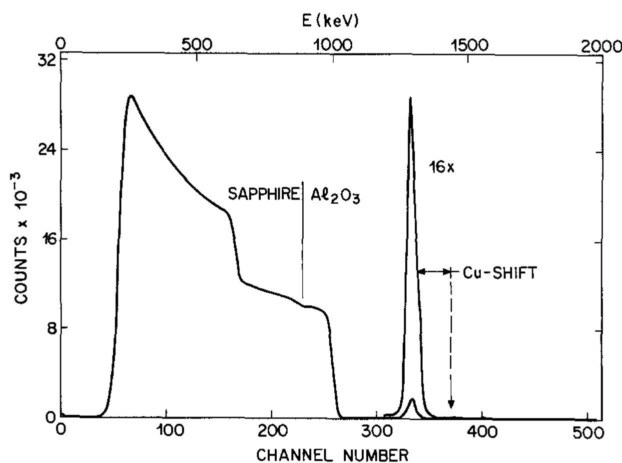

Fig. 7. Rutherford backscattering spectrum after complete oxidation of an Al/1 a/o Cu film on sapphire, $i = 5$ mA/cm², 0.1M citrate, pH = 6.0.

marked by a slight dip in the aluminum signal indicating the copper-rich layer at the aluminum oxide/sapphire interface. Films of higher copper content show less pronounced effects in the Rutherford spectrum as only thin oxides can be formed before oxide breakdown (5). In consequence relatively small copper enrichments are observed. For 2.9% Cu films, an enrichment by 1% is still observed after anodization to 70 V_H at $pH = 6.0$; whereas for 9% Cu, a quantitative result cannot be obtained due to the relatively small peak on a much larger signal. On metal films with copper concentrations higher than 10%, thick anodic oxides can no longer be formed and consequently the copper enrichment cannot be detected. Only a brittle, noncontinuous thick oxide is formed during long galvanostatic experiments (5).

Discussion

The results obtained from the Rutherford backscattering are in good agreement with the findings for aluminum and aluminum oxide implanted with copper (4). The implants show that copper has a higher mobility than aluminum in the oxide phase, and that it is not transferred from the metal to the oxide.

Starting with the native oxide of only a few angstroms a continuous film of aluminum oxide is formed during galvanostatic oxidation which does not contain copper. Rather the copper builds up at the metal/anodic oxide interface, its concentration increasing to approximately 1 a/o over the as-deposited uniform concentration. Once this critical enhanced concentration has been reached, further concentration increases do not occur, but rather the copper enhancement region becomes wider and the copper/oxide interface more diffuse. It is uncertain from the data whether this is due to the incorporation of a small concencentration of copper in the oxide near the interface or a roughening of the interface. This roughness could be caused by the formation of copper-rich inclusions of sufficient size, for example small crystals of the θ phase, that tend to restrict the growth of the anodic oxide in their vicinity. These inclusions are surrounded by the advancing oxide and remain in contact with the metal phase. This results in a roughening of the interface explaining the broadening of the leading edge of the copper signal. The potential distribution between the metal and the electrolyte across the anodic oxide is thus dependent on the microscopic location on the specimen surface. An increased field will occur at those parts of the anodic oxide where the copper-enriched metal intrudes into the oxide phase (Fig. 8). This could result in breakdown of the anodic film giving direct access of the electrolyte to the metal. As the metal inclusion is copper rich there is less tendency for repassivation and the increased corrosion at this point of the specimen will result in the complete perforation of the metal film. At this point the electrolyte comes into contact with the rear part of the metal film which loses adhesion to the supporting material and a bubble-like corrosion structure is observed (5).

The development of the copper enrichment peak under the anodic peak is the result of an anomalously high copper diffusion rate. This diffusion rate was measured by calculating the distance (ΔX) between the tailing edge of the copper plateau (which represents the metal film/ substrate interface) and the tailing edge of the copper enrichment peak. This distance decreases as the film is anodized and the copper enrichment peak moves into the film. The diffusion rate ($d\Delta X/dt$) was measured for Al/0.5% Cu and Al/1% Cu films and the results are shown in Fig. 9. The Al/0.5% Cu film shows constant anodization and copper diffusion rates up to 150V, the diffusion rate being measured at 3.5×10^{-8} cm/sec. In contrast the higher copper content film, while showing similar behavior at low anodization voltages, shows an increasing copper diffusion rate as the anodization voltage is increased above 80V. It can be postulated that this is due to the higher anodization rates which result from a roughening of the metal/anodic oxide interface.

Applying Einstein's relation ($D = x^{-2}/2t$) to the data for the Al/0.5% Cu film shown in Fig. 9, it is possible to obtain an approximate effective constant for this transport process, $D = 5.6 \times 10^{-15}$ cm²/sec. This estimated value is much higher than the value for volume diffusion for copper in aluminum, $D \approx 10^{-24}$ cm²/sec obtained by extrapolation to room temperature of the values measured in the range 433°-463°C (11). Room temperature grain boundary diffusion cannot be an explanation for this observation since the copper concentration profile was unchanged after several weeks of storage.

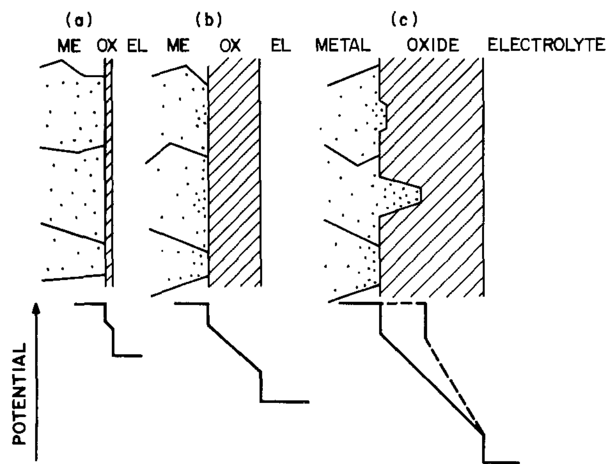

Fig. 8. Schematic representation of the different stages of oxide formation and the corresponding potential distribution (a) native oxide, (b) oxide with copper enrichment at the metal oxide interface, and (c) roughening of the interface leading to localized film damage.

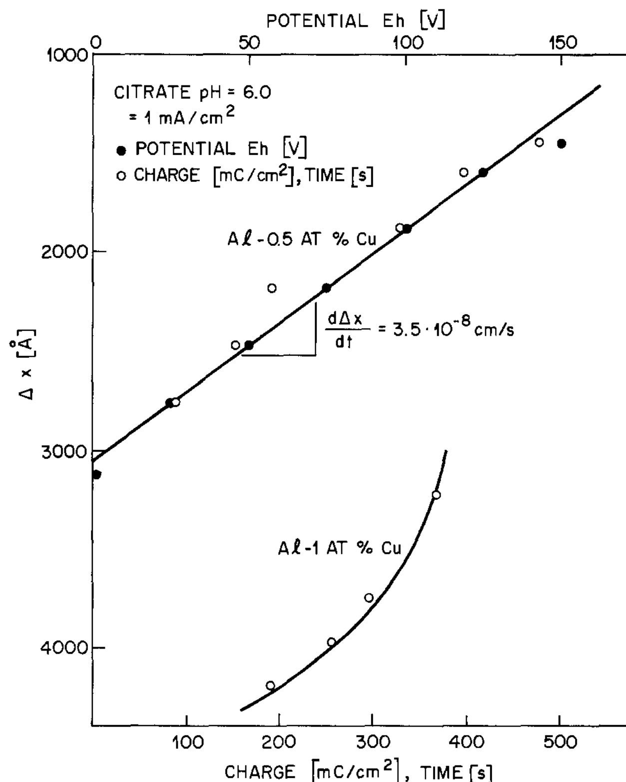

Fig. 9. In depth movement of the copper accumulation zone in the metal film during anodic oxide formation on Al/Cu films as a function of time and potential, $i = 1$ mA/cm², 0.1M citrate, pH = 6.0.

The comparatively fast transport of copper during anodization might be explained by diffusion over a highly disordered thin layer in the metal phase. The formation of an anodic oxide will produce stresses and vacancies at the metal/oxide interface. These vacancies will diffuse into the metal phase thus enhancing the transport of aluminum to the oxide phase and copper in the opposite direction. The breadth of the copper enrichment peak suggests that the vacancy-enhanced diffusion region extends over a depth of 650Å beneath the metal/oxide interface. A similar model has been postulated for the corrosion of binary alloys, involving a diffusion mechanism via divacancies to explain the observed fast transport (12).

The different behavior of the two components of the metal film are apparently a consequence of their differing standard potentials for oxide formation, as shown below (13):

$$2Al + 3H_2O \rightarrow Al_2O_3 + 3/2\ H_2\ (1\ atm) \qquad E_o = -1.35V$$

$$2Cu + H_2O \rightarrow Cu_2O + H_2\ (1\ atm) \qquad E_o = 0.47V$$

$$Cu + 2H_2O \rightarrow Cu(OH)_2 + H_2\ (1\ atm) \qquad E_o = 0.60V$$

$$Cu_2O + 3H_2O \rightarrow 2Cu(OH)_2 + H_2\ (1\ atm) \qquad E_o = 0.74V$$

This shows clearly that only aluminum oxide is in thermodynamic equilibrium with an aluminum film containing a few percent of copper. During galvanostatic experiments the anodizing voltage is largely dropped across the anodic film (14, 15). This field is necessary to maintain the constant current condition and the corresponding migration of oxygen and aluminum ions within the oxide phase. As long as the potential drop and the activity of the metals are not changed appreciably at the metal/oxide interface the formation of a copper oxide phase is not possible. If, however, an increased copper concentration at some part of the metal film should occur, along with an increased potential drop at the interface, the difference in the potentials for oxide formation might be overcome leading to the formation of copper oxide. The necessary additional overvoltage may be caused by an increasing kinetic hindrance for the Al^{3+}-transfer reaction due to copper accumulation at the interface. Some indication for this is given by the steep increase in the electrode potential just before film damage is observed (5). Alternatively, the formation of copper oxide at sites in the metal film where copper has become enriched to a critical concentration, could be another cause for the localized breakdown.

Conclusion

The following results were obtained by the examination of anodized aluminum-copper films with Rutherford backscattering.

1. The anodic oxide formed under galvanostatic conditions on Al-1% Cu films grew nearly linearly with time and potential and does not contain copper.

2. For anodic voltages up to 80 V_H, copper accumulated at the oxide/metal interface to an excess 1 a/o. Further anodization caused no general increase of the copper concentration, but rather its extension over a greater depth into the metal film.

3. The breakdown of the anodic oxide and the development of characteristic corrosion structures are thought to be related to the copper accumulation, and the local formation of an increased field strength at these locations results in film damage.

4. The accumulated copper is distributed over a depth of about 650Å. The formation of the anodic oxide causes copper diffusion into the metal phase. This transport is presumably enhanced by a disordered layer containing internal stresses and excess vacancies. The corresponding diffusion constant is increased by about eight orders of magnitude compared to the value for volume diffusion.

5. Copper is not incorporated into the oxide phase unless the potential drop at the metal/oxide interface is increased by an additional overvoltage. This is due to the significant difference of the standard potentials for the formation of the corresponding oxides and hydroxides.

Luminescence of Iron-Activated Lithium Meta Gallate

Jacob G. Rabatin*

General Electric Company, Advance Process Laboratory, Quartz and Chemical Products Department, Cleveland, Ohio 44110

ABSTRACT

$LiGaO_2$:Fe is an efficient phosphor under both ultraviolet and cathode-ray excitations, with peak emission at 742 nm in the near-infrared region. It is best prepared at about 1000°C with stoichiometric proportions of the host ingredients and 0.01 moles Fe_2O_3. At this optimum Fe^{3+} concentration, the relative quantum efficiency is about 80%. Potential use in fluorescent lamps is discussed in relation to plant growth applications for activation of the enzyme phytochrome.

The behavior of Fe^{3+} ions in various hosts has been studied extensively. In $LiAl_5O_8$ with a spinel-like structure (1), Fe^{3+} activator has a peak emission at about 680 nm under 254 nm excitation (2). On the other hand, Fe^{3+}-activated $LiAlO_2$ with a distorted tetragonal structure (3) emits at about 740 nm (4). In the search for efficient near-infrared emitting phosphors for special fluorescent lamp applications, the author examined several gallium-containing hosts for possible emission when activated with iron. $LiGaO_2$:Fe was found to be an efficient phosphor under both ultraviolet (u.v.) and cathode-ray (CR) excitation. This paper describes the preparation, luminescent properties, and performance of $LiGaO_2$:Fe in fluorescent lamps. Comparisons with $LiAlO_2$:Fe phosphors are also described. Some potential uses in fluorescent lamp applications are indicated.

Experimental

Phosphors were prepared from high purity Li_2CO_3, Al_2O_3, Fe_2O_3, and Ga_2O_3 starting materials. The desired formulations were intimately blended and fired twice in covered vessels at temperatures from 900° to about 1200°C and times of 2-4 hr. The final product was again ground finely and sifted through 325 mesh to remove oversize sintered aggregates of phosphor particles which generally were about 20% of the total weight.

The final phosphor powders were characterized by standard analytical methods for absolute density (pycnometer), particle size (Coulter Counter), surface area (BET), emission under 254 nm (Cary 14), refractive indexes (immersion oil method), and 254 nm absorption on plaques. Infrared emission was also measured on powder samples utilizing a RCA No. C31025C photomultiplier which has a flat energy response between 400 and 800 nm. The CR efficiency measurements were made on powder samples at 5 kV and 3 μA and were compared to Y_2O_3:Eu as a standard having 12% energy efficiency (5). The fluorescent lamp data were obtained on standard 40W lamps using organic based coating methods at 60% reflectance of visible light. The spectral emissions curves shown in Fig. 1 and 2 were performed on powder samples utilizing special apparatus designed by Dr. R. Bateman of GE Lighting Research Laboratory.

Results and Discussion

The preparations of $LiAlO_2$:Fe and $LiGaO_2$:Fe require similar conditions of firing temperatures and times with best results obtained by double firing procedures. Table I lists the effect of second fire temperatures on *IR* output of the phosphor. The optimum firing temperatures are 1000°C for $LiGaO_2$:Fe as compared to 1100°C for $LiAlO_2$:Fe. X-ray diffraction analyses indicate that $LiAlO_2$ and $LiGaO_2$, respectively, are the dominant phases. The resulting powders are well crystallized with some sintering occurring. The Coulter Counter particle size mediums are between 10 and 12 μm after the powders have been sifted through 325 mesh screens. The BET surface areas are between about 0.4 and 0.5 m^2/g. The data for absolute densities, refractive indexes, and crystal structure are listed in Table II. As expected $LiGaO_2$ has a higher absolute density and higher refractive index than $LiAlO_2$. It appears from x-ray diffraction data that both phases have tetragonal crystal structures.

The effect of compositional changes on the relative *IR* output of various Fe^{3+}-activated lithium aluminates are shown in Table III. The maximum *IR* output occurs at the stoichiometric *meta* aluminate composition. Small changes from this composition affect the *IR* output slightly. Similar results were also obtained for the lithium gallate phosphors. According to Palumbo (4), the differences in emission spectra of $LiAl_5O_8$:Fe at about 670 nm as compared to $LiAlO_2$:Fe at about 734 nm may be due to the Fe^{3+} ions having different site symmetries, namely, octahedral and tetrahedral, respectively.

The effects of Fe^{3+} activator concentrations on *IR* output are shown in Table IV for both $LiAlO_2$ and $LiGaO_2$ under 254 nm excitations. The optimum Fe^{3+} concentrations are 0.005 and 0.010 moles per mole of phosphor for $LiAlO_2$ and $LiGaO_2$, respectively. The percent absorptions are relatively large at 99%. Con-

centration quenching occurs at relatively high Fe^{3+} levels, especially in $LiGaO_2$.

Emission spectra under 254 nm excitation are shown in Fig. 1 for $LiAlO_2$:0.005Fe and in Fig. 2 for $LiGaO_2$:0.010Fe at 30° and 293°K, respectively. Both phosphors show zero phonon lines at about 710 nm at 30°K. Significant differences in crystal field splitting are observed at 30°K suggesting some differences in site symmetry between the two phosphors. At room temperature the spectra show single broad band emission peaks at 734 nm for $LiAlO_2$:Fe and at 742 nm for $LiGaO_2$:Fe.

The relative quantum efficiencies were measured and compared to a cool white calcium halophosphate at 92%. The results under 254 nm excitation are listed in Table V. Included also are the quantum efficiencies of iron-activated magnesium lithium aluminate and lithium gallium indate. Of more than 100 hosts examined only these four phosphors showed significant *IR* response. $LiGaO_2$:0.01Fe is somewhat more efficient than $LiAlO_2$:Fe.

The relative energy efficiencies of these phosphors were also measured under CR excitations at 5 kV and 3 μA based on the procedures suggested by Ludwig and Kingsley (5). Y_2O_3:Eu was used as the standard

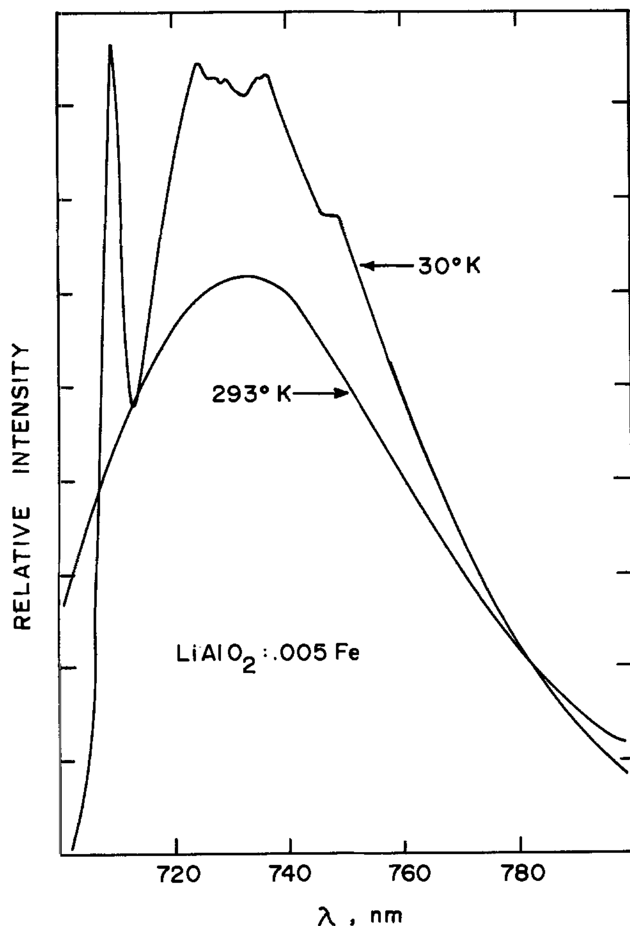

Fig. 1. Spectral emission curves for $LiAlO_2$:0.005Fe under 254 nm excitation.

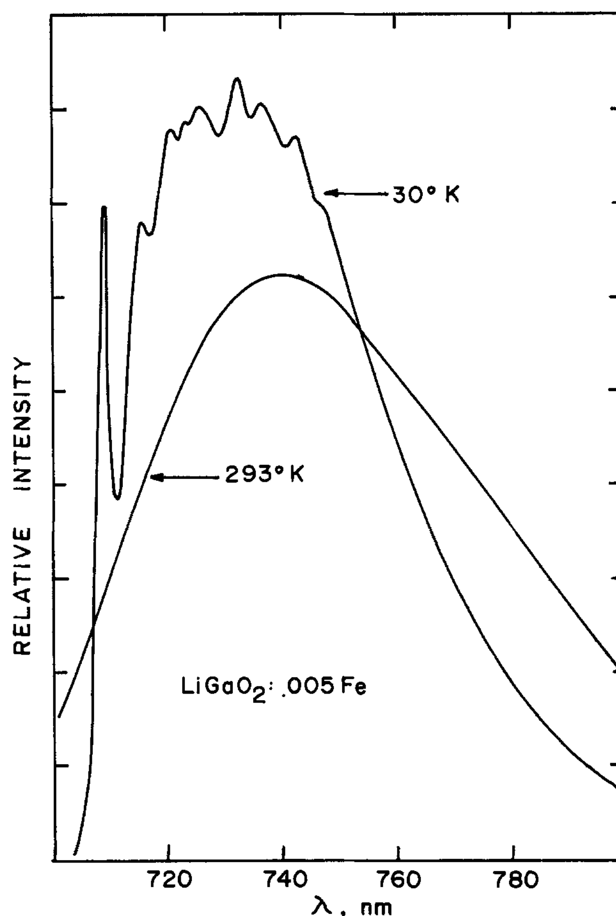

Fig. 2. Spectral emission curves for $LiGaO_2$:0.01Fe under 254 nm excitation.

at 12% energy efficiency. The results are presented in Table VI for the most efficient phosphor composition under CR excitations. Both phosphors are moderately efficient under CR excitations. The emission spectra are identical to those shown in Fig. 1 and 2. Under CR excitation, energy transfer from host to Fe^{3+} ions occurs with some nonradiative losses.

One of the more promising uses for a near *IR* emitting phosphor is in providing artificial illumination in plant growth applications (6). It has been shown that for balanced activation of the enzyme, phytochrome, which controls plant growth and flowering, light peaking at about 730 nm is needed (7, 8). Figure 3 shows the radiant power characteristics of $LiGaO_2$:0.01Fe in 40W fluorescent lamps. The fine narrow band emissions are due to the characteristic Hg emissions. The broad band peaking at about 740 nm is due to the Fe^{3+}

Table V. Relative quantum efficiencies of some *IR* phosphors under 254 nm excitations

emission in $LiGaO_2$. Due to the Stokes shift at 740 nm, the radiant power output is only about 70% that for a emission peaking at 540 nm, for example. Similar results were also obtained for $LiAlO_2$:0.005Fe phosphors.

In Fig. 4, the radiant power characteristics are shown for a plant growth fluorescent lamp emission which approximates the chlorophyll action spectrum in the visible region and also contains about 20% output peaking at 740 nm due to $LiGaO_2$:Fe. Such fluorescent

Table VII. Depreciation data for 40W F-lamps containing *IR* emitting phosphors

Phosphor composition, weight	100 hr loss (%)	500 hr loss (%)
Cool White halophosphate (CW)	2.4	5.9
85% CW + 15% $LiAlO_2$:0.005Fe	4.5	8.8
80% CW + 20% $LiGaO_2$: 0.01Fe	3.0	6.6

lamp would be especially useful where maximum flowering conditions are desired.

The percent lumen depreciation data for various phosphor blend compositions are listed in Table VII. A standard Cool White (CW) calcium halophosphate lamp was used for comparison with the listed blends. The data indicate that $LiGaO_2$:Fe has better maintenance in blends with Cool White in fluorescent lamps as compared to $LiAlO_2$:Fe.

Summary

$LiGaO_2$:Fe is an efficient phosphor with peak emission at 742 nm under both u.v. and CR excitations. The physical properties are similar to those of $LiAlO_2$:Fe reported earlier.

The solid-state preparation of $LiGaO_2$ is best performed at about 1000°C with stoichiometric compositions of the host ingredients at optimum Fe^{3+} concentrations of 0.01 moles. The relative quantum efficiency is about 80% under 254 nm excitation somewhat more efficient than $LiAlO_2$:Fe. Possible uses of $LiGaO_2$:Fe in fluorescent lamps are in plant growth applications

Quantified Conditions for Emitter-Misfit Dislocation Formation in Silicon

Richard B. Fair*

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

The conditions under which misfit dislocations are generated during phosphorus diffusion in silicon are discussed. Van der Merwe's concept of critical misfit is used to determine the critical surface region depth for a given P surface concentration which causes spontaneous misfit dislocation formation. Using this model the times required to form misfit arrays are calculated as a function of temperature and surface concentration. The effect of misfit dislocation generation in an oxidizing ambient is also discussed.

High concentration P diffusions in Si can induce localized lattice strain which is often relieved through the formation of either hexagonal edge dislocation networks or arrays of concentric loops (1). The networks are usually confined within the diffused region at depths within ¼ to ½ of the P junction depth and at high densities ($>10^9$ dislocations/cm²) (2-5). However, dislocations at densities of 10^5-10^7/cm² have been observed (6, 7) deeper than the junction as a result of climb (for <111> Si) or glide (for <100> Si) processes. In <111> Si, electrically active dislocation loops have been found to extend to considerable distances (~100 μm) outside of the planar-diffused region since primary slip occurs in the (111) plane (2, 8, 9).

For <100> oriented Si glide is easiest for 60° dislocations in (111) planes. When suitably oriented glide dislocations meet, they form a stable network at some depth in the Si (10). External dislocations are generally not observed outside the diffused region in <100> Si (8).

The influence of dislocations on impurity diffusion and the electrical performance of Si devices has been reviewed extensively by Lawrence (11). Depending on the stability and electrical activity of induced dislocations and whether or not residual metal impurities and structural imperfections exist in the Si prior to emitter diffusion, the following effects have been correlated with misfit dislocations: (*i*) reduced transistor current gain (1, 2, 12, 13), (*ii*) emitter-collector shorts and excess leakage (1, 12, 14-19), (*iii*) high junction leakage currents (1, 11, 20-23), (*iv*) increased low frequency noise figure (21), and (*v*) variable temperature dependence of transistor current gain (21). Therefore, the detrimental effects of phosphorus emitter-induced misfit dislocations have been well documented.

There are also beneficial effects associated with dense dislocation networks. It has been shown that the onset of effective ion-damage gettering in Si occurs when damage-induced dislocations in densities greater than 2×10^8 cm^{-2} coalese to form networks (24). Similarly, Poponiak *et al.* (25) have shown that for the case of gettering with boron-diffused layers in Si, no metal gettering occurs unless dense misfit dislocations are induced. For n-type dopant gettering, donor impurities at high concentrations will getter metallic impurities via ion-pairing and solubility-enhancement effects (26). However, the formation of unstable misfit dislocations during diffusion will enhance the gettering efficiency of the diffused layer. Such gettering will be beneficial provided the accumulation of metal impurities is away from the active device region.

Regardless of whether one wants to avoid misfit dislocations in a P emitter diffusion or one seeks the effective gettering properties of misfit dislocations, it is important to know when they occur. It is the purpose of this paper to quantify the conditions under which misfit dislocations are generated during P diffusion.

Analysis: Conditions for Misfit Dislocation Generation

The critical misfit condition.—The conditions under which misfit dislocations are generated have been discussed by many workers (21, 28-36). According to Prussin's model (31) the maximum stress caused by the lattice misfit strain of the undersized P atoms is proportional only to the surface concentration of P. When the yield stress of Si is exceeded, dislocations appear. Several workers (21, 32, 33) have shown that the Prussin model is not adequate. The integrated concentration of atoms per square centimeter appears to be a better quantity to correlate with the threshold stress for dislocation generation (9). Watanabe *et al.* (21) have determined the critical total concentration for boron in Si to be $Q_B \simeq 1.5 \times 10^{16}$ cm^{-2}.

An attempt was made to establish the critical total concentration for P in Si using Czaja's theory (3, 36). However, it was found that a more rigorous theory was needed. Such a theory of interfacial misfit dislocations has been advanced by Van der Merwe (35) for epitaxy and the diffusion zone of a bicrystal system. For a small misfit, Van der Merwe derived an equation for a single crystal top layer relating the ratio h/a (the top layer thickness in units of lattice parameters) with δ_c, the critical misfit. This equation reduces to (36)

$$\ln \frac{2\pi e \delta_c}{(1-\gamma)} + \frac{4\pi(1-\gamma)^2 h \delta_c^2}{(1-2\gamma)a} = 0 \qquad [1]$$

for diffusion-induced strain in Si. When the top layer thickness exceeds a critical value, spontaneous generation of a dislocation network occurs. Assuming Poisson's ratio $\gamma = 0.29$, Eq. [1] becomes

$$\ln 24.06\, \delta_c + 15.08 \frac{h}{a} \delta_c = 0 \qquad [2]$$

Below critical misfit, the lattice in the diffused layer should adjust itself to the Si substrate lattice through elastic deformation. The critical misfit is defined as

$$\delta_c = \eta \frac{\Delta r}{r} = \eta \frac{(r_{Si} - r_I)}{r_{Si}} \qquad [3]$$

where η is the solute or impurity fraction and r_{Si} and r_I are the tetrahedral covalent radii of Si and the impurity, respectively. Using the Van Vechten and

* Electrochemical Society Active Member.

Phillips values (37) for Si and P yields the critical thickness h_c as

$$h_c = \frac{-4.94 \times 10^{15}}{C_{avg}} \ln (1.753 \times 10^{-23} C_{avg}) \quad [4]$$

C_{avg} is the average doping in atoms per cubic centimeter in the strained layer.

For the case of high concentration P diffusion in Si, a near-surface, highly doped "flat" region exists in the dopant profile as a result of the n^2 dependence of diffusivity on electron concentration (38). The width of this region, x_o, is taken as the depth at which the electron concentration falls to n_e (see Fig. 1). Below $n = n_e$, the n^2 dependence of P diffusivity disappears (38). At 1000°C, $n_e \simeq 1.3 \times 10^{20}$ cm^{-3}. Using the approximation that

$$C_{avg} = C_s/2$$

where C_s is the total P surface concentration, and assuming that the flat-region depth corresponds to the layer thickness, h, in Eq. [1], then

$$h_c = x_{oc} = \frac{-9.88 \times 10^{15}}{C_s} \ln (8.76 \times 10^{-24} C_s) \quad [5]$$

The width of the high concentration region, x_{oc}, at which misfit dislocations occur has been set equal to h_c. Equation [5] is plotted in Fig. 2. Also shown are the C_s and x_o coordinates of numerous P diffusions into both <111> and <100> Si. The occurrence of high densities of misfit dislocations in these diffused layers has been determined by x-ray topography, TEM, or careful Sirtl etching. The open circle data (○-data) indicate that dense misfit dislocations were observed, and the closed circle data (●-data) indicate that no dislocations were observed. Diffusions performed over the temperature range of 900°-1235°C are represented in Fig. 2 with the bulk of the data coming from the published literature (2, 4-6, 14, 21, 27, 36, 39-43). It can be seen that the calculated curve described by Eq. [5] is a good "line of demarcation" between the dense dislocated and nondislocated P diffusion data. Moreover, the $C_s \cdot x_{oc}$ product at $C_s = 2 \times 10^{21}$ cm^{-3} is 4×10^{16} cm^{-2}, whereas at $C_s = 1 \times 10^{20}$ cm^{-3} the product is 7×10^{16} cm^{-2}. However, if a constant $C_s \cdot x_{oc} = 4.6 \times 10^{16}$ cm^{-2} line is plotted on the figure, it too might serve as a good boundary. This fine point will be resolved in the next section.

Referring again to Fig. 2, it can be seen that data are also plotted (x-data) which indicate that isolated

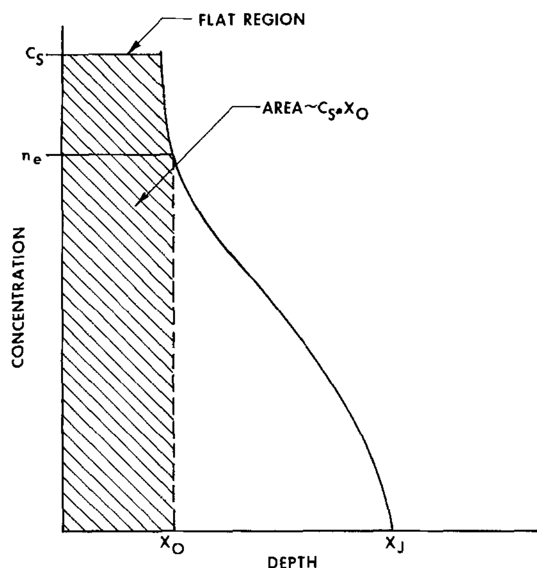

Fig. 1. Typical high concentration phosphorus diffusion profile in silicon. The surface region area is shown cross-hatched.

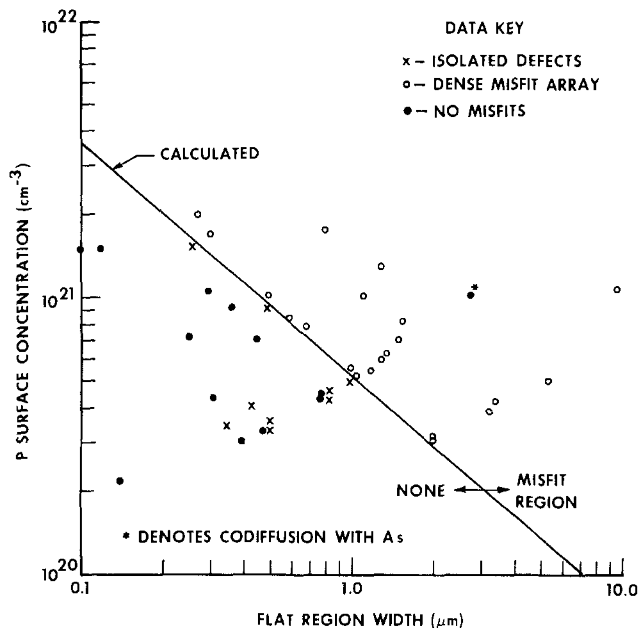

Fig. 2. Phosphorus surface concentration vs. the critical flat-region depth required for misfit dislocation formation.

defects (dislocations, stacking faults, etc.) occurred prior to the formation of dense misfit arrays. The increase of isolated defect density prior to "lattice collapse" has been recognized in the literature (3, 40, 43). The nucleation of these defects is dependent on the initial oxygen content and active dislocation density of the Si (21). Morris and Katz (14) have shown that even the existence of these isolated defects can affect junction yield.

The effect of codiffusing As with P is also indicated in Fig. 2. The effect of As is to inhibit dislocation formation since the As atoms are in interstitial sites in the Si. Thus, it has been proposed that the movement of Si atoms is obstructed by the interstitial As atoms making dislocation generation more difficult (44).

The effect of diffusion ambient on misfit dislocation generation.—Chemical source diffusions.—There have been various reports in the literature (2, 45) that the formation of misfit dislocations is dependent on the furnace ambient during drive-in of a predeposited P layer in Si. Duffy *et al.* (2) report the chemical predeposition of a P layer with an integrated concentration of ~2.5×10^{16} P atoms/cm^2 (970°C, 35 min in N_2 ambient with 2% O_2). No misfit dislocations were observed. However, misfits were observed after a 970°C drive-in cycle consisting of 5 min in dry O_2, 30 min in steam, and 40 min in dry O_2. At the end of this cycle the total P concentration was still ~2.5×10^{16} cm^{-2}. However, the $C_s \cdot x_o$ product had increased from ~3.5×10^{16} to ~4.6×10^{16} cm^{-2}. From the previous discussion of Fig. 2, a $C_s \cdot x_o$ product of ~4.6×10^{16} cm^{-2} is sufficient to create misfit networks. The effect of the oxidation drive-in cycle, then, has been to increase the amount of phosphorus in the "flat region" at the surface.

The effect can be understood by computer simulation of the P drive-in process. Duffy's P profile data for the predeposition step and the drive-in cycle are shown in Fig. 3. Also shown are the calculated profiles corresponding to computer simulations. Good agreement with the published data is obtained. Since the computer program prints out the P profile at the end of each drive-in step, a locus of points for the drive cycle can be generated to either the C_s *vs.* x_o plane or the C_{avg} *vs.* x plane. The locus for the oxidation cycle is shown in Fig. 4 where the average P doping in the surface layer was determined at each step. Point 1 cor-

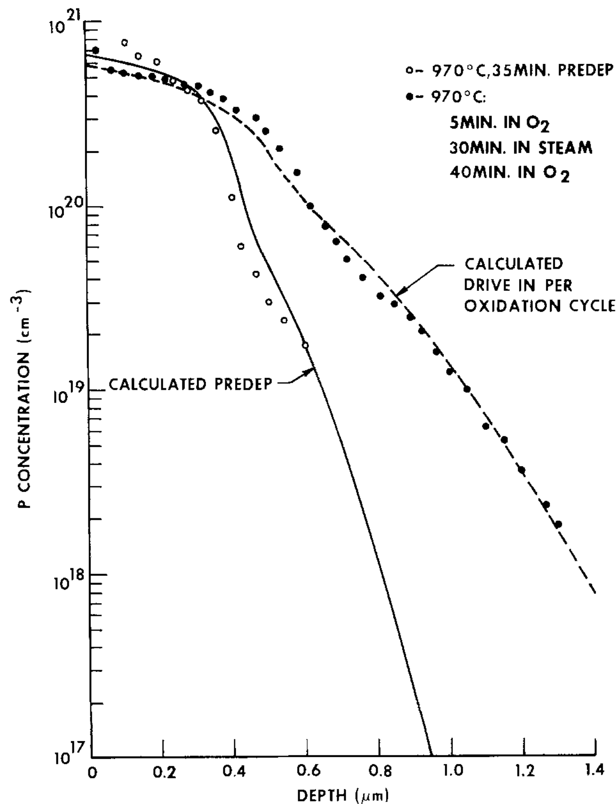

Fig. 3. Computer simulation of Duffy *et al.* phosphorus diffusion profiles.

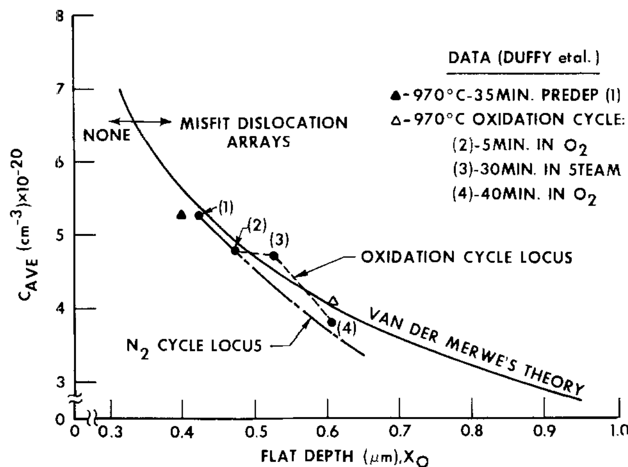

Fig. 4. Effect of drive-in ambient on the average phosphorus surface concentration vs. the flat region depth. Calculations and data are based upon Duffy *et al.* experiments.

responds to the profile after predeposition (▲-point is from Duffy's experimental data). Point 2 corresponds to a 5 min dry O_2 oxidation. Point 3 corresponds to the the 30 min steam oxidation. It can be seen that during the steam oxidation the average P doping in the surface only changed slightly, while the flat depth, x_o, increased. Therefore, during this step the locus crossed the no misfit/misfit line which is drawn on the figure according to Eq. [4] and Van der Merwe's theory. During the final dry O_2 step (40 min) the locus crossed the misfit line and terminated at point 4 (corresponds to the Δ-point from Duffy).

This same process has been simulated for the case where no oxidations were performed; all drive-ins were done in nitrogen for the same times and at 970°C. The resulting locus is also shown in Fig. 4. This locus does not cross the theoretical misfit line, and thus no misfit dislocation nets should be formed. This observation was verified by Fairfield and Schwuttke (8). Consequently, only the steam oxidation drive process which "snowplows" phosphorus has the potential ability to "push" the $C_{avg} \cdot x_o$ locus across the misfit line, if conditions for misfit formation have not already been incurred. Drive-ins in dry O_2 or neutral ambients will generate $C_{avg} \cdot x$ locii which tend to slope downward faster than the Van der Merwe curve in Fig. 4.

Diffusion of ion-implanted P layers.—For the case of ion-implanted phosphorus in silicon, Tamura, *et al.* (45) have shown that the dose required to generate misfit dislocations is 3×10^{15} cm^{-2} for drive-in in steam and 1×10^{16} cm^{-2} for drive-in in dry N_2. Implantation energies were 50-100 keV. It is clear that implantation-induced damage and stress make it very difficult to predict quantitatively when misfit dislocations will be formed. Because of the lower density of the amorphous Si layer created by high dose implantation, considerable expansion of the implanted layer occurs (46, 47). The disorder-induced stress can approach or even exceed the yield stress of Si ($\sim 4 \times 10^9$ dynes/cm^2). Since nonoxidizing atmosphere annealing results in the shrinkage of interstitial defects in Si and oxidation causes such defects to grow (48), higher doses of P are needed to generate dislocations during neutral ambient anneals.

For the case of ion-implanted As in Si, the critical dose for dislocation networks to form during steam drive-in is $\sim 2 \times 10^{16}$ cm^{-2} at 50 keV (45). Consequently, diffusion in a neutral ambient should occur first in order to anneal out damage and stress for a dislocation-free emitter process.

Phosphorus diffusion curves for misfit dislocation formation.—Curves of P surface concentration *vs.* diffusion time required to generate misfit dislocation arrays (MDA) are shown in Fig. 5. These curves are based on the time necessary for the critical flat region depth, x_{oc}, to be reached. The highest concentration point for each curve corresponds to the solid solubility at that temperature. For P concentrations above these limits, precipitation-induced stacking faults and dislocations will be formed in relatively short times (42). For a given C_s value the solid curves mark the boundaries beyond which in time dense misfit arrays will be formed.

Summary and Conclusions

A short review of the observed effects of emitter-misfit dislocations on Si device behavior has been presented. Generally, unstable dislocations created during high concentration P emitter diffusion are electrically active and have a high gettering efficiency for impurity atoms in Si. Thus, depending on the residual metal impurity concentrations and the densities of defects in the Si prior to emitter diffusion, misfit dislocations formed during emitter processing have been linked to

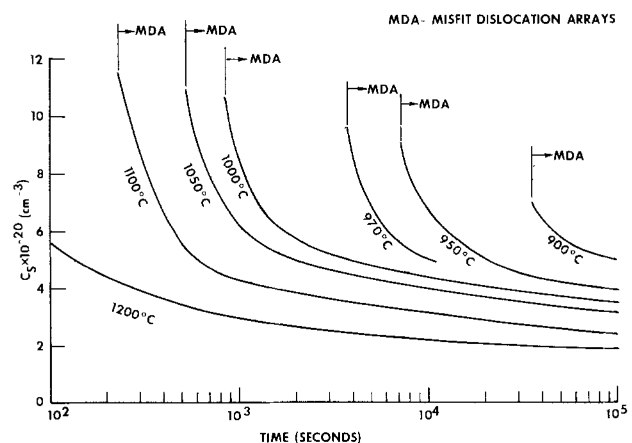

Fig. 5. Critical time to dislocation array formation for phosphorus diffusion in low oxygen ambients.

numerous transistor parameter nonuniformities and yield problems.

The conditions under which misfit dislocations are generated during P diffusion have been quantified using Van der Merwe's theory (35) of critical misfit. Curves have been generated which allow one to center P diffusion surface concentrations well into the dislocation-formation condition (for gettering) or well out of this condition.

ABSTRACT

The structure of silicon films deposited by low pressure, chemical vapor deposition in the 600°C temperature range has been investigated by x-ray diffraction and transmission electron microscopy. There is a critical temperature near 600°C, above which the deposited films are polycrystalline and below which amorphous films are obtained. This temperature is close to that used to deposit films for integrated circuit applications. When the films are polycrystalline, the <110> texture dominates. The polycrystalline films are reasonably stable upon annealing to temperatures up to approximately 1100°C. The initially amorphous films, however, easily crystallize. Crystallization has been observed to be well advanced after annealing at 800°C. Large stresses are built into the amorphous films, while the stresses in the polycrystalline films are lower.

In the past decade polycrystalline silicon has become important in several applications. Submicron films of polycrystalline silicon, especially, are of great commercial importance in silicon-gate MOS integrated circuits (1) and charge-coupled devices (2). Until recently, these films have generally been deposited in cold-wall reactors in which the silicon substrates lie flat on an externally heated susceptor. The low capacity and the high capital and operating costs of these reactors, however, may contribute significantly to the cost of the integrated circuit fabrication process.

Within the last two years, low pressure, chemical vapor deposition (LPCVD) systems for depositing polycrystalline silicon have been developed (3). The high capacity and lower costs of these systems have led to their rapid acceptance in high volume, integrated circuit manufacturing facilities. Since the deposition rate, temperature, and pressure in these reactors are markedly different from those conventionally employed, some characterization of the material deposited is needed to ensure that the characteristics and reliability of the integrated circuit in which it is used are not degraded. Because low pressure reactors are generally operated slightly above 600°C, a temperature close to the amorphous-crystalline transition temperature seen in silicon films deposited by chemical vapor deposition at atmospheric pressure (4, 5), the structure in the as-deposited film, and its stability upon further processing of the integrated circuit wafer are important topics to investigate.

The detailed properties of the polycrystalline silicon become especially important when it is used in critical applications, such as for high valued resistors in static memory circuits (6, 7). In image-sensing CCD's dependence of the optical transmission of the films on the structure will affect the device performance. Even in more conventional, silicon-gate applications, the stability of the structure may influence properties such as step coverage.

This paper reports the results of the first phase of a study being conducted at Stanford designed to investigate the properties of polycrystalline silicon deposited at low pressures. The crystal structure of the films is discussed and compared to that found in films deposited at atmospheric pressure, and the stability of the structure during further heat-treatment is reported.

* Electrochemical Society Active Member.

Key words: polycrystalline silicon, low pressure chemical vapor deposition, structure, annealing.

Film Preparation

Films were deposited in a Tempress (Unicorp) LPCVD reactor at several different temperatures and a pressure of approximately 0.35-0.5 Torr.[1] Silane was the deposition source gas, and no diluent was used. Although a temperature gradient is normally used along the length of an LPCVD reactor, for these depositions the temperature was adjusted to be uniform throughout the length of the deposition zone. A full load of 137, 3 in. diam silicon wafers was included in each deposition. Six of the wafers were sample wafers to be used in subsequent studies; the majority were dummy wafers included in order to avoid perturbing the gas flow with a different number of wafers in each deposition.

Films were deposited over the temperature range 580°-640°C. Samples of several different thicknesses were studied at the typically used, nominal deposition temperature of 620°C. The deposition temperatures, rates, and film thicknesses are summarized in Table I. The films were deposited on both <100>- and <111>-oriented, lightly doped silicon wafers which were covered with 1000Å of thermally grown silicon dioxide. The two different substrate orientations were used in order to allow investigation of the various crystallite orientations in the films without interference from the substrate.

Structure of As-Deposited Films

The films were investigated both by x-ray diffraction and by transmission electron microscopy. The x-ray

[1] The films were deposited by Intel Corporation.

Table I. Deposition conditions and x-ray texture

Deposition temperature (°C)	Film thickness (μm)	Deposition rate (A/min)	X-ray texture[a]			
			<111>	<110>	<311>	<331>
580	0.32	70	0	0	0	0
600	0.50	73	8	324	19	29
620	0.26	110	10	102	21	0
620	0.47	110	12	422	33	19
620	1.05	110	12	2000	56	221
640	0.45	99	11	259	21	19

[a] The magnitudes of the <111>, <220>, <311>, and <331> x-ray peak heights were divided by 1.00, 0.37, 0.18, and 0.054, respectively, (8-10) to obtain the x-ray texture.

texture (preferred orientation) was measured by observing the diffracted intensity at twice the angle of incidence of the x-ray beam in a Picker Model 3488K x-ray diffractometer with 20 keV copper radiation. The samples were tilted 2° to reduce substrate reflections. This tilt only slightly reduced the reflections from the polycrystalline films (Fig. 1). The intensity of the signal from the {220} planes in the 1.05 μm thick sample deposited at 620°C was reduced by a factor of approximately two for a 5° tilt, indicating a variation in the crystallite orientations of this magnitude. For comparison, a 2° tilt reduced the signal from the single crystal substrate by more than three orders of magnitude.

Resolvable reflections were observed from the {111}, {220}, {311}, and {331} planes in the thickest polycrystalline samples deposited at 620°C, but some of these peaks could not be observed in thinner samples or those deposited at lower temperatures. In no case was a signal corresponding to the {400} planes observed, indicating either the absence of grains with <100> orientation or the low sensitivity of the measuring technique to grains with this orientation.

After normalizing the measured peak heights by the signal expected from a randomly oriented sample, we obtain an indication of the relative importance of crystallites with various orientations (Table I). The standard normalization factors (8) for an infinitely thick sample have been modified (9) for this case where the samples are very much thinner than the reciprocal of the absorption coefficient [μ^{-1} = 71 μm (10)]. Table I shows that the <110> texture is dominant in all three of the films of different thicknesses deposited at 620°C. As the films become thicker, however, the amounts of <110> and <331> texture increase much more than linearly with film thickness, while the amounts of <111>- and <311>- oriented grains do not increase as significantly. The dramatic increase in <110> texture with increasing film thickness indicates that the preference for <110> texture is a growth phenomenon rather than nucleation behavior (11) and is similar to that seen in films deposited at atmospheric pressure (12). Table I also indicates that no texture could be resolved in films deposited at 580°C in two different depositions.

Samples were prepared for transmission electron microscopy by etching the supporting substrate and the oxide from the back of the polycrystalline film. The film was usually further thinned chemically from the back so that the electron beam could easily penetrate the film; in all cases, therefore, the results correspond to the portion of the film farthest from the substrate. After preparation the samples were examined in a Philips EM200 electron microscope with a 100 keV electron beam.

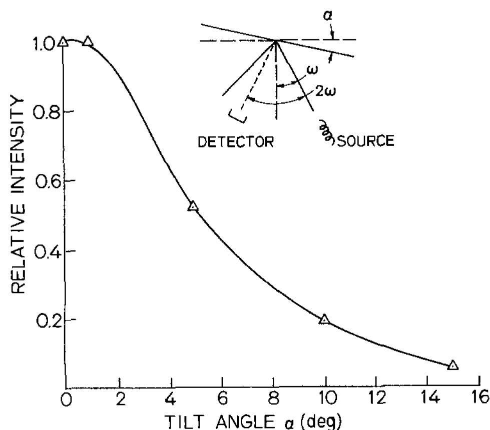

Fig. 1. Intensity of the diffracted x-ray signal intercepted from the <220> planes of the 1.05 μm, 620°C film as a function of the tilt angle α.

Typical micrographs are shown in Fig 2 for films deposited at 580° and 620°C, and the corresponding transmission electron diffraction (TED) patterns are shown below the micrographs. Films deposited at 600° and 640°C are similar to those deposited at 620°C. Films deposited at 600°C and above exhibit a more or less equiaxed, polycrystalline grain structure similar to that seen in films deposited at atmospheric pressure and somewhat higher temperatures in conventional CVD reactors (4, 12). Numerous twin lamella are seen within the grains. Films of different thicknesses deposited at 620°C appear to be qualitatively similar to each other, with the grain size near the top of the film increasing approximately linearly with increasing thickness. The grain size near the top of the film increases from about 0.05-0.1 μm in the 0.26 μm thick films to 0.15-0.2 μm in the 0.47 μm thick films, and to 0.3-0.4 μm in the thickest (1.05 μm) films. Transmission electron diffraction patterns (bottom of Fig. 2b) show the typical sharp rings and spots characteristic of polycrystalline material.

The films deposited at 580°C exhibit a different structure, although the results are not as consistent as in films deposited at higher temperatures. In some cases (Fig. 2a, top, left), a few crystallites appear to be embedded in a structureless background. In other cases some structure is seen (Fig. 2a, top, right), although the grains appear to be much smaller than those in the polycrystalline samples deposited at 600°-640°C. Variations in contrast as the sample is rotated a few degrees in the electron microscope indicate that there is crystalline character in at least some of these grains. However, no fine structure was observed within the grains. The less consistent results in the films deposited at 580°C suggest that this temperature is very close to the transition temperature between the deposition of amorphous silicon and polycrystalline silicon so that some regions of each are included in the deposited films.

The TED patterns of the films deposited at 580°C (bottom of Fig. 2a) appear qualitatively different from those of the films deposited at higher temperatures. Instead of sharp rings, only very diffuse halos are seen. Since these halos are suggestive of an amorphous structure (13), we will call these films "amorphous" in our discussion, although portions of the samples do show some crystalline character. Further evidence for classifying these films as amorphous is the absence of detectable x-ray texture in the as-deposited films and the dramatic change in the structure upon annealing, as considered in the next section.

From the results discussed above we may conclude that there is a transition between an amorphous and a polycrystalline structure at a deposition temperature very near 580°C. This temperature is somewhat lower than that at which a similar transition between amorphous and polycrystalline structure is seen in silicon films deposited by CVD at atmospheric pressure in a nitrogen ambient (4, 5).

The somewhat higher transition temperature in the latter case may be related to the reduction of the surface mobility of the depositing silicon atoms by adsorbed nitrogen or impurity atoms contained in the nitrogen (14). It may also be related to the higher deposition rates used at atmospheric pressure, rather than being directly related to the different pressures during deposition; deposition temperature and rate have been shown to be related over at least a limited range (15).

Structural Changes on Annealing

The presence of a transition from an amorphous to a polycrystalline structure for slight differences in deposition temperature and the use of markedly higher temperatures in subsequent IC fabrication steps lead to questions about the stability of the as-grown structure on further processing. To investigate the stability of the various structures, films grown at the different temperatures were annealed at 800°, 1000°, 1100°, and

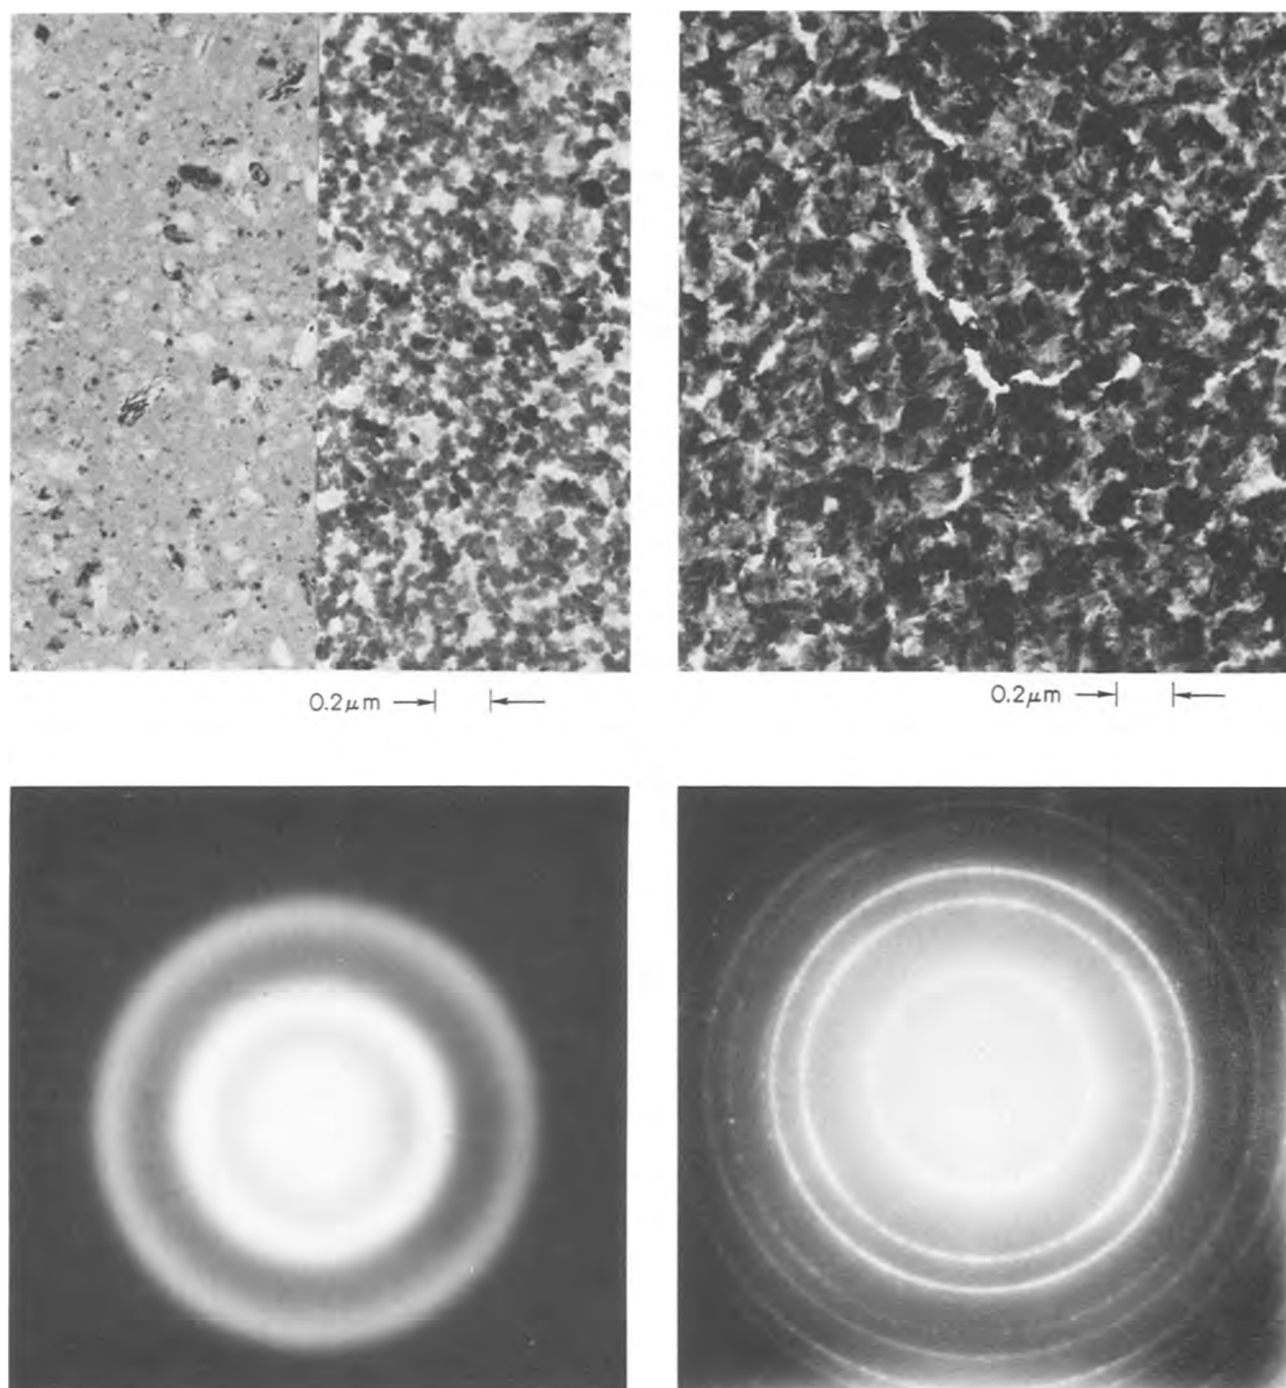

Fig. 2. Transmission electron micrographs of films deposited at (a, left) 580°C and (b, right) 620°C. The corresponding transmission electron diffraction patterns are shown below the micrographs.

1200°C for 1 hr in a nitrogen atmosphere in a standard diffusion furnace. A different piece of the film was used for each different annealing temperature, and the samples were rapidly inserted into the annealing furnace (within a few seconds). After annealing, the samples were investigated both by x-ray diffraction and by TEM, as before.

In some cases, especially at the higher annealing temperatures, the films were overcoated with a 0.5 μm thick layer of low temperature (480°C) deposited silicon dioxide before annealing in order to protect the silicon films from the furnace ambient. At the highest annealing temperature (1200°C) some deterioration of the optical quality of the films was observed after annealing when the films were not overcoated with oxide. However, no significant differences in the x-ray results were seen between bare and overcoated samples, indicating that the oxide cap does little to enhance or retard changes in structure during annealing.

The amorphous films deposited at 580°C were very unstable and showed marked changes in structure for all annealing temperatures. No structure was revealed by x-ray diffraction before annealing, while significant amounts were seen after annealing (Fig. 3a). The <311> texture appears to be dominant at intermediate annealing temperatures, while the <111> texture shows a tendency to increase at the highest annealing temperature employed. This preference for the growth of <311> and <111> textures on annealing is to be contrasted with the strong tendency of the <110> texture to develop during deposition and indicates that markedly different mechanisms may dominate during deposition and during annealing.

X-ray results taken after similar annealing are shown in Fig. 3b for the intermediate thickness film deposited at 620°C. Unlike the film deposited at 580°C, the higher temperature film, which is polycrystalline as deposited, is reasonably stable, showing

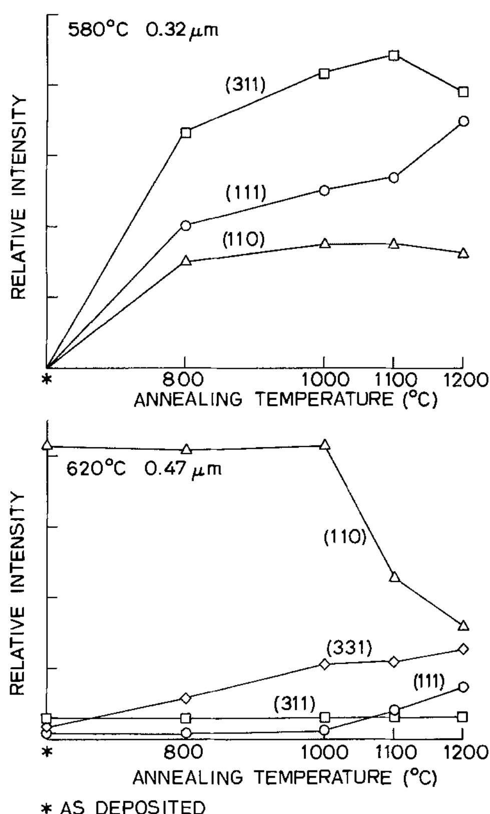

Fig. 3. Development of the x-ray texture after annealing at the indicated temperatures for films deposited at (a, top) 580°C and (b, bottom) 620°C.

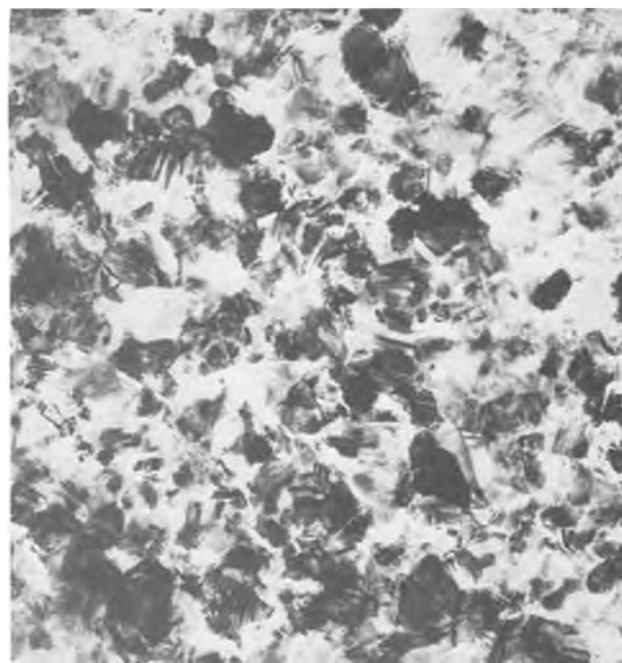
little structural change for annealing temperatures up to 1000°C; only some tendency for growth of <331> texture is observed. At 1100°C and above, however, significant change is seen; the <110> texture decreases significantly, and the <111> and <331> textures increase slightly.

Films were also observed by TEM after annealing. The films deposited at 620°C showed little change after annealing at 800° or 1000°C, while they showed a significant increase in grain size after annealing at 1100° and 1200°C (Fig. 4), consistent with the x-ray results. The initially amorphous films deposited at 580°C showed more dramatic changes. After an 800°C anneal, definite structure was seen (Fig. 5a). The grain boundaries were not very well defined, but fine structure was easily visible within the grains. After higher temperature annealing, the films appeared more crystalline, with better defined, larger grains (Fig. 5b). The rapid change in structure can be seen from the TED pattern of the 580°C film annealed at 800°C (Fig. 6). The transition from a diffuse halo pattern (bottom of Fig. 2a) to a ring-spot pattern indicates the rapid growth of crystal structure.

Additional Discussion

Further evidence of a qualitative difference between films deposited at 580°C and those deposited at higher temperatures was seen during sample preparation for transmission electron microscopy. After the substrate and oxide were chemically etched and the samples were removed from the wax which protected the surface, the unannealed films deposited at 580°C curled, indicating large stresses built into these films. No tendency to curl was seen in films deposited at higher temperatures or in annealed films deposited at 580°C. Thus, large stresses appear to be present in the amorphous films, but not in polycrystalline samples.

The results of the present annealing experiments may be compared to results of similar studies of initially amorphous silicon films deposited by evaporation (4) or by atmospheric pressure CVD in a nitrogen ambient (16). In the evaporated films (4) a dendritic structure is seen after annealing at 650°C. After an 850°C anneal, an equiaxed grain structure is dominant, but some dendritic structure is still seen, indicating a competition between the two types of nucleation. Presumably, the details of the nucleation behavior are influenced by the rate of heating to the annealing temperature. After a 1040°C anneal, only the equiaxed structure appears. Nagasima and Kubota (16) also observe a needlelike grain structure after a 700°C anneal, while an 1100°C anneal produces an equiaxed structure.



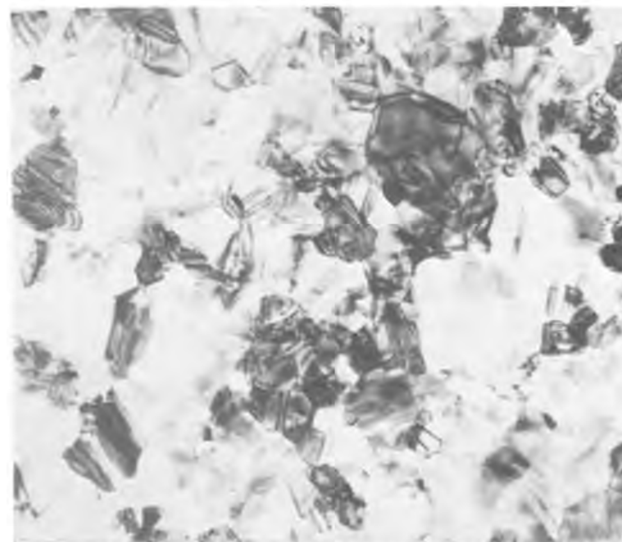


Fig. 4. Transmission electron micrographs of 0.47 μm thick films deposited at 620°C and annealed at (a, top) 1100°C and (b, bottom) 1200°C.

These observations are generally consistent with the results observed in the present investigation for the annealing of films deposited at 580°C. Both equiaxed grains and long, narrow structures are observed after

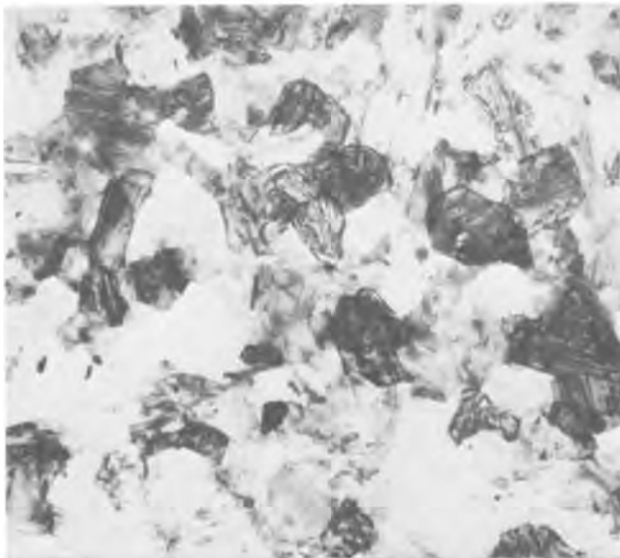

Fig. 5. Transmission electron micrographs of films deposited at 580°C and annealed at (a, top) 800°C and (b, bottom) 1200°C.

the 800°C anneal (Fig. 5a), while primarily a well-defined, equiaxed grain structure is seen after annealing at higher temperatures (Fig. 5b).

Anderson states (4) that stress in the as-deposited film provides the driving force for dendritic growth, while presumably the greater thermal energy at higher temperatures leads to the formation of the equiaxed structure. As we have seen, large stresses are present in the amorphous films considered in this study.

The structure which initially appears on crystallization of the amorphous films may possibly be related to the anomalous, dendritic structure seen in films deposited at atmospheric pressure and relatively low temperatures (12).

From this comparison, we see that the annealing behavior of amorphous silicon films deposited by several different techniques is qualitatively similar. However, residual impurities contained within the films

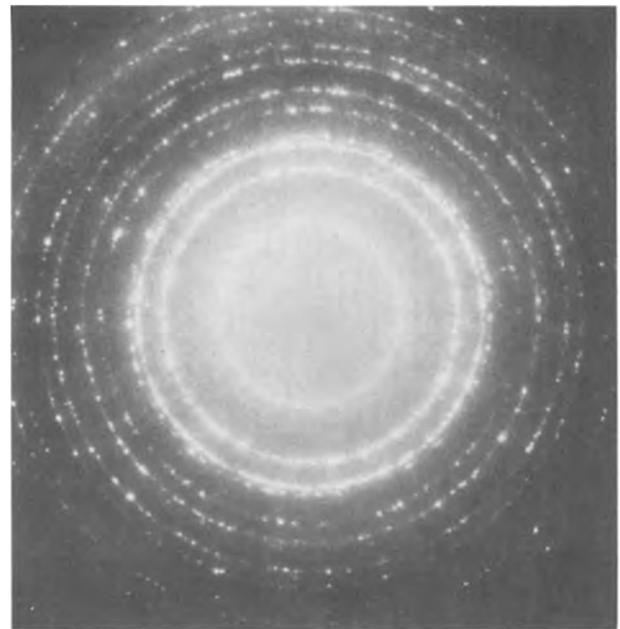

Fig. 6. Transmission electron diffraction pattern of film deposited at 580°C and annealed at 800°C.

may impede annealing, causing differing transition temperatures for the various types of films studied in the different investigations.

It should be emphasized that all of these results refer to annealing in an inert ambient. The presence of other gases or dopant sources during heat cycling may affect the structure of the film differently.

Conclusions

This study has shown that a critical transition temperature between amorphous and polycrystalline deposits exists for deposition temperatures close to those typically used to deposit films for integrated circuit applications. When the films are polycrystalline, the <110> texture is dominant, and this texture becomes of increasing importance in thicker films.

If silicon films deposited by low pressure CVD are initially polycrystalline, they should be reasonably stable and should not change markedly because of heat cycles normally seen in modern integrated circuit fabrication; however some changes may occur if temperatures above 1100°C are encountered. On the other hand, films deposited at slightly lower temperatures are initially amorphous and will crystallize during the thermal processing likely to be encountered. The implications of these changes on the electrical properties and reliability of integrated circuits incorporating these initially amorphous films must be considered further before the films can be used with confidence for device applications.

Framed Recessed Oxide Scheme for Dislocation-Free Planar Si Structures

I. Magdo and A. Bohg

IBM System Products Division, East Fishkill, Hopewell Junction, New York 12533

ABSTRACT

Recessed oxide isolation is widely used to reduce defects and increase packing density in Si integrated circuits. Unfortunately, the use of SiO_2/Si_3N_4 layers to mask the Si during the formation of the recessed oxide creates an unevenness in the surface, known as bird's-head, and the lateral oxidation due to the SiO_2 under the Si_3N_4 layer creates bird's-beak. Bird's-head and bird's-beak limit packing density and performance. In the framed recessed oxide-isolation process presented in this paper, the Si_3N_4 is allowed to cover the Si surface in narrow stripes to define the recessed oxide boundary; thus both limitations are avoided. The samples were analyzed by Sirtl etch and TEM methods. For a Si_3N_4 layer 500Å thick, no induced crystal defects were present, probably because of partial stress relief within the narrow Si_3N_4 stripes. For a Si_3N_4 layer more than 1000Å thick, dislocations appeared along the edges. The dislocations, which are of the 60° type on (111) slip planes with alternate Burger's vectors, relieve part of the intrinsic tensile stress of the Si_3N_4.

Much work has been done in recent years to improve isolation schemes for integrated devices. Recessed oxide isolation (1) (ROI), along with the LOCOS (2-6) and Isoplanar (7) technologies, has been developed to overcome the limitation that junction isolation imposes on packing density. In ROI processing, the silicon surface is thermally oxidized and silicon nitride is deposited. The Si_3N_4/SiO_2 layer is etched outside the active device regions. The exposed silicon areas are etched and then thermally reoxidized. Since the thermal oxide underneath the Si_3N_4 is exposed at the periphery and does not block oxygen diffusion during the formation of the recessed oxide, "bird's-head" and "bird's-beak" are created. The bird's-head causes uneven surface topology, and the bird's-beak (slowly increasing oxide thickness at the lateral silicon interface) limits the packing density.

Double or triple oxidation reduces the bird's-head (8), but does not improve the beak itself. The longer oxidation time causes the shallow bipolar structures to suffer, for example, by an increased outdiffusion from the subcollector.

Surface planarity can also be improved by using a thick Si_3N_4 film on a very thin SiO_2 pad (9), typically 2000Å Si_3N_4 on 50Å SiO_2. Too thick a layer of Si_3N_4 or too thin a layer of SiO_2, however, will introduce crystal defects in the silicon because of the high intrinsic stress in the Si_3N_4.

The new method described here eliminates bird's-beak in recessed oxide structures. Si_3N_4 is deposited directly on the silicon only at the perimeter of the ROI regions to form a frame around them. With the proper oxide-nitride thickness, a dislocation-free structure can be obtained.

Key words: Si structures, recessed oxide scheme, recessed oxide boundary.

Structure and Experimental Procedure

A conventional recessed oxide structure is shown in Fig. 1. Thermally grown SiO_2, 1000Å thick, is formed on a 0.3 Ωcm n-type (001) silicon wafer, and a Si_3N_4 film 1000Å thick is deposited by SiH_4-NH_3 reaction at 800°C. Annular regions with edges aligned along <110> are etched in the Si_3N_4/SiO_2 layers through an auxiliary 1000Å film of pyrolytic SiO_2. The exposed silicon substrate is isotropically etched, in a 1:2:5 volume ratio solution of 49% HF, CH_3COOH, 76% HNO_3, diluted in a 1:20 ratio with 75% HNO_3 (etch rate about 800 Å/min), to a depth of about 3400Å. The wafer is reoxidized for 360 min at 1000°C in wet ambient; the resulting SiO_2 layer is about 10,000Å thick.

The new framed recessed oxide structure is shown in Fig. 2. The thermally oxidized wafer is photoetched in an annular shape to expose the silicon surface (Fig. 2). The recessed oxide boundary defining the device areas then forms within the annular region. Next the Si_3N_4 layer is deposited as in the conventional process, and is etched so that it extends over the underlying SiO_2 layer by about 2.0 μm in the device areas. The silicon is etched in the solution used for the conventional process and then reoxidized to a thickness of about 10,000Å. Since the lateral oxygen diffusion is blocked at the perimeter of the ROI, the beak is completely eliminated. The head is reduced from about

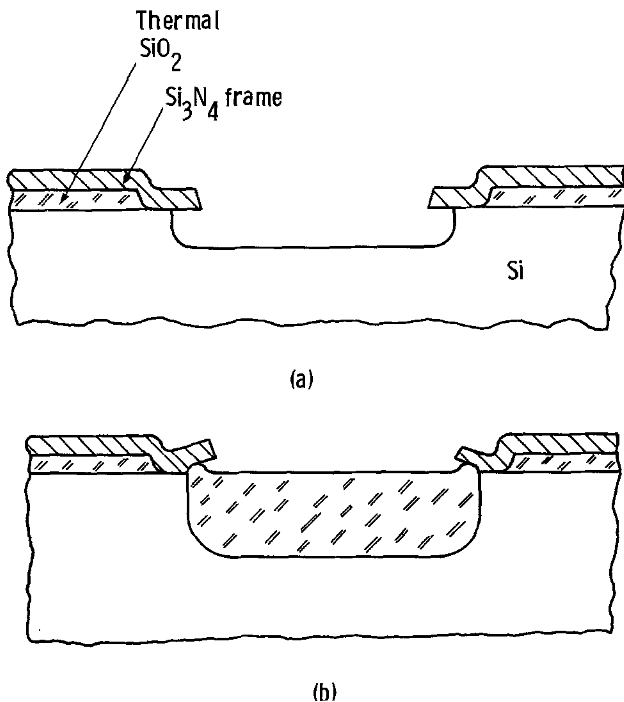

Fig. 2. Processing of framed recessed oxide structure. (a) After silicon etching; (b) after recessed oxide formation.

4500Å in structures made by the conventional process to less than 1000Å in the framed structure, as Fig. 2 shows. SEM micrographs of cross sections of both structures are shown in Fig. 3 for comparison.

The framed recessed oxide structure is usable only for geometries large enough to accommodate the thermally grown pad oxide, say $L > 2w$ (Fig. 4), where L is the width of the silicon island. For $L < 2w$, the Si_3N_4 is directly deposited on the silicon surface. In either case, the width of the Si_3N_4 stripes in direct contact with the silicon surface never exceeds $2w$ (4 μm in our case).

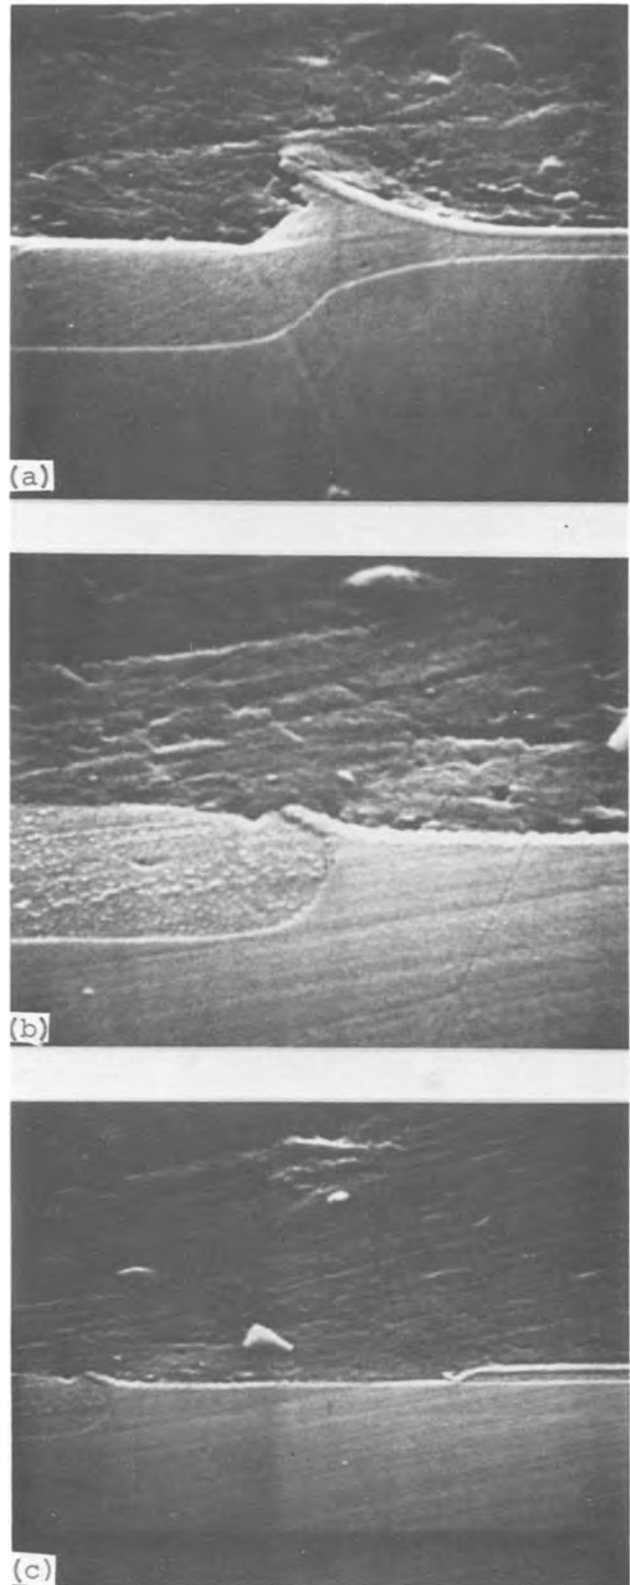

Fig. 3. SEM micrographs of 1 μm ROI. (a) Conventional ROI process; (b) framed ROI process; (c) framed ROI, depicting the lateral extent of the Si_3N_4/pad SiO_2.

As is well known, chemical vapor-deposited Si_3N_4 films exhibit a high intrinsic tensile stress [see Ref. (11) for a recent review] which may lead to crystal defects in the silicon. Therefore the effect of thermal SiO_2/Si_3N_4 layer thickness on crystal defects was investigated. Wafers were prepared by the framing process with three different combinations of thicknesses: 1000Å of SiO_2 on 1000Å of Si_3N_4; 500Å of SiO_2

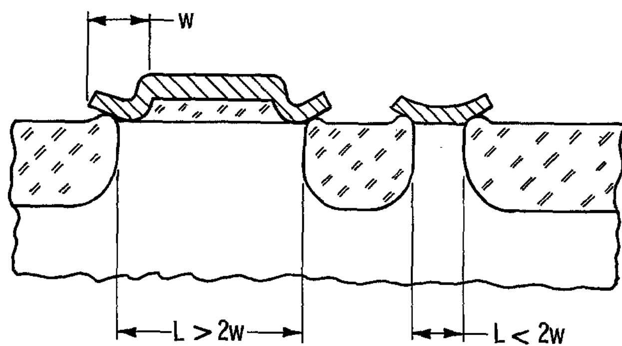

Fig. 4. Processing of silicon structures with $L > 2w$ (w is frame width) and $L < 2w$ with the framed recessed oxide scheme. The frame width used for this study was 2.5 μm. All edges are along <110>.

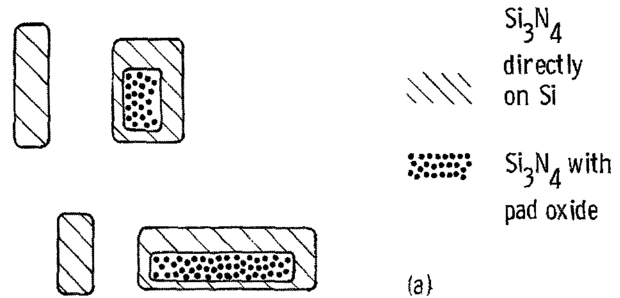

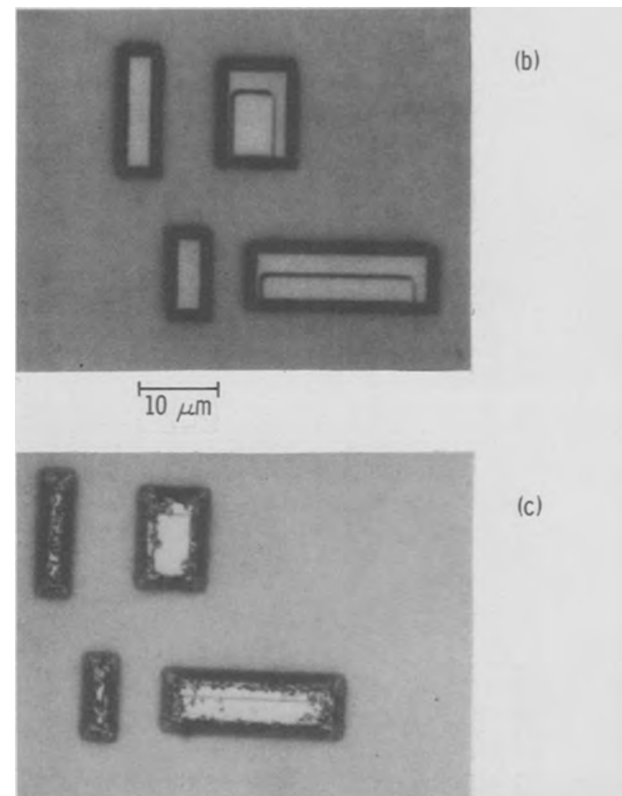

Fig. 5. Comparison of crystal perfection for Si_3N_4 thicknesses of 500 and 1000Å. (a) Layout of structures shown in (b) and in (c); the misalignment is intentional. (b) Sirtl-etched, 500Å Si_3N_4 on 500Å SiO_2, no dislocation. (c) Sirtl-etched, 1000Å Si_3N_4 on 500Å SiO_2, many dislocations.

on 500Å of Si_3N_4; and 1000Å of SiO_2 and 500Å of Si_3N_4. An experimental wafer with 1000Å of SiO_2 on 2000Å of Si_3N_4 was also processed. The general defect level was studied by Sirtl etching the wafer surface (after nitride stripping in hot phosphoric acid) and by Sirtl etching on vertical cleavage planes (110). Transmission electron microscopy (TEM) at 200 keV was used for detailed defect identification and Burger's vector analysis. The TEM samples were thinned by the combined ultrasonic dimpling/chemical etching method described in Ref. (14).

Crystal Defects in Silicon

The high intrinsic stress of the Si_3N_4 film generates crystal defects in the silicon substrate if the yield stress for silicon is locally exceeded during high temperature treatments. Using transmission electron microscopy, Tamura and Sunami (10) showed that straight dislocations of the 60° type form in the surface of a (100) silicon substrate as a result of nitride stress, if the wafer is completely covered with Si_3N_4. Westdorp and Schwuttke (14) had shown earlier that local stress concentrations near Si_3N_4 diffusion windows are preferred sites for dislocation generation, as was also reported for the recessed oxide structures investigated by Bassous, Yu, and Maniscalco (9). Calculations by Zeyfang (13) showed that the shear stress σ_{xz} near the edge of a stressed film window is about three times as high as the film stress σ_{xx} far away from the edge. The generation of dislocations is highly undesirable because these crystal defects may act as recombination centers or as gettering sites for impurities, and thus may cause artifacts to form during further processing. Therefore we have carefully checked the crystal perfection for all the thickness combinations, pad oxide on nitride, that we used.

In Table I, the perfection of the silicon crystal after framed recessed oxide processing is given for all the wafers studied, as concluded from Sirtl etching and confirmed by TEM. No dislocations were found along the recessed oxide edges on the wafers processed with 500Å of Si_3N_4 and 500 or 1000Å of pad oxide. Figure 5b shows the Sirtl-etched surface of a wafer processed with 500Å each of Si_3N_4 and of SiO_2. The absence of etch pits indicates that the substrate is free of dislocations; this finding was confirmed by TEM inspection. Increasing thickness of the Si_3N_4 to 1000Å, again for oxide thickness of 500Å, leads to dislocations in most of the structures (Table I). After Sirtl etching, the Si surface shows many etch pits along the former nitride edges (Fig. 5c). The in-depth distribution of the defects is revealed by Sirtl etching on a vertical (110) cleavage plane running through a device structure, which is shown in the series of light optical micrographs in Fig. 6a-6c. The etch pits start at the edges of the nitride islands and define V-shaped pairs of <211> directions, which are apparently the intersections of two {111} dislocation glide planes (normal to the plane of the micrograph) with the {110} cleavage plane (parallel to the plane of the paper). Dislocation generation on wafers with 1000Å Si_3N_4, however, was irregular. Many devices produced with the 500Å SiO_2/1000Å Si_3N_4 combination were entirely free of dislocations. For the 1000Å SiO_2/1000Å Si_3N_4 combination, only a few structures developed dislocations, and the rest remained dislocation-free, as was confirmed by TEM. Figure 7 shows the Sirtl-etched sili-

Table I. Crystal perfection after framed recessed oxide process for different combinations of nitride and pad oxide

The recessed oxide thickness in all cases is 10,000Å

Thickness of pad oxide (Å)	Thickness of Si_3N_4 film (Å)		
	500	1000	2000
500	No dislocations	Dislocations in most structures	—
1000	No dislocations	Dislocations in some structures	Dislocations in most structures

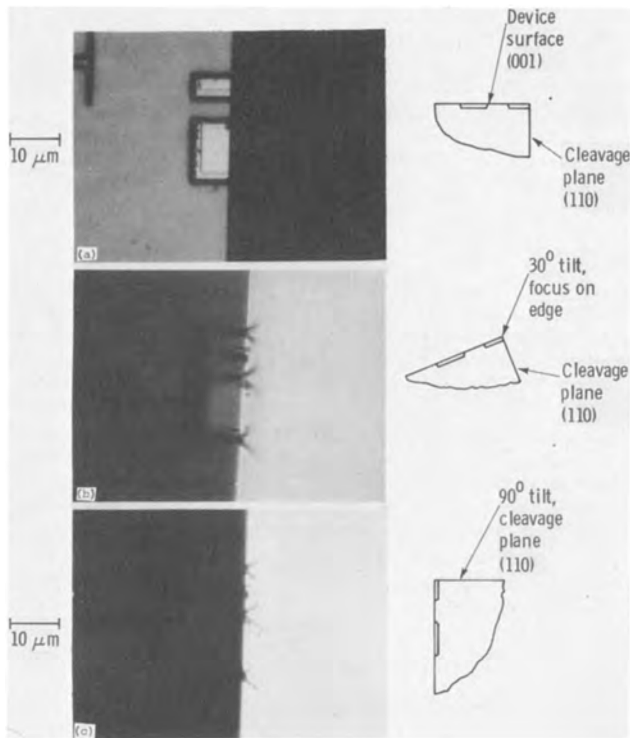

Fig. 6. In-depth distribution of dislocations (after Sirtl) for wafer with 1000Å Si_3N_4 on 500Å SiO_2.

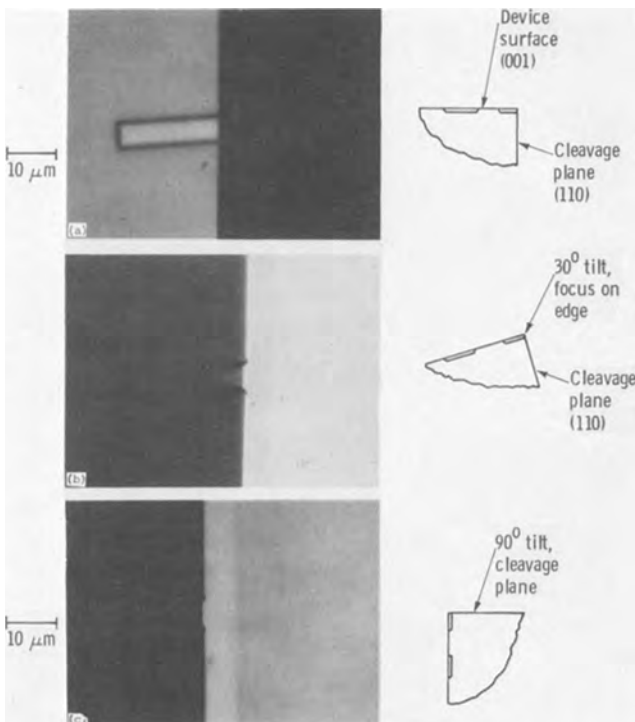

Fig. 7. Absence of dislocations on wafer with 1000Å Si_3N_4 on 1000Å SiO_2. Surface and cleavage plane Sirtl-etched as in Fig. 6.

con surface and cleavage plane of a typical device with 1000Å SiO_2/1000Å Si_3N_4: no dislocations are present. (The shallow notches visible at the device surface in Fig. 7c are caused by stress-induced preferential attack of the Sirtl etch solution at the recessed oxide edges.)

The defect structure introduced by thick ($\geqq$ 1000Å) Si_3N_4 along the edges was investigated by TEM. Figure 8 is a TEM micrograph of a recessed oxide structure produced with 1000Å Si_3N_4 on 500Å SiO_2. The nitride pattern was intentionally misaligned with respect to the pad oxide. For the TEM examination, the nitride and oxide were completely etched off for better electron transparency of the sample. The micrograph in Fig. 8 is composed of two contiguous prints of the same device obtained by different exposures of the same TEM negative in order to bridge the large contrast between the central silicon mesa region, about 1.5 μm thick, and the peripheral silicon, about 0.5 μm thick. Figure 8 shows that parallel to the former nitride edges many dislocations have been generated. At left, where the nitride edge was in direct contact with the silicon, the dislocation generation was the strongest. At right, where the nitride and the silicon were separated by an oxide pad 500Å thick, there are fewer dislocations. None at all were generated at the thin thermal SiO_2 step under the nitride (as is also apparent in Fig. 6); thus it seems that the thermal oxide alone is subjected to little stress during the formation of recessed oxide at 1000°C. The reduced number of crystal defects under the nitride edge with underlying pad oxide demonstrates that the oxide buffers the stress.

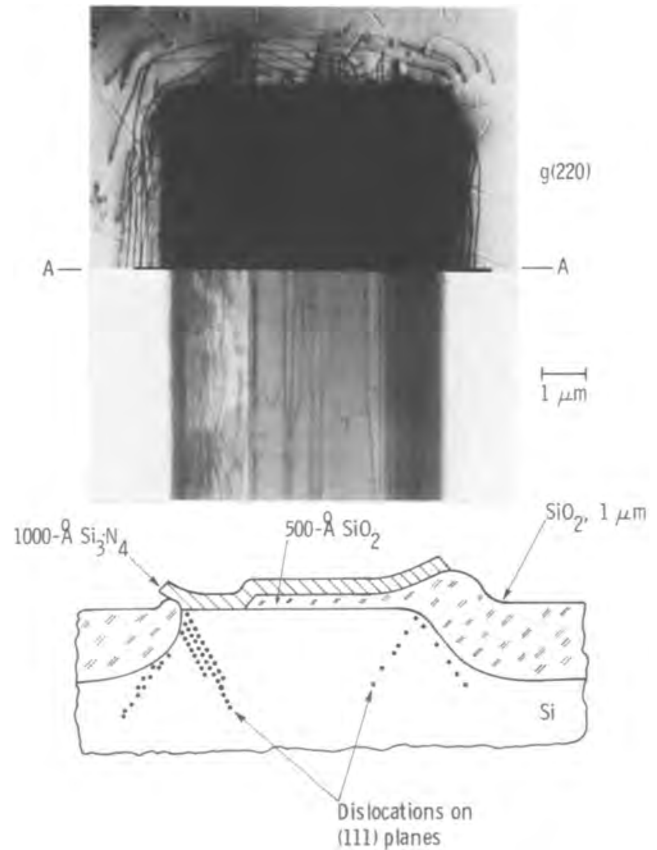

Fig. 8. TEM micrograph (top) and schematic cross section (bottom) along A-A through a structure with dislocations. For the TEM investigation, all Si_3N_4 and SiO_2 was etched off for better transparency. To bridge the large contrast range inside and outside the Si pedestal, the micrograph is composed of two contiguous prints with different exposures made from the same TEM micrograph. The misalignment between pad oxide and nitride was intended. Dislocation generation is strongest at left, where the Si_3N_4 and the silicon are in direct contact. Foil normal is $[00\bar{1}]$ with the nitride edges along <110>.

Figure 8 also gives a schematic cross section displaying the spatial arrangement of the dislocations, as deduced from stereo pairs of micrographs together with the Sirtl etching on the cleavage plane (Fig. 6). The dislocations emanate from the Si surface at the former position of the nitride edge and glide on the two {111}

planes, which contain the nitride edge as common intersection. Some dislocations are truncated by the advancing recessed oxide. Most of them are still within 1 μm from the edge, but some were able to glide as far as 5 μm under the influence of the edge stress and the repulsive force of neighboring dislocations.

The crystallographic nature of the dislocations was determined by using different diffraction vectors $\vec{g}$ and reversing the sense of $\vec{g}$. The results are explained with reference to Fig. 9, showing a section idealized by neglecting the occasionally observed dislocation reactions. The prominent dislocations are straight and parallel to the $[1\bar{1}0]$ nitride edge. They are all of the 60° type, with Burger's vectors inclined 45° towards the (001) Si surface. Outside the nitride edge, the dislocations occupy a common $(11\bar{1})$ slip plane. The Burger's vectors of this dislocation set lie within the $(11\bar{1})$ slip plane and alternate between the dislocations. Therefore the total silicon lattice displacement produced by the dislocations outside the nitride edge has only components normal to the nitride edge—none parallel to it. From the TEM analysis it was also established that the dislocations outside the nitride edge relieved a tensile strain near the silicon surface or a corresponding shear stress across the slip plane, as indicated by the ⊥ symbols in Fig. 9. A corresponding dislocation array exists on the $(\bar{1}\bar{1}\bar{1})$ plane extending beneath the nitride edge; again, the Burger's vectors alternate between the two <110> directions contained in the slip plane. From the shift of dislocation images upon reversal of the sense of $\vec{g}$, it follows that the dislocations under the nitride have relieved a compressive stress near the silicon surface, and thus a corresponding shear stress across the slip plane, as indicated by the T symbols in Fig. 9. On the average, the total deformation of the silicon under the nitride has only components normal to the nitride edge. To summarize these findings, 60° dislocations with four different Berger's vectors are found in the vicinity of the nitride edge, with most of the dislocations running parallel to the edges.

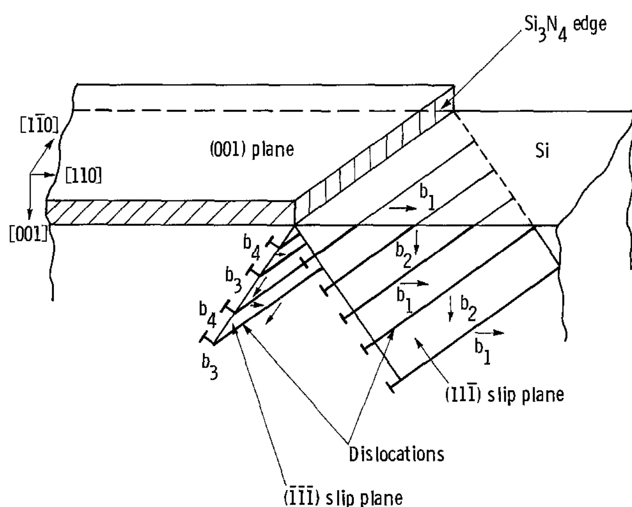

Fig. 9. Crystallography of dislocations along Si_3N_4 edges, idealized. The dislocations are parallel to the $[1\bar{1}0]$ nitride edge and glide on two {111} planes into the substrate. They are of the 60° type, with two alternating Burger's vectors. Outside the nitride-covered area, they have relieved a tensile strain in the silicon. Under the Si_3N_4 they have relieved a compressive strain in the silicon. The corresponding shear stresses are indicated by ⊥ and T.

Except for occasional deviations of dislocations from their ideal slip planes under the nitride and network formation by dislocation reactions, no other structural defects, such as stacking faults, were found.

Summary and Conclusions

The framed recessed oxide process described in this paper makes it possible to fabricate entirely beakless recessed oxide structures. No crystal defects were present for 500 or 1000Å thermal pad oxide, even under nitride patches which, because of their small lateral dimensions, had no central pad oxide. The structures prepared by the framed recessed oxide process showed no dislocations in spite of the direct contact of Si_3N_4 and silicon; this result is attributed to the fact that the nitride stripes in direct contact with the silicon are typically only 2.0 μm wide, and therefore allow a partial relief of the stress within the Si_3N_4.

Dislocation generation starts for nitride thickness of 1000Å and above. The dislocations are parallel to the (001) surface and glide on two symmetrical {111} planes that intersect at the <110> nitride edge. Each glide plane contains two sets of 60° dislocations with alternating Burger's vectors, relieving a tensile stress within the Si_3N_4 film (edge force points towards the nitride).

In our experiments, both the formation of a bird's-beak and the generation of dislocations were completely avoided for a nitride layer 500Å thick.

Photocharacteristics for Electrolyte-Semiconductor Junctions

Howard Reiss[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The electrolyte-semiconductor junction has lately received considerable attention as a half-cell electrode to be used with or without illumination. In spite of the activity in this field very little has been done toward deriving the electrical photocharacteristics based on the transport of carriers and the quantitative treatment of junction potentials. In this paper we attempt to remedy the situation by setting down the logic underlying the problem and undertaking the derivation of the photocharacteristics, in terms of various phenomenological transport and kinetic coefficients, for a number of fairly realistic systems. Our purpose is not to be exhaustive but to illustrate the process of derivation so that the reader will be able to extend it to other particular systems of interest. When possible we show the relation of our results to previous analyses (in the few cases where they exist). This comparison identifies the condition under which some of the previous results are valid. We have tried to be as critical as possible. Among the effects included in our model are those due to Guoy layers, redox systems, overvoltage, surface recombination, and hole-electron transport and recombination in the bulk of the semiconductor.

In recent years, the semiconductor-electrolyte interface has attracted much attention (1, 2). This has been especially true where photoeffects have been concerned, since promising schemes for both photoelectrolysis (3, 4) and solar cells (5-9) exist, based on such an interface. At this writing, many experiments have been performed on such systems, and a variety of current-voltage characteristics have been determined, both in the dark and under illumination. It appears, however, that very little theory exists for the interpretation of these characteristics. Perhaps the most advanced in this respect are papers by Butler (10), Andersen (11), and Laser and Bard (12). A pioneering paper is due to Dewald (13).

This situation is not surprising since. in a sense, the field contains a "cultural" as well as "physical" interface. On one side we have the solid-state and semiconductor device physicist, while on the other side there is the modern but, nonetheless, canonical electrochemist. The electrochemist seems to have made a valiant, if incomplete effort to understand the language of the semiconductor physicist while an admittedly inaccurate estimate seems to indicate that the reverse has not been nearly as true. As a result, an optimum rate of progress has probably not been realized.

For example, in the early days of semiconductor devices, current-voltage characteristics for all manner of junctions were calculated at an almost explosive rate. Shockley's classic treatment (14) of the p,n-junction and the treatment of the famous Schottky barrier diode (15) are prominent examples. These papers provided a phenomenological treatment of the transport of holes and electrons in semiconductor structures and contained both macroscopic transport and kinetic coefficients (*e.g.*, mobilities, recombination velocities, lifetimes, etc.) which could be measured or derived from microscopic theory once the phenomenological framework was available. In contrast, most of the electrochemical treatments mentioned above involve a direct passage to the microscopic level and are frequently aimed at only one of the many relevant fundamental processes. In this connection Butler's paper (10) on the photoelectrolysis of water using a WO_3 electrode seems to have been the most free from this criticism, but even here, the study is limited to the case of substantial reverse bias under circumstances such that the redox reaction in the electrolyte solution exercises no control over rate. As a consequence, the treatment becomes, essentially, one of the photovoltaic behavior of a conventional Schottky diode, and limited to reverse bias at that. However, even for Schottky diodes, current-voltage characteristics under illumination do not seem to have been generally derived. Butler's calculation is to a large extent an adaptation of a theory proposed by Gärtner (16) for the treatment of such diodes.

Since most of the photoeffects at the semiconductor-electrolyte interface occur in the body of the semiconductor, the current voltage characteristic can be derived using many of the ideas conventional to ordinary semiconductor device physics. On the other hand, additional ideas conventional to the treatment of phenomena at electrode surfaces are necessary. Frequently the effects of the redox couple can be treated as boundary conditions on the semiconductor surface. It is therefore possible to make considerable progress in the analytical treatment of the semiconductor-electrolyte junction by focusing on hole-electron transport in the semiconductor alone. It is therefore surprising that so little has been done in this respect.

Undoubtedly part of the problem lies with the above-mentioned, only moderate interest of the semiconductor device physicist, but an important aspect has to do with the great variety of models which may have to be invoked to match the assortment of differing physical systems which are encountered. For example, there are systems in which rate control may be due to any of a number of processes, *e.g.*, (*i*) due to the transport of carriers in the semiconductor, (*ii*) due to processes in the Helmholtz layer, (*iii*) due to processes in the Gouy-Chapman layer (17) in the electrolyte, (*iv*) due to transport in the electrolyte solution, etc. Furthermore, it is necessary to consider various seats of control of the barrier layer potential. For example, (*i*) Are surface states important in fixing the band bending? (*ii*) Is the semiconductor doped uniformly, and is it homogeneous as regards chemical constitution, etc? (*iii*) What is the relation between the Fermi levels, relative to vacuum, of the semiconductor and electrolyte, respectively? In addition, it may be appropriate in deriving current-voltage characteristics, depending on the case, to use thermionic emission, diffusion theory, or a combination of both (18). If one uses diffusion theory it becomes necessary to decide whether carrier generation and recombination must be accounted for (and to what extent) in the

[1] Permanent address: Department of Chemistry, University of California at Los Angeles, Los Angeles, California 90024.
Key words: photoelectrode, band bending, recombination, overvoltage, depletion layer, diffusion theory.

depletion layer, at the interface, etc. If thermionic emission theory is used it may be necessary to assess the effects of image potentials (19), quantum tunneling, etc.

Last but not least it may be necessary to incorporate into the general development, the quantitative aspects of various decomposition and corrosion processes (11), inseparable from the operation of the diode (especially at high photon fluxes).

Each different model which may have to be treated may involve an algebraic tour de force in tedium, although possibly based on straightforward manipulation. It is therefore not surprising that only the most elementary, incomplete situations have received any algebraic attention at all. A general treatment of a model involving all possible physical features is out of the question. However, a method applicable to a wide variety of models is easily demonstrated by working out a few examples.

The goal of the present paper will be just this, *i.e.*, to derive the current-voltage and photovoltaic characteristics for a few important models, each complete enough to have a measure of reality against which some existing measurements may be checked, and with the hope that the method will be well enough demonstrated so that any reader will be able to apply it to particular situations in which he may have an interest. Before doing this however, it is appropriate to make some additional prefatory remarks concerning contact potentials, Fermi levels, redox potentials, and photovoltaic circuits.

Some Critical Remarks on Fermi Levels

When an electrolyte phase (or for that matter any phase) is placed in contact with a semiconductor, electrons will usually be transferred between the two phases such that a double layer potential, V_{DL}, will result, given by

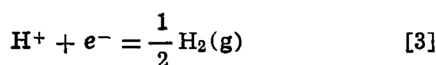
$$V_{DL} = E_F^{(E)} - E_F^{(S)} \qquad [1]$$

in which $E_F^{(E)}$ and $E_F^{(S)}$ are the Fermi levels (measured from a common reference level) in the electrolyte and semiconductor, respectively. The definition in Eq. [1] is such that V_{DL} is positive when the semiconductor is at a higher electrical potential than the electrolyte. The common reference level is generally chosen such that the energy of the electron in vacuum is set equal to zero. This is called the "vacuum" level.

It is customary for solid-state physicists to both measure and work with Fermi levels defined relative to vacuum, and so reasonable values for $E_F^{(S)}$ relative to vacuum are frequently available. On the other hand, the same is not true for $E_F^{(E)}$ in the electrolyte. However, for electrolytes which can serve as redox couples, redox potentials, measured relative to the standard hydrogen electrode, are available. Gerischer (17) has set forth a formula relating this standard redox potential, U, to $E_F^{(E)}$ measured relative to vacuum. This formula is

$$E_F^{(E)} = -qU + E_F^{(H)} \qquad [2]$$

in which q is the absolute value of the charge on the electron and $E_F^{(H)}$ is the Fermi level, relative to vacuum, of the standard hydrogen couple



$$H^+ + e^- = \frac{1}{2} H_2(g) \qquad [3]$$

Some additional critical remarks concerning $E_F^{(E)}$ and $E_F^{(H)}$ are in order. If a half-cell (such as the reaction in Eq. [3] is set up only as a solution in contact with H_2 gas and not in contact with another phase (not in contact with a platinum electrode for example, and not even in contact with the walls of a containing vessel) it will have a definite Fermi level relative to vacuum. It is this Fermi level to which $E_F^{(H)}$ refers. (The same is true of $E_F^{(E)}$, it is the Fermi level in the redox solution out of contact with additional phases.) As soon as the solution contacts another phase, if the Fermi level of that phase differs from the level in the solution, electrons will be transferred between the two phases. As a consequence the electrical potential of one phase will increase, relative to vacuum, while the potential of the other will decrease.

Since the position of the Fermi level, relative to the spectrum of electron energy levels (relative to vacuum), must remain fixed in the bulk of each phase, this means that, in general, the Fermi level in each phase will change, relative to vacuum, although, at equilibrium with respect to the transfer of electrons, the Fermi levels in both phases will be identical, although, in both cases, changed from the levels prior to contact. In the case that one of the phases can support very little space charge (*e.g.*, a metal) its Fermi level will be only slightly changed on contact.

In the measurement of U the redox couple and the hydrogen electrode are connected to form a full cell and U is measured as the emf of this cell. However, the common Fermi level of this full cell (for the reasons just mentioned) will be neither $E_F^{(E)}$ nor $E_F^{(H)}$. Since in the thermodynamic expression for U, the common Fermi level of the full cell cancels out, this is of no consequence.

In Eq. [1] and [2], $E_F^{(E)}$ and $E_F^{(H)}$ refer to isolated phases. Gerischer (20) invoking a cycle due to Lohmann (21) sets $E_F^{(H)}$ equal to -4.5 eV. In accordance with the above, the net process in this cycle must involve a redox couple out of contact with additional phases. A key step in the cycle involves the free energy of solvation of the Ag^+ ion which Lohmann takes as 4.96 eV. This value involves quantities estimated theoretically as well as some determined by experiment. However, the estimate is old. A newer estimate has been set forth by Gomer (22), namely, 4.64 eV. If this estimate is used in Lohmann's cycle, $E_F^{(H)}$ is predicted to be -4.8 eV. Certain other evidence for which there is not room for discussion in this paper indicates that the -4.8 eV figure may be the more reliable.

Except for the quantitative value of $E_F^{(H)}$, Gerischer's formula in Eq. [2] can be shown to be correct. On the other hand, a reasonably careful derivation (for which we have no space here) is necessary, especially when ionic activities cannot be represented by concentrations. We reserve this task for a later paper.

Photo Characteristics for a Circuit

When a semiconductor-electrolyte junction is illuminated with light of the proper wavelength, V_{DL} will be changed from its equilibrium value, prescribed by Eq. [1], to a new value, $V_{DL} + V_f$, where V_f may be called the photovoltage. If the junction is part of a closed circuit, involving a reversible counterelectrode (1) and a load resistance then the current, I, flowing in the circuit will be

$$I = \frac{V_f}{R_{int} + R_{load}} \qquad [4]$$

where R_{int} and R_{load} are the internal and load resistances, respectively. If an external bias voltage, V_b, is present in the circuit, then Eq. [4] is replaced by

$$I = \frac{V_f + V_b}{R_{int} + R_{load}} \qquad [5]$$

Equations [4] and [5] represent the circuit characteristics. The photocharacteristic is obtained by computing the relation between I and V_f based on the properties of the junction alone. Insertion of this expression into Eq. [5] gives V_f or I as functions of $R_{int} + R_{load}$. The open-circuit characteristic is obtained by setting I, determined from the junction alone, equal to zero.

Organization of Derivations of Photocharacteristics

The computation of the photocharacteristics is dominated by the fact that the problem may be subdivided into a number of independent (or quasi-independent) analytical components which must eventually be interfaced with one another. It is simplified because the internal behavior of each component may be studied separately but complicated by the need to establish the interfaces and to arrange the calculation so that each such connection is dealt with properly. It is therefore convenient, at the outset, to perform a "systems analysis," the result of which will be a recipe showing how the final solution is assembled out of its components. Figure 1 is useful for this analysis.

In this figure the semiconductor lies to the right of the vertical, solid line which represents the interface between the semiconductor and the electrolyte solution to the left. We shall assume the semiconductor to be n-type (no greater difficulty is encountered in treating the p-type case) with the bands bending up from the bulk toward the interface so that a "depletion layer" (23) of thickness W develops. The potential across this depletion layer is V_s with zero taken in the bulk of the semiconductor, *i.e.*, the potential of the interface is V_s. Near the interface, on the electrolyte side, we consider an interphase region which may only be several molecular diameters thick in which hole or electron transfer, or both, between the semiconductor and the redox system in the electrolyte takes place. Normally, at equilibrium there will be a potential V_{Ie} (where the subscript e denotes "equilibrium") across the interphase layer. When a current is flowing there may be an additional voltage η across the layer so that the total voltage becomes

$$V_I = V_{Ie} + \eta \quad [6]$$

Clearly η vanishes at equilibrium. Finally, there is a diffuse space charge region in the electrolyte to the left of the charge transfer region [sometimes called the Gouy-Chapman layer (17)] across which there will be a further potential V_E.

When no current is flowing and the junction is at equilibrium V_{DL}, the potential across the junction, will be given by

$$V_{DL} = V_{Ee} + V_{Ie} + V_{Se} = E_F^{(E)} - E_F^{(S)} \quad [7]$$

where V_{Ee} and V_{Se} are the equilibrium values of V_E and V_S. When current is flowing, due to the presence of an external bias V_b and illumination which produces a photovoltage V_f, the potential across the junction will be given by

$$V_f + V_{DL} = V_f + E_F^{(E)} - E_F^{(S)} = V_E + V_I + V_S \quad [8]$$

Clearly from Eq. [7]

$$V_f = V_E + V_I + V_S + E_F^{(S)} - E_F^{(E)} \quad [9]$$

so that the determination of V_f requires the evaluation of V_E, V_I, and V_S, in their dependences on other system parameters.

The great advantage of depletion layer theory is that W can be determined as a function of V_S, and that the potential $V(x)$, where x denotes position in the depletion layer, can be determined as a function of V_S and W, independent of whether or not a current I is flowing (see next section) Thus W can always be eliminated from any formulas for the transport of holes and electrons, and $V(x)$ is available for use in such formulas.

In our treatment we eventually limit consideration to the case where $\eta = 0$. There is, however, no fundamental difficulty in treating the case, $\eta \neq 0$, provided a model (possibly phenomenological) for the generation of η is available.

We will assume that the diffuse layer in the electrolyte relaxes to equilibrium so quickly that the potential distribution within it, and V_E in particular, may be computed (see below) by assuming an equilibrium distribution even though a current I is flowing. In this way we find that

$$V_E = \Gamma(V_f, ---) \quad [10]$$

where the dashes again indicate dependence on various material parameters. Now from Eq. [6] and [8] we find

$$V_S = V_S(V_E, V_f, ---) \quad [11]$$

and substitution of Eq. [10] into Eq. [11] gives

$$V_S = \Lambda(V_f, ---) \quad [12]$$

Hole and electron currents flowing in the semiconductor can be computed (see below) as functions of V_S, V_E, and other parameters of both the material and of illumination. The external current I may be readily related to the hole and electron currents at the interface so that

$$I = I(V_S, V_E, ---) \quad [13]$$

Substitution of Eq. [10] followed by inversion of Eq. [13] then yields

$$V_S = \psi(I, V_f, ---) \quad [14]$$

This may also be expressed as

$$I = I(V_f, V_S, ---) \quad [15]$$

Then substitution of Eq. [11] and [14] into Eq. [9] with V_I expressed by Eq. [6] gives

$$V_f = \Gamma(V_f) + \psi(I, V_f) + V_{Ie} + E_F^{(S)} - E_F^{(E)} \quad [16]$$

This may be inverted to yield

$$V_f = \theta(I, ---) \quad [17]$$

which is the photocurrent-voltage characteristic. The open-circuit photovoltage is obtained by setting I to zero. Substitution of Eq. [17] into Eq. [5] yields

$$I = \frac{\theta(I) + V_b}{R_{int} + R_{load}} \quad [18]$$

This is the photocurrent characteristic. Elimination of I between Eq. [17] and [18] yields the photovoltaic characteristic.

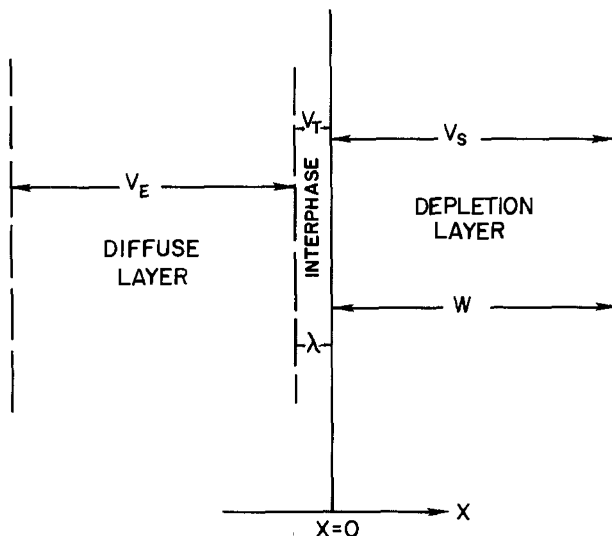


Fig. 1. Arrangement of the electrolyte-semiconductor junction, showing position of interface at $x = 0$, and the various layers, their potentials, and their widths. Note the total potential across the junction, $V_E + V_I + V_S$, equals the photovoltage V_f plus the difference in Fermi levels, $E_F^{(E)} - E_F^{(S)}$.

Potentials in the Various Layers

Equation [7] shows that the junction potential $V_f + V_b + V_{DL}$ consists of three components; one V_E,

across that part of the double layer in the electrolyte, V_I, across the charge interphase layer, and the other, V_S, extending across the portion of the double layer in the semiconductor.

Assume the junction to be plane parallel with the x direction normal to it. Furthermore let the semiconductor extend from $x = 0$ to $x = \infty$, while the electrolyte extends between $x = -\infty$, and $x = 0$. (We ignore the thickness, λ, of the interphase layer.) However the results we use can be shown to be the same as are obtained taking that layer into consideration so that the diffuse layer begins at $x = -\lambda$. For illustrative purposes we work out a simple example of the variation of potential within the junction double layer.

We assume V_{DL} to be negative, which according to Eq. [1] requires $E_F^{(E)} < E_F^{(S)}$. Furthermore, we assume the semiconductor to be doped uniformly n-type to the level N_D where N_D is the concentration of donor atoms. Furthermore we assume $N_D >> n_i$ where n_i is the intrinsic concentration of carriers in the semiconductor. Denoting the potential by V we set $V = 0$ in the bulk of the semiconductor. Invoking Schottky depletion layer theory (23) we have for Poisson's equation (using Gaussian units) in the depletion layer of the semiconductor

$$\frac{d^2V}{dx^2} = -\frac{4\pi q N_D}{\kappa_S}, \quad 0 < x \leq W \qquad [19]$$

where κ_S is the dielectric constant of the semiconductor, and W is the width of the depletion zone. The usual boundary conditions for depletion layer theory are

$$V(W) = 0 \qquad [20]$$

$$\left(\frac{dV}{dx}\right)_{x=W} = 0 \qquad [21]$$

$$V(0) = V_S \qquad [22]$$

The well-known parabolic solution to Eq. [19] subject to these boundary conditions is

$$V(x) = \frac{-2\pi q N_D}{\kappa_S}(x - W)^2, \quad 0 < x \leq W \qquad [23]$$

with

$$W = \left(\frac{-\kappa_S V_S}{2\pi_q N_D}\right)^{1/2} \qquad [24]$$

In approximating Poisson's equation by Eq. [19], *i.e.*, in invoking a depletion layer, we have implicitly assumed $V_S < 0$. This is in accordance with the assumption $V_{DL} < 0$, for the equilibrium situation. It may not, however, be accurate for a nonequilibrium case with sufficient forward bias. In any event, Eq. [21] and [22] show that $V(x)$ and the relation between V_S and W can be obtained independent of the flow of current.

On the electrolyte side we will first assume, for simplicity, that the diffuse space charge layer contains a uni-univalent electrolyte, ionizing as follows

$$MA = M^+ + A^-$$

and present in bulk concentration (at $x = -\infty$), c_0. Since $V(\infty) = V(W) = 0$ we must have

$$V(-\infty) = V_E + V_I + V_S \qquad [25]$$

Then, moving toward the Poisson-Boltzmann equation (24) we may write for $x < 0$

$$c_+ = c_0 \exp\left[-\frac{q}{kT}(V - V_E - V_I - V_S)\right] \qquad [26]$$

$$c_- = c_0 \exp\left[\frac{q}{kT}(V - V_E - V_I - V_S)\right] \qquad [27]$$

where k is the Boltzmann constant and T is temperature, and where c_+ and c_- are the local concentrations of cations and anions, respectively. Then the appropriate Poisson-Boltzmann equation (24) is

$$\frac{d^2V}{dx^2} = \frac{8\pi q c_0}{\kappa_E}\sinh\left\{\frac{q(V - V_E - V_I - V_S)}{kT}\right\} \qquad [28]$$

where κ_E is the dielectric constant in the electrolyte solution. This must be solved subject to the conditions

$$V(0) = V_S + V_I \qquad [29]$$

$$V(-\infty) = V_E + V_I + V_S \qquad [30]$$

$$\kappa_E\left(\frac{\partial V}{\partial x}\right)_{x=-0} = \kappa_S\left(\frac{\partial V}{\partial x}\right)_{x=+0} \qquad [31]$$

Equation [31] is an expression of the continuity of the electric induction at the interface and assumes the interphase layer to have no net charge. The solution of Eq. [28], subject to Eq. [29] and [30], can be carried out exactly (24). The result is

$$\ln\tanh\frac{q}{4kT}\{V - V_E - V_I - V_S\} - \ln\tanh\frac{q}{4kT}\{-V_E\} = x\sqrt{\frac{8\pi q^2 c_0}{\kappa_E kT}} \qquad [32]$$

Strictly speaking this equation applies to a diffuse layer in equilibrium; Eq. [26] and [29] are meant to hold at equilibrium. However, if the rate of adjustment (transport) in the layer is rapid enough, the layer will remain in quasi-equilibrium even though a current flows through it. Thus Eq. [32] may be adopted for a rapidly relaxing layer which, as indicated in the previous section, we assume. On the other hand, Eq. [23] and [24], incorporating the concept of a depletion zone, are in no way dependent on a differential equation based on the application of Boltzmann's law. Thus these equations hold for nonequilibrium situations quite generally.

Limiting our considerations to rapidly adjusting diffuse layers we may assume both Eq. [23] and [32] to apply to nonequilibrium situations. In these equations we then have two remaining unknown parameters, namely, V_E, and V_S. Equation [7] represents one relation which can be used for the determination of these parameters. Equation [31] is another which can be used for this purpose. Substituting Eq. [23] and [32] into Eq. [31] yields

$$[-2qN_D\kappa_S V_S]^{1/2} = -(8c_0\kappa_E kT)^{1/2}\sinh\frac{qV_E}{2kT} \qquad [33]$$

where we have used Eq. [24].

Substitution of Eq. [8] into Eq. [33] gives

$$[-2qN_D\kappa_S(E_F^{(E)} - E_F^{(S)} - V_f - V_E - V_I)]^{1/2} = -(8c_0\kappa_E kT)^{1/2}\sinh\frac{qV_E}{2kT} \qquad [34]$$

Equation [34] is the detailed version of Eq. [10], determining V_E as a function of V_f. Note that since we assume $\eta = 0$, $V_I = V_{Ie}$, where V_{Ie} is a fixed material parameter.

We have considered a uni-univalent electrolyte because in this case the Poisson-Boltzmann equation can be fully integrated to yield Eq. [32]. However redox couples do not usually consist of such symmetric electrolytes. Nonetheless the appropriate version of Eq. [10] can still be derived. We give an example.

To be definite, consider the case where the redox couple is

$$Fe^{+3} + e^- = Fe^{+2} \qquad [35]$$

Denote the concentrations of Fe^{+3} and Fe^{+2} at $x = -\infty$ by $c_3{}^0$ and $c_2{}^0$, respectively. The anion con-

centration which may consist, for example, of chloride ions will be denoted by c_1^0. These bulk concentrations will determine the redox potential U, and through Eq. [2], the Fermi level, $E_F^{(E)}$. The local concentrations of ions will be

$$c_3 = c_3^0 \exp\left[-\frac{3q}{kT}(V - V_E - V_I - V_S)\right] \quad [36]$$

$$c_2 = c_2^0 \exp\left[-\frac{2q}{kT}(V - V_E - V_I - V_S)\right] \quad [37]$$

$$c_1 = c_1^0 \exp\left[\frac{q}{kT}(V - V_E - V_I - V_S)\right] \quad [38]$$

Note that electroneutrality requires

$$3c_3^0 + 2c_2^0 = c_1^0 \quad [39]$$

The Poisson-Boltzmann equation now becomes

$$\frac{d^2V}{dx^2} = \frac{-4\pi q}{\kappa_E}\left\{3c_3^0 \exp\left[-\frac{3q}{kT}(V - V_E - V_I - V_S)\right] + 2c_2^0 \exp\left[-\frac{2q}{kT}(V - V_E - V_I - V_S)\right] - c_1^0 \exp\left[\frac{q}{kT}(V - V_E - V_I - V_S)\right]\right\} \quad [40]$$

This must be solved subject to the boundary conditions, Eq. [29] through [31]. It can be integrated once, immediately, subject to Eq. [30] and [31], with the result

$$\frac{dV}{dx} = \pm\left\{\frac{8\pi kT}{\kappa_E}\left[c_3^0\left\{\exp\left[-\frac{3q}{kT}(V - V_E - V_I - V_S)\right] - 1\right\} + c_2^0\left\{\exp\left[-\frac{2q}{kT}(V - V_E - V_I - V_S)\right] - 1\right\} + c_1^0\left\{\exp\left[\frac{q}{kT}(V - V_E - V_I - V_S)\right] - 1\right\}\right]\right\}^{1/2} \quad [41]$$

Equation [39] dictates the use of the positive sign in Eq.[41] if $(dV/dx) > 0$, and the negative sign for $(dV/dx) < 0$.

We choose the positive sign since in our examples $(dV/dx) < 0$. Then substitution of this equation and Eq. [29] into Eq. [31] yields

$$kT\kappa_E[c_3^0 e^{3qV_E/kT} + c_2^0 e^{2qV_E/kT} + c_1^0 e^{-qV_E/kT} - c_3^0 - c_2^0 - c_1^0]^{1/2} = -[-qN_D\kappa_S V_S]^{1/2} \quad [42]$$

Now we can again use Eq. [8] to eliminate V_S from Eq. [42] and determine V_E as a function of V_f, again giving the equivalent of Eq. [10].

It should, however, be indicated that large electrolyte concentrations (high ionic strengths) will cause V_E to approach zero, thereby eliminating the diffuse layer almost entirely. For example, in Eq. [34] a large c_0 coupled with the exponential dependence of the sinh function on V_E forces $V_E \to 0$. Since most junction measurements have involved such high ionic strengths, this has generally been the case. Thus the treatment of the diffuse space charge layer in the electrolyte may only represent an academic exercise and, in fact, in what follows we set $V_E = 0$. Incidentally rapid relaxation is facilitated by high electrolyte concentrations since small, mean ionic velocities may still correspond to large currents.

Modified Butler-Volmer Equation (25)

We need to determine a relation between the current in the interface layer and that in the semiconductor. Figure 2 illustrates the system we now deal with. In the figure the positive x-direction is horizontal and to the right. The interface lies at $x = 0$, marked in the figure. In the semiconductor, at positive values of x, the bands bend up to the left, a necessary consequence of the fact that it is doped n-type and that we are limiting consideration to cases where depletion layer theory is valid. Since electron energy is plotted in the figure, bands which bend up correspond to decreasing electrical potential. The negative of the potential is in fact shown as the dashed line designated by $-V(x)$. The width of the depletion zone is marked by W. The depletion zone necessarily contains positive space charge (marked by the word POSITIVE) due to ionized donors. Outside the space charge layer (marked by NEUTRAL) the semiconductor is neutral. The edges of the conduction and valence bands are respectively designated by E_c and E_v while the donor level is E_D. For equilibrium the common Fermi level is denoted by E_F. It is assumed that the collective energetics of the system is such that the donors are always fully ionized.

At the interface our model contains electronic traps all having level, E_T, shown in the figure. This trap will be capable of catalyzing the recombination of holes and electrons.

Outside of the semiconductor, in the electrolyte to the left of $x = 0$ we indicate the possible diffuse layer by DIFFUSE. Furthermore, the total decrease in potential, $V_E + V_I + V_S$, across the junction is shown as well as the components, $V_E + V_I$ and V_S.

At the interface itself holes, h^+, and electrons, e^-, can be transferred in the interphase layer to and from the redox system by the activated processes

$$M^{+2} + h^+ = M^{+3} \quad [43]$$

and

$$M^{+2} = M^{+3} + e^- \quad [44]$$

where for definiteness we assume that divalent and trivalent cations M^{+2} and M^{+3} are involved. The vertical bell-shaped curve with base along the interface represents a hypothetical density of electron states associated with M^{+2}. If this density of states is zero opposite both the conduction band and the valence band there can be essentially no coupling between the semiconductor and the redox process. If the density of states is zero opposite the conduction band, then

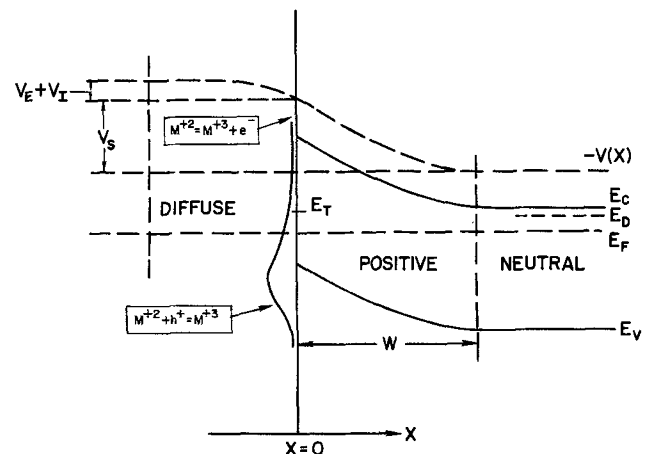

Fig. 2. Diagram of interface showing band bending, the various layers, and energy levels. The bell-shaped curve along the $x = 0$ ordinate is the redox system density of states. The interphase layer is not shown in order to avoid crowding.

only the process of Eq. [43], involving the valence band is possible. Equation [44] clearly applies to the conduction band.

In most situations the density of states will only be finite opposite one band, and, at the most, will have only a negligible tail opposite the other. We shall treat some examples in which the processes in both Eq. [43] and [44] are operative, but the more likely case, with n-type semiconductors and with bands bending up, is the situation in which only the process of Eq. [43] need be considered.

Consider Eq. [43] at equilibrium. We denote the forward rate, per square centimeter of interface by r_{fe}^+, where the subscript f stands for forward and subscript e for eqiulibrium. Then

$$r_{fe}^+ = \{k_f^+ e^{-E_f^+/kT}\} c_{2e}(0) p_e(0) \quad [45]$$

in which $c_{2e}(0)$ represents the equilibrium concentration of M^{+2} at $x = 0$ (at the interface), and

$$p_e(0) = \frac{n_i^2}{N_D} \exp(-qV_{Se}/kT) \quad [46]$$

where V_{Se}, the equilibrium value of V_S, represents the equilibrium (junction neither illuminated nor biased) concentration of holes in the valence band at $x = 0$. The product of these quantities appears in Eq. [45] in the normal chemical kinetic (mass action) sense. The quantity in curly brackets is the specific rate constant with k_f^+ the appropriate preexponential factor, and E_f^+, the activation energy. Similarly for the reverse process we may write

$$r_{re}^+ = \{k_r^+ e^{-E_r^+/kT}\} c_{3e}(0) n_v(0) \quad [47]$$

where the subscript r stands for reverse and where $c_{3e}(0)$ is the equilibrium concentration of M^{+3} at $x = 0$, and $n_v(0)$ is the essentially constant concentration of electrons in the valence band. At equilibrium the forward and reverse rates are equal, hence we define an exchange current

$$i_+ = r_{fe}^+ = r_{re}^+ = k_f^+ \exp(-E_f^+/kT) c_{2e}(0) p_e(0)$$
$$= k_r^+ \exp(-E_r^+/kT) c_{3e}(0) n_v(0) \quad [48]$$

When the junction is not at equilibrium, the transfer of a hole from the semiconductor to M^{+2} may occasion an "overvoltage" which adds, in the usual simple manner (26), to the activation energy. Denoting this overvoltage by η, the modified forward activation energy becomes

$$E_f^+ + \gamma_+ q\eta \quad [49]$$

where γ_+ is the transfer factor (possibly related to the position of the activated state along the reaction coordinate) (25) of the order of 1/2. Therefore, out of equilibrium, we may express the forward rate as

$$r_f^+ = \{k_f^+ e^{-(E_f^+ + \gamma_+ q\eta)/kT}\} c_2(0) p(0)$$
$$= i_+ \left\{ \frac{c_2(0) p(0)}{c_{2e}(0) p_e(0)} \right\} \exp(-\gamma_+ q\eta/kT) \quad [50]$$

where we have utilized Eq. [48] and $c_2(0)$ and $p(0)$ are the nonequilibrium concentrations of M_2^+ and holes.

For the reverse process we note that the transfer factor, γ_r, should be

$$\gamma_r = 1 - \gamma_+ \quad [51]$$

resulting in a nonequilibrium activation energy

$$E_r^+ - (1 - \gamma_+) q\eta \quad [52]$$

and the nonequilibrium rate

$$r_r^+ = \{k_r^+ e^{-[E_r^+ - (1-\gamma_+)q\eta]/kT}\} c_3(0) n_v(0)$$
$$= i_+ \left\{ \frac{c_3(0)}{c_{3e}(0)} \right\} \exp[(1 - \gamma_+) q\eta/kT] \quad [53]$$

The net nonequilibrium rate may now be expressed as

$$r_+ = i_+ \left\{ \left(\frac{p(0)}{p_e(0)} \right) \left(\frac{c_2(0)}{c_{2e}(0)} \right) \exp[-\gamma_+ q\eta/kT] - \left(\frac{c_3(0)}{c_{3e}(0)} \right) \exp[(1 - \gamma_+) q\eta/kT] \right\} \quad [54]$$

This is a modified Butler-Volmer equation (25).

An entirely parallel treatment yields, for the net rate corresponding to the process of Eq. [44]

$$r_- = i_- \left\{ \left(\frac{c_2(0)}{c_{2e}(0)} \right) \exp[-\gamma_- q\eta/kT] - \left(\frac{c_3(0)}{c_{3e}(0)} \right) \left(\frac{n(0)}{n_e(0)} \right) \exp[(1 - \gamma_-) q\eta/kT] \right\} \quad [55]$$

where the exchange current is

$$i_- = k_f^- \exp(-E_f^-/kT) c_{2e}(0) p_c(0)$$
$$= k_r^- \exp(-E_r^-/kT) c_{3e}(0) n_e(0) \quad [56]$$

The meaning of the symbols in Eq. [55] and [56] should be self-evident by comparing them with the corresponding symbols for the process of Eq. [43]. However, we will point out that $p_c(0)$ is the essentially constant concentration of holes in the conduction band, and

$$n_e(0) = N_D \exp(qV_{Se}/kT) \quad [57]$$

Equations [54] and [55] are the relations we wished to derive connecting the rates of charge transfer at the interface.

As we have mentioned several times, in this paper we shall limit consideration to cases where both V_E and η are zero. $V_E = 0$, is almost a rigorous practical requirement since electrolytes of high ionic strength are almost always involved, however cases in which $\eta \neq 0$ may occur and they must be treated by the introduction of some physically reasonable model for the generation of η. In any event, η, $V_E = 0$, has two immediate consequences for Eq. [54] and [55]. The first is the disappearance of the exponentials in these equations while the second, results in

$$c_{2e}(0) = c_2^0 \quad [58]$$

$$c_{3e}(0) = c_3^0 \quad [59]$$

where, as in the previous section, c_2^0 and c_3^0 are the concentrations of ions in the bulk of the electrolyte.

Transport in the Interphase

When $V_E = 0$, no field exists in the interphase region and transport from the bulk of the electrolyte to the semiconductor occurs by diffusion, possibly modified by convection. As a result the flux density of M^{+2} to the semiconductor is

$$J_2 = a_2[c_2^0 - c_2(0)] \quad [60]$$

while that for M^{+3} is

$$J_3 = a_3[c_3^0 - c_3(0)] \quad [61]$$

where a_2 and a_3 are phenomenological coefficients. Now the current, flowing externally, is given by

$$I = qAJ_2 = -qAJ_3 = qA(r_+ - r_-) \quad [62]$$

where A is the area of the interface. Combining Eq. [60] and [61] with Eq. [62] gives

$$c_2(0) = c_2^0 - \frac{I}{qAa_2} \quad [63]$$

$$c_3(0) = c_3^0 + \frac{I}{qAa_3} \quad [64]$$

so that, setting $\eta = 0$ and $c_e^0 = c^0$, we can write Eq.

[54] and [55] in the forms

$$r_+ = i_+ \left\{ \frac{p(0)}{p_e(0)} \left[1 - \frac{I}{qAa_2c_2^0} \right] - \left[1 + \frac{I}{qAa_3c_3^0} \right] \right\} \quad [65]$$

and

$$r_- = i_- \left\{ \left[1 - \frac{I}{qAa_2c_2^0} \right] - \frac{n(0)}{n_e(0)} \left[1 + \frac{I}{qAa_3c_3^0} \right] \right\} \quad [66]$$

Combining these equations with the last equation of Eq. [62] yields

$$I = qA \left\{ \frac{i_+ \left[\frac{p(0)}{p_e(0)} - 1 \right] + i_- \left[\frac{n(0)}{n_e(0)} - 1 \right]}{1 + i_+ \left[\frac{1}{a_2c_2^0} \frac{p(0)}{p_e(0)} - \frac{1}{a_3c_3^0} \right] - i_- \left[\frac{1}{a_3c_3^0} \frac{n(0)}{n_e(0)} + \frac{1}{a_2c_2^0} \right]} \right\} \quad [67]$$

Obviously the current can be determined once the ratios $p(0)/p_e(0)$ and $n(0)/n_e(0)$ are known.

Surface Recombination

Moving inward to the surface of the semiconductor, we next consider the recombination catalyzed by the surface trap whose energy levels are E_T and which are present at a specified surface density, σ_T. For this process we assume a simple Read-Shockley model (27). Then the rate of recombination (per square centimeter of surface) of holes and electrons will be given by (27)

$$\Omega = \frac{\xi\omega[p(0)n(0) - n_i^2]}{\xi[n(0) + n_1] + \omega[p(0) + p_1]} \quad [68]$$

where ξ and ω are constants (each of which is proportional to the surface density σ_T) and n_1 and p_1 are the concentrations of electrons and holes to be expected, respectively, in the conduction and valence bands when the Fermi level is at the trap level. Thus

$$n_1 = N_c e^{-(E_c - E_T)/kT} \quad [69]$$

$$p_1 = N_v e^{(E_v - E_T)/kT} \quad [70]$$

where N_c and N_v are the effective densities of states in the conduction and valence bands. In Eq. [68] n_i is the intrinsic concentration of carriers.

Formulation of the General Boundary Value Problem

We may denote the "particle" current densities, in the semiconductor, of holes and electrons, respectively, by $J_p(x)$ and $J_n(x)$. Then under steady-state conditions, particle conservation requires

$$J_p(0) = r^+ + \Omega \quad [71]$$

$$J_n(0) = r^- + \Omega \quad [72]$$

These represent two boundary conditions to be applied to the transport of holes and electrons at $x = 0$.

For $J_p(x)$ and $J_n(x)$ we employ diffusion theory (18) and use the standard expressions consisting of sums of diffusion and drift terms. Thus we have

$$J_p(x) = -D_p \left\{ \frac{\partial p}{\partial x} + \frac{q}{kT} \frac{\partial V}{\partial x} p \right\} \quad [73]$$

and

$$J_n(x) = -D_n \left\{ \frac{\partial n}{\partial x} - \frac{q}{kT} \frac{\partial V}{\partial x} n \right\} \quad [74]$$

where D_p and D_n are the diffusion coefficients of holes and electrons, respectively.

In our model we assume, like Gärtner (16) and Butler (10), that the semiconductor is illuminated by light of photon flux density ϕ_0 and optical absorption α so that the rate of photogeneration of hole-electron pairs, per cubic centimeter, is

$$g(x) = \phi_0 \alpha e^{-\alpha x} \quad [75]$$

The equations of continuity for holes and electrons, respectively, are then

$$-\frac{\partial J_p}{\partial x} + \phi_0 \alpha e^{-\alpha x} + \frac{p_0 - p}{\tau_p} = \frac{\partial p}{\partial t} \quad [76]$$

$$-\frac{\partial J_n}{\partial x} + \phi_0 \alpha e^{-\alpha x} + \frac{n_0 - n}{\tau_n} = \frac{\partial n}{\partial t} \quad [77]$$

In these equations t is time, and p_0 and n_0 are the unperturbed equilibrium concentrations of holes and electrons, respectively, while τ_p and τ_n are the thermal lifetimes of holes and electrons.

We shall neglect recombination in the depletion zone lying between $x = 0$ and $x = W$, hence in the depletion zone Eq. [76] and [77] may be written without the third terms (which specify the net rate of generation of holes and electrons per cubic centimeter) on the right of both equations. Thus we get

$$-\frac{\partial J_p^*}{\partial x} + \phi_0 \alpha e^{-\alpha x} = \frac{\partial p^*}{\partial t} \quad [78]$$

$$-\frac{\partial J_n^*}{\partial x} + \phi_0 \alpha e^{-\alpha x} = \frac{\partial n^*}{\partial t} \quad [79]$$

where the asterisk is used to denote quantities in the depletion zone.

Outside of the depletion zone, *i.e.*, for $x > W$, we take recombination into account, and hence retain Eq. [76] and [77], however, in this region $(\partial V/\partial x) = 0$ so that only diffusion currents need be considered for the minority carrier, *e.g.*, holes. At $x = W$, the majority electron concentration is only negligibly perturbed from the equilibrium value, N_D. Thus, as another boundary condition, this time at $x = W$, we have

$$n^*(W) = N_D \quad [80]$$

Because of Eq. [80], and because we shall evaluate the steady-state currents at $x = 0$, it proves possible to avoid the explicit study of the transport of electrons outside the depletion zone. However, it is still necessary to study hole transport. For this purpose we require additional boundary conditions. Clearly, outside the depletion zone at $x = \infty$, we have

$$p(\infty) = \frac{n_i^2}{N_D} \quad [81]$$

where the quantity on the right is the equilibrium concentration of holes in the bulk of the semiconductor. Furthermore at $x = W$, there are two conditions of continuity, namely

$$p^*(W) = p(W) \quad [82]$$

$$J_p^*(W) = J_p(W) \quad [83]$$

We now have enough differential equations and boundary conditions to constitute a determinative boundary value problem for the steady-state case in which all time derivatives are suppressed. For convenience we assemble these equations in one place

$$J_n^* = -D_n \left\{ \frac{\partial n^*}{\partial x} - \frac{q}{kT} \frac{\partial V}{\partial x} n^* \right\}, \quad 0 < x \leq W \quad [74']$$

$$-\frac{\partial J_n^*}{\partial x} + \phi_0\alpha e^{-\alpha x} = 0, \quad 0 < x \leq W \qquad [77']$$

$$J_n^*(0) = r^- + \Omega \qquad [72']$$

$$n^*(W) = N_D \qquad [80']$$

$$J_p^* = -D_p\left\{\frac{\partial p^*}{\partial x} + \frac{q}{kT}\frac{\partial V}{\partial x}p^*\right\}, \quad 0 < x \leq W \qquad [73']$$

$$-\frac{\partial J_p^*}{\partial x} + \phi_0\alpha e^{-\alpha x} = 0, \quad 0 < x \leq W \qquad [76']$$

$$J_p^*(0) = r^+ + \Omega \qquad [71']$$

$$p^*(W) = p(W) \qquad [82]$$

$$J_p^*(W) = J_p(W) \qquad [83]$$

$$J_p = -D_p\frac{\partial p}{\partial x}, \quad x > W \qquad [73'']$$

$$-\frac{\partial J_p}{\partial x} + \phi_0\alpha e^{-\alpha x} + \frac{\frac{n_i^2}{N_D} - p}{\tau_p} = 0, \quad x > W \qquad [76'']$$

$$p(\infty) = \frac{n_i^2}{N_D} \qquad [81]$$

Single and double primes on the equation numbers indicate that the equation was derived from an original equation having the number. Thus Eq. [74'], [72'], [80'], [73'], and [71'] are derived from the corresponding numbered equations by appending asterisks. Equations [76'] and [77'] are derived from Eq. [76] and [77] by appending asterisks and suppressing both time derivatives and terms corresponding to recombination. Equation [73''] is derived from Eq. [73] by setting $(\partial V/\partial x) = 0$, while Eq. [76''] is derived from Eq. [76] by replacing p_0 by n_i^2/N_D and suppressing the time derivative. The set of twelve equations [74'], [77'], [72'], [80'], [73'], [76'], [71'], [82], [83], [73''], [76''], and [81], constitute the complete steady-state boundary value problem. In the following sections we solve this problem for special limiting cases, and, eventually, generally.

Solutions for Infinite Interface Rate Constants

If either i_+ or i_- in Eq. [54] and [55], respectively, or ξ and ω in Eq. [68] are allowed to become infinite especially simple boundary value problems result.

If ξ and ω are infinite Ω may be very much larger than r^+ or r^-, and Eq. [71'] and [72'] will require

$$J_p^*(0) \approx \Omega \approx J_n^*(0) \qquad [84]$$

However, Ω will have to remain finite since $J_p^*(0)$ and $J_n^*(0)$ must be finite. Because of this the condition $\xi, \omega \to \infty$ requires, through Eq. [68], that

$$p(0)n(0) = n_i^2 \qquad [85]$$

Equation [84] indicates that photogenerated hole and electron currents "recombine" at the surface of the semiconductor so that essentially no external current flows under the stated conditions; the photovoltaic device will then deliver no power to be used externally. Obviously, an efficient device should avoid surface recombination as much as possible. The conditions to which Eq. [84] and [85] apply are therefore not very interesting. On the other hand, it is instructive to solve the boundary value problem for this case, and we now do this.

Substituting Eq. [74'] into Eq. [77'] and integrating twice with respect to x yields

$$n^*(x) = \exp[qV(x)/kT]\left\{K_2 + \frac{K_1}{D_n}I_1(x) + \frac{\phi_0}{D_n}I_2(x)\right\} \qquad [86]$$

where K_1 and K_2 are constants and where

$$I_1(x) = \int_0^x \exp[-qV(x)/kT]dx \qquad [87]$$

and

$$I_2(x) = \int_0^x \exp\{-[qV(x)/kT] - \alpha x\}dx \qquad [88]$$

A similar process based on the integration of Eq. [76'] together with Eq. [73'] yields

$$p^*(x) = \exp[-qV(x)/kT]\left\{M_2 + \frac{M_1}{D_p}S_1(x) + \frac{\phi_0}{D_p}S_2(x)\right\} \qquad [89]$$

where M_1 and M_2 are constants and where

$$S_1(x) = \int_0^x \exp[qV(x)/kT]dx \qquad [90]$$

and

$$S_2(x) = \int_0^x \exp\{[qV(x)/kT] - \alpha x\}dx \qquad [91]$$

Substituting Eq. [73''] into Eq. [76''] and integrating twice with respect to x, subject to the condition, Eq. [81] yields

$$p = \frac{n_i^2}{N_D} + M_3\exp(-x/L_p) - \frac{\alpha\phi_0 e^{-\alpha x}}{D_p\left(\alpha^2 - \frac{1}{L_p^2}\right)} \qquad [92]$$

where M_3 is still another constant and

$$L_p = \sqrt{D_p\tau_p} \qquad [93]$$

is the diffusion length for holes.

Using Eq. [86] in Eq. [74'] gives

$$J_n^*(x) = -K_1 - \phi_0 e^{-\alpha x} \qquad [94]$$

while Eq. [89] in Eq. [73'] gives

$$J_p^*(x) = -M_1 - \phi_0 e^{-\alpha x} \qquad [95]$$

and substitution of Eq. [94] and [95] into Eq. [84] gives

$$M_1 = K_1 \qquad [96]$$

Furthermore substitution of Eq. [86] and [89] into Eq. [85] gives

$$K_2M_2 = n_i^2 \qquad [97]$$

Equations [96] and [97] provide two relations on the five constants K_1, K_2, M_1, M_2, and M_3. Three more relations, making five in all, may be obtained from Eq. [80'], [82], and [83] into which we substitute Eq. [86], [89], [92], [94], and [95]. Solving these five equations for the five unknown constants gives, after some tedious, but straightforward, algebraic manipulation

$$M_1 = -\frac{B}{2} + \left(\frac{B^2}{4} - C\right)^{1/2} \qquad [98]$$

where

$$B = \frac{-D_nN_D}{I_1} - \frac{D_pn_i^2}{N_D(S_1 + L_p)} + \frac{\phi_0 I_2}{I_1} + \left(\frac{\phi_0}{S_1 + L_p}\right)\left[S_2 + \frac{e^{-\alpha W}}{\alpha + \frac{1}{L_p}}\right] \qquad [99]$$

and

$$C = \frac{\phi(\phi_0 I_2 - D_nN_D)(S_2 + \exp[-\alpha W/(\alpha + L_p^{-1})]N_D - \phi_0 I_2 D_p n_i^2}{N_D I_1(S_1 + L_p)} \qquad [100]$$

where I_1, I_2, S_1, and S_2 denote $I_1(W)$, $I_2(W)$, $S_1(W)$, and $S_2(W)$, respectively. Note that $C = 0$ when $\phi_0 = 0$, so that, according to Eq. [98], $M_1 = 0$. Then Eq. [96] requires $K_1 = 0$. From Eq. [94] and [95] we then have $J_n^* = J_p^* = 0$, which is just what is expected when the junction is not illuminated so that $\phi_0 = 0$.

With M_1 determined by Eq. [98] the other constants are determined by M_1 as follows

$$K_1 = M_1 \quad [101]$$

$$M_2 = \frac{n_i^2}{N_D - \frac{M_1 I_1}{D_n} - \frac{\phi_0 I_2}{D_n}} \quad [102]$$

$$K_2 = N_D - \frac{M_1 I_1}{D_n} - \frac{\phi_0 I_2}{D_n} \quad [103]$$

$$M_3 = \left\{ \frac{\phi_0 e^{-\alpha W}}{\alpha^2 L_p^2 - 1} - M_1 \right\} \frac{L_p}{D_p} \exp(W/L_p) \quad [104]$$

Thus the entire problem for the transport of holes and electrons in the semiconductor is solved.

As indicated earlier, however, the case of rapid surface recombination is of little interest since no external power is delivered, and therefore we have only solved it for illustrative purposes. We now consider a more useful case.

This is the case in which i_+ and i_- are infinite. Then since r^+ and r^- must remain finite Eq. [65] and [66] require

$$p(0) = p_e(0) \left\{ \frac{1 + (I/qAa_3c_3^0)}{1 - (I/qAa_2c_2^0)} \right\} \quad [105]$$

and

$$n(0) = n_e(0) \left\{ \frac{1 - (I/qAa_2c_2^0)}{1 + (I/qAa_3c_3^0)} \right\} \quad [106]$$

Equations [105] and [106] require

$$p(0)n(0) = p_e(0)n_e(0) = n_i^2 \quad [107]$$

so that if ξ and ω in Ω are finite, Eq. [68] demands

$$\Omega = 0 \quad [108]$$

Thus the problem we deal with now is the other face of the coin in which there is no surface recombination, and an external current flows, given by

$$I = qA(r^+ - r^-) \quad [109]$$

or, equivalently, by Eq. [67], where A is the area of the interface. Equations [72′] and [71′] substituted into Eq. [109] give

$$I = qA[J_p^*(0) - J_n^*(0)] \quad [110]$$

Furthermore since $\Omega = 0$, these same equations require

$$J_n^*(0) = r^- \quad [111]$$

and

$$J_p^*(0) = r^+ \quad [112]$$

Equations [105], [106], [80′], [82], [83], and [81] are to be used as new boundary conditions for the new boundary value problem.

In the present case Eq. [86], [89], and [92] still hold, and since

$$I_1(0) = I_2(0) = S_1(0) = S_2(0) = 0 \quad [113]$$

it follows from Eq. [86] and [89] that

$$K_2 = n(0) \exp(-qV_s/kT) \quad [114]$$

$$M_2 = p(0) \exp(qV_s/kT) \quad [115]$$

Furthermore Eq. [94] and [95] are still valid, and substitution of Eq. [92] into Eq. [73″] gives

$$J_p(x) = \frac{D_p M_3}{L_p} \exp(-x/L_p) - \frac{\alpha^2 \phi_0 e^{-\alpha x}}{\alpha^2 - \frac{1}{L_p^2}} \quad [116]$$

Once again we are confronted with the need to determine the five constants K_1, K_2, M_1, M_2, and M_3. For this purpose we can utilize Eq. [114], [115], [80′], [94], and [95], substituting Eq. [86], [89], [92], [94], [95], and [116]. With the constants determined in this manner, Eq. [94] and [95] yield

$$J_n^*(0) = -\frac{D_n N_D}{I_1} - \phi_0 \left[1 - \frac{I_2}{I_1}\right] + \frac{D_n}{I_1} n(0) e^{-qV_S/kT} \quad [117]$$

and

$$J_p^*(0) = \frac{-D_p n_i^2}{N_D(S + L_p)} - \phi_0 \left[1 - \frac{S_2}{S_1 + L_p}\right] + \frac{\phi_0 e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)(S_1 + L_p)} + \frac{D_p p(0) e^{qV_S/kT}}{S_1 + L_p} \quad [118]$$

Substitution of these equations into Eq. [110] yields the current. The result is

$$I = qA \left\{ \frac{\phi_0 e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)(S_1 + L_p)} + \frac{D_p p(0) \exp(qV_S/kT)}{S_1 + L_p} + \frac{\phi_0 S_2}{S_1 + L_p} - \frac{D_p n_i^2}{N_D(S_1 + L_p)} + \frac{D_n N_D}{I_1} - \frac{D_n n(0) \exp(-qV_S/kT)}{I_1} - \frac{\phi_0 I_2}{I_1} \right\} \quad [119]$$

where again I_1, I_2, S_1, and S_2 refer to the values of the respective functions at $x = W$.

In this equation $n(0)$ and $p(0)$ still need to be specified. For this purpose we make use of Eq. [105] and [106] as well as Eq. [46] and [57]. The results are

$$n(0) = N_D \left\{ \frac{1 - (I/qAa_2c_2^0)}{1 + (I/qAa_3c_3^0)} \right\} \exp(qV_{Se}/kT) \quad [120]$$

$$p(0) = \frac{n_i^2}{n_D} \left\{ \frac{1 + (I/qAa_3c_3^0)}{1 - (I/qAa_2c_2^0)} \right\} \exp(-qV_{Se}/kT) \quad [121]$$

Now substitution of Eq. [6], [7], and [8] with $\eta, V_E, V_{Ee} = 0$, into Eq. [120] and [121] yields

$$p(0) \exp(qV_S/kT) = \frac{n_i^2}{n_D} \left\{ \frac{1 + (I/qAa_3c_3^0)}{1 - (I/qAa_2c_2^0)} \right\} \exp(qV_f/kT \quad [122]$$

and

$$n(0) \exp(-qV_S/kT) = N_D \left\{ \frac{1 - (I/qAa_2c_2^0)}{1 + (I/qAa_3c_3^0)} \right\} \exp(-qV_f/kT) \quad [123]$$

Substitution of Eq. [122] and [123] into Eq. [119] yields

$$\frac{I}{qA} = \frac{D_p n_i^2}{N_D(S_1 + L_p)} \left[\left\{ \frac{1 + (I/qAa_3c_3^0)}{1 - (I/qAa_2c_2^0)} \right\} \exp(qV_f/kT) - 1 \right] + \frac{D_n N_D}{I_1} \left[1 - \left\{ \frac{1 - (I/qAa_2c_2^0)}{1 + (I/qAa_3c_3^0)} \right\} \exp(-qV_f/kT) \right] + \frac{\phi_0 S_2}{S_1 + L_p} - \frac{\phi_0 I_2}{I_2} + \frac{\phi_0 e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)(S_1 + L_p)} \quad [124]$$

This is a cubic equation in I, relating I to V_f and V_S, the latter quantity appearing in W, I_1, I_2, S_1, and S_2 (see Eq. [23], [24], [87], [88], [90], and [91]). The proper root or roots of Eq. [124] can be inverted to furnish a detailed equivalent of Eq. [14]. Because V_E is zero in our case, $\Gamma(V_f)$ in Eq. [16] can be set to zero. The photocurrent-voltage characteristics then follow from Eq. [17], and the photocurrent characteristic, from Eq. [18].

The open-circuit photovoltage may be easily obtained from Eq. [124] by setting $I = 0$. This yields

$$\frac{D_p n_i^2}{N_D(S_1 + L_p)}[\exp(qV_f/kT) - 1] + \frac{D_n N_D}{I_2}[1 - \exp(-qV_f/kT)] + \frac{\phi_0 S_2}{S_1 + L_p} - \frac{\phi_0 I_2}{I_1} + \frac{\phi_0 e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)(S_1 + L_p)} = 0 \quad [125]$$

However, W, I_1, I_2, S_1, and S_2 are still functions of V_S in this equation. V_S can be eliminated by using Eq. [9] which, in our case, specializes to

$$V_S = V_f + V_{Se} \quad [126]$$

Substitution of this equation into Eq. [125] yields a determinative relation for V_f. Under substantial reverse bias $\exp[qV(x)/kT]$ is very small and Eq. [90] and [91] indicate that $S_1(W)$ and $S_2(W)$ may be approximated by zero. Furthermore we note that because V_S is large and negative, under sufficient reverse bias, $\exp(-\alpha x)$ may be considered slowly varying with respect to $\exp[-qV(x)/kT]$. In Eq. [88] it may therefore be extracted from the integral and assigned its value where $\exp[-qV(x)/kT]$ has its largest value. This occurs at $x = 0$ so we get

$$I_2(W) \approx e^{-\alpha 0}\int_0^W \exp[-qV(x)/kT]dx = \int_0^W \exp[-qV(x)/kT]dx = I_1(W) \quad [127]$$

In semiconductors with bandgaps of approximately 3 eV, as in the case of WO_3 or TiO_2, we have at room temperature

$$n_i^2 \approx 10^{-80}$$

Assuming

$$N_D \approx 10^{15}\ \mathrm{cm}^{-3}$$

$$D_p \approx 1.0\ \mathrm{cm^2/sec}$$

$$L_p \approx 10^{-4}\ \mathrm{cm}$$

$$V_f \approx 1.5\mathrm{V}$$

possible reasonable values, we find

$$\frac{D_p n_i^2}{N_D L_p}\exp\left(\frac{qV_f}{kT}\right) \approx 10^{-31}\ \mathrm{cm^{-2}\,sec^{-1}}$$

By contrast the photon flux ϕ_0 will be orders of magnitude greater than unity, while $[e^{-\alpha W}/(\alpha + L_p^{-1})] - 1$ will be of order unity, implying that the last term in Eq. [125] will also be orders of magnitude greater than unity. Thus the first term can be neglected. Setting S_1 and S_2 equal to zero, and $I_1 = I_2$, in the remaining terms of Eq. [125] then gives

$$V_f = \frac{-kT}{q}\ln\left\{1 + \frac{\phi_0 I_1}{D_n N_D}\left[\frac{e^{-\alpha W}}{1 + \alpha L_p}\right]\right\} \quad [128]$$

This equation has been derived under the assumption of a reverse biased wide bandgap ($E_c - E_v \geqq 3.0$ eV) semiconductor. How well it can be used when these conditions do not prevail is uncertain. Furthermore although it appears to yield the usual logarithmic dependence of V_f on photon flux, ϕ_0, both I_1 and W depend on V_f; W less sensitively than I_1. In fact, we can approximate I_1 (see Eq. [87] and [126]) by

$$I_1 \approx K^* \exp(-qV_f/kT) \quad [129]$$

Substitution of Eq. [129] into Eq. [128] yields

$$W \approx \ln\frac{K^*\phi_0}{D_n N_D(1 + \alpha L_p)} \quad [130]$$

Then using Eq. [24] and [126] gives

$$V_f \approx -V_{Se} - \frac{2\pi q N_D}{\kappa_S}\left|\ln\frac{K^*\phi_0}{D_n N_D(1 + \alpha L_p)}\right|^2 \quad [131]$$

so that in this limit V_f depends on the square of the logarithm of ϕ_0. Furthermore V_f is maximized at $-V_{Se}$ (the flatband potential)[2] when ϕ_0 is such that the argument of the logarithm is unity.

Another simple limit of Eq. [124] occurs when a_2, $a_3 = \infty$, so that mass transport in the interphase layer exercises no rate control whatsoever. Then Eq. [124] becomes

$$\frac{I}{qA} = \frac{D_p n_i^2}{N_D(S_1 + L_p)}[\exp(qV_f/kT) - 1] + \frac{D_n N_D}{I_1}[1 - \exp(-qV_f/kT)] + \phi_0\left[\frac{S_2}{S_1 + L_p} - \frac{I_2}{I_1} + \frac{e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)(S_1 + L_p)}\right] \quad [132]$$

If once again Eq. [126] is used to express W, I_1, I_2, S_1, and S_2 in terms of V_f, Eq. [132] again gives the photocurrent-voltage characteristic. Again the open-circuit voltage is obtained by setting $I = 0$.

Before leaving this case we should investigate under what conditions Eq. [132] reduces to the result obtained by Butler (10) who considered the special example of photocurrent in a junction under substantial reverse bias and such that the rate control did not reside in the redox process. This would certainly be the case when $i_+ = i_- = a_2 = a_3 = \infty$ so that Eq. [132] which incorporates this condition is relevant.

Butler's equation is

$$I = qA\phi_0\left\{\frac{e^{-\alpha W}}{1 + \alpha L_p} - 1\right\} \quad [133]$$

Under reverse bias we can set $S_1 = S_2 = 0$, and use Eq. [127] in Eq. [132] which then becomes

$$I = qA\phi_0\left\{\frac{e^{-\alpha W}}{\alpha + \frac{1}{L_p}} - 1\right\} + qA\left\{\frac{D_p n_i^2}{N_D L_p}(e^{qV_f/kT} - 1) - \frac{D_n N_D}{I_1}(e^{-qV_f/kT} - 1)\right\} \quad [134]$$

The first term on the right is Butler's result, however, we still have to contend with the second term. For this term to vanish would require $V_f = 0$, obviously impossible under conditions of illumination. Another explanation is therefore necessary. One possibility is the following.

If we assume $i_- = 0$ so that the redox process coupled to the conduction band does not occur (a perfectly reasonable and, in fact, probable circum-

[2] The fact that V_f decreases when the flatband potential is exceeded indicates, as mentioned earlier, that depletion layer theory fails beyond this point.

stance) while i_+, a_2, and a_3 continue to be infinite, and, in addition, we assume ξ, $\omega = 0$, so that there is no recombination at the interface (a possible situation) then we must still retain Eq. [105], but in place of Eq. [106] we must have

$$J_n^*(0) = -K_1 - \phi_0 = 0 \quad [135]$$

since both r_- and Ω are now zero. Carrying through the same manipulations, but using Eq. [135] instead of Eq. [106] we arrive at the result

$$I = qAr^+ = qAJ_p^*(0) = qA\phi_0 \left\{ \frac{e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)(S_1 + L_p)} - 1 \right\} + qA \left\{ \frac{D_p n_i^2}{N_D(S_1 + L_p)} (e^{qV_f/kT} - 1) + \frac{\phi_0 S_2}{S_1 + L_p} \right\} \quad [136]$$

This is just Eq. [132] without the terms involving D_n, *i.e.*, without any current contribution from electron transport. If we now consider the case of sufficient reverse bias, we will once again have $S_1(W) \simeq S_2(W)$ 0, and $I_1(W) \simeq I_2(W)$. Then Eq. [136] becomes

$$I = qA\phi_0 \left\{ \frac{e^{-\alpha W}}{\left(\alpha + \frac{1}{L_p}\right)} - 1 \right\} + \frac{qAD_p n_i^2}{N_D L_p} (e^{qV_f/kT} - 1) \quad [137]$$

This equation would be identical with Butler's result if the last term could be ignored. Unfortunately V_f must be a forward voltage ($V_f > 0$) so that the last term cannot easily be suppressed unless the prefactor is quite small. Fortunately, for wide bandgap ($E_c - E_v > 3.0$ eV) semiconductors, the discussion between Eq. [127] and [128] assures us that this last term can be ignored and we do indeed recover Butler's result.

Finite Interface Rate Constants But No Recombination

If we assume no surface recombination, *i.e.*, $\Omega = 0$, then the boundary value problem posed at the end of the section on Surface Recombination can be solved even with i_+ and i_- finite. This is a fairly realistic situation and so we provide the solution in this section. The relevant problem now consists of Eq. [74'], [77'], [80'], [73'], [76'], [82], [83], [73''], [76''], and [81], together with Eq. [111] and [112] which now replace Eq. [72'] and [71']. The solution proceeds in essentially the same manner as in the preceding sections with Eq. [86], [89], [92], [94], [95], and [116] still valid. The constants in these equations are determined through the application of the various boundary conditions, (*e.g.*, Eq. [65], [66], [80'], [82], and [83]). Furthermore the current is specified by Eq. [110]. The final result, after considerable algebraic manipulation is

$$\frac{I}{qA} = \left\{ \frac{\frac{n_i^2}{N_D}\left\{ \frac{[1 + (I/qAa_3c_3^0) - (\phi_0/i_+)]\exp(qV_f/kT)}{[1 - (I/qAa_3c_3^0)]} - 1 \right\} + \frac{\phi_0}{D_p}\left\{ S_2 + \frac{e^{-\alpha W}}{\alpha + \frac{1}{L_p}} \right\}}{\frac{S_1 + L_p}{D_p} - \frac{n_i^2 \exp(qV_f/kT)}{N_D i_+ [1 - (I/qAa_2c_2^0)]}} \right\} + \left\{ \frac{i_- - \frac{\phi_0 \exp(-qV_f/kT) + i_-[1 - (I/qAa_2c_2^0)]\exp\left(\frac{-qV_f}{kT}\right)}{[1 + (I/qAa_3c_3^0)]} - \frac{\phi_0 i_- I_2}{D_n N_D}}{\frac{I_1 i_-}{D_n N_D} + \frac{\exp(-qV_f/kT)}{1 + (I/qAa_3c_3^0)}} \right\} \quad [138]$$

in which we have made use of Eq. [46], [57], and [126].

If we set i_+, $i_- = \infty$, then Eq. [138] reduces (as it should) to Eq. [124]. If on the other hand, we set i_+, a_2, $a_3 = \infty$, and $i_- = 0$, Eq. [138] reduces to Eq. [136] (as it should). However, Eq. [138] also applies to finite i_+ and i_- and is therefore valid for more general situations (in the absence of surface recombination). Equation [138] is a cubic in I, so to get the current-voltage characteristic the roots will have to be determined. The proper root can be inverted to furnish a detailed equivalent of Eq. [14], and with $\Gamma(V_f) = 0$, the photocurrent-voltage characteristic follows from Eq. [17], and the photocurrent characteristic from Eq. [18]. Again the open-circuit voltage is obtained by setting $I = 0$, in Eq. [138]. The result is

$$\left\{ \frac{\frac{n_i^2}{N_D}\{[1 - (\phi_0/i_+)]\exp(qV_f/kT) - 1\} + \frac{\phi_0}{D_p}\left\{ S_2 + \frac{e^{-\alpha W}}{\alpha + \frac{1}{L_p}} \right\}}{\frac{S_1 + L_p}{D_p} - \frac{n_i^2 \exp(qV_f/kT)}{N_D i_+}} \right\} + \left\{ \frac{i_-[1 - \exp(-qV_f/kT)] - \phi_0 \exp(-qV_f/kT) - \frac{\phi_0 i_- I_2}{D_n N_D}}{\frac{I_1 i_-}{D_n N_D} + \exp(-qV_f/kT)} \right\} = 0 \quad [139]$$

Expressing W, I_1, I_2, S_1, and S_2 as functions of V_S and then using Eq. [126] to express these quantities as functions of V_f, followed by substitution in Eq. [139] yields an equation on V_f whose root gives the open-circuit photovoltage.

If we let a_2, $a_3 = \infty$, in Eq. [138], so that there is no mass transport control in the interphase layer, the

cubic disappears and we obtain a relatively simple current voltage characteristic, namely, the equation obtained by replacing the zero on the right of Eq. [139] by I/qA.

Solution of the Full Problem

We now solve what is almost the full problem posed by Eq. [74'], [77'], [72'], [80'], [73'], [76'], [71'], [82'], [83'], [73"], [76"], and [81]. The only concession we make is to set r^- in Eq. [72'] equal to zero, thus replacing Eq. [72'] by

$$J_n^*(0) = \Omega \qquad [140]$$

It is in fact likely, in most real cases, that the overlap of the density of states of the redox couple with at least one of the bands will be negligible. The algebraic manipulation even with the modification contained in Eq. [140] is a tour de force in tedium (although straightforward) and it would be considerably more extensive if Eq. [72'] were retained. There is, however, no reason why it cannot be carried out for the full case if necessary.

Setting $r^- = 0$ in Eq. [109] eliminating Ω between Eq. [71'] and [140], and substituting r^+ from the result into Eq. [109] with $r^- = 0$ gives

$$I = qAr^+ = qA[J_p^*(0) - J_n^*(0)] \qquad [141]$$

Again Eq. [86], [89], [92], [94], [95], and [116] remain valid, and the constants must be determined by application of the various boundary conditions. Performing all of these operations and using Eq. [141] to evaluate the external current we obtain

$$\frac{I}{qA} = \frac{i_+(S_1+L_p)[1-(I/qAa_2c_2^0)]K_1}{i_+(S_1+L_p)[1-(I/qAa_2c_2^0)] - \dfrac{n_i^2D_p}{N_D}\exp(qV_f/kT)} + \frac{i_+\left\{[1-(I/qAa_2c_2^0)]\left[\dfrac{\phi_0 e^{-\alpha W}}{\alpha+\dfrac{1}{L_p}} - \dfrac{D_pn_i^2}{N_D} + \phi_0S_2\right] + D_p[1+(I/qAa_3c_3^0)]\dfrac{n_i^2}{N_D}\exp(qV_f/kT)\right\}}{i_+(S_1+L_p)[1-(I/qAa_2c_2^0)] - \dfrac{n_i^2D_p}{N_D}\exp(qV_f/kT} \qquad [142]$$

where, as usual, S_1 and S_2 refer to $S_1(W)$ and $S_2(W)$ and

$$K_1 = -\frac{Q_2}{2Q_1} + \left\{\left(\frac{Q_2}{2Q_1}\right) - \frac{Q_3}{Q_1}\right\}^{1/2} \qquad [143]$$

where

$$Q_1 = (S_1+L_p)\left\{\frac{\xi\omega I_1}{D_n} + \omega\exp(-qV_S/kT) + \frac{\xi I_1 i_+ N_D}{D_n n_i^2}[1-(I/qAa_2c_2^0)]\exp(qV_{Se}/kT)\right\} \frac{-D_p\xi I_1\exp(qV_S/kT)}{D_n} \qquad [144]$$

$$Q_2 = \left\{\xi\exp(qV_S/kT)\left(N_D - \frac{\phi_0I_2}{D_n}\right) - \frac{\xi\phi_0I_1e^{qV_f/kT}}{D_n} - \xi n_1 - \omega p_1\right\}\{D_p - i_+(S_1+L_p)[1 - (I/qAa_2c_2^0)]e^{-qV_f/kT}\} - \left\{\frac{\xi\omega I_1}{D_n} + \omega\exp(-qV_S/kT)\right\}$$
$$\left\{i_+(S_1+L_p)[1+(I/qAa_3c_3^0)] - \frac{D_pn_i^2}{N_D} + \phi_0S_2 - \frac{\phi_0e^{-\alpha W}}{\alpha+\dfrac{1}{L_p}}\right\} - (S_1+L_p)\left\{\xi\omega N_D - \frac{\xi\omega\phi_0I_2}{D_n} - \omega\phi_0\exp(-qV_S/kT)\right\} \qquad [145]$$

$$Q_3 = \left\{\xi\omega\left(N_D - \frac{\phi_0I_2}{D_n}\right) + \omega\phi_0\exp(-qV_S/kT)\right\}\left\{\frac{D_pn_i^2}{N_D} - \phi_0S_2 - \frac{\phi_0e^{-\alpha W}}{\left(\alpha+\dfrac{1}{L_p}\right)} - i_+(S_1+L_p)[1+(I/qAa_3c_3^0)]\right\} - \left\{\xi\omega n_i^2 - \phi_0\xi n_1 - \phi_0\omega p_1 - \xi\phi_0\exp(qV_S/kT)\left(N_D - \frac{\phi_0I_2}{D_n}\right)\right\}\left\{D_p - \frac{i_+N_De^{-qV_f/kT}}{n_i^2}(S_1+L_p)[1-(I/qAa_2c_2^0)]\right\} \qquad [146]$$

where I_1 and I_2 also refer to $I_1(W)$ and $I_2(W)$. In these equations I_1 I_2, S_1, S_2, and W can of course be expressed as functions of V_S and therefore of V_f by use of Eq. [124]. Although the equations are very complicated they can in principle be inverted to give the equivalent of Eq. [14] and then the characteristics can be derived by application of Eq. [16], [17], and [18]; $\Gamma(V_f)$ being set equal to zero, as usual.

As before, if we let a_2, $a_3 = \infty$ corresponding to no control by transport in the interphase layer, considerable simplifications result. Also, for the case $I = 0$, there is much simplification and the result can be used to obtain the open-circuit voltage.

A special case for which I should be zero occurs when $\phi_0 = 0$. In this case we note, setting I, ϕ_0, $V_f = 0$ in the quantity Q_3 that $Q_3 = 0$, and then, according to Eq. [143], $K_1 = 0$. Setting K_1, ϕ_0, $I = 0$ in Eq. [142] then yields $I = 0$, demonstrating the internal consistency of this complicated set of equations.

Concluding Remarks

In the foregoing sections we have derived photocharacteristics for fairly general electrolyte-semiconductor junctions. The resulting equations are sometimes complex but in certain limiting conditions exhibit considerable simplification.

We have confined our analysis to junctions where the diffuse Gouy-Chapman layer is, in essence, eliminated by high ionic strength, and where the density of surface traps is sufficiently low so as not to affect band bending. Furthermore, this density, as well as the density of states, is considered invariant. We have assumed that depletion layer theory can be applied to the semiconductor, and that recombination does not occur in this layer, although it may occur outside of it. The use of depletion layer theory compromises the accuracy of the derived characteristics under photon fluxes sufficient to flatten the bands. Insofar as the electrolyte is concerned we allow for possible rate control by mass transport in the interphase layer.

Even though many factors are included in the foregoing theory the resulting equations, already lengthy, are certainly not equal to the most general of situations. Unfortunately, there is no point in being more

general since an individual working on a specific experimental system should tailor the derivation to include those factors which seem to be important in his systems. For example, it is highly likely that surface states will play a dominant role in most cases, and we have hardly treated these adequately. However the same approach can be used for such cases.

Our development does illuminate some prior work. For example, the discussion surrounding Eq. [133] through [136] clearly shows the conditions necessarily underlying Butler's experiments and the theory which they fit.

A great deal of algebra has been performed to derive equations such as Eq. [140] through [146] and pains have been taken to eliminate all errors, typographical and otherwise. It is not likely that these full equations will ever have to be used but if they are they are at least available. They also demonstrate the level of complexity which may be necessary if too many factors are included simultaneously in the analysis. It is obviously necessary to be most judicious in this respect.

Although the "interphase" overpotential, η, has been set to zero in our analysis, in reality V_f, the photovoltage, is an overpotential because the band bending produces an additional "activation" energy for the transfer of electrons. What we really mean then is that the principal component of the overvoltage lies within the semiconductor rather than in the liquid.

In general our theory is based on macroscopic kinetic and transport coefficients. The calculation of these from a more microscopic theory represents still another task.

Acknowledgment

The author would like to express his appreciation to Drs. Adam Heller and Barry Miller, of Bell Laboratories, for many illuminating discussions during the conduct of the research reported in this paper.

Manuscript submitted Nov. 7, 1977; revised manuscript received Jan. 12, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by Bell Laboratories.

Some Properties of Palladium Photocathodes Used in the Electron Image Projection System (ELIPS)

W. Robert Sinclair,* L. H. Lin,[1] P. K. Gallagher, and R. A. Fastnacht

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Measurements of some properties of palladium photocathodes used in an electron image projection system (ELIPS) have been made to evaluate criticisms of their performance by Scott (1). It has been found that sputtered palladium films can be used successfully with 253.6 nm radiation, thus negating the claimed necessity of a tungsten impurity. It is suggested that the bulk impurity of H_2O [*ca.* 5 mole percent (m/o)] in the sputtered films found by evolved gas analysis is responsible for the necessary lowering of the work function of palladium. Surface contamination of the palladium is probably responsible for the observed lowering of the photocurrent and instabilities in the photocurrent, but is easily removed by heating externally with an infrared heater. It has been found that palladium-coated masks for ELIPS can be used for many exposures at 10^{-5} Torr by backfilling the chamber between exposures with tank nitrogen.

The electron image projection system (ELIPS) introduced by O'Keeffe *et al.* (2) has been investigated by others (1, 3) recently because it gives promise of rapid lithographic exposure of silicon wafers with better resolution than is possible with photolithography. As indicated in Fig. 1 the system uses a u.v. opaque mask (*e.g.,* chromium) on a quartz substrate with a semitransparent coating of an efficient photoelectron emitter over the mask and substrate. When the mask is illuminated as indicated in the figure, photoelectrons are emitted from the transparent areas and are accelerated to the anode under the combined influence of magnetic and electric fields. As a result a latent image of the mask is quickly produced in the electron resist-coated silicon slice (the anode).

Crucial for the practical use of this system are the properties of the photoelectron-emitting film. The photoemission must be sufficiently high that exposures are reasonable in length (*i.e.,* a few minutes or so), their output should be reasonably constant with time, and other properties such as susceptibility to contamination, adherence, etc., should be suitable.

Only two electron emitters, palladium and cesium iodide, have been described in the literature on ELIPS techniques. During the course of this study we have surveyed in a somewhat cursory fashion a variety of thin films: silver, gold, alloys in the silver-palladium system, tungsten, ruthenium, lead oxide, and indium oxide. None of these was found to be as intense an emitter under 253.6 nm radiation as palladium. Scott (4) has argued that palladium is inferior to cesium iodide for use in ELIPS. In particular, evaporated palladium films of reproducible photoemissivity are difficult to prepare. Scott also noted palladium's poor current stability, the requirement of a 10^{-7} Torr vacuum, and the poor stability of the films in air. We have not studied the performance of cesium iodide films. However, a disadvantage is the associated requirement for 184.9 nm radiation, which forces the use of extra high purity silica glass for the mask substrate and the vacuum window.

In this communication, we shall consider methods for improving the properties of palladium films for use in the ELIPS system.

Experimental Procedures and Results

All work was done in an apparatus essentially the same as that indicated in Fig. 1. In general, the pressure during exposures was about 2×10^{-5} Torr. We have found, however, that by rf sputtering palladium in argon, films can be made reproducibly which are active with 253.6 nm (4.89 eV) radiation despite the absence of tungsten, which Scott argues is necessary for lowering the work function. It is not certain why the work function of the sputtered palladium is lower than the ultrahigh vacuum value of 5.5 eV (5). Perhaps dissolved gases are the cause (6) (see below).

The other disadvantages claimed by Scott relate to poor current stability (up to 50% change during exposure), the necessity of working at 10^{-7} Torr, and instability in air. Each of these can be related to the mechanism of degradation of the palladium film activity. Livesay and Fritz (7) found that the main contaminants produced by the bombardment of the electron resist [poly-methyl-methacrylate (PMMA)] were oxygen and water. The dramatic effect of oxygen on the photocathode efficiency is shown in Fig. 2. In this experiment a bare silicon wafer or one coated with PMMA was bathed in photoelectrons for 2 min, a typical time for exposing an electron resist. Then the system was let down to atmospheric pressure in tank oxygen, air or tank nitrogen. It is evident that pure oxygen immediately impairs the usefulness of the photocathode and that the useful lifetime when exposed to nitrogen is much longer even when the lowest pressure encountered is only 2×10^{-5} Torr.

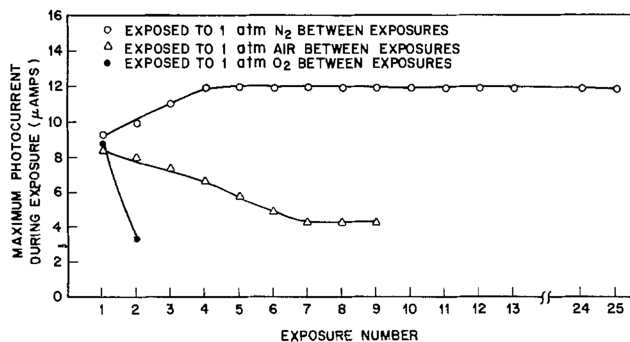

Fig. 2. Maximum photocurrent in 2 min exposure of palladium photocathode as a function of the number of exposures and as a function of the ambient (at 1 atm) that the photocathode was in contact with between exposures.

While irradiating a photocathode with 253.6 nm radiation one notes a continuous rise in the photocurrent as indicated in Fig. 3. This process of cleanup is inferior to that obtained by heating with 60W tungsten lamp, both in terms of ultimate photoemission and in terms of time required for cleanup. Livesay and Fritz (7) have also pointed out the cleanup effects of irradiation.

The lower curve of Fig. 4 shows the effects on the photocurrent of a series of 2 min irradiations at 2×10^{-5} Torr on a nonpreheated cathode followed by letting the system down to one atmosphere of nitrogen. In addition to the increased photoemission due to increased cleanup the current range during an exposure indicated by the height of the vertical bars at each data point decreases significantly as this clean up continues. As indicated by the upper curve of Fig. 4 the output of a film prebaked with a tungsten lamp in vacuum for 20 min varies about 10% when used in a 2 min exposure in a vacuum system at 2×10^{-5} Torr.

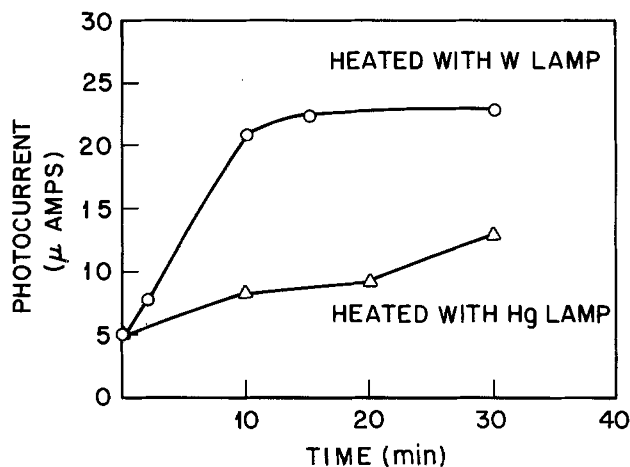

Fig. 3. Effect on photoemission of Pd films of long-term continuous irradiation by a 60W tungsten lamp or a mercury discharge lamp (253.6 nm). Pressure held at 2×10^{-5} Torr.

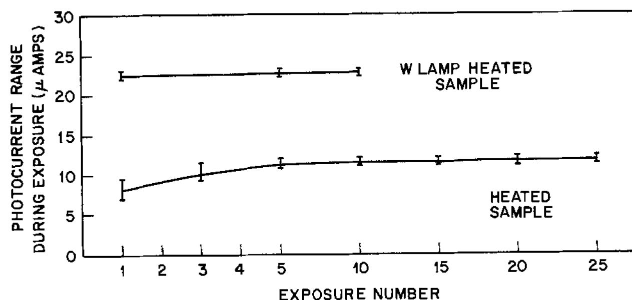

Fig. 4. Range of photocurrent in μA during 2 min exposure as a function of number of exposures. Samples let down to 1 atm of N_2 between exposures. One sample was precleaned by exposure to 60W tungsten lamp.

Using EGA techniques described by Gallagher (8) we studied palladium films on alumina substrates after aging in a room ambient. To minimize surface effects, films thicker than 4000Å were used for these measurements. The results show that the main impurity evolved is water. Figure 5 shows the intensity of the mass 18 line after subtraction of the normal background as a function of temperature at 10^{-7} Torr and at a heating rate of 10°C/min. A similar experiment on an alumina substrate treated identically but without a Pd film revealed no significant increase in mass 18 at temperatures beyond about 100°C. Clearly, a temperature of at least 400°C is necessary to drive off the main bulk of the water. Semiquantitative estimates indicate about 5 m/o of H_2O in the Pd. Auger analysis on a sample aged for several weeks in air at room temperature somewhat surprisingly shows very little oxygen or water (or anything else) on the palladium surface. To correlate these findings we suggest that surface oxygen or water is sufficiently lightly bound that it is easily desorbed by an electron beam and that this film accounts for the changes in photocurrent we have noted. The bulk impurity measured by EGA we suggest is responsible for the lowering of the work function of palladium. Such shifts of the photoelectric threshold with an oxygen impurity have been previously reported for other metals (6). It has already been shown by Sosniak (9) that rf sputtering in argon can lead to a considerable release of water from the sputtering chamber walls. The decreasing variation in photocurrent evidenced in Fig. 4 plus the results of EGA lead us to conclude that the main cause of photocurrent instability is due to contamination rather than changes in the intensity of the mercury line, as suggested by Scott. Of practical importance is the fact that masks stored at 150°C in an air ambient show excellent emission properties when inserted into the ELIPS apparatus reasonably quickly after removal from the oven.

Conclusions

In conclusion, we would like to make the following points: (*i*) Sputtered palladium films are efficient photoemitters using 253.6 radiation. (It is suggested that a bulk impurity of water in the film lowers the work function of palladium.) Thus, inclusion of tungsten from an evaporating coil is not required. (*ii*) Contamination is the prime source of current instability during irradiation of the film with mercury light. (*iii*) Heat-treatment with a 60W tungsten filament bulk leads to higher current output and relatively good (*ca.* 10%) current stability. (*iv*) It is suggested that palladium-coated masks be stored in an air heating oven kept at about 150°C.

Liquid Phase Epitaxy of II-IV-V_2 Chalcopyrite Compounds

S. M. Bedair[1] and M. A. Littlejohn

Department of Electrical Engineering, North Carolina State University, Raleigh, North Carolina 27607

and The Center for Synthesis and Study of Semiconducting Compounds, Research Triangle Institute, Durham, North Carolina 27703

ABSTRACT

Liquid phase epitaxial growth of single crystal chalcopyrite in an open tube system is reported for the first time. $ZnSnAs_2$ has been grown epitaxially on GaAs and InAs substrates from Sn solutions. Optical and electrical measurements have been made on these epilayers. The $ZnSnAs_2$/GaAs and the $ZnSnAs_2$/InAs heterojunctions were found to be abrupt and graded junctions, respectively.

Ternary II-IV-V_2 chalcopyrite crystals are currently of technological interest since they show promise for applications in such areas as visible and infrared light-emitting diodes, infrared detectors, and nonlinear optical devices (1). Despite such potential applications, these compounds are far less investigated than the III-V semiconductor compounds and information on them is still relatively scarce. Difficulties encountered in their preparations in the form of high quality single crystals have probably been responsible for this rather limited progress (2).

The present techniques for preparing single crystals of II-IV-V_2 compounds are either complicated or inadequate. For example, direct synthesis from constituent elements is usually not successful when incongruent melting or order-disorder transitions take place. With solution growth and chemical vapor deposition techniques, there is also very little control over crystal morphology and orientation, and platelet or needlelike crystals are often obtained (1). All these techniques are performed in closed tubes, thus limiting the flexibility during the growth process, and the possibility for explosion is usually present.

There have been very limited efforts devoted to the growth of epitaxial films of the chalcopyrite compounds, and most of these efforts have dealt with the growth on elemental or III-V compound substrates. For example, $ZnSiP_2$ has been grown on both Si and GaP single crystal substrates from Sn solutions (3), and by chemical vapor deposition (4). Also, several II-IV-V_2 layers of $CdSnAs_2$, $CdSnP_2$, $CdGe_xSn_{1-x}P_2$, and $ZnSn_xGe_{1-x}As_2$ have been deposited from Sn solutions on various substrates using different growth methods (3). However, the results show lack of epitaxy and the formation of polycrystalline layers. The liquid phase epitaxial growth (LPE) of $CdSnP_2$ on InP substrates from Sn solution seems to be the only such reported case which has been studied to date; but the growth was done in a closed-tube system with a tilting furnace.

Liquid phase epitaxial growth in an open tube system with a purified hydrogen environment is being extensively applied for the preparation of high quality layers of III-V semiconductor compounds. In principle this technique can also be applied for growth of the II-IV-V_2 chalcopyrites if the operating temperature is relatively low. This requirement is necessary to minimize the losses of the volatile components (mainly As and P) from the melt, and also to prevent any dissociations of the grown chalcopyrite layer (6). Such conditions can be met, with the proper choice of solvents, for most of the arsenide compounds and the low melting point phosphides. The open tube epitaxial technique is simple and flexible. Also, fundamental physical properties, such as photoluminescence, reflectance, mobility, and others can be readily performed on single crystal epilayers grown by this technique. Such measurements of material properties are greatly lacking and are presently being performed with crystals synthesized by the Bridgman technique.

We report for the first time the liquid phase epitaxial growth of single crystal chalcopyrite in an open tube system. $ZnSnAs_2$ has been synthesized epitaxially on GaAs and InAs substrates from Sn solutions. The optical and electrical properties of these grown layers have also been studied and are observed to be closely comparable to those obtained from material grown by other techniques.

Experimental

A vertical LPE dipping system was used (7). The essential components of the system are: a vertical tubular furnace, a quartz reaction tube through which a purified H_2 flow is maintained, a graphite crucible for the melt, and a substrate holder. The substrate can be dipped into the melt by a quartz tube, inside which a thermocouple is placed to measure the melt temperature directly. The starting materials consisted of 20g of 5*N* Sn and 6*N* $ZnAs_2$, and the $ZnSnAs_2$ concentration

[1] On leave from the Faculty of Engineering, Alexandria University, Alexandria, Egypt.

Key words: liquid phase epitaxy, chalcopyrite, zinc tin arsenide.

in the melt varied from 0.5-3 mole percent (m/o). The solution was homogenized for 1 hr at 550°C, and negligible vapor deposits were observed on the cold end of the growth tube.

The temperature at which the $ZnSnAs_2$ layer nucleates was determined in a set of experiments where (111) Si substrates were used. Si was chosen since it is not attacked by the Sn melt in the temperature range of interest (8). Cooling was accomplished at a linear rate of 10°C/hr, and the substrate was pulled from the melt after every cooling interval of 5°C for microscopic examination. Nuclei usually in the form of small triangular platelets of $ZnSnAs_2$ appeared, as shown in Fig. 1. Nucleations started at approximately 465°, 485°, and 505°C for $ZnSnAs_2$ of 1.4, 1.9, and 2.5 m/o in the melt. We realize that these are crude estimates; however, we found that these preliminary experiments were very useful when GaAs and InAs substrates were used. We were thus able to avoid dissolution of these substrates or growing low quality layers if the growth cycles were to start with an undersaturated or highly supersaturated melts, respectively. However, in some experiments additions of GaAs or InAs to the solution were made to prevent pitting of GaAs and InAs substrates, respectively.

Starting from slightly undersaturated solutions and cooling over an interval of 50°C resulted in continuous grown layers of approximately 40 μm thickness on (100) and (111)B oriented GaAs and on (111)B InAs substrates. While such thick layers were grown and used in these studies, there appear to be no limitations to the growth of thinner layers of a few microns in thickness. Future work with LPE of chalcopyrites will be directed toward thin layers more appropriate for some device applications. The Sn melt was found to adhere to some parts of the surfaces of the grown layers. This excess Sn was extracted with mercuric chloride (10.6g) in (50 ml) N-N dimethyl-formamide solution, followed by a chemical polish in a 1% solution of bromine in methanol. The surfaces of the grown layer that were not covered by Sn were shiny, whereas those parts revealed after Sn extraction were rough. For optical, electrical, and other measurements, we found that polishing with Al_2O_2 powder (0.05 μm) followed by etching in 10 HCl: 10 CH_3OOH: 1 HNO_3 was highly desirable.

We had also tried Ge substrates, however excessive dissolutions of Ge were observed.

Results and Discussion

In this section, results will be presented on composition profiles, orientation, crystal structure, electrical properties, and optical properties of the layers grown by open-tube LPE. Since the purpose of this paper is to demonstrate the technique of open tube growth of II-IV-V_2 chalcopyrite compounds, no attempt has been made to optimize or study in great detail the material properties with regard to device applications. It is intended to show that the measured material properties are comparable to those obtained from material grown by other techniques, and thus to conclude that the open tube LPE technique is a compatible materials growth technology for the II-IV-V_2 chalcopyrites. Future work in our laboratories will be directed toward refinements and improvements in material properties and oriented toward material for device applications.

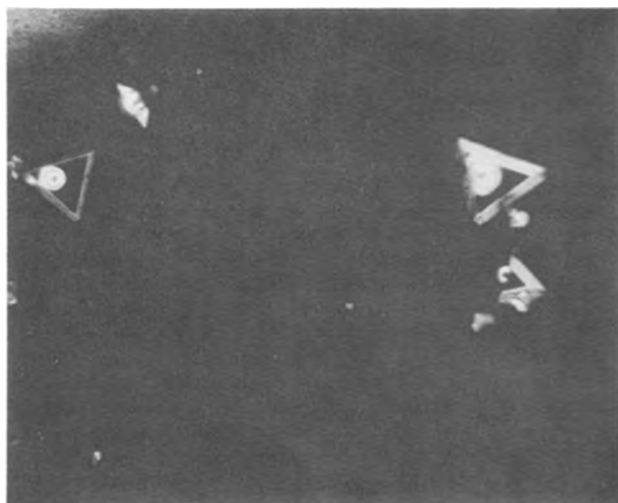

Fig. 1. The onset of nucleations of $ZnSnAs_2$ on Si (111) substrate (magnification 400×).

Composition of the grown layers.—The compositions of the grown layers were determined by electron microprobe (EMP) analysis. For dilute solutions of 0.5-3 m/o $ZnSnAs_2$, the grown layers had the stoichiometric composition of $ZnSnAs_2$. Scanning the grown layers surfaces indicated uniform composition (within the accuracy of the EMP technique). For more concentrated solutions of 10 m/o, precipitations of $ZnAs_2$ were observed with the EMP.

$ZnSnAs_2$ layers grown on GaAs substrates showed traces of Ga [less than 1 atomic percent (a/o)], where approximately 2-3 a/o of In was observed for layers grown on InAs substrates. The composition profile in the epilayers was studied on cleaved and angle-lapped sections of the samples. Scans across the heterojunction monitoring x-ray photons corresponding to Zn-Kα, Sn-Lα, and Ga-Kα or In-Lα are shown in Fig. 2. Figures 2a and b show that for layers grown on GaAs substrates, there are abrupt variations in composition at the junction. The scan across the angle-lapped junction, Fig. 2b, indicates that the first layers to be grown on GaAs are solid solutions having the composition $Ga_{2(1-x)}Zn_xSn_xAs_2$ with x approximately 10%. The value of x increases as the grown layer thickness increases and the epilayer is predominantly $ZnSnAs_2$ for spots greater than 30 μm off the junction. We believe that this is a result of partial dissolution of the GaAs substrate during the first stage of the cooling cycle followed by regrowth of $Ga_{2(1-x)}Zn_xSn_xAs_2$ layer. Similar observation had been reported for the dissolution and regrowth of GaAs from Sn solution (9). In order to examine the interface between the grown layer and the substrate, samples were mounted on glass slides and then the substrate was removed my mechanical polishing. Figure 3 shows an A-B etched (10) interface, where the process of dissolution and regrowth took place in symmetrical fashion. The triangular and rectangular structures indicate the corresponding symmetry for growth on the (111) and (100) GaAs substrates, respectively.

$ZnSnAs_2$ has a tetragonal structure (1) with a = 5.852Å and c/a = 2; thus a lattice mismatch of about 3.5% will be present with the GaAs substrate. However, the formation of the intermediate layer of $Ga_{(1-x)2}Zn_xSn_xAs_2$ will minimize the lattice misfit strain in the epilayer. The as-grown layer is shown in Fig. 4. The cross section of the cleaved junction is shown in Fig. 5 and the observed rough cleavage planes indicate that the epitaxial layer is still strained.

The situation is quite different for layers grown on InAs substrates. Graded junctions, with monotonic changes, from almost pure InAs to almost pure $ZnSnAs_2$ can be deduced from Fig. 2c. This result is consistent with the complete solid solubility previously observed for the InAs-$ZnSnAs_2$ system (11). The lattice mismatch between $ZnSnAs_2$ and InAs is also about 3.5%. The grading in the composition of the grown layer relieves the tension strains resulting from this lattice mismatch, thus avoiding cracking or even fracturing the grown $ZnSnAs_2$ epilayer.

Orientation and crystal structure.—In order to establish the epitaxial relationships, the x-ray diffraction and the back-Laue pattern methods were applied. For layers grown on (111) oriented substrates, the diffrac-

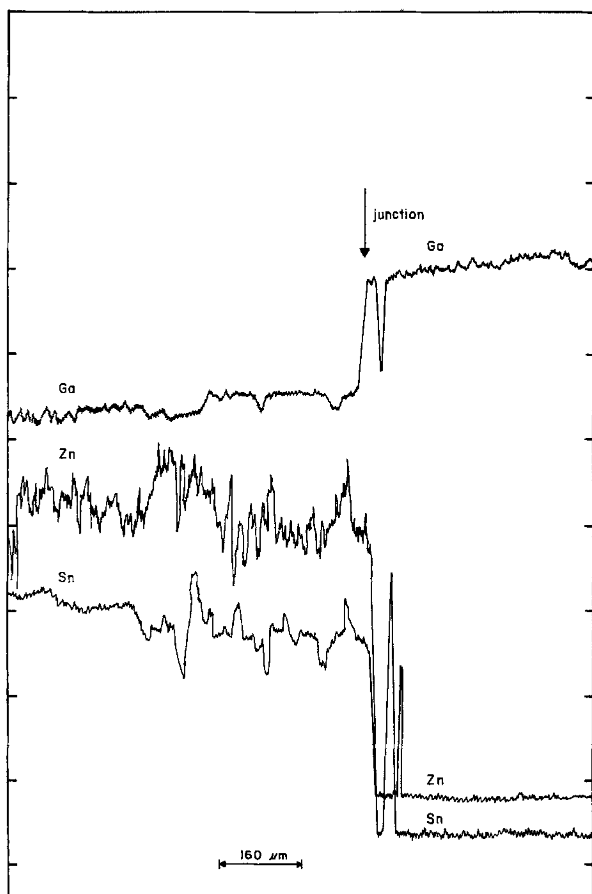
c. $ZnSnAs_2$/InAs, 2° angle lapped

Fig. 2. The composition profiles obtained by scanning across the heterojunction. Peaks appearing at the junction neighborhood are due to slight thickness nonuniformity at the interface and thus they show only for the angle lapped samples.



b. $ZnSnAs_2$/GaAs, 2° angle lapped

togram showed a single peak with an angle corresponding to the spacing of (112) $ZnSnAs_2$ having the chalcopyrite structure. Peaks corresponding to the (111) interplanar spacing of the substrates were also present with various heights depending on the thicknesses of the grown layers. For layers grown on (100) oriented substrates a single diffraction peak corresponding to either the (200) plane or the (004) plane was also observed. These two sets of planes have the same spacing in $ZnSnAs_2$, having a tetragonal structure with $c/a = 2$.

The back-Laue patterns showed the symmetry corresponding to the epitaxial growth on the (111) and (100) oriented substrates. Extra spots corresponding to the chalcopyrite structure were observed and no ring structures were detected. Careful examinations of these patterns show the presence of fourfold symmetry indicating that the epitaxial layers on (100) substrates has the (004) orientation. Such conclusions might be misleading since for $ZnSnAs_2$, $c/a = 2$, the intense reflection spots are either coincident or nearly coincident to those of the substrate. However, the Laue pattern for the grown layer alone was obtained and the results confirm the above conclusion of epitaxial growth over the entire substrate area of approximately 1 cm^2.

Electrical measurements.—Hall effect measurements were made on epitaxially grown $ZnSnAs_2$ on semi-insulating and n-type GaAs substrates. The results showed heavily doped p-type layers with carrier concentrations in the 10^{19} cm^{-3} range. A summary of the electrical properties measured at room temperature is shown in Table I. This low resistivity might be a result of arsenic deficiency accompanied by excess of Sn in the compound. Similar observations had been re-

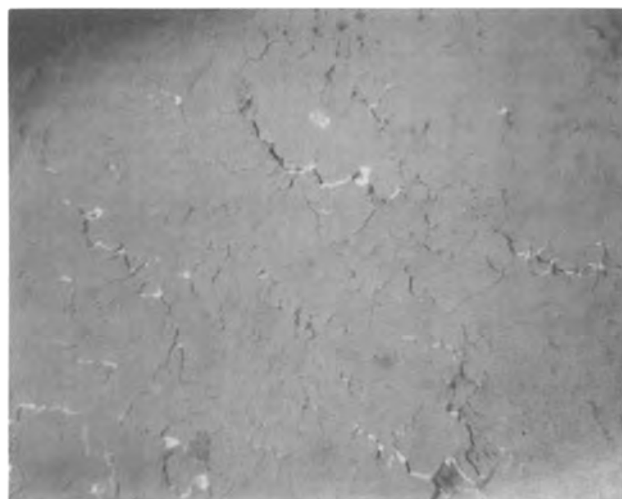

Fig. 4. The as-grown layer of $ZnSnAs_2$ on (111) GaAs substrate (magnification 80×).

ported for other solution-grown undoped chalcopyrites (13).

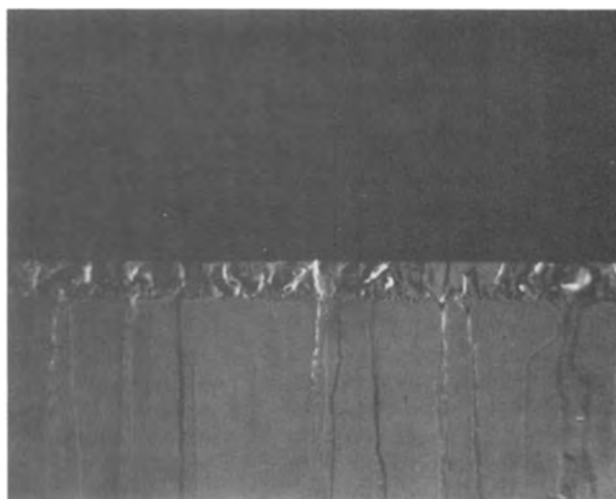

Fig. 5. Cross section of the cleaved $ZnSnAs_2$/GaAs heterojunction (magnification 120×).

It should be mentioned that for the same carrier concentrations, the mobility for these epilayers has the same value as for $ZnSnAs_2$ grown by Bridgman technique (12). Thus, even with the present relatively high lattice mismatch, this simple epitaxial growth technique does not at least degrade the carrier mobility. However, epitaxial $CdSnP_2$ grown on InP substrate in a closed tube system, shows a drastic decrease in the mobility and a value of 20 cm^2/V sec for carrier concentration of $\sim 5 \times 10^{18}$ cm^{-3} has been reported (14). The mobility in nominally pure ($n \simeq 10^{17}$ cm^{-3}) solution-grown $CdSnP_2$ is about 2000 cm^2/V sec.

Optical absorption.—Grown layers of $ZnSnAs_2$ mounted on separate glass (or quartz) slides were lapped until they became shiny, followed by chemical etching. The absorption measurement was done at room temperature with a Cary 14 double beam spectrometer. Sample areas were approximately 0.6 cm^2 having thicknesses in the range 10-20 μm. The absorption coefficient α was calculated after a correction had been made for the reflection coefficient (15), $R = 43\%$, and the results are shown in Fig. 6. The energy bandgap is related to the steep rise observed in the absorption spectrum. Extrapolation of the straight line portion in Fig. 5 gives a value of 0.63 eV for the energy gap at room temperature. This is in agreement with previous absorption edge measurements, where values of 0.6 (16), 0.66 (15), 0.67 (17), and 0.7 (18) eV have been reported for $ZnSnAs_2$. The reported carrier concentrations for both the absorption edge of 0.66 and 0.7 eV was 1.2×10^{18} cm^{-3} (15, 18). We believe the apparent shrinkage in the energy gap of our samples is a result of the present higher carrier concentrations in the 10^{19} cm^{-3} range. Similar observations had been reported for several heavily doped semiconductors (19).

Conclusions

Open tube liquid phase epitaxial growth of single crystals of $ZnSnAs_2$ on GaAs and InAs has been demonstrated for the first time. Optical and electrical measurements were made on these epilayers and found to

Table I. The electrical properties of $ZnSnAs_2$ epitaxially grown single crystals

Single crystal grown by Bridgman method Ref. (12)	0.03	10^{19}	30

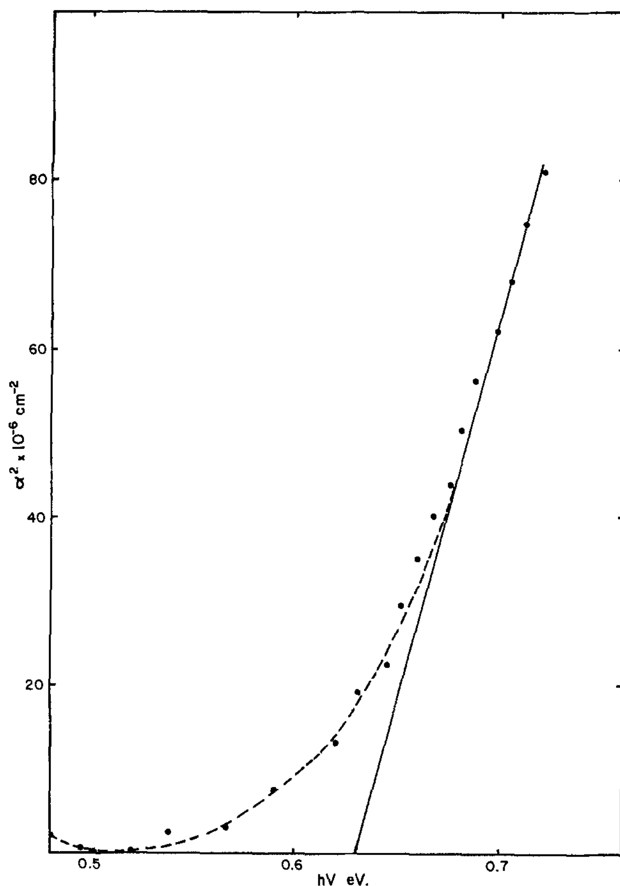

Fig. 6. Variation of the absorption coefficient of $ZnSnAs_2$ single crystal with photon energy.

be in agreement with those corresponding to $ZnSnAs_2$ crystals grown by Bridgman techniques. The composition profiles across the heterojunctions revealed that $ZnSnAs_2$-GaAs system has limited solid solubility where complete solid solubility is present in the $ZnSnAs_2$-InAs system.

We believe that such a simple growth technique can be applied with the proper choice of solvents and substrates to grow several other chalcopyrites. For example $ZnGeAs_2$, $CdGeAs_2$, and $CdGeP_2$ can be grown from bismuth solution, whereas $CdSnP_2$, $ZnSnP_2$, and $CdSnAs_2$ can be grown from tin solution.

Aluminum Diffusion into Silicon in an Open Tube High Vacuum System

Wojciech Rosnowski*

RCA Corporation, Materials and Processing Research Laboratory, Princeton, New Jersey 08540

ABSTRACT

A high vacuum, open tube method for aluminum diffusion into silicon has been described. This technique is simpler and more cost effective than the widely used sealed ampul diffusion. The process offers the possibility of aluminum doping with surface concentration from 10^{17}-10^{19} cm^{-3} and is suitable for high volume production. A simplified mass transport and diffusion model has been developed and used to evaluate the diffusion results. Aluminum diffusion coefficient into silicon has been determined to be: $D = 1.80 \exp(-3.2\ eV/kT)$ $cm^2\ sec^{-1}$ in the temperature range of 1025°-1175°C.

Aluminum diffusion into silicon is usually carried out in a sealed evacuated quartz tube (1-5). For large (2-in.) diameter wafers, the tube is backfilled with argon to prevent collapsing. The presence of argon decreases the aluminum partial pressure and, consequently, results in diffusions with low surface concentration (3, 5). The ampul process considerably limits the ability to widely control the surface concentration. Moreover, after each diffusion run, the quartz tube has to be discarded, thus increasing production costs. In this paper, an open tube, high vacuum method of aluminum diffusion into silicon is presented (6, 7). The process described uses a simple high vacuum setup and a reusable quartz diffusion chamber. The process offers the possibility of aluminum diffusions with surface concentrations from 10^{17} to 10^{19} cm^{-3} and is suitable for high volume production. Its cost per run compares favorably with the ampul technique.

Experimental

Figure 1 shows a sketch of the high vacuum, open tube system used for high volume diffusion. An aluminum disk with a diameter of 20 × 6 mm thick (99.999% purity) supported by an n-type silicon slab 20 × 20 × 5 mm is located on a flat 30 × 30 × 5 mm quartz block between the silicon wafers and at each end of the diffusion chamber of the quartz tube. A restrictor regulates, as illustrated, the aluminum vapor outflow rate during the process. The diffusion is carried out in a movable furnace having a thermal flat zone of better than ±1°C over the length of the diffusion chamber. Prior to diffusion, the quartz tube and boat must be passivated to eliminate the aluminum vapor interaction with the quartz. To accomplish this, two aluminum disks supported by silicon slabs of the same dimensions, as previously described, are located; one at the closed end of the tube and one at a distance of 10-12 in. from the closed end. The quartz boat and quartz blocks are inserted between the sources. The tube, without a restrictor, is then connected to the vacuum system. After evacuating, $<10^{-6}$ Torr for 1 hr, the furnace, set at 400°C, is moved over the tube. The temperature is raised at about 10°C/min to 1100°C. The furnace is heated for about 120 min at this temperature and then slow cooled at about 5°C/min to 400°C. During this process, vacuum is continuously maintained below 10^{-6} Torr. Under this condition, aluminum molecules easily evaporate from the aluminum vapor source since the aluminum partial pressure in the system is about three orders of magnitude higher than the pressure held in the vacuum system. The evaporated aluminum molecules hit the tube walls and react with the quartz: $3SiO_{2(g)} + 4Al_{(g)} \rightarrow 2Al_2O_{3(s)} + 3Si_{(s)}$. The product of this reaction next serves as a passivation layer during aluminum diffusion. The continuous pumping down during the passivation process eliminates the danger of poisoning the aluminum vapor source due to the oxidation by residues and moisture in the system. The development of an impervious skin on the aluminum vapor source surface, due to the reaction $2Al_{(g)} + 3/2\ O_{2(g)} \rightarrow Al_2O_{3(s)}$, is the main reason for diffusion runs which were unsuccessfully performed and so frequently observed in the sealed ampul technology. A thorough analysis of the thermodynamics of the Al-O-H-Si system has recently been presented elsewhere (8). When the passivation is complete, the furnace is slow cooled at 5°-7°C/min to 400°C. The furnace is then moved out over the tube. The tube is filled with nitrogen and disconnected from the vacuum system.

The diffusion process consists of (*i*) loading the cleaned wafers and aluminum-silicon assemblies into a previously passivated quartz tube; (*ii*) evacuating the system to $<10^{-6}$ Torr for about 1 hr and sliding the movable furnace over the tube. The temperature of the furnace when moved over the tube is set to 400°C; (*iii*) raising the temperature at about 10°-13°C/min to the desired deposition temperature and diffusing for the required time. This is usually between 1075° and 1175°C, since a higher temperature could cause the quartz tube to collapse; and (*iv*) cooling the furnace at about 5°C/min to 400°C, sliding the furnace back, filling the quartz tube with nitrogen, and disconnecting the tube from the pumping system and unloading. Wafers used in the experiment were n-type, 25-45 Ω cm resistivity, 2 in. diam float zoned silicon wafers cut to <111> surface orientation.

Mass Transport and Diffusion

The physical system considered in the present work consists of four components; aluminum diffusion source, wafers, tube walls, and gas phase.

During diffusion, the whole system is kept at a constant elevated temperature. Mass transport during

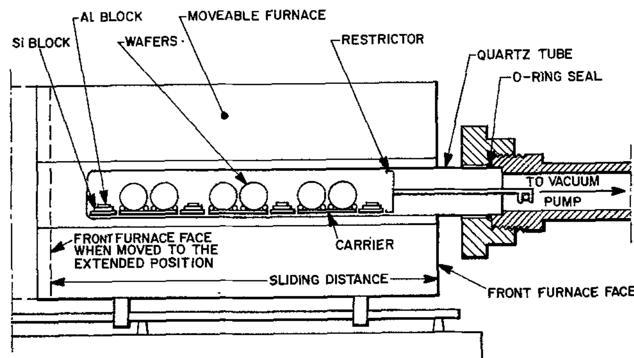

Fig. 1. Open tube, high vacuum aluminum diffusion system

* Electrochemical Society Active Member.

Key words: aluminum, diffusion, doping silicon, diffusion technique.

heating and cooling is not considered here, since it is negligible in comparison to that taking place in the over-all process. The diffusion into silicon and the transport of all material components in the diffusion chamber depend on (*i*) aluminum evaporation rate from the source, (*ii*) silicon evaporation from wafers, (*iii*) transport of the gaseous components, (*iv*) adsorption on the silicon wafers' surfaces, (*v*) adsorption on the tube walls and boat, (*vi*) diffusion into silicon, (*vii*) penetration into the tube walls and boat, and (*viii*) outflow of aluminum vapor from the diffusion chamber. The exact calculation of the contribution of each of these steps is either very difficult or impossible. Generally, adsorption effects at solid surfaces are rather complex and the material properties involved in most of the systems are not well known. Aluminum penetration through quartz proceeds through simultaneous diffusion and chemical reaction resulting in different by-products (4). Also, silicon vapor interacts with SiO_2 forming an SiO phase which evaporates rapidly (9, 10), therefore, the exact vapor composition in the diffusion chamber is difficult to establish. During the diffusion process, the system is connected to the vacuum pump and no equilibrium pressure of silicon and aluminum is maintained. However, by making some idealizations, the approximate mathematical calculations of the mass transport can be made:

1. During diffusion, aluminum evaporates from the surface of the Al-Si alloy. The particle current density of the evaporating atoms depends on the particle density and the activation energy of desorption via Arrhenius formula. In high vacuum, the evaporation per square centimeter·second can be obtained from kinetic theory as

$$\frac{\partial N}{\partial t} = \alpha (M/2\pi RT)^{1/2}\, p_{eq}$$

where P_{eq} denotes the aluminum partial pressure in equilibrium, M is the molecular weight, α is the evaporation coefficient, and R and T have generally accepted meanings. In the steady state, the evaporation per second from surface A is equal to

$$J_{evap} = \left(\frac{\partial N}{\partial t}\right)_{evap} = \alpha A (M/2\pi RT)^{1/2} (p_{eq} - p) \quad [1]$$

where p is the aluminum vapor pressure near the Al-Si alloy. We assume that the diffusing substance is emitted continuously from the source at a constant rate.

2. At the diffusion temperatures normally used, the silicon vapor pressure is about three orders of magnitude lower than that of aluminum (11) and, therefore, we assume that the transport mechanism in the gas phase is totally controlled by the aluminum vapor.

3. Due to the quartz tube passivation, aluminum-quartz reaction and aluminum penetration into quartz (tube walls and boat) are negligible. The reaction of aluminum with quartz results in a mixture of two solid products: Al_2O_3 and Si (passivation layer). The aluminum diffusion coefficient in Al_2O_3 is a few orders of magnitude lower than that of silicon. Therefore, we assume that the aluminum loss due to diffusion into Al_2O_3 can be omitted. The adsorption process inside the passivated quartz tube follows an exponential saturation characteristic (12)

$$S_W = S_{\infty W} \left\{ 1 - \exp\left(-\frac{t}{t_W} \right) \right\} \quad [2]$$

where the wall coverage S_W approaches the saturation value $S_{\infty W}$ with a time constant t_W. The absolute value of t_W depends on material properties and temperature. For silicon, the saturation time varies from minutes to seconds, between 1050° and 1200°C, respectively. For quartz, t_W is chosen to decrease with temperature with an absolute value somewhat higher than the saturation time for silicon (12, 13). Therefore, using a tube that has been previously passivated, we assume that wall coverage S_W approaches saturation value $S_{\infty W}$ in a very short time.

4. The outflow of aluminum vapor from the diffusion chamber can be represented by the "free molecular flow" through tubes and channels because of the very low pressure in the system. The mean free path of aluminum atoms is greater than the characteristic dimension of the tube. The rate flow is limited, not by collisions between molecules, but by collisions of molecules with the walls. For the tube of length L, cross section F, and perimeter B, the rate of the molecular outflow $J_{outflow}$ in the system is equal to (14)

$$J_{outflow} = \frac{\partial N}{\partial t_{outflow}} = \frac{4}{3} \frac{\bar{v}}{\int_0^L \frac{B}{F^2} dL} \Delta n = \frac{4}{3} \frac{\bar{v}}{\int_0^L \frac{B}{F^2} dL} \cdot n_2 \quad [3]$$

where $\bar{v} = (8RT/\pi M)^{1/2}$ is the mean molecular speed and Δn represents the difference between the number n_2 of molecules per cubic centimeter at pressure p_2 inside the diffusion chamber, and n_1 the number of molecules per cubic centimeter at pressure p_1 outside the diffusion chamber. We assume that $p_2 >> p_1$ and also $n_2 >> n_1$ and $\Delta n = n_2$.

In the open tube, high vacuum system, equilibrium is not reached and diffusion is carried out under a steady-state condition from the aluminum vapor continuously freed from the Al-Si alloy. In order to estimate the silicon surface concentration, we must know the arrangement of the wafers and the aluminum vapor source in the diffusion chamber. Figure 2a-d illustrates four different arrangements for which the surface concentration has been evaluated. Before the experiment began, we evaluated the evaporation flux using Eq. [1] and the outflow flux using Eq. [3] for different diffusion conditions. In those calculations, we assumed that evaporation coefficient α is equal to 1, $\alpha = 1$.

The computed results showed that for the designed physical conditions, the outflow flux of aluminum vapor

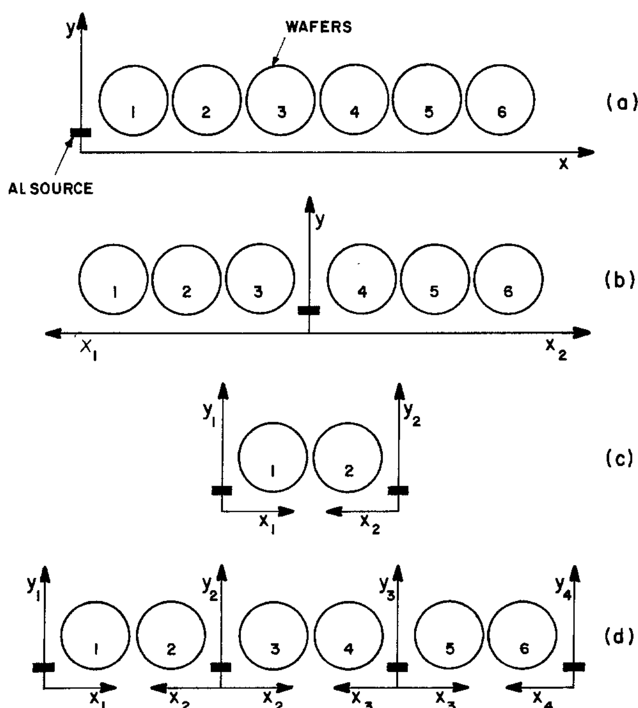

Fig. 2. Aluminum vapor source and wafers' arrangement in the diffusion chamber.

from the system is much smaller than the evaporation flux

$$J_{\text{evap}} >> J_{\text{outflow}} \quad [4]$$

so that

$$J_{\text{diff}} \simeq J_{\text{evap}} \quad [5]$$

The solution of Eq. [5] is

$$c = c_0\left[1 - \text{erf}\left\{\left(\left[\frac{\chi D}{hJ_{\text{evap}}}\right]x + y\right)\frac{1}{2\sqrt{Dt}}\right\}\right] \quad [6]$$

The details of the calculations are included in the Appendix. The relative decrease of C in the gas with increasing x is approximately

$$\frac{C(x,t)}{C_0} = \frac{c(x, y=0, t)}{c_0} \simeq 1 + x\left(\frac{\partial c}{\partial x}\right)_{x=0,y=0}$$

$$= 1 - \frac{2}{\pi}\frac{\chi D}{hJ_{\text{evap}}}\frac{x}{2\sqrt{Dt}} \quad [7]$$

Thus, the decrease in the gas phase is most marked for small values of t.

Equation [6] contains three unknown values, segregation coefficient χ, evaporation coefficient α, and $\Delta p = p_{eq} - p$, the segment in Eq. [1] for J_{evap}. Also h changes its value depending on the distance from the tube center. Introducing a new variable β

$$\frac{1}{\beta} = \frac{\chi}{\alpha \cdot \gamma (p_{eq} - p)} \quad [8]$$

where the γ-corection coefficient for h is defined as follows

$$\gamma = \frac{h}{H} \quad [9]$$

where H represents the inside tube diameter. By inserting Eq. [8] into Eq. [6] and combining with Eq. [1] for $y = 0$, we obtain

$$c = c_0\left[1 - \text{erf}\left\{\frac{1}{\beta}\frac{Dx}{2HA(M/2\pi RT)^{1/2}(Dt)^{1/2}}\right\}\right] \quad [10]$$

Equation [10] was used to evaluate the aluminum surface concentration as a function of distance x from the aluminum vapor source for the silicon wafers and aluminum vapor source arrangements illustrated in Fig. 2a and b. When the wafers and aluminum vapor source arrangements are represented as in Fig. 2c, doping will occur from two sources simultaneously. If the composition of these sources is identical, the second source only equalizes fluctuations between source 1 and source 2 without increasing the pressure over source 1. The surface concentration at any distance x from source 1 is equal to

$$c = c_1 + c_2 - c_{1(x=a)} \quad [11]$$

where a is the distance between two sources, and c_1, c_2 are the surface concentrations due to doping from source 1 and source 2, respectively. Combining Eq. [11] with Eq. [10] we obtain

$$c = c_{01}\left[1 - \text{erf}\left\{\frac{1}{\beta}\frac{Dx}{2HA(M/2\pi RT)^{1/2}(Dt)^{1/2}}\right\}\right] + c_{02}\left[1 - \text{erf}\left\{\frac{1}{\beta}\frac{D(a-x)}{2HA(M/2\pi RT)^{1/2}(Dt)^{1/2}}\right\}\right] - c_{1(x=a)} \quad [12]$$

Equation [12] was used for the calculation of the surface concentration *vs.* distance when the wafers and aluminum source arrangement was as shown in Fig. 2c and d. The computations were performed assuming different values for β. The results of the calculations are presented in the next section.

Results

Diffusion from the elemental aluminum vapor.—The purpose of this test was to investigate the possibility of the use of elemental aluminum as a vapor source. The silicon wafers and the elemental aluminum of 99.999% purity were placed in the diffusion chamber as illustrated in Fig. 2b. The quartz carrier contained only one wafer in every row. After evacuating the system for 1 hr, the furnace at 400°C was moved over the tube. The furnace was then heated to 1150°C. The total diffusion time was 180 min (incuding 47 min for heating from 400° to 1150°C). The results showed that the surface of the wafers placed nearest the aluminum source (wafers marked 3 and 4) in Fig. 2b were alloyed and contaminated with aluminum dots. The diameter of these dots varied depending on the distance from the source. The calculated surface concentration from Irvin's (15) curves using four-point probe data was close to the solubility limit (16) (2×10^{19} cm^{-3}). The enormous degradation observed on the silicon surface considerably limits the use of elemental aluminum as a vapor source for diffusion purposes without additional improvement in the pattern flow of the aluminum vapor.

Diffusion from the Al-Si alloy vapor.—For the next series of tests, the Al-Si alloy was used as an aluminum vapor source to avoid excessive alloying on the silicon surface. In the first tests, an Al-Si alloy was placed at the end of the diffusion chamber as illustrated in Fig. 2a. The Al-Si alloy was formed by fusing an elemental aluminum (99.999% purity) disk with an n-type silicon slab during the diffusion process when the temperature was raised to 1150°C. The purpose of this test was to investigate the variation in dopant concentration as a function of the distance from the Al-Si alloy. Results showed no surface alloying occurred on the wafers, even on those placed near the aluminum source. The surface concentration also decreased with distance from the aluminum vapor source. Figure 3 shows the experimental data and also the results of calculations based on Eq. [10]. The experimental data are best described when $\beta = 3 \times 10^{-3}$. When the wafers and aluminum vapor source arrangement is as illustrated in Fig. 2b, the aluminum vapor flow is symmetrical with respect to the y axis and, consequently, the aluminum surface concentration distribution is also symmetrical. The results of the experiment and the calculations based on Eq. [10] are shown in Fig. 4. All calculations were carried out for the following diffusion conditions: $T = 1150$°C, $t = 137$ min, $A = 12$ cm^2, $H = 3.5$ cm, and $D = 7.98 \times 10^{-12}$ cm^2 sec^{-1}. The value for D was calculated from the relation ob-

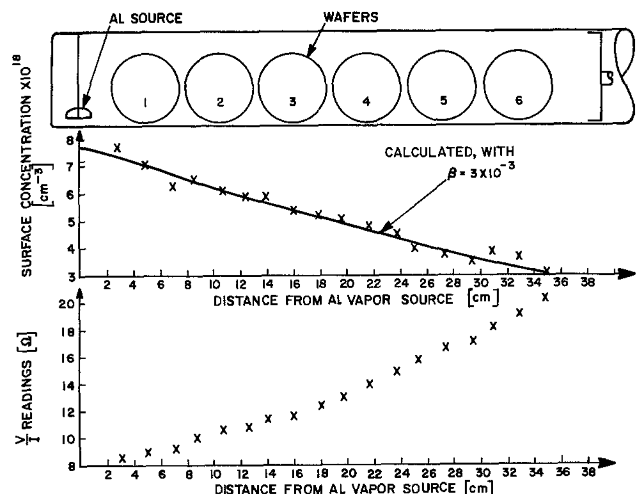

Fig. 3. Aluminum surface concentration *vs.* distance from Al vapor source (aluminum vapor source and wafers' arrangement as in Fig. 2a).

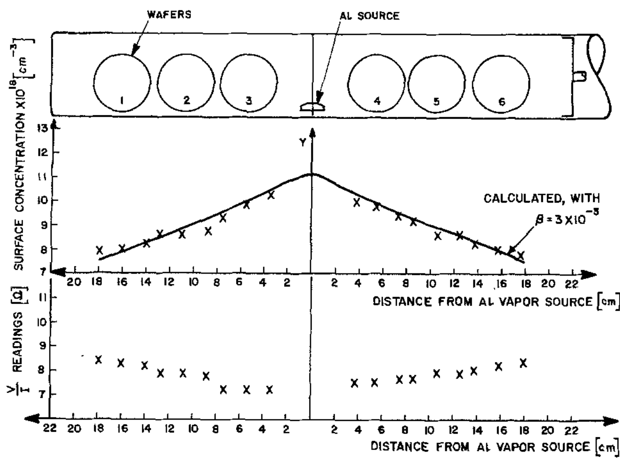

Fig. 4. Aluminum surface concentration vs. distance from Al vapor source.

tained from the experiments described in another section. If the wafers and aluminum source arrangement is as shown in Fig. 2c, the doping uniformity is significantly improved. The diffusion results presented in Fig. 5 show the changes in V/I readings and surface concentrations on two wafers, when two diffusion sources are used. The diffusion carried out for 66 wafers inserted in two rows in the boat for the same diffusion conditions resulted in almost the same V/I readings and surface concentration as obtained for 2 wafers/run. This is illustrated in Fig. 6. The results showed that the number of wafers does not influence the surface concentration. The calculations of the surface concentration based on Eq. [12] showed very good agreement with the experimental data. When the diffusion was carried out from a single aluminum vapor source, the calculations based on Eq. [10] showed less than a 2% discrepancy with experimental data. When the diffusion was performed for the wafers and aluminum vapor source arrangement represented in Fig. 2c and Fig. 1, the calculations based on Eq. [12] showed approximately a 5% discrepancy range with the experimental data.

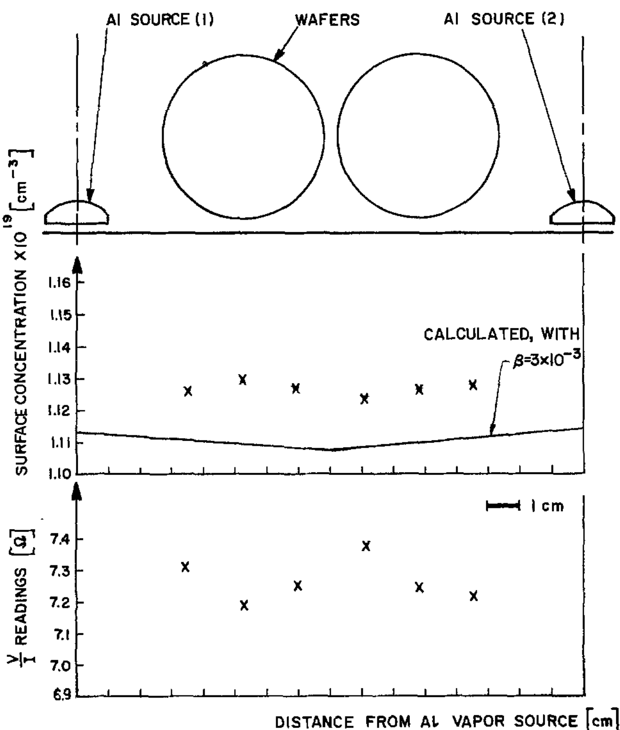

Fig. 5. Aluminum diffusion results for 2 wafers/run (one wafer placed in every row).

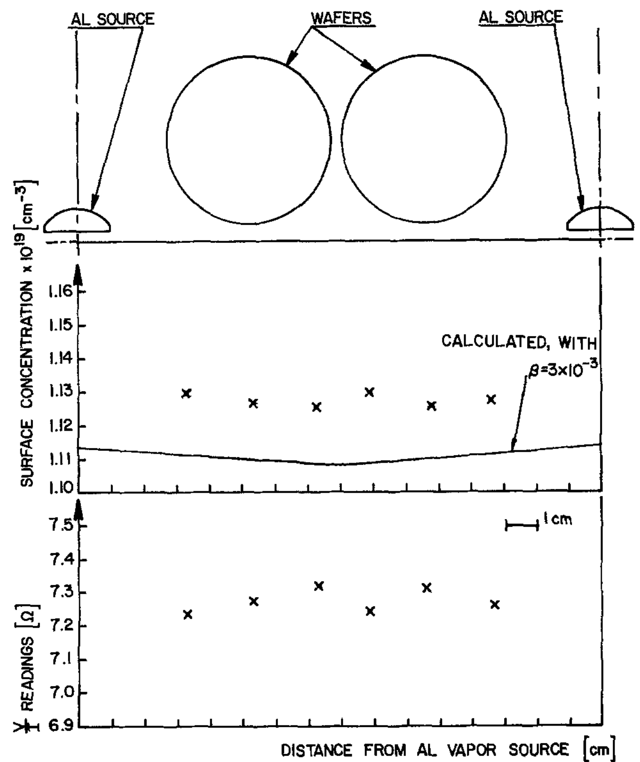

Fig. 6. Aluminum diffusion results for 66 wafers/run (33 wafers placed in every row).

High volume production process.—Several diffusion experiments were carried out for 198 wafers/run. The diffusion chamber was loaded as illustrated in Fig. 2d. It contained a triple wafer and aluminum source assembly as shown in Fig. 2c. The number of wafers diffused per run could be increased for a longer tube adding more sets of wafers and sources as shown in Fig. 2c. The next two figures represent the diffusion results obtained from the processing of 198 wafers/run. Figure 7 shows the spreading resistances obtained for

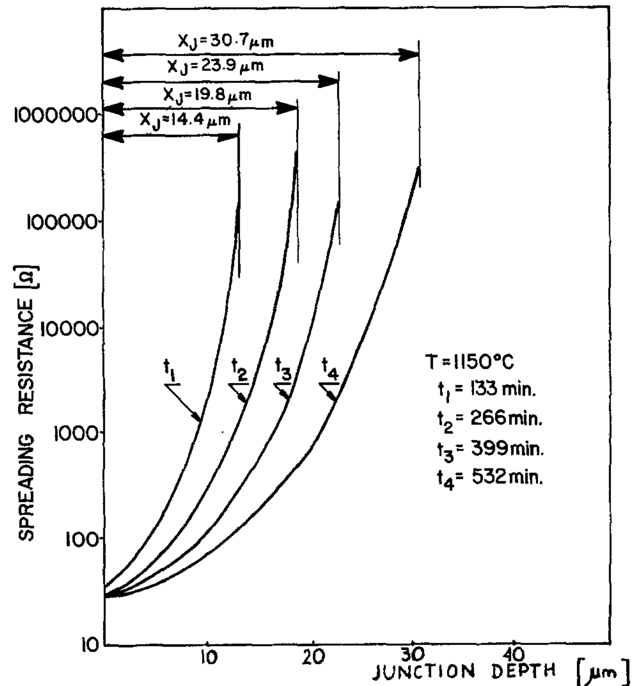

Fig. 7. Spreading resistance of aluminum diffused samples

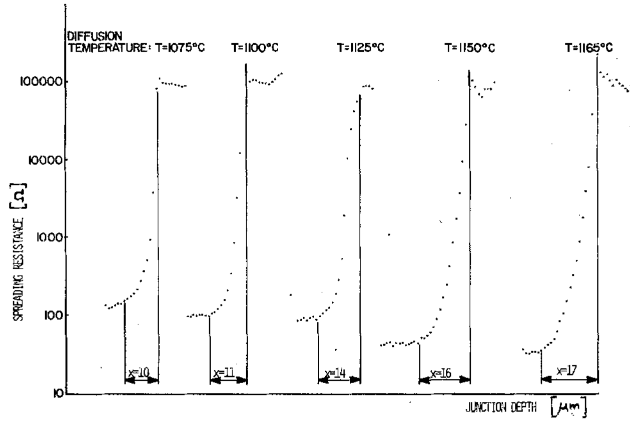

Fig. 8. Spreading resistance of aluminum diffused junctions vs. diffusion temperature.

aluminum diffusions carried out at 1150°C for $t = 133$, 266, 399, and 532 min. Assuming that the diffusions were performed under a steady-state condition, we should expect the surface concentration, as well as the spreading resistance, to be independent of diffusion time. Some differences obtained in spreading resistance measurements could be related to the error measurement introduced by the two-point probe method itself, since spreading resistance measurements tend to overestimate ρ_s more for shallower junctions than for deeper ones. Figure 8 illustrates the spreading resistance of aluminum diffused profiles obtained at different temperatures in the range of 1075°-1165°C. Several diffusion runs were also carried out to evaluate reproducibility of the process. The sheet resistances obtained varied from wafer to wafer and from run to run ±3%.

Temperature dependence of the diffusion coefficient.—Aluminum diffusion into silicon has been found to be a strong function of the way the dopant is transported to the silicon wafer and its surface activity. When the Al-Si alloy was first formed on the silicon surface by vacuum alloying and used (17) as a dopant source (solid-solid type diffusion), the calculated diffusion coefficient at 1200°C was about one order of magnitude higher than the one obtained for a diffusion carried out in a sealed evacuated ampul (2, 5) (vapor-solid type diffusion). On the other hand, when aluminum was incorporated (18) into the epitaxial layer by bubbling hydrogen through trimethyl aluminum, the diffusion coefficient was about one order of magnitude lower than that obtained in the ampul method. The calculations of the apparent activation energy and the diffusion constant were also performed from the diffusion results in an open tube, high vacuum system. Two-point probe spreading resistance data were used to determine junction depths and the surface concentrations. It was assumed that the impurity distribution followed a complementary error function. The relevant diffusion data obtained in this study, as well as data obtained by other researchers, are listed in Table I.

Discussion and Summary

In general, the relation between concentration and the distance from the diffusion source is seen in Eq. [10] and [12] depending on the wafers and the aluminum vapor source arrangement inside the diffusion chamber. In both of these equations, an artificial coefficient β appears which combines three coefficients with Eq. [8]: α, χ, and γ all of which have physical meanings. It appears that for a given experimental condition, those coefficients are constant. However, their values are difficult to evaluate theoretically.

In general, the aluminum evaporation coefficient strongly depends on the amount of moisture and oxygen in the system. The presence of either would cause the aluminum to react forming a stable Al_2O_3 skin on the diffusion source. A matte finish would be observed on those samples (8). The amount of evaporated molecules would also be insufficient to maintain the aluminum pressure resulting in doping with a high surface concentration. The reproducibility would also be inconsistent.

In this study, we found that after every diffusion run, the aluminum diffusion source showed a shiny surface. X-ray diffraction analysis performed has not revealed the presence of Al_2O_3 on those diffusion sources. The process has been reproducible, consistently resulting in doping with high surface concentration. We, therefore, concluded that the evaporation coefficient was constant during experiments performed with diffusion.

The value of the segregation coefficient χ on the aluminum vapor and silicon interface can clearly be read as a constant from Henry's law: $c = \chi \cdot p$, where c represents concentration on the silicon surface and p represents partial pressure of the doping element. It is well known that at low pressures Henry's law accurately describes experimental results. In an open tube, high vacuum system, we operate with low aluminum pressure and χ can be safely assumed to be a constant for a given experimental condition.

The correction coefficient γ depends on the characteristic tube dimensions only and is constant for a designed setup. Equation [8] also consists of segment $p_{eq} - p$ which expresses a deviation of the process from the equilibrium. For the isothermal and steady-state condition, this difference is constant due to the diffusion continuously proceeding and to the outflow of the vapor from the diffusion chamber. This difference is greater than zero: $p_{eq} - p > 0$. A theoretical calculation of all those coefficients: α, γ, and χ and $p_{eq} - p$ as well as β appears to be too complicated at this time.

In summary, the aluminum diffusion process has been described for high volume production. This process is different from the widely used sealed-ampul technology. It is less expensive, easier to control, and has more operational flexibility. Surface concentration and spreading resistance of aluminum-doped junctions were evaluated as a function of temperature and time. The process is described mathematically using an approximated mass-transport model. Equation [10] describes the aluminum surface concentration as a function of the distance from the vapor source. Equation [12] describes a similar relation for diffusion from two vapor sources. Equations [10] and [12] showed less than a 2% discrepancy and less than a 5% discrepancy range with the experimental data. The quality of the aluminum diffused junctions was tested on 224 × 224 mil square diodes, transistors, and thyristors. Reverse voltages measured were typically ~900V and 35 Ω cm

APPENDIX

If the arrangement of wafers and a single aluminum source is as shown in Fig. 2a, the distribution of the diffusant into the silicon wafer is a function of the space coordinates and time. Since, under the steady-state condition, the dopant is continuously liberated from the source, the diffusion is carried out from the aluminum vapor streaming continuously over the silicon surface as shown schematically in Fig. 9. The flow of vapor coincides with the x-direction. Assuming local equilibrium at the vapor-silicon interface, the ratio of concentrations in silicon c and vapor C is given by the segregation coefficient χ

$$\chi = \frac{c}{C} \qquad \text{[A-1]}$$

The flow of vapor into the silicon surface at point x is

$$-D\left(\frac{\partial c}{\partial y}\right)_{y=0} \qquad \text{[A-2]}$$

This must be equal to the decrease of the concentration of the vapor given by

$$-J_{\text{evap}}\, h\frac{\partial C}{\partial x} \qquad \text{[A-3]}$$

where h is the height of the vapor stream. Combining Eq. [A-1], [A-2], and [A-3] we obtain

$$\left(\frac{\partial c}{\partial y}\right)_{y=0} = \frac{J_{\text{evap}}\cdot h}{\chi D}\left(\frac{\partial c}{\partial x}\right)_{y=0} \qquad \text{[A-4]}$$

The vapor entering at $x = 0$ is of the concentration

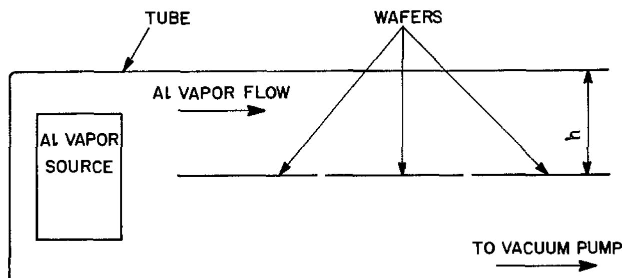

Fig. 9. Model for diffusion out of streaming vapor into Si wafers

C_0, thus $c_0 = \chi C_0$ at $x = 0$ and $y = 0$ for all $t > 0$. We further assume $c = 0$ at $t = 0$. We define the new variables as

$$\xi = (\chi D/hJ_{\text{evap}})\, x/2\sqrt{Dt}$$

and

$$\eta = y/2\sqrt{Dt} \qquad \text{[A-5]}$$

Fick's second law

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2} \qquad \text{[A-6]}$$

is transformed to

$$\frac{\partial^2 c}{\partial \eta^2} + 2\left(\xi\frac{\partial c}{\partial \xi} + \eta\frac{\partial c}{\partial \eta}\right) = 0 \qquad \text{[A-7]}$$

The boundary conditions in the new coordinates are

$$c = c_0 \text{ at } \xi = 0,\ \eta = 0;\quad c = 0 \text{ at } \xi = \infty,\ \eta = \infty$$

$$\frac{\partial c}{\partial \xi} = 2\sigma \text{ at } \eta = 0 \qquad \text{[A-8]}$$

A solution of Eq. [A-7] satisfying the boundary conditions of Eq. [A-8] may be obtained by assuming

$$c(\xi, \eta) = c(\sigma), \quad \sigma = \xi + \eta \qquad \text{[A-9]}$$

Substituting Eq. [A-9] into Eq. [A-4], we obtain the ordinary differential equation

$$\frac{d^2 c}{d\sigma^2} + 2\sigma\frac{dc}{d\sigma} = 0$$

The solution of this equation has been previously obtained (19) and is

$$c = c_0\left[1 - \text{erf}\left\{\left(\left[\frac{\chi D}{hJ_{\text{evap}}}\right]x + y\right)\frac{1}{2\sqrt{Dt}}\right\}\right] \qquad \text{[A-10]}$$

Gettering of Gold and Copper in Silicon during Gallium Diffusion

N. Momma, H. Taniguchi, M. Ura, and T. Ogawa

Hitachi Limited, Hitachi Research Laboratory, Hitachi, Ibaraki, Japan

ABSTRACT

The gettering of Au and Cu during the sealed tube diffusion of Ga has been studied by using neutron activation analysis and the spreading resistance microprobe technique. It was found that Au in silicon was gettered during Ga diffusion regardless of the cooling conditions. Most of the Cu in the surface layer of silicon diffused out during Ga diffusion, while Cu in the bulk silicon was gettered during the slow cooling process after diffusion. Increases in the minority carrier lifetime in p^+n diodes prepared by Ga diffusion occurred with increasing the amount of Ga used as a source. It was ascertained that in Ga gettering the Ga metal sources played an important role as impurity sinks.

In silicon device processing, high temperature steps, such as oxidation and dopant diffusion, often result in the soft reverse characteristics of pn junctions. The origin of this high leakage current is believed to be the localized high electric field caused by the precipitates of metals, such as Au and Cu (1). These metals in silicon also lead to the degradation of minority carrier lifetime (2-4) which affects the forward voltage drop and other device parameters. These undesired metallic impurities can be removed by so called "gettering" processes. Up to now, various gettering techniques have been reported (5-14). Among them, gettering during diffusion of dopant impurities, such as phosphorus, boron, gallium, and so forth, is most important, because the dopant diffusion is the typical method for making pn junctions. The gettering by phosphorus and boron diffusion has been widely studied analytically and electrically (5-9), but only a few works have been reported concerning the gettering during Ga diffusion (14). Because of the relatively high diffusion coefficient of Ga in silicon, Ga diffusion is often used for the formation of p-type layers of silicon power devices. In these devices high lifetime values are often desirable. Therefore, the maintenance of a minimum lifetime during Ga diffusion is an outstanding problem in the power device processing. Lambert and Köhl (14) reported that metallic Ga layers painted on the silicon surface show pronounced gettering effect. However, the precise features of Ga gettering have not been offered yet. It is the purpose of this study to investigate analytically the behavior of Au and Cu in the sealed tube diffusion of Ga and to reveal the mechanism of the gettering during Ga diffusion.

Experimental

Sample preparation.—The starting materials used in this study were float-zone, n-type silicon wafers, 130-180 Ω-cm, with mechanically lapped surface. The wafers were intentionally contaminated with a moderate to a large amount of Au or Cu to obtain impurity levels above the background level. Au-contaminated samples were prepared by the following procedure. First, the wafers were etched by HF/HNO_3 solutions to remove the surface-damaged layer produced by mechanical lapping. Au films were deposited on one side of the silicon wafers by vacuum evaporation and then annealed at 900°C for 30 min in an argon atmosphere. The wafers were etched in order to remove the surface layers of high Au concentrations. By these processes, Au was almost uniformly distributed through the wafers in the concentration of about 1×10^{14} atoms/cm^3. For the study of the gettering effect by crystal imperfections introduced mechanically, the surface of the silicon wafers with uniform Au concentration were roughened by 12 μm garnet powder. Meanwhile, Cu-contaminated samples were prepared by sealed tube diffusion. The starting silicon wafers were cleaned by ultrasonic washing in hot alkaline solution and dipping in aqua regia. After cleaning, the wafers were encapsulated in a quartz tube under vacuum together with a high purity (99.999%) Cu metal piece put in a silicon boat. The capsule was then heated at 1150°C for 1 hr. The Cu-contaminated samples obtained by this method showed somewhat complicated Cu distribution as shown in Fig. 5 and elsewhere. The Cu concentration in silicon near the surface was extremely high, nearly 10^{20} atoms/cm^3, but in bulk silicon the concentration was the order of 10^{14}-10^{15} atoms/cm^3. The Cu-contaminated samples were used for the gettering experiments without removing the surface layer of high Cu concentration, because the level of the limiting concentration of the activation analysis for Cu (10^{14}-10^{15} atoms/cm^3) might not be low enough to clarify the gettering phenomena analytically.

Ga diffusion and heat-treatment.—After cleaning by alkaline solutions and aqua regia, the contaminated samples were encapsulated in quartz tubes in argon atmospheres together with high purity Ga(seven nine's) placed on silicon slices. Ga diffusion was carried out at 1250° or 1256°C. Two different kinds of cooling conditions were used; in one case, the capsules were air quenched after the diffusion (this process is hereafter designated "fast cooling"). In the other case, the capsules were cooled in the furnace at a rate of 40°C/hr from the diffusion temperature to 600°C and then removed from the furnace (this process is designated "slow cooling"). For comparison, sealed tube heat-treatments in argon atmospheres without Ga sources were also carried out under the same conditions as those of Ga diffusion.

Measuring methods.—The concentrations of Au, Cu, and Ga in silicon wafers were determined by the neutron activation analysis. The samples were irradiated with thermal neutrons of 2.1×10^{12} n/cm·sec for 10 hr in the Hitachi Training Reactor. After the activation the wafers were individually subjected to the following processes. First, metals present on the wafer surface were removed by rinsing in boiling aqua regia and the surface densities of the metals were determined. Then, thin layers were etched off from the surface of the samples successively by HF/HNO_3 solutions and the activities of the etching solutions were measured after each etching step. The neutron activation analysis was also used for determination of the concentrations of Au and Cu in Ga sources and quartz tubes. After the activation Ga sources and quartz tubes were dissolved in HCl and HF solutions, respectively. Au and Cu in the

Key words: sealed tube diffusion, minority carrier lifetime, impurity sink, neutron activation analysis, spreading resistance.

solutions were separated from the other elements using anion exchange resin columns and the activities were measured. The Cu concentrations in Ga sources and quartz tubes were also determined by atomic absorption spectrometry. Ga sources and quartz tubes were dissolved in HCl and HF solutions, respectively. The solutions were then subjected to evaporation to dryness. The residual was dissolved in HNO_3 solutions and the atomic absorptions were measured. The distributions of electrically active impurities in silicon wafers were estimated by the spreading resistance measurement (15). The minority carrier lifetimes of p^+n diodes prepared by Ga diffusion were measured by the microwave technique (16). The decreasing rate of the excess carriers, injected by a light pulse from a xenon lamp, was determined by measuring the reflection of microwave energy. The standard diode samples, whose lifetime values were calibrated by the method proposed by Lederhandler and Giacoletto (17), were used to convert the decreasing rates to lifetime values.

Results and Discussion

The gettering of Au.—Figure 1 shows the Au concentration in silicon before and after heat-treatment without a Ga source determined by neutron activation analysis. In this experiment, in order to examine the gettering effect of mechanically damaged layers on wafer surfaces, two kinds of samples, with lapped and etched surface, were used. It is clear from this figure that, in both samples, a fraction of Au in the bulk silicon was transferred to the regions near surfaces but that the total amount of Au remained almost unchanged after heat-treatment. This means that without a Ga source Au in silicon cannot be removed from the wafers at all and that the gettering effect of a surface-damaged layer is insignificant.

After Ga diffusion the densities of Au on silicon wafer surfaces were found to be less than $2\text{-}4 \times 10^{10}$ atoms/cm^2 in both cases of fast and slow cooling. This means that Au is not accumulated on the surface (or in a thin layer of Ga, if any) after the diffusion. Figure 2 shows the Au concentration profile in silicon before and after Ga diffusion. In this figure and other figures exhibited in this paper, dashed lines represent the levels of the limiting concentration of the activation analysis and indicate that impurities more than these levels

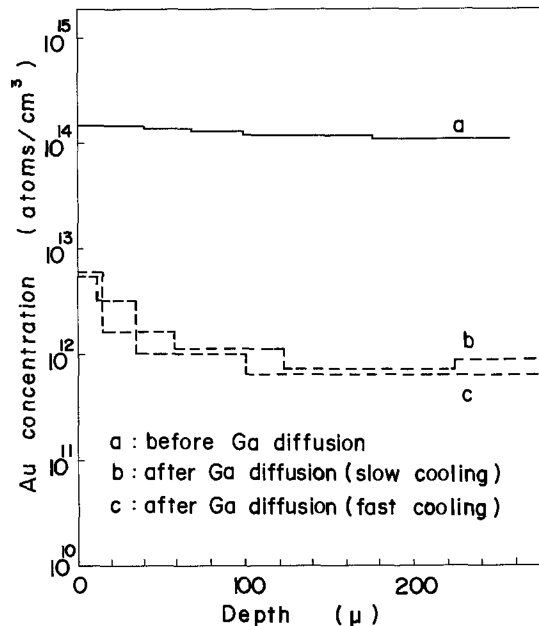

Fig. 2. Au concentration profiles after Ga diffusion (1256°C for 9.5 hr). Dashed lines indicate that no more Au than these levels can be detected.

could not be detected. The limiting concentration expressed in the unit of atoms/cm^3 varies from measurement to measurement, because it depends on the amount of sample (*i.e.* the thickness of the etched layer), the time interval between the activation and the activity measurement, the duration of the activity counting, and so on. It is clear from Fig. 2 that after Ga diffusion, the concentrations of Au decrease below the limiting concentration not only in the bulk silicon but also in the surface layer, whether the cooling is fast or slow. These results are also supported by the spreading resistance measurements as shown in Fig. 3. Before Au doping the level of spreading resistance lies around $3 \times 10^5\Omega$. On Au doping, the spreading resistance of n-type silicon increases to the order of $10^7\Omega$ due to the compensation by Au acceptors. After Ga diffusion, spreading resistance is restored to the same level as before Au doping, whether the cooling is fast or slow. These results suggest that both electrically

Table I. The total amount of Au in silicon wafers and Ga sources before and after Ga diffusion (1256°C for 9.5 hr)

Cooling	Au in Si wafers (atoms)		Au in Ga sources (atoms)	
	Before	After	Before	After
Fast	1.1×10^{14}	$<1.5 \times 10^{12}$	5.0×10^{12}	8.4×10^{13}
Slow	1.1×10^{14}	$<1.6 \times 10^{12}$	3.7×10^{12}	4.7×10^{13}

active and inactive Au is removed from silicon wafers during Ga diffusion regardless of the cooling conditions.

In order to reveal the aspects of Au transfer in the diffusion system, Au contents in silicon wafers and Ga sources before and after the diffusion were measured. The results are shown in Table I. The total amount of Au in the sample wafers before diffusion is 1.1×10^{14} atoms, whereas it is less than $1.5\text{-}1.6 \times 10^{12}$ atoms after diffusion. On the other hand, the amount of Au in Ga metal sources increases more than one order of magnitude during Ga diffusion. This increment of Au in Ga sources corresponds to one-third to two-thirds of the total amount of Au contained in the silicon samples before diffusion. This means that Au that diffuses from the silicon samples accumulates not in the Ga-diffused layer but in the Ga metal sources, in other words, Ga sources play an important role as Au sinks.

In the course of this experiment, oxidation of silicon occurred unexpectedly in some diffusion lots due to the presence of oxygen which was accidentally introduced together with argon gas into the sealed tube. The effect of oxidation on the gettering of Au is shown in Fig. 4. When oxidation occurs during diffusion, the gettering effect of Ga was considerably reduced and after the diffusion nearly one-half of the total amount of Au remains in the silicon wafers. This result suggests that the diffusion of Au out of the wafers is interrupted by the presence of silicon dioxide layers on the sample surfaces.

The gettering of Cu.—Figure 5 shows the behavior Cu before and after heat-treatment followed by slow cooling. As shown in this figure, residual Cu in the whole silicon wafers after heat-treatment is only

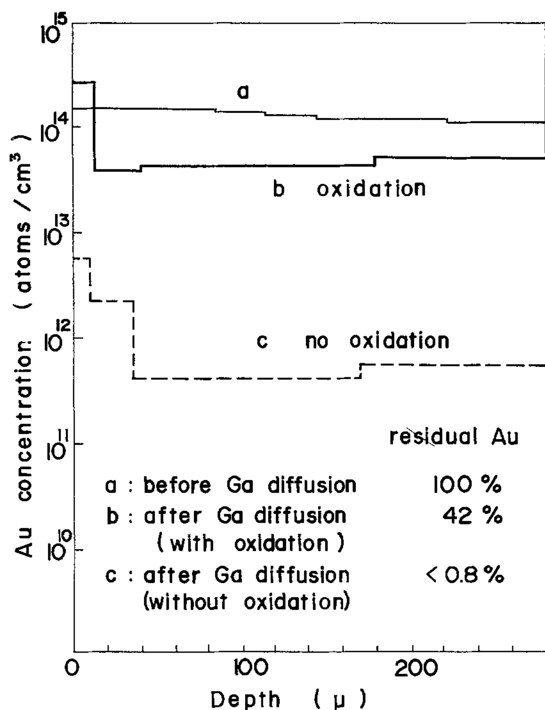

Fig. 4. The effect of oxidation on gettering of Au by Ga diffusion (1256°C for 8 hr). Dashed lines indicate that no more Au than these levels can be detected.

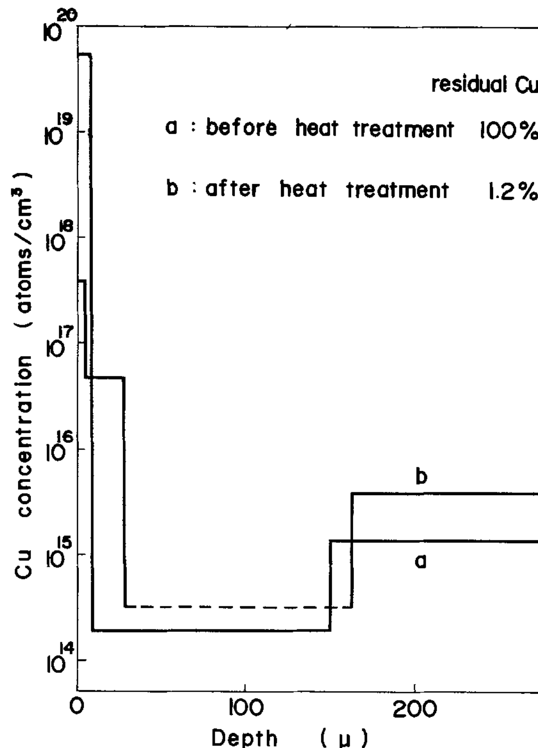

Fig. 5. Cu concentration profiles after heat-treatment (1256°C for 8 hr). Dashed line indicates that no more Cu than this level can be detected.

1.2%. This means that during the heat-treatment more than 98% of Cu diffused out from the samples. However, Cu in bulk silicon cannot be removed but rather increases as shown in this figure.

Figure 6 shows the concentration profiles of Cu before and after Ga diffusion. After Ga diffusion, and the following fast cooling, the percentage of residual Cu in silicon is 2.9%, that is, about 97% of the Cu diffuses out from the samples. But as shown in line b, Cu in bulk silicon, of the order of 10^{15} atoms/cm^3, remains. On the other hand, in the case of slow cooling, residual Cu is only 0.14-0.25% and the concentration of Cu in the bulk region decreases below the limiting

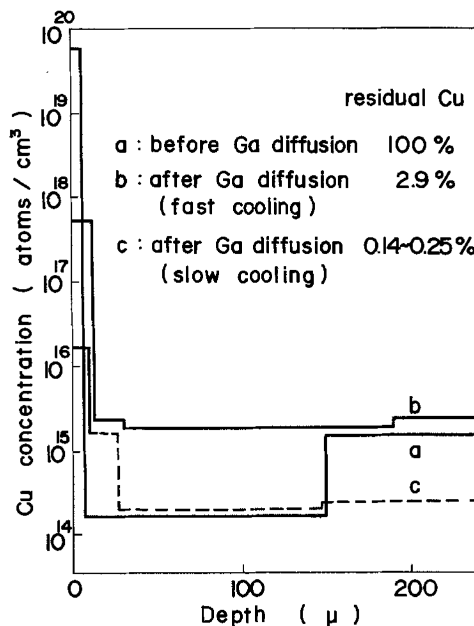

Fig. 6. Cu concentration profiles after Ga diffusion (1256°C for 8 hr). Dashed lines indicate that no more Cu than these levels can be detected.

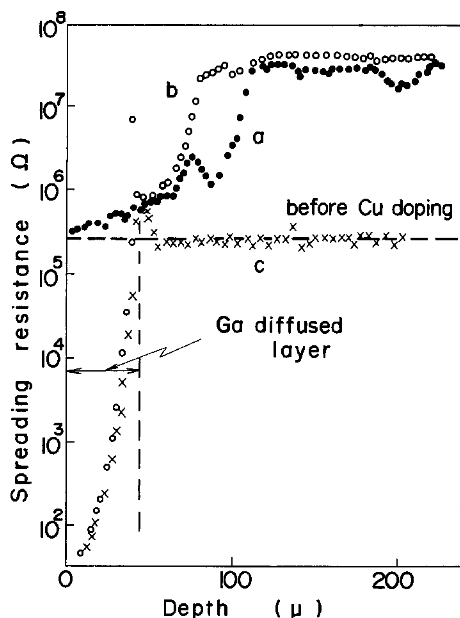

Fig. 7. Distribution of spreading resistance after Ga diffusion (1256°C for 8 hr): a, before Ga diffusion; b, after Ga diffusion (fast cooling); c, after Ga diffusion (slow cooling).

concentration, as shown in line c. These features of Ga diffusion are more clearly demonstrated by the results of the spreading resistance measurement as shown in Fig. 7. Spreading resistance before Cu doping is at the level of $3 \times 10^5 \Omega$. Curve a illustrates the distribution of the spreading resistance of a Cu-contaminated sample before Ga diffusion. As shown in curve b, in the case of fast cooling, the spreading resistance in the bulk silicon shows almost the same distribution as that of the Cu-contaminated sample before the diffusion. On the other hand, as shown in curve c, in the case of slow cooling, the spreading resistance is restored to the level it was at before Cu doping. From these results, it is considered that Cu diffuses out from the bulk silicon during the slow cooling process after diffusion.

The effect of oxidation on the gettering of Cu is shown in Fig. 8. Lines a and b are the concentration profiles of Cu after Ga diffusion followed by slow cooling with and without oxidation, respectively. In both cases, the concentration of Cu in the bulk silicon decreases below the limiting concentration. Moreover, the percentage of the total amount of Cu in the silicon wafer remaining after diffusion is almost the same in both cases. From these results, it is clear that the presence of a surface oxide layer does not affect the gettering of Cu. This is in marked contrast to the gettering of Au.

As stated before, the Ga sources play an important role in the gettering of Au. In order to know whether the same is true for the gettering of Cu, the behavior of Cu in the diffusion system was further examined analytically. Figures 9 and 10 show the Cu contents in the Ga source and in the quartz tubes before and after Ga diffusion, using silicon samples not intentionally contaminated with Cu. In these figures, open circles indicate the values obtained by the activation analysis and solid circles the values obtained by the atomic absorption spectrometry. The circles in parentheses represent the limiting concentration and indicate that no more Cu than this level could be detected. The Cu contents of the Ga source before diffusion are about 1.2×10^{15} atoms/g. After diffusion, even with uncontaminated samples, the Cu concentration increases to the order of 10^{17} atoms/g. On the contrary, it is revealed that the quartz tubes used in this experiment contain a considerable amount of Cu, 10^{14} to above 10^{15} atoms/g, before use. But after the diffusion, the Cu contents of the tubes decrease below 2×10^{13} atoms/g. It is clear that Cu that evaporates from the quartz tubes

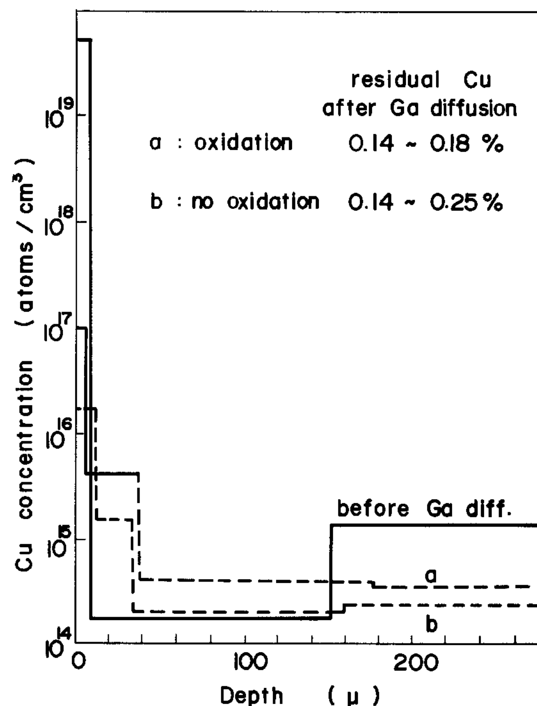

Fig. 8. The effect of oxidation on gettering of Cu by Ga diffusion (1256°C for 8 hr). Dashed lines indicate that no more Cu than these levels can be detected.

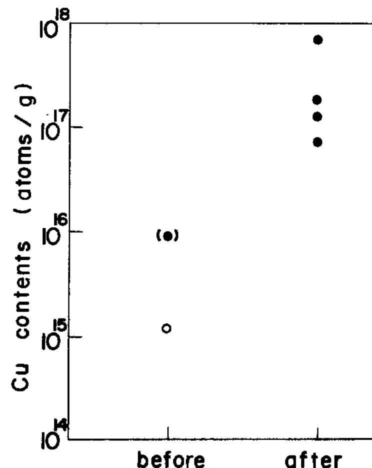

Fig. 9. Cu contents in Ga sources before and after Ga diffusion (1256°C for 86.5 hr): ○, activation analysis; ●, atomic absorption spectrometry. The circle in parenthesis indicates that no more Cu than this level can be detected.

accumulates in the Ga sources during the diffusion process. Considering the results mentioned above, it is suggested that during Ga diffusion, Cu is gettered mainly through out-diffusion and that Ga sources act as Cu sinks, in the same way that they act as Au sinks.

Minority carrier lifetimes of Ga-diffused wafers.—On the basis of the fact that Ga metal sources act as impurity sinks during Ga diffusion, it should be expected that the gettering would become more effective if the amount of Ga used as a source was increased. To confirm this view, the minority carrier lifetimes in the n-type layers of p^+n diodes prepared by Ga diffusion with different amounts of Ga used as sources were measured. In this experiment, in order to examine the gettering effect of Ga under conditions similar to those of the actual device fabrication, the sample wafers were not intentionally contaminated with impurities and Ga diffusion was carried out at 1256°C for 86.5 hr. The results are shown in Fig. 11. As was expected,

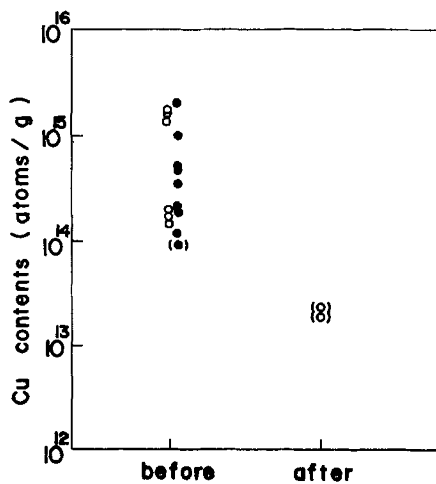

Fig. 10. Cu contents in quartz tubes before and after Ga diffusion (1256°C for 86.5 hr): ○, activation analysis; ●, atomic absorption spectrometry. The circles in parentheses indicate that no more Cu than these levels can be detected.

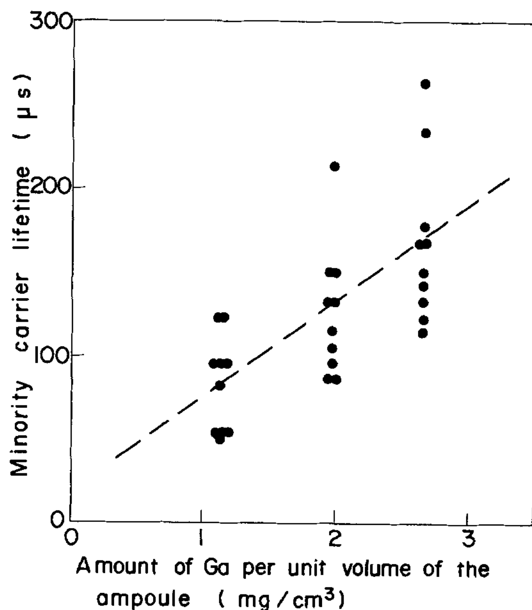

Fig. 11. The correlation between the minority carrier lifetime of p^+n diodes prepared by Ga diffusion (1256°C for 86.5 hr) and the amount of Ga used as a source.

lifetimes become longer when the amount of Ga used as a source is increased. Figure 12 shows the concentration profiles of electrically active Ga measured by the spreading resistance method. Figure 13 depicts the distribution of the total (active and inactive) Ga determined by the neutron activation analysis. It is clear from these figures that the concentration of Ga does not increase with increasing the amount of Ga used as a source. This means that there is no correlation between minority carrier lifetimes and Ga concentrations in p^+n diodes. In other words, the Ga layer on the surface of the silicon wafer does not play a significant role in Ga gettering but the Ga metal source itself plays an important role in the gettering. These features of Ga gettering are in striking contrast to phosphorus and boron diffusion gettering (5-9) in which the liquidus glass or high concentration diffused layers on silicon surfaces are important agents.

Summary

The gettering of Au and Cu during the sealed tube diffusion of Ga was studied by using neutron activation analysis and the spreading resistance microprobe technique. The results are summarized as follows;

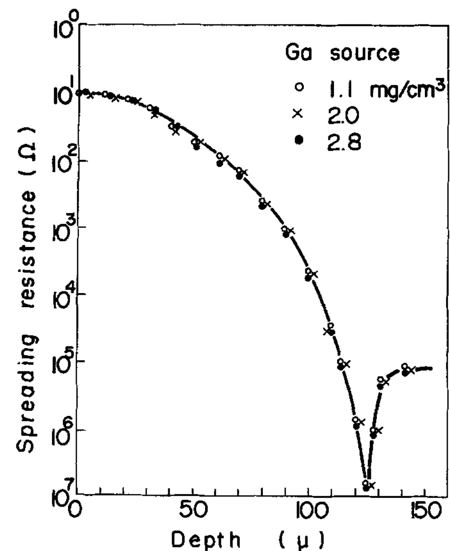

Fig. 12. Ga concentration profiles after Ga diffusion (1256°C for 86.5 hr) measured by spreading resistance microprobe technique.

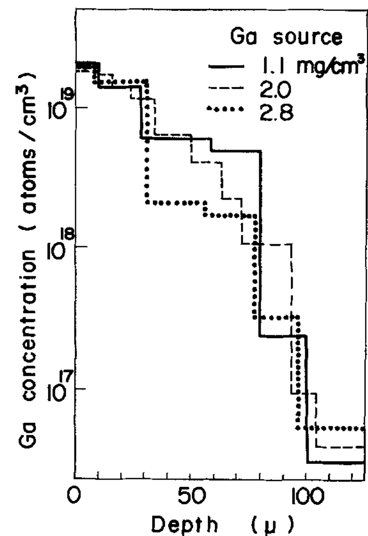

Fig. 13. Ga concentration profiles after Ga diffusion (1256°C for 86.5 hr) determined by activation analysis.

1. Au in silicon is gettered during Ga diffusion regardless of the cooling conditions.
2. Most of Cu in the surface layer of silicon diffuses out during Ga diffusion, while Cu in the bulk silicon is gettered during the slow cooling process after Ga diffusion.
3. The minority carrier lifetime in p^+n diodes prepared by Ga diffusion increases with increasing the amount of Ga used as a source.
4. In Ga gettering, Ga metal sources play an importatn role as impurity sinks.

The Optical Constants of Silicon and Dry Oxygen Oxides of Silicon at 5461A

E. A. Taft*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The index of refraction of oxides grown on silicon in dry oxygen has been found to be a function of the growth temperature. There is an orientation effect for oxides grown at low temperatures. The index decreases with temperature, saturating above 1190°C at 1.4620, a value consistent with the index of fused quartz when stress corrections are made. The apparent density of oxide grown at 800°C is 3% greater than that grown above 1190°C. The complex index of refraction of silicon at 5461Å has been determined to be 4.086 − i0.031.

There is considerable variation in the literature of the reported values for the complex index of refraction of silicon and of the index of grown oxide at a wavelength of 5461Å. In 1972, papers on silicon (1) and on thermally grown silicon oxide (2) summarized some previous work and concluded with the best values for the index of silicon and of silicon oxide. The two values (two papers) for the complex index of refraction, n-*ik*, for silicon were 4.056 − i0.028 and 4.05 −i0.028. The index values obtained for thermally grown SiO_2 were 1.458 and 1.460. All results were measured at 5461Å. Except for the fact that both papers appear to explain away conflicting data, these ellipsometric studies agree quite closely in their results for both silicon and silicon dioxide. The value 1.458, however, does not agree with earlier results (3, 4) for SiO_2 which were obtained using different optical measurements. The earlier value for silicon oxide is 1.462. Moreover, more recent reports, again using ellipsometry (5, 6) have found still different results for the real part of the index of refraction of silicon and the index of the oxide. The new values advanced are 4.085 − i0.028 for silicon and 1.47 for the oxide.

In this paper we will present experimental results for the complex index of refraction of silicon; values of the index of oxide grown in dry oxygen on <111> and <100> silicon surfaces; and the variation of the index of silicon dioxide with growth temperature.

Experimental

Extinction coefficient of silicon.—As the ellipsometer is not well suited to the accurate measurement of small coefficients [van der Meulen (5) gives a short discussion as does Archer (7)], the extinction coefficient *k*, of silicon has been chosen by most workers from the available absorption data (8, 9). The original data of Dash and Newman (8), taken in this laboratory and available to me, actually gives *k* a value of 0.031, not 0.028, as often quoted. This still agrees with the published curve of Braunstein *et al.* (9).

The extinction coefficient is best established from absorption measurements in single crystal silicon; therefore, an independent check at 5461Å was made. Four wafers of 10 Ω-cm silicon crystal were chemically thinned so that reasonably uniform thickness was obtained. The thickness was determined from infrared interference measurements between 7.5 and 20 μm wavelengths where the index of refraction of silicon remains constant at 3.42 (10). A typical example is given in Fig. 1. The crystals were from 5 to 11 μm thick. The transmission of each of these crystals was measured using a prism monochromator with the 5461Å line from a mercury vapor lamp. The readings were corrected for background radiation and for silicon reflection to obtain an extinction coefficient for each sample. The values obtained are given in Table I. The average value of the extinction coefficient from the four determinations is $k = 0.031 \pm 5\%$; in excel-

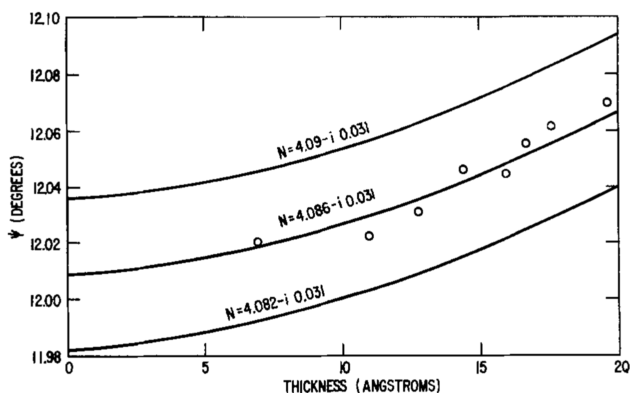

Fig. 4. Analyzer reading, $A = -\Psi$, for a thin transparent film on a slightly lossy substrate. The angle of incidence is 70° and λ is 5461Å.

lent agreement with Dash and Newman's earlier results.

Real part of index of refraction of silicon.—After careful alignment of a Gaertner L119 ellipsometer a measurement was made upon a clean optical quartz glass sample (G. E. Type 151) in order to check the instrument alignment and to verify the setting of the angle of incidence at 70°. Ψ calculated from two-quadrant measurements was 21.60° where $-\Psi$ is the analyzer reading.

Values of Ψ for transparent ($k = 0$) reflecting materials at a 70° angle of incidence are given in Fig. 2. They are obtained from usual ellipsometric formulas (11), the phase change, Δ, being 0° or 180° for a transparent material. Figure 3 is a highly expanded portion of this curve near the index for fused quartz of 1.4601 at 5461Å (12), Ψ should be 21.59°. This value is within the ± 0.01° precision of our instrument measurement.

Having verified, in this way, the ellipsometer calibration. we determined the real part of the index of refraction for Si. Ψ and Δ were observed for several hours on a freshly HF-etched and water-rinsed polished silicon wafer. Δ is used as the measure of thickness for very thin films. Ψ is plotted in Fig. 4 along with calculated curves of Ψ *vs.* film thickness on silicon. Ψ changes quite slowly as a film is formed on a clean Si surface. [van der Meulen (5) and Archer (7) also discuss this problem of a film-free surface.] The usual 6-8Å film on freshly HF-dipped and water-rinsed silicon gives a Ψ reading only 0.01° greater than a film-free sample. The index of the air-grown film is assumed to be 1.5 but any value up to 2.7 would change the measured thickness <20%. The Ψ value of 12.02° ± 0.01° obtained on numerous nearly film-free samples indicates that the real part of the index of refraction of silicon should be 4.086. Assuming that over-all errors, referred to a reading for Ψ, are ± 0.02°, this value for the index of silicon is correct to ± 0.003. No chemically etched silicon samples nor commercial chem-mechanically polished wafers have shown any appreciable deviation from this index.

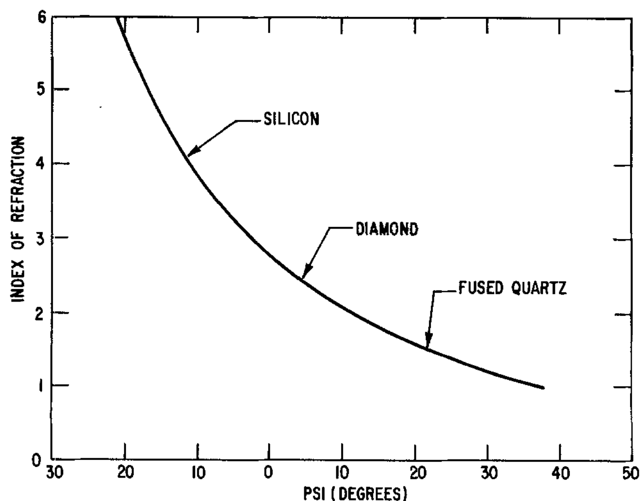

Fig. 2. Index of refraction of transparent materials as a function of the analyzer reading, $A = -\Psi$, of the ellipsometer. Angle of incidence is 70° and λ is 5461Å.

Thermally grown oxide films.—With the substrate index now assigned at 4.086 − i0.031, the index of thermally grown oxide films can be determined. Observers (1-5, 7) have found that the assumption of a constant index with changes in thickness of oxide did not disagree with their data. The same assumption is used here, although all of the films measured were in the small thickness range of 1000-1400Å. This range is the best for accurate determination of the film index and has been used by van der Meulen *et al.* (13) who also have shown a change of index when the growth temperature was changed.

For this study, chem-mechanically polished silicon wafers (<111>, p-type, 1 Ω-cm and <100>, n-type, 1 Ω-cm) were used. The wafers were usually scrubbed and solvent rinsed, but sometimes were given simply a buffered HF acid dip and water rinse. A quartz oxidation tube carying several cubic feet per minute of dry oxygen was used for growing the films. As a check of the furnace, a few oxides grown in other furnaces were also measured. The furnace was controlled to ±10°C after several hours of bake out at higher tem-

peratures. Oxidation times of the silicon in dry oxygen necessary to obtain 1000-1400Å of oxide at temperatures from 1290° to 750°C ranged from 2×10^1 to 1×10^4 min. The indexes of refraction of the oxide films grown at different temperatures are given in Fig. 5 and 6 for the two orientations. The bars show the estimated uncertainty in an oxide measurement.

Discussion

Preliminary data leading to this work were obtained on silicon of various orientation, resistivity,

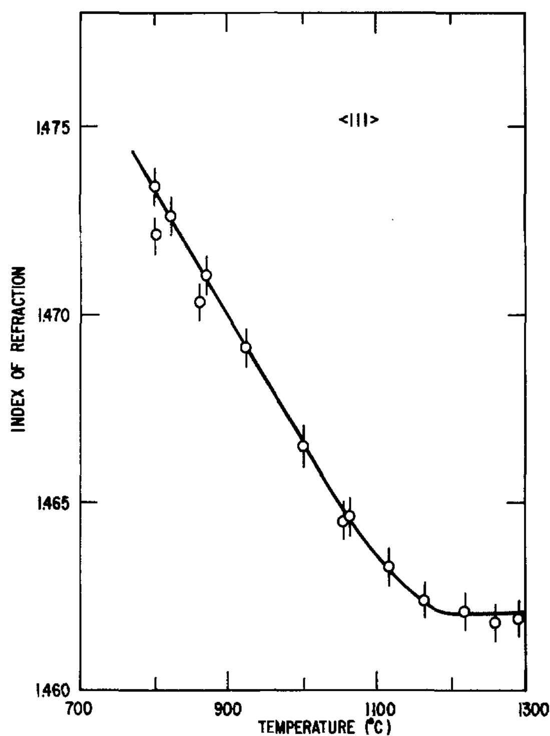

Fig. 5. Index of refraction of oxide grown on <111> silicon as a function of the growth temperature. $\lambda = 5461$Å.

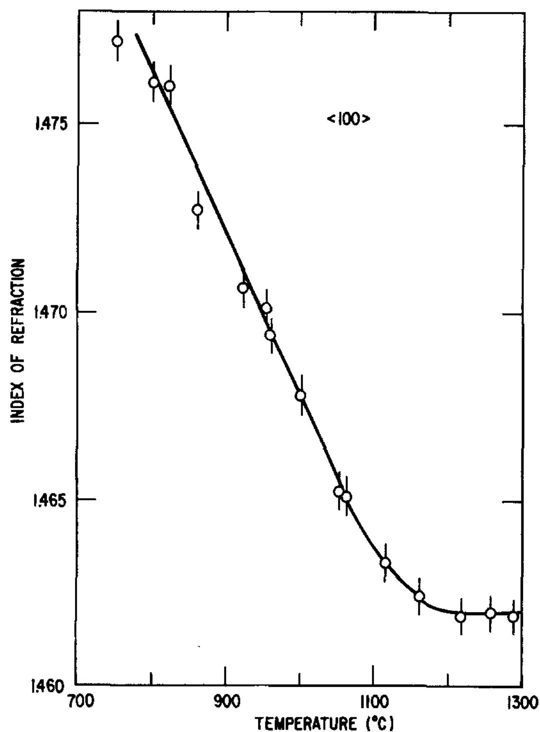

Fig. 6. Index of refraction of oxide grown on <100> silicon as a function of the growth temperature. $\lambda = 5461$Å.

and type. The oxidation temperatures were not always calibrated; precautions for holding a pure dry oxygen atmosphere were not rigorously observed. Despite these shortcomings, the ellipsometer data clearly indicated the refractive index-temperature variation. Some of these samples have been left in the data presentation and are always points below the line. (One exception was a very heavily doped n-type crystal.) The systematic study carried out as described above yielded the points which all fall on the curves to ± 0.0005 in the index value. The lower points, from the earlier, more casual oxidations, are most likely due to water vapor or other furnace contamination. No points above the curves have ever been observed using lightly doped silicon substrates.

The extrapolation of the straight line portion of these curves intersects the fused quartz index value of 1.4601 at 1190°C. At temperatures of 1190°C and above, the index appears to remain constant at the higher value of 1.4620. This high index suggested a film of higher density than fused quartz, while the constant value clearly indicated a stable material and the need for further analysis. If the two-dimensional compressive stresses on the film are considered (14), then we can calculate the volume decrease of the film $= 1 - 2\sigma/E\ (P_1 + P_2 + P_3)$ where σ is Poisson's ratio, E is Young's modulus, and P_1, P_2, P_3 are the orthogonal stresses.

The volume decrease in the film can also be estimated using the Lorentz-Lorenz relation (15) relating the volume, or density, ρ, of a transparent material to the index of refraction, n. This can be written $n^2 - 1/n^2 + 2\ (1/\rho) =$ a constant. Assuming that the oxide film is quartz glass with a normal index of 1.4601, an index of 1.4620 corresponds to a density increase of 0.0036. We may now calculate the stress on our oxide. If σ is 0.164 and $E = 0.76 \times 10^{12}$ dyne cm^{-2} (16), the compressive stresses in the plane of the film, $P_1 = P_2$ are found to be 2.1×10^9 dynes cm^{-2}. (As the film is not constrained in the third direction, $P_3 = 0$.) This value is considerably lower than the stresses of 3.1×10^9 dynes cm^{-2} reported by others (17-19). However, Primak and Post (16) find that fused quartz does not follow the Lorentz-Lorenz relation closely as their elasticity volume coefficient of refractive index of -0.34 is to be compared with the value from a Lorentz-Lorenz calculation of -0.53. Using their experimentally determined coefficient, the calculated stress on the high temperature film is then in good agreement with the reported values. The conclusion drawn here is that our measured value of the index of refraction for the higher temperature oxides is no different from that of pure fused quartz under compressive stress.

The strain in these high temperature silicon oxide films, therefore, using the above volume coefficient, causes a calculated density increase of 0.57% while the measured index of refraction increases by 0.0019. Jaccodine and Schlegel (17) show that the stress on grown oxides drops with growth temperature and appears to result from a simple thermal expansion difference. The refractive index increases of Fig. 5 and 6 would require (for an 800°C film) the equivalent of an isostatic pressure of >10 kbar on quartz glass (20).

Clearly the films grown at lower temperatures require a mechanism other than stress-strain for their high refractives indexes.

An assumption made here is that the films are stoichiometric SiO_2. The analysis of Deal and Grove (21) shows that oxides grown in dry oxygen actually contain about 5×10^{16} cm^{-3} of dissolved oxygen. The rapid appearance of large amounts of excess silcon in films grown at less than 1190°C in an excess oxygen environment seems improbable. Metastable high density quartz glass has been studied by Cohen and Roy (22), who discuss possible structural variations. Their

samples exhibited up to five times greater changes than have been observed here. Some grown-in structural change, which would be orientation sensitive, might be responsible for our results. (A quick look at the infrared absorption bands of some of these films with a Perkin Elmer 457 spectrophotometer yielded inconclusive results.)

The orientation effect of the silicon substrate on the oxide index is not apparent at the higher growth temperatures, but is pronounced at the lowest temperatures. If we look at the time required to grow a film of 1000-1400Å thickness on the <111> and <100> orientations at $>$1100°C, there is essentially no difference. At 1050°C, 20% more time is needed for the <100> film to get to the same thickness as the <111> silicon-based film. At 900°C, however, the difference has increased so that twice as much time is needed to grow the same oxide thickness on the <100> wafer.

It might be asked as to whether the long times involved in growing the oxide at the low temperature may be a factor. An 1150Å oxide was grown on <111> silicon at 1000°C in a nitrogen-oxygen atmosphere. It required the same total time to attain this thickness as is necessary for a growth temperature of ~775°C in pure oxygen. The index measured actually fell below the curve at 1000°C. As low readings have been noted before with oxide films grown in furnaces which have not been high temperature fired, I would assume some contamination, perhaps H_2O affected the 60 hr 1000°C oxidation. At least, the high index film associated with the usual dry oxygen oxidation at low temperatures was not observed. The actual formation temperature appears to be the dominant influence on the index.

Summary

It has been shown that there is growth temperature dependence of the index of refraction of oxide films grown on silicon in dry oxygen. At temperatures above 1190°C the index becomes constant at a slightly higher value than that for bulk fused quartz. This higher value can be accounted for entirely by the strain in the oxide, making the index at 5461Å the same as that of fused quartz. The lower temperature films have an orientation dependence. The index increase at low temperatures is over 1% with a calculated corresponding density increase of over 3%. The best value for the index of refraction of the silicon crystal substrate is 4.086 − *i*0.031.

ABSTRACT

The sublimation of ZrI_4 was studied by a torsion effusion-gravimetric technique in which the molecular weight of the effusing gas and its pressure in the effusion cell were measured simultaneously. The sublimation pressures of ZrI_4 were found to depend on the orifice size of the effusion cell. The measured pressures were extrapolated to zero orifice size to obtain the equilibrium vapor pressures, which could be represented by the equation

$$\log P(ZrI_4, \text{atm}) = 9.79 \pm 0.19 - \frac{6798 \pm 86}{T} \text{ (from 410° to 480°K)}$$

Enthalpies above room temperature, up to 703.1°K for solid zirconium tetraiodide were measured in a copper-block, drop calorimeter. The enthalpy increments above 298.15°K were expressed by the equation

$$H_T^\circ - H_{298}^\circ \text{ (kcal/mole)} = 29.498 \times 10^{-3}T + 1.906 \times 10^{-6}T^2 + 62.3 \cdot 10^2 T^{-1} - 9.173 \text{ (298°-772°K)}$$

The data were combined with literature vapor pressure data obtained at higher temperatures and a second law treatment used to derive the enthalpy and entropy of sublimation (31.88 kcal/mole and 46.9 cal/mole-degree, respectively, at 298°K). These values were used to evaluate the enthalpy of formation of gaseous ZrI_4 (−84.9 kcal/mole) and the absolute entropy of solid ZrI_4 (59.8 cal/mole-degree) at 298°K.

Zirconium and its alloys are susceptible to stress corrosion cracking in iodine vapor, and certain failures of nuclear reactor fuel rods have been ascribed to that cause (1). The mechanism of the iodine-induced stress cracking is not understood but it presumably involves the chemistry of the reactions of zirconium with iodine, and these reactions are themselves little understood. The present study of the vaporization of ZrI_4 is part of our program to investigate the chemistry of the zirconium-iodine system.

Zirconium forms several solid iodides and several gaseous iodides (2-5), of which tetraiodide is the highest oxidation state in both phases. Molecular constant and structural information for the gaseous molecule are available for calculation of the absolute entropy of the gas, and the enthalpy of formation of the solid has been measured. The vaporization thermodynamics interrelates these quantities between the equilibrium phases. We have supplemented vapor pressure data from the literature (6-8) with a torsion-effusion study and since the only available values for the heat capacity of the solid were estimated value, we have made measurements of the high temperature enthalpies. With those data we have derived values for the absolute entropy of the solid and the enthalpy of formation of the gas.

Experimental

Materials.—Zirconium tetraiodide was prepared directly from the reaction of high purity (99.9+%) zirconium powder (Ventron Corporation) and reagent grade iodine. A mixture of a 10% excess of zirconium with iodine was sealed under high vacuum in a 20 cm long and 1.6 cm diam thick-wall Pyrex tube. The sample tube was put in a tilted tube furnace and the temperature was then slowly raised to 485°C. After the tube was heated for 10 hr, the upper end was exposed to room temperature so that the zirconium tetraiodide condensed there. The reaction products were zirconium tetraiodide, which condensed in the upper end of the tube, and a small amount of black powder that contained the excess zirconium, presumably as a lower iodide in the lower end. The tube was carefully transferred to a dry box under an atmosphere of argon, purified over hot titanium sponge. The sample tube was cracked in the center, and a lump of reddish brown product was collected and stored in the dry box for the vapor pressure measurements. A part of the material was transferred to a glass bulb, sealed under vacuum and shipped to the Albany Metallurgical Research Center. Chemical analyses of the calorimetric sample gave 84.85% I by the AgI gravimetric method, and 15.15% Zr by an H_2SO_4-digested sample ignited to ZrO_2. Theoretical percentages for ZrI_4 are 84.77% I and 15.23% Zr. The stoichiometry of the sample was $ZrI_{4.026}$. Spectrographic analysis of a sample showed the total metallic impurities were less than 100 ppm, including Hf.

Vapor pressures.—All of the effusion measurements were made with graphite cells. Cell geometrical constants were measured with a traveling microscope and are given in Table I. Each cell had two sample chambers with essentially the same orifice size. The average constants were used since the orifice sizes were very similar. The constants of each cell were checked by measuring the torsion-effusion vapor pressure of KCl. The molecular weights were within 2% of KCl

and the pressures within 5% of the data reported by Pugh and Barrow (9).

About 0.6g of the sample was loaded into each chamber of the cell in the dry box. The sample was protected from exposure to air during the transfer of the cell to the torsion apparatus as follows. The orifices were initially filled with naphthalene. When the apparatus was evacuated, the naphthalene sublimed from the orifices. The sample was then heated slowly to operating temperatures. Initially (while about 0.5% of the sample evaporated), the molecular weights were smaller than that of zirconium tetraiodide (599) due to the evolution of HI, but they soon reached a steady-state value close to 600. Measurements were recorded only after the molecular weight reached the steady-state value. Analysis of the residues left in one effusion cell, after a series of measurements that removed 30% of sample, gave 4.05 ± 0.02 for the I-to-Zr ratio, indicating congruent vaporization had occurred.

A schematic diagram of the torsion effusion-gravimetric apparatus is shown in Fig. 1. Details of this method have been described briefly in our previous publications (10-12). Recently it has been used successfully to study the decompositions of metal sulfates (13). In this arrangement, the torsion element and the effusion cell were suspended directly from the arm of a Cahn Model RH electrobalance and simultaneous measurements were made of the angular displacement and the total mass of the effusate. The cell region was heated by a Kanthal-wound electric furnace surrounding the 8.5 cm diam quartz vacuum enclosure. Temperatures were measured with a platinum 13% rhodium-platinum thermocouple made from wires calibrated at fixed points by the manufacturer (Sigmund Cohn Company) with the junction located adjacent to the effusion cell. Three layers of copper sheet were located between the aluminum damping disk and the molybdenum radiation shields to trap ZrI_4 vapor so as to avoid error in the mass loss measurements caused by the condensation of the effusate on the disk.

The torsion element was a 58.6 cm long Pt-10% Ni ribbon having a torsion constant of 0.07814 dyne cm/rad. Angular deflection of the cell was measured with a telescope by sighting a scale reflected in a mirror on the suspension system. Extraneous oscillations were damped magnetically, but the magnets were removed during the deflection measurements.

From the torque angle measurements the pressures, P, in the effusion cell can be calculated from the relation

$$P = \frac{2k\theta}{\Sigma afq} \quad [1]$$

where k is the torsion constant of the fiber, θ is the measured angular deflection, and a, f, and q are the area, force factor, and moment arm of each effusion orifice. When the rate of mass loss of the effusion cell is measured simultaneously with the angular deflection, the vapor molecular weights, M, can be calculated from the expression

$$M = 2\pi RT\{[\dot{W}(\Sigma afq)]/[2K\theta(\Sigma Ca)]\}^2 \quad [2]$$

where R is the gas constant, T is the absolute temperature, W is the total rate of mass loss, and C is the orifice Clausing factor.

High temperature enthalpies.—Enthalpies above 298.15°K were measured with a copper-block, drop calorimeter, essentially as described by Douglas and King (14). The calorimeter was modified by replacing the potentiometer and galvanometer with a more sensitive system (a six-dial microvolt potentiometer and electronic nanovolt null detector) which was capable of detecting a temperature change of ± 0.00005°K. Before and after the series of measurements on the ZrI_4 sample the calorimeter was calibrated electrically and the entire system was checked by measuring the enthalpy of MgO sealed in a Pt-10% Rh container. Measurements on MgO agreed with literature (15) values to less than 0.1%. Results of measurements are expressed in terms of thermochemical kilocalorie (1 kcal = 4184.0J). Temperatures refer to the International Practical Temperature Scale of 1968 (16). Weighings were corrected to vacuum.

The sample container was a silica glass capsule. After the capsule was filled with powdered sample in a dry box, it was transferred to a vacuum system without exposure to the air. The capsule was then evacuated and fusion sealed with a flame while the portion of the capsule containing the sample was immersed in ice water. The mass of ZrI_4 was 17.3459g. The mass of the silica was 4.2694g. The internal volume of the container was 6.21 cm^3, and the volume of the ZrI_4 was calculated to be 3.56 cm^3 based on the density (4.87 g/cm^3) calculated from the x-ray crystallographic data.

The temperature of the sample in the furnace was measured with a Pt-10% Rh-Pt thermocouple whose calibration was checked against the melting point of gold during this series of experiments. The mass of the sample and container was periodically checked for constancy during the series of measurements.

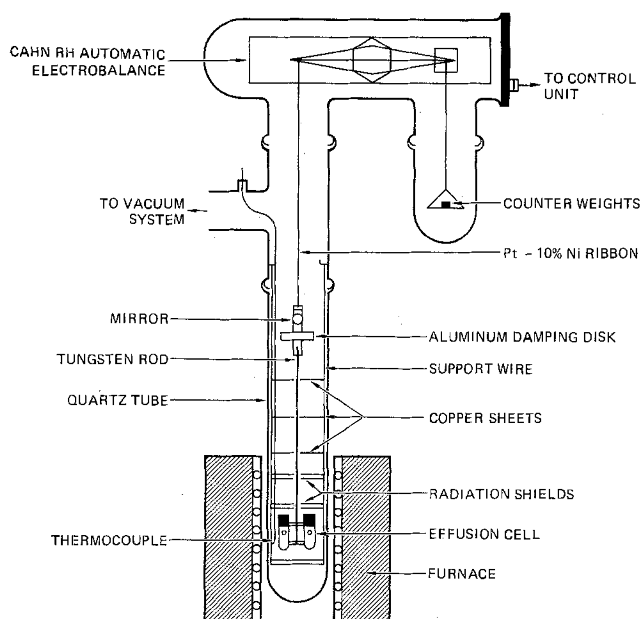

Fig. 1. Schematic diagram of the torsion effusion gravimetric apparatus.

Results

Vapor pressures.—The results of measurements on the four effusion cells with different orifice sizes are presented in Table II and Fig. 2. The equations given in the table represent the measured effusion pressures.

The measured pressures showed an orifice size dependence, which has frequently been observed in effusion studies. The pressures were treated by the Whitman-Motzfeld model for effusion, which relates the measured pressures (P) with equilibrium pressures (P_{eq}) by the equation

$$1/P = (1 + \beta Ca)/P_{eq} \quad [3]$$

In which a is the orifice area, C is the Clausing factor for the orifice, and β a parameter that depends on sample surface area and evaporation coefficient. A plot of $1/P$ against Ca should have a slope equal to β/P_{eq} and an intercept equal to $1/P_{eq}$. The data obtained with the four cells, extrapolated where necessary, are plotted in that way in Fig. 3. Straight lines were fit to the data at each temperature by the least squares method. The deviations of the points from the lines show some regularity, especially at the lower temperatures; the deviations were possibly due to differences in sample surface conditions for different loadings but were not

investigated further. Values of β calculated from the least squares slopes of the lines in Fig. 3 ranged from 38 to 42. An average value of 40 for β was selected to calculate equilibrium pressures by Eq. [3]. The calculated equilibrium pressures are given in Table II. They are well represented by the equation

$$\log P_{eq}(\text{atm}) = 9.79 \pm 0.19 - (6798 \pm 86)/T; \quad (\text{from } 410° \text{ to } 480°\text{K}) \quad [4]$$

which is shown as a dashed line in Fig. 2.

High temperature enthalpies.—The enthalpy of the ZrI_4 was obtained by subtracting the enthalpy due to the silica capsule, which was about 50% of the total, from the measured value. The enthalpy of the silica glass was determined as a function of temperature in a separate series of measurements. The measured values for the enthalpies of ZrI_4 above room temperature are given in Table III. A very small correction was made to the two highest temperature values for the enthalpy of vaporization of the ZrI_4 in the capsule, using the method of Ref. (14). For that correction, the vapor pressure and enthalpies of vaporization were derived from the results given later in this paper (Eq.

[12]). The x-ray diffraction pattern of the sample after the measurements was the same as the starting material.

Data Analysis

High temperature enthalpies.—The measured enthalpies were computer fitted with curves by polynomial functions as described by Justice (17). These functions were then used to calculate the smoothed values of enthalpies and derived thermodynamic properties at selected temperatures given in Table IV. Extrapolation of enthalpies from the last experimental measurement at 703.1°-772°K, the melting point adopted from Rahlfs and Fischer (7), was based on a reasonable projection of the smoothed values. The smoothed enthalpies are estimated to have an uncertainty of ±0.4%.

The smoothed enthalpies were fitted with an equation using the method described by Kelley (18). The derived equation is given below with the temperature range of validity. The average deviation of the equation from the smoothed data is <0.01%, and from the experimental values <0.1%.

$$H^\circ_T - H^\circ_{298}\ \text{(kcal/mole)} = 29.498 \times 10^{-3}T + 1.906 \times 10^{-6}T^2 + 62.3T^{-1} - 9.173;\ (298^\circ\text{-}772^\circ\text{K}) \quad [5]$$

Vapor pressures.—The equilibrium vapor pressures were analyzed by a modified Sigma-treatment (19) to derive the entropy and enthalpy changes associated with the sublimation reaction. In this treatment one calculates from each equilibrium pressure measurement a value for Sigma defined as

$$\Sigma = -R \ln P_{eq} - (\Delta fef\ \text{incr})$$

$$\Delta fef\ \text{incr} = \frac{1}{T}[(H^\circ_T - H^\circ_{298}) - T(S^\circ_T - S^\circ_{298})]_{gas} - \frac{1}{T}[(H^\circ_T - H^\circ_{298}) - T(S^\circ_T - S^\circ_{298})]_{solid}$$

The function (Δfef incr) depends only on the heat capacities of the gas and the solid. The heat capacity of the solid was obtained from Eq. [5]. The molecular constants of the gas have been established by measurements, and the heat capacity and absolute entropy are given in the JANAF Tables (5). An equation derived to represent the (Δfef incr) function in the Sigma treatment was

$$(\Delta fef\ \text{incr}) = -2.800 + 6.68 \times 10^{-3}T - 1.136 \times 10^{-6}T^2 + 8.06 \times 10^4/T^2\ (298^\circ \text{ to } 772^\circ\text{K}) \quad [6]$$

For a sublimation reaction like the present one

$$ZrI_4(s) = ZrI_4(g) \quad [7]$$

it can be shown (19) that the values of Sigma are related to the room temperature entropy and enthalpy of sublimation by the equation

$$\Sigma = \frac{\Delta H^\circ_{298}}{T} - \Delta S^\circ_{298} \quad [8]$$

Table IV. Smoothed high temperature thermodynamic properties of ZrI_4 (c)

T (°K)	C_p° (Cal/deg-mole)	$S^\circ_T - S^\circ_{298}$ (Cal/deg-mole)	$H^\circ_T - H^\circ_{298}$ (kcal/mole)

700	32.04	26.42	12.498
750	(32.25)*	(28.64)	(14.105)
772	(32.34)	(29.57)	(14.816)

* Values in parentheses are extrapolations.

The molecular weights were determined with cells A, B, and C and were equal to the molecular weight of ZrI_4 within about 5%, which is a reasonable experimental error for these measurements. This result, which is in agreement with the vapor density measurements of Rahlfs and Fischer (7), led to two conclusions. First, the vaporization was congruent, which means that from phase rule considerations the system acted as a one-component system, and the vapor pressure depended only on temperature and not on the amount of material removed during the vaporization study. Second, the gas was monomeric ZrI_4 with no measurable amounts of gaseous polymers. Therefore, the thermodynamic functions for the gas could be calculated from the molecular constant data available for ZrI_4.

Sale and Shelton (6) have made effusion-mass loss measurements on ZrI_4 using cells with three orifice sizes. A plot of reciprocal pressure against orifice size for their data was not linear, and they treated their data in a different way and derived the following equation for the equilibrium pressures

$$\log P_{eq}(\text{atm}) = 9.15 - 6342/T;\quad (\text{from } 425^\circ \text{ to } 500^\circ\text{K}) \quad [9]$$

Rahlfs and Fischer (7) measured the vapor pressure of ZrI_4 in a higher range of temperatures using a liquid tin manometer. They also measured the gas molecular weight by a vapor density method and found values in the range of 563-606, which are within experimental error of that of ZrI_4. Their vapor pressure measurements could be represented by the equation

$$\log p(\text{atm}) = 9.17 - 6455/T;\quad (\text{from } 558^\circ \text{ to } 671^\circ\text{K}) \quad [10]$$

Gerlach *et al.* (8) used an oscillating quartz fiber method to measure the vapor pressure, and gave the following equation for their data

$$\log p(\text{atm}) = 7.71 - 5730/T;\quad (\text{from } 393^\circ \text{ to } 453^\circ\text{K}) \quad [11]$$

The vapor pressure curves from these sources are shown in Fig. 4. In the lower pressure range the three sets of data are not in good agreement. The data of Ref. (6) and (8) are about a factor of two higher than the present data. We believe that the accuracy of the present data is significantly greater than that of the effusion study performed by Sale and Shelton (6), for the following reasons. The calibrations of the present cells, obtained from geometrical measurements, were checked by measuring the vapor pressure of KCl. The molecular weights of the effusing gas were determined and only when low molecular weight gases (presumably HI) had stopped effusing were measurements recorded. The orifice dependence of pressures followed the expected Whitman-Motzfeldt behavior. The results of Gerlach *et al.* were obtained by an unproven method of unknown reliability.

The present results are in excellent accord with the data of Rahlfs and Fischer as seen from Fig. 4. A Sigma treatment of these two sets of data yielded the following values for the sublimation reaction (Eq. [7])

$$\Delta H^\circ_{298} = 31.88 \pm 0.08\ \text{kcal/mole, and}$$

$$\Delta S^\circ_{298} = 46.9 \pm 0.16\ \text{cal/mole-degree}$$

The agreement between the two sets of data, as indicated by the relatively small standard deviations over the large pressure range (10^{-7}-1 atm), is very good. The vapor pressure equation derived from that treatment for ZrI_4 is

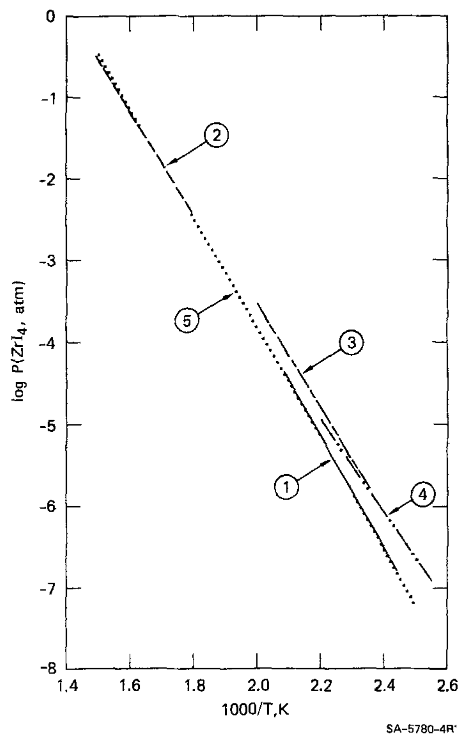

Fig. 4. Comparison of vapor pressure equations. 1, —, Present measurements, Eq. [4]. 2, - - -, data of Rahlfs and Fischer, Eq. [10]; 3, — - —, data of Sale and Shelton, Eq. [9]; 4, — · · —, data of Gerlach *et al.*, Eq. [11]; 5, ..., Sigma treatment, Eq. [12].

$$\log P(\text{atm}) = -\frac{1}{4.575}\left[\frac{31,880}{T} - 49.7 + 6.68 \times 10^{-3}T - 1.131 \times 10^{-6}T^2 + 8.06 \times 10^4/T^2\right]$$

(from 450° to 670°K) [12]

This equation is represented as a dotted line in Fig. 4.

Discussion

The measured enthalpies and derived quantities for ZrI_4 are about 2% lower than the estimates made in the JANAF Tables, and this reasonable agreement shows a good degree of acceptability for the estimation techniques.

The enthalpy measurements showed no indication for any thermal effects associated with phase transitions. That result was important in the interpretation of the vapor pressure data as follows. Stevenson and Wicks (20) found that the vapor pressure of solid hafnium tetraiodide decreased after the sample had been heated at 300°-310°C for some time. They attributed that behavior to the conversion of the solid from a metastable form to more stable forms. Because of the great similarity of the chemistry of zirconium and hafnium, we investigated the possibility of such a transformation in ZrI_4. We heated a sample of ZrI_4 in a sealed, evacuated Pyrex bulb for one week at 300°C. The x-ray pattern of the sample after heating was the same as that before heating and the same as that of the material used for the vapor pressure measurements. A series of torsion effusion vapor pressure measurements was made with the heat-treated sample in cell A. The results were about 5% below the values given in Table I. We consider that to be within the experimental error of the measurements. Therefore, we conclude that our measurements give the vapor pressure of the stable form of ZrI_4. (An alternative explanation for the low values obtained by Stevenson and Wicks in their run 2 is that they resulted from a reaction of the sample with the metallic container. The enthalpy of sublimation for their "metastable" HfI_4 is almost the same as that of ZrI_4. The very large change, namely 20 kcal/mole, to the "stable" form is more typical of a chemical reaction than a structural transformation.)

As indicated earlier, the thermodynamic quantities associated with vaporization can be used to derive related values for the solid or gas. The authors of the JANAF Tables have analyzed the data of Ref. (6) and (7) by a third law treatment; however, they used an estimated value for the absolute entropy of the solid. The sublimation thermodynamic data they obtained were $\Delta H°_{298} = 30.2$ kcal/mole, and $\Delta S°_{298} = 44.5$ cal/mole-degree. Those values differ somewhat from the present ones based on our second law treatment of the vapor pressures. We feel that the present values derived from experimental information are preferable to the JANAF values, which are based on the estimated entropy. Alcock *et al.* (21) have also analyzed the results of Ref. (6) and (7) and have derived an equation to fit them; however, for the reasons stated above we consider the present analysis to be more accurate.

The enthalpy of formation of solid ZrI_4 has been measured by Turnbull (22), and from his data the JANAF group has calculated an enthalpy of formation of -116.8 ± 1.5 kcal/mole for the solid. Therefore, the standard enthalpy of formation of the gas at 298°K is -84.9 ± 1.6 kcal/mole. This value differs from the JANAF Tables (-86.6 ± 2 kcal/mole) because of the new data and modified treatment.

The absolute standard entropy of the gas calculated from structure and molecular constant data was given in the JANAF Tables as 106.7 ± 0.03 cal/mole-degree; thus, the absolute entropy of the solid at 298°K becomes 59.8 ± 0.2 cal/mole-degree from our results. Our value is somewhat smaller than the JANAF value (62.2 ± 1 cal/mole-degree) that was estimated from data for other zirconium tetrahalides. We believe the present value is more accurate because it is based on measured quantities.

Acknowledgments

The authors are grateful to Dr. Donald L. Hildenbrand (SRI International) for the use of the torsion effusion-gravimetric apparatus and for extensive technical discussions.

Financial support for the vaporization research was provided by the U.S. Department of Energy, Division of Basic Energy Sciences under Contract No. E(04-3)-1339 to SRI International. Calorimetric measurements were performed at the Albany Metallurgical Research Center, Bureau of Mines, U.S. Department of the Interior, where chemical analyses were made by Robert R. Brown and x-ray diffraction analyses by Robert A. McCune.

Manuscript submitted Sept. 2, 1977; revised manuscript received Nov. 2, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by SRI International.

Properties of Polycrystalline AlAs/GaAs on Graphite Heterojunctions for Solar Cell Applications

W. D. Johnston, Jr.* and W. M. Callahan

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

Polycrystalline heterojunction material of N-AlAs/p-GaAs and P-AlAs/n-GaAs was grown in a chloride arsine vapor-phase reactor on graphite substrates. P^+AlAs/p-n GaAs structures were produced as well by postgrowth Zn diffusion. Control of nucleation and ohmic contact of the GaAs layer to the graphite was achieved with Zn doping during growth, or Ge or Sn coating of the substrate prior to growth, for p- or n-type GaAs, respectively. The N-AlAs/p-GaAs material appears promising for possible solar cell applications, but we have not succeeded in overcoming the high spreading resistance due to grain boundary scattering in the AlAs layer.

An area of primary current interest in compound semiconductor materials research is the growth and characterization of thin polycrystalline films for devices potentially suitable for large-scale photovoltaic solar energy conversion.

Over a decade ago Vohl and co-workers (1) reported fabrication of Schottky barrier solar cells of polycrystalline GaAs with solar conversion efficiencies up to 5%. No significant improvement in the efficiency of thin-film polycrystalline cells of III-V semiconductor materials has been reported since. Little is known about the effect of grain boundaries on the minority or majority carrier properties of such films, nor is there any real understanding as yet of the range of control of film characteristics or grain boundary effects possible through variation of growth conditions, doping techniques, or substrate treatment.

The AlAs/GaAs heterojunction pair would appear to provide numerous potential advantages over other material combinations for polycrystalline thin-film solar cells. The device-related properties of single-crystal GaAs are well understood. $Al_xGa_{1-x}As$/GaAs single crystal solar cells grown by liquid phase epitaxy (LPE) claim the highest solar conversion efficiency yet demonstrated (2) for any solar cell. LPE is not well suited to large area growth of thin films on cheap foreign substrates, however, but single crystal cells with similar characteristics have also been prepared recently by halide transport vapor phase epitaxy (3). Preliminary work on an N-AlAs/p-GaAs/graphite thin film cell showed promise of high intrinsic efficiency and good minority carrier and junction properties (4). That work also disclosed an unanticipated difficulty with poor majority carrier transport, giving rise to unacceptably high spreading resistance in the N-AlAs upper layer. In this paper we present further results of our investigation of these N-AlAs/p-GaAs grown heterojunction cells. We have now also prepared grown-junction and diffused-junction P-AlAs/n-GaAs/graphite material for comparison; this material in present form has inferior characteristics to the N-on-p material, however.

We have attempted various doping schemes in an effort to ameliorate the top layer spreading resistance, which we have concluded arises from scattering of majority carriers in (or from) the depletion regions associated with grain boundary states. This resistance is thus thought to be similar to the blocking resistance at a metal-semiconductor contact. We have found that indeed appropriate doping by Zn diffusion does eliminate the grain boundary scattering in P-AlAs, but the conditions are such that the minority carrier properties (lifetime and p-n junction characteristics) are drastically compromised. We have not been able to obtain similar results in N-AlAs. The grain boundary scattering appears to be a fundamental problem which will be independent of growth process. It is certainly possible, however, that other growth techniques, operative at lower temperatures than the ~ 1000°C used in this work for the growth of the AlAs layer, may permit introduction of donor elements with better control, or eliminate the need for postgrowth diffusion with Zn.

Growth Technique

The growth apparatus was essentially unchanged from that described previously (4), and is comprised of Al_2O_3 ceramic components in a four-zone furnace.

* Electrochemical Society Active Member.
Key words: films, growth, photovoltaic, solar.

Substrates cut from Type 5890 PT graphite obtained from the Carbone Corporation, Boonton, New Jersey, were used exclusively, as our past experience had shown that polycrystal GaAs films on this material were tightly adherent in contrast to films on graphite from other suppliers which flaked off during or after growth. The typical structure for test cells is shown in Fig. 1. The critical features are the GaAs-graphite interface, No. 1, the junction, either at the heterointerface, No. 2, or somewhat within the GaAs, and the AlAs-top contact interface, No. 3. Control of the initial stage of GaAs growth ideally should result in low resistance ohmic conductivity across the GaAs-graphite interface and ensure uniform, pinhole-free coverage by the time the desired thickness, of the order of 5μm, is reached. The AlAs layer grows epitaxially (and preferentially) on the polycrystalline GaAs, reflecting and extending the morphology of the first layer. It is similar in all respects to growth on single crystal substrates as described in Ref. (2) and identical AlAs growth conditions were found to be optimum in this work. Heavy doping of the top surface at the last stage of (or after) growth is required to achieve an ohmic, low resistance contact to a transparent conducting oxide layer as shown in Fig. 1. This layer is not necessary if the AlAs can be made to have low lateral resistivity (~ 100 Ω/□) which permits a metallic grid contact to be used directly as for single crystal cells. This may be achieved by Zn diffusion following growth for P-AlAs, but we were unable to obtain sufficiently heavy donor concentration with Sn, Se, or S during or after growth to achieve ohmic contact of N-AlAs to transparent, conductive films of indium-doped tin oxide (ITO) (5) or Cd_2SnO_4 (6) films.

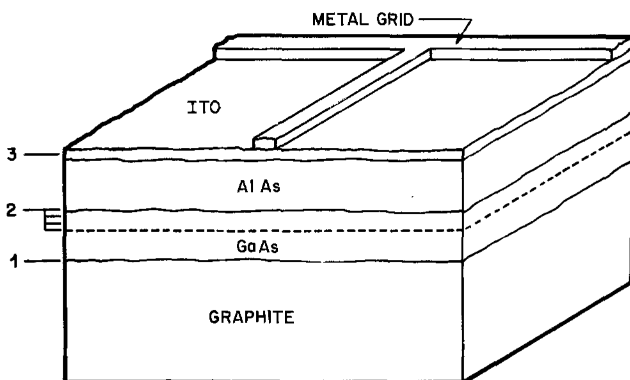

Fig. 1. Polycrystal cell structure. The p-n junction is located at interface No. 2 for N-AlAs/p-GaAs cells or just within the GaAs layer for diffused P^+AlAs/p-nGaAs structures. The AlAs layer is typically 10-20 μm thick, the GaAs layer 5-10 μm thick, the graphite substrate 350 μm thick.

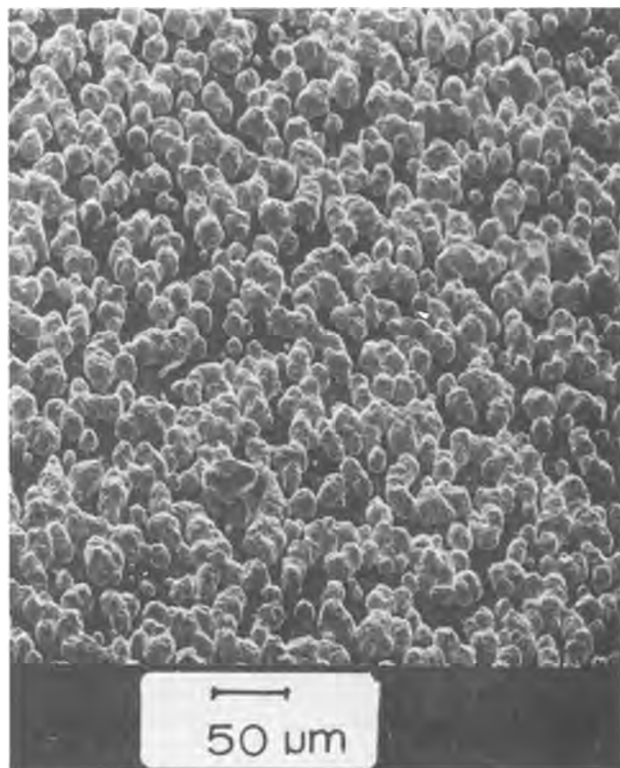
Our initial observations confirmed that growth of undoped GaAs on the clean graphite substrate was nonpreferential relative to the Al_2O_3 ceramic walls of the growth reactor. We also observed that the density of nucleation and indeed whether any growth at all was obtained was relatively insensitive to substrate temperature, temperature gradient at the substrate, or gas flow parameters but was affected by geometrical relationships and the immediate past history of the reactor components. Reproducibility was obtained when the polycrystalline GaAs deposit over the reactor tube walls had reached a steady condition. Only periodic cleaning of a purely mechanical nature (scraping and vacuuming) was employed. These conditions leave much to be desired for carrying out precise doping studies or obtaining high purity material, but they are adequate for the qualitative investigations of the fairly heavily doped material reported here.

An early finding was that Zn doping drastically affected the nucleation of the GaAs layer to produce a continuous film rather than a panoply of nuggets. This difference is readily apparent in Fig. 2 which shows scanning-electron micrographs of undoped and Zn-doped polycrystalline GaAs grown under identical conditions (except for the temperature of the Zn metal source). Slight modification of the substrate position resulted in pinhole-free films over all of the 1 × 3 cm substrate except immediately contiguous to the Al_2O_3 substrate holder arms. Continuous films of this sort were only achieved at much greater total thickness for undoped GaAs growth on bare graphite. The level of



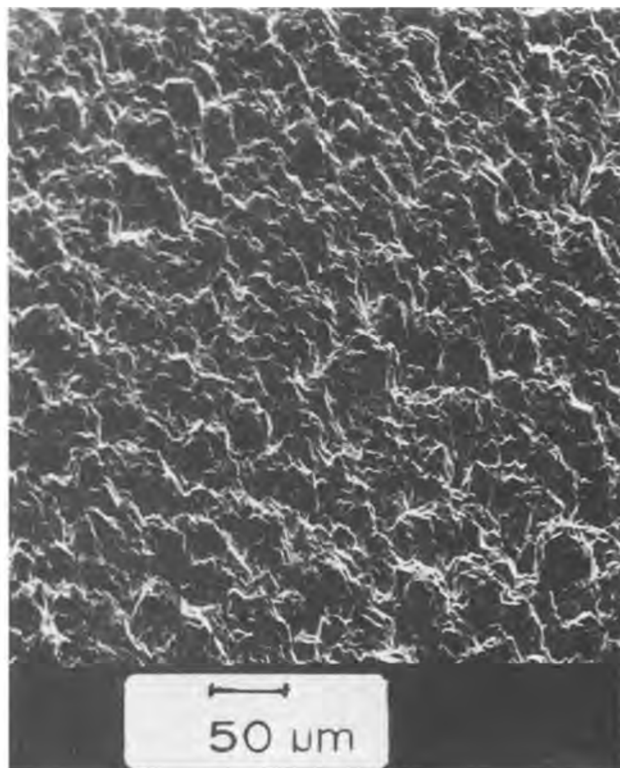


Fig. 2. SEM views of undoped (left) and Zn-doped (p ~ 10^{18} cm^3) GaAs grown on graphite under otherwise identical growth conditions

Zn doping necessary for this improved nucleation is consistent with that needed for good heterojunction performance ($p \sim 10^{18}cm^3$). An additional important, albeit fortuitous, result is that the p-GaAs layer so formed makes low resistance ohmic contact to the graphite.

Characterization of these polycrystalline semiconductor layers on conducting substrates is difficult. Photoluminescence spectra suggest a net ionized acceptor density in the $1 \sim 5 \times 10^{18}$ range, while capacitance voltage plots and reverse breakdown characteristics of heterodiodes formed with undoped AlAs favor the lower end of this range. Higher Zn concentration can be readily obtained, up to $2 \times 10^{19}cm^{-3}$ or greater, with increased Zn source temperature.

For an N-AlAs/p-GaAs heterodiode, the AlAs layer is grown without intentional dopant addition. Metallic contact to this layer is readily made with spark-welded Au-Sn(2%) alloy or sintered layers of Sn, Ni, and Au which may be evaporated or electrodeposited. Anodization (7) of the polycrystalline layer is not satisfactory for passivation and antireflective purposes. The high spreading resistance and rough surface also make it more difficult to obtain uniform electroplated contacts than on single crystal AlAs, and in contrast to results on that material (8), evaporated contacts are to be preferred for thin polycrystal layers.

We tried doping the AlAs layer with Se (introduced as H_2Se) and/or Sn (introduced as the metal and transported with HCl). Hall measurements on single crystal AlAs samples showed no increase in ionized donor concentration. We verified transport of Sn by weight loss measurements, but it was evidently not incorporated at the 1030°C growth temperature even at Sn/Al ratios of unity where the AlAs growth began to deteriorate. There was no observable effect for Se up to gas-phase Se/As ratios of 0.1. Postgrowth diffusion with As_2S_3 and elemental sulfur sources and from thin (≤ 50Å) layers of Sn, Sn-Ni, Sn-Au, and Sn-Ni-Au were evaluated in an effort to increase the surface doping to allow ohmic contact of the N-AlAs to ITO or Cd_2SnO_4 films. The latter were deposited in an rf plasma apparatus with various argon/oxygen ratios and sample temperatures. Of the various combinations, only evaporation of Sn, Ni, and Au in successive layers exceeding 50, 50, and 200Å, respectively, sintered at 450°C, produced the desired result. This contact is relatively opaque owing to the substantial amount of Au. Because of surface roughness, not all grains are effectively contacted with these small quantities of the metals. Whether ITO or Cd_2SnO_4 was used made no difference, although Cd_2SnO_4 could be deposited to form an ohmic contact on n-GaAs (Si-doped, $n \sim 2 \times 10^{18}cm^3$) to which ITO was always blocking.

In view of these difficulties with the N-AlAs top layer we attempted to prepare P-AlAs/n-GaAs structures since a shallow Zn diffusion (20 min at 550°C with a Zn_3As_2 or $ZnAs_2$ source) produces a high surface concentration of ionized acceptors and ohmic contact between P-AlAs and metallic conductors. Single crystal AlAs can be grown p-type, albeit heavy Zn concentration in the growth atmosphere must be used and growth conditions favoring minimum native donor concentration must be chosen (9). This material is heavily compensated ($n_a - n_d \sim 1 \times 10^{17}$, $n_a \sim n_d \sim 10^{18}$) but resistivity ($\sim 10$ Ω-cm) is not excessive for current flow transverse to the thin layer. Accordingly, work to control the nucleation and growth of n-type GaAs films on graphite was begun. Undoped "films" as in Fig. 2a become continuous when grown sufficiently thick (~ 100-200 μm) but they make blocking contact to the graphite and are, of course, far thicker than desired for inexpensive solar cells. Doping with H_2Se added to the gas stream or HCl-transported Sn, in contrast to the results with Zn, had no effect in improving the nucleation of film growth. Coating the substrates with electroplated Au and Sn-Ni alloy gave rise to dramatic VLS (vapor-liquid-solid) growth of Au-capped needles.

We also tried a series of substrates onto which 500Å layers of Si, Sn, or Ge had been evaporated. (This thickness is nominal and corresponds to thickness on monitor microscope slides—the actual surface area of the graphite greatly exceeds the projected area.) Electron micrographs of these samples are shown in Fig. 3 and 4. Since the evaporated films were thought to be amorphous and the Sn film is "liquid" at the 640°C GaAs growth temperature, it was not anticipated which films if any would favorably affect nucleation, and the initial intent was to ensure ohmic contact. All show improvement relative to nucleation on untreated graphite; Ge is the best, possibly reflecting the fact that the lattice constant of crystalline Ge is an excellent match for GaAs. The Sn-coated substrate shows nearly equivalent results, however, under conditions which certainly do not permit definition of a lattice constant whether the Sn film is truly liquid or not. Use of either Sn or Ge resulted in ohmic contact to the GaAs layers. No additional dopants were added to these layers; they are estimated to have background carrier concentrations $n \sim 5 \times 10^{17}cm^3$ from photoluminescence spectra.

Two techniques were employed to form heterodiodes to these n-GaAs films. AlAs was grown with up to 1% Zn vapor added to the gas phase, or undoped for subsequent deep Zn diffusion. Neither of these approaches was found satisfactory in regard to reproducibility, but the best diodes obtained, although inferior to the N-AlAs/p-GaAs devices, were in each case good enough to permit limited electrical characterization as described in the next section.

The growth conditions for the various combinations of AlAs and GaAs polycrystal layers we found to be optimum, in the sense primarily of best providing reproducible, pinhole-free layers, are summarized in Table I.

Electrical Characteristics

Rigorous characterization of this polycrystalline material is not possible by traditional methods, such as measurement of Hall conductivity, because of the highly conducting substrate and high spreading resistance of the layers. The heterojunction material may be represented conceptually as in Fig. 5, where diodes with characteristics similar to single crystal cells are connected in parallel between a conducting plane and the nodes of a resistance grid. The diode characteristics can be obtained with a broad area metallic top contact which shunts the spreading-resistance grid, and the spreading resistance in the top layer can be obtained between two stripe contacts provided the diode characteristics give adequate isolation from the conductive substrate. Physically this model corresponds to considering each grain as a heterojunction cell. Scanning electron micrographs of broken cross sections of this material suggest that this

is indeed a good picture—most grains appear to be columnar and continuous across the AlAs-GaAs interface.

In Fig. 6 typical log current-voltage data are presented for N-AlAs/p-GaAs and Zn-diffused P-AlAs/p-n GaAs samples. Electron beam-induced current (EBIC) examination in the scanning electron microscope indicated that for the N/p material the electrical junction coincided with the heterointerface, at least to within the estimated ±400Å resolution accuracy. For the P/n sample in Fig. 5, the junction appeared in EBIC traces to lie within 1000Å inside the GaAs. The diffusion coefficient for Zn in single crystal AlAs was determined to be 80 times larger than in single crystal GaAs under the conditions used here, so that there is a tendency for the AlAs layer to be completely diffused in spite of the irregularity of its surface and thickness, while the junction remains fairly close to the AlAs interface throughout the GaAs.

From the model of Fig. 5, we expect the dark current density-voltage relation for these diodes to be of the form

$$J = J_o\,[\exp\{e(V - JR_s)/nkT\}\ 1] + (V - JR_s)/R_p \qquad [1]$$

Here J_o is the reverse saturation current and n the "diode factor," R_s and R_p are the effective series and diode shunt specific resistances. Provided R_p exceeds a few hundred Ω-cm^2 and R_s is less than about 10 Ω-cm^2, the intermediate region of the plot of log J *vs.* V is linear. The slope in this region determines

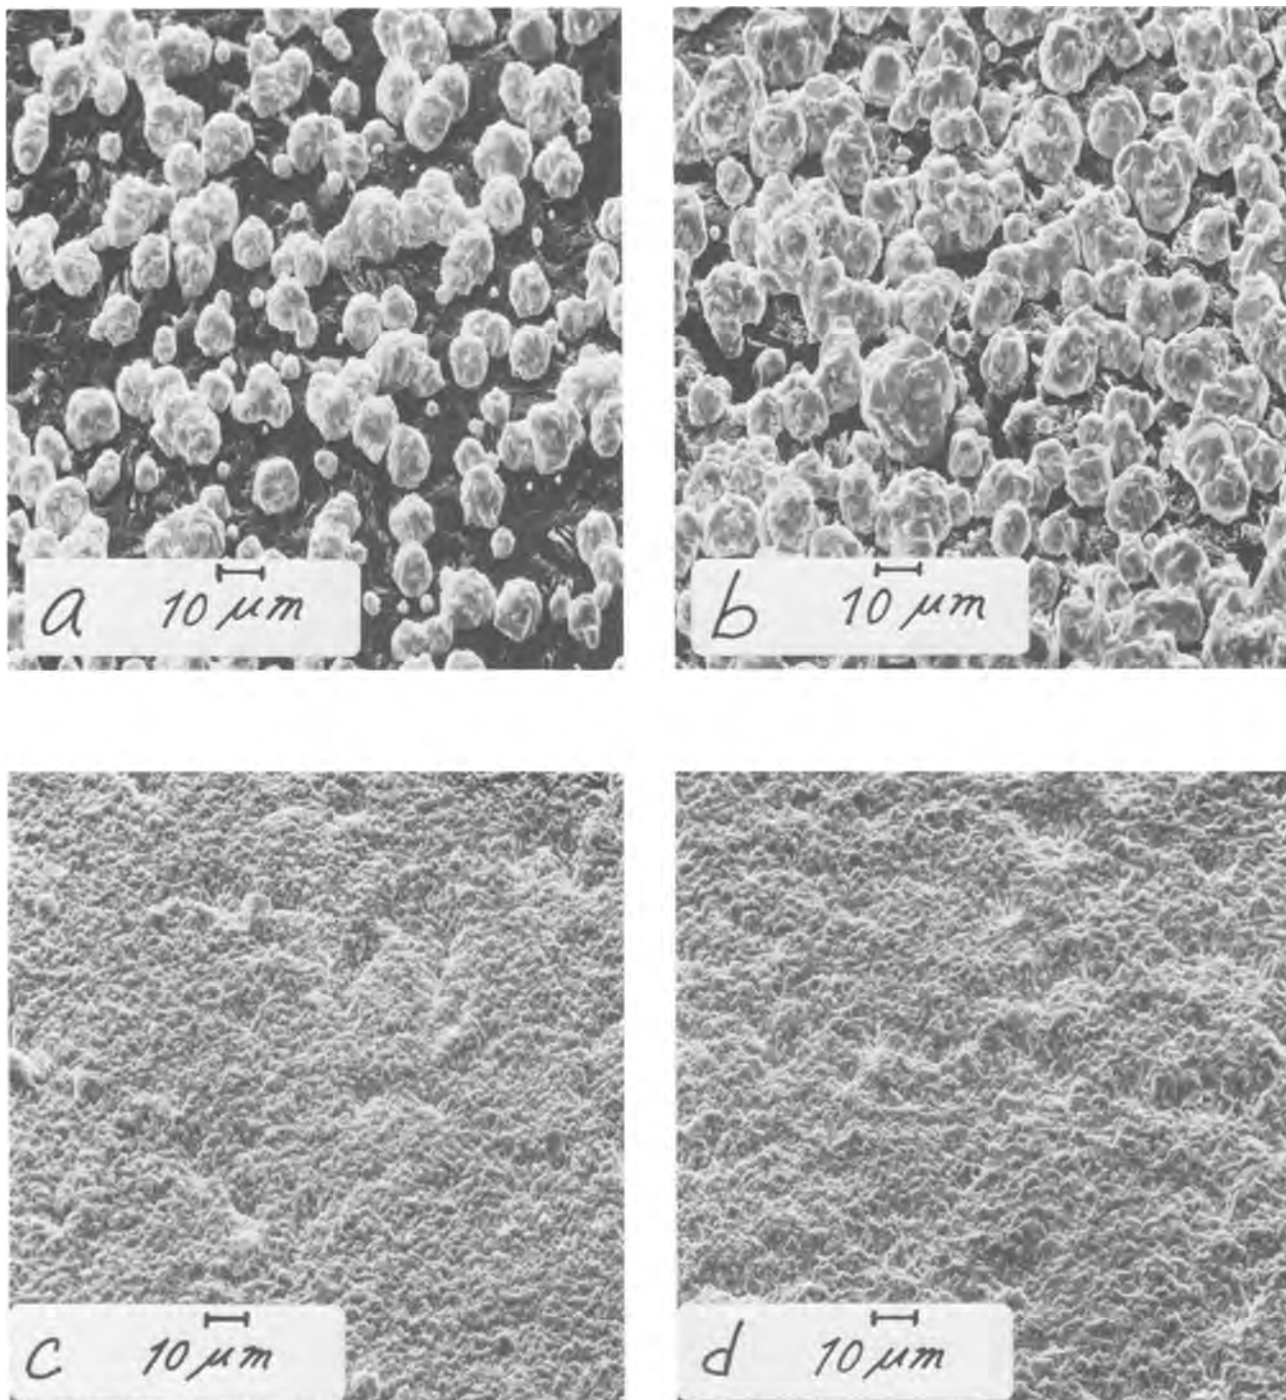

Fig. 4. SEM views at higher magnification of undoped GaAs grown on: a, uncoated graphite; b, Si (500Å); c, Ge (500Å); and d, Sn (500Å).

the diode factor n, which was generally between 1.9 and 2.0. R_s and R_p may be determined from the voltage and current offsets of the actual plot from the extrapolated linear portion, respectively. When the log J-V plot does not show a substantial linear region, as for the P/p-n diffused junction diode in Fig. 6, Eq. [1] may still be used by curve fitting, although as a practical matter such material is of little interest for solar cell application.

We attempted to produce P-AlAs/n-GaAs polycrystalline grown junctions using the conditions in Table I, with only a shallow Zn surface diffusion used for contacting. EBIC examination showed that the electrical junction was variably located within the AlAs layer; apparently some grains were grown p-type and others were not. This material showed good current-voltage characteristics with values of $R_p > 10^5$ Ω-cm^2 and $R_s < 5$ Ω-cm^2, but very low photocurrent response. Apparently either the native background donor concentration or the Zn incorporation varies from grain to grain. The larger (and presumably faster growing) grains remain n-type. There were no indications from EBIC scans of Zn incorporation preferentially along grain boundaries during growth. The relatively good diode characteristics permitted a lower-limit measurement of the spreading resistance which for this material exceeded 10^5 Ω/□.

The linear current-voltage characteristics of diffused P-AlAs/p-n GaAs and grown N-AlAs/p-GaAs polycrystal material are presented in Fig. 7. The detrimental effect on the potential fill factor arising from the shunt resistance in the diffused material is ap-

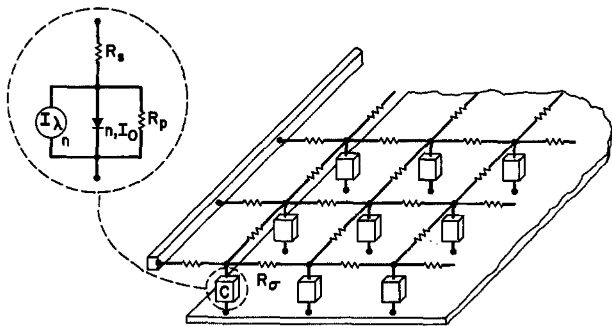

Fig. 5. Electrical equivalent circuit model of polycrystal heterojunction solar cell consisting of subunits (C) joined in parallel by a spreading resistance grid R_σ. The units (C) consist of the parallel combination of a current generator of quantum efficiency η, an idealized diode characterized by diode factor n and reverse dark current I_0, and shunt resistance R_p all in series with resistance R_s.

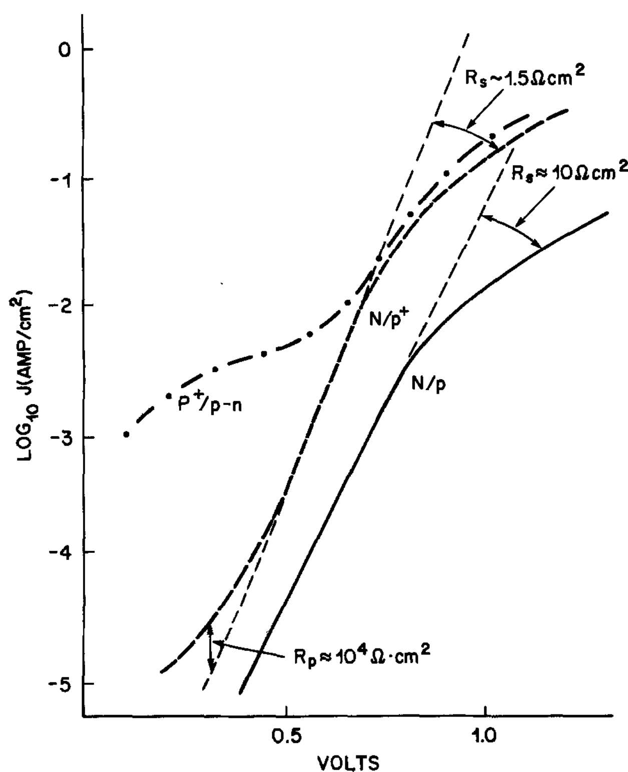

Fig. 6. Logarithmic current density-voltage characteristics for diffused P^+AlAs/p-nGaAs (dash-dot), and two grown N-AlAs/p-GaAs cells (dashed, $p^+ \sim 5 \times 10^{18}$; solid, $p \sim 10^{18}$). The two cells with lower R_s had evaporated top contacts, the other an electroplated metallization.

parent. This shunt resistance also makes analysis of the junction by capacitance-voltage measurement difficult and prevents determination of the top layer spreading resistance. The semiconductor layers can be removed as flakes of ~ 1mm² by arcing the substrate (which, in 300 μm thickness, is fairly flexible) and scribing along the GaAs-graphite interface with a scalpel tip. The resistance of these flakes (contacted on the AlAs layer) was typically 3000 Ω/□, at least three orders of magnitude lower than undiffused polycrystalline material. We were unable to separate the AlAs from the GaAs on these thin flakes, but it is reasonable to assume this reduction in resistance occurred in the diffused AlAs layer.

The diffused P-AlAs/p-n GaAs material shows poor photocurrent efficiency. The photocurrent spectrum shows a weak long wavelength response tail, and the response is low throughout the visible range. Power conversion efficiencies for natural sunlight were less

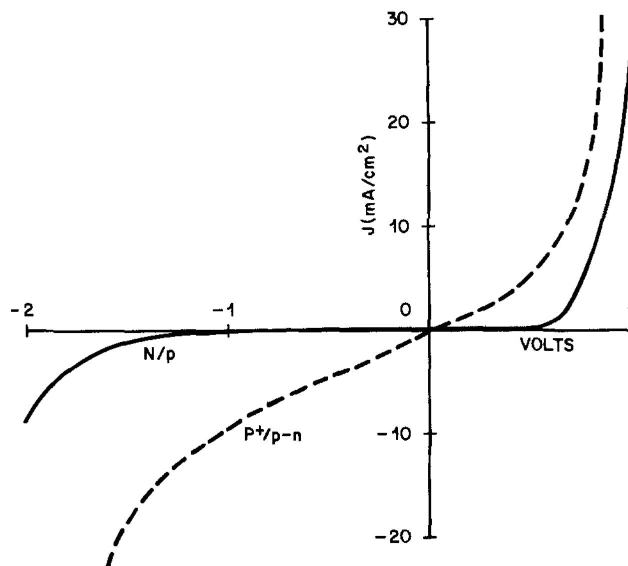

Fig. 7. Linear current density-voltage characteristics for N-AlAs/p-GaAs (solid) and P^+AlAs/p-n GaAs-diffused junction (dashed) cells.

than 1%. The photoluminescent spectra before and after diffusion showed the peak shift to longer wavelengths and broadening typical of Zn-diffused GaAs (10) with a weak tail extending below 1 μm. The precise reason for the very poor photoefficiency is not known at this time; perhaps the Zn diffuses preferentially along the grain boundaries and/or decorates them to form recombination centers. This would account qualitatively for the appearance of lower shunt resistance following diffusion as well. It is also true that the grain size is smaller in the n-GaAs films grown on Sn- or Ge-coated substrate (2-3 μm as compared to 3-5 μm for the Zn-doped p-GaAs). This should not, however, restrict the minority carrier diffusion length to excessively small values.

Discussion and Conclusions

The primary motivation for this work was to assess the possibility of fabricating thin-film, potentially cheap analogs of the high performance single crystal AlAs-GaAs heterojunction solar cells. In this context the best candidate still appears to be the combination of undoped AlAs on Zn-doped GaAs, resulting in a grown-junction, N on p structure. The Zn doping and nucleation of the GaAs layer can be reasonably well controlled, and good diode characteristics and high internal quantum efficiency result (4). Elimination of the high lateral resistance in the AlAs top layer requires that the doping level be raised at the top surface to provide an N^+ layer with a mobile carrier concentration in the high 10^{19} cm³ range, either to provide ohmic contact to a transparent conductive top window or to provide low resistance contact between AlAs grains. Our attempts to achieve this with Se or Sn during growth or with S diffusion after growth have not met with success.

The alternative p on n structure appears relatively unpromising in comparison. Zn doping during growth does not produce uniform P-type doping of the polycrystalline AlAs; some grains remain N-type. Postgrowth Zn diffusion does result in a sufficiently high surface doping that ohmic contact to pressed metals, silver paint, or transparent conductive oxides may be readily accomplished, and the contact between grains seems also to be rendered satisfactory. However, the diode characteristics are deteriorated by an increase in reverse saturation current and the appearance of significant, indeed dominant, ohmic shunt conductance. Changes in the photoluminescent spectra lead us to suspect that postgrowth Zn diffusion results in Zn aggregation along grain boundaries and that this is

the cause of the poor electrical behavior. The photocurrent response of these structures is also poor. This is not due to opacity of the Zn-diffused AlAs layer since the integrated photoluminescent efficiency of the GaAs layer does not change appreciably following diffusion. Evidently, recombination centers result from the Zn diffusion, either in the bulk of the grains or, more probably in our view, at the grain boundaries.

Several other findings are of interest. The observation that Zn-doped polycrystalline GaAs makes low resistance ohmic contact to graphite and that nucleation of a continuous film is facilitated by Zn doping, both at reasonable levels resulting in $p \sim 10^{18}cm^3$, was not anticipated. Advantage of this has been taken to obtain ohmic contact between graphite and thin films of other p-type semiconductors, notably InP, which form ohmic contact to p-GaAs but which cannot be made ohmic to graphite directly. Similarly the use of thin layers of Ge or Sn to obtain simultaneous ohmic contact and nucleation improvement may be of utility for Schottky barrier cell fabrication. It is not clear whether the nucleation improvement with Ge is due to the close lattice match to GaAs, but Sn at least should be useful for growth of other n-type III-V compounds or graphite.

Finally, we feel that there are limitations to the chloride transport growth system used in this work from the point of view of practicality for cheap, large-area fabrication, which are much more significant than for the earlier single crystal cell work. The growth of the GaAs film is slow, and relatively inefficient use of the reactants is made. The high temperature of the AlAs growth certainly contributes to the difficulty of obtaining high surface doping during growth and necessitates postgrowth diffusion. Lower temperatures can be used for growth of the AlAs layer by metal-organic pyrolysis, for instance (11), and for that reason such other growth techniques would appear more interesting for future work.

The stability of the semiconductor material is also a matter of concern if large-area terrestrial application is considered. The only cells which we have observed to undergo apparent deterioration over 6-12 months in a low humidity environment are those that were overcoated with ITO. Several of these showed separation of the ITO-semiconductor layer from the graphite, suggesting the graphite/GaAs interface is the weak point under strain. It does not seem that AlAs would require more stringent measures for encapsulation than other thin film semiconductor materials. The erosion products will be toxic, but that is true as well for all other materials being considered in the role of terrestrial photovoltaics save Si.

In conclusion, it appears that formidable difficulties, albeit not those initially anticipated, lie in the way of demonstration of a cheap thin film analog of the high performance AlAs/GaAs heterojunction cell, at least insofar as chloride transport growth is concerned.

Acknowledgment

It is a pleasure to thank Dr. L. A. Coldren for the deposition of high quality films of ITO and Cd_2SnO_4 on a number of polycrystalline and single crystal samples.

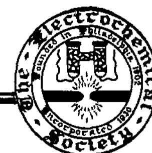
Technical Notes



TiO_2 Antireflection Coatings by a Low Temperature Spray Process

H. J. Hovel

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Antireflection coatings are an important aspect of solar cells and other optical devices. High efficiency Si and GaAs solar cells require coatings with absorption edges well below 4000Å and with refractive indexes of around 2. Films of TiO_2, Ta_2O_5, and Sb_2O_3 are among the best candidates to meet these requirements. TiO_2 is a particularly attractive material because it can be sprayed onto a sample in air (1-3), eliminating costly and time-consuming evaporation steps.

In the simplest spraying method, a nonoxidizing carrier gas such as N_2 or He is passed through a flask

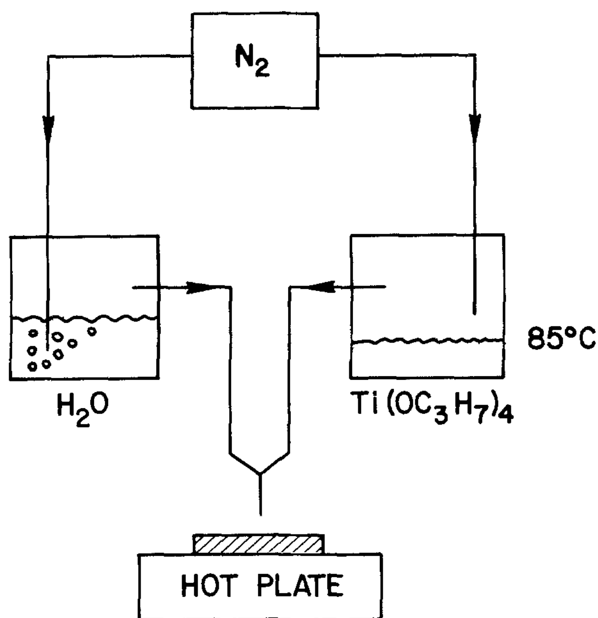


Fig. 1. TiO_2 film deposition system

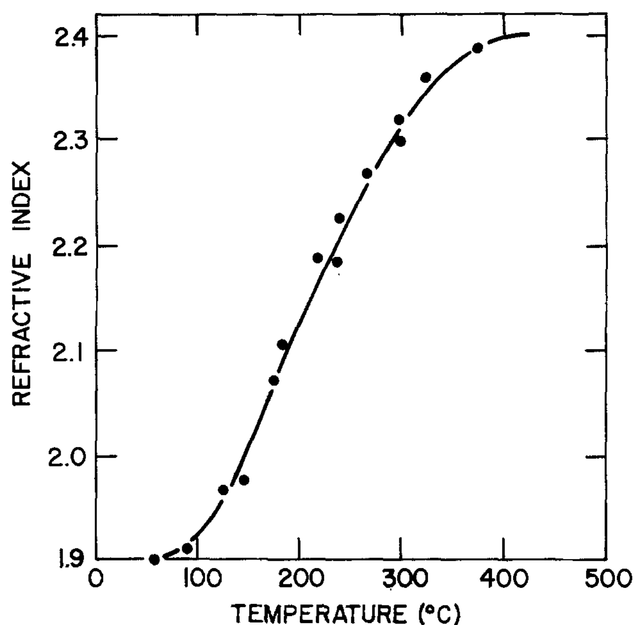

Fig. 2. Refractive index at 6328Å as a function of deposition temperature.

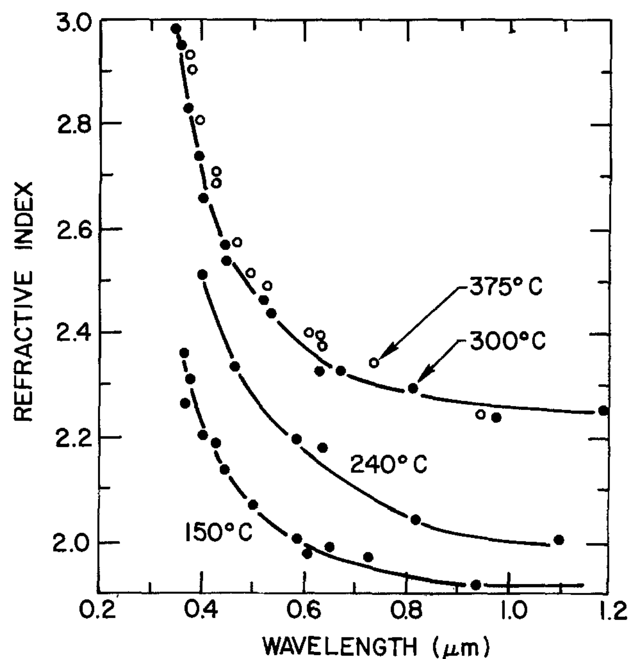

Fig. 3. Refractive index vs. wavelength for several deposition temperatures.

containing the liquid tetraisopropyl titanate (TPT) held at 80°-90°C (Fig. 1). A second stream of carrier gas is bubbled through a flask containing water at room temperature. The two gas streams are brought together at the output of a nozzle which is held from 1 to 2 cm away from the sample surface. The sample rests on a hot plate adjusted to the desired deposition temperature. Uniform coatings can be obtained by moving the nozzle (or sample) in a circular or figure-eight pattern. The deposition rate can be controlled within the range of 1-10Å/sec using different carrier gas flow rates. A certain amount of "trial-and-error" experimentation is required to find the optimum flow rates, TPT temperature, and nozzle-to-substrate distances which lead to TiO_2 coatings free from alcohols or solid TiO_2 particles (1). In the work reported here, flow rates of 500 cm^3/min (2-5Å/sec deposition), a TPT temperature of 85°C, and a distance of 1 cm were used.

The optical properties of the TiO_2 films depend very little on the deposition rate but depend strongly on the deposition temperature. In order to determine the temperature accurately, the 1 in. diam Si or Al_2O_3 substrates were backed with a liquid Ga/In/Sn mixture and placed upon a thick copper block sitting on the hot plate. A thermocouple was imbedded in the copper block, and the sample temperature was assumed to be the temperature indicated by the thermocouple.

The refractive index as a function of deposition temperature of TiO_2 films deposited on Si wafers is shown in Fig. 2. These measurements were made by ellipsometry using a He-Ne laser (6328Å). The index is around 1.9 for temperatures below 100°C, increases linearly between 120° and 340°C, and saturates at about 2.4 for temperatures above 400°C. The dispersion in the refractive index with wavelength is shown in Fig. 3 for films deposited at several different temperatures. (These data points were obtained from the reflectivity maxima and minima positions as a function of wavelength.) For any deposition temperature, the refractive index increases strongly at short wavelengths. Similar results have been reported by Hass (4) for oxidized evaporated titanium films and by Krylova *et al.* (5) for films deposited from $Ti(OC_2H_5)_4$ solution.

The optical absorption as a function of wavelength was obtained from the transmittance of TiO_2 films on Al_2O_3 substrates using a Beckman DK2 spectrometer. The absorption was least for films deposited at the lowest temperatures, as shown in Fig. 4. The absorption edge shifts to longer wavelengths with increasing deposition temperatures up to 200°C, reverts to a shorter wavelength between 200° and 240°C, and then continues its shift to longer wavelengths once more. Transmission electron micrographs of TiO_2 films deposited at various temperatures on GaAs indicate that there is a transformation in the films from an amorphous phase to a polycrystalline phase at a temperature between 200° and 300°C. This agrees well with published reports of a transition from the amorphous phase to the anastase form when films deposited below 200°C are annealed at 300°C or above (1, 4).

The effect of annealing on the refractive index of the TiO_2 films was also studied. Films deposited at 100°-150°C and then annealed at 300°-400°C for 1 hr experience an increase in refractive index of about 10% and a decrease in thickness by the same amount, leaving the optical thickness unchanged. Ad-

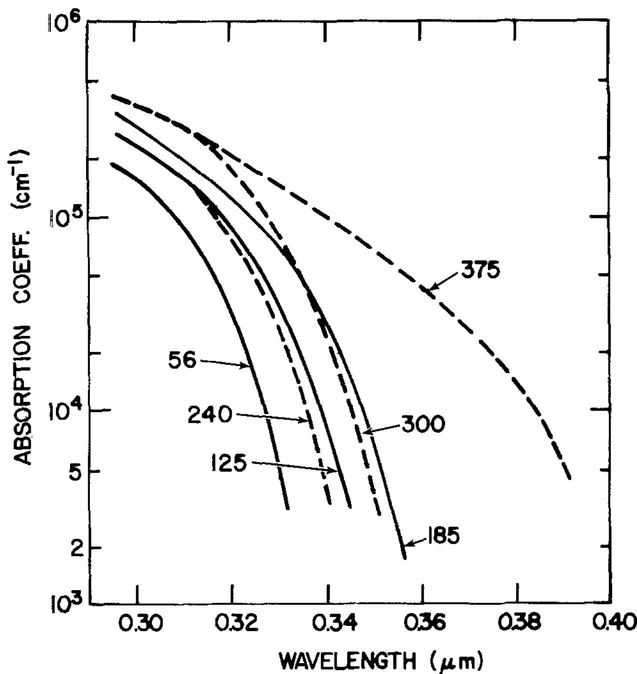

Fig. 4. Absorption coefficient vs. wavelength for several deposition temperatures.

ditional annealing for up to 6 hr brings no further changes.

The specular reflection as a function of wavelength of TiO_2 coated Si wafers is shown in Fig. 5. An index of 2 (150°C deposition) leads to a nearly ideal reflectance curve with less than 0.1% reflectance at the minimum. The results are identical for TiO_2-coated GaAs wafers.

The Effects of HCl Residual Treatment on MNOS Memory Transistors

R. M. McLouski* and M. C. Peckerar*

HCl residual treatment improves the pulse and d-c responses of metal-nitride-oxide-semiconductor (MNOS) transistors prior to cycling (1). This treatment consists of exposing the native silicon surface to a gas mixture of HCl and N_2 at 750°C before subsequent processing of the MNOS structure. It has recently been shown that this treatment may not provide devices with long-term endurance and retention properties (2). However, studying the mechanism of time-zero improvement brought about by HCl treatment is valuable. Such study sheds light on the importance of prenitride surface treatment in MNOS performance. It also delineates the effects of processing on the thin-oxide tunnel layer of the transistor.

* Electrochemical Society Active Member.

Key words: HCl residual treatment, MNOS transistors, pulse, d-c responses.

In this paper the methods of preparation for the parts used in this study are described. The effects of different processing steps on the pulse clear, d-c write, and d-c clear levels are shown. Auger, sputtering, and ellipsometric analyses of the tunnel oxide layer are presented.

It is shown that HCl treatment makes the native silicon surface more resistant to nitrogen attack during the nitride deposition process. The nitrogen-incorporated layer does not provide as good a memory response as a layer which is more like silicon dioxide. A mechanism which explains this passivation with respect to nitrogen is proposed.

Fabrication of Samples

Two types of samples were employed for this study. There were MNOS test capacitors and monitor wafers

run along with the MNOS capacitors and withdrawn at various stages in processing for analysis. Fabrication of the structure proceeded as follows. Starting material was (100)-silicon (n-type), 4-8Ω-cm. Wafers were immersed in 48% HF solution (to remove any oxides present) for 2 min. Wafers were rinsed and sent through a series of sulfuric and nitric acid baths (to simulate the acid bath exposure of an MNOS-memory transistor during processing) followed by a 100:1 HF solution dip and rinse. Some surfaces received HCl residual treatment, others were set aside as controls. HCl residual treatment was accomplished by placing the wafers vertically on a quartz boat which was inserted into an open-tube furnace set at 750°C. Wafer surfaces were then exposed to a mixture of nitrogen and HCl gas in the furnace. HCl comprised 2, 5, and 10% of the total flow. Total gas flow was 2 liters/min. The time of HCl exposure was 10 min.

Immediately after HCl treatment wafers and controls were placed in a vertical nitride CVD reactor. A silicon nitride film of 495 ± 25Å was deposited on the wafer by the reaction of ammonia and silane gases on the hot wafer surfaces. Heating was accomplished by means of an rf-heated, silicon carbide-coated graphite susceptor. After nitride deposition, the wafers received an aluminum gate metallization. Aluminum was deposited by an electron-beam source through a shadow mask.

The completed structure can be shown to exhibit flatband voltage shifts after positive or negative biases. The shifts come about as a result of charges stored in the nitride-oxide interface region. For structures of equal nitride thickness, the shift after bias is roughly proportional to the change in charge stored in this region. The operation of these devices has recently been reviewed by Chang (3). *C-V* curves generated for these structures allow us to estimate flatband and threshold voltage shifts.

Electrical Measurements

Electrical measurements were performed on the *C-V* dots in the following fashion. A voltage of −20V was applied to the metal dot with respect to substrate ground for 60 sec, then the bias was removed. 15 sec later a high frequency *C-V* curve (referred to as the d-c write curve) was developed in a bias range from 0 to −20V. Next, the dot was biased at +6.0V. Bias was shifted rapidly negative to a value of −20V. The d-c clear curve was obtained by biasing the dot to +20V for 60 sec and then returning the dot to +6V. 15 sec later the device bias was swept from +6 to −20V and the *C-V* curve was developed over this bias range. Threshold voltages in the d-c written pulse cleared and d-c cleared state were estimated from these curves. [See Ref. (1) for further explanation of this technique.]

In Table I, the pulse and d-c thresholds obtained for the various processes are tabulated. Ten capacitors from each type of process studied were sampled. The mean threshold for the ten thresholds is recorded. As can be seen, HCl residual processing tends to make for more positive d-c clear thresholds. The pulse clear levels are also considerably more positive than those for non-HCl processing. D-c write levels are only slightly more positive. These represent significant improvements in device performance brought about by HCl. D-c hysteresis windows are larger. Pulse characteristics are closer to d-c characteristics.

Table I. Electrical performance of MNOS memory test capacitors processed with and without HCl treatment

Process	D-c write threshold (volts)	D-c clear threshold (volts)	Pulse clear threshold (volts)
Non-HCl treated	−12.5	+1.9	−3.2
2% HCl	−12.0	+3.7	+0.8
5% HCl	−11.0	+5.3	+1.0
10% HCl	−9.5	+4.6	+1.9

There is some improvement (*i.e.*, a more positive threshold shift) in pulse response on going from 2% to 5% HCl treatments. Going from 5% to 10% HCl there is further improvement in pulse response. However, d-c write is affected poorly (it has shifted positively also) with no attendant positive shift in d-c clear. Some pitting of the silicon surface is observed at the 10% level. Thus, the 10% HCl exposure is considered deleterious.

J-V measurements were also made on these capacitors (see Fig. 1). At the 5% HCl level there was no difference in *J-V* characteristics when compared with the non-HCl treated samples. This once again illustrates the often noted fact that conductivity in thin oxide MNOS devices is a nitride bulk limited phenomenon. (4).

An electrical parameter of prime importance in MNOS memory transistor fabrication is retention slope. As stated above, the effect of process in retention slope and endurance was previously reported (2). HCl treatment does not degrade the retention slope prior to

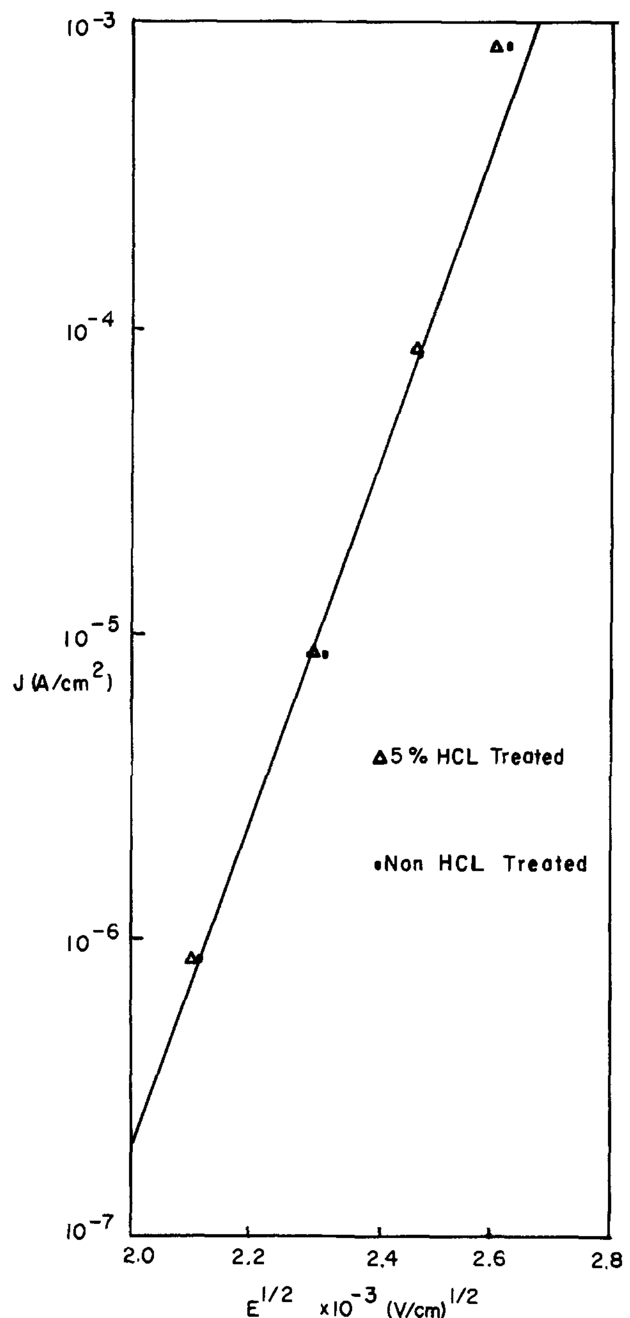

Fig. 1. *J-V* analysis of HCl and non-HCl-treated films. Four data points are included for comparison.

cycling. More recent comparisons of HCl- and non-HCl-treated transistor retention slopes prior to cycling support this claim. Two groups of fifteen transistors each were measured for retention slope prior to cycle stress. The mean retention slope of the write decay of the HCl-treated sample was 0.20 V/decade with a 0.06 V/decade standard deviation. That of the non-HCl treated film was 0.30 V/decade with a 0.16 V/decade standard deviation. Thus there is no statistically valid difference in retention slope between the two groups.

Auger, Sputtering, and Ellipsometric Analyses

Detailed Auger analyses of MNOS structures are reported elsewhere (5, 6). The aim of this research was to delineate changes in the oxide tunneling layer during processing. Wafers were drawn for analysis at the following points in processing (5 groups in all): (*i*) After 100:1 HF dip; (*ii*) after HF dip and sulfuric/nitric acid bath (prenitride clean); (*iii*) after HCl residual treatment at 5% HCl (to simulate actual memory transistor fabrication); (*iv*) after the prenitride depositor (PD) warm-up cycle in the vertical reactor (2 groups, one which had 5% HCl and one which received no HCl).

The PD warm-up cycle is the period the wafers spend in the nitride reactor while the susceptor is stabilized to temperature. This takes 15 min for the case at hand. During the first 14 min, the wafer is exposed to pure N_2 gas at atmospheric pressure. For the last 1 min of the cycle, NH_3 is introduced into the reactor. After the 15 min warm up, SiH_4 would normally be bled in and deposition would commence. For this study, wafers were withdrawn before this would occur.

Table II summarizes the results of Auger analyses performed on the surfaces of the 5 groups. A defocused beam is used to minimize damage produced by the incident electrons. The values of the peak-to-peak heights in the conventional derivative spectrum are given in arbitrary units. No attempt was made to normalize the signal strengths. The mixing of oxidized silicon and silicon-silicon spectra (between 1500 and 1619 eV) can be grouped into three categories according to the relative strengths of the observed peaks (Fig. 2): (a) the pattern characteristic of the HCl-treated samples. All high energy spectra revert to the (a) form after 2 min sputtering (Ar^+, 10 $\mu A/cm^2$; 10 Å/min removal rate). Patterns of the type (c) pass through a (b) stage before revealing the pure (a) silicon spectrum.

Those wafers which did not receive HCl treatment incorporated significantly more nitrogen during the PD warm-up cycle than those that did receive the treatment. The ratios of the nitrogen/oxygen signals for the HCl-treated specimens (column 5, Table II) are 7-50 times lower than those of the untreated samples (column 6, Table II). Column 2 represents clean silicon with some hydrocarbons, CO, and other contaminants absorbed to the surface. The high energy spectrum, which samples more of the deeper lying material, is virtually pure silicon-silicon.

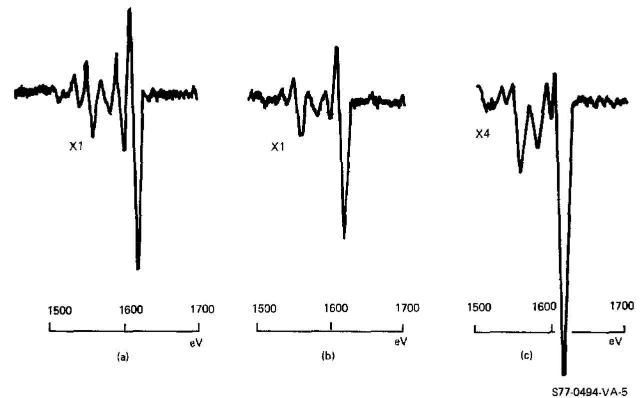

Fig. 2. Three types of $Si\text{-}SiO_2$ spectra between 1500 and 1700 eV. Primary electrons 5 keV modulation voltage, 3V peak-to-peak for curves (a) and (b), 6V peak-to-peak for curve (c). See text for discussion.

The prenitride cleaning cycle (PNC) yields spectra (column 3) which are indistinguishable from the HF-only spectra. Thus the acid baths following HF dip could not be responsible for nitrogen uptake. Nitric acid did not cause nitrogen uptake initially. In columns 4 and 5, the effect of the HCl treatment is seen to be the production of silicon-oxygen bonds, without significant nitrogen pickup. Enough of an oxide overlayer is produced to affect the high energy silicon spectrum. The thickness of the oxide layer is estimated to vary between 10 and 20Å. The sputtering times necessary to reduce the oxygen signals to reabsorption levels support this estimate. Also, during the predeposition warm-up cycle (PD), more free silicon is being oxidized as evidenced by the decrease of the 92 eV line with respect to the 75-85 eV oxide line.

Column 6 gives results obtained from wafers which were not treated with HCl residual. In one case, no 92 eV line was observed, but the nitrogen signal was as strong as the oxygen signal, indicating the formation of an oxynitride. The layer is thick enough to affect the high energy Si spectrum, but does not generate the characteristic (c) spectrum. In two other cases, incomplete or flawed oxide layers are produced (only one included in Table II), with a strong line at 92 eV and a high energy spectrum typical of pure (100) Si.

Ellipsometry of the thin native silicon oxide reveals an extremely thin, silicon-rich film. Using the McCrackin program (7), it is found that this film is approximately 13Å thick with an exceptionally high refractive index (averaging 1.97). Following the PD cycle, the untreated films thickened to about 17Å and the refractive index becomes an averaged value 1.89. Elipsometry of the HCl-treated films becomes impossible as a result of roughing of the surface. Attempts at ellipsometry of these films before the PD cycle would indicate that they are exceptionally thick (20-50Å). The refractive index was also high for these films

Table II. Summary of auger results

The numbers refer to peak-to-peak heights in the conventional dN(E)/dE-spectra obtained with a cylindrical mirror analyzer (arbitrary units.) Primary electrons 5 keV, modulation 3V peak-to-peak.

* Not typical of oxide, more probably oxynitride.
** Not measured.

(averaging 1.7). The PD-cycled HCl-treated films are, according to the McCrackin program, thicker (ranging from 40-80Å) but of lower refractive index (1.22). This is in conflict with the sputtering results. The roughing and pitting of the surface, so evident at the 10% HCl level, probably explains these strange ellipsometric results. No ellipsometric estimate of film thickness can therefore be given for HCl-treated films.

None of the analytic techniques employed in this study were sufficient to determine the presence of hydrogen in the thin oxide films or at the oxide semiconductor interface. However, this was not judged to be a serious drawback. As Kooi has shown (8) heat-treatment of uncoverd oxides above 600°C for a few minutes is sufficient to drive off hydrogen from the oxide-semiconductor interface. After HCl treatment, the nitride reactor predeposition cycle keeps the uncovered tunnel oxides at temperatures in excess of 700°C in dry nitrogen for times longer than 10 min. Furthermore, annealing in hydrogen gas in place of HCl in the HCl-treatment cycle has no beneficial effect on d-c or pulse memory performance.

A Model for the Effect of HCl on the Tunnel Layer

The model for the effect of the HCl residual treatment on the thin oxide tunneling layer is shown in Fig. 3. Initially, the native oxide surface is far from homogeneous. There are regions in which silicon-oxygen bonding is not complete and impurities (probably carbon based, as that was the only atom other then silicon or oxygen which was detected) dot the surface. These departures from homogeneity are viewed as weak spots with respect to nitrogen attack during the PD warm-up cycle. HCl tends to etch out large agglomerates of impurities and regions of incomplete silicon-oxygen bonding without affecting a fully bonded silicon dioxide. This etching which is visibly evident at the 10% HCl level roughens the surface. When the HCl heat-treated surfaces are reexposed to air, a more perfect oxide film forms. This film is less susceptible to nitrogen inclusion.

Discussion

The improvement in device response comes about for three possible reasons. Even though the surfaces become rougher, the oxide films on HCl treated surfaces may remain thin through PD (as sputtering indicates). Untreated surfaces thicken nitrogen during PD. Thin tunnel layers allow for easier communication between nitride traps and the silicon, improving device pulse response (9). Also, the inclusion of nitrogen may adversely affect tunnel layer conductivity, degrading performance. A final possibility is that the rough surface contains many high field points, supplying more impetus for charge transfer, improving the device response.

This last possibility is viewed as least likely, due to the electrical performance data. The HCl at the 5% level is not so severe as to effect J-V characteristics. In addition, the retention slope is not at all degraded by HCl treatment. If this initial charge transfer into the insulator is mediated by high fields due to surface roughening only, this should show up as an increase in retention slope which is not observed.

There is some possibility of tunnel layer thickening during HCl treatment due to oxygen or water vapor present in the HCl treatment. This cannot be the cause of improved performance, though. As Wallmark and Scott (10) clearly show, such thickening leads to device hysteresis window degradation.

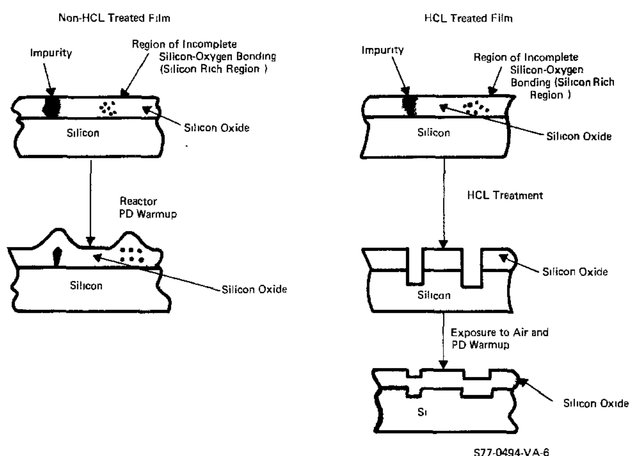

Fig. 3. Illustration of processing effects of MNOS tunnel layers

Summary and Conclusions

It has been shown that prenitride HCl surface treatment significantly affects the initial performance of MNOS devices. Untreated surfaces incorporate nitrogen during the predeposition warm-up cycle of a vertical reactor. Evidence points to nitrogen incorporation as being deleterious to device performance, degrading pulse response, and making d-c clears less positive. (However, the role of surface roughing from HCl gas has not been fully delineated, making this conclusion tentative at present.) HCl treatment makes the surface more resistant to nitrogen attack. This probably occurs because HCl etches away impurities and regions of incomplete silicon-oxygen bonding, (*i.e.*, silicon-rich regions). Silicon-oxygen bonding is promoted without any significant increase in oxide thickness. It is these impurities and/or silicon-enriched areas that are most susceptible to nitrogen attack during the prenitride reactor warm-up cycle.

MOS Characterization of Low Leakage Native Oxides on AlGaAs

E. H. Nicollian,* B. Schwartz,* L. A. Koszi, and N. E. Schumaker*

Bell Laboratories, Murray Hill, New Jersey 07974

It is reported here that a highly insulating native oxide on (36%) AlGaAs has been prepared that is comparable in dielectric strength to thermally grown SiO_2. This high dielectric breakdown strength and low electrical conductivity prior to breakdown are in contrast to those observed for anodically grown oxide films on GaAs with similarly evaporated gold electrodes which were conducting appreciable current even at an oxide thickness of 0.2 μm. The presence of the aluminum therefore makes the electrical conductivity of the anodic film on AlGaAs much less than that on an anodic film on GaAs below breakdown. However, the native oxides we grew on AlGaAs still had sufficiently large interface trap densities to make them unsuitable for most device applications at the present time. The reduction of these trap densities is the subject of continued development.

Experimental Procedures and Results

Sample preparation.—Two samples of nominally undoped 36% Al ternary material were grown by LPE on n^+ GaAs substrates doped with silicon to 1×10^{18} cm^{-3}. One of the epitaxial layers about 1.5 μm thick was found to be p-type from *C-V* curves, and the doping density was found to be 3×10^{16} cm^{-3} from the slope of a $(C_{ox}/C)^2$ *vs.* *V* curve (C_{ox} is the oxide layer capacitance, see Fig. 1). The second epitaxial layer, also about 1.5 μm thick, had an apparent n-type doping level of about 2×10^{15} cm^{-3} at 23°C (see Fig. 2). The substrate side of both samples was ohmically contacted by a Sn-Pd-Au metallization.

Because we had observed that GaAs and (36%) AlGaAs had different anodization characteristics, it was necessary to determine the thickness-voltage curve for the latter. Figure 3 shows the results of anodizing p-type Ge-doped to 3.5×10^{17} cm^{-3} (36%) AlGaAs in on aqueous solution of H_3PO_4 at a $pH = 2.5$. In the generation of the thickness data shown in Fig. 3, it was assumed that the refractive index for the native oxides on GaAs (1.80) (1) and AlGaAs are the same, and a calibrated GaAs color chart could therefore be used. Whereas 20 Å/V was the previously reported oxide growth parameter for GaAs (1), we note here that for AlGaAs, this parameter is only about 15 Å/V.

Both test samples were then anodized[1] to grow an oxide layer about 1200Å thick and then baked in a nitrogen purged oven at 250°C for 2 hr. Gold dots (either 127, 254, or 380 μm in diameter) were then evaporated, through a metal mask, directly onto the surface of the oxide.

Minority carrier response time.—Minority carrier response time (t_R) was measured because it is an important parameter in applications such as CCD's where long minority carrier response time means long retention time and low dark current. The minority carrier response time of an MOS capacitor is the time it takes for the system to reach thermal equilibrium after the applied field has been abruptly changed. The mechanism by which the system reaches thermal equilibrium is thermal generation of carriers in the space charge region of the semiconductor (2). The t_R was obtained in the AlGaAs samples by applying a step

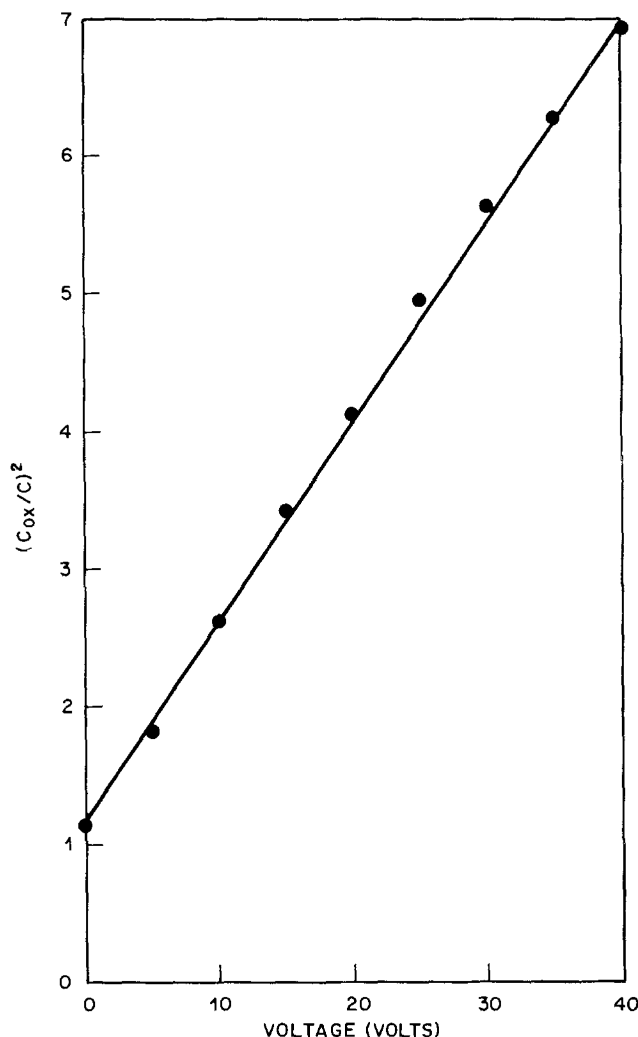

Fig. 1. $(C_{ox}/C)^2$ *vs.* *V* measured at 1 MHz with a voltage ramp of 0.1 V/sec on a p-type AlGaAs MOS capacitor with gold dots. $T = 23°C$.

voltage of 15V, which drove the semiconductor into deep depletion, and then measuring the time required to reach thermal equilibrium again; equilibrium was reached when the capacitance stopped increasing. Response times of 150, 250, and 300 sec were found on three different AlGaAs samples (3). These are relatively long response times and can be explained on the basis of the large bandgap of the AlGaAs (~1.53V) (4); because of the bandgap, the intrinsic carrier concentration, n_i, will be quite small. Thus, even though minority carrier lifetime may be short, the small value of n_i will determine the generation rate and the generation current will be relatively small, making t_R rather long (2). Such long values of t_R make this material attractive for such devices as CCD's.

Current vs. voltage characterization technique.—To measure the *I-V* characteristics and determine the breakdown voltage of the oxide layer, the samples were placed in a dry-nitrogen-purged light-tight box used to minimize spurious currents due to moisture

* Electrochemical Society Active Member.

leakage and photovoltaic effects. A voltage ramp of 0.2 V/sec was applied between a gold dot and the back contact of the wafer using a point probe to contact the gold dot. The resulting current was measured with a logarithmic picoammeter whose output was fed to the y-axis of an X-Y recorder. Feeding the output of the ramp generator to the x-axis of the X-Y recorder permitted the plotting of an I-V curve. To minimize spurious currents due to cable vibration, a rigid General Radio coaxial transmission line was used between

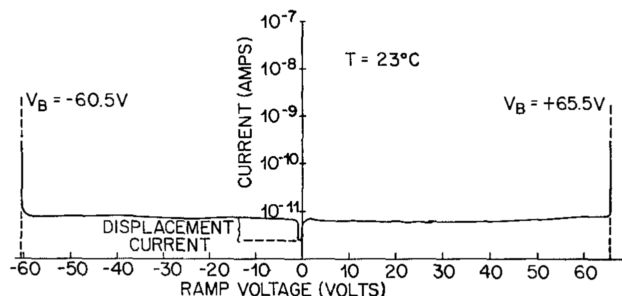

Fig. 4. Logarithm of current vs. voltage measured at 23°C for both positive and negative polarity. V_B is breakdown voltage. The sample was the same as in Fig. 1.

the point probe and the input of the picoammeter. The polarity of the ramp voltage is the polarity of the dot with respect to the back contact.

Results with gold gate electrode.—Figure 4 shows the resulting I-V characteristics of two representative MOS capacitors measured on the p-type AlGaAs epilayer, with Au-dots, for both positive and negative polarity. The only current measured prior to catastrophic breakdown was displacement current shown in Fig. 4 to be in the 10^{-12}A range. Breakdown voltage is defined as the voltage at which the current suddenly increases and is shown labeled as V_B in Fig. 4. Melting at various spots on the metal gate electrode is usually observed after breakdown and the MOS capacitor is invariably a short circuit. Thus, the measurement of breakdown voltage is destructive and each measurement must be made on a different dot. It is seen from Fig. 4 that breakdown with positive polarity occurred at +65.5V while with negative polarity, breakdown voltage was −60.5V. There were a minority of dots which broke down around 10V. On another p-type sample, breakdown voltages were +65 and −20V with a few dots which broke down at voltages as low as +38 and −20V.

The important thing to note is that for p-type material, the breakdown voltages were always higher for positive than for negative polarity. This effect follows from the fact that the voltage across the oxide near breakdown must be lower for positive than for negative polarity. At large positive values of gate voltage, the p-type semiconductor is in deep depletion because t_R is so long that minority carriers cannot follow the sweep rate. Therefore, the space charge region is much wider than it is at negative gate voltages where the semiconductor surface is in strong inversion. The semiconductor surface is in inversion at all negative gate voltages up to breakdown because of a large positive oxide charge density characteristic of these oxides (5). A smaller fraction of the applied voltage must appear across the oxide at positive polarity than at negative polarity because of the large difference in space charge widths. Similar reasoning applies for the n-type samples where the semiconductor surface is in deep depletion at high negative voltages and in inversion at large positive voltages because there is a large negative oxide charge density (5). For example, it was observed on an n-type sample that the breakdown voltages were +59 and −64V.

The breakdown field, which is the field across the oxide at breakdown, should be polarity independent. At large negative voltages, the p-type semiconductor is in inversion. Subtracting the voltage drop across the semiconductor space charge region, which cannot exceed 1.5V in inversion (band bending equal to the bandgap), from the breakdown voltage given in Fig. 4 as −60.5V gives 59V and a breakdown field of 4.9×10^6 V/cm where the oxide thickness was estimated to be 1200Å. This value of breakdown field and the observation that no leakage current (<0.01 pA) is measured prior to catastrophic breakdown makes this ox-

ide comparable to thermally grown SiO_2 with respect to room temperature dielectric breakdown strength. The resistivity of this film is estimated to be greater than 2×10^{17} Ω-cm.

There are two more observations, however, which indicate that the native oxide of AlGaAs is different from thermally grown SiO_2. The first is that the dielectric breakdown voltage decreases with storage time at room temperature. For example, the n-type sample exhibited a breakdown voltage of 180-200V immediately after it was prepared. After a few months, the breakdown voltages decreased into the 60V range. The second is that the breakdown voltages are temperature dependent decreasing with increasing temperature. Figure 5, which shows breakdown voltages on the same p-type sample as Fig. 4, but measured at 100°C, illustrates this observation. In Fig. 5, the breakdown voltages were +35.5 and −47V. Another pair of dots on the same sample yielded breakdown voltages of +33 and −41V. Notice that the breakdown voltage for positive polarity is less than for negative polarity, the reverse of what was measured at room temperature. Furthermore, the reduction in breakdown voltage for both polarities is rather large for a relatively small increase in temperature (100°C). The decrease in breakdown voltage with increasing temperature can be explained as follows. At high positive voltages, the semiconductor surface goes from deep depletion to inversion as temperature increases because minority carrier response time gets shorter with increasing temperature. Thus, the semiconductor surface space charge region decreases in width and the fraction of the applied voltage across the oxide increases with increasing temperature. The breakdown voltage for positive polarity decreases with increasing temperature as observed. For high negative voltages, the semiconductor surface goes from inversion to depletion as temperature increases. As temperature increases, the Fermi level moves toward midgap reducing net positive interface trap charge density sufficiently to allow gate bias to make the surface go from inversion to depletion. Thus, the space charge width again decreases with temperature and the fraction of the applied voltage across the oxide increases with increasing temperature. The breakdown voltage for negative polarity also decreases with increasing temperature as observed. Based on this reasoning, the breakdown voltage should decrease more for negative polarity than for positive polarity; but just the opposite occurs. The reason for this is not understood. As this reasoning does not explain all the observations, it is obviously an oversimplification of the true situation.

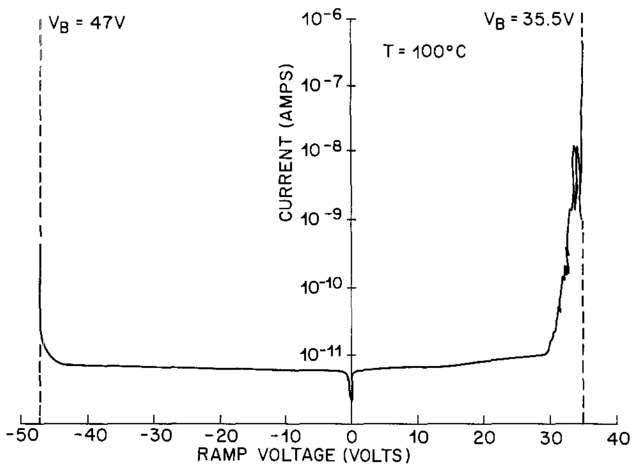

Fig. 5. Logarithm of current vs. voltage measured at 100°C for both positive and negative polarity. Sample is the same as in Fig. 1.

Conclusions

The long minority carrier response time and the high dielectric breakdown strengths observed make it appealing to pursue the development of native oxides on AlGaAs. The major problem in their use will be to reduce the large interface trap density sufficiently so that they no longer play such a dominant role in the MOS characteristics. The solution of this problem will result in an oxide which is quite suitable for numerous device applications.

Acknowledgments

The authors would like to thank A. Timko for measuring minority carrier response times of the AlGaAs samples, and G. E. Smith and J. R. Brews for a critical reading of the manuscript.

The "D.L.P." Model in $Ga_xIn_{1-x}P$:N Alloys Correlation with Electronic Properties

A. Marbeuf and J. C. Gillaume

CNRS, Laboratoire de Physique des Solides, Briand, 92190 Meudon/Bellevue, France

Several studies on $Ga_xIn_{1-x}P$ alloys have shown the interest of these materials for electroluminescent devices (1-4). If nitrogen is used as a dopant, the recombination of excitons bound to this isoelectronic impurity gives a luminescence in the green and yellow portion of the visible spectrum (5-8).

Mariette and Chevallier (8) have recently shown that enhancement of the external luminescence efficiency in nitrogen-doped alloys, when x decreases, is partly due to the band-structure effect on the radiative lifetime of the excitons bound to nitrogen atoms. On the other hand, the alloys have a different luminescence behavior when x is varied: for $x > 0.98$, the line due to nitrogen is similar to the so-called A-line which is usually observed in GaP:N, whereas for $x < 0.98$ nitrogen gives rise to a broader luminescent A_0-line at lower energy than that of the A-line (6, 8).

An explanation of this behavior can be obtained by using the thermodynamic model developed by Stringfellow (the Delta lattice parameter or "D.L.P." model) (9). Based on the Philips and Van Vechten dielectric theory (10, 11), this model uses the concept that the bonding energy of a semiconductor is proportional to the bandgap. Neglecting dehybridization and, for heteropolar alloys, bond ionicity effects, the bonding energy or atomization enthalpy ΔH^{at} may be written

$$\Delta H^{at} = Ka_o^{-2.5} \quad [1]$$

where K is a positive constant which can be evaluated from pseudobinary III V-III'V or III V-III V' systems (9).

In consequence, the activity coefficients in the solid will reflect the nature of the constituent atoms and the electronic properties of the material. From the "D.L.P." model, the free energy G^s of a crystal $A_{x1}{}^s B_{x2}{}^s C_{x3}{}^s D_{x4}{}^s$ depends on its lattice parameter a_o and its composition in the following manner

$$G^s = Ka_o^{-2.5} + RT\left[\sum_{i=1}^{2} x_i{}^s \log x_i{}^s + \sum_{j=3}^{4} x_j{}^s \log x_j{}^s\right] \quad [2]$$

In this note all the relations will be expressed in $1/K$ units.

Assuming Vegard's law, the chemical potentials $\mu_{ij}{}^s$ of the four binary III_iV_j systems can be expressed in the following manner

$$\mu_{ij}{}^s = 2.5\,Ka_o^{-3.5}[x_k{}^s x_j{}^s(a_{ij} - a_{kj}) + x_i{}^s x_{k'}{}^s(a_{ij} - a_{ik'}) + x_k{}^s x_{k'}{}^s(a_{ik'} + a_{kj} - 2a_{kk'})] + RT\log x_i{}^s x_j{}^s - Ka_o^{-2.5} \quad [3]$$

where a_{ij}, a_{kj}, etc . . ., represent the lattice parameters of the defined binary compounds AC, AD, BC, and BD which are given in the Table I, and where k and k' are indexes defined by

$$k = 1, 2 \quad k = i \quad \text{and} \quad k' = 3, 4 \quad k' = j$$

Because $-Ka_{ij}^{-2.5}$ is the standard chemical potential $\mu_{ij}{}^{os}$ of the III_iV_j compound, we can define the activity coefficient $\gamma_{ij}{}^s$

$$RT\log\gamma_{ij}{}^s = 2.5Ka_o^{-3.5}[x_k{}^s x_j{}^s(a_{ij} - a_{kj}) + x_i{}^s x_{k'}{}^s(a_{ij} - a_{ik'}) + x_k{}^s x_{k'}{}^s(a_{ik'} + a_{kj} - 2a_{kk'})] + K(a_{ij}^{-2.5} - a_o^{-2.5}) \quad [4]$$

assuming regular behavior of the solid solution between the four binary III_iV_j systems.

Table I. Lattice parameters used in the calculation of $\gamma_{ij}{}^s$

	GaP	GaN	InP	InN
a (Å)	5.4512 (9)	4.4894* (13)	5.8688 (9)	4.9919* (14)

* Parameters calculated from volume of the wurtzite-hexagonal cell.

A series of $Ga_xIn_{1-x}P$:N alloys were prepared by liquid phase epitaxy (LPE). The method described by Mariette *et al.* (12) was used. An In-rich melt was cooled down slowly from 830° to 800°C, and the four $\gamma_{ij}{}^s$ coefficients were calculated for the 830°C isotherm using relation [4] and the lattice parameters listed in Table I. The calculated dependence of $\log\gamma_{ij}{}^s$ (in $1/K$ units) *vs.* x, is shown in Fig. 1.

The $\log\gamma_{InN}{}^s$ curve clearly demonstrates that the interaction energy between InN and the $Ga_xIn_{1-x}P$ matrix is positive only for $x \lesssim 0.97$. This value does not depend on the doping concentration, since [N]

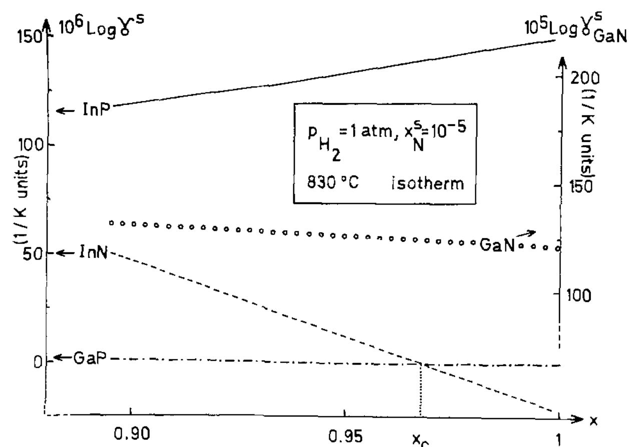

Fig. 1. Variation of the logarithm of the activity coefficients in the solid with alloy composition at 830°C.

Key words: D.L.P. model, $Ga_xIn_{1-x}P$:N alloys, electronic properties.

was varied between 10^{15} and 10^{19} atoms per cm^3. On the other hand, log $\gamma_{GaN}{}^s$ is always positive and becomes progressively greater as x decreases. Noting that the free energy of formation of InN is negative (−2.9 kcal·mole^{-1}) under the growing conditions at 830°C (15), whereas that of GaN is positive [1 kcal·mole^{-1}, Ref. (16)], then during the growth of alloys with $x < 0.97$ the more energetically favored NIn_4 tetrahedrons will be formed preferentially to NGa_nIn_{3-n} (n = 1, 2, 3) and even NGa_4 tetrahedrons. The ionic character f_i is more pronounced for In-N bonds than for Ga-N bonds [f_i In-N = 0.578, f_i Ga-N = 0.500 on the scale established by Philips, Ref. (10)]. Consequently, one can predict a different electronic behavior of nitrogen in $Ga_xIn_{1-x}P$:N alloys for $0.97 < x < 1$ and for $x \lesssim 0.97$, and so different luminescence spectra.

Experimentally, the critical value $x_c = 0.97$ corresponds to the appearance of the A_o-line, as previously described by Garbuzov and co-workers (6), and Mariette and Chevallier (8). These authors have noted that the short-range potential V created by nitrogen, more electronegative than phosphorus, should be different for the A-line and the A_o-line, which appears for $x < x_c$.

Indium is more electropositive than gallium, so that, for the NIn_4 tetrahedrons, the potential well created by nitrogen is surrounded by a curb which gives a greater effective potential. The A-line probably still exists for $x < x_c$ but becomes immersed into the A_o line.

Such effects cannot exist in GaP_yAs_{1-y}:N. Its lattice only contains NGa_4 tetrahedrons and P and As atoms, second neighbors of N-atoms, have a relatively small influence on the nature of Ga-N bonds. The electronic nitrogen behavior in GaP:N, GaP_yAs_{1-y}:N and $Ga_xIn_{1-x}P$:N is summarized in Fig. 2.

In recent work, Brühl and co-workers have shown the strong tendency of gallium and indium in $Ga_xIn_{1-x}P$ bulk-crystals toward segregation and have predicted that the effect of clustering should be more pronounced in as-grown epitaxial alloys (17). They also expect a strong effect of this nonrandom distribution on electronic properties created by doping.

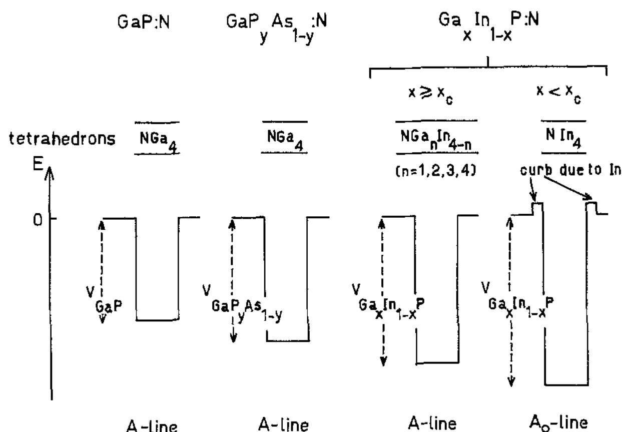

Fig. 2. Comparison of the potential well created by nitrogen in GaP, GaP_yAs_{1-y} and $Ga_xIn_{1-x}P$.

Hence, the "D.L.P." model connects the thermodynamic macroscopic properties to the electronic ones. A complete calculation of the quaternary phase diagram Ga-In-P-N can be considered. In relation with nitrogen-profile measurements, it should provide a precise knowledge of nitrogen-doping conditions in L.P.E. $Ga_xIn_{1-x}P$ alloys.

Acknowledgments

We thank D. Bourneix for his contribution to the LPE experiments and Doctors Chevallier, Ghazali, and Mariette for useful discussions and their interest for this work.

Phase-Memory Effect in a p-Type Photoconductor

Osamu Yoshie and Mitsuo Kamihara

Department of Electronics, Kogakuin University, Nishishinjuku, Shinjuku-ku, Tokyo, Japan

The phase-memory effect was previously found by one of the present authors in evaporated thin films of CdS and (Cd, Zn)S at low temperatures (1, 2). It was reported (2-5) that the memory effect in these films was due to trap-controlled high field domains caused by the field-quenching effect (6-8). The phase-memory

Key words: phase-memory effect, p-type photoconductor, Se film, domain velocity, maximum memory time.

effect was also found in bulk CdS single crystal (9) and Cr-doped GaAs single crystal (10). The mechanism of the memory effect in CdS was explained to be at least associated with both the deep hole traps and the deep electron traps (9). Thus, the phase-memory effect was investigated in detail in n-type semiconductors, while no reports have been made on it in p-type semiconductors. We have found and investigated the phase-memory effect in p-type thin films of Se.

Experimental

The thin films of Se (about 1 μm thick) were prepared by vacuum evaporation at $1 \sim 5 \times 10^{-5}$ Torr. A cleaved mica plate kept at room temperature was used as a substrate. After evaporation, the Se film was annealed at 100°C for 5 min in vacuum. The sample had a planar-type (gap-type) structure with silver paste electrodes (width: 1 ~ 2 mm, interelectrode spacing: 1 ~ 3 mm). The sample was illuminated with monochromatic light of wavelength approximately corresponding to the absorption edge of Se. The measurements were made at 40°K, and the probe potential of the sample was measured by a high impedance electrometer.

Results and Discussion

Figure 1 shows the very low frequency photocurrent oscillation in the Se film and the phase-memory effect for light interruption at 40°K. When the light illumination is turned off at a phase "P" during the periodic photocurrent oscillation, the oscillation stops and the current decays; by turning on the light again an arbitrary time later, the oscillation begins at the phase "P," which it had at the moment of turning off. This fact indicates that the phase of the oscillation can be memorized by turning off the light (light-controlled phase-memory effect). The above memory effect is also observed with regard to the probe potential of the sample. The traveling of the trap-controlled high field domain could not be confirmed since the crystallization of the Se film on the mica plate was very inhomogeneous. From the similarity to the phase-memory effect in CdS (2, 5, 6), however, we can deduce that the phase-memory effect in the Se film is also due to a trap-controlled high field domain. That is, the traveling high field domain stops and remains unchanged when the light is turned off during the domain traveling, and it begins to travel by turning on the light again. The observed maximum memory time has been confirmed to be longer than 12 hr at 40°K.

Figure 2(a) shows that the light-controlled phase-memory effect can also be observed even if the applied bias voltage is interrupted for an arbitrary time during the phase-memory state (nonvolatile phase-memory effect). This fact suggests that, if the bias voltage is interrupted during the phase-memory state, the dipole space-charge layer (*i.e.*, high field domain) disappears, but the layer-like spatial inhomogeneity of conductivity in the sample remains unchanged. Therefore, when the voltage is switched on again, the dipole space charge layer is reformed at the same position where the voltage was interrupted. The maximum memory time in this case has also been confirmed to be longer than 12 hr at 40°K.

Figure 2(b) shows that the phase-memory effect can also be observed when the bias voltage is interrupted

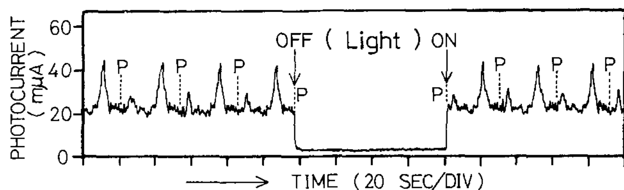

Fig. 1. Light-controlled phase-memory effect in a Se film at 40°K. Interelectrode spacing, 1.7 mm; bias voltage, 900V; illumination, 6700Å.

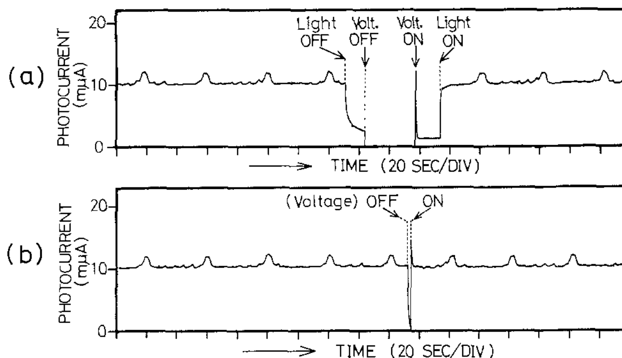

Fig. 2. (a) Nonvolatile phase-memory effect; and (b) voltage-controlled phase-memory effect at 40°K. Spacing, 1.7 mm; voltage, 200V; illumination, 6350Å.

for a very short time under light illumination (voltage-controlled phase-memory effect). In this case, if the voltage is interrupted for a time longer than 1 ~ 2 sec, the above memory effect can not be observed. This fact suggests that the layer-like spatial inhomogeneity of conductivity disappears in a certain time by light illumination under the condition of removed bias voltage.

It has been found that the dependence of the domain velocity v_d upon the light intensity B in the Se film is represented by $v_d = kB^x$ ($x = 0.7 \sim 1.0$), where k and x are constants and x is independent of the bias voltage. From this equation, it can be expected that if the light intensity decreases to zero during the domain traveling, the domain velocity also decreases to zero, *i.e.*, the domain stops and can remain unchanged; accordingly the light-controlled phase-memory effect can be expected.

We believe that the negative differential conductivity responsible for the domain formation is caused by the field-quenching effect which is defined for p-type photoconductors as a redistribution of trapped electrons from slow to fast recombination centers caused by an electric field, resulting in a shorter lifetime of the photoexcited free holes. Thus, the layer-like spatial inhomogeneity of conductivity in the sample is formed by the redistribution of the trapped charges. Therefore, if the trapping levels are deep enough or the temperature of the sample is sufficiently low, the thermal excitation of the trapped charges to the valence or to the conduction band is scarcely possible. Consequently, once a layer-like spatial inhomogeneity of conductivity is formed by the field quenching, it remains unchanged even if the light is turned off (light-controlled phase memory effect) or even if both the light and the bias voltage are turned off (nonvolatile phase-memory effect).

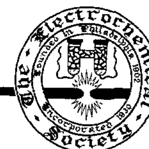
DISCUSSION SECTION



This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 124, No. 7, and 9, July and September 1977.

A Quantitative Model for the Diffusion of Phosphorus in Silicon and the Emitter Dip Effect

R. B. Fair and J. C. C. Tsai
pp. 1107-1118, Vol. 124, No. 7

F. A. Kroger:[1] The authors make an impressive effort to solve the problem of diffusion of P in Si. Although the proposed model appears to give a satisfactory representation of $D(x)$ (Fig. 15 in the paper being discussed), it does not give the proper dependence of n on C_T close to the surface. Also there are a few incorrect statements and inconsistencies that need correction. A new simple model is proposed in which only PV^- accounts for all the variations observed. In the following, numbers of references and equations are those of the paper under discussion.

1. The derivation of Eq. [6], intended to be the justification of Eq. [1], contains an inconsistency. Equation [5] (on which Eq. [6] is based) was derived from Eq. [4] with the unstated assumption $C_{P+} = n$. Experimentally, at high P concentrations, $C_T \approx 2n$ and thus $C_T = 2C_{P+}$. But $C_T = C_{P+} + C_{PV}$. Hence $C_{P+} = C_{PV-}$. But then $C_{P+} \neq n$, contrary to what was assumed! Evidently the more complete neutrality condition $C_{P+} = n + C_{PV-}$ has to be used. This leads to

$$C_{PV-} = \frac{Kn^3}{1 - Kn^2} \qquad \text{instead of Eq. [5]}$$

and

$$C_T = n + \frac{2Kn^3}{1 - Kn^2} \qquad \text{instead of Eq. [6]}$$

Here $K = K_V K_v K_P$ with

$K_v = C_V{}^\times, K_v = C_V{}^=/C_V{}^\times n^2,$

and $K_P = C_{PV}{}^-/C_P{}^+C_V{}^=$

2. For $n \approx C_{PV-} = ½\, C_{P+}$, $C_T = C_P + C_{PV-} = 3n$; for $n = 2C_{PV-} = 2/3\, C_{P+}$, $C_T = 2n$. Thus $C_{PV-} \leqq n$, and not $> n$ as assumed in Fig. 13.

3. Formulae [1] and [6] suggest that since $C_T = C_{P+} + C_{PV-}$, the first term represents C_{P+}, with $C_{P+} = n$, and the second C_{PV-}. This is not the case. At large C_T, $C_{P+} > n$ with $n \approx C_{PV-}$. Only at small C_T is $C_{P+} \simeq n$.

4. Equation [15] and the accompanying text suggest that the pair PV^- loses an electron to the conduction band when $E_F = E_c - 0.11$ eV. However, the energy indicated corresponds to the energy level of free $V^=$ and not of $V^=$ as present in the pair: the latter will have a level close to that of free V^-, at $E_c - 0.39$ eV. Therefore PV^- itself does not give up an electron. However, PV^- is in equilibrium with P^+ and $V^=$ through Eq. [12]. Therefore when $V^=$ loses an electron, $C_{V=}$ decreases and thus C_{PV-} decreases, reaction [12] proceeding to the left. On the other hand, the neutral associate, PV, remains at a low concentration because of its smaller binding energy. Equation [15] is correct as far as its left and right parts are concerned; the central part is in error. Equation [16] remains correct if $n = C_{P+}$ (which is correct when C_T has decreased sufficiently, *i.e.*, at 1000°C, $C_T \approx 10^{20}$ cm^{-3}). However, when $n = n_e$, C_{PV-} has no longer the value it has at the surface but must have decreased. Therefore one should not use [13], and [17] must be incorrect.

5. Expressions [2] and [7] for $D(n)$ are not as generally valid as the authors (and Shaw) believe. If X is the defect transporting the chemical element Y, with a total concentration C_T, the flux of X or Y is equal to

$$J_Y = J_X = -D_X \frac{\partial C_X}{\partial x} = -D_X \frac{\partial C_X}{\partial C_T} \frac{\partial C_T}{\partial x}$$

with $(D_Y)_{\text{effective}} = D_X \dfrac{\partial C_X}{\partial C_T}$

This effective diffusion coefficient is a function of concentration or, if X is charged, of the electron concentration or the Fermi level, if $\partial C_X/\partial C_T = f(C_T,n)$. This is the case, if X is a minority species. However, $\partial C_X/\partial C_T$ is constant if X is a majority species. Then $\partial C_X/\partial C_T = f =$ constant with $f = 1$ or a simple fraction. A situation in which $\partial C_X/\partial C_T$ is dependent on C_T but independent of n occurs when $C_T \approx C_{PVP}{}^\times$ with $C_{PV-} \approx C_{P+}$, PV^- being the P-carrying species. Owing to the triplet formation reaction $PV^- + P^+ \rightleftarrows PVP^\times$

$$\frac{C_{PVP}}{C_{PV-}C_{P+}} = K_T,\ C_{PV-} = f(C_T)$$

However, because of $P^+ + V^= \rightleftarrows PV^-$

$$\frac{C_{PV-}}{C_{P+}C_{V=}} = K_P \text{ or } C_{V=} = K_P{}^{-1}\frac{C_{PV-}}{C_{P+}} = K_P{}^{-1}$$

and, since $n \propto C_V{}^{1/2}$, n is also constant. One of these situations may apply to Si:As at high arsenic concentrations (see Fig. 11), arsenic being transported by AsV^- and not by $AsV^\times$ as assumed by the authors (see Fig. 6).

6. The conclusion that electric field effects play a role independent of the charge of a migrating species cannot be correct: the charge is the very reason for this effect. Reference (22) does not contain information proving that As migrates as As^+V^-. An argument that could possibly be based on Figure 11 was refuted above (see 5).

7. Reference (53) does not mention ΔH_V. The value $\Delta H_{V^\times} = 2.66$ eV is not mentioned in Ref. (22), but in ftn.[2] However, no values for ΔH_{V-} and $\Delta H_{V=}$ are given. It is unlikely that the latter should be larger than $\Delta H_{V^\times}$ if the Fermi level is at E_c (as stated); in that

[1] Department of Materials Science and Electrical Engineering and Chemistry, University of Southern California, University Park, Los Angeles, California 90007.

[2] *Phys. Rev. B*, **14**, 3551 (1976).

case energy is gained by the attachment of electrons to $V^\times$ and therefore ΔH_{V^-} and $\Delta H_{V^=} < \Delta H_{V^\times}$.

8. Figure 13 shows assumed profiles for PV^- and e^-, showing no gradient in the concentrations of these species at low x. This, of course, cannot be correct; if there is no gradient, there can be no diffusion. What must happen is that D is large and therefore the gradient required to maintain a flow of P is small. The actual penetration profiles (Fig. 4 and 15) indeed show a concentration gradient at the surface.

9. For the surface concentrations at 1000°C as given in Fig. 4, $C_T \approx 2.52n$. With $C_T = C_{PV^-} + C_{P^+}$ and $C_{P^+} = C_{PV^-} + n$, simple algebra shows that $n = 0.58\ C_{P^+} = 1.38\ C_{PV^-}$. Therefore $C_T = 8.3 \times 10^{20}$, $C_{P^+} = 5.8 \times 10^{20}$, $n = 3.29 \times 10^{20}$ and $C_{PV^-} = 2.5 \times 10^{20}$, all cm^{-3}. The pairing constant of Eq. [12], $K_{P^1} = C_{PV^-}/C_{P^+}C_{V^=} = 4 \exp E_b{}^=/kT$. For $E_b{}^= = 0.81$ eV and $T = 1000$°C, $K_{P^1} = 5.9 \times 10^3$ or 1.14×10^{-19} cm^{-3}. With this value of the constant and C_{PV^-} and C_{P^+} as given above, one finds $C_{V^=} = 3.8 \times 10^{18}$ cm^{-3}, much larger than the value 1.2×10^{15} cm^{-3} expected at $n = 2 \times 10^{20}$ cm^{-3}. The reason probably lies in the low value assumed for $E_b{}^=$. If $E_b{}^- = 0.55$ eV (which seems reasonable), $E_b{}^=$ should be ≈ 1.1 eV, giving $(K_{P^1})_{1000°C} = 3.5 \times 10^5 = 6.8 \times 10^{18}$ cm^3 and $C_{V^=} = 6.34 \times 10^{16}$ cm^{-3}, a more acceptable value. Concentrations of other defects at the surface are found using the equations and mass action constants

$$V^- + e^- \rightleftarrows V^=; \quad K_2 = \frac{C_{V^=}}{C_{V^-}n} = \left(\frac{h^2}{2\pi m_e{}^*kT}\right)^{3/2} \exp 0.11\ \text{eV}/kT$$

$$V^\times + e^- \rightleftarrows V^-; \quad K_1 = \frac{C_{V^-}}{C_{V^\times}n} = \left(\frac{h^2}{2\pi m_e{}^*/kT}\right)^{3/2} \exp 0.5\ \text{eV}\ kT$$

$$P^+ + V^- \rightleftarrows PV^\times; \quad K_P = \frac{C_{PV^\times}}{C_PC_{V^-}} = 4 \exp 0.55\ \text{eV}/kT$$

$$P^+ + V^\times \rightleftarrows PV^+; \quad K_{P^+} = \frac{C_{PV^+}}{C_{P^+}C_{V^\times}} = 4 \exp 0.25\ \text{eV}/kT$$

with $m_e{}^* = 1.25$, $(K_2)_{1000°C} = 8.6 \times 10^{-21}$ cm^3, $(K_1)_{1000°C} = 3 \times 10^{-19}$ cm^3, $(K_P)_{1000°C} = 1.2 \times 10^{-21}$ cm^3 and $(K_{P^+})_{1000°C} = 7.6 \times 10^{-22}$ cm^3. The result is: $C_{V^-} = 2.2 \times 10^{16}$, $C_{V^\times} = 2.2 \times 10^{14}$, $C_{PV^\times} - 1.53 \times 10^{17}$ and $C_{PV^+} = 9.7 \times 10^{13}$, all cm^{-3}.

10. Starting from the concentrations established by complete equilibrium at the surface (see above), one can calculate defect concentrations as $f(C_T)$ inside the crystal, making one of various possible assumptions: (*i*) assume that all processes except vacancy formation reach equilibrium, but that the vacancy concentration remains fixed at the value established at the surface, *i.e.*,

$$(C_V)_T = C_{PV^-} + C_{PV^\times} + C_{PV^+} + C_{V^=} + C_{V^-} + C_{V^\times} = 2.5 \times 10^{20}\ \text{cm}^{-3}$$

(*ii*) assume that all processes, including vacancy formation reach equilibrium (calculate n from

$$C_T = n + 2\,C_{PV^-} = n + \frac{7.72 \times 10^{-47}n^3}{1 - 3.86 \times 10^{-42}n^2}$$

(*iii*) assume (*ii*) up to a certain depth below the surface, and change to (*i*) at greater depths. Results of calculations according to (*i*) and (*ii*) using values of the constants as mentioned under 9 are given in Tables I and II. Although (*i*) seems to be best in line with the assumption of excess vacancy generation by splitting of PV pairs, Table I shows this model gives a decrease of n faster than proportional to C_T, contrary to what is observed (see Fig. 4). Case (*ii*) (Table II), on the other hand, shows the proper variation of n with C_T, but does not show the increase of C_{PV^+}/C_T or $C_{PV^\times}/C_T$ with decreasing C_T required to explain the increase of $D \propto n^{-2}$. Case (*iii*) may give the best over-all description.

Table III shows the result for the case that vacancy equilibration is frozen in ≈ 0.8 μm from the surface, where $C_T \approx 2 \times 10^{20}$ cm^{-3}. Table III shows that C_{PV} and C_{PV^+} are always << C_{PV^-} and therefore will not play an important role in P diffusion. On the other hand the ratio $r = C_{PV^-}/C_T$ shows the variation needed to explain the observed variation of D_P with concentration: r decreases with decreasing C_T from 8.3 to 2.1×10^{20}, accounting for the decrease of D_P; r increases from $C_T = 2 \times 10^{20}$ to $C_T = 7 \times 10^{19}$, accounting for the increase in D_P, r then becomes approximately constant at a value close to ½ (giving D_P= constant); r finally decreases (which should give a decreasing D_P) but by now we are well below the concentration (Fig. 6, $n = 10^{19}$) down to which D_P was measured. The agreement can probably be im-

C_{PV^-}/C_T	1.6×10^{-1}	10^{-1}	1.2×10^{-1}	1.8×10^{-1}	3.0×10^{-1}	4.0×10^{-1}	1.9×10^{-1}

proved by a slight modification of the various constants. Even the result as presented, however, seems sufficiently satisfactory to allow us to conclude that the entire diffusion behavior of P can be explained on the basis of PV^- as the only P-transporting species.

R. B. Fair and J. C. C. Tsai:[3] The first point raised by Professor Kroger concerns the relationships between ionized phosphorus concentration, C_{P^+}, the phosphorus-double ionized vacancy concentration, C_{PV^-}, and electron concentration, n, in P-doped Si. We have assumed $C_{P^+} = n$ to derive the equilibrium relation between total P concentration, C_T, and n. Therefore, C_{P^+} only refers to the unpaired P^+ atoms in the Si. Dr. Kroger's argument that this leads to an inconsistency is not valid. The claim that $C_T \simeq 2n$ is only true near $n = 2 \times 10^{20}$ cm^{-3} (see Fig. 5). Thus, $C_{P^+} = C_{PV^-}$ only at this concentration indicating that 50% of the P atoms are paired with $V^=$ vacancies. The total P concentration is

$$C_T = C_{P^+} + C_{PV^-} \qquad [1A]$$

At higher electron concentrations, $C_{PV^-} > C_{P^+}$ and the relation $C_{P^+} = n$ cannot be proven wrong by saying Eq. [1A] above is invalidated as Kroger argues.

If one prefers to account for the ionized P through the relation

$$C_{P^+} = n + C_{PV^-} \qquad [2A]$$

as Kroger proposes, the relationship between C_T and n still turns out approximately the same. On this basis

$$C_T = n + \frac{2Kn^3}{1 - Kn^2} \qquad [3A]$$

plots very nicely on our Fig. 5 with $K = 8.3 \times 10^{-42}$ cm^6. However if one uses Kroger's relation for C_{PV^-}, then

$$C_{PV^-} = \frac{Kn^3}{1 - Kn^2}$$

$$\propto n^5 (n \lesssim 1.5 \times 10^{20}) \qquad [4A]$$

Our Eq. [13] predicts $C_{PV^-} \propto n^3$ which is supported by the $n_s{}^3$ dependence of the tail region diffusion coefficient shown in our Fig. 9. Therefore, the data would suggest that using $C_{P^+} = n$ is still reasonable.

In order to make easier reference. the remaining comments will be numbered to coincide with the items in Kroger's discussion.

2. By using Eq. [4A] above it can be shown that for $C_T > 7.5 \times 10^{20}$ cm^{-3}, $C_{PV^-} > n$. Thus, at high concentrations, Fig. 13 is correct.

3. Again, it all depends upon how you wish to do your accounting. However, this argument Kroger presents is not valid since $n = C_{PV^-}$ is not generally true.

4. The tightly bound PV^- pair has a level at $E_C - 0.39$ eV. However at diffusion temperatures the vacancy can move to second and third neighbor sites without completely dissociating from the P^+ atom. This is a result of the distributed nature of the charge associated with a vacancy and the long-range Coulomb binding of the pair. During these excursions the effect of pair association on shifting the ionization energy of the vacancy's second acceptor level would be reduced. If the vacancy gives up an electron from this level while at a third neighbor site, the pair binding enthalpy would be reduced by ~0.3 eV and pair dissociation would be assured.

Equation [17] in our paper is not rigorously derived because of the simplifying assumption that the concentration of PV^- pairs at $n = n_e$ is proportional to the surface electron concentration ($\propto n_s{}^3$). The argument is that the PV^- concentration is relatively constant out to a distance that is within "jumping distance" of $n = n_e$. Thus, we assume only a "quasi-equilibrium" of PV^- pairs at $n = n_e$ which reflects the equilibrium conditions near the surface.

5. For the case of P in Si the flux equation for PV^- pairs must include an electric field term since the PV^- pairs are in equilibrium with C_{P^+} (and thus, n). One cannot dispute the fact that a built-in electric field exists in the diffused layer, since n decreases with increasing depth into the Si. Kroger's flux equation should be written as

$$J_Y = J_X = -D_x \frac{\partial C_x}{\partial C_T} \frac{\partial C_T}{\partial x} - D_x C_x \frac{1}{n} \frac{\partial n}{\partial x} \qquad [5A]$$

The total flux consists of PV^- (or $P^+V^=$) pairs, PV (or P^+V^-) pairs and PV^+ (or $P^+V^\times$) pairs. Thus

$$J_T = J_{PV^-} + J_{PV} + J_{PV^+} \qquad [6A]$$

At very high P concentrations, the dominant diffusing species is the PV^- pair. Thus

$$J_{PV^-} = -D^= \left[\frac{\partial C_{PV^-}}{\partial C_T} \frac{\partial C_T}{\partial x} + \frac{C_{PV^-}}{n} \frac{\partial n}{\partial x} \right]$$

$$= -D^= \left[1 + \frac{\partial n}{\partial C_T} \left(\frac{C_{PV^-}}{n} - 1 \right) \right] \frac{\partial C_T}{\partial x} \qquad [7A]$$

At values of $C_T \lesssim 7 \times 10^{19}$ cm^{-3}, $\partial n/\partial C_T \simeq 1$ and $C_{PV^-} << n$. Thus, $J_{PV^-} \simeq 0$. At $C_T \gtrsim 3 \times 10^{20}$ cm^{-3}, $\partial n/\partial C_T \simeq 1/3$ (from Fig. 5 in our paper). For the case of no electric field

$$J_{PV^-} = -D^= \left[1 - \frac{\partial n}{\partial C_T} \right] \frac{\partial C_T}{\partial x} \qquad [8A]$$

The ratio of J_{PV^-} (with E field)/J_{PV^-} (no field) varies from ~1.3 at $C_T = 3 \times 10^{20}$ cm^{-3} to 2.7 at $C_T = 1 \times 10^{21}$ cm^{-3}. Therefore, the effect of the built-in field on on the diffusion of PV^- pairs is important and is approximated by the field factor, $h \simeq 2$, in Eq. [2] and [7] from our paper.

For the case of As in Si, if AsV^- were the dominant species transporting As, an n^2 dependence would be observed for As diffusivity at high concentrations. However, As diffusivity increases linearly with n, supporting the $AsV^\times$ (or As^+V^-) pair model.

6. As we have just shown, the equilibrium distribution of electrons created by the unpaired P^+ atoms creates the built-in field which, in fact, influences P diffusion regardless of the charge state of the domi-

[3] Bell Laboratories, Reading, Pennsylvania 19604.

nant vacancy responsible for diffusion. Thus, for each kind of P-vacancy pair, an equation similar to Eq. [7A] above can be written.

7. We disagree that the formation enthalpy of V^- and $V^=$ should be less than for $V^\times$. True, energy is gained when an electron attaches to $V^\times$. However, because a vacancy has no central ion core, another carrier of opposite charge must be created (in the valence band). Thus, energy must be added to take an electron from the valence band to the conduction band, and ΔH_{V^-} and $\Delta H_{V^=} > \Delta H_{V^\times}$ by the ionization entropies ΔH_I^- and $\Delta H_I^=$, respectively. Van Vechten and Thurmond have discussed this in recent papers.[4,5]

8. Figure 13 is only claimed as a simplified, ideal profile.

9. We agree that the binding energy for the PV^- pair may be too low ($E_b^= = 0.81$ eV). Since we arrived at $E_b^=$ from the expression

$$E_b^= = \Delta H_{V^=} + Q_E^= - Q_I^=$$

where $\Delta H_{V^=} = 3.93$ eV is the formation enthalpy of $V^=$ vacancies, $Q_E^= = 1.25$ eV is the pair migration energy, and $Q_I^= = 4.37$ eV is the phosphorus diffusion energy, we are subtracting relatively large numbers from each other. With the uncertainty associated with these numbers, it is not unreasonable to be off by 0.3 eV in the calculation of $E_b^=$.

10. It is clear to us that none of the examples presented in Kroger's Tables I, II, or III are correct. As Kroger points out, the model presented in Table I yields a decrease in n faster than proportional to C_T, and the results in Table II cannot account for $D \propto n^{-2}$, both contrary to what is observed. However, the same can be said for the results in Table III where a large difference is calculated between C_T and n. Experimentally, $C_T = n$ for all concentrations below $\sim 5 \times 10^{19}$ cm^{-3} (see Fig. 5). The Table III model also predicts that P is only transported by PV^- pairs. This is unreasonable. The data in Fig. 7 of our paper show that for high concentration diffusions below 1000°C, the tail region diffuses faster than the surface region. For example, at 900°C the tail diffusivity is $\sim 10^{-13}$ cm^2/sec for a P profile with $C_S \simeq 5 \times 10^{20}$ cm^{-3}. The peak P diffusivity in the surface is 3×10^{-14} cm^2/sec. This result suggests that a different species is transporting P in the tail which we contend is the P^+V^- (or PV^x) pair and which has approximately a four times larger intrinsic diffusivity than the PV^- pair at 900°C. Also, the data in our Fig. 7 show that below $n \simeq 7 \times 10^{19}$ cm^{-3}, the diffusion coefficient of P no longer shows an n^2 dependence. When the surface concentration is also below $\sim 7 \times 10^{19}$ cm^{-3} (or $n_s/n_i \lesssim 7$), Fig. 11 shows that P diffusivity is constant (except for the electric field contribution). These two observations support our model that the PV^- pair only exists at high P concentrations ($n > n_e$). When $n_s/n_i \lesssim 7$, the dominant diffusing pair is the P-neutral vacancy ($P^+V^\times$) specie.

In conclusion, we feel that our model is valid to the extent that we have assumed quasi-equilibrium conditions at $n = n_e$ which reflects surface equilibrium. It is clear to us that this is the most consistent model to emerge among the dozen or so P diffusion models proposed over the past 20 years. However, our model does not predict the "anomalous" reduction in junction depth with increasing surface concentration as observed by Duffy *et al.*[6] Recent work by one of us (RBF) has shown that the misfit strain introduced by high concentrations of P causes the Si bandgap to be narrowed by as much as -0.13 eV at the P solubility limit. This bandgap shrinkage results in a reduction of PV^- pairs through mass action effects which can reduce P diffusivity by as much as 70%. These results are explained with our present model as a basis, and will be published in the near future.

Auger Analysis of Thermally Oxidized GaAs Surfaces

I. Shiota, N. Miyamoto, and J. Nishizawa
(pp. 1405-1409, Vol. 124, No. 9)

R. W. Kee:[7] In the paper under discussion, there are several important errors made by the authors in analyzing the Auger depth profiles of thermally oxidized GaAs. The initial statement was made that the higher energy states, $L_3M_{4,5}M_{4,5}$, for Ga and As were used for in-depth profiling in order to avoid peak overlapping as observed in the lower energy range (<100 eV) and to obtain precise peak-to-peak values of their Auger signals. However, their Auger equipment parameters, specifically the modulation amplitude, time constant, and sweep rate which were 5 eV, 1 sec, and 6 eV/sec, respectively are such as to prevent accurate peak measurement. As shown in Fig. 1,

[7] Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523.

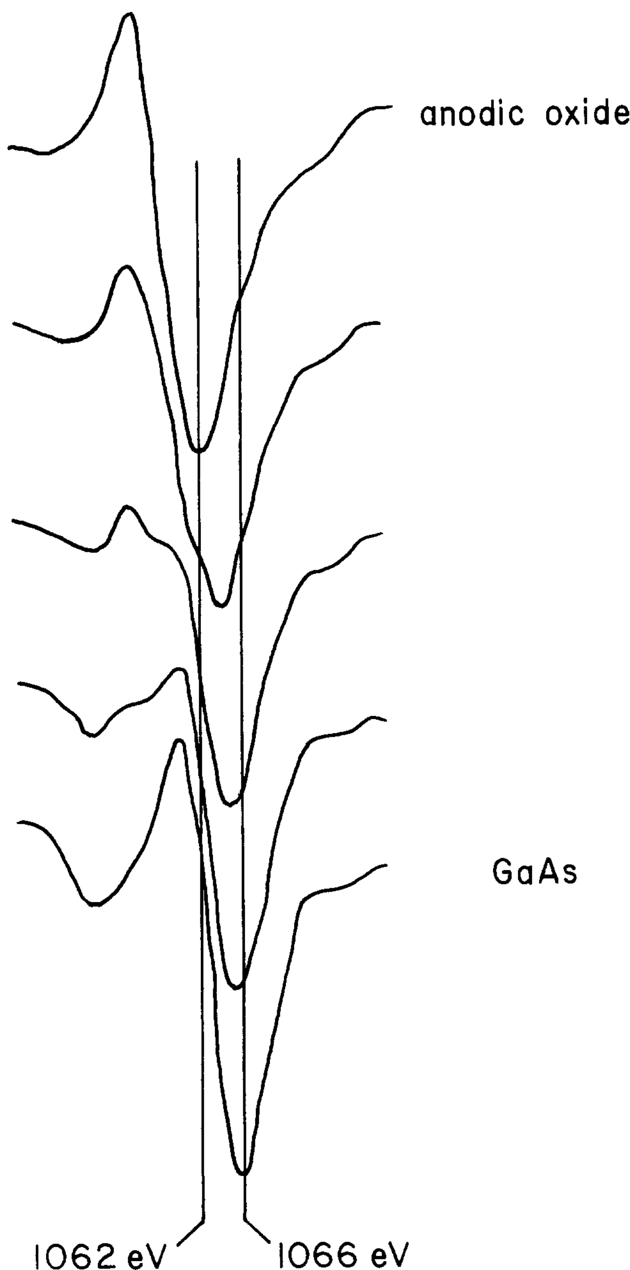

Fig. 1. Ga LMM Auger line progression from the outer anodically grown oxide, through the interfacial region, and into the GaAs substrate.

which was taken from work in our own laboratory on anodic oxide/GaAs structures, peak overlap occurs because the Ga LMM line for Ga_2O_3 is some 4 eV lower than that for GaAs, and since both chemical states are distinct.[8] The Ga LMM line progression of Fig. 1 was obtained by using a low modulation voltage of 2 eV, a reduced sweep rate of 1 eV/sec, and recording the individual Auger peaks for Ga while sputtering through the oxide and into the GaAs substrate.

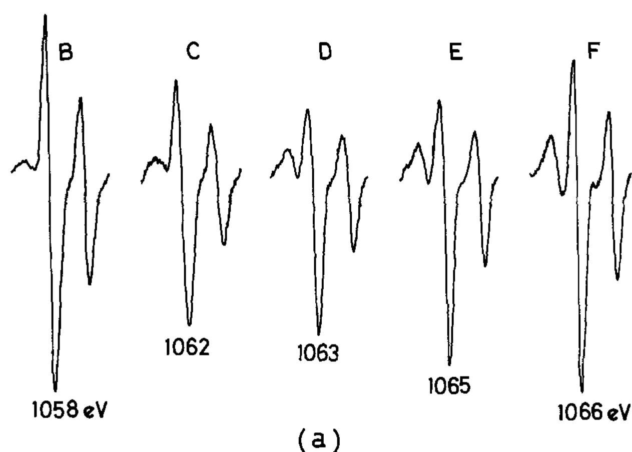
Several researchers have found that the "valley" which occurs at the interface of a grown oxide/semiconductor[9,10] or metal[11] structure is merely an artifact due to the simultaneous addition of the Auger lines for a given element in two distinct chemical states, and does not necessarily indicate a depletion of that given element in or near the interface. The depletion or even accumulation of an element can only correctly be deduced when a concentration *vs.* depth profile has been constructed by taking into account the relative Auger sensitivities[12] for the elements involved and the effects of overlap of the two distinct states. It is important to note that the Auger sensitivity for an element can change with chemical state.[8,13] From Fig. 4 and 6 of the authors' paper, one observes that from simply considering the chemical configuration, *e.g.*, Ga_2O_3 (thermal oxide) and GaAs, Ga should occur in concentrations of 40% and 50%, respectively, however, the Auger peak-to-peak height for Ga in Ga_2O_3 is roughly 40% greater than that of GaAs, which is not consistent with their statements.

Upon construction of a concentration *vs.* depth profile by the authors, they will probably find that the occurrence of a Ga depletion at the oxide-GaAs interface is a phenomenon only observed in the Auger peak-to-peak profile, and is not found in the concentration *vs.* depth profile.

The authors' technique of defining the oxide thickness based upon whether the Auger peak ratio, 0/Ga, starts to decrease from the value of 1.75 for the bulk oxide, is rather unique since most researchers define the oxide thickness by drawing tangent lines to the 0 KLL peak-to-peak amplitudes and labeling the oxide thickness by either, where the 0 KLL peak height reaches 10% of its original value,[14] or where the tangent line in the interfacial region intersects the tangent line from the zero level of 0 KLL in the substrate.[9] If either of these conventions were employed in the present article, the constructed data values for the activation energy, E_a, would change due to the contribution of the increased interfacial width with increased oxide thickness. An additional complication would come from the Auger peak-to-peak height profile which was given in Fig. 5 for the 700°C thermal oxide on GaAs (111)B. If the depth profile results of Fig. 5 were reproducible, then the situation is indeed interesting, however, a misalignment of the ion and electron beams can also give a similar broadening of the interfacial region.[9]

I. Shiota, N. Miyamoto, and J. Nishizawa:[15] First of all, we must make a simple and important correction about a measuring parameter of AES; the time constant of the lock-in amplifier was not 1 sec, which was stated erroneously in the original paper, but 0.1 sec in all our AES measurements.

Now, the main point of the rebuttal made by R. W. Kee is that the Ga depletion observed



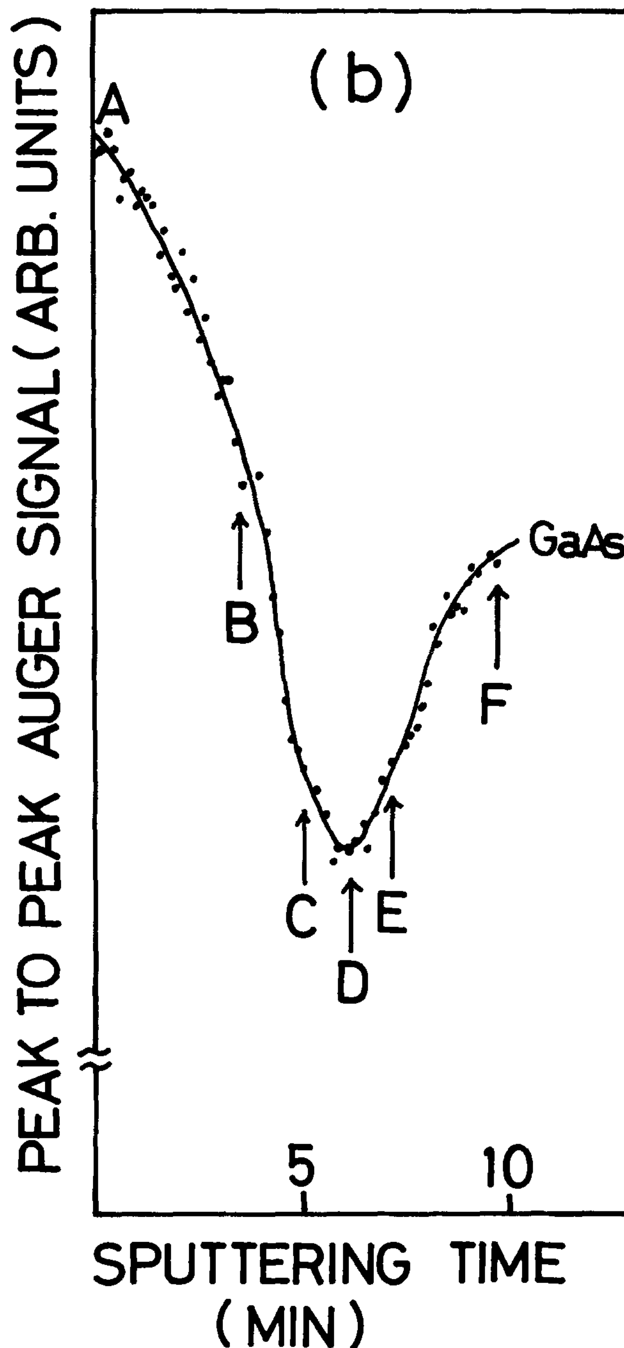


Fig. 2. The Ga $L_{2,3}M_{4,5}M_{4,5}$ Auger spectra. Each spectrum in (a) was resulted correspondingly from each point on depth-profile as shown in (b). Argon sputtering voltage is 2 kV and a Ga $L_3M_{4,5}M_{4,5}$ peak was monitored.

near a thermal oxide-GaAs interface is merely an artifact characteristic of in-depth profiling by using peak-to-peak Auger height. It is of course most suitable to discuss the matter quantitatively from a concentration *vs.* depth profile as indicated, but it is even possible to deduce some conclusions based on a qualitative and a careful observation of the AES spectra and on the assistance from concrete phenomena concerned. In the case of SiO_2-Si interfaces, Si Auger peaks such as KLL one show a clear splitting into 1618 and 1606 eV in our spectrometer[16] leading to the apparent decrease in concentration of Si if only the over-all peak-to-peak height is monitored. At the thermal oxide-GaAs interface we could not observe any splitting of the $GaL_3M_{4,5}M_{4,5}$ peak as shown in Fig. 2. (Measuring parameters are the same as those of original depth profiling data and as follows; modulation amplitude 5 eV, scanning rate 6 eV/sec, and time constant 0.1 sec. No peak splitting was observed in the $GaL_3M_{4,5}M_{4,5}$ peak even under the more precise condition of MA 2 eV, SR 1 eV/sec, and $\tau = 0.1$ sec, while the lower part $GaM_{2,3}M_4M_4$ peaks showed a clear splitting as seen from a spectrum 3 of the original Fig. 3.) Auger peak shape varies in a rather simple manner, as going from oxide to GaAs and the positive peak suppression seen at the anodic oxide-GaAs interface is not so serious in our case.

Peak-to-peak width ΔE takes a maximum value around a point C located just outside the bottom of the valley and ΔE is equal at a point E and a point F. Therefore, the region from the point C to D seems to be the one with a largest chemical effect to the GaLMM Auger peak. Since the region E and F almost consist of Ga and As, there seems to be little difference in Auger sensitivity, especially in escape depth, comparing with that of GaAs bulk. This is supported from the fact that the appearance energy, ΔE, and the shape in Ga LMM peak are almost the same in E and F point.

From above qualitative discussions the decreasing trend from F to E seems to be fundamental, while around the bottom of the valley the tendency may be enhanced by the chemical effect. The same conclusion is conducted from the behavior of $GaM_{2,3}M_4M_4$ peak seen from spectra 4 and 5 in the original Fig. 3.

Further supports are obtained from such actual phenomena that there is observed a large orientation dependence in the shape of the valley and that the Ga valley is closely related to the As accumulation near the interface. We explained the reason of appearance of the Ga valley in the original paper as follows; it was responsible for a selective oxidation of GaAs with a resulting product of Ga_2O_3 and another constituent of As necessarily accumulated around the interface, in other words, the depletion of Ga was accompanied. Therefore, the Ga depletion at the interface is more easily generated by thermal oxidation than by anodic one because of a larger amount of As incorporation in the oxide state in the latter.

Finally, although our method to determine the oxide thickness is not always popular, we could not determine the thickness definitely by the conventional method because of a large dependence of the width of the interface region on oxidation conditions.

Analyzing point is a center of sputtered crater and so the edge effect can be safely ignored in our system.

Electrolytic Etching of Aluminum from an Al-Al_3Ni Two-Phase Matrix in Aluminum Chloride Containing Molten Salts

C. L. Hussey, J. C. Nardi, L. A. King, and J. K. Erbacher
(pp. 1451-1454, Vol. 124, No. 9)

K. P. Quinlan and J. J. Hutta:[17] The paper by Hussey *et al.* describes an electrolytic procedure where aluminum is etched away from Al_3Ni fibers. These fibers are formed in an aluminum matrix utilizing a unidirectional solidification technique.[18] These fibers, when isolated, may possibly have wide applications extending from the area of catalysis[19] to microelectronic devices. In their electrolytic etching procedure, Hussey *et al.* used two molten salts containing aluminum chloride which requires inert atmospheres and high temperatures. We have developed a procedure where high quality Al_3Ni fibers can be obtained using 1*M* potassium hydroxide as the electrolyte. The method is carried out within a time period where the Al_3Ni fibers are not attacked by the 1*M* KOH. The advantages of a 1*M* KOH electrolyte over molten salts containing aluminum chloride are obvious.

Control potential electrolyses were accomplished with a potentiostat/galvanostat (Princeton Applied Research Corporation, Model 173) equipped with a current to voltage converter (PAR, Model 176). A universal programmer (PAR, Model 175) controlled the voltage output of the potentiostat. The cell consisted of a reference saturated calomel electrode, a platinum counterelectrode, and the aluminum-Al_3Ni ingot as the working electrode. The electrolyte was the 1*M* KOH solution. An agar-saturated KCl salt bridge was used with the calomel electrode. Contact to the Al-Al_3Ni ingot was made by wrapping platinum wire around the ingot. Electrolyses were carried out for 1 1/2 hr at a potential of -0.2V in unstirred solutions. Maximum anodic current was observed at -0.2V in the anodic polarization curve of the Al-Al_3Ni electrode. The current density decreased from an initial value of 0.02 to 0.01 A/cm^2 during the electrolyses. The ingot turned black and was composed of a matted mass of Al_3Ni fibers. Scanning electron micrographs of the product illustrated the preferential etching of aluminum leaving well-defined fibers. Energy-dispersive x-ray analysis verified their composition of aluminum and nickel.

The present method has the additional advantage of being applicable to a continuous process where the fibers can be removed and the KOH replenished.

Stress Corrosion Crack Initiation Sites in Zirconium Alloys Exposed to Iodine Vapor

D. D. Cubicciotti* and R. L. Jones

SRI International, Menlo Park, California 94025

Stress corrosion cracking (SCC), induced by fission products, is believed to be responsible for occasional service failures of the cladding of light water reactor fuel rods (1). It has been known for some time that iodine, an abundant fission product, is capable of promoting slow crack growth at cladding service temperatures in zirconium alloys (2). Both experimental results (2, 3) and theoretical considerations (4) indicate that the formation of a sharp crack in the metal surface is the key event in the overall iodine SCC failure process but it has proved difficult to elucidate the crack initiation mechanism (2).

We have recently completed an investigation of iodine-induced crack initiation and have found that the crack nuclei responsible for iodine-induced SCC failure invariably form at sites in the metal surface that contain unusually large local concentrations of alloying elements or impurities (3). In our study, samples of nuclear grade zirconium alloy sheet or thin walled tubing were deformed at about 600 K by pressing a 1.6 mm steel ball against them. As a result, a small region of the surface opposite the indenter was deformed to a strain of a few percent in biaxial tension while being exposed to a gas containing a small pressure of iodine vapor. After the test, the deformed region was cut out, cleaned by argon-ion milling, and examined for cracks in an SEM equipped with an energy dispersive X-ray analyzer.

In the absence of iodine, cracks in the metal were observed only under very severe mechanical conditions and were probably due to creep-rupture failure. When iodine was present cracks occurred under much milder mechanical conditions but not in the complete absence of strain. Therefore, we attributed the cracks formed in the presence of iodine to SCC. Two distinctly different types of iodine-induced cracks were observed in all materials tested (stress relieved Zircaloy-4, stress relieved Zircaloy-2, and annealed Zircaloy-2). Small cracks were observed in all samples strained in iodine, and in occasional samples relatively large cracks were also observed.

The small cracks, which were rarely larger than one or two grain diameters, generally formed at microstructural inhomogeneities (such as certain grain boundaries in recrystallized material) that would be expected to be associated with large local stress concentrations in an anisotropic material undergoing plastic flow. These crack initiation sites were not associated with any detectable chemical inhomogeneities. Some typical small cracks are shown in Figure 1. The larger cracks, which ranged in size up to ten or more grain diameters, were observed in about 30% of the samples and differed from the small cracks in that they were consistently associated with local concentrations of impurities (Al, Si, or Ti) or alloying elements, i.e., Fe, Cr, Sn.

To investigate the relation of these two types of cracks to iodine-induced SCC failure, two lengths of annealed Zircaloy-2 tube were pressurized for 30 minutes at 595 K with helium and iodine mixtures. The pressures were such that the nominal hoop stresses were 210 MPa and 310 MPa which are respectively below and above the threshold stress for iodine induced failure of the tubing, (~ 280 MPa, see Reference 3). Sections of the inner surfaces were ion cleaned and examined in the SEM. Small intergranular cracks similar to those in Figure 1 were observed in both samples. Larger cracks associated with chemical inhomogeneities occurred at many sites in the sample stressed at 310 MPa

*Electrochemical Society Active Member.

Key words: Cracking; Metals; Nucleation; Fission

but were not observed in the sample stressed at 210 MPa. An example of a larger crack is shown in Figure 2. The crack is associated with a local impurity concentration and follows the boundary of the impurity-rich region. The crack in Figure 2 is of exactly the same type as the larger cracks observed in the indenter tests.

We interpret these results to indicate that initiation of the cracks that result in iodine-induced SCC failure occurs most readily at sites in the metal surface that contain higher-than-average local concentrations of alloying additives or impurities. It is possible that microsegregation of alloying elements and impurities also plays an important role in crack initiation in other cases of SCC. If so, improved resistance to SCC failure may be achievable by devising treatments that eliminate microsegregation in component surfaces because the conditions required for crack initiation frequently define the SCC failure threshold for as-fabricated components.

Reduction of Oxygen on Teflon-Bonded $NiCo_2O_4$/Graphite Electrodes

A. C. C. Tseung* and K. L. K. Yeung**

Department of Chemistry, The City University, St. John Street, London EC1, England

1. INTRODUCTION

King and Tseung (1)(2)(3) studied the reduction of O_2 on freeze-dried $NiCo_2O_4$ and found that it possessed high activity for the reduction of oxygen (∿ 250 mA/cm^2 at 0.65V, 5N KOH, iR corrected, 100% O_2 room temperature). However, the performance decreased to less than 2 mA/cm^2 within 2-3 hrs. X-ray and thermogravimetric measurements and solid state chemistry considerations suggest that the spinel $NiCo_2O_4$ phase, prepared by freeze-drying of the mixed nitrates, followed by thermal treatment at 400°C for 10 hrs, has the following electronic structure:

$$Co^{2+}_{0.9}\ Co^{3+}_{0.1}\ (Ni^{2+}_{0.9}\ Ni^{3+}_{0.1}\ Co^{3+})\ O^{2-}_{3.2}\ O^{-}_{0.8}$$

where cations outside the brackets are in tetrahedral sites and those inside the brackets are in octahedral sites. The existence of loosely bound O^- on the surface is most probably responsible for the high activity of $NiCo_2O_4$ at room temperature. It was thought that the decay in performance was associated with the substitution of OH^- into the lattice (2) and more probably the partial reduction of $NiCo_2O_4$ (4).

Some further investigation on the mechanism of decay is presented in this paper.

2. EXPERIMENTAL

Freeze-dried $NiCo_2O_4$ (1) was used as the catalyst in Teflon-bonded electrodes. The BET surface area was 40 m^2/g and the specific resistivity of the powder $NiCo_2O_4$ was less than 10 ohm-cm. A small number of $NiCo_2O_4$ electrodes were prepared by immersing 100 mesh nickel screens into 2M $Co(NO_3)_2.6H_2O$/1M Ni $(NO_3)_2.6H_2O$ solution, followed by thermal decomposition at 400°C in air. The process was repeated until the $NiCo_2O_4$ leading reached 35 to 40 mg/cm^2. These electrodes were examined by X-ray powder diffraction techniques before and after electrochemical testing.

Electrochemical testing was done on a 'floating' half cell. The potential of the working electrode was monitored with a Dynamic Hydrogen Electrode (DHE). A piece of Pt foil was used as the counter electrode. The potential of the working electrode was controlled by a Chemical Electronics Potentiostat.

3. RESULTS AND DISCUSSION

3.1. Cyclic Voltammetric Studies.--Figure 1 shows the cyclic voltammogram of a Teflon-bonded $NiCo_2O_4$ electrode operated in the floating mode in air, 5N KOH, room temperature. The electrode was continuously scanned from the open circuit voltage (Ca. 1.10 V) to 500 mV vs DHE.

There was a rapid decay over 1 hr. when the current density at 500 mV vs DHE decreased from 120 mA/cm^2 to 50 mA/cm^2. On the other hand, there is practically no change in the performance when the voltage is scanned continuously from open circuit to 750 mV. (Figure 2).

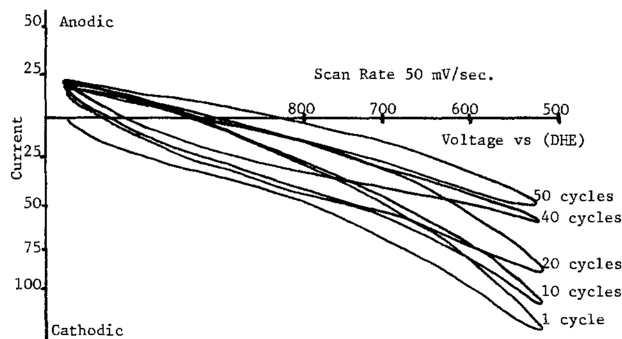

Fig.1. Cyclic Voltammogram of Teflon-bonded $NiCo_2O_4$ electrode from O.C.V. to 500 mV vs DHE, Air, room temperature, 5N KOH

As it is difficult to get clear X-ray powder diffraction patterns of the catalyst in a Teflon-bonded $NiCo_2O_4$ electrode, the electrodes prepared by direct decomposition of the mixed nitrates on nickel screens were used in the X-ray studies.

Table I. X-ray powder diffraction analysis of the $NiCo_2O_4$ electrode in 5N KOH at room temperature

Electrode	Potential (mV) (vs DHE)	Atmosphere	Time	Phases Present
1	500	Air	1 week	Co_2O_3, NiO, CoO, NiOOH, $CoO.H_2O$
2	750	Air	1 week	$NiCo_2O_4$ spinel
3	open circuit	Air	1 week	$NiCo_2O_4$ spinel
4	500	N_2	3 days	Co_2O_3, NiO, CoO, NiOOH, $CoO.H_2O$
5	750	N_2	3 days	$NiCo_2O_4$ spinel

The results clearly show that the $NiCo_2O_4$ spinel is stable at potentials above 750 mV vs DHE. At 500 mV vs DHE, the $NiCo_2O_4$ spinel structure is destroyed completely and the resultant product is a mixture of Co_2O_3, NiO, CoO, $CoO.H_2O$, NiOOH, none of which are active for O_2 reduction. Therefore, it is reasonable to assume that if a Teflon-bonded electrode is operated at or above 750 mV vs DHE, the performance should be stable. This is indeed the case — the performance of a Teflon-bonded $NiCo_2O_4$ electrode remained unchanged at 25 mA/cm^2, 750 mV, 5N KOH, Air over a test period of 130 hrs.

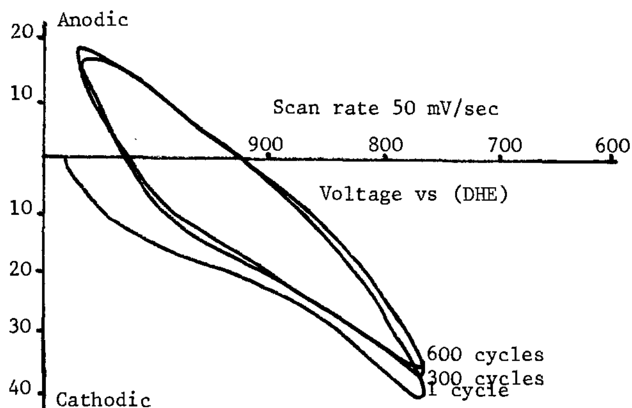

Fig. 2. Cyclic Voltammogram of Teflon-bonded $NiCo_2O_4$ electrode from O.C.V. to 700 mV vs DHE, Air, room temperature, 5N KOH.

Controlled-potential coulometric studies at 500 mV in a stream of N_2 showed that the reduction current is over 4 times greater than the amount required to reduce the loosely bound oxygen, thus giving additional evidence that the bulk of $NiCo_2O_4$ is reduced.

3.2. Performance of Teflon-bonded $NiCo_2O_4$/Graphite electrodes.—Since the current density of $NiCo_2O_4$ electrodes at or above 750 mV vs DHE is only of the order of 30 mA/cm^2 at room temperature, it is necessary to improve the performance by mixing $NiCo_2O_4$ with high surface area graphite (500 m^2/g). Previous work by Goldstein and Tseung (5) on the cobalt-iron oxide/graphite system showed that the reduction of oxygen can be treated as a two step process:

$$(1) \quad O_2 + H_2O + 2e = HO_2^- + OH^-$$

$$(2) \quad 2HO_2^- = O_2 + 2OH^- \text{ (catalytic decomposition)}$$

The evolved O_2 is then recycled for further reduction in (1). The maximum possible enhancement for a cobalt-iron oxide/graphite electrode is a doubling of a graphite electrode's i_o. Cobalt-iron oxide is a non-conductor which has good H_2O_2 decomposition activity but it cannot reduce oxygen. On the other hand, since $NiCo_2O_4$ is a good peroxide decomposition catalyst, as well as a relatively active oxygen reduction catalyst, we expect such combinations to be more active. The performance of Teflon-bonded $NiCo_2O_4$/graphite, and graphite electrodes at 20 and 70°C shows (Figure 3) that 10 wt% $NiCo_2O_4$/graphite electrodes give 200 mA/cm^2 at 750 mV, significantly better than graphite electrodes. Further optimization should lead to more significant improvements.

Effects of Calcium, Potassium, and Iron Ions on Degradation of β″-Alumina

Itaru Yasui[1] and R. H. Doremus*

Department of Materials Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The influence of calcium, potassium, and iron impurities in sodium-sulfur cells on β″-alumina electrolytes were studied. Sections of the ceramic were analyzed with the electron microprobe after cyclic electrolysis of the cells. No degradation by iron was detected. The distribution of potassium in the β″-alumina became more uniform as electrolysis proceeded, and the cell impedance increased by factors of two or three. Calcium was the most damaging impurity; even in small concentrations it caused large increases in cell impedance and calcium concentrated in the grain boundaries of the β″-alumina.

Impurities can degrade the performance and life of the β″-alumina electrolyte in a sodium-sulfur cell (1-6). In the absence of an electric field potassium exchanges with sodium in large grains in β-alumina in contact with a sodium source, and cracks result (6). In this work the influence of potassium, calcium, and iron impurities on degradation of β-alumina after cyclic electrolysis was studied with the electron microprobe and the scanning electron microscope. Calcium was found to be the most damaging impurity; even in small concentrations it causes large increases in the resistance of β″-alumina, and can also cause it to crack.

Experimental

Two different cells were used, as shown in Fig. 1. In one there was sodium inside the β″-alumina tube and sulfur-polysulfide outside; in the other there was Na_2S_4 in both chambers. Impurities were added to the outer chamber as sulfides.

Two different β″-aluminas were used, one with 9.0% Na_2O and 0.8% Li_2O (9.0-0.8) and the other with 8.85% Na_2O and 0.75% Li_2O (8.85-0.75).

The cells were baked at 350°C for 12 hr at 0.02 mm Hg before filling. Sulfur (sublimed) was dried under a reduced pressure at about 70°-80°C and sodium was filtered through a glass frit at about 150°C. Commercial Na_2S_4 (Alfa) was washed with toluene and then dried in vacuum at 130°C for 48 hr. All reactants were placed into the cell under a dry atmosphere and then melted into the cell. The cell was sealed with dry argon at a third of atmospheric pressure. For the Na/S cells 15g of Na and 30g of S were used.

The Na/S cells were first discharged until the composition of the outer chamber reached about Na_2S_4, and then charged and discharged in a 4 hr cycle. The current density was 25-30 mA/cm² for both charging and discharging, and this value was low enough to exclude the possibility of degradation due to the high current density mechanism. The composition of the outer chamber was near Na_2S_4, owing to the short cycle time and the low current density. Simulation cells were also operated in 4 hr cycles with a current density of 25-30 mA/cm².

The temperature of the cells was 350°C. A conductivity bridge (Leeds & Northrup) was used to measure the impedance of the cell at 1000 Hz. After the cell was cooled down and disassembled, the β''-alumina electrolyte was cut into pieces (or rings) and some samples were analyzed with the electron microprobe or SEM equipped with EDA.

For microprobe (MAC-400) analysis a piece of the β''-alumina was mounted in epoxy resin and polished through 1μ diamond; water was used only for rough sanding and then any contact with water was avoided. The specimen was coated with carbon, distributions of impurities were photographed directly, and several spots were analyzed for the impurities. A back-scattered electron (BSE) image of the analyzed area was taken for identification in the optical microscope.

Standard β''-alumina samples containing known amounts of each of the impurities were prepared. Mixtures of Na_2CO_3, Li_2CO_3, $CaCO_3$, and Al_2O_3 (Linde B) were calcined at about 1000°C and then pressed into pellets, 1 cm diam and about 2 mm thick. These pellets were sintered at 1550°-1580°C for 10-20 min and then annealed at 1400°C for 2-3 hr, all in powder of the same composition.

Sample surfaces were observed in the SEM equipped with EDA (AMR-1000); they were coated with gold for observation or carbon for EDA. Optical micrographs of the analyzed area were taken after etching in HF-HNO_3.

An ion-exchange experiment was performed to clarify the difference between the results with and without electric current. A piece of β''-alumina (9.0-0.8) was immersed in a melt of either $NaNO_3$ or Na_2S_4 with impurity and analyzed with the microprobe and optical microscope.

Experimental Results

The results of cell operation are presented in Table I. The β''-alumina from cell Fe-1 had fine crystals on its surface, as shown in Fig. 2. EDA showed much sulfur and some sodium and calcium in these crystals and no iron in them. Microprobe analysis of a cross section of the ceramic showed less than 0.05 weight percent (w/o) iron; thus iron does not penetrate into the β''-alumina.

In cell K-1 cracks were found on the surface of the β''-alumina that contacted Na_2S_4 containing K^+; the cracks ran almost perpendicular to the surface. A nonuniform distribution of K^+ was observed in the microprobe in sections of β''-alumina from cells K-1 and K-2. The correspondence of the K^+-rich area to particular grains was not clear; large grains did not contain more K^+ than the surroundings. The K^+-rich region contained about 0.6-1.0 w/o of K_2O, showing that up to one tenth of the Na^+ ions in β''-alumina conduction paths were replaced with K^+ ions. The concentration of potassium in larger grains barely exceeded the detection limit, and it was estimated to be no more than 0.05 w/o. There were no appreciable differences in potassium concentrations along cracks.

In cells K-3 and K-4 the distribution of potassium was more uniform than in cells K-1 and K-2, suggesting that the potassium becomes uniformly distributed throughout the ceramic after long operation and that any stress resulting from the initial nonuniform distribution of potassium disappears gradually.

The Na_2S_4 from cell Ca-1 was washed out with methanol, and some white-gray powder was found on the graphite electrode and felt. Analysis of the powder by EDA showed Na, Ca, and S. X-ray diffraction of this powder showed complicated patterns and some peaks were identified as CaS, but most of them were not from CaS. This powder, therefore, was probably a mixture of CaS and some other compounds of Na, Ca, and S.

A section of the β''-alumina from cell Ca-1 was analyzed by means of the electron microprobe. Figure 3 shows the distribution of Ca and an optical micrograph of the same region and shows that Ca tends to take positions in grain boundaries or in smaller grains and that the larger grains contain less Ca than the surrounding regions. The Ca counts obtained for the large grains barely exceeded the background, indicat-

Table I. Summary of cell designs

Name	Impurity (w/o)	Electrolyte	Cell	Duration days	Impedance	Cracks
Fe-1	FeS 1	9.0-0.8 disk	Na_2S_4	28	Constant	No
K-1	$K_2S_{3.5}$ 1	9.0-0.8 disk	Na_2S_4	9	Constant for 100 hr, then sharp increase and unstable	Yes
K-2	$K_2S_{3.5}$ 0.2	9.0-0.8 disk	Na_2S_4	6	Nearly constant	
K-3	$K_2S_{3.5}$ 0.2	8.85-0.75 tube	Na_2S_4	28	Slow increase to 3 times initial	No
K-4	$K_2S_{3.5}$ 0.2	8.85-0.75 tube	Na/S	33	Slow increase to 2 times initial	No
Ca-1	CaS 1	8.85-0.75 tube	Na/S	6	Rapid increase to 20 times initial in 50 hr, then unstable	No
Ca-2	CaS 0.2	8.85-0.75 tube	Na/S	16	Rapid increase to 20 times initial in 130 hr, then unstable	Yes
Ca-3	CaS 0.05	8.85-0.75 tube	Na/S	28	Slow increase to 8 times initial at 300 hr, then constant	No

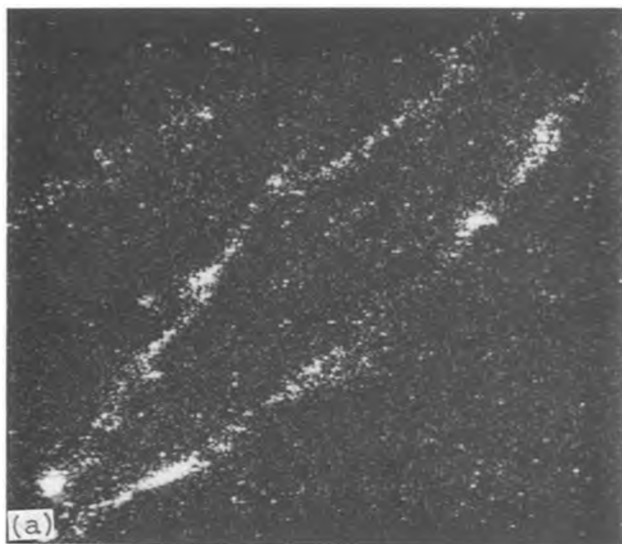
ing that the concentration of CaO in large grains was less than 0.05 w/o. For the Ca-rich region the CaO concentration was estimated to be about 3-4 w/o. If each Ca^{2+} ion replaces two Na^+ ions, the formula of the ion exchanged β''-alumina can be written as

$$(1 - x)\ Na_2O \cdot xCaO \cdot 6.20Al_2O_3$$

with an x for the Ca-rich region of about 0.4-0.5.

Cracks were found on the electrolyte from cell Ca-2 that were different from cracks in the cells K-1 and K-2, and a small piece of the electrolyte came off from a part of surface. The cracks ran diagonally with respect to the surface, unlike cracks from K^+ impurity. Microprobe analysis showed that Ca^{2+} was not distributed evenly along the cracks (Fig. 4); the concentration of Ca was about the same as for cell Ca-1.

Pieces of β''-alumina (9.0-0.8) were kept in the outer chambers of the cells Ca-1 and Ca-2. Microprobe analyses of sections of these pieces are in Fig. 5 and 6, and show a high concentration of Ca in smaller grains or grain boundaries. The concentration of CaO in Ca-rich region was close to that of $CaO \cdot 6Al_2O_3$.



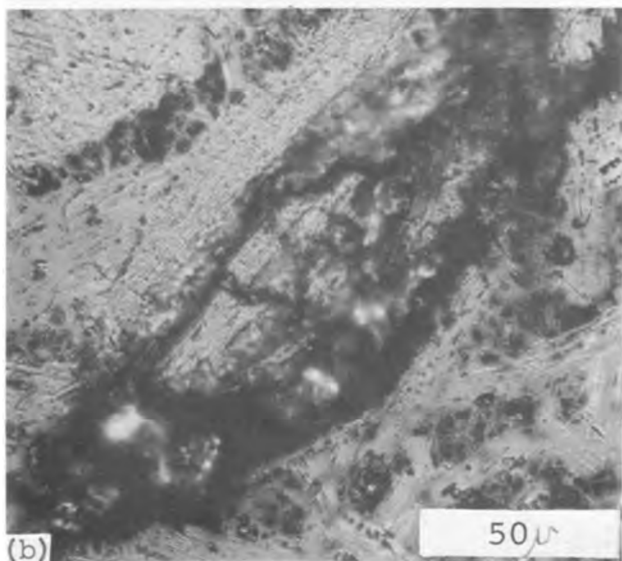


Fig. 4. Distribution of Ca along the cracks found in the electrolyte of the cell Ca-2.

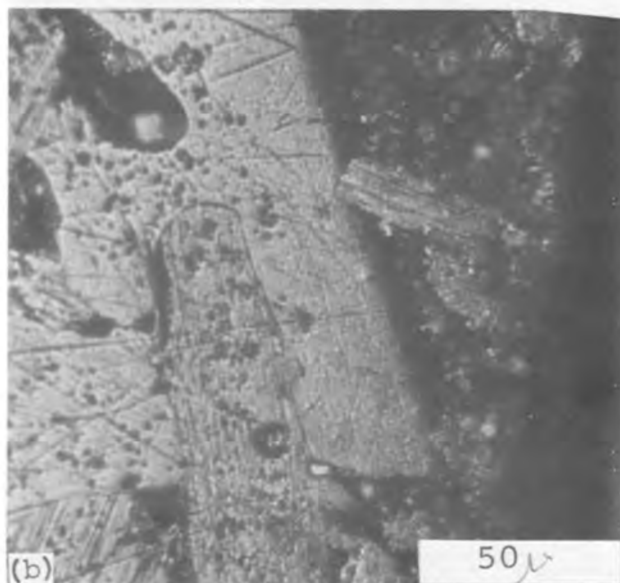

Fig. 5. Distribution of Ca in a piece of β''-alumina (9.0-0.8) which was kept in the sulfur chamber of the cell Ca-2.

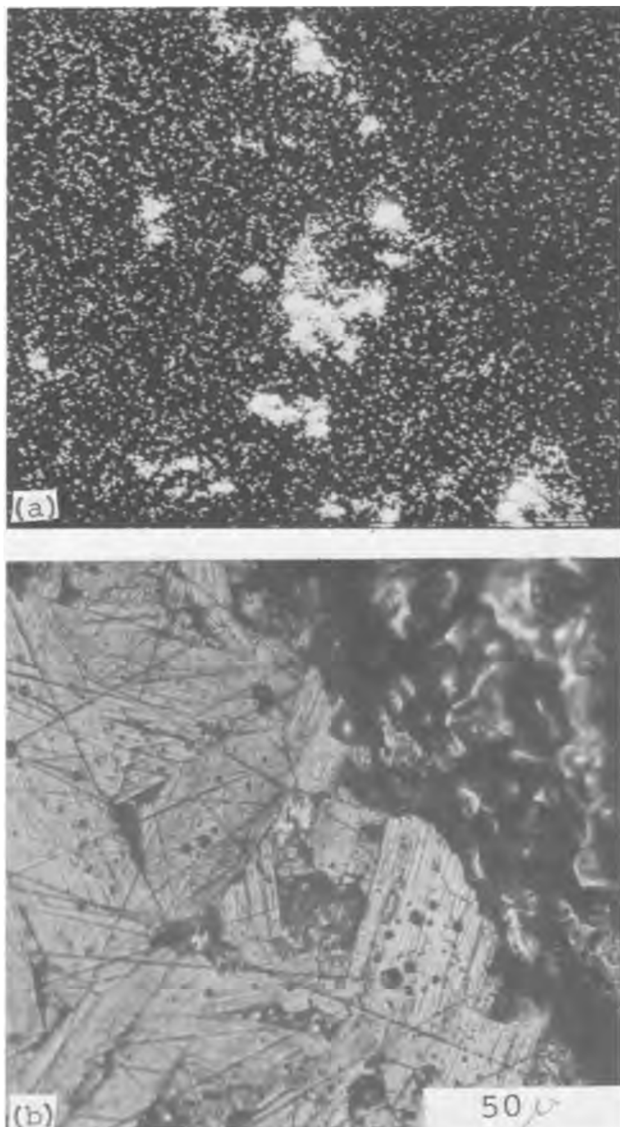

Fig. 6. Distribution of Ca in a piece of β″-alumina (9.0-0.8) which was immersed in the melt of Na_2S_4 containing 1.0 w/o of CaS. The surface of the ceramic cut with a slow speed diamond saw is shown here.

Discussion

Iron has been suggested as a degrading impurity for β″-alumina, because sodium-sulfur cells with stainless steel cases often fail at shorter lifetimes than expected. The present results indicate that iron does not deposit directly on the surface of β″-alumina or penetrate into it. Large amounts of iron compounds are found in the sulfide compartments of failed cells with stainless steel cases, and it is probable that these compounds interfere with cell operation and lead to failure.

In the absence of an electric field potassium penetrates into β″-alumina only in large grains in contact with the melt containing potassium; grain boundaries appear to act as barriers for potassium penetration (6). In contrast the present results show that with a cycling electric field the potassium slowly penetrates into the ceramic, becoming more uniformly distributed at longer cycle times. This result suggests that damage (cracking) from potassium impurity is more likely early in cell life, when the distribution of potassium in the β″-alumina is nonuniform. Once this critical period is past, damage from potassium probably becomes less likely. Small amounts (0.2% in the melt) of potassium can lead to increases by factors of two to three in the cell impedance.

Calcium was found in β″-alumina from failed sodium-sulfur cells in our laboratory (7), but has usually been ignored as a source of degradation of β″-alumina. The present results suggest that it can cause degradation in both conductivity and strength of β″-alumina. Figures 3 and 5 show that calcium concentrates in grain boundaries in β″-alumina either with or without an electric field. Quite small amounts of calcium (0.05% in the melt) can lead to large increases in impedance of the ceramic. This concentration of calcium in the grain boundaries can apparently also lead to cracking of the ceramic, as shown in Fig. 4. Thus calcium can seriously degrade the performance of β″-alumina in a sodium sulfur cell.

Thermal Analysis of Lead-Acid Cells for Load-Leveling Applications

K. W. Choi* and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Modeling studies have been conducted to determine the temperature field in a lead-acid cell contemplated for load-leveling applications, with daily duty cycles and a weakly equalization charge. The results show that under the proposed daily cycling and without a forced cooling, a maximum temperature rise of 16°C can be expected at the center of a proposed 9.76 kW-hr cell (48.26 cm length × 45.72 cm width × 127 cm height). For such tall lead-acid cells, reduction of cell length by about one-half would reduce the temperature rise by 7°-8°C without employing forced cooling. Conventional water cooling at the cell terminals has little effect in lowering the cell maximum temperature. Moreover, cooling may induce a large temperature gradient in the vertical direction of the cell, which may cause a nonuniform current distribution over the electrode leading to a gradual loss of cell capacity and cycle life. Practical cells in use often incorporate "air lift pump" that facilitates electrolyte stirring or an electrolyte circulation design to minimize the extreme temperature gradients. Gassing during the weekly equalization charge of loading-leveling cells may also enhance internal heat transfer, causing a more uniform temperature distribution. After the weekly equalization charge, the cell temperatures resume their initial values at the end of the rest period.

Thermal behavior in lead-acid batteries during cycling is an important factor affecting battery performance and cycle life. Temperature effects become even more critical for the advanced batteries employed in electrical vehicle propulsion and utility load-leveling applications. Poor battery design can result in significant temperature rise and temperature gradient in the battery during charge and discharge cycles. This temperature rise may cause enough variation in the physical and chemical properties of the battery components to lead to a gradual loss of cell capacity and cycle life. Baker, Gidaspow, and Wasan (1) have given a review for the thermal phenomena in fuel cells and batteries as well as the mathematical treatment to obtain the analytical solution for the temperature fields in fuel cells and batteries. They derived general solutions for maximum cell temperatures at steady state with a boundary condition of constant cell wall temperature. A similar approach has also been applied for the calculation of the maximum temperature in silver-zinc batteries at steady state and at isothermal wall conditions by Meredith and Uchiyama (2). The present work employs finite difference method to study transient thermal phenomena in load-leveling lead-acid cells under conditions of variable cell wall temperature. The same method was applied by us recently to a study of a transient thermal phenomena in lead-acid cells which were designed for electric vehicle propulsion (3). That study (3) addressed heat transfer behavior across the electrode, the electrolyte and their interface for a PbO_2 electrode; the temperature field in a composite lead-acid battery; and the proposed battery cooling methods. However, due to the difference in the battery specifications, construction, and use cycles for the batteries in electric vehicle propulsion and in load-leveling uses, it is expected that the thermal behavior of the batteries for the two applications will not be the same.

In the following, the temperature field and its variation in the cell designed for load-leveling use during daily duty cycles and weekly equalization charge are examined. This study also examines how the cell geometry and the cell designs (with and without water cooling at the electrode terminal) affect the temperature distribution. The proposed utility cycles for these calculations include five daily duty cycles and one weekly equalization charge per week. Three proposed cell designs, designated by Designs A, B, and C (with and without water cooling at the cell terminals) were analyzed. The design characteristics of the cells are summarized in Table I which compares the rated cell capacity and the dimensions of the respective cell designs (4, 5). The terminal water cooling was provided by running the coolant through cooling tubes next to the top of electrodes as shown in Fig. 1. The basic mathematical treatment is quite similar to that of the previous study (3); some modifications, however, have been added and will be discussed in the next section.

Mathematical Treatment

The elements within a single cell container consist of positive electrodes, negatives electrodes, separators and electrolyte. There are electrolyte reservoirs around the compact electrode element. As shown in Fig. 2 for a two-dimension cross section, region I represents the electrode element which is composed of the positive electrodes, negative electrodes, separators and electrolyte; and region II represents the electrolyte reservoir at the surrounding. Previous work (3) has shown that the compact electrode element may be regarded as a unit, and the averaged temperature may be assumed to represent the local temperature at any location within the electrode element, approximately. Following this approximation, Region I will be treated as a homogeneous medium with the averaged physical parameters (density, specific heat, thermal conductivity, and electrical conductivity) and the heat generated within the electrode element may be averaged over the whole region I.

Key words: lead-acid cells, utility load-leveling, temperature distribution, terminal water cooling.

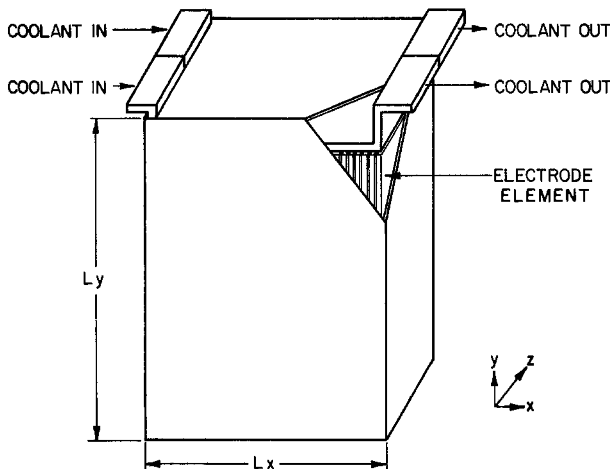

Fig. 1. Lead-acid cell for load-leveling application with a terminal water cooling design.

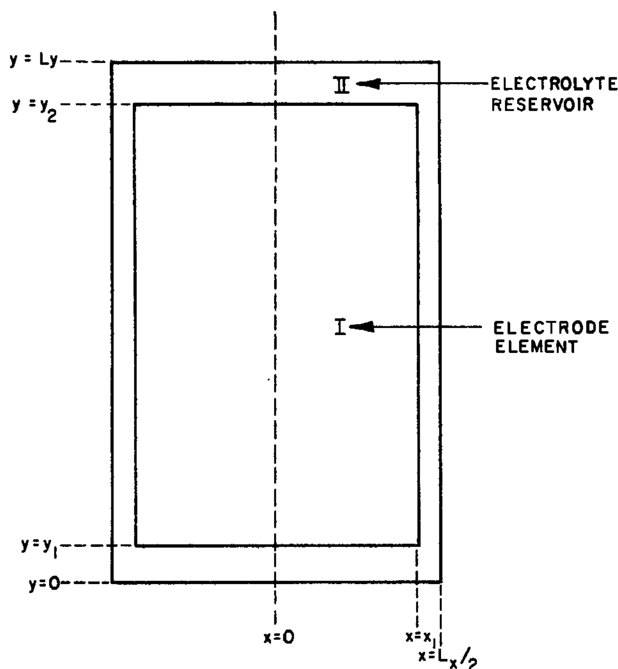

Fig. 2. Cell cross section in two-dimensions

In the previous study of the lead-acid cells for electric vehicle (EV) propulsion use (3), the temperature of the electrolyte in the top reservoir was assumed uniform because of limited amount of electrolyte in the reservoir. The numerical calculation was thus simplified. For the lead-acid cell in load-leveling use, the cell dimensions are much larger than that of the EV cells, and the energy density is not so critical as the EV cells. Generally there is large electrolyte reservoir around the compact electrode element so that the assumption of uniform temperature for the electrolyte reservoir is no longer applicable. Therefore in the following treatment, the numerical solutions for temperature field were obtained by matching region I (the electrode element) and region II (the electrolyte reservoir in the surrounding) with suitable boundary conditions. The calculation method is as follows.

For region I, the governing energy equation is written as

$$\rho\hat{C}\frac{\partial T}{\partial t} = k\frac{\partial^2 T}{\partial x^2} + k\frac{\partial^2 T}{\partial y^2} - \rho\hat{C}\,U\frac{\partial T}{\partial y} + \dot{q} \qquad [1]$$

where ρ, $\hat{C}$, k are the average density, specific heat, and thermal conductivity for the electrode element in region I, respectively. If gassing occurred in the cell during charge cycle, the thermal conductivity k is correlated similarly to the treatment in Ref. [3] as

$$k = k_o\,[1 + a(1 - \xi)i] \qquad [2]$$

where k_o is the thermal conductivity when there is no gassing, a is the gassing correlation constant. ξ is the current efficiency. i is the superficial current density on the electrode. U is the superficial velocity of the electrolyte in y-direction, which relates the electrolyte movement due to the change of electrode porosity in region I. $\dot{q}$ is the rate of internal heat production per unit volume. The velocity gradient may be expressed as

$$\frac{\partial U}{\partial y} = -\frac{\partial \epsilon}{\partial t} \qquad [3]$$

where ϵ is the porosity of the electrode element in region I. The derivative of ϵ with respect to time is written as

$$\frac{\partial \epsilon}{\partial t} = i\left\{\sum_{\substack{\text{solid phase}\\\text{product}}} s_i\overline{V}_i - \sum_{\substack{\text{solid phase}\\\text{reactant}}} s_i\overline{V}_i\right\} / n\mathbf{F}\,W_t \qquad [4]$$

based on the general expression for cell reaction as

$$\sum_{\text{reactant}} s_iM_iz_i = \sum_{\text{product}} s_iM_iz_i \qquad [5]$$

s_i is the stoichiometer coefficient of species i; z_i is the charge carried by species i; $\overline{V}_i$ is the partial molar volume of species i; n is the number of electron transfer for the cell reaction; and W_t is the total thickness of the positive electrode, the negative electrode and the separator. The rate of heat production per unit volume $\dot{q}$, is dependent on the cell reaction, temperature, cycling condition, current efficiency, and cell geometry. Following the derivation as in the previous study (3), $\dot{q}$ may be expressed as a combination of functions $f\left(i, \xi, W_t, V, \sum_j \Delta H_j^\circ\right)$ and $G\left(i, \xi, W_t, \sum_j \Delta C_{p,j}\right)$ as follows

$$\dot{q} = f\left(i, \xi, W_t, V, \sum_j \Delta H_j^\circ\right) + G\left(i, \xi, W_t, \sum_j \Delta C_{p,j}\right)\cdot(T - T_o) \qquad [6]$$

Function f represents the heat production due to the ohmic drop and the heats of cell reactions at the reference temperature (T_o). Function G represents the heat production due to temperature variation for the cell reactions. They may be expressed as

$$f\left(i, \xi, W_t, V, \sum_j \Delta H_j^\circ\right) = \frac{i}{W_t}\left[V - \xi\frac{\Delta H_r^\circ}{n_1\mathbf{F}} - (1 - \xi)\frac{\Delta H_g^\circ}{n_2\mathbf{F}}\right] \qquad [7]$$

and

$$G\left(i, \xi, W_t, \sum_j \Delta C_{p,j}\right) = -\frac{i}{W_t}\left[\xi\frac{\Delta C_{p,r}}{n_1\mathbf{F}} + (1 - \xi)\frac{\Delta C_{p,g}}{n_2\mathbf{F}}\right] \qquad [8]$$

where ΔH_r° and ΔH_g° are the heats of reaction for the faradaic cell reaction and the gas evolution reaction, respectively; n_1 and n_2 are the number of electron transfer for the cell reaction and the gassing reaction, respectively; $C_{p,r}$ and $C_{p,g}$ are the algebraic sums of species partial molar heat capacities for the cell reaction and the gassing reaction, respectively. V is the cell voltage. Other symbols have their initial meanings. For the electrolyte in the reservoir (region II), the energy equation is expressed as

$$\rho_l \hat{C}_l \frac{\partial T}{\partial t} = k_l \left(\frac{\partial^2 T}{\partial t^2} + \frac{\partial^2 T}{\partial y^2} \right) \quad [9]$$

where ρ_l, $\hat{C}_l$, and k_l are the density, specific heat, and thermal conductivity of the electrolyte, respectively. Similar correlation for the thermal conductivity due to gassing (Eq. [2]) will also be applied to the electrolyte in region II.

The initial and boundary conditions may be written as

$$\text{At } t = 0, \text{ any } x, \text{ and any } y, T = T_o \quad [10]$$

where

T_o is the initial cell (outer atmospheric) temperature.

$$\text{At } x = 0, \text{ any } y \frac{\partial T}{\partial x} = 0 \quad [11]$$

At $x = L_x/2$, any y

$$-k\left(\frac{\partial T}{\partial x}\right)_{x-\delta,y} + k\left(\frac{\partial T}{\partial y}\right)_{x,y+\delta} - k\left(\frac{\partial T}{\partial y}\right)_{x,y-\delta} = h(T - T_o) \quad [12]$$

where h, the heat transfer coefficient from the cell wall to the outer atmosphere,[1] is an infinitely small value.

At $y = 0$, any x

$$k\left(\frac{\partial T}{\partial y}\right)_{x,\delta} - k\left(\frac{\partial T}{\partial x}\right)_{x+\delta,y} + k\left(\frac{\partial T}{\partial x}\right)_{x-\delta,y} = h(T - T_o) \quad [13]$$

At $y = L_y$, any x

$$-k\left(\frac{\partial T}{\partial y}\right)_{x,y-\delta} - k\left(\frac{\partial T}{\partial x}\right)_{x+\delta,y} + k\left(\frac{\partial T}{\partial x}\right)_{x-\delta,y} = h(T - T_o) \quad [14]$$

At the interface between the electrode element of region I and the electrolyte of region II, the heat transfer across the two medium should be conserved. The boundary conditions at the interface may be written as

At $x = x_1$, $y_1 < y < y_2$

$$k\left(\frac{\partial T}{\partial x}\right)^{\mathrm{I}} = k_l\left(\frac{\partial T}{\partial x}\right)^{\mathrm{II}} \quad [15]$$

At $y = y_1$, any x

$$k\left(\frac{\partial T}{\partial y}\right)^{\mathrm{I}} = k_l\left(\frac{\partial T}{\partial y}\right)^{\mathrm{II}} \quad [16]$$

At $y = y_2$, any x

$$k\left(\frac{\partial T}{\partial y}\right)^{\mathrm{I}} = k_l\left(\frac{\partial T}{\partial y}\right)^{\mathrm{II}} \quad [17]$$

$(\partial T/\partial y)^{\mathrm{I}}$ and $(\partial T/\partial y)^{\mathrm{II}}$ represent the temperature gradients at region I and region II, respectively.

For the design with cooling at the top of the electrode (at $y = y_2$) the boundary condition may be rewritten as

At $y = y_2$, any x

$$-k\left(\frac{\partial T}{\partial y}\right)^{\mathrm{I}} + k_l\left(\frac{\partial T}{\partial y}\right)^{\mathrm{II}} = \Lambda(T - T_c) \quad [18]$$

where Λ is the averaged heat transfer coefficient across the cooling tube which relates to the material properties and geometries of the cooling tube.

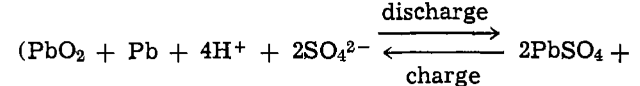
[1] In the present calculation, constant values of h and T_o for a single cell were assumed. In a practical load-leveling battery plant which consists of hundreds of series-parallel connected single cells, the values of h and T_o will generally be affected by the heat transfer between the neighboring cells. However, the assumption of constant h and T_o will still be valid if proper air ventilation for cooling is provided for the space between the cells.

Numerical Calculation

Numerical solutions for Eq. [1]-[4] and [9] were obtained, subjected to the initial and boundary conditions (Eq. [10]-[18]) by finite difference method. Implicit alternating-direction (6, 7) techniques followed by an elimination algorithm were employed. The convergence criterion was set so that the difference between two successive solutions at all mesh points is less than 0.001%.

Description of daily duty cycles and weekly equalization charge.—The calculation was made for five daily duty cycles and one weekly equalization charge. For each daily duty cycle, the cell was discharged at constant current for 5 hr to 100% of the rated capacity, followed by 7 hr constant current charge and 2 hr taper charge. The cell potential was assumed to reach 2.35V at the end of the 7 hr constant current charge and was maintained at 2.35V for the 2 hr taper charge. About 84% of daily discharge capacity was delivered back to the cell at the end of the 7 hr constant current charge. At the end of the 2 hr taper charge, 100% of the daily discharge capacity was returned to the cell. Because the cell voltage was not allowed to exceed 2.35V during the daily charge, the current efficiency was assumed 100%. The weekly equalization charge was operated right after the end of the fifth daily charge cycle, which was a 5 hr constant voltage charge at 2.65V. About 20% excess of the rated capacity was charged to the cell during the 5 hr weekly equalization charge. As most of coulombs during this equalization charge would result in gassing, the current efficiency was assumed to be 5%. The variations of cell potential and cell current during the daily discharge and charge were represented in Fig. 3.

Physical parameters used in the calculation.—The heat of reaction (ΔH_r) for the cell faradaic reaction



$$(PbO_2 + Pb + 4H^+ + 2SO_4^{2-} \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftarrows}} 2PbSO_4 + 2H_2O)$$

varies with the electrolyte concentration and the electrolyte concentration changes during cell cycling. An empirical correlation for the dependence between ΔH_r and state of discharge (or charge) was made by assuming that the specific gravity of the electrolyte was equal to 1.12 at fully discharged state of the rated capacity, and equal to 1.28 at the fully charged state. Based on the reported values by Vinal (8), this correlation may be expressed as

$$\Delta H_r(298\text{K}) = 367{,}422 + 20{,}900\, Q + 11{,}520\, Q^2 \text{ J/mol} \quad [19]$$

where Q represent the state of charge. When the cell is fully discharged (the specific gravity of the electro-

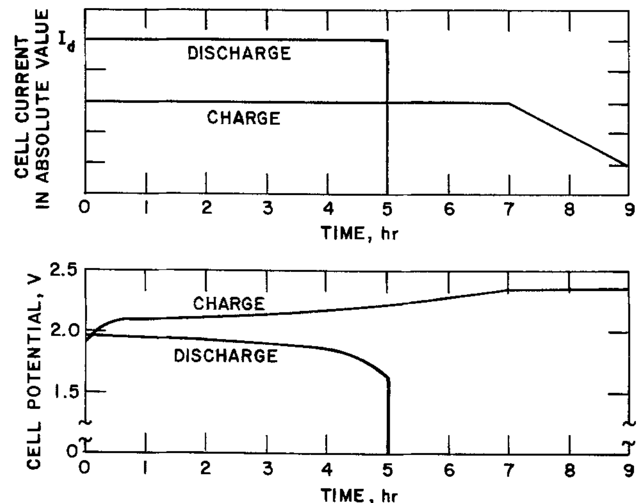


Fig. 3. Variations of cell potential and cell current with time during the daily discharge and charge cycles.

lyte is about 1.12), Q is equal to zero. Q is equal to 0.5 when the cell is charged to one-half of its rated capacity, and equal to 1.0 when the cell is fully charged (the specific gravity of the electrolyte is about 1.28).

The gas evolution reaction during charge may be generally expressed as

$$H_2O \rightarrow H_2 + \tfrac{1}{2} O_2 \quad [20]$$

since the dependence of the heat of the gas reaction to the acid concentration is quite small, the heat of gas reaction (ΔH_g) was assumed to be constant and is equal to 285,786.6 J/mol (9). The heat generation due to the changes of the species partial molar heat capacities with concentration and temperatures are also small. Therefore, the algebraic sums of the species partial molar heat capacities for the faradaic cell reaction ($\Delta C_{p,r}$) and for the gas reaction ($\Delta C_{p,g}$) were assumed constants, equal to -47.53 J/mol-K(8) and -32.89 J/mol-K(10), respectively.

The values of other parameters and data for calculations are listed below.

$a = 2500$ cm^2/A
$\rho\hat{C} = 2.85$ J/cm^3-K
$\rho_1\hat{C}_1 = 3.8087$ J/cm^3-K
$k_o = 0.04433$ W/cm-K
$k_1 = 0.00521$ W/cm-K
$V_{Pb} = 18.25$ cm^3/mole
$V_{PbO_2} = 25.54$ cm^3/mole
$V_{PbO_4} = 48.9$ cm^3/mole
$W_t = 0.9779$ cm
$h = 3.76 \times 10^{-4}$ J/cm^2-sec-K
$\Lambda = 0.2$ J/cm^2-sec-K

For Design A
$L_x = 48.26$ cm, $x_1 = 21.72$ cm
$L_y = 127.0$ cm, $y_1 = 10.16$ cm
$y_2 = 111.76$ cm

For Design B
$L_x = 22.12$ cm, $x_1 = 10.06$ cm
$L_y = 121.92$ cm, $y_1 = 8.13$ cm
$y_2 = 109.71$ cm

For Design C
$L_x = 22.12$ cm, $x_1 = 10.06$ cm
$L_y = 76.2$ cm, $y_1 = 5.08$ cm
$y_2 = 68.58$ cm

Results

The calculated temperature profiles for Cell Design A under the utility cycles (five daily duty cycles and one weekly equalization charge) are shown in Fig. 4 for the case without water cooling. In Fig. 4, curve 1 represents the profile for the maximum cell temperature near the cell center; curve 2 represents the temperature variation at the top of the electrode element (at $x = 0$, $y = y_2$); curve 3 is the temperature variation of the reservoir electrolyte 5.1 cm above the top of the electrode element (the height of the electrolyte above the top of the electrode element is 12.7 cm). These curves in Fig. 4 show that the temperatures profiles are similar throughout the daily duty cycles. A maximum temperature near the cell center (curve 1) may reach as high as 16°C above the ambient temperature. The temperature distribution in the vertical direction of the cell is not uniform, as shown by curves 1, 2, and 3. During the 5 hr weekly equalization charge at 2.65V, the temperature difference in the vertical direction is reduced somewhat due to vigorous gassing. After the weekly equalization charge, the cell temperatures return to nearly their initial temperature at the end of the 2 day rest period during the weekend. Figure 5 compares the profiles of maximum cell temperature for Cell Designs A, B, and C. Curve A is for the Cell Design A without cooling; curve A′ is for the Cell Design A with water cooling at the terminals. The water is circulated in such a rate that the coolant temperature may be assumed to be constant. For curve A′, the coolant temperature is set equal to 298°K; curve A″ is for the same design with a coolant temperature of 283°K. When water cooling is used, the location of maximum cell temperature is no longer near the cell center, but shifts downward from the terminal. Also shown in Fig. 5 are the maximum cell temperatures for Cell Design B (curve B) and for Cell Design C (curve C) without water cooling. Cell dimensions for the three cell designs were listed in Table I. The results with the Cell Design A showed that the water cooling has little effect in reducing the maximum cell temperatures (comparing curves A, A′, and A″ in Fig. 5). The water cooling essentially reduces the temperature at the region near the electrode terminals, as illustrated in Tables II and III. Tables II and III are the maps to show a complete temperature distribution over the one-half of the cell for Cell Design A under the conditions with and without water cooling. However, when the cell length of Design A is reduced from 48.26 to 22.12 cm (that of Design B), the maximum cell temperature in the absence of forced cooling is correspondingly reduced by nearly one-half, or 5°-6°C, as shown in Fig. 5. When the cell height is reduced from 122 cm (for Design B) to 76 cm (for Design C), the maximum cell temperature is reduced by only about 1°C. Figures 6, 7, and 8 compare the temperature profiles in the vertical direction for Cell Designs A, B, and C with and without water cooling. The results clearly show that a large temperature difference in the vertical direction is induced by the water cooling at the cell terminals.

Discussion

Cell Design A without forced water cooling.—Under the proposed utility cycles for load-leveling applications, the numerical results show that a maximum cell temperature (near the cell center) may rise by 16°C above the ambient temperature during daily charge cycles as shown by curve 1 in Fig. 4. The maximum temperature near the cell center is however not readily measurable experimentally. In practice, the electrolyte temperature in the top reservoir is usually measured. In this calculation, the electrolyte temperature 5.1 cm above the top of the electrode element (curve 3 in Fig.

4) was shown to rise by about 7°C relative to the ambient temperature during the daily charge cycles. During the weekly equalization charge, the rigorous gassing enhances the internal heat transfer and gives the rise of the electrolyte temperature in the top reservoir by as much as 10°C. The cell temperatures also become somewhat more uniform during the equalization charge due to the gassing (comparing curves 1, 2, and 3 in Fig. 4). The temperature variation throughout the daily duty cycles is almost identical. This suggests that for the similar system, computation of the temperature variation for one or two daily cycles will be adequate to estimate that for the remaining days of the week. After the weekly equalization charge, the cell temperatures return to their initial values at the end of 2 day rest period due to the natural air cooling.

Cell Design A with forced water cooling.—The numerical results, which are plotted in Fig. 5, indicate that the forced water cooling is not effective to reduce the cell temperature at the region away from the terminals. The location of maximum cell temperature shifts from the cell center to the region near the cell bottom as the water cooling is applied at the top terminals (see Fig. 6). The results further show that the maximum cell temperature is reduced by only about 0.8°C for a coolant temperature of 298°K, and by about 2.6°C for a coolant temperature of 283°K (Fig. 5 and 6). This ineffective terminal cooling is related to the limitation of internal heat conduction within the cell. The uneven cooling was shown to yield large temperature difference over the electrode in the vertical direction (Fig. 6). The temperature difference across the electrode in vertical direction is about 12°C for a coolant temperature of 298°K, and 27°C for a coolant temperature of 283°K. This temperature difference over the electrode may induce a nonuniform current distribution because of the change of electrolyte properties such as conductivity, viscosity, and species diffusivities. The nonuniform current distribution may further cause a nonuniform gassing over the electrode during the charge cycles. Therefore the region of the electrode with heavier gassing, may have a serious shedding and softening effects on the active materials. Also the utilization of active material may be very nonuniform due to the nonuniform current distribu-

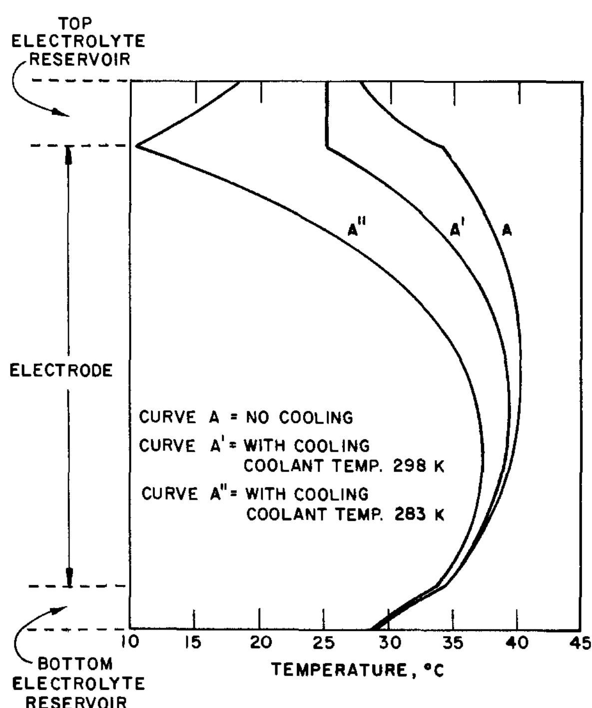

Fig. 6. Temperature distribution across the cell in the y-direction at the end of the second daily cycle for Cell Design A, $x = 0$. Cell dimensions: 48.26 cm L × 45.72 cm W × 127 cm H. Initial cell temperature: 25°C.

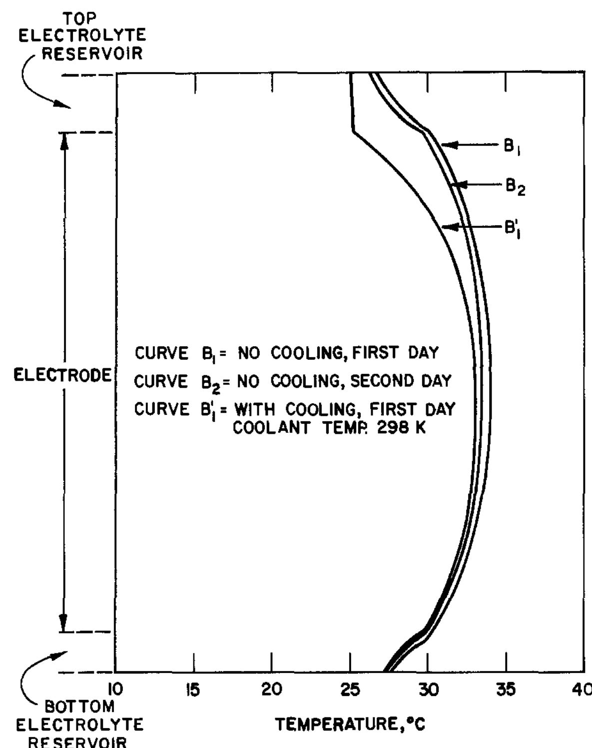

Fig. 7. Temperature distribution across the cell in the y-direction at the ends of daily charge cycles for Cell Design B, $x = 0$. Cell dimensions: 22.1 cm L × 45.72 cm W × 121.92 cm H. Initial cell temperature: 25°C.

tion. The part of the electrode which has poor utilization of active material may gradually become inactive. These effects as caused by the nonuniform temperature distribution, are interrelated and contribute to the deterioration of the cell capacity and cycle life as cycling continues without a proper thermal management.

Cell Designs B and C with and without forced water cooling.—When the cell length is slimmed from 48.26 cm for Cell Design A to 22.1 cm for Cell Design B, the maximum rise of cell temperature is accordingly reduced from 16° to 9°C (curvesA and B in Fig. 5) under the same proposed cycling conditions without forced cooling. When the cell height is reduced from 121.92 cm for Cell Design B to 76.2 cm for Cell Design C, the maximum cell temperature is reduced only by 1°C (curves B and C in Fig. 5). The results indicate that the heat transfer is preferred in the horizontal direction (x-direction) than the vertical direction (y-direction) because of the longer conduction path in the vertical direction of the tall cells. For Cell Design B and Cell Design C, the maximum temperature difference over the electrode may be about 3°-4°C under the proposed duty cycles without forced cooling (curves B_1 and B_2 in Fig. 7; curves C_1 and C_2 in Fig. 8). This temperature difference is tolerable for practical cell operation. The results suggest that without the forced cooling, the cell geometry plays an important role for effective heat transfer and for control of the temperature field provided that the ambient temperature could be properly controlled by air ventilation. When the forced water cooling is applied to the terminals, significant temperature gradients are induced for all three cell designs, and yet without the benefit of reducing significantly the maximum cell temperatures. The large temperature gradients may significantly be reduced by electrolyte circulation (3) or by the electrolyte stirring effected by an air lift pump (4).

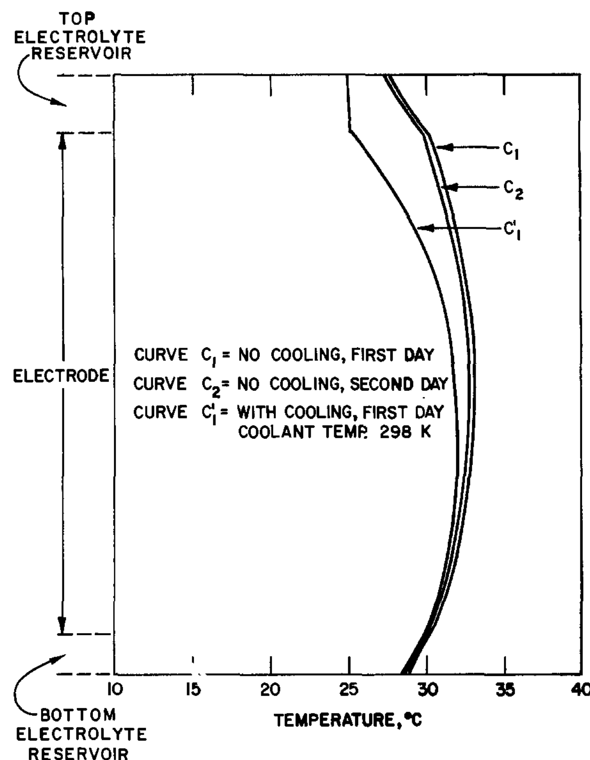

Fig. 8. Temperature distribution across the cell in the y-direction at the ends of daily charge cycles for Cell Design C, $x = 0$. Cell dimensions: 22.1 cm L × 45.72 cm W × 76.2 cm H. Initial cell temperature: 25°C.

The model.—In this study, the model treats the composite of grid, active materials of negative and positive plates, separator, and the electrolyte in the electrodes as a homogeneous medium. The composite is called the electrode element in the text. Since the grid has a much higher thermal conductivity relative to that of its surrounding (the grid surrounding consists of active materials of positive and negative plates, separator, and electrolyte), this often leads to a speculation that the heat generated in the cell may be effectively transferred through the grid and is released from the grid terminal to the outer atmosphere. One may therefore question the validity of the prediction

based on the present model which did not treat the heat transfer in the grid separately. What follows describes the basis for assuming homogeneity of the composite as treated in the present model.

In a lead-acid cell, most of the heat generated during cycling is contributed by the ohmic loss across the positive plate to the negative plate plus the activation. The contribution of heat due to the ohmic loss in the grid is relatively small, which is about 10% of the total heat generated. Therefore the heat released through the grid terminal to the outer atmosphere will be governed by the rates of heat transfer from the grid surrounding to the grid, from the grid interior to the grid terminal, and from the grid terminal to the outer atmosphere. A parallel but supportive model to describe the heat transfer processes in the grid and in its surrounding has been developed, and discussed in the Appendix.

The results from the supportive model in Appendix indicate that the temperatures of the grid and the grid surrounding are almost identical for Cell Design A during a daily cycle. The results furthermore show that the heat released from the grid terminal to the outer atmosphere is primarily limited by conduction in the grid. The amount of heat released from the grid terminal during the 14 hr daily operation (5 hr discharge plus 9 hr charge) is only about 15% of the total heat generated in the cell. The heat remaining in the cell contributes to the rise of cell temperature (see Fig. A-2). Furthermore a large temperature difference in the vertical direction of the cell is induced by the cooling of the grid terminal (see Fig. A-3). The results from the supportive model imply that (*i*) the heat released from the grid terminals in a tall cell design is not as effective as what has been commonly perceived, and (*ii*) temperatures of the grid and the grid surrounding are nearly identical so that they may be treated as a homogeneous medium in the heat transfer analysis of a whole cell. This assumption of a homogeneous medium was therefore adapted in the present model treatment.

Conclusion

Under the proposed utility cycles for lead-acid cells in load-leveling application, the daily cell temperature profiles are almost identical throughout the daily duty cycles. For a tall cell design (122-127 cm height), without forced water cooling, the maximum rise of cell temperature near the cell center may be reduced by about one-half, from 16° to 9°C, if the cell length is reduced, *e.g.*, from 48.26 cm for Cell Design A to 22.1 cm for Cell Design B. Reduction of the cell height, *e.g.*, from 121.92 cm for Cell Design B to 76.2 for Cell Design C, has little effect in reducing the maximum cell temperature. This preferential heat transfer in the horizontal direction, *i.e.*, through the cell case, than in the vertical direction, *i.e.*, through the terminals, is simply reflecting the longer conduction path in the vertical direction and that heat transfer within the cell is indeed limited by conduction. The above predicted results are based on the assumption of constant heat transfer coefficient from the cell wall to the ambient atmosphere of constant temperature. This assumption will be valid provided that adequate air ventilation exists for cooling the space between the cells in the load-leveling battery plant. The forced water cooling at electrode terminal has no significant effect in reducing the cell temperature at the region away from the terminal, but instead inducing a large temperature difference across the electrode. The large temperature gradients may cause a nonuniform current distribution over the electrodes leading to a gradual loss of cell capacity and cycle life. In practice, however, large battery cells, *e.g.*, lead-acid submarine cells, often incorporate "air lift pump" or electrolyte circulation design to minimize the temperature gradients within the cells. The gassing during equalization charge of load-leveling cells further enhances the internal heat transfer leading to a more uniform cell temperature distribution. After the weekly equalization charge, the 2 day rest period is enough to permit the cell temperature to return to its initial ambient temperature.

APPENDIX

Heat Transfer in the Electrode Grids and Their Surrounding in a Lead-Acid Cell

For a composite lead-acid cell, the arrangement of the electrode grids and their surrounding may be represented by Fig. A-1. Medium I in Fig. A-1 repre-

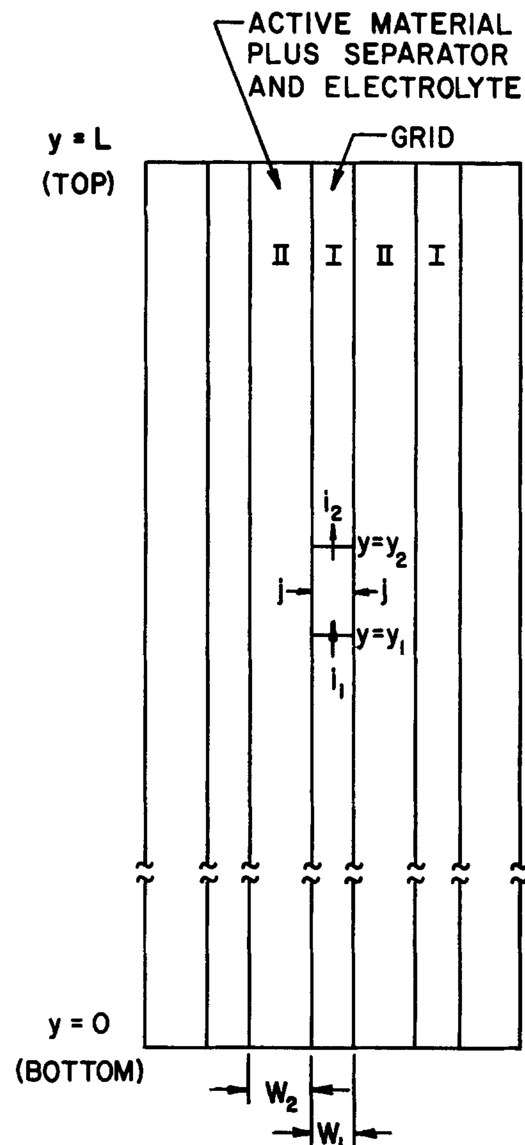

Fig. A-1. A cross section for the arrangement of the electrode grids and their surrounding in a composite cell.

sents the electrode grid; medium II represents the grid surrounding consisting of the active materials of positive and negative plates, separator, and electrolyte. For a tall cell design, the plate thickness is much smaller compared to the plate height. It is assumed that the temperature of the grid and its surrounding is uniform in the direction of the plate thickness. Only the temperature variations in the vertical direction are considered. In order to investigate the effectiveness of the heat being released through the grid terminal located at the top of the cell, the heat transfer through the side walls of the cell is not considered here. The mathematics are therefore simplified to a one-dimension model.

During cell cycling, the governing energy equations for the grid (medium I) and for the grid surrounding (medium II) may be expressed as

$$\rho_1 \hat{C}_1 \frac{\partial T_1}{\partial t} = k_1 \frac{\partial^2 T_1}{\partial y^2} + \dot{q}_1 \quad [A-1]$$

and

$$\rho_2 \hat{C}_2 \frac{\partial T_2}{\partial t} = k_2 \frac{\partial^2 T_2}{\partial y^2} + \dot{q}_2 \quad [A-2]$$

respectively. ρ_1 and ρ_2, $\hat{C}_1$ and $\hat{C}_2$, k_1 and k_2 represent the densities, specific heats, and thermal conductivities of the grid and the grid surrounding, respectively. $\dot{q}_1$ represents the rate of heat production in the grid, which is contributed by the ohmic loss and the heat transferred from the grid surrounding, and is expressed as follows

$$\dot{q}_1 = \left(\frac{2jy}{W_1}\right)^2 / K_1 + 2h(T_2 - T_1)/W_1 \quad [A-3]$$

where j represents the apparent current density over the plate. W_1 is the thickness and K_1 is the electrical conductivity of the grid. T_2 is the temperature of the grid surrounding. h is the heat transfer coefficient across the grid and the grid surrounding. $\dot{q}_2$ represents the rate of heat production in the grid surrounding, which is the major heat source in the cell, $\dot{q}_2$ is contributed by the electrochemical and chemical reactions plus the heat transferred from the grid. $\dot{q}_2$ may be expressed as

$$\dot{q}_2 = \left(jV - \sum_i j_i \Delta H_i / n_i \mathbf{F}\right) / W_2 - 2h(T_2 - T_1)/W_2 \quad [A-4]$$

where V is the potential difference between the positive and the negative grid, which may be approximately represented by the cell potential. W_2 is the thickness of the grid surrounding. Other parameters have already been described.

At the bottom of the cell, there is an electrolyte reservoir. By assuming that the heat transferred from the grid and from the grid surrounding to the bottom electrolyte reservoir is instantaneous, the boundary conditions at the bottom may be expressed as

$$y = 0, \quad \rho_l \hat{C}_l V_b \frac{\partial T_1}{\partial t} = k_1 \frac{\partial T_1}{\partial y} - h^*(T_1 - T_0) \quad [A-5]$$

$$\rho_l \hat{C}_l V_b \frac{\partial T_2}{\partial t} = k_2 \frac{\partial T_2}{\partial y} - h^*(T_2 - T_0) \quad [A-6]$$

where ρ_l and $\hat{C}_l$ are respectively the density and the specific heat of the electrolyte. T_0 is the outer atmospheric temperature. h^* is the heat transfer coefficient across the bottom cell wall to the outer atmosphere. V_b is the reservoir volume at the bottom.

At the top of the cell, the grid terminal is subjected to water cooling. The temperature of the grid terminal may be assumed equal to the coolant temperature (T_c). The boundary condition is then

$$y = L, \quad T_1 = T_c \quad [A-7]$$

For the top of the grid surrounding, following the same treatment as that for the bottom, the boundary condition is

$$y = L, \quad \rho_l \hat{C}_l V_t \frac{\partial T_2}{\partial t} = -k_2 \frac{\partial T_2}{\partial y} - h^*(T_2 - T_0) \quad [A-8]$$

where V_t is the reservoir volume at the top.

Equations [A-1] and [A-2] were solved subjected to the boundary conditions (Eq. [A-5]-[A-8]) by finite difference method. The Crank-Nicolson implicit techniques (11) followed by elimination algorithm was used. The calculation was carried out for a daily charge (5 hr discharge + 9 hr charge + 10 hr rest period) with the Cell Design A. The values of physical parameters for the calculation are

$\rho_1 = 11.34$ g/cm^3
$\rho_2 = 2.884$ g/cm^3
$\hat{C}_1 = 0.2196$ J/g-K
$\hat{C}_l = 1.054$ J/g-K
$W_1 = 0.128$ cm
$W_2 = 0.85$ cm
$T_0 = 298$°K
$k_1 = 0.353$ W/cm-K
$k_2 = 0.004725$ W/cm-K
$L = 101.6$ cm
$T_c = 298$°K

The numerical results show that the temperatures of the grid and the grid surrounding are nearly identical at any position in the vertical direction. Figure A-2 shows the temperature variation of the grid with time during the first daily cycle. In the figure, Q_t represents the total heat generated in the cell during the 14 hr cell operation; Q_{g1} represents the heat released from the grid terminal to the outer atmosphere during the same period; Q_{g2} represents the total heat released from the grid terminal to the outer atmosphere during the entire day (24 hr); r_1 is the percentage of the heat released from the grid terminal to the outer atmosphere relative to the total heat generated in the cell during the 14 hr cell operation; r_2 is the percentage of the total heat released from the grid terminal to the outer atmosphere relative to the total heat generated in the cell during the entire day. It is shown that the heat released from the grid terminal is limited by the heat conduction in the grid. Much of the heat generated remains in the cell and contributes to the rise of the cell temperature as shown in Fig. A-2. Figure A-3 shows that a large temperature difference over the grid will exist as result of the water cooling at the top grid terminal. The temperature distribution profiles over the grid during the daily cycle are also illustrated in Fig. A-3.

Further Experimental Tests of the Convective Flow Theory of Zn Secondary Electrode Shape Change I

Drannan Hamby* and Jeffrey Wirkkala[1]

Linfield Research Institute, Linfield College, McMinnville, Oregon 97128

ABSTRACT

Additional experiments have been carried out to test the convective flow theory of zinc electrode shape change. The assumptions implied by the theory that overpotential and current distribution should be uniform over a flat rectangular porous zinc electrode operated with severely limited convective flow are not supported by these measurements. Several possible explanations of the observed behavior are suggested. Evidence of deterioration of anodic performance of the limited flow porous zinc electrode on cycling is presented. A flooded, non-vented Hg-HgO reference electrode without head space is described.

Choi, Bennion, and Newman have described a one dimensional mathematical model of the porous zinc secondary electrode with "normal" convection.[1,2] The model is based on the hypothesis that lateral movement of active material over the surface of the electrode, commonly called shape change, is determined primarily by convective flow driven by membrane pumping effects. In experiments designed to test the theory, material redistributions and volume average fluid flow rates in a zinc-silver oxide cell with "normal" convection were found to be in agreement with predictions based on the model (2). Zinc electrodes cycled in a cell designed to operate with severely limited convective flow in the zinc compartment showed insignificant material redistribution (2). During this latter series of experiments, several questions arose concerning the behavior of the zinc electrode when operated under limited flow conditions. It was observed that flooded, nonvented, limited flow cells constructed from porous zinc and silver electrodes having 12 and 6 A-hr theoretical capacities, respectively, would accept less than 1 A-hr of charge at charging rates from 15 to 30 mA/cm^2 before the onset of severe polarization. Qualitative, visual observation of used zinc electrodes from cells with limited convection in the zinc compartment indicated, through nonuniform zinc metal distribution, that current and potential distributions over the surface of the electrode were not uniform as implied by the convective flow theory.

It was found that the initial charge accepting capacity of the flooded, nonvented cells could be more than doubled by venting and enlarging the silver electrode compartment; however, capacity deteriorated with cycling. These and other observations indicated that the silver electrode was responsible for certain of the poor performance characteristics of these cells. However, since the cells were constructed without reference electrodes it was impossible to measure overpotentials at each working electrode, and, thereby, relate measured cell terminal potential differences to individual electrode behavior. Since one objective of our present investigations is to obtain information which will be useful in determining how the convective flow theory might be useful in the design of long-lived porous zinc secondary batteries, it was decided to design and operate a modified limited convection cell, incorporating several reference electrodes, which would provide information on the values of zinc electrode overpotential at various points over the zinc test electrode surface both on charge and discharge. In order to avoid confusion with phenomena associated with the silver electrode, it was decided to use a precharged zinc counterelectrode in the new cell.

Equipment and Procedures

Electrodes.—All electrodes used in this work to date have been furnished by AFAPL (Air Force Aero Propulsion Laboratory, Wright-Patterson Air Force Base, Ohio). The zinc electrodes come in the discharged state wrapped in Viskon (cellulose rayon) paper and consist of pressed, blended ZnO, HgO, and Teflon binder on expanded silver screen (3.23×10^{-2}g of Ag/cm^2). These electrodes are prepared according to the procedure described by Keralla (3). They are approximately 10.2 cm long, 6.4 cm wide, and 0.2 cm thick. Different batches of electrodes are found to vary slightly in composition, and different electrodes within the same batch differ in initial weight by as much as 8%. Previous analysis of both used and unused electrodes indicated a layered structure in the active material (2). By color, it appears that the layer near the collector screen is rich in HgO. This layer also appears finer grained, more coherent, and more firmly bound together than the material which covers it. The quantity of ZnO present on each electrode is adequate to yield a theoretical capacity, at 100% utilization, of approximately 12 A-hr. Initial HgO content in the electrodes is 33 mg HgO/g ZnO as determined in earlier work using an atomic absorption spectrophotometer (2). The silver electrodes also come in the discharged state. They have approximately the same apparent surface area, 66 cm^2, are 0.4 mm thick, and consist of porous sintered silver (1% palladium) on expanded silver screen. They were prepared according to the procedure of Falk and Fleischer (4). Estimated theoretical capacity of these electrodes at 100% utilization is 6.5 A-hr.

Acrylic electrode holders.—In Cell I the zinc test electrode faces a precharged zinc counterelectrode across two layers of 0.001 in. thick RAI P 2291 (40/20) separator.[3] Figure 1 illustrates the 1 in. thick acrylic holder for the porous zinc test electrode. The rectangular chamber milled into the center of the holder is just large enough to contain the dry electrode. The Hg, HgO reference electrodes designated, a through i, described more fully below, are located behind the test electrode. Sealed electrical contact is made to the test electrode through the cell wall, j, Fig. 1, and a, Fig. 2. Ports m and k are used for vacuum evacuation and filling of the cell with electrolytic solution. In the experiments to be described, the ports m and k are sealed after the filling operation is completed and the test electrode is normally operated flooded and not vented. Details of filling ports and port plugs are shown in Fig.

[3] RAI Corporation, 225 Marcus Boulevard, Hauppauge, New York 11787.

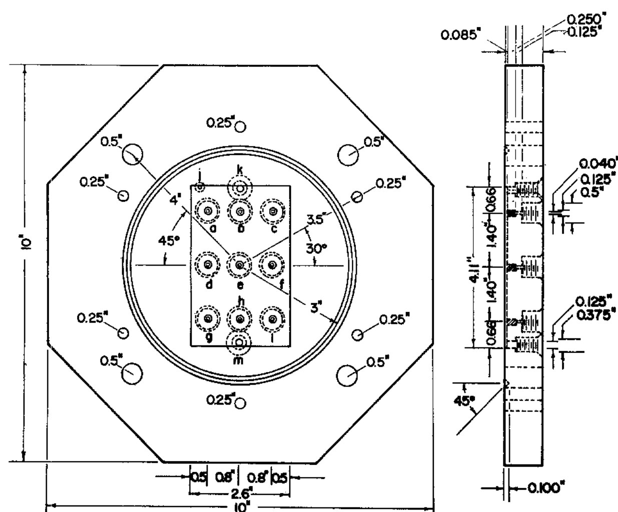

Fig. 1. Acrylic electrode holder for the zinc test electrode. Hg-HgO reference electrodes are designated a-i; k and m are filling ports; j is the electrode lead exit port.

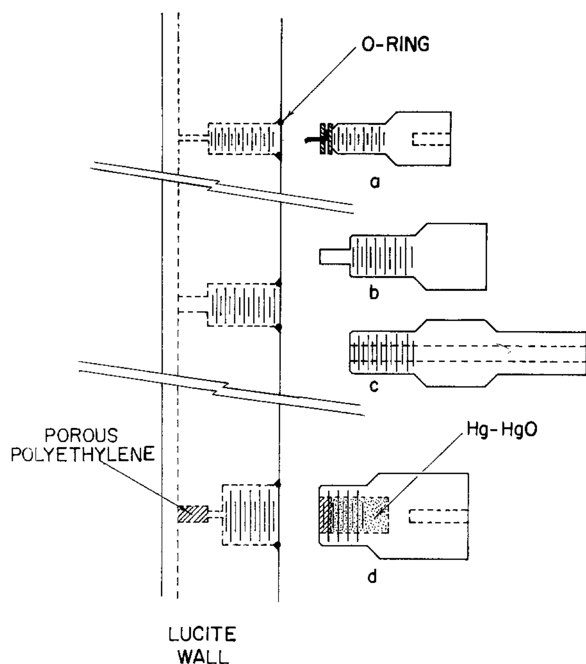

Fig. 2. (a) Schematic illustration of the arrangement for making sealed electrical contact to the electrode through the acrylic wall. (b) Filling port plug. (c) Attachment for vacuum filling through filling port. (d) The Hg-HgO electrode. Items labeled a, b, and c are silver plated brass. Item d, the container of the Hg-HgO paste is #304 stainless steel.

2. A large O ring, laid into the V groove surrounding the Zn electrode, seals the cell when the test electrode holder is bolted to the counterelectrode holder with six 0.25 in. bolts. The larger 0.5 in. holes are used to support the cell when in operation. During cell operation, convective flow rates in the zinc test electrode compartment are low, limited by pressure distortion of chamber dimensions and changes in partial molar volumes of materials participating in the cell reaction.

The acrylic holder for the zinc counterelectrode is similar to that for the test electrode. It also provides a milled rectangular chamber just large enough for its electrode. However, a 0.125 in. deep reservoir space is provided behind the counterelectrode and the compartment is normally vented through pipes attached to the filling ports. The counterelectrode and its reservoir are separated by a 0.125 in. thick sheet of porous polyethylene sheet.[4] To avoid distortion of the counterelectrode and its polyethylene backing plate due to pressure buildup in the test electrode chamber it was necessary to provide additional backing support for the polyethylene sheet. This was accomplished with additional sections of porous polyethylene sheet placed in the reservoir. Evacuation and filling ports and sealed electrical contact are as on the test electrode side. After all preparative procedures are complete, the cell is operated with the zinc electrodes positioned horizontally, the test electrode below the counter, with the counterelectrode filling ports used to connect the counterelectrode compartment to solution-filled reservoir tubes, gas collection tubes and external Hg-HgO in glass reference electrodes above the cell. During cell operation, the counterelectrode is always flooded but vented. Cell I in its normal, horizontal operating position is shown in Fig. 3.

Reference electrodes.—It was desired that convective flow be minimized in the test electrode chamber; therefore, a completely filled, nonvented reference electrode without head space was required. Use of a reference electrode of ordinary design, *i.e.*, an open electrode or an electrode which was vented or had head space would, because of pressure variations in the cell, result in periodic flow of fluid between the reference and test electrode chambers.

In preliminary experiments small electrodes fabricated from Cd, amalgamated Cd, commercial Cd negatives, and commercial nickel positives were all tested in the cell as reference electrodes; none of these performed satisfactorily. In all cases large differences (10-125 mV) in potential between apparently similarly prepared electrodes were observed and the potentials drifted erratically with time. The Hg-HgO system was then adapted to fit the needs of these experiments. The Hg and HgO used to prepare the electrodes were "Baker Analyzed" reagent-grade chemicals without further purification. Preparation of the Hg-HgO paste was done according to the procedure described by Falk and Salkind (5). The #304 stainless steel electrode holders shown in Fig. 2d were washed and then rinsed in distilled water and dried before the Hg-HgO paste was packed into the holders. In a preliminary experiment six of the Hg-HgO in steel references were prepared and placed in the cell wall. The cell container without zinc electrodes was then assembled and vacuum filled with the ZnO-saturated KOH solution. Two additional Hg-HgO electrodes in glass H cells (5) were prepared similarly and connected to the cell container with latex tubing filled with the same electrolytic solution. Initial potential differences between the eight electrodes, using one particular electrode as a

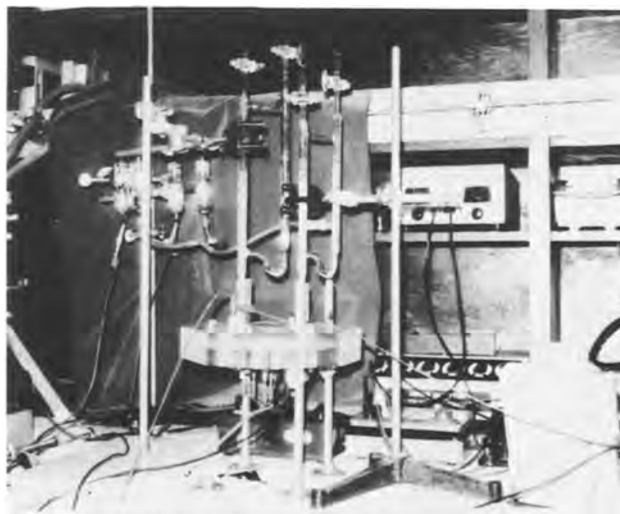

Fig. 3. Cell I in its normal, horizontal operating position. Gas collection burets are above the cell and above and to the left two external Hg-HgO in glass reference electrodes are visible.

[4] Obtained from ERB and Gray Scientific, Culver City, California, described as having an average pore size of 70 μm, designated F-13639.

reference, decreased with time to less than ± 0.2 mV after 28 hr. Daily observations of the electrodes over a seven-day period indicated that this level of agreement was being maintained over that period of time. Intentional polarization of one of the references by 0.25 mA indicated that the electrode had a fairly high resistance, 150Ω; however, after polarization for 10 sec at 0.25 mA the electrode returned to within less than 1 mV of its initial potential within about 1 sec.

Electrical equipment.—All cell-cycling experiments were carried out at constant current. Power sources were commercially available galvanostats. Potential differences across the cell terminals, *i.e.*, between the zinc test and zinc counterelectrode, were recorded continuously using one channel of a Hewlett-Packard 7100B two-channel recording voltmeter. A second, less sensitive, recording voltmeter was used in conjunction with a power resistor in series with the cell to monitor cell current to ± 25 mA. A Flexopulse Hg 108A6, repeat-cycle timer, was used as a reversing switch which allowed continuous variation in cell charge and discharge times. The switch also allowed for brief intervals of a few minutes duration with no cell current between half-cycles. Potential differences between the various Hg-HgO in steel reference electrodes and test, counter, or external, Hg-HgO in glass reference electrodes were monitored periodically using the other channel of the Hewlett-Packard recorder connected sequentially to different pairs of electrodes by an Eagle Signal Model MT-19 Step Switch controlled by another repeat-cycle timer.

Chemical analysis of used electrodes.—The distributions of metallic zinc and zinc compounds over electrode surfaces after cycling were of interest. The unused electrodes consist of mixtures of ZnO, HgO, and inert binder on expanded silver screen. Used electrodes contain, in addition to the substances listed above, metallic zinc and mercury, possibly various amalgams of zinc and silver, potassium hydroxide, and probably several hydroxides and hydroxy complexes of zinc (6). Selective dissolution methods for analysis were tested but found unsatisfactory because of air oxidation of electrolytic zinc. The following method was subsequently used to determine the distribution of zinc compounds over the electrodes. After removal from the cell each electrode was sectioned into fifteen samples and each section was labeled. Care was taken to record the position which the sample occupied on the electrode with respect to the electrode lead and the reference electrodes. Each section was treated with excess 6*N* HCl, the resulting solution filtered, buffered, and then titrated with standard EDTA and the result calculated and reported in terms of ZnO. It was subsequently learned that freezing the samples to prevent air oxidation of zinc and collection of the evolved H_2 upon treatment of the sample with acid would have permitted determination of both zinc metal and zinc compounds; however, at the time these electrodes were analyzed the rapidity of air oxidation of the electrolytic zinc was not realized, they were not frozen before storage, and the zinc metal information which was obtained from gas evolution data was not representative of the electrodes at the end of cycling.

Electrolytic solution.—The solution used for filling the cells was prepared from singly deionized distilled water and reagent-grade chemicals. KOH was first dissolved in water to prepare a concentrated solution. This solution was diluted to a specific gravity of 1.40 at 20°C. Fine grained reagent grade ZnO was then added in excess of the amount required to saturate the solution, and magnetic stirring continued for several days. The solution with excess crystalline ZnO was stored in tightly capped polyethylene bottles.

Cell filling.—Filling of the cell was carried out with the electrodes positioned vertically with respect to the earth's surface. The filling procedure in all cases involved evacuation of the cell and rubber filling lines by mechanical pumping followed by slow, simultaneous vacuum filling of the compartments with solution from a common reservoir. Following return of pressure in the filled cell to atmospheric, the cell was left to soak for at least 24 hr before the appropriate ports were plugged and cycling was begun.

Treatment of data.—The distribution of total zinc as ZnO over used and unused electrodes was determined. Because it is difficult to measure accurately the dimensions of the samples and because of total weight differences between different electrodes, the collector screen material is used to normalize the data. The normalization ratio used for each sample is

$$\frac{Q_{ZnO}}{Q_{ZnO^*}} = [W_{ZnO}{}^i/(W_{cs}{}^i\, 66.0\ \text{cm}^2/\sum_i W_{cs}{}^i)]/[\sum W_{ZnO}{}^i/66.0\ \text{cm}^2]$$

where $W_{ZnO}{}^i$ = weight of total zinc expressed as zinc oxide, sample i, and $W_{cs}{}^i$ = weight of collector screen, sample i. Assuming that the weight per unit area of the collector was uniform, the numerator of the normalization ratio Q_{ZnO}, is the weight of ZnO per unit area of sample. Similarly, the denominator, Q_{ZnO^*}, is the average weight of ZnO per unit area for the whole electrode. The ratio, Q_{ZnO}/Q_{ZnO^*}, compares the ZnO per unit area at a particular position on the electrode with the average value for the electrode as a whole and serves as a measure of electrode uniformity.

Comparisons of samples from used electrodes with samples from unused electrodes on the basis of the normalized data involves the assumption of uniformity of weight/area for the used collector screens.

Counterelectrode charging.—The zinc counterelectrodes were charged by assembling the cell with the counterelectrode in its normal position but with two porous silver electrodes in the test electrode compartment rather than the test electrode. Charging of the counter was normally carried out at 0.150A to a charge of 4.0-4.5 A-hr. The cell was then drained, opened, the silver electrodes replaced with the test zinc electrode, new membrane separator placed in the cell followed by cell closure and refilling. These operations were carried out as quickly as possible to avoid air oxidation of the charged counterelectrode.

Specific precycling treatment, Cell I.—Prior to counterelectrode charging the cell was vacuum filled with electrolyte and allowed to soak for 24 hr. Charging was carried out with the cell attached to the filling pipes. The counterelectrode was charged 29.5 hr at 0.150A and then 16.5 hr at 0.015A for a total of 4.67 A-hr. After placing the test electrode in the cell, the nine Hg-HgO reference electrodes in steel containers were prepared as described above and placed in the cell wall and the cell was again vacuum filled. The various reference electrodes were observed to be in agreement with one another to within ± 4 mV when cycling began approximately 48 hr after the final filling.

While the cell was still in the vertical position and attached to the filling tubes, it was taken through two complete cycles at 0.15A such that when the first-charge half-cycle started at the 1.0A rate there was nominally 0.63 A-hr charge on the test electrode and 4.04 A-hr charge on the counterelectrode.

Subsequent to the initial low current density cycles, the cell was vacuum-treated to remove gas and then carried through one complete cycle at 1.00A total cell current while still mounted in the upright position and attached to the filling pipes. This cycle was intended to provide data for comparison with cell data taken after the cell was placed in the horizontal position and the test electrode closed (no noticeable difference was observed in the two cases).

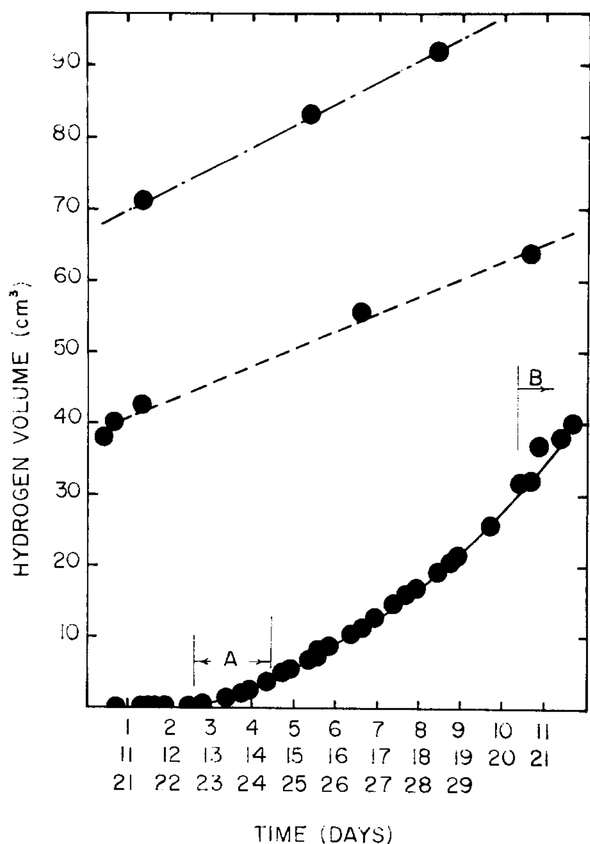

Fig. 4. Cumulative volume of gas at 25°C and 1 atm pressure evolved from the vented counterelectrode as a function of time.

The cell was then positioned horizontally, the test electrode closed, and the cell was cycled at 1.00A constant current; initial duration of each half-cycle was 2.0 hr but half-cycle lengths were decreased as cycling continued. Gas evolved from the counterelectrode chamber of the cell was trapped above the cell and the volume of evolved gas was measured as a function of time.

Results

The average cumulative amount of gas evolution from the vented counterelectrode was observed after the lower electrode was closed. The data are plotted in Fig. 4. The rate was observed to be very low during the initial 48 hr after closure but then to increase. After twelve complete cycles of operation at 1.00A the cell was subjected to several low current cycles at 0.150A (labeled period A, Fig. 4), to see if this might decrease the rate of gas evolution. It did not. The average rate of gas evolution decreased only after cycling of the cell was stopped (B, Fig. 4). The rate of gas production during cycling reached approximately 6.6×10^{-6} moles/hr corresponding to a loss of 4.3×10^{-4}g of zinc per hour.

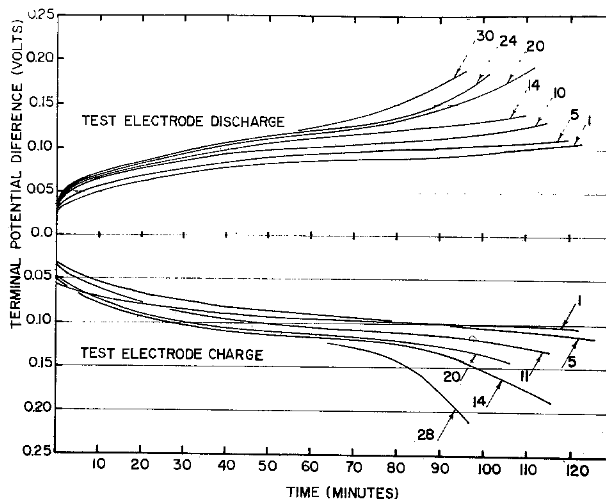

Fig. 5. Summary of behavior of Cell I during the first thirty cycles. Cycles are numbered. Potential differences between the zinc test electrode and zinc counterelectrode are plotted as functions of time.

A summary of Cell I behavior during the first thirty 1.00A, constant current cycles is shown in Fig. 5. As cycling continued, total cell polarization increased for both half-cycles. By adjusting half-cycle lengths total polarization was kept below 200 mV and symmetry of polarization of the cell during the half-cycles was approximately maintained; however, as cycling continued at constant current, both half-cycle lengths had to be shortened to avoid large values of cell polarization.

The presence of the Hg, HgO reference electrodes allowed periodic measurement of reference to test electrode potential differences at different areas over the test electrode surface. Some selected values of overpotential of the test electrode at different sites during charge and discharge are shown in Tables I and II. The data in Table I are from near the middle of the half-cycle and near the end. The trend which is illustrated is that the overpotential behavior of the test electrode on charge remains essentially the same as cycle number increases. This was found to be so even though there were sharp increases in some cases in the total cell polarization. On test electrode discharge, *i.e.*, when the test electrode was behaving as an anode, there were large increases in overpotential near the end of the half-cycle as cycle number increased, and, large differences in overpotential between different sites on the electrode began to appear. Although a well-defined pattern in the magnitudes of the overpotentials was not clearly developed in the early cycles, 2-20, a pattern did develop between cycles 20-23 (see Table II) which carried through for much of the remaining operation of the cell (with the obvious exception of electrode h). In Fig. 6-9 potential differences between the various Hg-HgO reference electrodes and the test electrode have been plotted to

emphasize the development of differences in anodic overpotential between sites on discharge and the fact that certain sites near electrodes a, c, and d, and to a lesser extent f and i developed higher anodic overpotentials than others as the experiment progressed.[5]

The same pattern of test electrode behavior illustrated above was observed throughout all stages of cell cycling; *i.e.*, relatively low overpotential at all times and sites when the test electrode was acting as a cathode, even when total cell polarization was high, and large overpotential with large differences in between sites developing when the electrode was acting as an anode and total cell polarization was high. This phenomenon has now been observed in the operation of several similarly prepared cells and is believed to be typical of the electrode-cell design. Furthermore, additional measurements on the counterelectrodes in

similarly prepared cells indicate that they behave in a similar manner, *i.e.*, consistently low cathodic overpotential on charge, consistently higher overpotential on discharge, increasing in magnitude as cycling continues.

Additional features of the data taken during operation of Cell I, which deserve mention are (*i*) slow (hours) relaxation of the anodic overpotential at the test electrode, at the end of discharge and (*ii*) the observation of an irregular periodic fluctuation in test electrode overpotential after termination of cell current.

Cell I was operated through a total of 83 cycles at 1.00A constant-cell current. Near the end of testing the cycle lengths were greatly reduced, *e.g.*, discharge half-cycle 78 shown in Fig. 9 was 44 min in length. The test electrode was removed from the cell in the partially discharged condition after 83 cycles, sectioned, and analyzed by the gas evolution and EDTA titration technique described above. The results are summarized in Fig. 10. It was found that the reaction rate with HCl for the used electrode samples was much slower than that observed with pure granular zinc samples used in standardizing the method. Figure 11 illustrates volume of hydrogen gas evolved as a function of time for sample 2, test electrode, Cell I. These data are typical of the observed behavior.

The reference electrodes were checked against one another, and against the Hg-HgO in glass electrodes after cell relaxation several times during the experiment and at the end of the experiment. Agreement between members of the set was observed to improve as cycling continued, *e.g.*, after relaxation of the cell for 12 hr after 83 cycles eight of the electrodes were in agreement to ± 1 mV.

Visual observations indicated a significant resistive effect in the current collector on the distribution of metallic zinc over the electrodes on charge. This effect was most obvious when, after charging the counter-

electrode, the cell was opened and the counter could be observed in the charged condition. Zinc was most heavily plated near the lead with the amount per square centimeter apparently diminishing with distance from the tab.

Discussion and Conclusions

According to the initially published one dimensional convective flow theory (1), material redistributions as well as differences in potential and current distribution which develop longitudinally along porous zinc electrodes in cells with normal convection are caused by the membrane pumped flows. The theory implies that these effects would not develop if the convective flows were stopped. These implications are only partially supported by the measurements reported here. The development of nonuniformity of overpotential has been directly demonstrated and nonuniformity of current has been indicated by qualitative observations of zinc metal distribution after charge.

Data concerning active material distribution reported as ZnO over the test electrode surface, Fig. 10, are similar to those reported previously for an electrode operated under limited flow conditions (2) which reinforces our conclusions from the previous results that the rate of lateral shape change is significantly reduced by limiting convective flow parallel to the apparent electrode surface. The standard upon which this conclusion is based is the data reported by Choi for the longitudinal redistributions of zinc over the surface of zinc electrodes operated in cells with normal convection for periods of time and at operating currents similar to those reported here (2, 11). The redistributions in those cases were drastic and involved the depletion in zinc compounds to approximately 20% of their initial values over the end of the electrode nearest the cell reservoir. Thus, although the data in Fig. 10 do indicate some redistribution of material, the observed redistribution is much less than that reported by Choi for the same kind of electrode, operated under similar conditions of current density and number of cycles in a cell with normal convection.

These experiments indicate that some of the difficulties previously reported with respect to cycling cells with flooded, nonvented porous zinc electrodes with limited convection were the result of problems with the performance of the zinc electrode as an anode. Cycling of the flooded nonvented AFAPL zinc electrodes at constant cell current to approximately 15% of theoretical capacity in an environment in which convective flow is severely limited commonly results in the development of an average anodic overpotential which increases with number of cycles. No corresponding change in average cathodic overpotential has been observed. This observation is quite different from that reported by McBreen for a cell with normal convection (10). His observations indicated increasing cathodic overpotential on charge as cycling proceeded with large anodic overpotentials developing only after over 100 cycles.

In order to keep the anodic overpotential of the zinc electrode below a preset value it was found necessary to shorten the half-cycle duration as cycling continued, *i.e.*, the electrode capacity decreased, or the available zinc decreased. Vacuum refilling of the cell has some beneficial effect on capacity but does not restore the electrode to its initial state (2). The data indicate that the anodic effect is not limited to occurrence at the limited convection test electrode but occurs with equal severity at the vented counterelectrode. The rate of H_2 evolution from the cell is not great enough to explain the loss in available zinc.

Certain areas of the test electrode of Cell I exhibited consistently higher overpotentials than other areas over much of the lifetime of cell operation, *e.g.*, inspection of Fig. 6-9 indicates that areas near electrodes a, c, and d suffered, on the average, between cycles 23 and 78, the highest overpotentials; next, in order, were areas near electrodes f and i. On the average, during this same period, electrodes b, e, and h, those along the middle of the electrode, exhibited the smaller anodic overpotentials. Thus, a tendency toward greater overpotential at the top and outer edges on the electrode is discernible. Those areas a, c, and d which consistently exhibited the highest overpotentials suffered the greatest material loss; however, areas near f and i which exhibited, on the average, the next highest overpotentials, actually appear to have gained material. It is, therefore, difficult to conclude, on the basis of the data, that a correlation exists between observed overpotential and extent of material redistribution. The cause or causes of the observed increases in anodic overpotential on discharge remain a subject for further investigation. Passivation of porous zinc electrodes by thin film formation (called blockage of the second kind by some authors) has been suggested (7, 8) as has the development of anodic overpotential through plugging of the porous electrode through deposition of reaction products in the electrode pores (called blockage of the first kind by some authors) (12). Redistribution of zinc and zinc oxide parallel to the electric current flow, termed x-direction shape change as opposed to lateral shape change, has been suggested as an important limiting factor in the performance of certain porous zinc electrodes (12, 9). The separation of metallic zinc from the current collector has also been reported (2, 13) and serious concentration overpotential at the zinc electrode has been predicted (1). Data currently available on the cells of interest are not adequate to allow identification of which or to what extent each of these various possible mechanisms is contributing to the limitation of anodic performance of these particular electrodes.

Physical nonuniformities of real electrodes and membranes may contribute to the deviation of cell performance from theoretical predictions. In addition, the real electrodes differ from the original model in the resistive effect of the current collector; *i.e.*, the initial nonuniform zinc metal distributions observed on the charged counterelectrodes indicate a significant resistive effect in the current collector of the electrode which was not taken into consideration in modeling the electrode.

ABSTRACT

The role of electrochemically coprecipitated cobalt hydroxide and nickel hydroxide has been investigated at a nickel microelectrode for purposes of elucidating the effect of cobalt hydroxide on the electrode reactions of battery active nickel hydroxide. Hydroxide films were deposited onto the electrode surface from boiling ethanol solutions of $Ni(NO_3)_2$ in the presence and absence of $Co(NO_3)_2$; their behavior in 30% KOH solution was studied by cyclic voltammetry, chronoamperometry, and chronocoulometry. In general, the presence of coprecipitated cobalt hydroxide appears to render the charge-discharge reaction more reversible thereby allowing charging to occur at less positive potentials, this apparently increases the charging efficiency by minimizing concurrent oxygen evolution. The microelectrode was also used to characterize the cathodic deposition process for the nickel hydroxide.

The effect of cobalt hydroxide as a performance enhancing additive on the nickel hydroxide electrode has been known for some time (1). It has been reported that Edison was aware of the effect of cobalt hydroxide addition as early as 1908 (2). In 1925 it was confirmed that an addition of cobalt increased the capacity and life of the positive active material in nickel-iron and nickel-cadmium batteries (1). Cobalt is now used by most manufacturers, but barium, bismuth, cadmium, and lithium have been used as additives with similar effects. In general, it has been thought that these additives optimize the lattice imperfections in the electrode active material so that conductivity is increased and charging efficiency is improved.

Recently there have been quantitative empirical studies on the effect of cobalt addition to sintered plate electrodes. Ritterman, Lerner, and Seiger found that about 20 atom percent (a/o) of the active material as cobalt was optimum for electrodes manufactured using the chemical vacuum impregnation procedure (3), while Kroger found that about 10% was optimum for electrochemically impregnated electrodes (4). Workers at Bell Laboratories have also shown that additions of about 5% cobalt will extend the cycle life of electrochemically impregnated electrodes significantly (5).

* Electrochemical Society Active Member.
Key words: nickel hydroxide electrodes, alkaline cells, cobalt hydroxide additive, cyclic voltammetry, chronocoulometry.

The Air Force process for electrochemical impregnation (6) routinely uses 7-15% cobalt nitrate in the ethanolic nickel nitrate solution used in the preparation of positive plates to improve high temperature charge acceptance, extend the cycle life, and increase charge capacity.

This study was undertaken to gain a better understanding of why positive plate improvement should occur when cobalt hydroxide is coprecipitated with nickel hydroxide in the deposition process. Because the previous studies, which were conducted with large electrodes in actual working cells, had yielded little voltammetric data about the effect of cobalt hydroxide coprecipitation, it was decided that a microelectrode would be employed in this study to gain accurate potential information. Since nickel hydroxide microelectrodes were fabricated by cathodic deposition (6), some preliminary voltammetric studies were conducted to better understand this process. Most of the studies reported herein, however, were conducted with cathodically deposited nickel hydroxide electrodes immersed in 30% KOH. Charge-discharge characteristics were studied by slow scan cyclic voltammetry in a manner similar to that of MacArthur (7) and by double potential step chronoamperometry and chronocoulometry. Both types of experiments were conducted in the presence and absence of coprecipitated cobalt hydroxide.

Experimental

All experiments were conducted at a nickel working electrode with a Princeton Applied Research Model 170 electrochemical system (PAR). The working microelectrode was constructed by forcing a 0.05 in. nickel wire through a Teflon sleeve and grinding the end flat. The resulting disk electrode was then etched with 6M HCl and subjected to the cathodic deposition process to cover it with a uniform nickel hydroxide film. All experiments were conducted in a polyethylene cell fitted with a nickel auxiliary electrode. All potentials were measured against an aqueous KCl saturated calomel electrode (SCE) fitted with a 20 cm sidearm salt bridge with a pin-hole junction at its end. After every few hours of experimentation, the solution in the sidearm was withdrawn and replaced with fresh saturated KCl solution; in this manner it was possible to use the SCE reference even in 30% KOH solution.

Cathodic deposition of nickel hydroxide was carried out in an almost boiling ethanol-water [50 volume percent (v/o)] solution containing 1.8*M* $Ni(NO_3)_2$ alone and in the presence of 0.18*M* $Co(NO_3)_2$; typically, the potential of deposition was maintained at −1.5V *vs.* SCE. After charge-discharge studies in 30% KOH, the electrode surface was ground down and etched again with 6M HCl before being subjected to additional deposition. In order to characterize the voltammetry of the deposition process, some cyclic voltammetry experiments were conducted on $Ni(NO_3)_2$ solutions in ethanol-water mixtures containing KNO_3 as a supporting electrolyte. These experiments were conducted at an etched nickel electrode in quiescent solution at ambient temperature.

Charge-discharge studies were conducted in 30% KOH solution using the cell described above. It was soon discovered that charge or mass transport through the nickel hydroxide film was the current limiting step in the charge-discharge process; thereafter, and for most of this work reported herein, cyclic voltammetry and double potential step chronoamperometry and chronocoulometry experiments were conducted in stirred solutions. This technique has been used successfully in previous studies of membrane covered electrodes (8, 9). Cyclic voltammetry sweep rates employed were very slow. Double potential step experiments were initiated at the rest potential of a fully discharged electrode and after stepping to the desired charging potential for the desired time period of charge, the potential was returned to the initial rest potential for discharge measurements.

Cathodic Deposition Studies

In the Air Force process (6) for cathodic deposition of nickel hydroxide, sintered nickel plates are immersed in an ethanol-water solution of nickel nitrate at temperatures near the boiling point of the solution and cathodized at a constant current density (*ca.* 0.35 A/in.²) for a predetermined time (*ca.* 100 min). The current density that is selected is sufficient to cause the solvent supporting electrolyte system to decompose to liberate hydroxide ions. This may occur by the direct liberation of hydrogen gas at the electrode

$$H_2O + 2e \rightarrow H_2 + OH^- \quad [1]$$

or by reduction of the nitrate ion

$$\begin{array}{l} H_2O + NO_3^- + 2e \rightarrow NO_2^- + 2OH^- \\ \vdots \\ 6H_2O + NO_3^- + 8e \rightarrow NH_3 + 9OH^- \end{array} \quad [2]$$

where a variety of reduction products may form in addition to OH^-. This hydroxide ion then diffuses away from the electrode and reacts with a nickel ion present in the bulk of the solution to precipitate battery active nickel hydroxide within the pores of the nickel plaque

$$Ni^{+2} + 2OH^- \rightarrow Ni(OH)_2 \quad [3]$$

Of some concern in this process is the possible deposition of metallic nickel within the pores of the plaque material

$$Ni^{+2} + 2e \rightarrow Ni \quad [4]$$

because its presence would presumably exclude active material from the electrode. Initial experiments were directed towards the characterization of the deposition process to compare the relative likelihood of reactions [1] and [2] and reactions [3] and [4].

This was achieved by carrying out the voltammetry of a saturated KNO_3 solution at a nickel electrode. The results of multiple scans into anodic and cathodic background are shown in Fig. 1a and 2a, respectively. Figure 1a suggests that nickel ion reduction occurs at less negative potentials than hydroxide ion generation through solvent-supporting electrolyte decomposition. Note that the sweep into anodic background generates nickel ion which is electrodeposited in the vicinity of −1.0V *vs.* SCE (10) during sweep 2 of curve 1a. (This is also illustrated in sweeps 2 and 3 of curve 1b which were obtained from solutions containing a small amount of Ni^{+2}. The absence of a reduction wave during the first sweep indicates that the nickel electrode must first be activated to electrodeposit metallic nickel from nickel ions in solution.) Extrapolation of this result into the higher temperatures of the deposition process indicates that some care must be exercised during deposition to adjust the electrode potential sufficiently negative (at moderate current density in a galvanostatic deposition) to generate enough hydroxide ion to shield the electrode (by reaction [3]) from nickel deposition. Battery plates fabricated at low current densities by the Air Force process in preliminary experiments appeared gray in color and exhibited poor charging characteristics (11). These voltammetric results suggest that this was probably due to nickel deposition at potentials too positive for hydroxide generation.

Fig. 1. Multiple scan voltammetry into the anodic background process for ethanol-water mixtures saturated with KNO_3. A bare nickel electrode was employed and the scan rate was 1 V/sec. Curve a: saturated KNO_3; curve b: saturated KNO_3 containing 2 g/liter $Ni(NO_3)_2$.

Figure 1b illustrates the effect of adding a small amount of Ni^{+2} to the saturated KNO_3. The large oxidation wave in the vicinity of 0.4V *vs.* SCE on the reversal of sweep 2 is probably due to the charging of $Ni(OH)_2$ formed during hydroxide ion generation at the activated electrode. The absence of a similar peak in curve 2b suggests that anodic activation of the nickel surface (prior to cathodic deposition) may also be beneficial to the formation of active material.

Figure 2 shows the effect of scanning into cathodic background without anodically activating the nickel electrode. Note that even in the presence of small concentrations of Ni^{+2} (Fig. 2b), the reduction wave at −1.0V *vs.* SCE is absent, just as it was in the first scans of 1a and 1b. This indicates that if this wave has been correctly assigned to the direct reduction of Ni^{+2}, this reduction readily takes place only at an anodically activated nickel electrode. In either the presence or absence of the nickel ion, however, the reduction of the NO_3^--solvent system generates a product that oxidizes in the vicinity of 0.6V *vs.* SCE. The only effect of nickel ion addition is the disappearance of the reversal of this oxidation wave upon scan reversal; compare the second scan of 2b with that of 2a. This indicates that the oxidation product of the cathodically generated species reacts with nickel ion. Since the same species forms in the presence and absence of nickel ion, the species that oxidizes at 0.6V *vs.* SCE is probably one of the products of nitrate reduction; see Eq. [2].

It has been proposed that nitrite ion formed during nitrate reduction causes the oxidation peak at 0.6V *vs.* SCE (12). This hypothesis was investigated by obtaining the voltammograms shown in Fig. 3. Note that while the product of nitrate reduction oxidizes at 0.55V *vs.* SCE, nitrite ion oxidizes at 0.85V *vs.* SCE under identical conditions. Thus, while it appears that nitrate ion reduction produces the hydroxide ion used in the deposition process, it also seems unlikely that the nitrate ion is reduced to nitrite. No further experiments were conducted to identify the product of nitrate ion reduction.

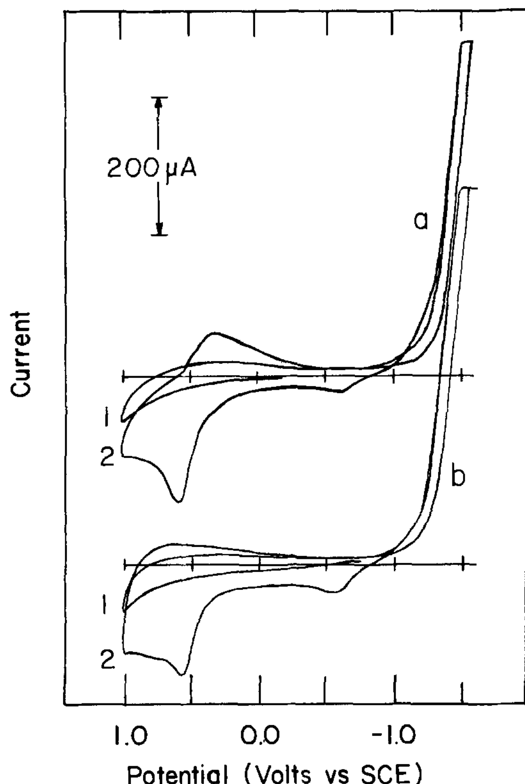

Fig. 2. Multiple scan voltammetry into the cathodic background process for ethanol-water mixtures saturated with KNO_3. See Fig. 1 for experimental details.

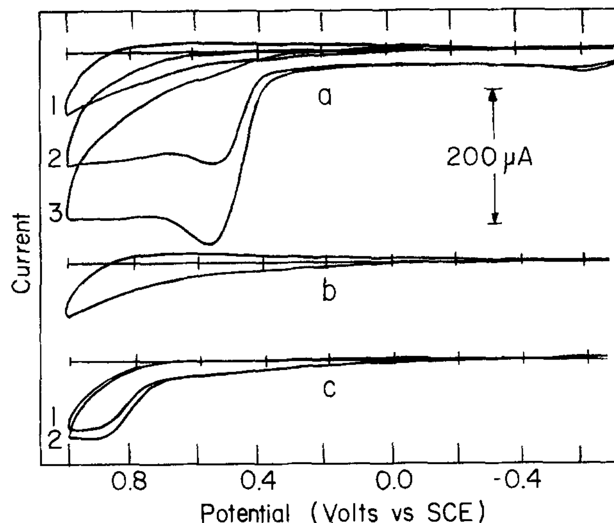

Fig. 3. An investigation of the products of nitrate reduction. Curve a, sweep 1, and Curve b: sweeps in saturated KNO_3 without reaching cathodic limit. Curve a, sweeps 2 and 3: the oxidation of the product of nitrate reduction formed during the cathodic background limiting process (not shown). Curve c: scans over the same range as curve b with 0.010M $NaNO_2$ added. The scan rate was 0.5 V/sec throughout, and the solution contained 2 g/liter $Ni(NO_3)_2$.

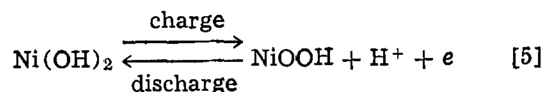
These studies also revealed deleterious effects if the cathodic deposition potential was too negative (at high galvanostatic current densities). When very negative potentials were employed (in the vicinity of −2.0V *vs* SCE), the green, hydrated nickel hydroxide formed on the surface of the electrode. This green hydroxide usually dislodged from the electrode surface during charge-discharge studies and was, therefore, unsatisfactory as an active material. Apparently, the generation of too much hydroxide ion causes the precipitation to occur at greater distances from the electrode. Thus, deposition occurs in a water-rich environment and the hydrated form of $Ni(OH)_2$ is loosely deposited on the electrode surface.

The above experiments suggest that potentiostatic control of the deposition process may result in superior loading of $Ni(OH)_2$ in positive plates. If this is prohibited due to cost or other considerations, great care must be exercised in the selection of an optimum current density for galvanostatic deposition.

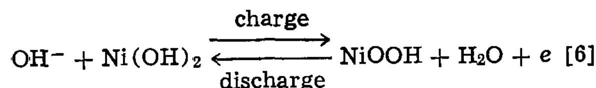
Charge-Discharge Studies

Electrodes prepared by the cathodic deposition process were placed in 30% KOH solution for charge discharge studies. The charging process for electrodes of this type may be viewed as the conversion of $Ni(OH)_2$ (which exists in α and β forms) to NiOOH



$$Ni(OH)_2 \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftarrows}} NiOOH + H^+ + e \quad [5]$$

which remains in the charged state on the electrode surface (1). Alternately, one could write the charge-discharge reaction to emphasize the roles of OH^- and H_2O mass transport in rate-limiting either process



$$OH^- + Ni(OH)_2 \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftarrows}} NiOOH + H_2O + e \quad [6]$$

Alternate reactions have been proposed (7, 13, 14) and proton diffusion has been proposed as the rate-limiting process (15). For simplicity, and because it provides solution species to control charge and discharge rates through diffusion and migration, Eq. [6] has been adopted as the model for this work.

In preliminary experiments, the electrodes prepared by the deposition process were subjected to slow scan cyclic voltammetry in 30% KOH; the results are shown in Fig. 4. In this figure, the behavior in the absence of coprecipitated cobalt hydroxide (curve a) is contrasted with the behavior in its presence (curves b, c, and d). Extremely slow scan rates (0.5 mV/sec) were employed in these studies; if rates much higher than 2 mV/sec were employed, the current maxima shown in Fig. 4 were not observed. (It is anticipated that a detailed discussion of the scan rate dependence at higher scan rates will be the subject of a future communication.) The appearance of current maxima even though the solution was being stirred during the experiment suggests that the rate of charge transfer is mass transport controlled (*i.e.*, by diffusion or migration) within the thin layer hydroxide film on the surface of the electrode. More importantly, Fig. 4 illustrates that the coprecipitation of cobalt hydroxide from a solution containing *ca.* 10% Co^{+2} allows the electrode to charge at a significantly less positive potential (0.13V instead of 0.23V *vs.* SCE). In addition, the charging process appears to occur more reversibly in the presence of coprecipitated cobalt hydroxide than in its absence (ΔEp is 75 mV instead of 150 mV). Thus, the cobalt additive apparently allows the charging process to occur more easily and more reversibly.

Regardless of the presence or absence of cobalt hydroxide, the voltammograms of Fig. 4 all exhibit a considerable increase in recorder noise when the charging process takes place. This 60 Hz noise persists so long as the active material remains in the charged state, but decreases upon discharge. This suggests that the impedance of the nickel hydroxide film increases appreciably in the charged state thereby increasing the probability of noise pickup. This hypothesis was verified by measuring a sixfold increase in cell resistance when the microelectrode was in the charged state instead of the discharged state. Thus, charge transfer appears to be controlled primarily by mass transport through a solid in which the conductivity depends upon the state of charge.

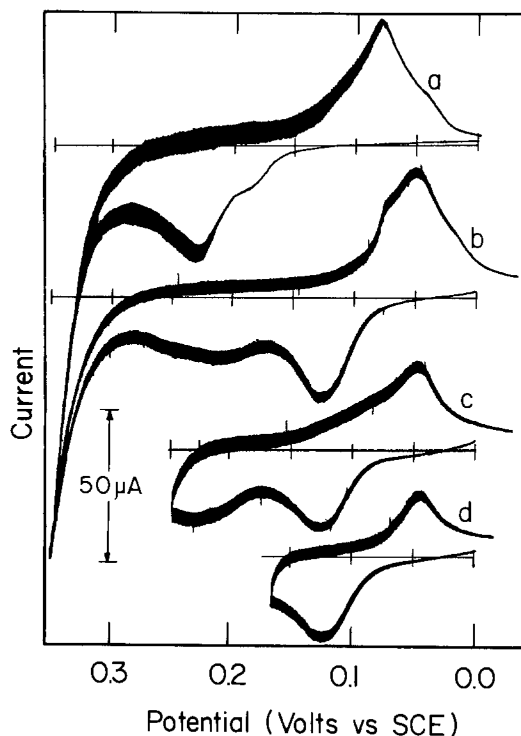


Fig. 4. Slow scan cyclic voltammetry of 30% KOH solutions at the nickel hydroxide electrode. Curve a: containing no coprecipitated cobalt hydroxide. Curves b c, and d: containing cobalt hydroxide coprecipitated from 1.8M $Ni(NO_3)_2$ containing 0.18M $Co(NO_3)_2$. The scan rate employed was 0.5 mV/sec. The solutions were stirred during the recording of these scans.

Typical quiescent solution cyclic voltammograms for nickel hydroxide electrodes containing coprecipitated cobalt are shown in Fig. 5. Although there is a variation in peak height with scan rate, there is not significant difference between voltammograms obtained using stirred or unstirred solutions (see Fig. 4). This indicates that convection is not an important mode of mass transport and that the mass transport that governs the voltammetry shown in Fig. 4 and 5 occurs primarily in the active layer of nickel hydroxide film and not in the solution in the vicinity of the electrode.

Characteristic cyclic voltammetry parameters obtained from Fig. 5 are shown in Fig. 6 as a function of sweep rate. In diffusion controlled cyclic voltammetry in liquid electrolytes, $i_{pa}/v^{1/2}$ is constant regardless of sweep rate for a kinetically uncomplicated redox reaction; for an adsorption process, i_{pa}/v is expected to be constant at different scan rates. In this system, neither condition is obtained, however, and

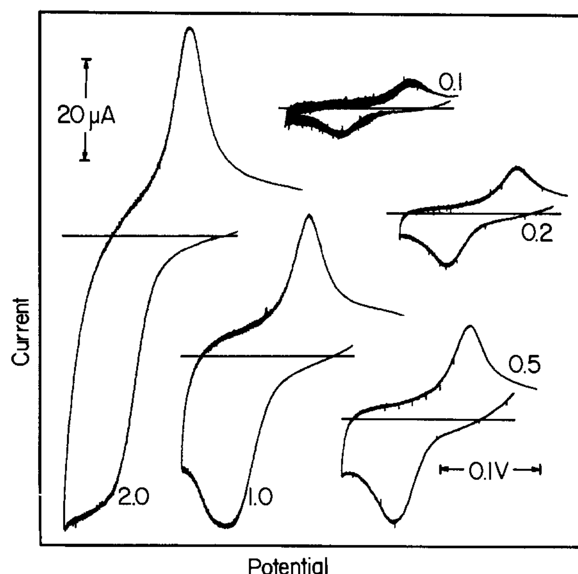

Fig. 5. Slow scan cyclic voltammetry of 30% KOH solution at a $Ni(OH)_2$ electrode containing some coprecipitated $Co(OH)_2$. Scan rates in mV/sec are shown associated with each figure. The solution was quiescent during the recording of these scans.

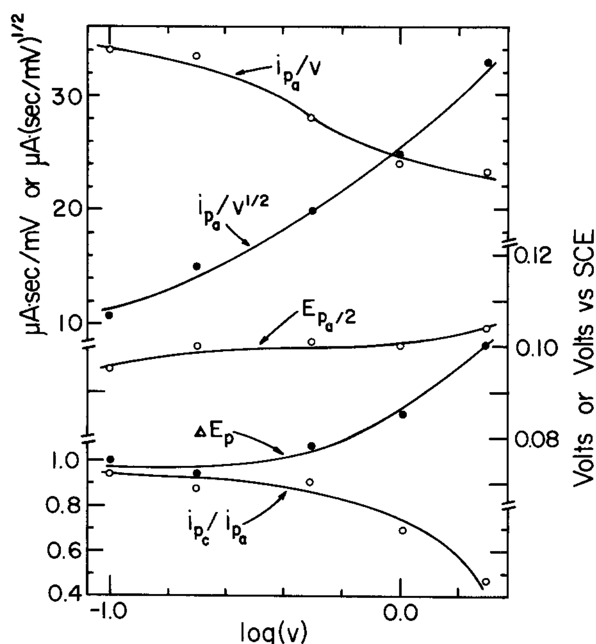

Fig. 6. The variation of cyclic voltammetry parameters with scan rate for a nickel hydroxide electrode (with cobalt hydroxide) in 30% KOH. The scan rate (in mV/sec) is shown logarithmically; other quantities have their usual electrochemical significance.

behavior somewhere between these two extremes might be proposed to explain the first two curves shown in Fig. 6. This behavior seems reasonable for a diffusion-controlled adsorption mechanism which takes place within the hydroxide film containing a limited number of chargeable sites. That the half-peak potential ($E_{pa/2}$) is fairly constant indicates that the same process is taking place at all scan rates. The peak to peak separation ($\Delta E_p = E_{pa} - E_{pc}$) generally increases at high scan rates from a minimum of 75 mV. Thus, on the basis of liquid electrolyte reversibility criteria, the reaction approaches reversibility only at low sweep rates. Since no attempt was made at iR compensation, increases in ΔE_p observed at higher sweep rates may be due to greater uncorrected potential differences at higher currents. Finally, it may be observed that the discharging to charging peak current ratio (i_{pc}/i_{pa}) generally decreases at higher scan rates from a near ideal value of 0.95. This may indicate that at the higher currents associated with faster sweep rates, the charging of the electrode is essentially complete, thereby allowing the generation of oxygen; this current would not be recovered upon discharge.

Chronoamperometric studies generally support the observations made on the basis of cyclic voltammetry. In addition, chronoamperometry reveals that the presence of coprecipitated cobalt hydroxide may cause charging to occur at a faster rate. Current-time curves in the absence of coprecipitated cobalt are shown at various charging potentials in Fig. 7; Fig. 8 shows this behavior in its presence. While curve 7a shows little more than double layer charging, curves 7b and 7c show both double layer charging currents and faradaic currents. At the potentials of curves 7e and 7f, the double layer charging current can no longer be distinguished from the faradaic current because the latter current is much higher at these potentials. At the intermediate charging potentials of curves 7b, 7c, and 7d, however, one may note that a delay time is necessary to achieve a maximum rate of charge. This may be contrasted with the behavior exhibited by all curves in Fig. 8 where no such delay time is observed in the presence of coprecipitated cobalt. Thus, at intermediate potentials, it appears that the presence of coprecipitated cobalt permits the charging to occur at a faster rate. Moreover, it also permits charging to occur at less positive potentials. (Compare the charging potentials of Fig. 7 with those in Fig. 8) This supports the observation made previously on the basis of cyclic voltammetry.

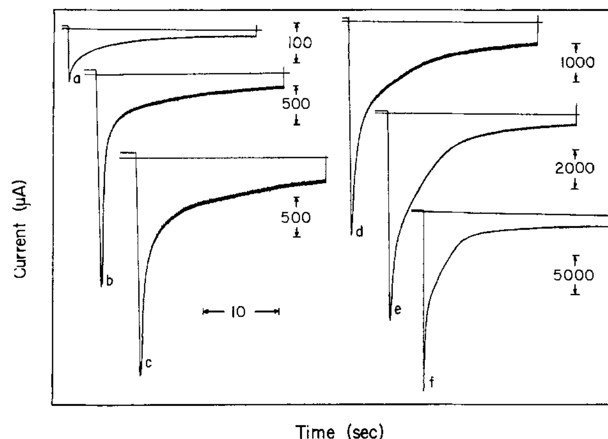

Fig. 8. Single step chronoamperometry of KOH solution at a nickel hydroxide electrode containing *ca.* 10% cobalt hydroxide. Potential steps to 0.10, 0.15, 0.20, 0.24, 0.28, and 0.32V *vs.* SCE were used in curves a through f, respectively.

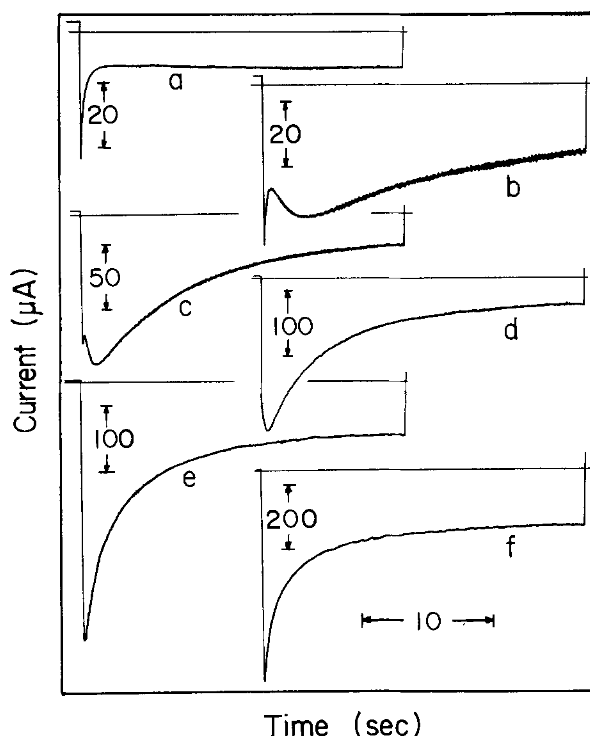

Fig. 7. Single potential step chronoamperometry of 30% KOH at a cobalt-free nickel hydroxide electrode. Curves a through f were obtained by stepping to 0.24, 0.26, 0.28, 0.30, 0.32, and 0.34V *vs.* SCE, respectively, to bring about the charging process.

Behavior like that shown in Fig. 7 has been reported by MacArthur (15) for similar electrodes; however, the mathematical model developed therein failed to explain the unexpected delay times observed in 7b, 7c, and 7d. No satisfactory model for this chronoamperometric behavior has yet been proposed. This thin layer cell problem is not unlike one considered recently in a study of immobilized enzyme electrodes (8, 9) in that mass transport and chemical reaction apparently take place in a film deposited on an electrode. Digital simulation techniques employed in the development of a mathematical model for the enzyme system appear to be applicable to this problem, and work is currently underway to model this chronoamperometric behavior using this technique.

Double potential step chronocoulometry was ultimately used to characterize the potential dependence of the rate of charge and the charging efficiency. A typical charge-time curve is shown Fig. 9. Here it is important to note that the initial potential and the potential of discharge were always maintained at the rest potential of a fully discharged electrode. With the electrode in a fully discharged state, then, the potential was stepped to some predetermined value

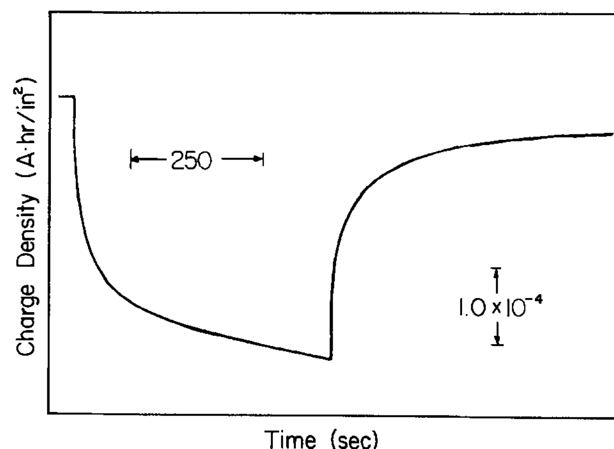

Fig. 9. Double potential step chronocoulometry using a nickel hydroxide electrode containing cobalt hydroxide. The potential was stepped from the rest potential (zero current) of a discharged electrode to +0.175V *vs.* SCE and then back to the rest potential after a 500 sec charge.

and the delivered charge was recorded as a function of time for a specified time interval. The potential was then returned to the initial value and the recovered charge was measured as a function of time until sufficient time had passed to restore the zero current condition. In this manner, the charge delivered and the charge recovered could be measured as a function of charging potential and time of charge.

Elimination of the latter quantity as a variable of interest was accomplished through the results illustrated in Fig. 10. In this experiment, the charging potential was always maintained at 0.175V *vs.* SCE, but the time of charge was varied. The time of discharge was also varied, but the zero current condition was always obtained. Thus, the charge that was recovered was always the maximum that it possibly could be. From the data in Fig. 10 and similar experiments, it soon became clear that complete charging of the microelectrode took place in less than 500 sec. Even though longer charging times were employed, these resulted in no additional recoverable charge when the microelectrode was discharged. Thus, for the electrode employed in these studies, 500 sec was found to be the maximum time necessary to achieve full charge. This time of charge was employed in all subsequent experiments.

The results of several 500 sec charges at various potentials are shown in Fig. 11. Panel I shows charge delivered as a function of charging potential in the

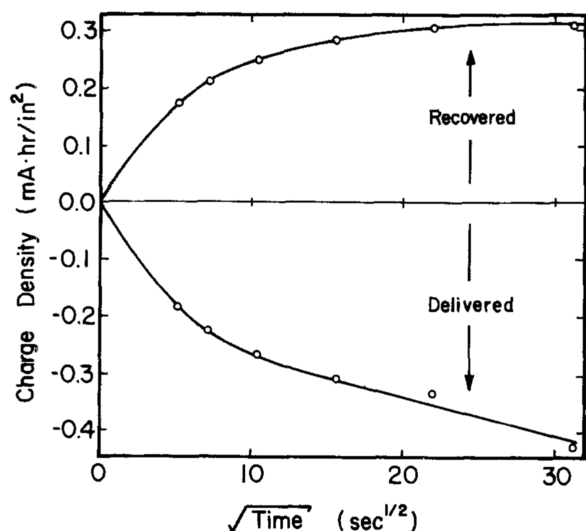

Fig. 10. A comparison of charge recovered to that delivered under potentiostatic conditions at various charging times. Experimental conditions are given in Fig. 9.

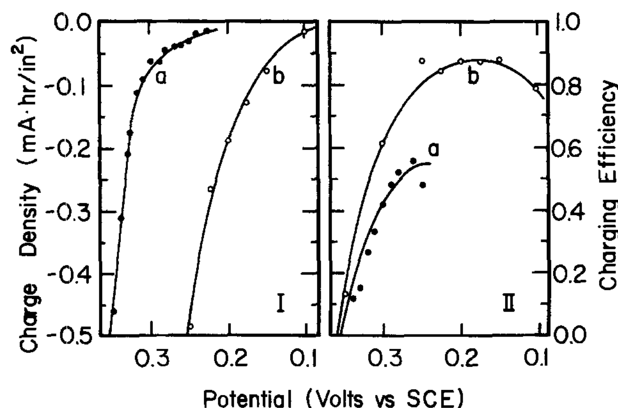

Fig. 11. Panel I: A comparison of charge delivered as a function of electrode charging potential in the presence and absence of coprecipitated cobalt hydroxide. Panel II: A comparison of charging efficiency under the same conditions. In either panel, curve a is for cobalt hydroxide absent; curve b, present. A 500 sec charge was employed throughout.

absence (curve a) and presence (curve b) of coprecipitated cobalt. From this panel, it is clear that the presence of coprecipitated cobalt allows charging to take place at less positive electrode potentials. Panel II shows the charging efficiency (charge recovered charge delivered) as a function of charging potential. In either curve, the charging efficiency falls off at more positive charging potentials because of concomitant oxygen evolution. Since coprecipitated cobalt (curve b) allows charging to occur at less positive potentials, however, less oxygen is evolved and much higher charging efficiencies are observed in its presence. Thus, the presence of cobalt hydroxide allows the electrode to be charged at less positive potentials (as indicated also by the voltammetry) and with greater efficiency because concomitant oxygen evolution is minimized. (This evidence that potentiostatic charging is less than 100% efficient even in the absence of any observable oxygen evolution is most intriguing. This aspect of this problem is being investigated in more detail because the potentiostatic charging efficiency should represent the maximum efficiency that can be obtained from an individual electrode within a cell.)

Data of the form of that given in Fig. 10 permit one to estimate the thickness of the $Ni(OH)_2$ film using Faraday's law and the known density of $Ni(OH)_2$ (2.5 g/cm^3). In this case, the film thickness is calculated to be 2.5 μm thick.

Conclusions

The microelectrode techniques used in this work have been shown to be useful in the study of solid film electrodes of this type. Mass transport (other than convection) occurring within the nickel hydroxide film has been found to determine the rate of the charge-discharge process. This observation suggests that the techniques developed above may be superior to conventional (Tafel plot) methods for studying electrode kinetics in this kind of electrode.

Some insight to the improvement of nickel hydroxide electrodes through cobalt hydroxide coprecipitation has been provided by this work. In general, coprecipitation increases potential range over which charging may occur and also makes the electron transfer process more reversible. Thus, coprecipitated cobalt hydroxide may be viewed as an electrocatalytic agent, but the mechanism of this catalysis is not known. Careful scrutiny of the voltammetry in Fig. 4 might lead one to propose that the presence of the cobalt causes the principal charge acceptor to be α-$Ni(OH)_2$ instead of β-$Ni(OH)_2$ as in the absence of cobalt, but no hard evidence exists to prove this conclusively. If this is the case, however, it appears that the improvement in reversibility could be due to the increased reversibility seen in charge-discharge studies of the α-$Ni(OH)_2$ form (7).

Breakdown and Efficiency of Anodic Oxide Growth on Titanium

C. K. Dyer[1] and J. S. L. Leach

Department of Metallurgy and Materials Science, University of Nottingham, Nottingham NG7 2RD, England

ABSTRACT

The breakdown voltage, as defined by low coulombic efficiency of film formation, increases as the rate of anodic oxide growth on Ti increases. Ellipsometric determination of film thickness shows that the field across the oxide is not constant despite constant ionic flux. Changes in the ionic conductivity of the oxide are proposed to explain the nonlinear voltage/time behavior, and a range of high ionic conductivity is found at high growth rates preceding breakdown and crystallization.

The breakdown of anodic films on valve metals is usually accompanied by a significant decrease in the voltage gradient during growth at constant current density and there is gas evolution, sparking (1), crystallization (2), or a combination of these depending on the metal. The breakdown voltage of most valve metals depends on the metal and the electrolyte used in anodizing. Also, in the cases of Al and Ta, which may be considered typical valve metals, the breakdown voltage is independent of current density, and breakdown usually occurs after the passage of a fixed amount of charge or when a given thickness is reached (3, 4).

Titanium, which is also a valve metal, is reported to show indistinct breakdown at voltages as low as ~5V (2) but film growth continues to higher voltages with the formation of crystalline oxide (2) and oxygen evolution (1). Crystallization is also associated with breakdown of amorphous anodic oxide films on Al and Ta but generally at higher voltages than on Ti. In considering the breakdown behavior of these three valve metals, Yahalom and Zahavi (2) considered that while the link between crystallization and breakdown was established, cause and effect could not be distinguished; the authors assumed that prior to the low voltage breakdown on Ti, the anodic films were amorphous. The poorly defined breakdown behavior of Ti and the uncertainties as to the cause of breakdown and the prebreakdown condition of the anodic film prompted the present work. There is work which indicates that the cause of breakdown of some anodic films is a change in the oxide film such as generation of compressive stresses (3), while other reports show that there is a strong dependence on the anodizing electrolyte (5). In order to determine whether there are any changes within the oxide films on Ti during anodic growth, which might lead to breakdown, ellipsometric and weight gain measurements were made in the prebreakdown growth region to establish the film thickness and, therefore, the field strength and the film density. The coulombic efficiency of anodic film growth could then be determined.

As a result of the findings presented in this paper, we have considered it necessary to redefine the breakdown voltage (V_B) in terms of a change in efficiency of film growth since conventional ways to define it, such as by the change in slope of the voltage/time relation at constant current density, are deceptive in the case of Ti in that such changes are not always accompanied by a change in coulombic efficiency.

Experimental

Galvanostatic anodic film growth on Ti electrodes was measured by the change in cell voltage using a Cambridge potentiometric recorder in conjunction with a Tektronix 532 oscilloscope for the initial response to current. Application of constant current to polished Ti electrodes gives an initial voltage step followed by a voltage transient with slope (dV/dt) decreasing with time to a steady value (after ~2V). Extrapolation to $t = 0$ from this part of the voltage/time oscilloscope trace (of constant slope) was used as the origin for determination of the anodic film voltage. The intercept was subtracted from measured cell voltages to give a "film voltage" which excludes series contributions from sources such as electrolyte resistance and preexisting surface films. Ellipsometrically determined film thicknesses and the weight gains were plotted as a function of this film voltage in the present work.

Ellipsometry.—A manually operated ellipsometer was constructed using modified Glan-Thompson polarizing prisms mounted in divided circles which could be read to 2 min of arc. An additional divided circle carried a quarter-wave plate mounted between the polarizer and spectrometer stage. The light source was a 100W high-pressure Hg lamp. A narrow band mer-

Key words: amorphous, current density, ellipsometry, film.

cury green filter was incorporated in the telescope arm of the spectrometer and a photomultiplier tube was used to detect the intensity minima. The arrangement was aligned and calibrated as described by Archer (6).

An experimental cell machined from a solid "Perspex" cylinder had an open top. Light incident normally on an annealed glass window mounted in one side of the cell could also be incident normally on another similar window after 70° reflection at a flat electrode surface. Soft PTFE washers provided seals between the Perspex and the glass windows, which were found to be strain-free within the experimental accuracy of the system (intensity minima detectable to better than ~0.1°). The electrode surface could be centered in the cell (on the ellipsometer axis) and corrected for tilt by a finely adjustable clamp and stand.

Spectroscopically pure Ti rod (Table I) was cut, milled and abraded to expose a 0.33 cm² flat surface parallel to the rod axis at maximum rod width. The end of a Ti contact wire was inserted into a tapered hole in the curved surface of the specimen which provided good electrical contact. After degreasing in acetone the specimen and wire were anodized in 3 weight percent (w/o) ammonium hydrogen tetraborate at a high current density (50 mA/cm²) in order to grow an anodic film to a high voltage ~200V.

The specimen and contact wire were dried, coated with Araldite epoxy resin, and hot cured, which gave a leak-proof seal. Several coatings were applied and cured. Seals tested by anodizing to high voltage showed no color changes and, therefore, no further film growth below the hard transparent resin-covered surface. To reduce the risk of surface beveling during subsequent polishing, the specimen was mounted in thermosetting plastic in a standard metallurgical mounting press. The mounted specimen was abraded until the metal surface emerged, which was finally polished using alumina powder (5-30 nm particle diameter). Surfaces obtained in this way were satisfactorily flat. Surface treatments involving HF were avoided since this influences the film growth (7).

The cell was filled with electrolyte and eight readings of the azimuths of the polarizer (P) and analyzer (A) were taken, *i.e.* four pairs of values for minimum light intensity after reflection from the test surface. The ratio of the resultant reflected amplitudes in the plane of incidence and normal to this plane ($\tan \psi$) and the change in phase (Δ) were calculated from the mean P and A values (6) for the polished surface and after each increment in anodic film formation voltage under galvanostatic conditions. In Fig. 1, polar plots (8) of the vector, $\overline{Z} = (\tan \psi) e^{i\Delta}$, are compared with those derived from the Drude equations for theoretical values of the film thickness, d, the complex refractive indexes of the metal substrate and film [$\overline{n}_s = n_s (i - ik_s)$ and $\overline{n}_f = n_f (1 - ik_f)$, respectively] and the refractive index of the electrolyte, n_m (determined to four significant figures by Abbé refractometer). The rapid reaction of Ti with trace amounts of oxygen or water to form an oxide layer precluded attempts to measure the "bare" surface optical properties. Published data (9) for "atomically clean" Ti surfaces (after physical cleaning in UHV or chemical polishing) were unrelated to the present experimental results, giving data points unrealistically remote from extrapolations of the initial segments of the experimental polar plots in the direction of decreasing film thickness. Substrate constants n_s and k_s were determined by comparison with theoretical polar plots on the assumption of a

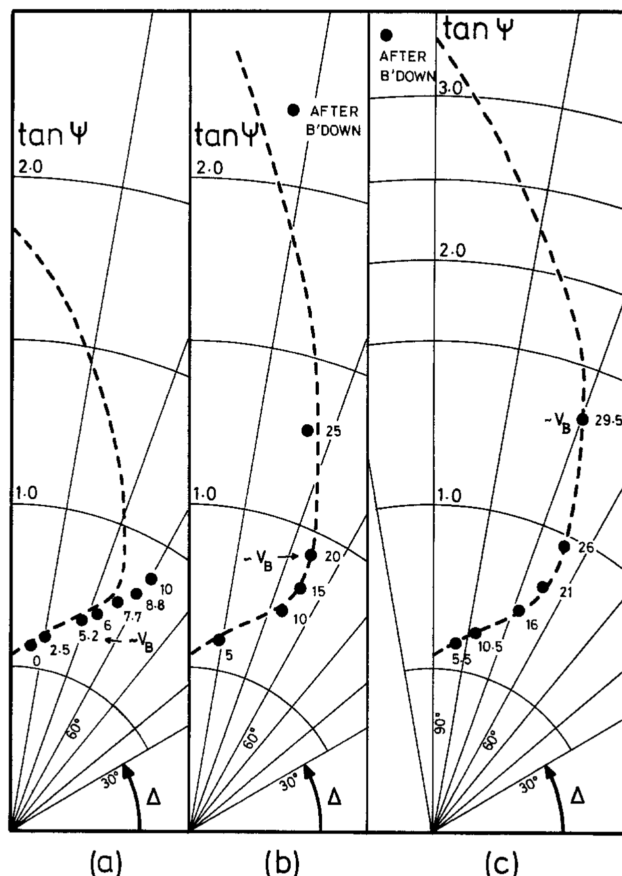

Fig. 1. Theoretical polar plots (– – –) of $\overline{Z} = (\tan \psi)e^{i\Delta}$ for substrate with $n_s = 2.0$, $k_s = 2.7$, and films with (a) $n_f = 2.008$, $k_f = 0$; (b) $n_f = 2.10$, $k_f = 0$; (c) $n_f = 2.14$, $k_f = 0$. Experimental data (●) at each film formation voltage (indicated) for (a) 1 mA/cm², (b) 10 mA/cm², (c) 50 mA/cm² anodic growth on Ti in carbonate buffer. $\lambda = 546.1$ nm, angle of incidence = 70°, $n_m = 1.335$.

constant film refractive index (to 1-3%) for different thicknesses. This gave a good fit to the data (to V_B) with $n_s = 2.0$ and $k_s = 2.7$ at wavelength $\lambda = 546.1$ nm (Fig. 1). The alternative, using as-polished P and A values to calculate n_s and k_s, led to a large increase then decrease in refractive index with increasing film thickness, which seems unlikely under conditions of galvanostatic anodic growth. With these substrate values, McCrackin's computer program (10) was used to check for constant film refractive index and to determine film thickness from the experimental data.

Interruption of film growth was necessary to allow time for measurement of P and A values with the manual ellipsometer. Some experiments were performed using an automatic ellipsometer, but its following-speed only allowed P and A values to be recorded during continuous anodic growth at ≤ 1 mA/cm². This equipment, which used a photoelectric detection system with Faraday effect modulation and with a Moiré fringe counting system, was sensitive to 0.002° changes and is described elsewhere (11).

Weight gain.—Specimens were weighed during film growth in order to determine the film density using the ellipsometric thickness data. 99.9% Ti foils (area ~70 cm²) were mechanically polished with alumina powder (particle diameter < 0.1 μm) then anodized in 3 w/o ammonium hydrogen tetraborate or a carbonate buffer solution at 1-50 mA/cm². Foil specimens were removed after increments in film formation voltage, washed, dried in air at ~150°C, and weighed on a microbalance to ± 10 μg.

Optical microscopy.—Anodic growth on the spectroscopically pure Ti specimen was observed *in situ* using a standard metallurgical microscope with water im-

mersion objectives. Crossed nicols were used in this microscope to detect the formation of crystalline TiO_2 during growth since the three crystalline forms of TiO_2 are noncubic and, therefore, birefringent. Cubic crystals or isotropic noncrystalline oxide would appear dark under crossed nicols.

Electrolytes.—All solutions were made from "analytically pure" reagents and doubly distilled water. Most work was done using a 3 w/o ammonium hydrogen tetraborate solution or a carbonate buffer solution (0.1M Na_2CO_3 + 0.1M $NaHCO_3$). At the highest current densities used (100 mA/cm²) the initial voltage step is ~20V in an ammonium hydrogen tetraborate solution, which means determination of film voltage is less accurate owing to the lower oscilloscope amplification which must be used. The carbonate buffer solution has an order of magnitude higher conductivity so that determination of the film voltage is inherently more accurate. A constant surface pH was also thought to be desirable in a study of film breakdown over the wide range of current densities used and anodic films of TiO_2 are known to be stable at the buffered pH of ~9.7 (12). The film voltage/time characteristics obtained for filmed Ti in this buffer solution were similar to those found in the borate solution. All experiments were carried out at room temperature.

Results

The film voltage/time characteristics of the mechanically polished Ti electrodes (Table I) were highly reproducible in either of the two electrolytes used (Fig. 2 and 3). In Tables II and III the details of these curves are shown in the form of the charge per volt. These details varied slightly on repolishing the specimen surface or between specimens, *i.e.*, charges per volt could differ by ± 12% and the extent of the voltage ranges of approximately constant slope could also vary by the same percentage, but the general characteristics remained the same.

The total charge passed, up to a particular voltage, can be determined from Fig. 2 and 3 where the abscissae show a rate of 0.5 C/cm²/division and 0.1 C/cm²/division, respectively, for all current densities. It is then clear from these figures that, for a given charge, the film voltage reached is higher at higher current densities but it is not obvious where breakdown occurs. The typical anodic film growth characteristic of nearly constant slope (dV/dt) after initial transients

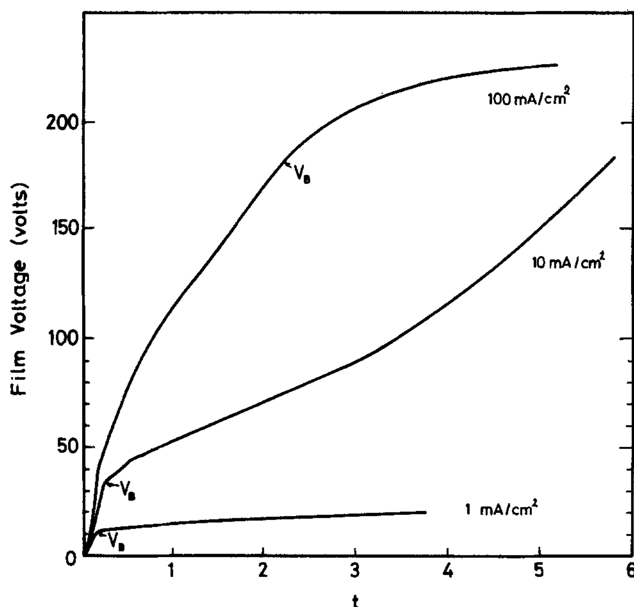

Fig. 2. Galvanostatic anodic film growth on a Ti electrode in 3 w/o ammonium borate solution at: 1 mA/cm² (t = 500 sec/div), 10 mA/cm² (t = 50 sec/div), 100 mA/cm² (t = 5 sec/div).

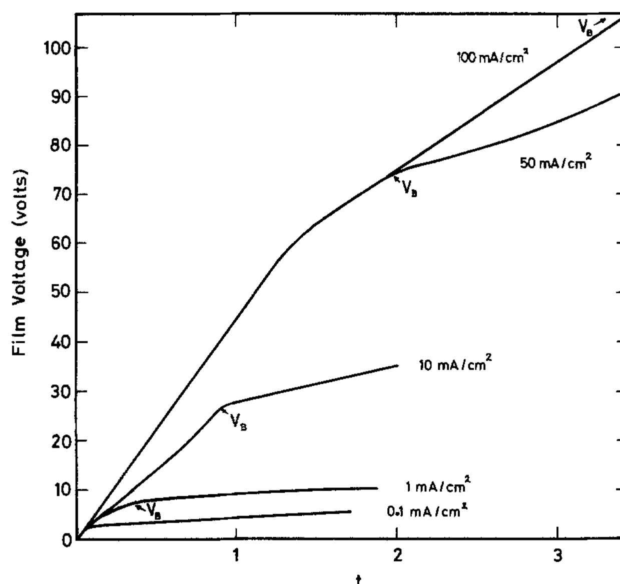

Fig. 3. Galvanostatic anodic film growth on a Ti electrode in 0.1M Na_2CO_3 + 0.1M $NaHCO_3$ solution at: 0.1 mA/cm² (t = 1000 sec/div), 1 mA/cm² (t = 100 sec/div), 10 mA/cm² (t = 10 sec/div), 50 mA/cm² (t = 2 sec/div), 100 mA/cm² t = 1 sec/div).

at constant current, only extends over a narrow initial voltage range which increases with current density in both electrolytes. There are significant changes of slope before the voltage/time curves develop a nearly constant gradient. We were concerned with these changes in slope at constant current density since a decrease would normally indicate breakdown.

Anodization at 1, 10, and 50 mA/cm² was followed by ellipsometry to establish the film thickness at different voltages on the same surface. At 1 mA/cm², film growth was followed continuously by the automatic ellipsometer but at 10 and 50 mA/cm² changes were too fast for automatic balancing and the growth was interrupted at 5V intervals while readings were taken with the manual ellipsometer.

Figures 4-6 show the derived thicknesses, from ellipsometric measurements, of films grown on a freshly polished surface anodized to the voltage shown, either continuously (Fig. 4) or with interruptions (Fig. 5 and 6). Changes in gradient (nanometers per volt) occurred at each current density. Repeated experiments on the same Ti specimen after repolishing the surface showed the same general behavior of variable slope

(nm/V) differing only in the absolute values of the gradients by up to ± 12%. The data at $V = 0$ in Fig. 4-6 are for an as-polished surface before voltage is applied while all other data are corrected to exclude all but the voltage due to anodically grown film. The measurements on as-polished surfaces with no applied voltage gave an initial film thickness of 4.3 nm using $n_f = 2.008$ (Fig. 4) which was used to derive thicknesses of films grown at 1 mA/cm^2. There were no solutions for this initial film using the higher anodic

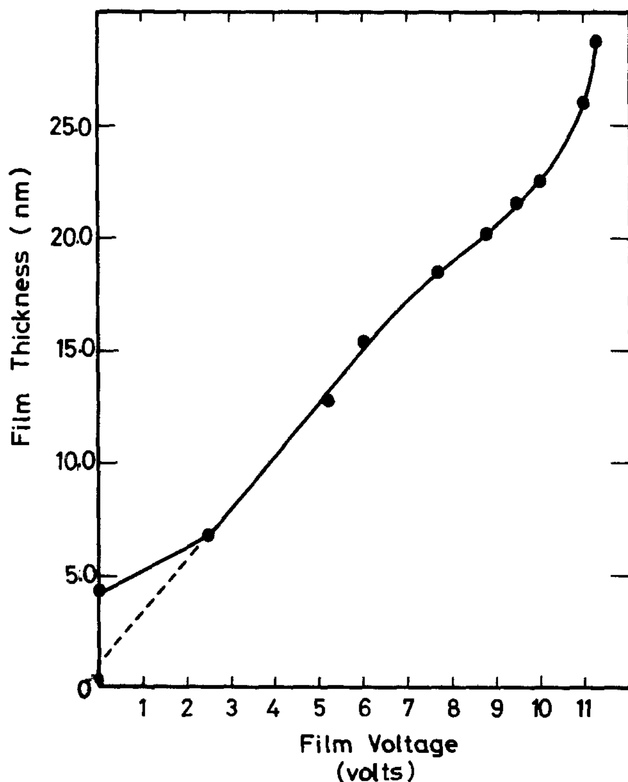

Fig. 4. Ellipsometric film thickness during interrupted anodization at 1 mA/cm^2 in 0.1M Na_2CO_3 + 0.1M $NaHCO_3$. λ = 546.1 nm, $n_f = 2.008 \pm 1\%$, $k_f = 0$. V_B ~5.2V.

film refractive indexes required in calculations for film growth at 10 or 50 mA/cm^2. The refractive index of this initial surface film is more than 3% below that of these anodic films and so is outside the limits set for the calculation where n_f is constant to 1-3%. Extrapolations from the first data points in Fig. 5 and 6 to $V = 0$ (and the 1 mA/cm^2 data excluding the data point at $V = 0$) do not pass through the origin as would be expected. This is probably due to overcorrection of the measured cell voltage because of extrapolation from the linear portion of the voltage/time oscilloscope trace.

Table IV. Coulometric and ellipsometrically determined film thickness/volt during 10 and 50 mA/cm² (interrupted) growth and 1 mA/cm² continuous growth in 0.1M Na_2CO_3 + 0.1M $NaHCO_3$ (from Fig. 4-6)

* V_B.
† Assuming optically derived densities.

Table IV shows the charge per volt passed during each stage of film growth followed ellipsometrically. The film density was estimated from the refractive index and weight gain (see Discussion section) so that the film thickness per volt could also be calculated from the charge passed. Comparison of this with the ellipsometrically determined thickness per volt shows the efficiency of film growth in Table IV. V_B is the voltage above which film growth proceeds at low coulombic efficiency. Ellipsometric experiments in ammonium borate solution also gave changes in gradient of film thickness/voltage relationships.

The effect of a change in current density on V_B, during continuous growth, is shown in Table III. After anodizing to only 3V at 1 mA/cm², an increase to 10 mA/cm² resulted in inefficient film growth above 11.5V which is considerably lower than if anodization had been at 10 mA/cm² throughout ($V_B \sim$ 28V). Anodizing history is therefore another factor in determining V_B.

The weight gain accompanying film growth is shown in Fig. 7 and was subject to an error of ± 0.3 μg/cm² in weighing.

At $\sim V_B$, optical microscopy showed local variations in color (indicative of different optical properties and/or thickness) and the presence of birefringent (noncubic crystalline) growths on which oxygen evolution was centered became apparent as the voltage increased above V_B. Below V_B the color was more uniform and no birefringence was observed.

Discussion

Film thicknesses derived from the ellipsometric measurements were not a linear function of film voltage (Fig. 4-6). There were changes in gradient (nm/V) during growth at 1 and 10 mA/cm² while at 50 mA/cm² there was film growth over a wide voltage range at small thickness per volt [column (c), Table IV]. These results suggest a variable oxide field strength during growth at constant current density. In the 10 and 50 mA/cm² experiments there were voltage ranges where the field strength was different by a factor of ~2× at the same current density. This behavior for an anodic film on a valve metal is usually associated with a change in the coulombic efficiency of oxide film growth. We will now try to determine this efficiency and its constancy during anodic growth, where a decrease in efficiency is linked with breakdown.

The ratio of the ellipsometrically determined film thickness with that expected from coulometry is a measure of coulombic efficiency of film growth. The calculation of coulometric thickness requires a knowledge of the film density and this we can derive in two ways: directly, from the refractive index of the film and, indirectly, from the weight gain data of the Ti foil assuming in the latter case the same thickness/voltage relationships as in the ellipsometric experiments. We will also consider the evidence in the present results for an amorphous film prior to breakdown.

Firstly, the assumption in this work of a constant film refractive index should be justified. We have already mentioned the experimental difficulty in obtaining a bare metal surface on Ti owing to its high reactivity with oxygen or water so that substrate optical constants cannot be determined directly. Immersion techniques cannot be used because suitable liquids for immersion have refractive indexes only up to ~1.7 and the lowest reported refractive index of TiO_2 is greater than 2.0 (13). Using n_s and k_s values calculated from ellipsometric readings of the as-polished specimen surface, we obtained an increase then decrease in refractive index from 2.27 to 2.29 to 2.07 for film growth at the 10 mA/cm² rate but the shape of the thickness/voltage relationship was similar to that shown in Fig 5, *i.e.*, the gradients were: 2.5 nm/V (2.5-10V), 1.2 nm/V (10-20V), and 2.8 nm/V (20-25V). At 50 mA/cm² there was also only a small difference in gradient (1.35 nm/V for the 0-26V range compared with 1.4 nm/V in Fig. 6) when using the apparent substrate constants derived from measurement of the polished specimen surface. The refractive index in this case

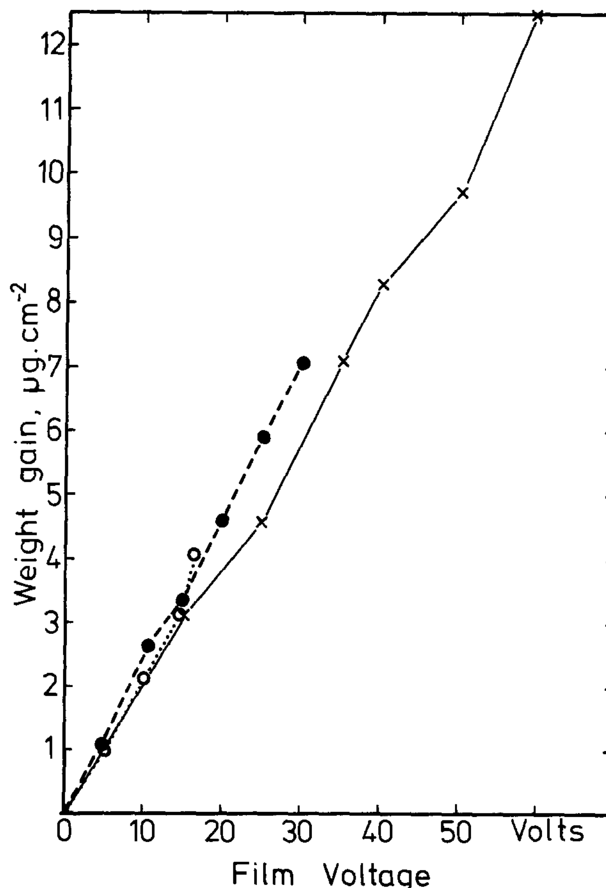

Fig. 7. Film voltage vs. weight gain of mechanically polished Ti sheet (annealed) during growth at 1 mA/cm² (○), 10 mA/cm² (●), 50 mA/cm² (×) in 0.1M $NaHCO_3$ + 0.1M Na_2CO_3.

varied from 2.26 to 2.16. The shape of the thickness/voltage curve at 1 mA/cm^2 was also only slightly altered by the use of as-polished substrate data. Data points were moved in the direction of greater film thickness by 2-3 nm for the three different film growth rates when as-polished substrate data were used.

Because we are cognizant of the inappropriate values for substrate constants obtained from as-polished surface measurements on Ti, we prefer to adopt the more reasonable assumption of a constant refractive index during anodic film growth, although it makes little difference to the results.

The relative insensitivity of n_f to variations in the thickness/voltage gradient in Fig. 4-6 is an interesting and important finding and is supported by observations from entirely different anodic oxides on Al (14). Here it was found that a change from amorphous to crystalline Al_2O_3 resulted in a 100% increase in growth field (at constant current), while the refractive index, as measured by an immersion technique, had only changed from 1.65 (15) to ~1.70. Structural changes in the anodic oxide films on Ti during growth might also be responsible for the changes in field strength.

Direct structural information on the anodic film on Ti is not easily acquired in the early stages of film growth. Other authors (2) have assumed that at least during the first 5V the film is amorphous, above this voltage they find crystalline TiO_2 (anatase) by electron diffraction of stripped 85V anodic oxide films, they report that the crystallinity in the films is apparent in polarized light. However, the problems of stripping very thin films (<10V) and the chance of crystallization in the electron microscope make convincing evidence for amorphous oxide prior to breakdown on Ti difficult to obtain.

In the present work, an *in situ* technique was used to test for amorphous oxide in the early stages of anodic growth. Optical microscopy of the specimen surface during film growth showed no birefringence under crossed nicols until gas evolution occurred. This must indicate the growth of an optically isotropic film such as an amorphous oxide, since the reported crystalline forms of TiO_2 are all noncubic. Better evidence that the growing film is initially amorphous is the low refractive index and density (Table V) of films compared with crystalline forms of TiO_2 which have refractive indexes in the range 2.49-2.90 (16) and densities in the range 3.90-5.5 g/cm^3 (16).

In discussing the breakdown of these anodic films during growth, we must consider whether the changes in gradient, dV/dt, are accompanied by a change in efficiency of formation of the barrier oxide film. Figures 2 and 3 show V/t curves where there are decreases in gradient. However, these would indicate breakdown only if accompanied by a decrease in coulombic efficiency for barrier film growth. Figures 4-6 only indicate the effect of oxide field strength during growth and provide no information about coulombic efficiency. However, in Table IV, the charge passed in each voltage range of anodic growth is tabulated (as mC/V) for the three growth rates and is seen to vary in the same direction as the thickness per volt, *e.g.*, at 10 mA/cm^2 both the charge and thickness per volt are decreased by ~50% in the 10-20V range compared with the 2.5-10V range. The actual film thickness, d, at a given voltage is given by the following equation

$$d = \frac{qM}{4F\rho} \cdot \eta \quad [1]$$

and

$$\eta = \frac{4dF\rho}{qM} \quad [2]$$

where M is the molecular weight of the oxide, ρ its density, and q is the charge passed. η is the fractional coulombic efficiency of oxide growth. To calculate η, a knowledge of the film density is required. Assuming the oxide has the same density as anatase [$\rho = 3.9$ g/cm^3 (16)] which has been reported in anodic films on Ti (2) (though at higher film voltages than used here) the maximum film thickness expected in the 2.5-5V range at 1 mA/cm^2 (*i.e.*, assuming 100% efficiency) is 2.1 nm/V. This is significantly below the ellipsometric value of 2.3 nm/V (Table IV) and is contradictory since 100% efficiency was assumed. The film density must be less than that of anatase. Similar calculations for the 10 and 50 mA/cm^2 rates lead to the same conclusion.

The optical polarizability of a crystalline oxide can be estimated (17) from the refractive index and density using the Lorentz-Lorenz relationship

$$\alpha_m = \frac{3M}{4\pi N\rho} \frac{(n_f^2 - 1)}{(n_f^2 + 2)} \quad [3]$$

where α_m is the molecular electronic polarizability and N is the Avogadro number. There are three crystalline forms of TiO_2: anatase, brookite, and rutile which are tetragonal, orthorhombic, and tetragonal, respectively. For comparison with the anodic TiO_2 which is optically isotropic, we will consider hypothetical crystalline oxides made of randomly oriented microcrystals of single crystal density so that average refractive indexes for the three crystal forms of TiO_2 are 2.5246, 2.6226, and 2.7545 (16) and densities are 3.9, 4.13, and 4.23 g/cm^3 (16) for anatase, brookite, and rutile, respectively. The respective values for α_{TiO_2} from Eq. [3] are 0.522, 0.508, and 0.515 $\times 10^{-23}$ cm^3 which, despite the different crystal systems and densities are remarkably similar. It is reasonable, then, to suppose that α_{TiO_2} for the anodic oxide is similar to an averaged value of 0.515 $\times 10^{-23}$ cm^3 between the crystal forms. This value would be for wavelength, $\lambda = 588.9$ nm but the correction for $\lambda = 546.1$ nm is only ~0.001 $\times 10^{-23}$ cm^3 and will be ignored.

Using an average value of α_{TiO_2} of 0.515 $\times 10^{-23}$ cm^3 and values of n_f as calculated in this work of 2.008, 2.10, and 2.14, Eq. [3] gives the following estimates of ρ: 3.09, 3.28, and 3.35 g/cm^3 for growth at 1, 10, and 50 mA/cm^2, respectively. The value of n_f for 1 mA/cm^2 growth is more accurate since it is derived from measurements with the automatic ellipsometer. Calculations of film thickness/volt using these film density values in Eq. [1] lead to the coulombic efficiencies shown in Table IV. In all the early stages of film growth, efficiency is nearly 100% and this is supported by the absence of gas evolution over these voltage ranges.

The film density can be independently calculated from the weight gains during anodization (Fig. 7) using the thicknesses per volt determined from ellipsometry shown in Table IV. Values derived in this way are shown in Table V and are within 10% of the average density calculated from the refractive indexes. Film growth, therefore, is highly efficient in the early stages of growth. It is important to note also that efficiency is ~100% over voltage ranges where the measured field strength is different by a factor of ~2× at the same current density. These changes in the field are not due to changes in ionic flux as might be anticipated from the well-known field-assisted ionic transport equation for anodic film growth which to a first approximation, can be written

$$i = i_0 \exp - (U/kT) \exp (qaE/kT) \quad [4]$$

Table V. Film densities derived from weight gain data (Fig. 7) and ellipsometric film thickness (Fig. 4-6)

Current density (mA/cm^2)	Film voltage range (V)	d (nm)	Weight gain ($\mu g/cm^2$)	TiO_2 ($\mu g/cm^2$)	ρ (g/cm^3)
1	0-7.5	14	1.6	4.0	2.86 ± 9%
10	2.5-25	44	5.35	13.37	3.04 ± 3%
50	2-29.5	43	5.20	13.00	3.02 ± 2%

where E is the field, U is the activation energy, q is the ionic charge, and a is the jump distance.

Coulombic data for continuous growth (in Tables II and III) have been used in Eq. [1] to calculate thicknesses per volt from the same densities used in Table IV. The derived values show apparent changes in field strength in similar sequences to those shown in Table IV. A more rapidly balancing ellipsometer would be required to determine film thicknesses and field strengths during continuous film growth at high rates. However, in common with interrupted growth data, Tables II and III also show a decrease in mC/V at 10 mA/cm^2, which implies an increase in field strength (assuming $\eta = 1$) at constant current density. The alternative explanation in the case of continuous growth is that there is an increase in efficiency at higher voltages which is contrary to experience of the breakdown phenomenon. In Tables II and III, high values of mC/V indicate that $V > V_B$.

We shall define breakdown for Ti as the beginning of the voltage range in which the efficiency is significantly below 100%. Such changes can be seen in Table IV and the voltage at the beginning of each range is denoted by V_B. At higher current densities (10 and 50 mA/cm^2), V_B appears at higher voltages than at 1 mA/cm^2. At 50 mA/cm^2 there is a decrease in field strength before breakdown (at 26-29.5V) and at 10 mA/cm^2, a decrease in efficiency to 48% cannot explain, in terms of Eq. [4], a decrease in field strength to less than half. The decrease in field strength at these current densities may not be attributed to joule heating (18) since these were interrupted growth experiments so that heat generated in the film was rapidly dissipated before the measurements were made. So, just before breakdown at 50 mA/cm^2, and associated with breakdown at 10 mA/cm^2, there may be an increase in ionic mobility such that a constant ionic flux is maintained at a lower field. This change in the intrinsic oxide field strength is delayed to higher voltages at faster growth rates as is breakdown and it may be that the increased ionic mobility is a precursor of breakdown.

The reasons for changes in intrinsic oxide field strength at constant ionic flux may be structural differences in the films which could significantly influence field-assisted ionic transport by, for instance, changing the activation energy (see Eq. [4]). Such changes could occur without affecting bulk properties such as density or refractive index by more than a few percent as has already been observed for anodic Al_2O_3 (14). However, unlike Al_2O_3, the structure during efficient oxide growth at high rates is not envisaged to be crystalline at any stage, since the film refractive index is approximately 15% below that of the least dense crystalline phase, anatase, and a crystalline oxide on Ti is associated with breakdown.

Evidence that breakdown is accompanied by crystallization was provided by optical microscopy which showed the presence of noncubic crystalline oxide at voltages $> V_B$. Oxygen evolution was sited on such crystalline regions leading to the low efficiency by which breakdown was defined. This is not unexpected as it is generally recognized that impurities have a greater influence on semiconduction in crystals than in noncrystalline materials (19) and anodic films are known to contain impurities such as electrolyte anions incorporated during anodic growth. So crystallization could result in high electronic conductivity which would enable the observed gas evolution to occur.

If the structural reorganization involved in formation of the crystalline oxide requires ease of ionic movement, then the increased ionic mobility found at high growth rates just before V_B could be the cause of breakdown on Ti.

Summary

The anodic film breakdown behavior of Ti is characterized by a change in film growth such that efficient growth of amorphous oxide gives way to a new anodic behavior: low efficiency oxide growth and gas evolution associated with crystalline oxide in the film. Changes in the slopes of the voltage/time relations at constant current density can occur at ~100% efficiency for growth indicating that there is a variable oxide field strength.

Breakdown occurs at higher voltages at higher rates of film growth. Just prior to breakdown at the highest growth rates there is a decrease in field strength in the oxide.

Electropolishing of Titanium in Perchloric Acid-Acetic Acid Solution

I. Auger Electron Spectroscopy Study of Anodic Films

J. B. Mathieu,* H. J. Mathieu,** and D. Landolt**

Materials Department, Swiss Federal Institute of Technology, Lausanne, Switzerland

ABSTRACT

Anodic films on titanium formed in a perchloric acid-acetic acid electropolishing electrolyte were investigated by Auger electron spectroscopy (AES) depth profile analysis. Films formed in 1*N* H_2SO_4 at different potentials were used as standards for determining sputter rate and stoichiometry. Obtained results show linear film growth to occur up to the onset of electropolishing when film thickness abruptly decreases and becomes independent of potential. The electropolishing film observed by AES contains chloride ions, the concentration of which exhibits a maximum at the metal-film interface.

Perchloric acid-acetic acid electrolytes are commonly used in metallurgical laboratories for electropolishing of titanium (1). Anode potentials as high as 25-40V are necessary to achieve good polishing indicating that anodic films play an important role. Recently Auger electron spectroscopy (AES) has become available as a powerful technique for surface analysis which allows one to study chemical composition of outermost surface layers with high resolution (2). By combining AES analysis with atom layer removal by argon ion sputtering concentration depth profiles can be determined. The applicability of this technique to the investigation of thickness and stoichiometry of titanium oxide films has recently been investigated (3) and it was concluded that useful information can be obtained provided complicating effects resulting from beam-surface interactions and from impurity adsorption are taken into account properly.

The purpose of the present study is to investigate the thickness and chemical nature of anodic films formed on titanium at different stages of the polishing process by using AES. In a subsequent paper polarization behavior and dissolution stoichiometry of titanium in perchloric acid-acetic acid electropolishing solution will be discussed (4).

Experimental

A preliminary series of experiments were performed with films produced by anodizing in 1*N* sulfuric acid (5). For this purpose 7 mm diam titanium disks were electrochemically polished in a solution of 30 ml $NaClO_4$, 270 ml methanol, and 175 ml butyl cellosolve at a potential of 25V and a temperature of $-10°C$. After this the samples were rinsed and then anodized for 5 min at constant voltage ranging from 5 to 35V at a temperature of 25°C. This procedure leads to the formation of TiO_2 films, the thickness of which increases linearly with potential at a rate of approximately 25 Å/V (5, 6).

Rotating disk electrodes as well as stationary electrodes were employed for anodization in perchloric acid-acetic acid solution. The rotating disk electrode was fabricated from a 7 mm diam titanium rod (99.97%, Materials Research) embedded in a 15 mm diam Teflon cylinder. Rotation rate was 1200 rpm in all experiments. A cylindrical platinum counterelectrode of 45 mm diam and a saturated mercury sulfate reference electrode with a Luggin capillary perpendicular to the disk surface were employed. The electrolyte solution was prepared by mixing 1000 ml glacial acetic acid ($\rho = 1.05$) with 100 ml 70% perchloric acid ($\rho = 1.67$). Electrolyte composition corresponded to 1.1 mole/liter $HClO_4$ and 15.9 mole/liter CH_3COOH. The temperature during experiments was 25°C. Before each run the titanium anode was mechanically polished on 6 μm diamond paste, then washed and rinsed with double distilled water. Starting from open circuit a voltage ramp of 20 mV/sec was applied until a preset potential was reached at which the anodization was stopped. The titanium rotating disk electrode was then removed from the cell and was cut carefully parallel to its surface such that an approximately 2 mm thick disk was obtained. Stationary electrodes consisted of a thin titanium disk insulated on three sides and therefore no cutting operation was needed. The thin metal disks were washed with soap solution, rinsed with distilled water, and dried with acetone before being inserted into the vacuum system for AES analysis.

A potentiostat (Amel Type 552) with function generator (Amel Type 564) was used as power supply. To allow potentiostatic operation at anode potentials of up to 50V an operational amplifier with voltage divider was employed in the reference electrode circuit. Potentials were measured with an electrometer and recorded as function of current using an X-Y recorder.

AES analysis was performed using a commercial apparatus (Physical Electronics Model 545 A) including UHV system and cylindrical mirror analyzer. After insertion of the samples to be analyzed, the apparatus was evacuated to a base pressure of approximately 10^{-9} Torr. High purity argon was then leaked in and the pressure was allowed to increase to 5.0×10^{-5} Torr for *in situ* argon ion sputtering. Ion beam energy was 2 kV in all experiments. AES analysis was performed at a primary electron beam energy of 5 keV and a current of 3-20 μA.

Most concentration depth profiles were derived from complete Auger spectra recorded at different sputter times, but in some cases peak amplitudes were plotted directly as a function of time using a multiplexer unit. The amplitudes of the following peaks were monitored: 381 eV titanium, 416 eV titanium, 508 eV oxygen, 181 eV chlorine, 270 eV carbon, and 145 eV sulfur. For a more detailed discussion of the Auger spectra of different titanium oxides the reader is referred to Ref. (3).

Results

Films formed in H_2SO_4.—Figure 1 shows AES concentration depth profiles for oxygen, titanium (Ti_1 = 381 eV peak, Ti_2 = 416 eV peak), sulfur, and carbon for a film produced at 7.5V. The oxygen peak-to-peak

** Electrochemical Society Active Member.

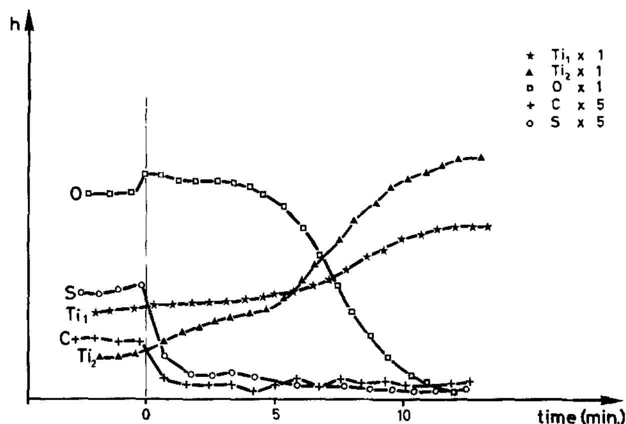

Fig. 1. AES concentration depth profile of titanium oxide film produced by anodizing in H_2SO_4 at 7.5V. h = peak amplitude in arbitrary units.

amplitude exhibits a plateau within the bulk oxide, then decreases at the oxide-metal interface to become zero in the metal. The amplitudes of the two titanium peaks [Ti_1] and [Ti_2] increase at the oxide-metal interface. In the oxide the [Ti_1] amplitude is higher than the [Ti_2] amplitude but in the metal the inverse is true. This change in relative peak height is due to differences in the shape of the titanium peaks between oxide and metal (3). For the purposes of the present study the behavior is of no further consequence. Sulfur and carbon are present at the outer oxide surface in noticeable amounts because of adsorption of sulfate from the electrolyte and of carbon compounds from the air or the UHV system. In the interior of the oxide the magnitude of the Auger signals for these elements is of the order of the background noise only and therefore essentially zero.

Film thickness can be deduced from concentration depth profiles using the relation $l = v_o t_l$, where l is the film thickness, v_o is the sputter rate, and t_l is the time needed for sputtering through the film. For oxide films one usually defines t_l as the time at which the oxygen peak amplitude at the metal-oxide interface has decreased to 50% of its steady-state value in the oxide (3).

In Fig. 2 measured t_l values for titanium oxide films formed in 1N H_2SO_4 are given as a function of anodizing potential. A linear increase in t_l with potential is observed. Since film thickness is also a linear function of anodizing voltage it follows that the sputter rate v_o is constant, *i.e.*, independent of film thickness. Assuming a film formation constant of 25 Å/V the sputter rate v_o was evaluated from the slope of the straight line and used for estimating film thickness from depth profile data. For the oxide film formed under open-circuit conditions (−0.3V *vs.* SCE) a value of 70Å was thus obtained in satisfactory agreement with values published in the literature (6).

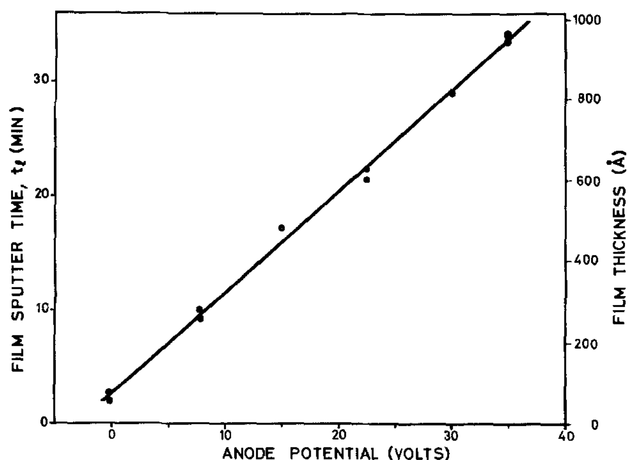

Fig. 2. Film sputter time, t_l, and estimated thickness of titanium oxide films produced by anodizing in H_2SO_4 as a function of potential.

For studying the stoichiometry of titanium oxide films by AES depth profile analysis it is usually preferable to use relative rather than absolute peak amplitudes (3). In Fig. 3 the amplitude ratio Q defined by Eq. [1] is plotted as a function of sputter time for different H_2SO_4 formed films

$$Q = \frac{h_o}{h_l} \quad [1]$$

In Eq. [1] h_o is the amplitude of the 508 eV oxygen peak and h_l the amplitude of the 381 eV titanium peak. The data of Fig. 3 show that the steady-state plateau value, Q_p, is reproducible. For the given Auger analysis conditions its value depends on oxide stoichiometry which for sulfuric acid formed films corresponds to TiO_2 (3). Film thickness may be deduced from Q *vs.* time profiles by determining the film sputter time t_l which now corresponds to the time necessary for Q to reach the value Q_l given by Eq. [2]

$$Q_l = \frac{h_{op}}{(h_{lp} + h_{lm})} \quad [2]$$

Here h_{op} and h_{lp} are the amplitudes of the oxygen peak and the 381 eV titanium peak in the steady-state plateau region in the oxide and h_{lm} is the steady-state 381 eV titanium peak amplitude in the metal. In Fig. 3, Q_p and Q are given by the broken lines. It may be noted that t_l defined by Eq. [2] does not exactly correspond to the t_l defined above in terms of oxygen amplitude only. The reason is that the increase in [Ti_1] peak amplitude at the oxide-metal interface is not symmetrical to the decrease in oxygen peak amplitude (see Fig. 1). In the present study differences in film thickness estimated by the two methods were within experimental error, however. A considerable advantage of the use of Q *vs.* time profiles is the possibility of using thick films exhibiting well-defined amplitude plateaus for evaluating Q_l which subsequently may serve for determining the thickness of thin films which do not exhibit a well-defined plateau (Fig. 3).

Films formed in perchloric acid-acetic acid solution.—The anodic polarization behavior of titanium rotating disk electrodes in perchloric acid-acetic acid solution is illustrated by Fig. 4. Each point shown corresponds to a different experiment performed by scanning from open circuit up to the potential indicated. Because each such experiment corresponded to a newly prepared anode surface, the points of Fig. 4 show considerable scattering. Anodic films formed during the different potential scan experiments were subjected to AES depth profile analysis and the amplitude ratio Q

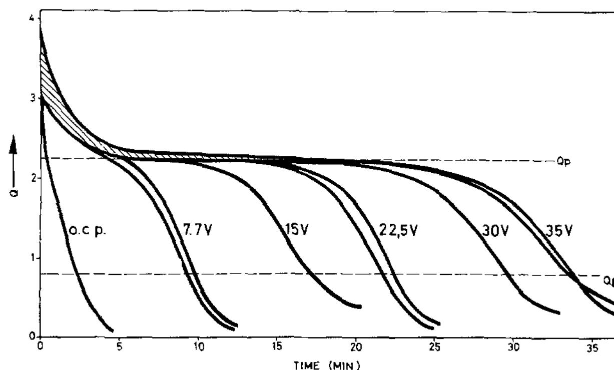

Fig. 3. Relative oxygen amplitude Q as a function of sputter time for titanium oxide films produced by anodizing in H_2SO_4 at different potentials or by immersion at open circuit (ocp).

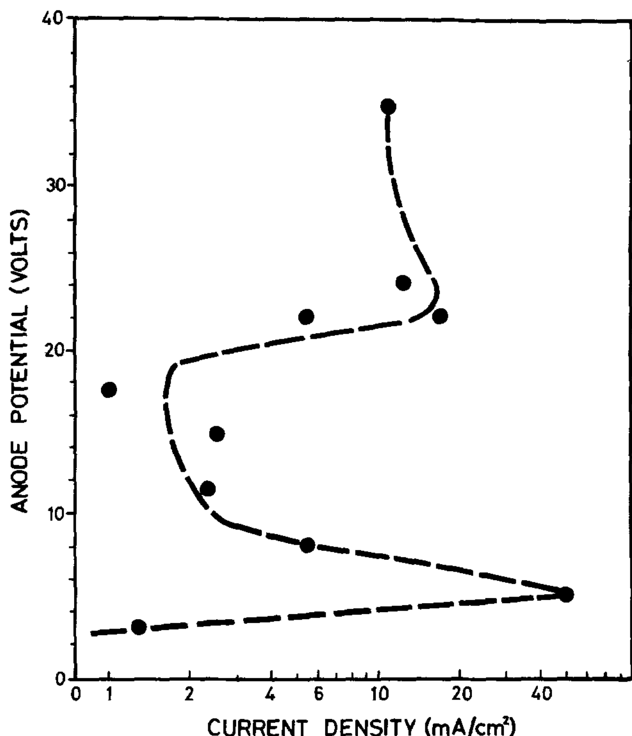

Fig. 4. Potentiodynamic polarization curve (schematic) for titanium rotating disk anode in perchloric acid-acetic acid solution. The experimental points given correspond to the depth profile experiments of Fig. 5 and 6.

was determined as a function of sputter time. Obtained results corresponding to the experimental points of Fig. 4 are shown in Fig. 5. Also indicated in the figure is the steady-state value Q_p for H_2SO_4 formed films. This value corresponds quite well to the steady-state value of Q measured for perchloric acid-acetic acid formed films indicating that film stoichiometry is the same in both cases, namely TiO_2. The plateaus for perchloric acid formed films are less well defined, however, and transition zones at the oxide metal interface are broader than in case of H_2SO_4 formed films. This is in part due to the different polishing procedure employed in the two sets of experiments: electrode surfaces anodized in H_2SO_4 were prepared by electropolishing, while those anodized in perchloric acid-acetic acid solution were prepared by mechanical polishing.

The film sputter time t_l was determined from Q *vs.* t graphs as described above and film thickness was estimated by assuming that the sputter rate for $HClO_4$ formed films is equal to that of H_2SO_4 formed films. This assumption appears justified in view of the similar composition of the films. Measured film sputter times as a function of anode potential are given in Fig. 6. The data indicate that above an anodizing potential of 2-3V film thickness increases with potential in a linear fashion up to a potential of *ca.* 22V. At this potential observation of the sample surface shows coexistence of thick colored films and bright pits (4). At higher potentials measured sputter times decrease drastically and become independent of potential. The abrupt change in measured sputter time coincides with the onset of electropolishing. The measurements shown in Fig. 6 were performed without the simultaneous use of oxide standards for calibrating sputter rates and therefore no film thickness values are given. However, an identical series of measurements was carried out with a stationary electrode. Before each depth profile the sputter rate was newly calibrated using H_2SO_4 formed titanium oxide film. Results are given in Fig. 7 in which film thickness is plotted as a function of potential. It follows that film thickness increases up to *ca.* 400Å before breakdown occurs at a voltage of *ca.* 20V. For samples polarized under elec-

tropolishing conditions measured film thicknesses scatter considerably but they are always smaller than 100Å, *i.e.*, of the same order as that of natural oxide films formed in air.

To characterize the chemical composition of the films, concentration depth profiles for Ti, O, C, and Cl were determined using the multiplexing unit. Typical results are given in Fig. 8-10. The titanium amplitudes shown correspond to the larger of the two titanium peaks, *i.e.*, to the 381 eV peak in the oxide and to the 416 eV peak in the metal (cf. Fig. 1). Figure 8 shows a film formed by scanning up to 12V. The data are typical for concentration depth profiles obtained with films in the prepolishing region where film thickness increases linearly with potential. The strong carbon signal at the outer oxide surface is due to adsorption

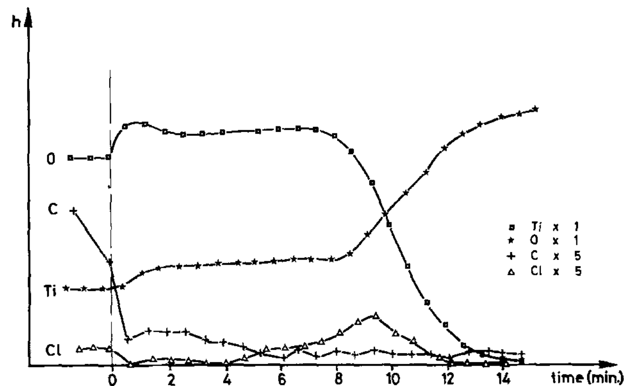

Fig. 8. Concentration depth profile of anodic film typical for the prepolishing region obtained by scanning to a potential of 12V.

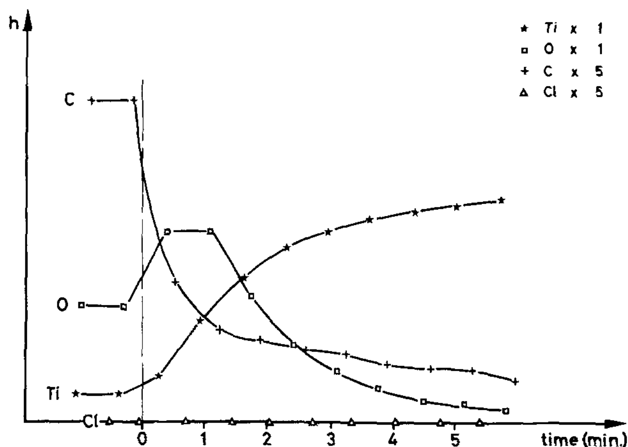

Fig. 10. Concentration depth profile of natural oxide film on mechanically polished titanium.

of carbon compounds taking place during or after the polarization experiments. Only a weak carbon signal is observed in the interior of the oxide. This signal could well be an experimental artifact (3) and will therefore not be considered for further interpretation. The same holds true for the carbon signals of Fig. 9 and 10. Of particular interest is the behavior of the chlorine peak amplitude. At the outer oxide surface it exhibits a definite value indicating the presence of adsorbed species. After removing the outermost surface layers by sputtering the chlorine amplitude decreases to a very small value which is of the same order of magnitude as the background noise. However, on approaching the oxide-metal interface the chlorine amplitude increases again and a clearly defined maximum is reached before the amplitude decreases to zero in the interior of the metal. It is concluded that chlorine species such as perchlorate or chloride ions may accumulate at the metal oxide interface. Figure 9 shows concentration depth profile data for the electropolishing region. Compared to the data of Fig. 8 the chlorine amplitude is larger and chlorine species are present throughout the film. A pronounced maximum is again observed near the oxide-metal interface. For comparison, Fig. 10 shows concentration depth profiles of a thin oxide film formed by exposure of a mechanically polished sample to air. No chlorine signal is observed in this case which proves that the chlorine observed in Fig. 8 and 9 is indeed due to anodization in perchloric acid.

Discussion

The data of the present study show that when titanium is anodically polarized in a perchloric acid-acetic acid electropolishing electrolyte anodic films grow in a similar way as in H_2SO_4 anodizing solution. From the data of Fig. 7 one deduces a growth constant of 20 Å/V which is somewhat lower than the growth constant of 25 Å/V typical for H_2SO_4 formed films. However, the accuracy of the growth constant derived for perchloric acid-acetic acid formed films is limited because of the ill-defined transition zones in the Q *vs.* t profiles and, furthermore, growth conditions for perchloric acid-acetic acid and H_2SO_4 formed films were not identical. Therefore no further interpretation of observed growth constants is warranted.

According to the data of Fig. 3 and 5 the oxide formed in perchloric acid-acetic acid solution is TiO_2 because observed Q_p values correspond to those of H_2SO_4 formed films measured under identical analyzing conditions. This conclusion is strictly valid for films anodized in the prepolishing region because they exhibit well-defined steady-state Q_p values. However, comparing the Q *vs.* t plots (Fig. 5) for 24 and 22V films corresponding to electropolishing conditions with those for 5 and 3V films corresponding to the prepolishing region one observes a close similarity. This suggests that the oxygen-titanium ratio for electropolishing films corresponds also approximately to TiO_2. However, the electropolishing films contain much more chlorine than the films formed in the preelectropolishing region. This is illustrated by the data of Fig. 8 and 9. A quantitative interpretation of these data taking into account matrix effects and possible preferential sputtering effects is not possible, but, following Ref. (7) a semiquantitative estimation of the chlorine concentration can be made using Eq. [3]

$$C_i = \frac{h_i/s_i}{\Sigma\, h_j/s_j} \quad [3]$$

Here C_i is the concentration of element i (chlorine) in atomic percent, h_i is the amplitude of the chlorine Auger signal, and s_i is the so-called "sensitivity factor," an empirically determined parameter characteristic for each element (7). According to this the chlorine concentration at the interface is estimated to be

approximately 1% for the 12V film of Fig. 8 and approximately 4% for the 28V film of Fig. 9.

To learn more about the chemical nature of the chlorine species detected by AES analysis samples polarized in the prepolishing and in the polishing region were subjected to ESCA analysis. The analysis was carried out using the equipment and procedures described by Augustinsky *et al.* (8, 9).

In the pitting region chlorine was found to be present in form of Cl^- (binding energy of Cl 3/2 p at 205-207 eV with respect to Cl 1s at 290 eV) and ClO_4^- (binding energy of Cl 3/2 p at 213-215 eV). In the polishing region, on the other hand, only Cl^- but no ClO_4^- could be detected in the film. From the ESCA data the total chlorine concentration was estimated at 1-2 atomic percent (a/o) for both films in reasonable agreement with the AES results.

Based on the different data available the AES concentration depth profiles for chlorine in the prepolishing region can be explained by postulating that the prepolishing film contains flaws which allow the perchlorate ion to penetrate up to the metal surface where it is reduced to chloride. Only strongly adsorbed species are detected in the AES analysis of anodized samples because other species will have been removed by washing the anode after polarization experiments. For this reason perchlorate or chloride ion dissolved in the electrolyte, which during anodization fills the microscopic flaws, do not appear in the AES spectra and the observed chlorine concentration within the film is therefore negligibly small. On the other hand, at the metal-oxide interface chloride ion adsorbed at the metal give rise to a well-defined AES signal. The measured signal intensity corresponds to the average chloride concentration on the analyzed surface area but according to the proposed flaw model the chloride concentration should be highly localized. It is therefore concluded that at the bottom of flaws the chloride concentration is much higher than the measured average value of 1%.

AES analysis of surfaces polarized under electropolishing conditions reveals the presence of a thin layer contaminated by chlorine species, the concentration of which is maximum at the metal-film interface. Only Cl^- but no ClO_4^- was detected by ESCA and therefore it is concluded that the latter ion upon entering into contact with the metal surface is reduced. This conclusion is supported by stoichiometric measurements (4) and it is in agreement with observations made during aluminum corrosion in presence of oxidizing anions (9). Several authors have postulated that electropolishing requires the presence of a thin porous film which is permeable to cations (10-12) while others (13, 14) proposed that electropolishing proceeds in presence of an anhydrous layer of adsorbed anions. The AES data presented here show that electrolyte anions may indeed enter into contact with the metal surface since the chlorine signal amplitude there goes through a maximum. AES depth profile analysis also reveals the presence of an oxide film, the thickness of which corresponds roughly to the thickness of the natural oxide film formed in air. Since AES is not a method permitting *in situ* measurements under anodic polarization conditions it is very possible that part of the observed AES signals are the result of oxidation reactions which took place after the polarization experiments, *i.e.*, in the electrolyte solution after current cutoff or during the transfer of the anode from the electrochemical cell to the Auger apparatus. The present AES data can therefore be interpreted in terms of the thin porous oxide film concept of electropolishing as well as in terms of the adsorbed anhydrous anion layer concept.

Conclusions

1. The present study illustrates that AES depth profile analysis is a useful method for the investigation of the thickness and chemical composition of electropolishing films as a function of formation conditions.

2. Anodic polarization of titanium in perchloric acid-acetic acid electropolishing solution leads to formation of an anodic film of TiO_2 which grows linearly with potential up to 20-22V when electropolishing sets in coinciding with removal of the prepolishing film.

3. AES concentration depth profile analysis in the prepolishing region indicates that prepolishing film removal is initiated by penetration of ClO_4^- ions through flaws and reaction to Cl^- under simultaneous metal dissolution thus leading to film removal by under-cutting.

4. After electropolishing the anode is covered by a thin Cl^- contaminated oxide layer, the thickness and nature of which is comparable to the natural oxide film. Present AES and ESCA experiments do not indicate whether this film is present under electropolishing conditions or is formed only after completion of anodic polarization experiments.

Electropolishing of Titanium in Perchloric Acid-Acetic Acid Solution

II. Polarization Behavior and Stoichiometry

J. B. Mathieu* and D. Landolt**

Materials Department, Swiss Federal Institute of Technology, Lausanne, Switzerland

ABSTRACT

Anodic polarization behavior and reaction stoichiometry during electropolishing of titanium in perchloric acid-acetic acid solution has been investigated using a rotating cylinder electrode. Formation and breakdown of anodic films result in strongly time-dependent polarization behavior. The onset of electropolishing coincides with a current plateau in the potentiostatic polarization curve but solution side mass transfer effects are masked by the presence of a layer of reaction products. The apparent valence of dissolution in perchlorate-containing solution is unusually low because perchlorate ion is reduced at the anode.

Electropolishing includes smoothing and brightening of a metal surface by anodic dissolution (1). Smoothing is usually associated with a diffusion-controlled dissolution process but no agreement exists in the literature as to the nature of the diffusion-limiting species. According to some authors diffusion of acceptor ions or water molecules from the bulk toward the anode is rate limiting (2-4) while others consider diffusion of anodic dissolution products from the anode toward the bulk solution to be the rate-controlling process (5-7). According to both views smoothing occurs because the diffusion path from protruding parts of a rough surface is smaller than from receding parts and hence dissolution of protruding parts is favored. A diffusion-controlled mechanism of smoothing is consistent with the observation that electropolishing occurs usually in the presence of a highly viscous layer at the anode (Jacquet layer) (8). The latter has the effect of slowing down diffusion processes, thus favoring the establishment of diffusion-controlled dissolution conditions. According to Hoar (9, 10) brightening requires the presence at the anode of a thin solid film which is permeable to metal cations. The film which covers the surface uniformly suppresses the influence of crystallographic orientation on dissolution and thus prevents crystallographic etching of the anode. A similar concept has been advanced by Epelboin and coworkers (4, 11, 12) who postulate the presence of an anhydrous layer as a condition for brightening. The existence of thin surface layers responsible for brightening has been deduced from mercury drop wetting experiments (9), polarization curves (1), and impedance measurements (4).

The majority of studies on the mechanism of electropolishing have been performed with copper in phosphoric acid solution (1, 2, 5, 7, 13-19) but relatively little is known about the phenomena leading to electropolishing of valve metals which are capable of forming thick oxide films. Garreau and Epelboin (20) studying electropolishing of aluminum in perchlorate-ethanol solution concluded that electropolishing occurred under diffusion control but limiting current plateaus were masked by heating effects. On the other hand, Ippolitova and Korovin (21) found no evidence for diffusion-limited conditions during electropolishing of tantalum in a solution of HF, H_2SO_4, and ethylene glycol.

The most common electropolishing electrolytes for titanium are mixtures of perchloric acid and acetic-acid (8). Good electropolishing is obtained at anode potentials of 20-30V but little is known about the mechanisms involved. Froment (22) studying the stoichiometry of dissolution of various metals including titanium in perchloric acid-acetic acid electrolytes found that the perchlorate ion is being reduced during the dissolution process. He postulated that Ti^{+} and Ti^{2+} ions are formed by anodic dissolution and subsequently react with the perchlorate ion. On the other hand, it is well known that usually in aqueous solution titanium dissolves to Ti^{3+} or Ti^{4+} (23). Johnson and Shreir (24) measured anodic polarization curves for titanium in 3M $AlCl_3$-diethyl ether solutions at a stationary electrode. They found a current plateau in the potential region where electropolishing occurred but the nature of this plateau was not further investigated. Beck (25, 26) studying pitting of titanium in different chloride and bromide electrolytes found brightening to occur at the bottom of pits and he attributed this behavior to the presence of a salt film. Powers and Wilfore (27) studying ECM behavior of titanium also found evidence for pitting and brightening. According to these authors brightening of the entire surface occurs at high current densities when individual pits merge together.

In a previous paper (28) Auger electron spectroscopy was employed to study chemical composition and thickness of the solid films formed anodically on the titanium in perchloric acid-acetic acid electropolishing solution. It was found that a thick TiO_2 film grows linearly with applied potential up to the potential where electropolishing sets in which leads to an abrupt decrease in film thickness. The anodic layer observed after completion of experiments is of the same nature and thickness as the natural oxide film and it contains substantial amounts of chloride. The aim of the present paper is to investigate the electrochemical behavior of titanium in perchloric acid-acetic acid electropolishing electrolytes in order to elucidate the processes leading to removal of the protecting titanium oxide film at high potential and to study the role of mass transfer in the polishing process. For this purpose potentiostatic and galvanostatic polarization measurements were performed under controlled hydrodynamic conditions, and anodic reaction stoichiometry as well as surface texture resulting from dissolution were investigated.

Experimental

Polarization measurements were performed on a rotating cylinder electrode of 1 cm diam and 0.7 cm height. Rotation rates ranged up to 6000 rpm. A cylindrical platinum wire mesh electrode of approximately 3 cm diam served as counterelectrode. Anode poten-

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.

tials were measured against a mercury sulfate reference electrode.

A potentiostat (Tacussel PRT 100-2) was used as current source. To allow potentiostatic operation at anode potentials of up to 50V an operational amplifier with a voltage divider at its output was inserted between reference electrode and reference signal input of the potentiostat. Potentiostatic polarization curves were measured using a slow sweep generator Amel Type 564 to drive the potentiostat. In addition, potentiostatic and galvanostatic experiments were performed by applying a potential or current step while following the resulting current or potential response of the anode as a function of time.

Weight loss measurements at different applied potentials and/or currents were performed in a separate cell in which a stationary cylindrical titanium rod inserted from the bottom served as anode. The charge passed during an experiment was measured using a current integrator (Amel Type 558). The apparent valence of dissolution was calculated using Eq. [1]

$$n = \frac{MQ}{\Delta m \mathbf{F}} \quad [1]$$

Here n = apparent valence of dissolution, M = molecular weight of titanium, Q = electric charge passed, Δm = measured weight loss of the anode, $\mathbf{F}$ = Faraday constant.

In a few experiments, the amount of Cl^- ion produced was determined by potentiometric titration. All experiments were performed with 99.5% pure titanium (Kobe). The composition given by the supplier is: H, $\leq$0.01%; O, $\leq$0.2%; N, $\leq$0.05%; Fe, $\leq$0.25%; and Ti, remainder. Perchloric acid-acetic acid electrolytes were prepared by mixing 70% $HClO_4$ with 100% acetic acid (Merck). Unless otherwise noted, experiments were performed in a solution containing 10 cm^3 conc $HClO_4$ per 100 cm^3 glacial acetic acid which corresponds to a $HClO_4$ concentration of 1.1 mole/liter. Preliminary experiments had shown that good electropolishing can be achieved in this solution. The temperature was maintained at 25°C. Before experiments, the samples were mechanically polished with 600 emery paper, washed and rinsed with double-distilled water.

Results

Figure 1 shows potentiodynamic polarization curves obtained at a scan rate of 100 mV/sec using a rotating cylinder anode at various rotation rates. The curves exhibit a passive zone ranging up to approximately 15V. The current then increases steeply until a maximum is reached at approximately 22V which corresponds to the beginning of electropolishing. The value of the current at or below the maximum was independent of rotation rate. The electrode appearance in the passive region was yellowish due to the presence of an anodic film. With increasing potential, the color turned to dark blue and local film attack and gas evolution were observed. In the electropolishing region white solid reaction products spalled off the anode. No well-defined diffusion-limited currents were observed under polishing conditions but the shape of the current voltage curves above the current maximum at *ca.* 22V depended on rotation rate (Fig. 1). In a second series of experiments, a constant potential was applied to the anode and the current was followed as a function of time. Typical data obtained at a rotation rate of 3000 rpm are given in Fig. 2. At relatively low potentials, the current decreases with time due to growth of an anodic film. At higher potentials, the current decreases first and then increases while exhibiting irregular fluctuations. The behavior indicates that film breakdown takes place. To gain more insight into the time-dependent polarization behavior galvanostatic measurements were performed. Typical data are given in Fig. 3. At low currents (1.7 mA/cm^2), the potential increases linearly with time up to a limiting value close to 20V. At currents > 10 mA/cm^2, the initial potential rise is followed by a characteristic overshoot and at still higher current densities, correspond-

ing to electropolishing, periodic oscillations occur. The oscillation amplitude is of many volts and it depends on current density. This is illustrated by Fig. 4 which gives average steady-state potential values measured at constant current for two different rotation rates. Three zones corresponding to no visible attack of the anode surface, to pitting, and to polishing are schematically indicated in the figure. Measured steady-state potential values in the first zone are 20V, independent of current density. Rotation rate did not affect obtained results in a systematic way.

The appearance of the anode surface corresponding to prepolishing and to polishing conditions is illustrated by the scanning electron microscope pictures of Fig. 5-7. Figures 5 and 6 show a sample surface after polarization for 100 sec at a current density of 45 mA/cm^2 and a rotation rate of 3000 rpm. Three types of surface textures are visible; passive, nonattacked areas where mechanical polishing marks are still present; areas showing noncrystallographic, more or less hemispherical pits; and areas covered by loosely adherent dissolution products. The dissolution products could be removed easily by scraping, revealing underneath a bright pitted surface (Fig. 6). The products were of white color, distinctly different from the adjacent passive film. X-ray analysis showed no diffraction pattern, indicating that the dissolution products were amorphous. Figure 7 illustrates an electropolished surface obtained by polarizing anodically for 100 sec at 200 mA/cm^2 and 3000 rpm. The surface exhibits irregular

Table I. Stoichiometry

	Q, charge passed (coulomb)	Δm, weight loss (mg)	n, apparent valence	m_{Cl}, mass of Cl^- in electrolyte (mg)	Q_{Cl}, charge corresponding to Cl^- (coulomb)	n_{corr}, corrected valence
1	300	101.8	1.46	18.7	410	3.46
2	300	107.8	1.39	22.2	480	3.61
3	300	98	1.52	22.16	480	3.95
4	300	102.1	1.46	21.17	460	3.69

lution at potentials below 20V the apparent valence is very high indicating that little dissolution takes place. At higher potentials, on the other hand, the apparent valence is 1.3-1.6 independent of potential. Table I shows that the perchlorate ion is reduced during the anodic dissolution process in agreement with previous findings by Froment (22). The data were obtained by carrying out electropolishing experiments in a small electrolyte volume and measuring the amount of chloride formed by potentiometric titration. A corrected value for the apparent valence of dissolution n_{corr} was calculated using Eq. [2]

$$n_{corr} = \frac{M(Q + Q_{Cl})}{\Delta m F} \quad [2]$$

Here Q_{Cl} is the equivalent charge corresponding to reduction of perchlorate to chloride according to Eq. [3]. It was calculated from the amount of chloride ion found by chemical analysis

$$ClO_4^- + 8H^+ + 8e = Cl^- + 4H_2O \quad [3]$$

Numerical values for n_{corr} are given in the last column of Table I. For all experiments n_{corr} is between 3.5 and 4. A few experiments were performed in acetic acid electropolishing solutions in which part or all of the $HClO_4$ was replaced by HCl. The apparent valence in an acetic acid solution containing 0.55M $HClO_4$ and 0.55M HCl was equal to that found for 1.1M $HClO_4$ acetic acid electrolytes and the electropolishing behavior was generally the same. In an acetic acid solution containing 1.1M HCl and no $HClO_4$, on the other hand, the apparent valence for dissolution was $n = 4$. Obtained data points are indicated in Fig. 8.

Discussion

It was not possible to measure steady-state polarization curves in the present study because the polarization behavior was found to be a function of time. Obtained results depended on the experimental technique employed as well as to a lesser extent on surface treatment and electrode geometry. The reason for this behavior lies in the previously observed formation and removal of anodic films (28). Indeed, if titanium in perchloric acid-acetic acid solution is anodically polarized to potentials below a critical breakdown potential a thick passivating film of TiO_2 is formed. Under potentiostatic conditions this leads to a steady decrease of observed current with time (Fig. 2), under galvanostatic conditions to a slow rise in potential (Fig. 3). If the anode is polarized above the critical breakdown potential pitting occurs. This is evidenced by the SEM micrographs of Fig. 5 and 6 as well as by the polarization data of Fig. 1-3 which exhibit a current or potential *vs.* time behavior typical for metals undergoing pitting (29); under potentiostatic conditions the current increases autocatalytically with time while under galvanostatic conditions typical potential overshoots are observed. Following the criteria defined by Smialovska and Czachor (29) the critical potential for pit nucleation in the galvanostatic and potentiostatic step experiments is $20V < E_{np} < 25V$ while a somewhat lower value is deduced from the potentiodynamic data of Fig. 1.

Dissolution from pits proceeds at a high rate leading to formation of solid reaction products and to local surface brightening (Fig. 7). The loose solid products which apparently consist of amorphous TiO_2 accumulate near the anode surface where they form a gelatinous layer reminiscent of the viscous layer originally described by Jacquet (8). The existence of a current plateau (Fig. 1) at high potentials suggests a diffusion-controlled process, but the presence of the viscous product layer, as well as the heterogeneous nature of the anodic attack tend to mask the influence of solution side mass transfer processes on limiting current. As a consequence the anodic polarization behavior depended only little on rotation rate of the titanium cylinder electrode except for the fact that at sufficiently high rotation rates the highly viscous layer could be mechanically removed by shear forces thus leading to an increase in observed currents (Fig. 1).

The data of Fig. 8 show an apparent valence of dissolution for titanium which is unusually low. Different explanations have been advanced in the literature to explain such low value. According to Straumanis and co-workers (30, 31) abnormally low valences in metal dissolution are usually due to anodic disintegration, *i.e.*, selective attack of grain boundaries leading to removal of metallic particles from the anode. However, such a mechanism can be excluded in the present case for different reasons. First of all, no selective grain boundary attack is apparent in the micrographs in Fig. 5-7 and no evidence of metallic titanium could be found in the dissolution products by x-ray analysis. Titanium metal does not corrode rapidly in the solutions employed here and therefore it is not likely that metallic particles after breaking away from the anode could have completely corroded before analysis was carried out. Another explanation for unusually low valence of dissolution has been given by Epelboin and co-workers (11, 32). According to these authors anodic dissolution of aluminum and beryllium in anhydrous perchlorate media leads to formation of monovalent species which in turn may react chemically with perchlorate ion in a homogeneous reaction following dissolution. Such a mechanism has been postulated for titanium dissolution in perchlorate electrolytes by Froment (22). No direct observation of the subvalent species has been possible up to now, however, and it must be assumed that if they exist they are extremely short lived (33).

Recently Neumann and Klimmek (34) studied the stoichiometry of anodic dissolution of molybdenum in mixed organic solvent-water electrolytes. They found an apparent valence of 3 in the presence of perchlorate but an apparent valence of 6 in the presence of chloride. The present data for titanium show a similar behavior. Under otherwise identical conditions, an apparent valence of 1.3-1.6 is observed in acetic acid containing 1.1M $HClO_4$ or 0.55M $HClO_4$ + 0.55M HCl, but an apparent valence of 4 in acetic acid containing 1.1M HCl. If dissolution would involve formation of a dissolved subvalent species which subsequently could react chemically in the electrolyte the apparent valence for dissolution should be the same for $HClO_4$ and HCl containing acetic acid solution since homogeneous chemical reactions following the charge transfer step do not affect weight loss. In view of the observed differences in apparent valence between $HClO_4$ and HCl containing solutions it is therefore concluded that the perchlorate ion intervenes directly at the metal sur-

face where it apparently reacts with adsorbed reaction intermediates of the dissolution process such as monovalent adsorbed ions or metallic adatoms. Stoichiometric measurements do not allow us to identify the reacting titanium species. The term "anodically activated titanium surface" will therefore be used independent of the exact nature of the reacting species.

It is interesting to note that the observed low values for the apparent valence are apparently not due to the anhydrous nature of the solution employed but to the presence of perchlorate ion. Indeed, recent experiments on high rate dissolution of titanium performed in our laboratory showed that similarly low values for the apparent valence of dissolution as in the present study are obtained in aqueous 5M $NaClO_4$ solution provided the critical potential for film breakdown is exceeded.

The proposed reaction of perchlorate ion with an anodically activated titanium surface poses an apparent paradox since for such a reaction to be thermodynamically possible the anode potential at the metal surface must be more cathodic than the reversible potential for reaction [3], the standard potential of which is 1.386V (35). On the other hand, the data of Fig. 1-4 show that measured anode potentials under polishing conditions are $>$ 20V. To explain the discrepancy one has to postulate that the actual potential at the reaction sites is different from that measured experimentally. It is well established that local potentials in corrosion pits can be much more negative than the apparent over-all anode potential (36, 25). Beck studying pitting of titanium in HBr observed hydrogen evolution at over-all anode potentials of several volts (25). He proposed that the principal factor causing the local potential differences was the ohmic resistance of a thin salt film. Since under present experimental conditions similar films of solid reaction products were present, it is very possible that local anode potentials at the metal surface were indeed much lower than those imposed externally. A separate experiment in a nonstirred electrolyte was performed in which anodically produced gas was collected and subjected to gas chromatographic analysis. Hydrogen as well as oxygen were found. The total amount of gas evolved was small, however, and therefore did not affect the over-all charge balance of Table I.

The proposed hypothesis involving reduction of perchlorate ion by reaction with an anodically activated titanium surface is consistent with the AES and ESCA data described in a previous study (28) which showed a chloride ion to exist at the film-metal interface in the breakdown and polishing region. According to present results passive film breakdown is initiated at discrete sites leading to dissolution by pitting. It is likely that these sites correspond to preexisting flaws in the anodic film which allow the perchlorate ions to penetrate into the film under the influence of the electric field and to react at the metal interface. With increasing potential the fraction of the surface accessible to anions increases and eventually the protecting TiO_2 film is completely removed by way of undercutting due to lateral growth of pits.

Conclusions

1. To achieve electropolishing of titanium in perchloric acid-acetic acid solutions anode potentials in excess of 20V are required to cause breakdown of the anodic film of TiO_2 which protects the metal from dissolution at lower potentials. Electropolishing is the result of merging together of bright pits.

2. Electropolishing coincides with the appearance in the current voltage curve of a current maximum or plateau. Its value depends little on hydrodynamic conditions because a gelatinous matrix consisting of solid reaction products covers the anode and masks the influence of convection on anodic mass transport processes.

3. During anodic dissolution under electropolishing conditions perchlorate ion is reduced to chloride which leads to an apparent valence of dissolution of 1.3-1.6 independent of applied current or potential.

4. Dissolution experiments performed in chloride and chloride containing perchlorate electrolytes and previous ESCA and AES analysis of electropolishing films provide strong evidence that perchlorate reduction proceeds by a heterogeneous reaction on an anodically activated titanium surface. This suggests that the effective anode potential at the metal surface is much lower than that measured externally.

Linear Defects Observed in Nickel Electrodeposits

S. Nakahara*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

During the course of a transmission-electron microscope characterization of nickel electrodeposits, it was found that deposits contain a high density ($\sim 1 \times 10^{15}/cm^3$) of linear defects whose image contrast is not the same as is expected from dislocation lines. A detailed analysis of these defects using electron diffraction techniques showed that these images are similar to a line of dilatation. It has been suggested that these linear defects probably are generated at growth steps as a result of the incorporation of hydrogen during electrocrystallization.

Recently, the inclusion of hydrogen in the form of gas bubbles was found to cause a loss in the ductility of electroless copper films (1). This loss was attributed to high pressure ($\sim 10^4$ atm) hydrogen gas bubbles, resulting in the so-called hydrogen embrittlement. In most electroplating systems in which the cathodic reactions involve both metal deposition and hydrogen evolution, the incorporation of hydrogen into deposits is inevitable as indicated by the high hydrogen content detected in electrodeposited metals (2). Consequently, hydrogen in electrodeposited films is known to greatly influence their mechanical properties such as ductility (3) and internal stress (4). A study of electrodeposited films, therefore, is of practical importance in understanding the relationship between incorporated hydrogen and mechanical properties.

A transmission-electron microscope (TEM) study was made on the structure of nickel electrodeposits to determine if hydrogen was incorporated as inclusions. During the course of this investigation, we discovered a high density of linear defects whose image contrast was different from that of dislocation lines. In order to understand the nature of these defects, a detailed analysis of their image contrast was carried out using TEM. This paper reports a preliminary account of this study and attempts to discuss the role of hydrogen in the formation of these linear defects.

Experimental

Nickel films were electrodeposited on a (001) copper film, as well as on a sheet of annealed OFHC polycrystalline copper. The composition of the electrolyte was 0.43M $NiSO_4 \cdot 6H_2O$ and 0.5M H_3BO_3. The pH of the bath was adjusted to 1.5. Plating was carried out at room temperature and at current densities of 5 and 15 mA/cm^2. Nickel films were stripped off the substrate in a copper-stripping solution (500 g/liter CrO_3 and 50 g/liter H_2SO_4). Specimens for TEM observation were jet polished in an electrolyte known as Borrmann solution (5). All TEM micrographs were taken using a JEM 200 microscope operated at an accelerating voltage of 200 kV.

Results

The structure of a (001) nickel film which was plated epitaxially on (001) copper film at a current density of 5 mA/cm^2 was carefully examined using several reflections under the so-called two-beam conditions (6) in TEM. Figure 1(a), 1(b), and 1(c) show micrographs of the film taken with reflecting vectors $\bar{g}$ = 200, $2\bar{2}0$, and $\bar{1}3\bar{1}$, respectively. Dislocations and growth twins are seen to exhibit various contrast features for these three reflections. Symbols x, y, and z indicate images of dislocations. In addition to the usual images of dislocations and growth twins, a high density of defects that exhibits a faint strain contrast as indicated by four fine arrows is also seen in Fig. 1(c). The existence of black-white oscillatory features suggests that the defects are linear along the direction of the oscillation. These linear defects (LD's) were not readily discernible with low-order $\bar{g}$'s such as 111, 200, and 220. Imaging with 311 type reflections was found to be most useful in obtaining detectable images of these defects. A subsequent characterization of these defects, therefore, was made using 311 type reflections. Typical results are shown in detail in Fig. 2 where $\bar{g}$ = 311. Examples of the LD's are indicated by symbol C, while that of dislocation is shown by symbol D. It can be seen clearly that the strain contrast associated with these LD's is much weaker than that associated with dislocation (compare C with D). It also appears that the image topography of the defects is different from that of dislocations. The density of these LD's was found to be $\sim 1 \times 10^{15}/cm^3$, which is much higher than that of grown-in dislocations ($\sim 6 \times 10^{13}/cm^3$) in these films.

In Fig. 2, a careful examination of the LD's in comparison with the images of dislocations indicates that the LD images possess a black-white oscillatory feature which has a periodicity of the order of the extinction distance for the operating reflecting vector $\bar{g}$. These oscillations, therefore, indicate that the LD's must be inclined in the foil. Stereoscopic analysis showed that the defects were indeed inclined in a form of linear segments which appear to be spacially distributed as a network. Furthermore, it was found that most of the LD's terminate inside the foil, as opposed to dislocations which except for small dislocation loops, terminate at the top or bottom surface of the film. This evidence, therefore, supports the hypothesis that the LD's are not dislocations.

In order to analyze further the nature of these LD's, in particular, relative to dislocations, the images were taken using $\pm\bar{g}$ reflections. Figures 3(a) and 3(b) show micrographs taken with $\bar{g}$ = $\bar{3}11$ and $3\bar{1}\bar{1}$, respectively. The images of dislocations are indicated by symbols x and y. Changing the reflecting vector, $\bar{g}$, from $+\bar{g}$ to $-\bar{g}$ results in the inversion of the image

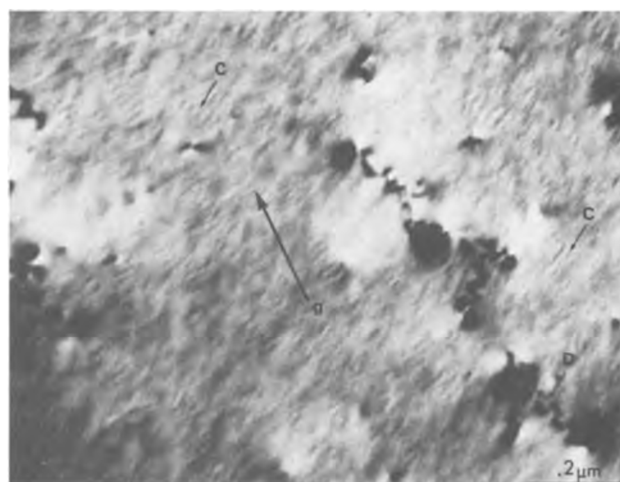

Fig. 2. TEM micrograph of a (001) nickel film imaged with $g = \bar{3}11$. Symbols C and D indicate the images of linear defects and dislocation, respectively.

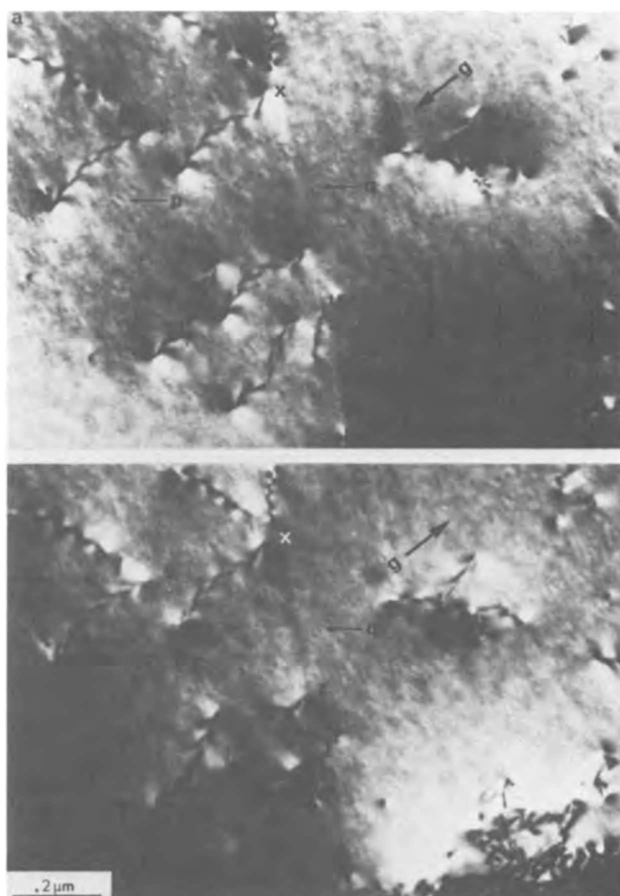

Fig. 3. Structure of a (001) nickel foil imaged with (a) $\bar{g} = \bar{3}11$; and (b) $3\bar{1}\bar{1}$. The micrograph was taken along a zone axis near 103. The images of dislocations are indicated by symbols x and y; those of LD's are shown by symbols p and q.

of a threading dislocation about the center of the image, i.e, the image is reversed with respect to the top and bottom surfaces of the foil and side for side with respect to the dislocation line. On the other hand, no such inversion occurs in the images of LD's as indicated by symbols p and q. Furthermore, it is seen that the LD images taken with the reflecting vector $+\bar{g}$ bear no relationship to those obtained with the reflecting vector $-\bar{g}$. In addition to the $\pm\bar{g}$ behavior of the image contrast, the images of the LD's contain a center of inversion (see Fig. 3). This symmetry property, however, does not exist for images of a dislocation. Based upon the symmetry properties of defect images obtained from theoretical micrographs (7), it can be concluded that the observed LD is not a dislocation, but a line of dilatation. The condition for invisibility of a line of dilatation is that the reflecting vector lies exactly along the dilatational line (7). In order to achieve such invisibility condition it was necessary to determine the direction of the line of dilatation.

The determination of the direction of the line of dilatation was made using the standard stereographic trace analysis. Figure 4 shows a micrograph of the (001) nickel foil imaged with $\bar{g} = \bar{3}11$ along its projected direction $\bar{z} \sim [1\bar{1}4]$. Most of the observed LD's were found to project along three major directions. In

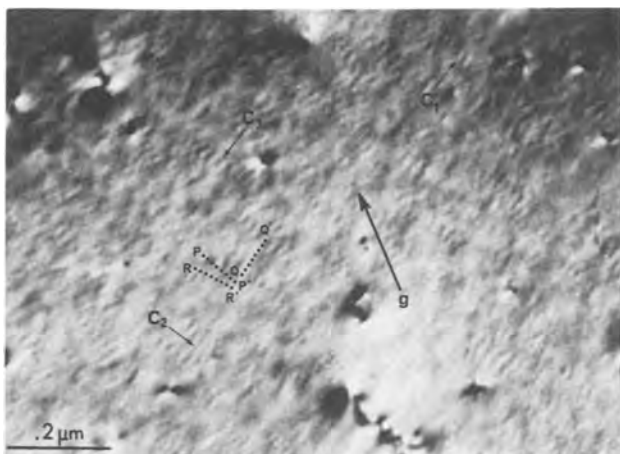

Fig. 4. TEM micrograph of a (001) nickel film imaged with $g = \bar{3}11$. Three dotted lines indicated by symbols PP', QQ', and RR' correspond to the line direction of LD's denoted by C_1, C_2, and C_3, respectively. $\bar{z} = \bar{1}\bar{1}4$.

Fig. 4, these three projected directions onto the ($\bar{1}\bar{1}4$) plane are indicated by symbols PP', QQ', and RR' which correspond to those of the LD's denoted by C_1, C_2, and C_3, respectively. The (001) stereogram in Fig. 5 shows the result of plotting great circles which correspond to the traces of the LD, C_1, obtained from the projections along [001], [103], and [125] directions. As seen in Fig. 5, within the experimental accuracy, the LD, C_1, lies approximately along the [001] direction, which is coincident with the foil normal. Similarly, the defects C_2 and C_3 were found to lie along the [100] and [010] directions, respectively. All the observed LD's in the (001) nickel foil are, therefore, found to lie primarily along <001> type directions.

The condition for invisibility of a line of dilatation can be achieved if the reflecting vector is chosen to lie exactly along the line of dilatation. It was possible to obtain such reflecting vectors for LD's labeled C_2 and C_3. For testing the invisibility condition h00 and 0h'0 type reflecting vectors were chosen for LD's, C_2, and C_3, respectively. The choice of 200 or 020 reflection, however, failed to give an unambiguous condition for invisibility, as the reflection itself does not produce detectable images of LD's. The use of 400 or 040 reflection nearly satisfied the invisibility condition for defects C_2 or C_3, although such detectability was also found to be rather difficult due to the relatively high order reflection. The difficulties encountered for achieving an invisibility condition are discussed further in the following section.

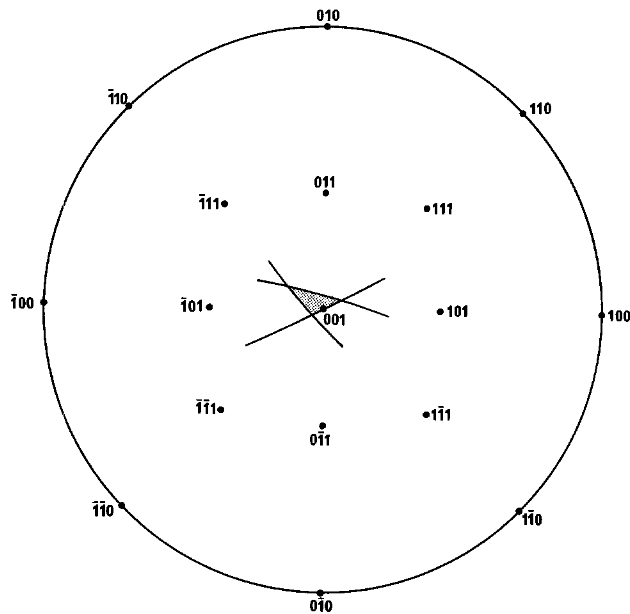

Fig. 5. A (001) stereogram showing the result of plotting great circles which correspond to the traces of the LD marked in Fig. 4, obtained from the projections along 001, 103, and $\bar{1}25$.

Discussion

It is, to the best of author's knowledge, the first time that lines of dilatation have been observed in electrodeposited nickel films. The fact that low order reflections such as $\bar{g} = 111$, 200, and 220, do not provide appreciable strain contrast from these defects undoubtedly accounts for the fact that they have not been observed. It is, however, rather surprising to find that LD's exist in such a high density ($\sim 1 \times 10^{15}/\text{cm}^3$), which is about more than one order of magnitude higher than the density of grown-in dislocations ($6 \times 10^{13}/\text{cm}^3$).

The crystallographic alignment of the observed LD's along <001> in (001) nickel foils resembles that of organic molecules incorporated in copper electrodeposits. It was recently found (8) that a chain of O-phenanthroline molecules, which are deliberately added to an electrolyte as an addition agent, are incorporated into (001), (011), and (103) copper foils along <001>. From morphological studies, it was concluded that the molecules are adsorbed at growth steps (multi-atomic steps) during growth processes and are subsequently incorporated into the deposit at the steps. This result clearly suggests that the observed lines of dilatation must have been generated at the growth steps of (001) planes by the incorporation of impurities during the crystallization process. In fact, morphological studies using a scanning electron microscope have shown that (001) nickel foils contained primarily three growth facets which are bounded by (001), (010), and (100) planes. On these growth facets, therefore, there are three stair steps along [100], [010], and [001], respectively. It can be easily seen that these stair steps can serve as the most probable sites for trapping gaseous and/or organic impurities. In the present experiment, the former impurity is likely to be hydrogen; the latter could be a trace of organic contaminant which is left in the electrolyte. As the electrolyte has been highly purified, it is not likely that a high density of organic impurities is incorporated in the form of lines of dilatation. Hence, impurities forming the observed LD's are most likely to be hydrogen. It should also be pointed out that the deliberate use of low pH($\sim$1.5) in the bath further increases the probability of incorporating hydrogen into the deposit. Figure 6 shows a proposed model

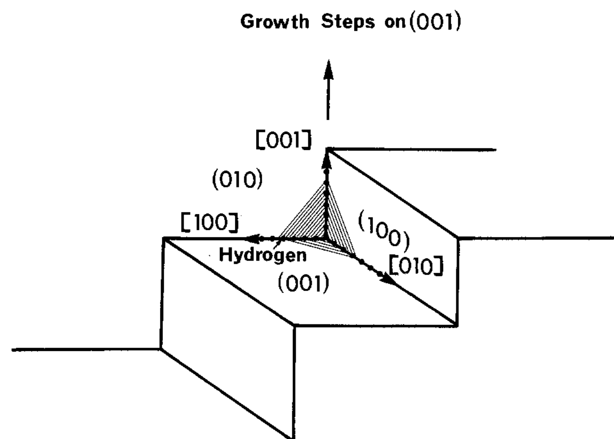

Fig. 6. Schematic illustration showing how a line of hydrogen molecules can be trapped along [100], [010], and [001] and subsequently incorporated into (001) deposit.

which illustrates how lines of hydrogen molecules can be trapped and then incorporated at growth steps along <001>. If this proposed model is correct, it is expected that the geometry and distribution of lines of dilatation should closely follow the pattern of growth facets on the (001) nickel foil. Furthermore, from this model it is easy to understand why such a high density ($\sim 1 \times 10^{15}/cm^3$) of LD's can be incorporated during the film growth.

Since this model predicts that LD's are generated at growth steps, it might be possible to change the LD structure by changing the structure of growth steps. In order to test this hypothesis, the deposition rate was varied by raising the current density from 5 to 15 mA/cm^2. Figure 7 shows the structure of a nickel film plated at a current density of 15 mA/cm^2 on a textured copper foil. The image was taken with $\bar{g} = 311$. Figure 7 shows that under this condition there are many features similar to the images of spherical inclusions whose strain field is indicated by three arrows. Although the images of these randomly distributed inclusions are visible in high density, inclusions of the type found in the (001) nickel films plated at 5 mA/cm^2 are not observed. These spherical-like inclusions were studied under so-called kinematical imaging conditions (6) using the defocus contrast technique (9). The defocus contrast revealed that the images of inclusions behave effectively like spherical voids. In other words, the inclusions are seen as white dots surrounded by black rings in the underfocused condition, and as black dots surrounded by white rings in the overfocused condition. This observation led us to conclude that the observed inclusions are pressurized spherical voids, probably containing hydrogen. The question then arises as to whether or not these inclusions bear any relation to the LD's.

A further close examination of the image features in Fig. 7 revealed that the images of closely spaced spherical inclusions somewhat resemble those of LD's. This observation motivated us to consider the possibility that LD's are, in fact, composed of strings of closely spaced spherical voids. Based upon this assumption, a (001) nickel film was reexamined to see if the LD's are associated with voids. Although high resolution defocus contrast technique was used, the presence of voids could not be assessed due to the resolution limit of the microscope (~5A). Therefore, it was concluded that if voids are present, they must be less than 5A in size. If the observed LD's are strings of spherical voids rather than lines of dilatation, they would not be invisible for a reflection which is parallel to them but show strong contrast, as pointed out by Borggreen and Thölén in their computer-simulation work (10). As described in the previous section, some difficulties were encountered in obtaining an unambiguous invisibility condition and this might be related partly to the fact that the LD's are not exactly pure lines of dilatation but are strings of spherical voids in a microscopic sense. Another possible explanation for this difficulty is, of course, that the LD's do not lie exactly along <001> directions. Nevertheless an increase in current density appears to modify the structure of growth steps, and consequently to change LD's into randomly distributed spherical voids. These results strongly suggest that this type of linear defects might be found in other thin films if the process of film formation involves the incorporation of gaseous and/or organic impurities. It should be pointed out, however, that strain fields associated with these defects might be extremely small and the use of high order reflections will be essential for their detection.

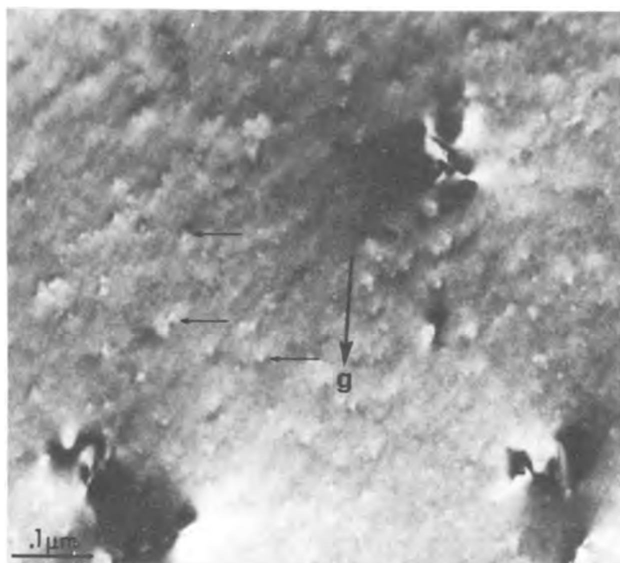

Fig. 7. TEM micrograph of a nickel film plated at a current density of 15 mA/cm^2 on a textured OFHC copper foil. The image was taken with $\bar{g} = 311$. Arrows indicate images of spherical inclusions.

The presence of such a high density of LD's in electrodeposited films is certainly expected to influence the level of internal stresses and, therefore, their contribution to the internal stress in electrodeposited films must be considered. Although most of the internal stress analyses in thin films has been based primarily upon stress gradient that is caused by variations in the density of grown-in dislocations along the direction of growth (11), the fact that the LD's are distributed along specific crystallographic directions <100> suggests that the LD's might contribute even more significantly to an anisotropy of internal stress in electrodeposited nickel films than do randomly distributed grown-in dislocations.

Further work will be required to determine whether the LD's are lines of expansion or lines of compression. The fact that the LD's were not found in very thin (<300A) foils indicates that mobile impurities incorporated along lines of dilatation might have escaped as the line segments intersect the film surfaces. This evidence appears to imply that gaseous impurities, such as hydrogen, are trapped along LD's but may be released at surfaces in thin areas of the film. Although the presence of hydrogen along the dilatational line still must be proven it is interesting to mention that LD's still were found in (001) foils after storage for as long as four years. Thermal stability of the LD's at various temperatures will be the subject of a future publication. Presently, a theoretical analysis based on computer-simulated electron micrographs is being carried out in order to determine the compressive or tensile nature of these LD's.

Acknowledgments

The author wishes to thank Dr. D. M. Maher for his experimental and technical guidance in obtaining our initial results without which the present work could not have been obtained. Thanks are also due to Drs. G. Y. Chin, S. Mahajan, and D. M. Maher for their constructive comments on this manuscript.

ABSTRACT

A study is presented of the liquid phase epitaxial growth of the quaternary mixed crystal $Al_yGa_{1-y}As_{1-x}Sb_x$. Samples were grown over the composition range $0 < x < 0.2$, $0 < y < 0.6$, at temperatures from 785° down to 715°C, below which a miscibility gap in solid composition was observed. With the inclusion of strain energy terms, a phase diagram calculation was found to describe all of the experimental results. Although strain effects on composition are small, in general, using this model, they are significant in the region of the miscibility gap.

The quaternary mixed crystal $Al_yGa_{1-y}As_{1-x}Sb_x$ has found application in such optoelectronic devices as lasers (1, 2), LED's (3), and photocathodes (4, 5). Its preparation was first reported by Sugiyama and Saito, who briefly described its use in a double heterostructure (DH) laser (1). Advances in the preparation of this material have since permitted such DH lasers to operate continuously at room temperature at wavelengths near 1 μm (2).

Very little data have so far been available on the growth and characterization of $Al_yGa_{1-y}As_{1-x}Sb_x$ (4, 5). In one study, limited to low Sb concentrations, $x \leq 0.065$, it was shown that the addition of Al to the ternary $GaAs_{1-x}Sb_x$ system had only a small effect on the Sb to As ratio in the solid (4). At higher Sb concentrations, our study of the Al-Ga-As-Sb phase diagram demonstrates that the addition of Al does significantly reduce the incorporation of Sb into the solid. In this study, layers were grown by liquid phase epitaxy with compositions over the range $0 < x < 0.2$, $0 < y < 0.6$, at temperatures between 715° and 785°C. Below 715°C, a miscibility gap was observed in the solid compositions of the grown layers. A phase diagram calculation has been carried out which provides good quantitative agreement with all of the experimental liquidus and solidus data. Lattice strain energy was found to significantly affect the results in the vicinity of the miscibility gap under the present conditions of epitaxial growth. The bandgaps of all the grown layers, along with the compositions, have permitted a mapping of the bandgap-lattice constant space of the $Al_yGa_{1-y}As_{1-x}Sb_x$ mixed crystal system.

* Electrochemical Society Active Member.

Experimental Methods

Liquid phase epitaxial growth was carried out in a horizontal, multiwell graphite boat and slider assembly in a flowing H_2 ambient. Solutions were prepared from elemental Ga (99.9999% pure), Sb (99.9999% pure), and Al (99.999% pure), with undoped polycrystalline GaAs as a source of As. The atomic fraction of Al in the liquid, X_{Al}^l, was varied over the range 0-0.007, while X_{As}^l was in the range $\approx$0.004-0.007. The As solubility could only be estimated in these experiments, because an amount of GaAs in excess of that required for saturation was always used. All solutions were prepared with a fixed Sb to Ga weight ratio of 1.074, resulting in $X_{Ga}^l \simeq 0.62$ and $X_{Sb}^l \simeq 0.37$.

The epitaxial quaternary solid solutions were grown at a cooling rate of 0.6°C/min on substrates consisting of three compositionally step-graded $GaAs_{1-x'}Sb_{x'}$ layers which served to accommodate the lattice-mismatch with the GaAs (100) seed. The double seed technique used for successful preparation of DH lasers (2) was used to equilibrate the growth solutions. In each case, the first two step-graded $GaAs_{1-x'}Sb_{x'}$ layers were grown with $x' = 0.03$ ($X_{Sb}^l = 0.09$, 792°-790°C) and $x' = 0.06$ ($X_{Sb}^l = 0.18$, 790°-788°C). The third "matching" layer was then grown with $X_{Sb}^l = 0.27$ from 788°C down to the starting temperature for the quaternary layer. This layer continuously graded in composition and lattice constant during growth and provided a reasonable lattice match for the quaternary. During the growth of the third layer, the quaternary solution was in contact with the equilibrating seed and, therefore, became partially depleted of Al. As a result, although the initial value of X_{Al}^l was known

accurately, the exact value at the time of growth was not well known. Finally, each quaternary layer was grown on such a graded substrate by cooling over 15° to a final temperature T between 715° and 770°C.

The solid composition at the surface of each $Al_yGa_{1-y}As_{1-x}Sb_x$ sample was measured with an x-ray microprobe analyzer. The compositions were determined using Colby's "MAGIC" computer program (6) by comparing the x-ray intensities of the quaternary unknowns to those of the same elements measured on GaAs, Sb, and Al standards. Room temperature bandgaps for most of the samples were determined from photoluminescence spectra, which were excited by a pulsed u.v. N_2 laser (3371Å) and analyzed with a ¾ meter spectrometer and S-1 photomultiplier. The bandgap E_g was taken as the peak of the photoluminescence curve in each case.

Experimental Results

Liquid and solid compositions.—Table I summarizes the experimental results for 14 different samples. The measured compositions x and y are given, along with the room temperature bandgaps E_g, for different initial X_{Al}^l and final growth temperatures T. Using Vegard's law (Eq. [B-2], Appendix B), the lattice constants a of the quaternaries have been calculated and are included in the table. The values of X_{Al}^l are those of the initial solutions, which were then partially depleted by the equilibrating seed as discussed above. In one case, for the initial growth (near the interface with the substrate) of sample B at 785°, this depletion amounted to only 3° growth on the equilibrating seed and could be neglected. By microprobe analysis of an angle-lapped section of B, the initial growth composition corresponding to $X_{Al}^l = 3.87 \times 10^{-3}$ and 785°C was determined, and is given as A in Table I. This particular data point was used to fit the phase diagram calculation described below.

Several conclusions can be drawn immediately from the data of Table I. It is clear that the addition of Al decreases the incorporation of Sb into the quaternary. By comparing the 760°C data of samples C, D, and E or the 730°C data of samples H, I, and J, a significant decrease of x with increasing y is evident. Such a strong dependence of x on y was not established in the earlier report of epitaxial growth in this system (4). On the other hand, when y was held approximately constant and the growth temperature reduced (for example in the series D, F, G, I, and L) x increased as it does in the limiting case of $GaAs_{1-x}Sb_x$ (7). Note that the apparent decrease of y with decreasing growth temperature for a constant starting value of X_{Al}^l (in samples A, B, D, F, G, H, and K) is due to Al depletion by the equilibrating seed and is therefore only an artifact of the growth procedure.

* All solutions had liquidus compositions $X_{Ga}^l \simeq 0.62$, $X_{Sb}^l \simeq 0.37$, and were saturated with As using excess GaAs. Except for sample A, the X_{Al}^l's were not equilibrium compositions, but were chosen initial values, as described in the text. All samples were grown through 15° to a final temperature T. The solid compositions x,y at the sample surfaces were measured with an electron microprobe and the lattice parameter a was calculated with Vegard's law. The bandgaps E_g were determined from photoluminescence spectra at room temperature. For sample N, the composition was measured just before the abrupt change corresponding to the miscibility gap at ~715°.

A striking change in the morphology of the samples occurred when growth was continued below 715°C. Above this temperature, the surfaces of the layers were shiny but had a crosshatched appearance. This structure, observed as well in graded $GaAs_{1-x'}Sb_{x'}$ layers (7), consists of microscopic ridges and valleys aligned along the [110] directions and is believed to arise from spatial deposition rate variations originating in misfit dislocation networks. Below 715°C, the surface became very rough, and a microprobe analysis in the appropriately angle-lapped layer revealed that the composition had changed abruptly during growth. Figure 1 shows the measured composition of this layer as a function of distance from the $GaAs_{1-x'}Sb_{x'}$ "matching layer" substrate. At 725°, growth of the quaternary first began with $x = 0.189$, $y = 0.311$. The composition remained nearly constant for about 3 μm until a temperature estimated to be about 715°C (given as sample N in Table I). Slightly below this point, the composition jumped to $x \approx 0.8$, $y \approx 0.04$, indicating the existence of a miscibility gap at this temperature under these conditions of growth. The significance of this miscibility gap region is discussed later.

Compositional dependence of the bandgap.—Figure 2 shows the compositional dependence of the bandgap for the data of Table I, in the form of E_g *vs.* lattice constant a. The points are the measured values for the different samples, and the curves are calculated bandgap-lattice constant isoconcentration lines. They are shown solid in the region where the direct bandgap is lowest and dashed in the region where an indirect bandgap has the lowest energy. The dotted curve is the boundary between these two regions. The direct bandgap of the quaternary has been approximated by

$$E_g(x, y) = E_g(0, 0) + Ax + Bx^2 + Cy + Dy^2 + Exy + Fxy^2 + Gyx^2 \quad [1]$$

The direct bandgap variations for three of the limiting ternaries give $E_g(0, 0) = 1.43$, $A = -1.9$, $B = 1.2$ eV for $GaAs_{1-x}Sb_x$ (7), $C = 1.042$, $D = 0.468$ eV for $Al_yGa_{1-y}As$ (8), and $C + E + G = 1.129$, $D + F = 0.368$ eV for $Al_yGa_{1-y}Sb$ (9). The bandgap variation

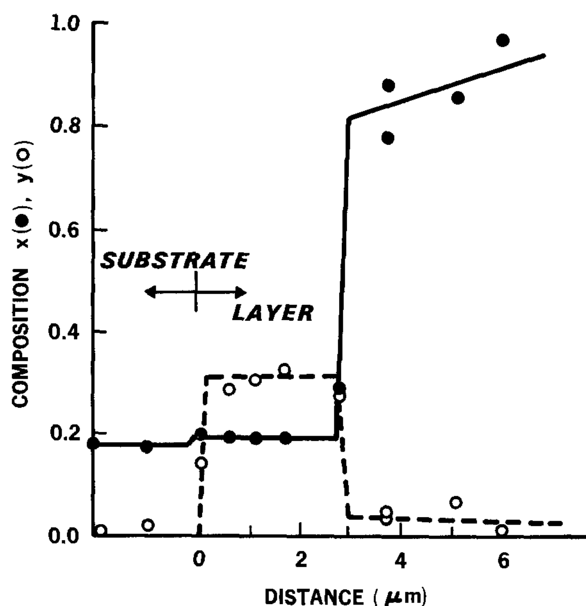

Fig. 1. Composition x, y *vs.* distance for sample N (grown from 725° to 710°C), obtained by electron microprobe measurements on an angle-lapped section. At a distance of 3 μm into the layer, the composition jumps abruptly, corresponding to the miscibility gap at ~715°C.

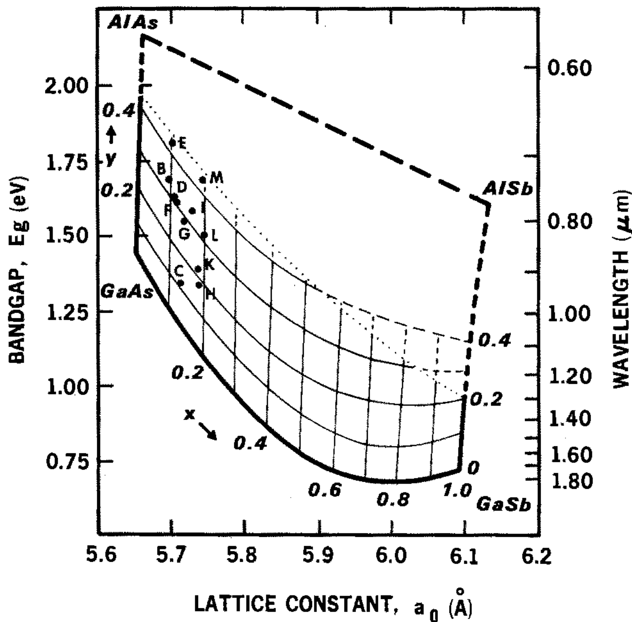

Fig. 2. Bandgap vs. lattice constant of $Al_yGa_{1-y}As_{1-x}Sb_x$. The points are measured values (Table I) and the curves are calculated isoconcentration lines. The dotted line separates the direct bandgap region (solid curves) and the indirect bandgap region (dashed curves).

for $AlAs_{1-x}Sb_x$ being unknown, a least squares fit of the data was used to determine E and G separately. It is clear from Eq. [1] that this determination cannot be very precise for a limited range of x, but the values obtained from the fit give the result $E \approx 1.0$ and $G \approx -0.9$ eV so that in eV

$$E_g(x, y) = 1.43 - 1.9x + 1.2x^2 + 1.042y + 0.468y^2 + 1.0xy - 0.1xy^2 - 0.9x^2y \quad [2]$$

The dashed curves for the indirect bandgap near the $Al_yGa_{1-y}Sb$ limit have been estimated from Ref. (9).

Quaternary Phase Diagram

The Al-Ga-As-Sb quaternary phase diagram can be calculated using the model and computational procedure outlined in Appendix A, as taken from the work of Ilegems and Panish (10) and Jordan and Ilegems (11). Table II lists the parameters used in the calculation, including the temperatures of fusion T^F, entropies of fusion ΔS^F, and interaction parameters α for the binary pairs in the liquid and β for the ternaries in the solid. The interaction parameters $\alpha_{As\text{-}Sb}$ and $\beta_{GaAs\text{-}GaSb}$ were taken from previous work on the Ga-As-Sb system over the same temperature range studied here (7). The parameter $\beta_{AlAs\text{-}AlSb}$ was obtained from $\beta_{GaAs\text{-}GaSb}$ by applying the δ-lattice-parameter model (12) and scaling according to $(\Delta a)^{2.5}$. The other parameters have been taken from Panish and Ilegems (13).

Table II. Parameters used in the phase diagram calculation*

	T^F (°K)	ΔS^F (eu/mole)	α,β (cal/mole)	a (Å)
Al-As	2043	15.60	$-12.0T + 600$	5.6622
Ga-As	1511	16.64	$-9.16T + 5160$	5.65321
Al-Sb	1338	14.74	-6000†	6.1355
Ga-Sb	983	15.80	$-6.0T + 4700$	6.09593
Al-Ga			104	
As-Sb			-600‡	
AlAs-GaAs			0	
AlSb-GaSb			0	
AlAs-AlSb			4700†	
GaAs-GaSb			4000‡	

* Parameters include the temperatures of fusion T^F, entropies of fusion ΔS^F, binary lattice parameters a, and the interaction parameters α for the liquid and β for the solid.** Except as noted, all parameters are from Ref. (13).

** The interaction parameters β are related to α_{12}^s and α_{34}^s of Appendix A by

$$\alpha_{12} = x\beta_{AlSb\text{-}GaSb} + (1 - x)\beta_{AlAs\text{-}GaAs}$$

$$\alpha_{34} = y\beta_{AlAs\text{-}AlSb} + (1 - y)\beta_{GaAs\text{-}GaSb}$$

† Present work.

‡ Ref. (7).

The only parameter not known sufficiently well in this temperature range from other sources is $\alpha_{Al\text{-}Sb}$. It was therefore evaluated by fitting the experimental liquidus and solidus data of sample A (Table I) at 785°C, as shown in Fig. 3. A value of $\alpha_{Al\text{-}Sb} = -6000$ cal/mole gives good agreement between calculated and measured (sample A) compositions $y = 0.397$ and $X_{Al}^l = 3.87 \times 10^{-3}$. Note from Fig. 3 that y is only weakly dependent on temperature between 785° and 745°C. This feature could not be verified experimentally because of the Al depletion already discussed.

A comparison of the results of the phase diagram calculation with the experimental solidus data of Table I is made in Fig. 4. The solid lines are the com-

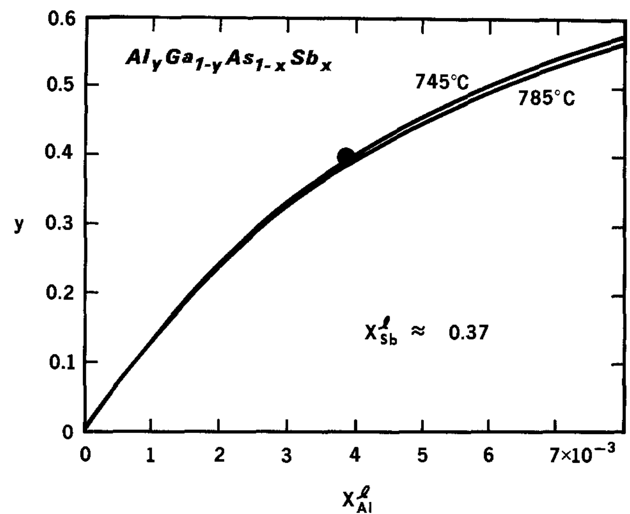

Fig. 3. Compositions y in the solid vs. X_{Al}^l in the liquid. The point corresponds to the measurements on sample A, and the curves are calculated at two different temperatures.

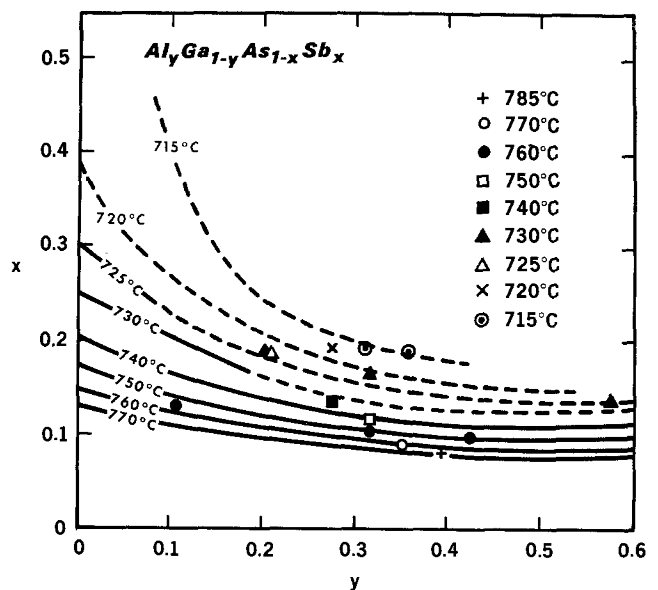

Fig. 4. Section of the Al-Ga-As-Sb phase diagram showing the solidus compositions x vs. y. The points correspond to the data of Table I. The dashed curves are obtained with the inclusion of strain energy effects. The solid curves are isotherms calculated in the strain-free case and are essentially unchanged by the inclusion of strain effects during continuous growth, as discussed in the text.

puted isotherms of x vs. y at temperatures between 725° and 770°C. The calculation follows the trends of the experimental results: x increases with decreasing temperature for a fixed value of y, and at a given temperature x decreases as y increases. Detailed comparison of the data with the calculated curves shows good agreement over the range 770°-740°. The epilayer compositions fall on calculated isotherms about 10°C lower than the final growth temperatures, but this deviation is quite small considering that no parameters were adjusted to specifically fit the experimental solidus points. This 10° difference may in fact be significant and due to a phenomenon previously observed in the Ga-As-Sb system (7). There, 10° of constitutional supercooling, arising from As-diffusion-limited growth, was observed for the same cooling rate of 0.6°C/min.

A striking discrepancy between the calculated phase diagram and the data occurs at temperatures below 740°C. Sections of the solid curves do not exist in this region of Fig. 4 since the calculation predicts a miscibility gap, with an abrupt jump in composition toward the GaSb limit, as the temperature is lowered. The compositional width of the predicted gap is a function of temperature: For example at 730°C it exists for $y > 0.2$, while at 725°C it should occur for $y > 0.1$. Experimentally, however, seven epilayers (samples H-N) have been grown below 740° in this region where the phase diagram calculation shows no solid solution miscibility. For instance, for a constant $y \approx 0.3$, the miscibility gap has not been observed until a temperature slightly below 715°C (Fig. 1). No changes in either the value of $\beta_{AlAs\text{-}AlSb}$ or the adjustable parameter $\alpha_{Al\text{-}Sb}$ could be made which would shift the calculated gap region from 740° to the observed 715°C at $y = 0.3$ without causing drastic disagreement with the known $y = 0$ ternary boundary (7) or with the data measured above 740°C.

Strain Energy Effects

We propose that this discrepancy can be resolved by the inclusion of lattice mismatch strain energy effects in the phase diagram calculation (14, 15). The details of the calculation are described in Appendix B. The mismatch strain energy is proportional to $(a - a_o)^2$, where a is the lattice parameter of the growing layer and a_o is that of the underlying layer. The contribution of this term to the free energy should be especially important in situations where solid compositions (and lattice parameters) can vary rapidly during growth, as in the region near a miscibility gap. In the neighborhood of such a gap there are two widely different compositional ranges of the solid in near-equilibrium with the liquid phase at a given temperature. With lowering temperature, the crystal tends to grow near the composition which minimizes the strain energy and thus continues to change composition slowly, rather than abruptly jump across the miscibility gap. At a sufficiently low temperature the strain energy term no longer dominates the free energy and a rapid change in composition finally occurs. This phenomenon would be observable as an effective reduction in the miscibility gap temperature, in agreement with the experimental results.

To quantitatively include this effect in the calculation, we note that the strain energy term can be written in the form

$$G^{st} = \sigma \left(\frac{a - a_o}{a_o} \right)^2 \text{ cal mole}^{-1} \qquad [3]$$

where σ is an elastic coefficient dependent on the material. This term has been included in the phase diagram calculation as described in Appendix B. The calculation was carried out successively at small temperature intervals, $\Delta T = 1°$, beginning at a temperature corresponding to the start of experimental growth. At each step, a_o was taken as the lattice constant of the composition calculated at the previous step. In this way the composition was calculated step-by-step for each temperature as the crystal grew, accounting for the changing lattice parameter of the underlying material. The temperature intervals of 1° used in the calculation were found to be adequately small to describe the continuous crystal growth. The calculation was continued to lower and lower temperatures, until an abrupt change of composition occurred. For any nonzero value of σ, the temperature at which this change occurs is lower than the miscibility gap temperature in the absence of the strain energy term.

The value of the elastic coefficient which lowers the calculated miscibility gap temperature to the observed range near 715°C was found to be $\sigma \approx 1 \times 10^5$ cal mole^{-1}. The computed results for this value are shown by the dashed isotherms in Fig. 4. For the region below 740° down to 715°C the dashed isotherms are now in good agreement with the experimental data points. In the region of the original solid isotherms, away from a miscibility gap, the inclusion of the strain energy has a negligible effect. This is because, as shown in Appendix B, the magnitude of the strain energy contribution to the total free energy of mixing is, in general, quite small. The inclusion of the strain energy term, therefore, has only a small effect on the solid composition, except near the miscibility gap, where a small change in the free energy of mixing is sufficient to cause a large shift in the solid composition. The magnitude of the elastic coefficient obtained by the above curve-fitting procedure, $\sigma \sim 1 \times 10^5$ cal mole^{-1}, is close to, but somewhat smaller than, the value 6×10^5 cal mole^{-1} estimated (Appendix B) from the elastic properties of the material (16). This difference, however, is reasonable in view of the fact that the theoretical prediction should give only an upper limit to the strain effects, since it ignores strain-relieving mechanisms such as interfacial misfit dislocations.

Conclusions

We have discussed the liquid phase epitaxial growth of the quaternary mixed crystal $Al_yGa_{1-y}As_{1-x}Sb_x$ over a wide range of compositions, $0 < x < 0.2$, $0 < y < 0.6$, at temperatures between 715° and 785°C. An abrupt change in composition has been observed in samples grown through ~715°, corresponding to a miscibility gap in the solid solution. The entire growth region investigated, including the miscibility gap, is successfully described by a phase diagram calculation. It was found that strain energy contributions to the free energy of mixing are required to bring the calculated results into agreement with the experimental data for temperatures in the region of the miscibility gap. Except for the miscibility gap region, the strain energy is shown to have a negligible effect on the phase diagram of the Al-Ga-As-Sb system. This strain energy model should be generally valid for all III-V solid solutions, but it alone cannot explain the strong lattice-pulling effects reported in some of these systems (14, 17, 18).

APPENDIX A

Quaternary Phase Diagram Calculations in the Equilibrium (No Strain) Case

A general technique for solving the solid-liquid equilibrium in quaternary systems involving compound semiconductors forming continuous series of solid solutions of the type $A_u\, B_{1-u}\, C_v\, D_{1-v}$ was pre-

sented in Ref. (10-11). (We retain the u, v notation here to be consistent with Ref. (11), and note that $u = y$ and $v = 1 - x$.) Explicit equilibrium equations were obtained for the case where the quaternary solid solution may be approximated by a regular mixture of the atoms A, B, C, and D subject to the site restrictions of the zinc blende lattice, and where the thermodynamic properties of the quaternary liquid may be approximated through the use of the simple-solution model.

The equilibrium equations between liquid and solid phases are written, in general form, in terms of the chemical potentials

$$\mu_{ij}^s = \mu_i^l + \mu_j^l \qquad \text{[A-1]}$$

where

$$ij = AC, AD, BC, BD$$

or, equivalently,

$$ij = 13, 14, 23, 24$$

for the four binary components of the quaternary solid. Of the four equations [A-1] only three are independent because of the relation

$$\mu_{13}^s + \mu_{24}^s = \mu_{14}^s + \mu_{23}^s \qquad \text{[A-2]}$$

The chemical potentials of the binary components, μ_{ij}^s, can be expressed in terms of the chemical potentials of the pure binary compounds (superscript o) according to

$$\mu_{ij}^s(T) = \mu_{ij}^{os}(T) + RT \ln x_i^s x_j^s + RT \ln \gamma_{ij}^s \qquad \text{[A-3]}$$

where $x_i^s x_j^s$ is the mole fraction of the binary component ij in the quaternary solid (random mixing on each sublattice) and γ_{ij}^s is the corresponding activity coefficient. The activity coefficients are obtained by partial differentiation of the excess free energy of mixing, G_M^e

$$RT \ln \gamma_{ij}^s = \frac{\partial G_M^e}{\partial n_{ij}} \qquad \text{[A-4]}$$

where n_{ij} represents the number of moles of component ij in n moles of the quaternary solid ($n = n_{13} + n_{23} + n_{14} + n_{24}$).

It has been shown that (11)

$$G_M^e = \frac{1}{n} [\alpha_{12}^s n_1 n_2 + \alpha_{34}^s n_3 n_4 + \alpha_c^s (n_{14} n_{23} - n_{13} n_{24})] \qquad \text{[A-5]}$$

where n_i represents the number of moles of component i. The quantities α_{12}^s and α_{34}^s are the interaction parameters for mixing on the Group III and Group V sublattices, respectively, while α_c^s is a combination of the interaction energies between elements residing on different sublattices. It can be verified that the γ_{ij}^s's obey the condition

$$RT \ln [\gamma_{14}^s \gamma_{23}^s / \gamma_{13}^s \gamma_{24}^s] = \alpha_c^s \qquad \text{[A-6]}$$

After making the appropriate substitutions for the chemical potentials in the four equilibrium equations [A-1], and after combining (10) all terms which depend on the composition X^l and parameters of the liquid phase together in the quantity Q_{ij}, the equilibrium equations are obtained in the simple form

$$\ln \gamma_{ij}^s x_i^s x_j^s = Q_{ij}; \quad ij = 13, 14, 23, 24 \qquad \text{[A-7]}$$

Again, only three out of the four equations [A-7] are linearly independent in accordance with the condition [A-2]. For the computer solution of the phase equilibrium, these three independent equations, rearranged in an equivalent symmetrical form as given in Ref. (10), are solved for u, v, X_4^l for a given set of input values X_2^l, X_3^l, and T using the numerical constants listed in Table II.

APPENDIX B

Quaternary Phase Diagram Calculation in the Elastic Strain Case

When the epitaxial layer is elastically strained such that its lattice constant a is made to conform to the lattice constant a_o of the underlying layer, there is an additional strain contribution to the total excess free energy of mixing

$$G_M^{e,\text{total}} = G_M^e + G_M^{st} \qquad \text{[B-1]}$$

The lattice constant of the quaternary solid is given by Vegard's law

$$a = uv\, a_{13} + u(1 - v) a_{14} + (1 - u) v a_{23} + (1 - u)(1 - v) a_{24} \qquad \text{[B-2]}$$

where the a_{ij} are the lattice constants of the binary compounds ij, given in Table II, and $u = y$ and $v = 1 - x$.

The strain energy contribution, evaluated per mole of epitaxial layer growth, can be estimated from the expressions given by Jesser and Kuhlmann-Wilsdorf (15)

$$G_M^{st} = \sigma \left(\frac{a - a_o}{a_o} \right)^2 \qquad \text{[B-3]}$$

with

$$\sigma = 2C \frac{1 + \nu}{1 - \nu} V_m \qquad \text{[B-4]}$$

where C is the interfacial shear modulus of the layer [$C = \frac{1}{2} c_{44}$ for growth on the (100) plane], ν the Poisson ratio, and V_m its molar volume. In these equations it is assumed that the thickness of the epitaxial layer is much smaller than that of the underlying layer so that the strain energy contribution from this underlying layer can be neglected.

To quantitatively include the effects of strain in the phase diagram calculation we evaluate the activity coefficients γ_{ij}^s in the solid solution, as in [A-4]

$$RT \ln \gamma_{ij}^s = \frac{\partial}{\partial n_{ij}} (G_M^e + G_M^{st}) \qquad \text{[B-5]}$$

For the strain contribution (superscript st), one obtains

$$RT \ln \gamma_{ij}^{s,st} = \frac{\partial}{\partial n_{ij}} \left[\sigma \left(\frac{a - a_o}{a_o} \right)^2 n \right] \qquad \text{[B-6]}$$

Finally, after differentiation

$$RT \ln \gamma_{ij}^{s,st} = \frac{\sigma}{a_o^2} (a - a_o)(2a_{ij} - a - a_o) \qquad \text{[B-7]}$$

In order for the $\gamma_{ij}^{s,st}$'s to satisfy condition [A-6], it is required that

$$\gamma_{13}^{s,st} \gamma_{24}^{s,st} / (\gamma_{14}^{s,st} \gamma_{23}^{s,st}) = 1 \qquad \text{[B-8]}$$

or after substitution that

$$a_{13} + a_{24} = a_{14} + a_{23} \qquad \text{[B-9]}$$

In general, an exact equality is not expected in [B-9], in view of the approximate formalism used to express G_M^{st}. In the AlGaAsSb system, however, $a_{13} \approx a_{23}$, and $a_{14} \approx a_{24}$, so that the relation [B-9] is closely satisfied. Therefore, in the computer calculation, which requires [B-9] to be an exact equality, the lattice constant values used in the evaluation of γ_{ij}^{st} [B-7] were replaced by average values: a_{13} and a_{23} by $(a_{13} + a_{23})/2$, a_{14} and a_{24} by $(a_{14} + a_{24})/2$.

An order of magnitude estimate of the strain contribution can be made taking the following values (16) to be representative of the $Al_uGa_{1-u}As_vSb_{1-v}$ quaternary with $u \sim 0.3$, $v \sim 0.8$, and $T \sim 1000°K$

$$\nu = 0.3$$
$$c_{44} = 5.1 \times 10^{11} \text{ dynes cm}^{-2} = 1.22 \times 10^4 \text{ cal cm}^{-3}$$
$$V_m = 28.6 \text{ cm}^3 \text{ mole}^{-1}$$

which yields

$$\sigma \sim 6 \times 10^5 \text{ cal mole}^{-1}$$

Since the maximum lattice mismatch which can be elastically accommodated without the generation of mismatch dislocations is expected to be well below 1%, the maximum strain energy contribution to the free energy of mixing is, from [B-3]

$$G_M^{st} << 60 \text{ cal mole}^{-1}$$

This value should be compared with the excess free energy of mixing in the absence of strain, evaluated using [A-5] and the parameters of Table II

$$G_M^e \sim 660 \text{ cal/mole}$$

Therefore, $G_M^{st} << G_M^e$, so that this strain energy contribution generally will have only a minor effect on the equilibrium solid composition. In cases near a miscibility gap, however, such a small change in $G_M^{e,total}$ may lead to large shifts in solid composition. These conclusions are verified by the detailed calculations carried out for the $Al_uGa_{1-u}As_vSb_{1-v}$ system as discussed in the text.

The Anodic Decomposition Pathways of *Ortho*- and *Meta*-substituted Anilines

Rodney L. Hand[1]

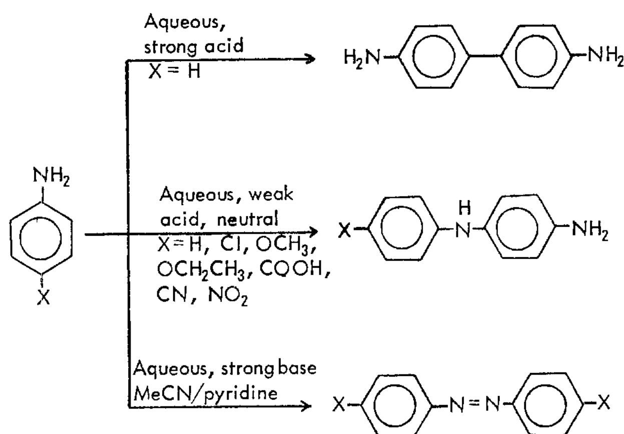
ABSTRACT

A survey of the anodic electrochemistry of a number of *ortho*- and *meta*-substituted anilines in 6*N* H_2SO_4 at carbon paste and graphite cloth electrodes has been carried out. It was found that the electrogenerated cation radicals decompose to form the correspondingly substituted benzidines and 4-aminodiphenylamines by tail-to-tail and head-to-tail coupling routes, respectively, in agreement with previous studies. Steric restraints hinder or exclude benzidine formation in some systems. The 4-aminodiphenylamines undergo hydrolytic degradation by different routes for the *ortho*- and *meta*-substituted derivatives, but in both cases 2-substituted *p*-benzoquinones are the end product. The quinones with electron-withdrawing substituents undergo a 1,4-addition of water to form substituted trihydroxybenzene derivatives which are also electroactive. Products and intermediates formed were verified, where possible, by comparison with authentic samples. Preparative-scale electrolyses resulted in substantial yields of some of the substituted *p*-benzoquinones of a magnitude comparable with chemical oxidations. A reaction mechanism is proposed which is consistent with the electroanalytical data and products formed for the series of compounds.

Recent articles have contributed significantly to our understanding of the decomposition pathways of ring-substituted anilines. Bacon and Adams have found that *para*-substituted anilines couple head-to-tail to form the corresponding diphenylamines and that aniline and o-toluidine couple head-to-tail and tail-to-tail to form the corresponding diphenylamines and benzidines in a *p*H-dependent process (1). Wawzonek and McIntyre have shown that aniline and a number of ring-substituted anilines couple head-to-head to form hydrazo compounds in acetonitrile with pyridine (2) and in aqueous alkaline solutions (3). These various coupling reactions are summarized below



The reaction mechanism proposed by Bacon and Adams involved cation radical coupling reactions (or, alternatively, in view of considerable circumstantial but no conclusive evidence as to the existence of these cation radicals, a dication-parent aniline coupling reaction) to form the benzidines and diphenylamines. The reaction mechanism did not appear to account for the observed *p*H dependence of the benzidine-to-diphenylamine ratio in the aniline and o-toluidine systems.

Wawzonek and McIntyre proposed initial generation of the cation radical via a one-electron oxidation. The cation radical was subsequently deprotonated (pyridine as the base in MeCN/pyridine and the parent aniline as the base in MeCN) to give the neutral free radical. The neutral free radicals then coupled to form diphenylamines and hydrazo compounds which were further oxidized. The diphenylamine-to-hydrazobenzene ratio was reportedly controlled by the ring substituent present though no general conclusions as to substituent effects were presented or evident.

A later study of N-alkylanilines in MeCN and aqueous solutions again demonstrated the formation of diphenylamines and benzidines (4). The diphenylamine-to-benzidine ratio was observed to increase with decreasing bulk of the alkyl substituent, increasing *p*H, increasing parent concentration, and decreasing current density. To explain these observations, two discrete decomposition pathways were proposed for the electrogenerated aniline cation radicals. N-ring coupling of a neutral free radical and parent amine to give diphenylamines was proposed when the cation radical-to-parent ratio was low (low curent density, high parent concentration) and deprotonation of the cation radical was facilitated (increasing *p*H). Direct coupling of cation radicals was proposed when the cation radical-to-parent ratio was high (high current density, low parent concentration) and solution conditions were not conducive to deprotonation (low *p*H). The reaction mechanism is somewhat speculative but did account for the observed product distributions as a function of solution conditions.

In an effort to relate these studies more clearly and to provide additional insight into the reaction mechanism through observations of steric and electronic ring substituent effects, we have investigated the electrochemistry of a series of *ortho*- and *meta*-substituted anilines in strong acid solution. The results of this study are reported herein.

Experimental

Solvents, supporting electrolytes, and reagents.—All aqueous solutions were prepared from doubly distilled water and reagent grade H_2SO_4 or standard buffer re-

agents. o-N,N-dimethylaminoaniline hydrochloride (Eastman), o-phenylenediamine dihydrochloride (Eastman), o-methoxyaniline (Eastman), o-methylaniline (Eastman), o-fluoroaniline (Aldrich), o-chloroaniline (Aldrich), o-bromoaniline (Columbia Organic Chemicals), o-iodoaniline (Aldrich), o-acetylaniline (Aldrich), ethyl anthranilate (Eastman), o-trifluoromethylaniline (Maumee Chemical Corporation), and o-cyanoaniline (Aldrich) were obtained commercially and used without further purification. o-Nitroaniline (Eastman) was obtained commercially and purified by column chromatography. 2-Aminobiphenyl was obtained from Aldrich and purified by benzene/alumina (Woelm) chromatography and recrystallization from benzene/ethanol. *m*-N,N-dimethylaminoaniline hydrochloride (Eastman), *m*-methoxyaniline (Aldrich), *m*-chloroaniline (Aldrich), *m*-bromoaniline (Matheson, Coleman and Bell), *m*-iodoaniline (Aldrich), *m*-trifluoromethylaniline (Maumee Chemical Corporation), *m*-cyanoaniline (Aldrich), and *m*-nitroaniline (Eastman) were obtained commercially and used as received. 3,3'-Dimethoxybenzidine (Aldrich), 3,3'-dimethylbenzidine (Eastman), and 3,3'-dichlorobenzidine (K and K) were obtained commercially and purified by recrystallization. 3,3'-Dinitrobenzidine was prepared by a standard method (5), as were 2,2'-dichloroazobenzene and 3,3'-dichloroazobenzene (6). 2,2'-Dicyanoazobenzene and 2,2'-dinitroazobenzene were prepared by a hypochlorite oxidation of the corresponding anilines in neutral aqueous media (7). Hydroquinone (Aldrich), 2-methylhydroquinone (Aldrich), 2-chlorohydroquinone (Pfaltz and Bauer), 2-bromohydroquinone (Pfaltz and Bauer), and catechol (Aldrich) were obtained commercially and used without further purification. 2-Nitrohydroquinone was prepared by a standard literature method (8), as was the 2-methoxyhydroquinone (9). Ethyl-2,5-dihydroxyanthranilate was prepared by esterification of 2,5-dihydroxybenzoic acid (Pfaltz and Bauer). 4-Amino-3-methylphenol and 4-amino-2-methylphenol were obtained commercially (Eastman) and used without further purification. All other materials were reagent grade and used without further purification.

Instruments, cells, and electrodes.—The instrument used for the electroanalytical studies was a standard operational amplifier-based potentiostat-amperostat employing a three-electrode configuration. Current-voltage and current-time curves were monitored with a Hewlett-Packard 7030 X-Y recorder. Coulometric *n*-values were obtained with a Wenking 68FR 0.5 fast-rise potentiostat equipped with a digital integration system. Preparative electrolyses were effected with a "home-built" ±65V ±2.5A potentiostat (10).

Electroanalytical studies.—The electroanalytical experiments were conducted in a one-compartment cell containing a carbon paste working electrode, platinum wire auxiliary electrode, and aqueous SCE reference electrode. The carbon paste was prepared by mixing 4g of powdered graphite (Ultra Carbon Corporation, WCP-1-M, Lot 989-2) and 6 ml of Nujol mineral oil. A new carbon paste surface was prepared for each individual aqueous electroanalytical experiment.

In the chronoamperometry experiments, the initial potentials were always at least 200 mV cathodic of the peak potentials of the substituted anilines and the final potentials were at least 100 mV anodic of the peak potentials unless otherwise stated.

Coulometric *n*-values were obtained in a two-compartment cell using a carbon rod auxiliary electrode, a carbon cloth working electrode, and a SCE reference electrode. The working and auxiliary compartments were separated by a porous sintered glass frit. The coulometry experiments were terminated when the electrolysis current was 1% of the initial current or when a steady-state current was reached (typically 1-5% of the initial current). Background corrections were obtained by electrolyzing the appropriate solvent and supporting electrolyte for various times at the appropriate potential. In all cases oxidation potentials were at least 100 mV anodic of the parent peak potential. A typical coulometry experiment involved the oxidation of approximately 60 mg of substituted aniline in 50 ml of 6*N* H_2SO_4. Typical initial currents were 250 mA and typical final currents were 2.5 mA.

Preparative electrolyses.—Preparative electrolyses were conducted in a two-compartment cell using a carbon rod auxiliary electrode, a carbon cloth working electrode backed by a platinum foil (10 × 20 cm), and a SCE reference electrode. The cells were 400 and 600 ml beakers and the auxiliary and working compartments were separated by a porous ceramic cup (25 mm diam, 76 mm height), Coors Model No. 70001. Electrical contact to the working electrode was made at several points to avoid local potential gradients. Oxidation potentials were at least 100 mV anodic of parent peak potentials, and electrolyses were terminated when a low steady-state current was reached. A typical preparative electrolysis involved the oxidation of 1g of substituted aniline in 300 ml of 6*N* H_2SO_4. Typical initial currents were 2.5A and typical final currents were from 25-100 mA. Electrolysis times were usually on the order of 1 hr.

Preparative chemical oxidations.—Chemical oxidations were performed under the same solution conditions as the electrochemical oxidations, *i.e.*, 1g of substituted aniline in 300 ml 6*N* H_2SO_4. $(NH_4)_2Ce(NO_3)_6$ and $Ce(SO_4)_2$ were used as chemical oxidants. The chemical oxidant was added in excess or until the disappearance of the parent aniline peak in cyclic voltammograms of the solution was observed.

Product isolation.—Following electrochemical reduction at 0.2V the 6*N* H_2SO_4 electrolysis solutions were extracted several times with benzene. The solution pH was then raised to pH 2-3 with Na_2SO_3 and the benzene extractions were repeated. Extractions were again repeated at *p*H 4-5, *p*H 7-8, and *p*H 10-11. Relatively small amounts of reasonably pure substituted hydroquinones were isolated from the 6*N* H_2SO_4 extracts. From *p*H 2-3 to *p*H 7-8 substituted hydroquinones, increasing quantities of substituted benzidines, increasing quantities of aniline "polymers," and any remaining unoxidized parent aniline were isolated. At *p*H 10-11, only unidentified intractable, highly colored "tars" or "polymers" and small amounts of substituted benzidines were isolated. The benzene extracts were concentrated and chromatographed on neutral alumina. Unoxidized anilines were eluted with benzene, benzidines, and then hydroquinones with $CHCl_3$ and hydroquinones and polymers with acetone.

Results

The electrochemistry of these compounds in 6*N* H_2SO_4 can be broadly characterized as involving coupling reactions followed by a series of hydrolysis and substitution steps; the initially formed cation radicals couple tail-to-tail and/or head-to-tail to form substituted benzidines and/or diphenylamines. The benzidines are oxidized onto chemically inert dications for an over-all two-electron process. The diphenylamines are also oxidized to the dication state, but these dications undergo two succesive hydrolysis steps to generate a molecule of the parent aniline and one of the correspondingly substituted *p*-benzoquinone, an over-all process involving four electrons per parent aniline molecule. In some cases, the 2-substituted benzoquinones undergo a 1,4-addition reaction to generate a substituted trihydroxybenzene, which can then undergo an additional two-electron step, leading to a maximum *n*-value of 6. The results and discussion given below illustrate how and why these processes can be correlated with the various substituents in the *ortho*- and *meta*-substituted anilines studied.

[h] Averaged data taken from hydroquinone and 2-methylhydroquinone and used for comparison as a model two-electron system.
[i] Two poorly defined anodic waves, $Ep/2$ approximately 0.66 and 0.82.

The electroanalytical data for the *ortho*- and *meta*-anilines in 6*N* H_2SO_4 are shown in Table I. The electroanalytical data for two model two-electron compounds, hydroquinone and 2-methylhydroquinone, were averaged and used as a basis for comparison. Electrode filming was encountered in long-term experiments for all but the electron-donating substituents and signs of filming are evident in voltammograms of many of the substituted anilines. The extent to which filming affected the electroanalytical data is unknown, although the data presented in Table I are easily reproducible within the ±5% normally attributed to the reproducibility of the carbon paste electrode surface. The onset of large background currents begins at 1.2V (*vs.* SCE) and therefore the maximum potential used for chronoamperometry and coulometry experiments was 1.2V. This limit resulted in chronoamperometry and coulometry experiments being performed 80 mV anodic of the peak potential in the *meta*-trifluoromethylaniline and *ortho*-nitroaniline systems and 20 mV anodic of the peak potentials in the *meta*-cyanoaniline and *meta*-nitroaniline systems.

The peak current data for the anilines generally indicate an n-value of near two at short times with a gradual increase as the ring substituent becomes more electron withdrawing. The n-value of two is consistent with the initial formation of benzidines and diphenylamines via a fast ECE process (4).

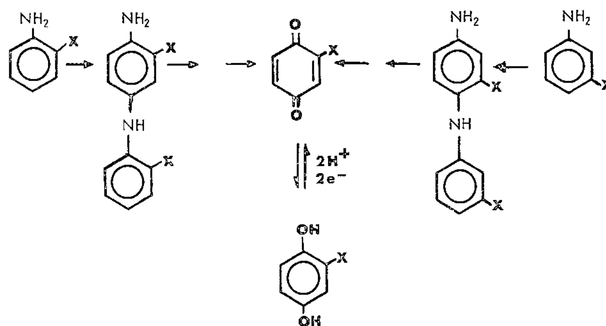
The chronoamperometric data are more sensitive to changes in n-values caused by the hydrolysis reactions in these systems due to the 1-10 sec time gate available. The chronoamperometric data in Table I reflect the relative amounts of benzidine and diphenylamine formed from the parent aniline. The n-values increase from near two for the electron-donating groups to over five for the electron-withdrawing groups. This trend reflects the increase in dephenylamine formation as the *ortho* substituent becomes more electron withdrawing, the decomposition of the diphenylamines, and the decomposition reaction of the quinones. The higher n-values for the corresponding *meta*-anilines reflect the increased diphenylamine formation in the *meta* systems. The low n-values for *meta*-trifluoromethyl-, *meta*-cyano- and *meta*-nitroaniline reflect incomplete oxidation due to the +1.2V background limit and filming. Filming could also be a factor for *ortho*-chloro- through *ortho*-nitroaniline and *meta*-chloro through *meta*-iodoaniline, as filming was observed in the longer term experiments in these systems.

The coulometric data indicate the long-term behavior of these systems. Again, the n-values increase as the ring substituent becomes more electron withdrawing, reflecting the increased diphenylamine formation and ensuing follow-up reactions. The higher n-values for the corresponding *meta*-anilines again reflect the increased diphenylamine formation in the *meta* systems. Incomplete electrolysis due to filming and/or background limitations were observed for *meta*-chloro through *meta*-nitroaniline. Filming could also be a factor in the *ortho*-chloro- through *ortho*-nitroaniline systems.

Following is a brief treatment of the various groups of compounds studied that could be lumped together as a result of similar electrochemical behavior. These data are critical to understanding the rationalizations forwarded in the Discussion section.

o-Phenylenediamine, o-N,N-dimethylaminoaniline, m-N,N-dimethylaminoaniline.—The cyclic voltammograms and electroanalytical data for the phenylenediamines indicate behavior markedly different from the remainder of the *ortho*- and *meta*-substituted anilines. The decomposition pathways for the phenylenediamines were not pursued.

o-Methoxyaniline, m-methoxyaniline, o-methylaniline, m-methylaniline, o-isopropylaniline, and o-phenylaniline.—The *ortho* compounds in this group exhibited nearly identical behavior on cyclic voltammograms, an example of which is shown in Fig. 1 for the methoxy derivative. The couple labeled "1" is assigned to the 2-substituted quinone/hydroquinone couple which can be generated by successive hydrolyses of the 2′,3-disubstituted-4-aminodiphenylamines and the 2,3′-disubstituted-4-aminodiphenylamines resulting from head-to-tail coupling in the *ortho*- and *meta*-aniline systems, respectively



These quinone/hydroquinone couples were identified by matching of cyclic voltammograms (Fig. 1) and ESR spectra, in the case of the methyl derivative, with authentic samples.

The couples labeled "2" are assigned to the substituted 4-aminodiphenylamines generated by head-to-tail coupling or an intermediate in the two-step hydrolysis reaction which generates the 2-substituted quinone (see the Discussion section). Some uncertainty exists as to the identity of this couple as it was not possible to isolate the compounds responsible for it; comparisons with authentic samples were not possible as the compounds which could be responsible for this couple are not commercially available and their preparations would be difficult and time-consuming, since the aminodiphenylamines are easily air oxidized.

The couple labeled "3" in Fig. 1 was assigned to the 3,3′-disubstituted benzidines generated by tail-to-

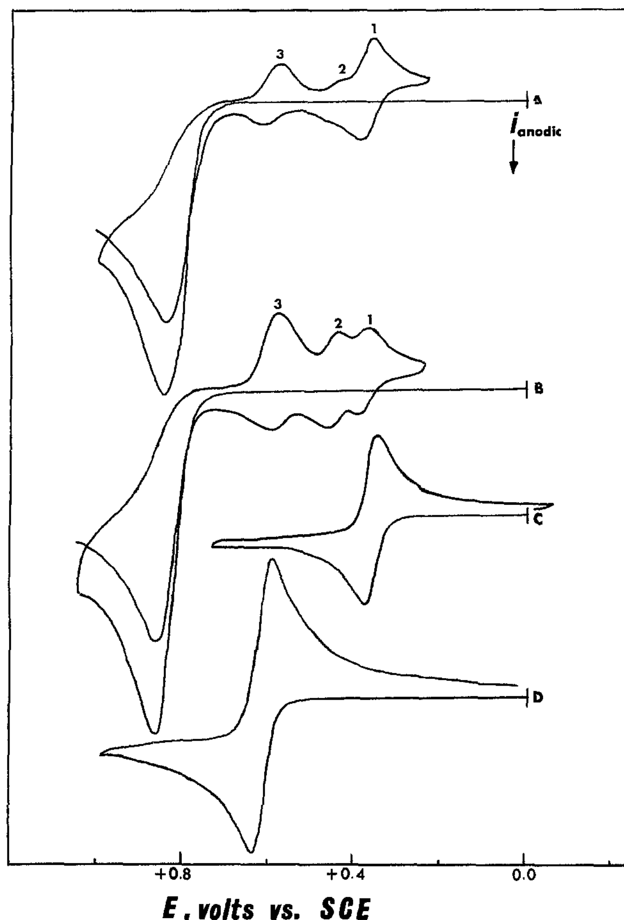


Fig. 1. Cyclic voltammograms in 6N H_2SO_4 at carbon paste. Curve A, 1.1 × 10^{-3}M o-methoxyaniline, sweep rate = 50 mV/sec; curve B, same, sweep rate = 450 mV/sec; curve C, o-methoxyhydroquinone; curve D, 3,3′-dimethoxybenzidine.

tail coupling; this assignment was confirmed by matching of cyclic voltammograms (Fig. 1) and optical spectra of products isolated from mass electrolyses with authentic samples. The 3,3′-disubstituted benzidines, the substituted 4-aminodiphenylamines (or intermediates) and the 2-substituted hydroquinones are clearly visible on cyclic voltammograms and the quinone-to-diphenylamine ratio clearly increases as the scan rate is decreased. The short time gate (peak current) n-value of approximately two is consistent with the formation of benzidines and diphenylamines via a fast ECE process and hydrolysis of the diphenylamines (or intermediates). The benzidine/diphenylamine ratio is also affected by steric considerations; in going from methyl to isopropyl to phenyl as the *ortho* substituent the relative amount of benzidine increases due to the steric crowding involved in diphenylamine formation with a bulky *ortho* substituent. In addition, the diphenylamine in the phenyl system appears to be more stable than that in the methyl analog, due, presumably, to the steric effect on the hydrolysis rate of the central nitrogen.

Numerous preparative-scale mass electrolyses were performed on *ortho*-methoxy- and *ortho*-methylaniline. The n-values resulting from these electrolyses were slightly higher (2.9 *vs.* 2.48 and 3.4 *vs.* 3.20) than those obtained in the coulometry experiments. The n-values resulting from the reduction of the oxidized preparative-scale electrolysis solutions were 0.6 for *ortho*-methoxyaniline and 1.2 for *ortho*-methylaniline. Both reduction n-values are lower than would be expected, indicating formation of electroinactive species, *i.e.*, tars and polymers. Large amounts of an insoluble precipitate, reminiscent of those obtained in aniline electrolyses, were obtained in the *ortho*-methoxyaniline oxidations. Crude yields of isolable product averaging 25% for *ortho*-methoxyaniline and 40% for *ortho*-methylaniline were obtained from the electrolysis solutions according to the work-up procedure described in the Experimental section; no attempts were made to maximize the product yields. The crude products were purified according to the procedure in the Experimental section. Interestingly, chemical oxidation of o-methylaniline produced only 2-methylhydroquinone in an approximately 40% yield.

The cyclic voltammograms of *meta*-methoxyaniline indicate that the major product is the diphenylamine or intermediate, as shown in Fig. 2. In addition, two small couples are visible anodic of the diphenylamine couple; the less anodic corresponds in potential to the *p*-*p*-benzidine for this system and the minor redox pair (arrows) could be due to the o-*p*-benzidine, although the latter assignment is purely speculative. The cyclic voltammograms of *meta*-methylaniline (Fig. 2) show only the single product identified as the diphenylamine or intermediate. The higher n-values obtained in the electroanalytical experiments for *meta*-methyl- and *meta*-methoxyaniline reflect the increased diphenylamine formation (and subsequent hydrolysis reactions) over their *ortho* analogs. Preparative-scale mass electrolyses for these two compounds were similar to those for *ortho*-methyl- and *ortho*-methoxyaniline. Forward n-values were slightly above those obtained from coulometric determinations and reverse n-values were 0.8 for *meta*-methylaniline and 0.4 for *meta*-methoxyaniline, again indicating formation of electroinactive species. Cyclic voltammograms following mass electrolysis indicated that the major product for *meta*-methoxyaniline was the same product obtained in the coulometry experiments. The product has not been

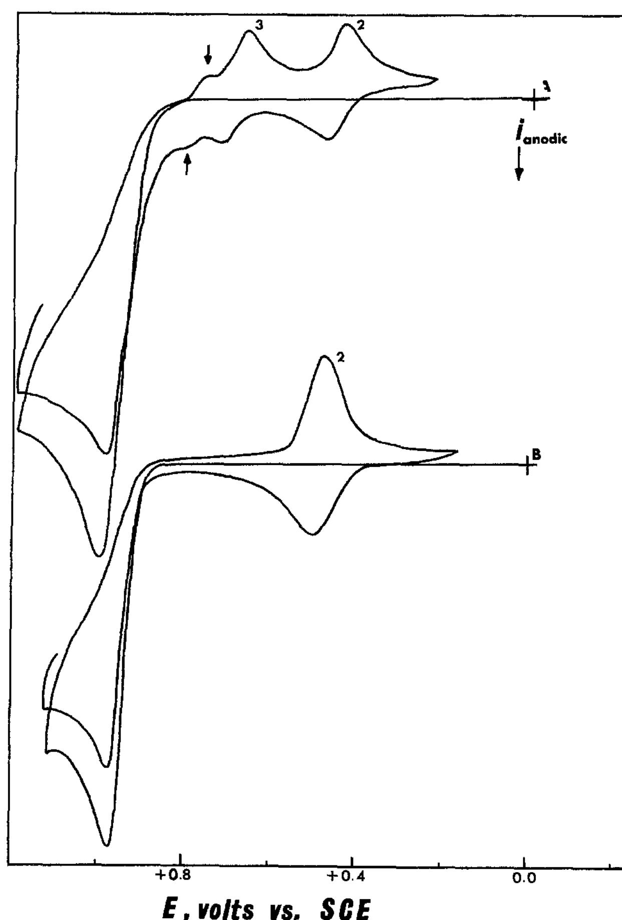

Fig. 2. Cyclic voltammograms in 6N H_2SO_4 at carbon paste. Curve A, 2.12 × 10^{-3}M m-methoxyaniline, sweep rate = 100 mV/sec; curve B, 1.18 × 10^{-3}M m-methyaniline, sweep rate = 150 mV/sec.

positively identified but is presumed to be 2-methoxy-*para*-aminophenol. Cyclic voltammograms of *meta*-methylaniline following mass electrolyses indicate the final product in this system is 2-methylhydroquinone, whereas 2-methyl-*para*-aminophenol was found to be produced in the short coulometry experiments. This result is consistent with the known slow hydrolysis of 2-methyl-*para*-aminophenol to 2-methylhydroquinone (11).

In addition to the products identified and identification methods described in the above discussions, cyclic voltammograms of authentic samples of 2-methylhydroquinone, 2-phenylhydroquinone, and 3,3'-dimethylbenzidine matched product couples in voltammograms of their respective amines.

o-Fluoroaniline, o-chloroaniline, o-bromoaniline, o-iodoaniline, m-fluoroaniline, m-chloroaniline, m-bromoaniline, and m-iodoaniline.—The *ortho*-substituted compounds in this group exhibited nearly identical behavior on cyclic voltammograms. The 3,3'-disubstituted benzidines, substituted 4-aminodiphenylamines (or intermediates), and 2-substituted hydroquinones are clearly visible in the voltammograms and the quinone-to-diphenylamine ratio increases as the scan rate decreases as shown in Fig. 3. The cyclic voltammograms of the *meta*-substituted compounds show little variation with scan rate and, with the exception of *m*-fluoroaniline, show only the single product couple identified as the diphenylamine or intermediate. The second product couple in the *meta*-fluoroaniline voltammogram corresponds in potential to that which would be expected for the 2,2'-disubstituted benzidine. The similar behavior of the *ortho* compounds, and the similar behavior of the *meta* compounds lead to the conclusion that there is little difference between the electronic effects of the various halogens, and the absence of the 2,2'-disubstituted benzidines in the *meta*-chloro-, *meta*-bromo-, and *meta*-iodoaniline systems is, therefore, attributed to steric effects.

The higher short time-gate *n*-values reflect the increased diphenylamine formation for the *meta* compounds and the increased hydrolysis rates of the diphenylamines in both the *ortho* and *meta* systems due to the electronegative halogen substituents. The higher long time-gate *n*-values for the *meta*-substituted anilines (*meta*-bromo- and *meta*-iodoaniline film the electrode) again reflect the increased diphenylamine formation and, in addition, some decomposition of the hydroquinone to the substituted trihydroxy compound.

Cyclic voltammograms following coulometry experiments for the *ortho*-halogens indicate only benzidine and hydroquinone as products (Fig. 4). Similar voltammograms for the *meta*-substituted anilines indicate the presence of large quantities of hydroquinone, small amounts of the trihydroxy compound, and small amounts of the substituted *para*-aminophenol. The fact that the hydroquinone was the almost exclusive product indicates that the halogen-substituted *para*-aminophenols hydrolyze faster than the methoxy- and methyl-aminophenols, which were the major products following coulometric determinations for the *meta*-methyl- and *meta*-methoxyanilines. The increased hydrolysis rate for the halogen-substituted *para*-aminophenols is consistent with the expected substituent effect.

Numerous preparative-scale mass electrolyses were performed on *ortho*- and *meta*-chloroaniline. Filming was severe for both of these compounds and meaningful *n*-values could not be obtained. Several electrode changes were required to effect even partial electrolyses (50-75%) of these anilines. Crude yields of isolable products averaging 35% were obtained by the work-up procedure described in the Experimental section; the crude products were purified according to the procedure in the Experimental section. 2-Chlorohydroquinone was identified as the product from both *ortho*- and *meta*-chloroaniline electrolyses by matching ESR spectra of the corresponding semiquinone radical, generated by chemical oxidation in an O_2-saturated aqueous $NaHCO_3$ solution, with an authentic sample, and 3,3'-dichlorobenzidine was identified as a product from *ortho*-chloroaniline electrolyses by the same procedures described for the 3,3'-dimethoxybenzidine.

Chemical oxidations of *ortho*- and *meta*-chloroaniline produced approximately 40% yields of the 2-chlorohydroquinone.

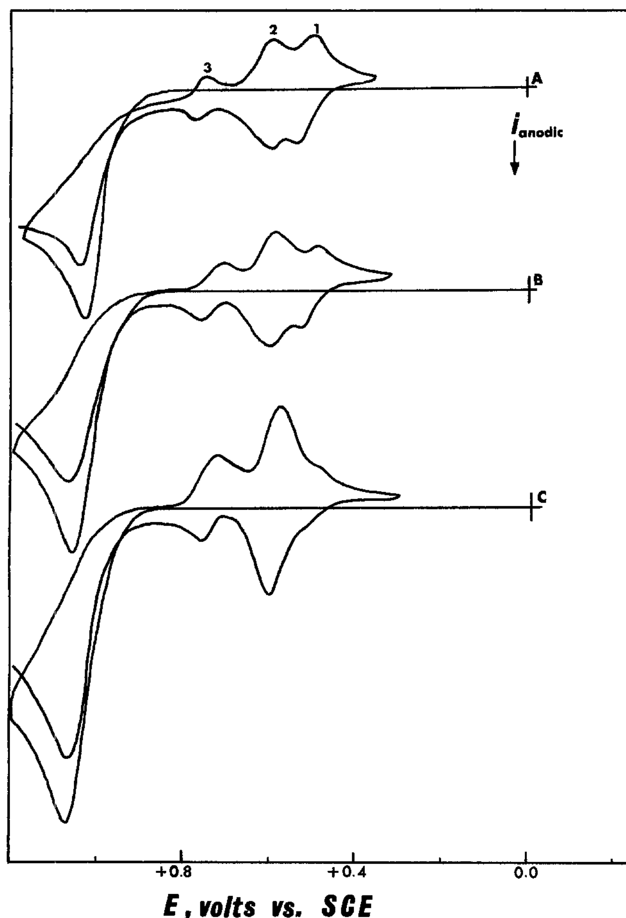

Fig. 3. Cyclic voltammograms in 6N H_2SO_4 at carbon paste, $2.86 \times 10^{-3}M$ o-chloroaniline. Curve A, sweep rate = 17 mV/sec; curve B, sweep rate = 100 mV/sec; curve C: sweep rate = 583 mV/sec.

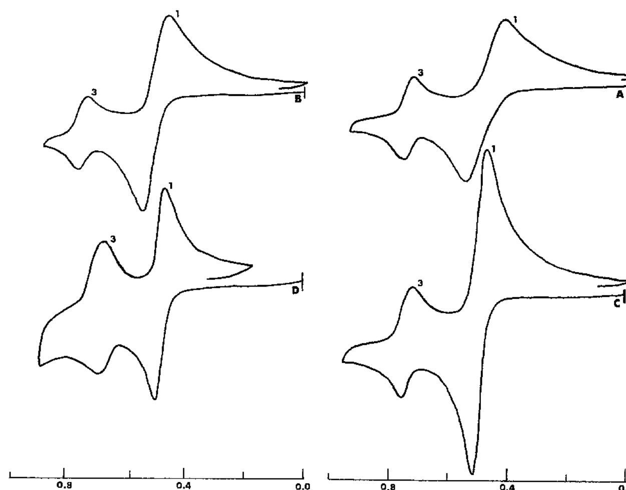

Fig. 4. Cyclic voltammograms in 6N H_2SO_4 following exhaustive electrolysis. Curve A, $10^{-3}M$ o-fluoroaniline; curve B, $10^{-3}M$ o-chloroaniline; curve C, $10^{-3}M$ o-bromoaniline; curve D, $10^{-4}M$ o-iodoaniline.

o-Aminoacetophenone, ethyl anthranilate, o-trifluoromethylaniline, o-cyanoaniline, o-nitroaniline, m-trifluoromethylaniline, m-cyanoaniline, and m-nitroaniline.—The compounds in this group exhibited similar, though far from the nearly identical, behavior to the compounds in the previous groups.

o-Aminoacetophenone and ethyl anthranilate are similar in the complexity of their cyclic voltammograms. This complexity makes interpretations difficult, but an inspection of these curves indicates that the amounts of couple "4" identified as the substituted trihydroxy compound, and couple "2," the diphenylamine or intermediate, vary with scan rate in a manner that suggests couple "2" decomposes to generate the trihydroxy compound, presumably through the quinone. The higher n-values for the peak-current data reflect the increased diphenylamine formation and the increased rate of the follow-up hydrolysis reactions. The chronoamperometric n-values of about 5 are consistent with partial formation of the trihydroxy compound via the 1,4-addition reaction mentioned previously. The cyclic voltammograms of ethyl anthranilate following electrolysis for coulometric determinations indicate the major long-term product is the trihydroxy compound, as shown by comparison with an authentic sample of ethyl-2,5-dihydroxybenzoate in Fig. 5; the small couple "4" is the trihydroxy compound, formed by hydrolysis of the quinone.

Benzidine formation could not be verified for these compounds due to the complexity of the cyclic voltammograms and the absence of authentic samples, but redox couples are present whose potentials, based on comparisons with systems known to generate benzidines, would indicate benzidine formation.

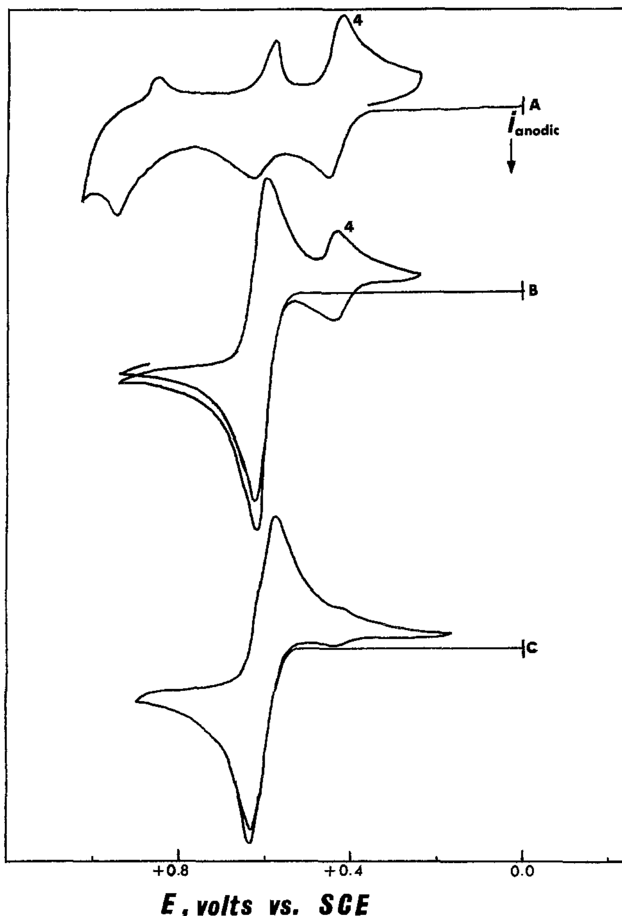

Fig. 5. Cyclic voltammograms in 6N H_2SO_4 at carbon paste. Curve A, $10^{-4}M$ ethylanthranilate following exhaustive electrolysis, sweep rate = 100 mV/sec; curve B, $1.76 \times 10^{-3}M$ ethyl-2,5-dihydroxybenzoate, sweep rate = 33 mV/sec; curve C, same as B, sweep rate = 350 mV/sec.

o-Trifluoromethylaniline and *m*-trifluoromethylaniline exhibit the common product couple which has been characteristic of all of the *ortho-meta* pairs. The diphenylamine or intermediate is the only product couple visible in the *meta* system, while the substituted benzidine and a small amount of the trihydroxy compound are also visible in the *ortho* system. Cyclic voltammograms of *ortho*-trifluoromethylaniline following electrolysis for coulometric determinations indicate the presence of the 2,2′-disubstituted benzidine, the diphenylamine (or intermediate), or hydroquinone (the voltammogram is not well defined), and the trihydroxy compound. Similar voltammograms for *meta*-trifluoromethylaniline indicate the major product is the substituted *para*-aminophenol with small amounts of the substituted trihydroxy compound.

o-Cyanoaniline and *m*-cyanoaniline reinforce trends that were only vaguely apparent in the *ortho*- and *meta*-trifluoromethylaniline systems. Cyclic voltammograms of *ortho*-cyanoaniline show only the trihydroxy couple at low scan rates, and small amounts of the diphenylamine or intermediate plus the trihydroxy couple at high scan rates. Cyclic voltammograms following coulometric determinations indicate that the trihydroxy compound is the major product. Cyclic voltammograms of *meta*-cyanoaniline show large amounts of the diphenylamine or intermediate, small amounts of the trihydroxy compound, and small amounts of an unidentified low-potential product. Cyclic voltammograms folowing coulometry indicate two major products, 2-cyano-*para*-aminophenol and the trihydroxy compound.

The identification of couple "2" as the diphenylamine or intermediate in both the trifluoromethyl- and cyano-systems was made on the basis of the difference in behavior of couple "2" between the *ortho*- and *meta*-systems. In both the *m*-trifluoromethyl- and *m*-cyanoaniline systems, couple "2" appeared to be considerably more stable than the corresponding couple in the *ortho* systems. The difference in stability could not be explained if couple "2" were hydroquinone, as the same 2-substituted hydroquinone would result in both the *ortho*- and *meta*-systems. The identification of couple "2" as the diphenylamine or intermediate forces the conclusion that the substituted quinone, once generated, rapidly undergoes 1,4-addition to the trihydroxy compound, as a couple for this quinone is not visible in the cyclic voltammograms. This is consistent with the electrochemistry of the hydroquinones containing electron-withdrawing substituents (Fig. 5 and 6), as well as their published rate-constant data (11, 12).

m-Nitroaniline exhibits behavior similar to the preceding compounds while o-nitroaniline appears to decompose by a different, as yet unidentified, pathway. Voltammograms of *m*-nitroaniline indicate the formation of the diphenylamine or intermediate, small amounts of the quinone, the substituted trihydroxy compound, and an unidentified low-potential product. Cyclic voltammograms following coulometry show the substituted trihydroxy compound as the major product, as shown in Fig. 6. Cyclic voltammograms of *ortho*-nitroaniline indicate the major product is not the substituted trihydroxy compound. The product couple is cathodic of the trihydroxy couple in the *m*-nitroaniline system and the 2-nitrohydroquinone system. Voltammograms of various possible products, 2,2′-dinitroazobenzene, 3,3′-dinitrobenzidine, 2-nitrohydroquinone, o-benzoquinonedioxime peroxide, o-benzoquinonedioxime, and 2-nitrophenol failed to account for the product couple. Further investigation of the various possible products, synthesis and investigation of the diphenylamine, and investigation of other possible decomposition pathways will be required to establish the identity of the product couple in the *ortho*-nitroaniline system.

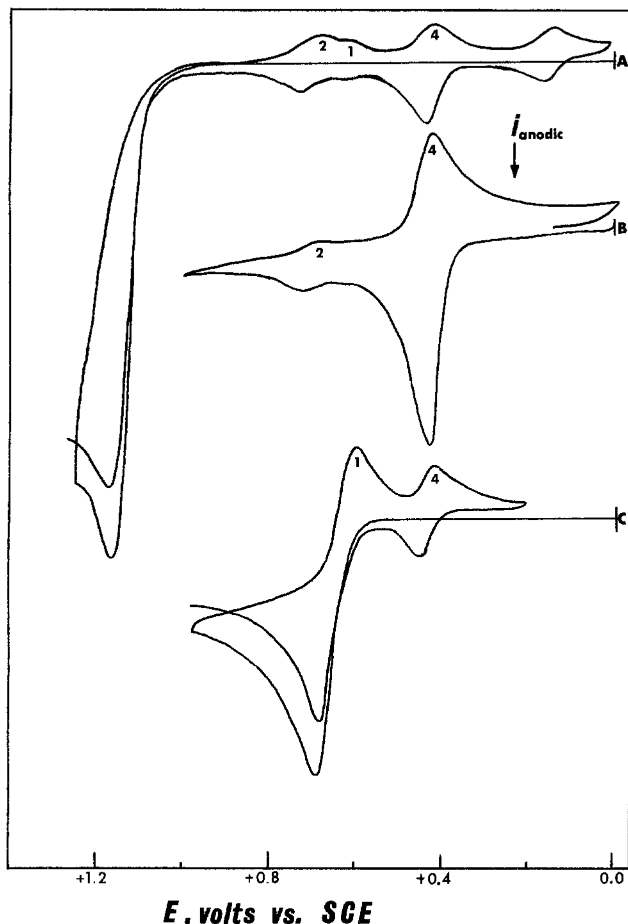

Fig. 6. Cyclic voltammograms in 6N H_2SO_4 at carbon paste. Curve A, 1.2 × 10^{-3}M *m*-nitroaniline, sweep rate = 50 mV/sec; curve B, same solution as A following exhaustive electrolysis at +1.2V, sweep rate = 100 mV/sec; curve C, 8.5 × 10^{-4}M 2-nitrohydroquinone, sweep rate = 250 mV/sec.

The electroanalytical data for all of the *ortho*- and *meta*-electron-withdrawing substituents are a bit suspect because of filming and background problems. The peak current data for all but *ortho*-nitroaniline indicate processes consistent with those of the preceding compounds. The higher n-values simply reflect the increased diphenylamine formation and the increased rates of the follow-up reactions. The short time-gate n-value for *ortho*-nitroaniline indicates a rapid four-electron process. The chronoamperometric data reflect the same trends as the peak current data but are complicated by filming and background limits.

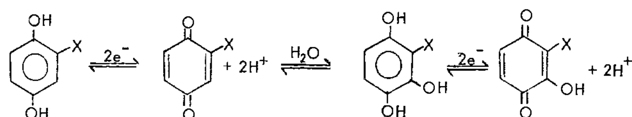
Preparative-scale electrolyses and chemical oxidations of several members of this group were quite unsuccessful. The only electroactive species present in solution following oxidation were unoxidized parent aniline and a small amount of 3,3′-disubstituted benzidine in the *ortho*-trifluoromethylaniline system. Filming was severe in all cases, and numerous electrode changes were required to effect even partial oxidations. Large quantities of precipitates formed in these systems and, in all cases, voltammograms of the precipitates indicated they were electroinactive. Attempts to purify and identify the precipitates or constituents of the precipitates were unsuccessful. The behavior of these compounds indicates that the decomposition products are not stable to prolonged electrolysis and are presumably involved in multiple coupling reactions to generate products of an unknown composition.

The failure to isolate products from electrolysis solutions and the lack of authentic samples, except for several of the 2-substituted hydroquinones, necessitated considerable speculation for identification of the product couples in this group of compounds. The speculation was, however, based on the established reaction pathways of the previous groups of compounds and the established 1,4-addition reaction of quinones with electron-withdrawing substituents (11-13). Additional studies involving synthesis of the substituted diphenylamines and substituted quinones will be necessary to firmly establish the identification of the various product couples in this group of compounds. For the survey purposes of the present study, however, their behavior, as well as it could be elucidated, is consistent with trends noted for the more electron-donating substituents.

Discussion

The chemistry involved in these systems is complex but orderly. Summarizing, the couples labeled "3" in the cyclic voltammograms can be assigned to the substituted benzidines generated by tail-to-tail coupling of the anilines. Cyclic voltammograms indicate that the amount of benzidines formed decreases as the ring substituent in the *ortho* series becomes more electron withdrawing, in agreement with the previously proposed mechanism (4) whereby as the amine nitrogen becomes more acidic deprotonation of the electrogenerated cation radical is facilitated, leading to diphenylamine formation. Couples corresponding to the 2,2′-disubstituted benzidines are visible only in the methoxy, methyl, and fluoro derivatives in the *meta*-substituted anilines, and the relative amounts are consistent with the trend seen in the *ortho* systems, but here the overriding consideration for *para-para* coupling appears to be steric in nature.

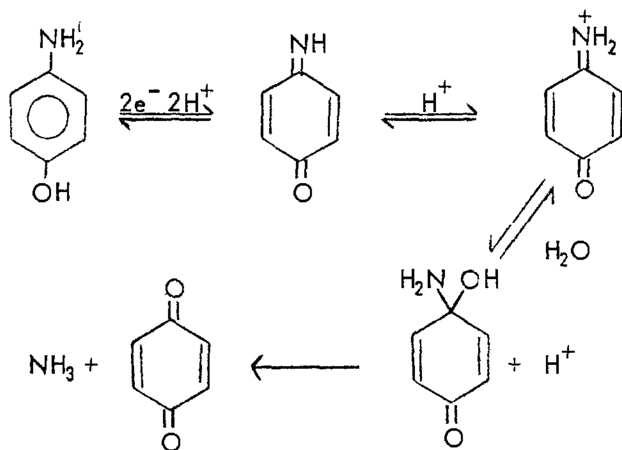
The couples labeled "4" in the cyclic voltammograms are decomposition products of the 2-substituted *para*-benzoquinones (the "1" couples). Investigations of the 2-substituted hydroquinones have demonstrated that *mono*-substituted hydroquinones with electron-withdrawing substituents (—NO_2, —CHO, —$COCH_3$, COOH) undergo a nucleophilic 1,4-addition of water to form the substituted trihydroxy compounds (14-16). The reaction mechanism is shown below



Of particular interest is the fact that the product of the 1,4-addition is a substituted hydroquinone which is susceptible to further oxidation giving an over-all four-electron process. The end products of the hydrolysis reactions in the *ortho*- and *meta*-substituted aniline systems are substituted *para*-benzoquinones which, according to the reaction mechanism present above, could undergo a 1,4-addition and a subsequent two-electron oxidation. The addition of this decomposition pathway to the previously established mechanism indicates that a maximum n-value of 6 electrons could be obtained for anilines with an electron-withdrawing substituent. The rate of the 1,4-addition reaction was found to increase as the 2-substituent becomes more electron withdrawing (11, 12), and in all cases the rate is fast enough to be evidenced in coulometric n-value determinations, as can be seen in Fig. 5 and 6.

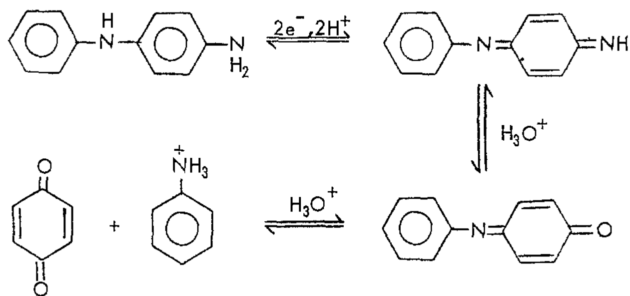
The couples denoted as "2" in the cyclic voltammograms have been referred to as "diphenylamines or intermediates," that is as the appropriately substituted 4-aminodiphenylamine formed by head-to-tail coupling or a derivative generated by hydrolysis of the diphenylamine; a discussion of the hydrolysis chemistry of these systems follows.

Studies of the hydrolysis mechanism and reaction rates of a family of related compounds, various substituted *para*-aminophenols, have produced the following reaction pathway (14, 15, 17-19).

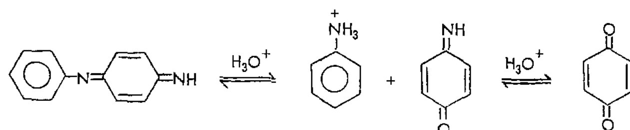


Correlations between hydrolysis rates and substituent effects for this general reaction have been successfully demonstrated only for N-(*para*-phenyl) substituted *para*-aminophenols (16, 20). For this class of aminophenols, the hydrolysis rate was found to increase as the N-*para*-phenyl substituent became more electron withdrawing (see Table II) Correlations for the ring-substituted *para*-aminophenols were largely unsuccessful (15, 21). One difficulty that possibly precluded establishing general substituent effects was that there were only a few substituted *para*-aminophenols involved in the correlation study. Inspection of the limited available hydrolysis rate data for *para*-aminophenols collected in Table II permits the following tentative conclusion: Substituents *ortho* to the N-C bond increase the hydrolysis rate, probably due to facilitating the formation of the tetrahedral carbinolamine intermediate, and substituents *meta* to the N-C bond decrease the hydrolysis rate. In addition, from Leedy's work we would expect the hydrolysis rate to increase as the substituent becomes more electron withdrawing, as seen in Table II.

In addition to the *para*-aminophenols, 4-aminodiphenylamine (4-ADPA) and the various substituted derivatives resulting from head-to-tail coupling in the N-alkylanilines system have been shown to undergo hydrolyses to *para*-benzoquinone and aniline or an N-alkylaniline (4, 16). Leedy proposed that the hydrolysis of 4-ADPA proceeds in a two-step mechanism as shown below



This proposal was based on HMO calculations of the fully protonated diimine and not on experimental observations (16). Cyclic voltammograms of 4-ADPA and mass electrolysis of 4-ADPA show only aniline, *para*-benzoquinone, and 4-ADPA. The intermediate in this mechanism, N-phenyl-*para*-benzoquinoneimine, was not detected in solution. The only plausible alternative mechanism is shown below



Again, the intermediate in this mechanism, *para*-benzoquinoneimine, was not detected in solution (16). In view of the experimental evidence, or the lack

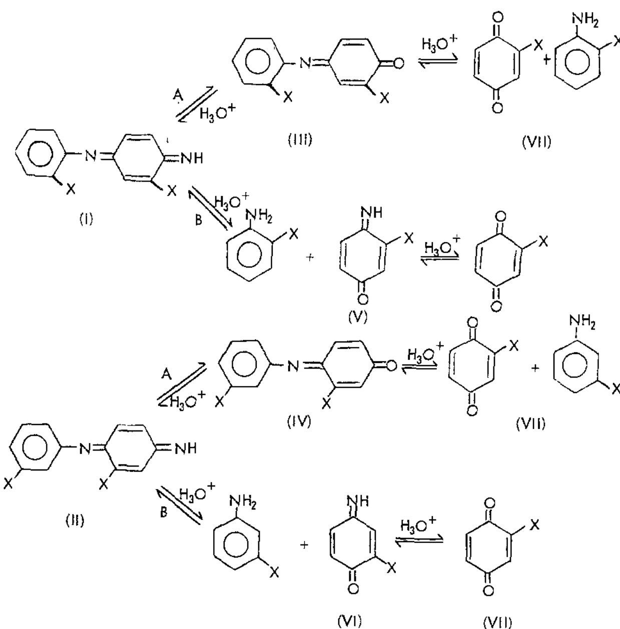
[2] Data taken from Ref. (20).

thereof (especially the absence of either intermediate), it was not possible to determine which mechanism was operative though the former was favored on the basis of HMO calculations. If the two decomposition pathways are drawn for the diphenylamines in the *ortho*- and *meta*-substituted aniline systems, the intermediates shown below would result



If the decomposition pathways for diimines (I) and (II) are evaluated in terms of the somewhat speculative conclusions reached from the data in Table II, then path A would be favored for diimine (I) and path B for diimine (II). Path A would be favored for diimine (I) because of the substituent *ortho* to the N-C double bond and path B would be favored for diimine (II) for the same reason. Continuing along the same lines, the N-phenyl-*para*-benzoquinoneimine (III) would be expected to decompose faster than the *para*-benzoquinoneimine (VI) because of the influence of the *ortho* substituent.

The cyclic voltammetric data presented indicate that the *ortho*- and *meta*-substituted anilines appear to have a common product in couple "2." However, couple "2" in the *meta* systems appears to be considerably more stable than couple "2" in the *ortho* systems. Figure 7 shows the cyclic voltammograms of several of the *ortho*- and *meta*-substituted anilines following exhaustive electrolysis for coulometric determinations. These voltammograms indicate the long-term behavior of the compounds and verify trends seen in Fig. 1-3 for couple "2." The compounds responsible for couple "2" in the *ortho* systems appear to have completely hydrolyzed to to the quinones, while the hydrolysis of couples "2" in the *meta* systems varies from nearly none for the *meta*-methoxy and *meta*-methylanilines to nearly complete hydrolysis for the more electronegative substituents. The stability of couple "2" in the *meta*-methoxy and *meta*-methyl systems provides additional mechanistic information when the coulometric n-values in Table I are considered. The n-values for both of these compounds approach four, indicating that the formation of the substituted *para*-benzoquinones in these two systems are not necessary to reach this n-value. The n-value of near four eliminates the substituted 4-aminodiphenylamine as couple "2" (unless, of course, the DPA has the same peak potential as the *para*-benzoquinoneimine and is responsible for couple "2" prior to exhaustive electrolysis) and, if pathway A for the diimine (II) were followed, formation of the *para*-benzoquinone would be necessary to attain an n-value of four. The above considerations reasonably establish path B as the decomposition pathway of the diimine (II) generated in the *meta*-anilines systems. Additional verification is possible for the *meta*-methylaniline system, as a cyclic voltammogram of 2-methyl-*para*-aminophenol (Fig. 8) matches the voltammogram of *meta*-methylaniline following electrolysis, both in peak potential and wave shape.

The hydrolysis pathway for the *ortho*-anilines remains to be resolved. A cyclic voltammogram of 3-methyl-*para*-aminophenol does not match with any couples seen in the voltammograms of *ortho*-methylaniline either before or after electrolysis, further suggesting that pathway A is being followed for the *ortho*-aniline systems. As couple "2" is not visible for *ortho*-anilines in the cyclic voltammograms following electrolysis, and as there is no difference in n-values between the diimine (I) and the N-phenyl-*para*-benzoquinoneimine (III), there is little to choose from to identify one or the other as couple "2" in the *ortho*-aniline cyclic voltammograms. Based on the behavior of the *meta*-aniline systems, however, the *para*-benzoquinoneimine (III) would be expected to be responsible for couple "2" in the *ortho*-aniline systems [again, unless the diphenylamine has the same peak potential as (III)].

Therefore it appears that the diimine (I), generated in the *ortho*-aniline systems, undergoes a rapid hydrolysis to the N-phenyl-*para*-benzoquinoneimine (III) which slowly hydrolyzes to the substituted *para*-benzoquinone (VII), and the diimine (II), generated

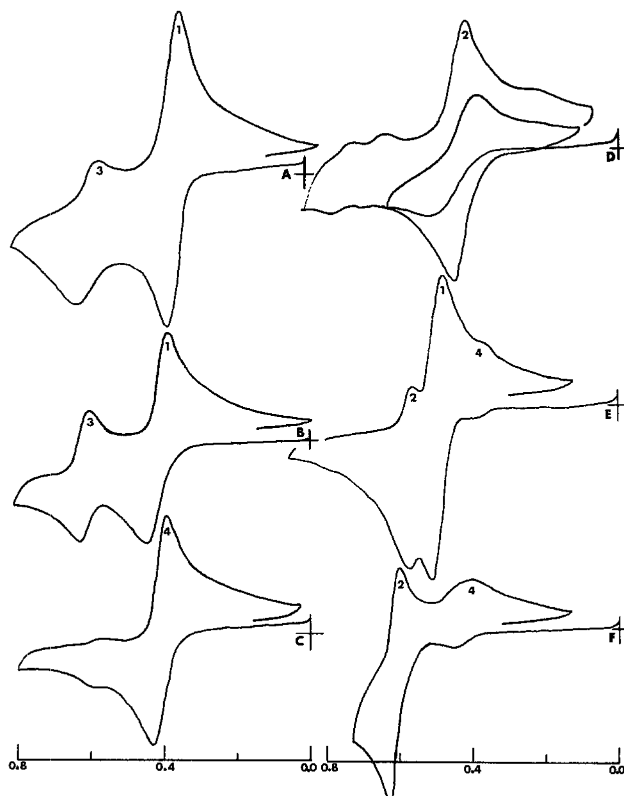


Fig. 7. Cyclic voltammograms in 6N H_2SO_4 at carbon paste following exhaustive electrolysis of 1.0 × $10^{-3}M$ solutions. Curve A, o-methoxyaniline; curve B, o-methylaniline; curve C, o-cyanoaniline; curve D, m-methoxyaniline; curve E, m-bromoaniline; curve F, m-trifluoromethylaniline.

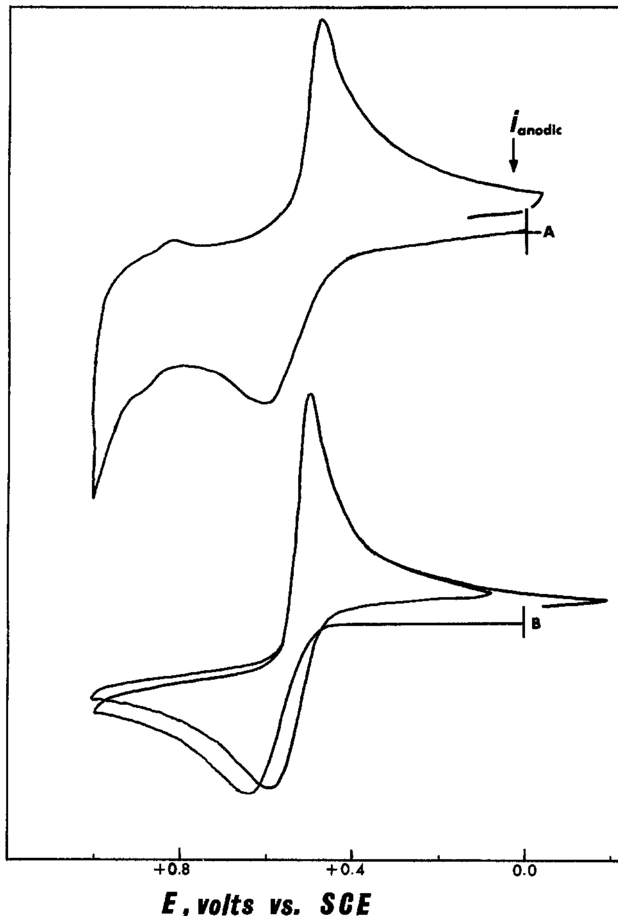

Fig. 8. Cyclic voltammograms in 6N H_2SO_4 at carbon paste. Curve A, 1 × $10^{-4}M$ solution of m-methylaniline following exhaustive electrolysis, sweep rate = 100 mV/sec; curve B, 6.8 × $10^{-4}M$ 2-methyl-p-aminophenol, sweep rate = 100 mV/sec.

in the *meta*-aniline systems, undergoes a rapid hydrolysis to the *para*-benzoquinoneimine (VI) which slowly hydrolyzes to the *para*-benzoquinone (VII).

The alternative to that proposed above would involve identifying the substituted diphenylamines as couple "2" in the cyclic voltammograms presented. The decomposition pathway of diimine (I) would then involve a slow hydrolysis of the 4-amino group followed by rapid completion of the hydrolysis sequence to give the substituted *para*-benzoquinone, and the decomposition of diimine (II) would involve a slow hydrolysis of the center amine.

The only difference in the two proposals is the reaction rate of the first hydrolysis step. If couple "2" in the voltammograms is the diphenylamine, then the first hydrolysis is slow (more rapid for the *ortho*'s than the *meta*'s), while if couple "2" is the N-phenyl-*para*-benzoquinoneimine (*ortho's*) or the *para*-benzoquinoneimine (*meta*'s), then the first hydrolysis is rapid. In addition, if the substituted diphenylamine is couple "2" this necessitates that the diphenylamine and the substituted *para*-benzoquinoneimine in the *meta* system have the same peak potential.

Resolution of this "fine" point must await synthesis of the diphenylamines and the intermediates or generation of more data on substituent effects on hydrolysis rates.

With the exception of the low potential couple in the *ortho*-cyano- and *ortho*-nitroaniline systems, the couples labeled "1" through "4" appear to adequately describe the decomposition pathways of the *ortho*- and *meta*-substituted anilines. For the *ortho*-anilines, benzidine formation decreases and diphenylamine formation increases as the *ortho*-substituent becomes more electron withdrawing. In addition, as the *ortho*-substituent becomes more electron withdrawing, the diphenylamines decompose more rapidly to the quinones and the quinones begin decomposing to the trihydroxy compounds. The same trends are reflected in the *meta* systems, except that there is much less benzidine formation and the diphenylamine or intermediate (substituted *p*-aminophenol) appears to be more stable.

The general reaction mechanism for the *ortho*- and *meta*-substituted anilines is shown in Fig. 9. This reaction mechanism is similar to that proposed for the N-alkylanilines except that the hydrolysis reactions of the diphenylamines are shown to occur by two discrete pathways and the 1,4-addition reaction of the quinones with electron-withdrawing substituents has been added. In addition, the diphenylamines derived from *meta*-substituted anilines are shown hydrolyzing to the corresponding substituted *p*-quinoneimines and thence to the analogous *p*-benzoquinones. The reaction mechanism depicts diphenylamine formation occurring by deprotonation of the cation radical and reaction with a parent aniline molecule in accordance with our previous observations for the N-alkylanilines. The observed effects of substituents on the diphenylamine-to-benzidine ratio in this present study are consistent with this pathway. The diphenylamine-to-benzidine ratio increases as the substituent becomes more electron withdrawing, presumably by more facile deprotonation of the primary cation radical.

Substituted azobenzenes and/or substituted hydrazobenzenes were not detected during the course of this work and initial formation of the hydrazobenzenes, followed by a benzidine rearrangement, is not proposed as an over-all mechanism, since product distributions were not consistent with those obtained from benzidine rearrangements. A particularly striking example involves the oxidation of *meta*-methylaniline in which no 3,3'-dimethylbenzidine was detected, whereas acid-catalyzed rearrangemnts of 3,3'-dimethylhydrazobenzene result in quantitative yields of 3,3'-dimethylbenzidine (22). Therefore, rather than proposing initial formation of the hydrazobenzene in all solutions, and

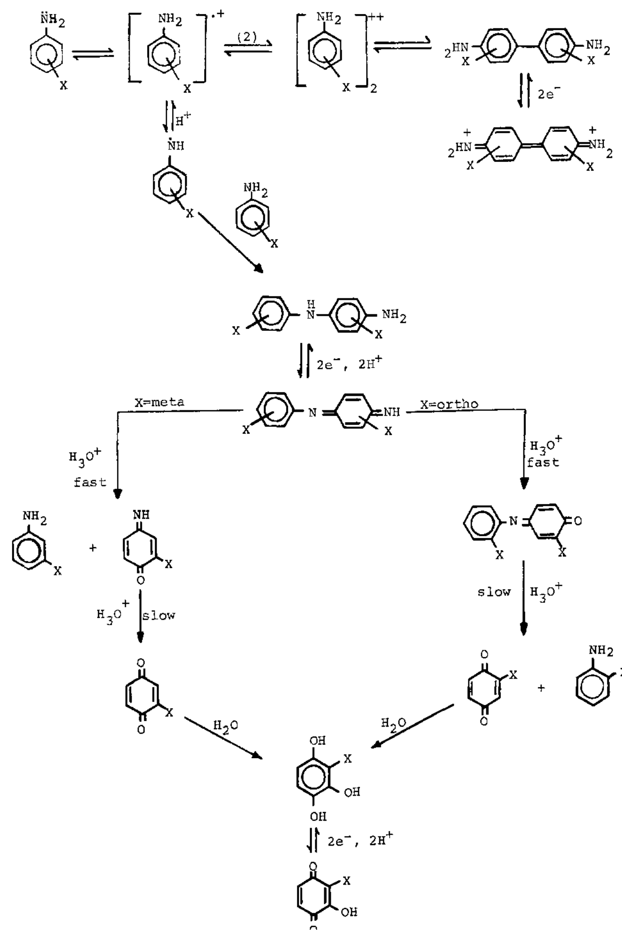

Fig. 9. Proposed reaction pathways for the *ortho*- and *meta*-substituted anilines in 6*N* H_2SO_4.

subsequently proposing that the stability of the hydrazobenzene is the factor which affects product distributions as a function of pH, we would propose that as the solutions become more basic, deprotonation is facilitated and the resulting free radicals couple in basic solutions to form the hydrazo compounds, as in the work of Wawzonek (2, 3).

It is anticipated that studies now under way will show that with increasing pH (compared to 6*N* H_2SO_4) the *ortho*- and *meta*-anilines will, upon electro-oxidation, form less benzidines, more diphenylamines (and attendant hydrolysis products), and, eventually, azo- and hydrazobenzenes.

Studies of Ruthenium-Oxy Species in Basic Solutions by Cyclic Voltammetry

Kim W. Lam, Keith E. Johnson,* and Donald G. Lee

Department of Chemistry, University of Regina, Regina, Saskatchewan, Canada S4S 0A2

ABSTRACT

Ruthenium(VI) solutions in alkaline media have been investigated by cyclic voltammetry using platinum and ruthenium dioxide electrodes. Four pairs of peaks were observed. The oxidation states of the electrolysis products were evaluated by coulometry and absorption spectra. The first and second pairs of peaks correspond, respectively, to the oxidation reduction of Ru(VIII)/Ru(VII) and Ru(VII)/Ru(VI) with a catalytic reaction. The third pair shows reduction of Ru(VI) to Ru(IV) with a following reaction giving ruthenium dioxide. The electron transfer product is postulated as $Ru(OH)_6^{-2}$. The last or most cathodic pair revealed a reduction peak composed of two waves. The first is from the reduction of the electrode surface oxide layer or adsorbed oxygen and the second, the reduction of Ru(IV) to Ru(III). The corresponding pairs of peaks are also observed from ruthenium dioxide electrodes in sodium hydroxide solutions.

During the last few years the ruthenium dioxide electrode has attracted considerable interest due to its corrosion-resistant properties and low overpotential for chlorine and oxygen evolution. However, little is known about its electrochemical reactions and for those (1-3) reported, the electrode was used in acidic media where it exhibits more corrosion-resistant characteristics. Difficulties in examining its electrochemical surface properties, besides those encountered in identifying its oxidation or reduction products, arise from its ill-resolved current-potential curve and potential-time charging curve. Here we have indirectly characterized its surface reactions through the investigation of ruthenium-oxy species in alkaline solutions.

The higher oxidation states of ruthenium exist only as oxy-species in basic media with ruthenate being most stable. However, a survey of the literature revealed that few have reported on the voltammetric behavior of ruthenate. The earlier studies (4, 5) determined the standard potentials of Ru(VIII)/Ru(VII) and Ru(VII)/Ru(VI) couples and touched on the disproportionation reaction of ruthenate (5) and perruthenate (6), but attempts to follow ruthenate reduction reactions failed. Though two other reports (7, 8) have appeared recently, the results and conclusions drawn were contradictory because of uncertainties in coulometric results and current-potential profiles. In one (7) it was postulated that ruthenate reduces first to ruthenium dioxide, then to Ru(III), and finally to the metal itself; the other (8) proposed that ruthenium dioxide, the final electrolysis product, was formed via Ru(V). We have obtained experimental results from cyclic voltammetry which offer a different point of view and which resolve the earlier uncertainties. The present paper reports on the electroreactions of the various ruthenium-oxy species, while the kinetics of the proposed mechanisms are reported in a later paper.

Experimental

Stock ruthenate solutions were prepared by oxidizing ruthenium dioxide (Ventron, Alfa Products) with commercial bleach (9). The product was extracted into carbon tetrachloride and washed several times with distilled water to remove traces of bleach and any water-soluble inorganic materials (10). The ruthenium tetroxide was then extracted into portions of from 0.1 to 0.5M sodium hydroxide solutions in which it reacted to give perruthenate (11). If perruthenate was desired, the solution was immediately stored in a freezer where crystals were observed to form. To obtain ruthenate the solution was allowed to stand at room temperature for several days or heated gently overnight (12). Spectroscopically pure ruthenate or perruthenate solutions of about 0.03M were obtained by this method. The concentrations of solutions prepared by diluting the stock with sodium hydroxide solutions were calculated from the molar absorptivities of 2150 at 385 nm for perruthenate and 1730 at 465 nm for ruthenate (13). The absorbance values were measured using a Unicam SP500 spectrophotometer while spectra were taken on a Beckman DK-2A spectrophotometer. The basicities of any one series of solutions were either measured

by a pH meter (Radiometer PHM-4d) with a high pH glass electrode (Beckman) or by titration with potassium hydrogen phthalate after reduction of the oxidant to eliminate any obscuring color.

All electrochemical techniques were performed on a Princeton Applied Research Model 170 electrochemistry system. The instrument is equipped with an X-Y recorder having a rise time of approximately 0.3 sec such that rather accurate voltammograms with sweep rates as fast as 200-500 mV sec^{-1} can be obtained without using an oscilloscope.

The cell used was of conventional three-electrode design. The stability of the silver-silver chloride reference electrode was checked from time to time by comparing its potential with other silver-silver chloride electrodes or calomel electrodes. A double salt bridge was used in conjunction with the reference electrode. It consisted of 1M potassium chloride in contact with the electrode and whatever electrolyte (whose ionic strength was also adjusted to 1M by addition of sodium perchlorate) was being used in contact with the test solution. The tip of the second bridge was brought as close to the working electrode as possible but not close enough to interfere with diffusion. The use of a double salt bridge is a necessity since chloride ion can cause the decomposition of the ruthenate solution (4). The counterelectrode was a coiled platinum wire. In performing coulometric experiments it was isolated in a separate compartment, one end of which was in contact with the test solution through a fine fritted disk. The working electrode was a platinum electrode or a ruthenium dioxide electrode. Though a gold electrode was tried, it did not seem to offer any advantage over platinum.

Ruthenium dioxide electrodes were prepared following the procedure given in the literature (2) by thermal decomposition of ruthenium trichloride in air at 350°-400°C on a metal support of either platinum, tantalum, or titanium. Electrodes generated electrochemically were also prepared. It was found that films deposited by controlled potential in a quiescent solution gave better adhesion than with a small controlled current. Better surface uniformity, as evident from observations with a microscope, was also obtained by cycling the electrode several times between its oxidation and reduction potentials with a fast sweep. However, care was taken such that the electrode was not allowed to be swept past its cathodic limit or the film could collapse rather easily (2).

All other working electrodes were made of platinum wire (0.02 in. diam) with exposed lengths of approximately 4 and 7 mm. The electrodes were soaked in dilute nitric acid between use and cycled over the potential range employed before running the experiment. Any ruthenium dioxide deposited on the electrode could be removed either by electrochemical or chemical oxidation with permanganate (14). In coulometric experiments, the electrode used was a platinum wire gauze. Its apparent area was 43.2 cm^2. The solution volume was 50 ml. Stirring was achieved with a magnetic stirring bar and by bubbling nitrogen. Before running the experiment, the wire gauze electrode was subjected to oxidation or reduction in a blank solution depending on the potential chosen for the experiment. Coulometric data were recorded as charge-time curves through an electronic current integrator. Whenever the charge-time curve exhibited a sloping plateau, a line drawn through the origin and parallel to the slope was used as the base line to measure the charge instead of using the blank recorded immediately before the experiment.

Results and Discussion

A composite current-potential curve of ruthenate derived from several voltammograms with potential ranges of 1.0-0.1, 0.7- −0.25, 0.3- −0.8, and 0.1- −1.1V is shown in Fig. 1. Four pairs of peaks are observed. The cathodic and anodic peaks are labeled correspondingly in Roman numerals. The cyclic voltammogram of

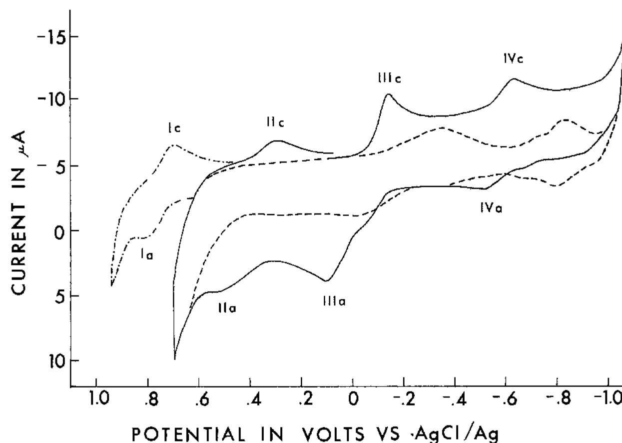

Fig. 1. Composite diagram drawn from cyclic voltammograms of ruthenate. Scan rate was 50 mV/sec; ——— ruthenate concentration was 2.56 × 10^{-4}M in 2M NaOH; – – – – blank, 2M NaOH; –·–·–· ruthenate concentration was 2.56 × 10^{-4}M in 8.5 × 10^{-3}M NaOH.

the platinum electrode in a blank solution is also reproduced for reference. However, it does not represent the true blank when ruthenate is added due to changes in surface conditions which are discussed later. Thus, the magnitudes of the well-known platinum oxide peaks should not be taken seriously. To avoid a prominent platinum oxide peak overshadowing the ruthenate reduction peaks in scanning toward the cathodic limit, the starting or initial potential was set at about +0.1V where oxidation of the electrode does not occur to an appreciable extent.

Peak I.—The pair of peaks labeled I is observed only with less basic solutions (below approximately pH =12) where the anodic limit of the platinum electrode is pushed to more positive potentials. Attempts to determine the number of electrons transferred by coulometric oxidation of ruthenate or perruthenate solutions were unsuccessful. The charge-time curve, except for an initial exponential rise, was continuously rising, making measurements impossible. The same trend was also observed when the electrolysis potential was set on the rising portion of the oxidation peak which was more than 150 mV negative of the anodic limit. Thus, the continuing supply of charge was not due to the electrolysis of the supporting electrolyte. The u.v.-visible absorption spectrum of the electrolysis product is similar to that of perruthenate. Coulometric reductions of the electrolysis product to perruthenate required between 0.5 and 1e.

Cyclic voltammetry of perruthenate solutions gives well-defined anodic and cathodic peaks for scan rates of 10 mV sec^{-1} or greater. However, the appearance of peaks is more likely to be observed at lower hydroxide concentrations. For scan rates below 5 mV sec^{-1} peaks are not observed. Instead, the anodic wave rises to a sloping plateau which blends into the anodic limit, while on reversing the scan, the cathodic wave simply returns to the foot of the anodic wave. The voltammograms are shown in Fig. 2 where the initial scan is toward the anodic direction. The voltammograms have been corrected for the blank. Two interesting points can be observed from this figure: (*i*) the current around the switching potential in the voltammogram for 1 mV sec^{-1} curves back toward the zero current line after reaching a maximum current; and (*ii*) the anodic current, $i/\sqrt{v}$ (v stands for scan rate), is higher for slower scan rates. The first effect is due to the subtraction of the blank. Before the subtraction, the wave rises to a sloping plateau.

The effect of scan rate on the anodic peak current is shown in Fig. 3. The shape of the voltammograms and the effect of the scan rate (15) strongly suggests that perruthenate is catalytically regenerated after being

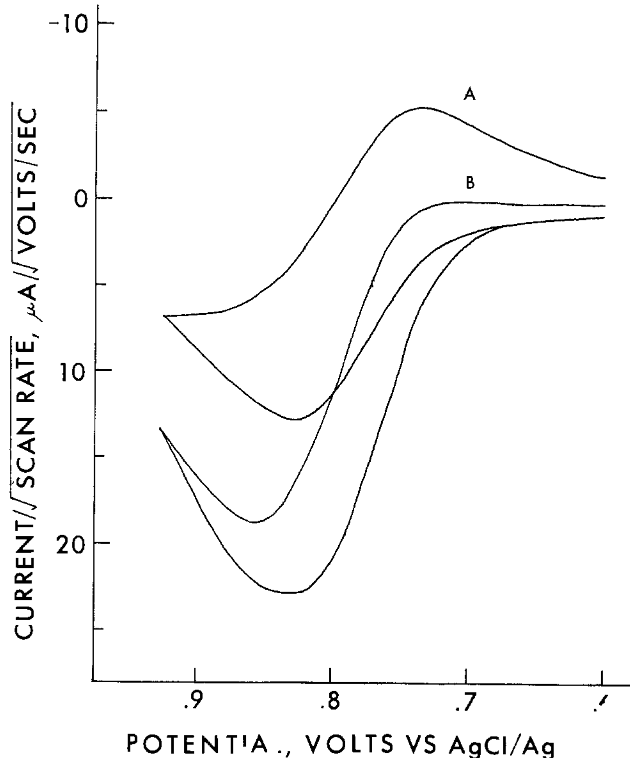

Fig. 2. Cyclic voltammograms of perruthenate oxidation. Initial sweep was in the anodic direction. Perruthenate concentration was ~ 2×10^{-4}M in 5×10^{-3}M NaOH and 1M $NaClO_4$. Scan rate was A, 100 mV/sec; B, 1 mV/sec.

oxidized. This in turn fits the coulometric observations. For the catalytic case the kinetics affect the voltammogram less at higher scan rates. It is found that for a hydroxide concentration of 1×10^{-3}-1×10^{-2}M, the voltammograms for a scan rate of approximately 20 mV sec^{-1} fit those of a simple reversible case with one electron being transferred. However, separation between the anodic and cathodic peaks is about 80 mV, which is greater than that predicted for the simple reversible system. As the scan rate increases or decreases from approximately 10 or 20 mV sec^{-1}, anodic and cathodic peak separation becomes larger. The ratio of the cathodic to anodic peak currents, though difficult to estimate because of uncertainties in the cathodic baseline, is seen to be approximately one (using scan rates of from 0.5 to 200 mV sec^{-1}). The above then suggests the following reaction scheme

$$RuO_4^- \leftrightarrow RuO_4 + e^- \quad [1a]$$

$$4RuO_4 + 4(OH^-) \rightarrow 4RuO_4^- + 2H_2O + O_2 \quad [1b]$$

which is consistent with the fact that ruthenium tetroxide is known to react with hydroxide to give perruthenate (11). The electron transfer, though reversible, may not be as fast, since, as observed by increasing the scan rate, anodic and cathodic peak separation becomes larger. The separation increases from about 80 mV at 20 or 10 mV sec^{-1} to 100 mV at 100 mV sec^{-1}. Likewise, the peak width $(Ep - Ep/2)$ increases from 57 to 63 mV.

From the reaction scheme, the curving near the anodic limit for slow scan rates can be explained as follows. At slower scan rate or higher hydroxide concentrations the catalytic reaction exerts more effect. One of the products of the catalytic reaction is oxygen which is also a product of the anodic limit reaction. Thus, the liberation of oxygen from the catalytic reaction pushes the anodic limit to a slightly more positive potential which in effect means the magnitude of the blank voltammogram in this region decreases. The voltammograms drawn in Fig. 2 had only their respective apparent blank voltammograms subtracted from them and thus are overly corrected giving the curving shape.

The formal potential for the redox couple can be determined from the potential midway between the cathodic and anodic peak potentials or where no peaks are observed from the average of the anodic and cathodic half-wave potentials. The average results of five sets of experiments are given in Table I. Within each set of experiments, one to three solutions were used. The solutions had the same initial hydroxide but different ruthenium concentrations. A number of scan rates were used and each was repeated several times. For each scan rate the results were averaged. The averaged results for all scan rates were again averaged and these averaged values are given in Table I. The reproducibility of the results within each set of experiments was generally good (within ±3 mV). However, the reproducibility of the anodic or cathodic peak potentials was ±6 mV. The potential thus determined at an ionic strength of 1M is 1.00V *vs.* the standard hydrogen electrode. This value agrees exactly with that of Silverman and Levy (4) whose value was, however, approximately corrected for activity coefficients.

Peak II.—The properties of peak II are similar to peak I. Coulometric oxidation of the ruthenate solution after the peak potential also gave a continuously rising charge-time curve preceded by an initial exponential rise. However, the rise, which is dependent on

the amounts of both hydroxide and ruthenate, is so much slower than in the previous case that the charge can be determined after drawing a baseline parallel to the sloping plateau. The number of electrons required was found to be 1.1 ±0.1. Figure 4, curve A shows the spectrum of the electrolysis product. It is identical to that of perruthenate (13). The spectrum is shown here for comparison with other spectra to be discussed later. The spectra reproduced have not been corrected for instrumental baseline and the molar absorptivities are thus higher than the literature values.

The cyclic voltammograms have properties similar to those of perruthenate oxidation, except in this case the baseline (or the anodic limited reaction) has a lesser influence and depending on the hydroxide or ruthenate concentration a plateau instead of a peak may be seen on the oxidation wave. The shape of the voltammogram and the effect of scan rate on the anodic peak current again indicate that a catalytic reaction is involved. Thus, the reaction for peak II may be written as

$$RuO_4^{-2} \rightleftharpoons RuO_4^- + e \quad [2a]$$

$$4RuO_4^- + 4(OH^-) \rightarrow 4RuO_4^{-2} + 2H_2O + O_2 \quad [2b]$$

Besides the catalytic reaction, no other side reactions can be detected (except at low pH where the decomposition of ruthenate to ruthenium dioxide exerts an influence on the voltammogram). This is supported by the observation that the ratio of the cathodic to anodic peak currents has a value of unity. (Baselines for measuring cathodic peak currents were established by holding the electrode potential at about +0.6V before sweeping cathodically). Thus, the only difference between reaction schemes [1] and [2] is that in the present system, the electron transfer kinetics plays a more important role and the catalytic reaction rate is much slower. The slower electron transfer rate can be observed from the wider peak separation. For the same scan rate the separation is about twice as wide. The current, which is controlled by both electron transfer and chemical kinetics, is smaller than that of Ru(VII)/Ru(VIII). For example, in 8.5×10^{-3}M sodium hydroxide with 2.4×10^{-4}M perruthenate or ruthenate, the peak current for Ru(VII)/Ru(VIII) at a scan rate of 5 mV sec^{-1} is 3.2 times as large. Although electron transfer kinetics may have caused the peak current for Ru(VI)/Ru(VII) to be smaller, the difference is so large that it cannot be attributed to the slower electron transfer rate alone. Comparing the case where the electron transfer is completely reversible without chemical complications with the irreversible system and assuming the transfer coefficient is 0.5, the peak current for the reversible system is theoretically only 1.27 times larger than for the irreversible case. Thus, the homogeneous reduction of perruthenate by hydroxide occurs at a slower rate than that of the tetroxide.

The average of the cathodic and anodic peak potentials of half-peak potentials should correlate to the standard potential of the redox couple. However, unlike Ru(VIII)/Ru(VII), the average potential for Ru(VII)/Ru(VI) is highly dependent on the ionic strength of the solution. Furthermore, it is affected by both the hydroxide and ruthenate concentrations. The effects do not affect the over-all reaction scheme proposed above, but do indicate a more complicated mechanism for the catalytic reaction involving a rate-determining step in which the stoichiometric ratio of perruthenate to hydroxide is not equal to one. (These results together with the detailed mechanism are reported in an upcoming paper.) It suffices to say here that the average potential does fall in the same potential region as reported in the literature (4, 5) for Ru(VII)/Ru(VI).

Peak III.—The reduction of ruthenate has raised a few questions in the past; even the nature of the reduction product has been uncertain (4, 7, 8). It seems appropriate at this time, with the recent surge of interest in the ruthenium dioxide electrode, to reexamine the reduction of ruthenate.

Coulometric reduction of ruthenate solution, after first reducing the platinum electrode used, gave very well-defined charge-time curves with an initial rise to a horizontal plateau. The number of electrons obtained for ten determinations with the electrode potential set on the rising or decaying portions of the wave was 2.00 ±0.06. The electrolysis product was obtained simultaneously in three forms, as a film deposited on the electrode (the color can be an orange-brown, purplish-blue, or black depending on the potential chosen and the amount of ruthenate used), as a black precipitate, and as a pale yellowish-green solution. Prolonged electrolysis for 12 hr or more did not change the yellowish-green solution or the number of electrons obtained. The solution upon standing for a period of time gave a clear solution with a black precipitate. Coulometric oxidation of either the film or the yellowish-green solution gave the characteristic orange color of ruthenate. (The yellowish-green solution was subjected to either centrifugation or filtration through a sintered glass crucible before oxidation.) The absorbances of the resulting ruthenate solutions were measured and the number of electrons obtained for both the film and the solution was between 1.70 and 1.85. The result was expected to be low since the ruthenate solution obtained was rather dilute and error was introduced in taking its absorbance value. Thus, the over-all reaction for the reduction of ruthenate involves two electrons and since no other complexing agent except hydroxide was in the solution, the ruthenium in the final electrolysis product had an oxidation state of (IV). [The uncertainty associated with the coulometric oxidation of the products may not account for the low electron value. The products, then, may have an oxidation state of slightly higher than (IV).]

The black precipitate, which also includes drop-offs from the film, showed no x-ray diffraction pattern. X-ray diffraction was also taken of commercial hydrated ruthenium dioxide and as reported in the literature (16), no pattern was observed. A diffraction pattern was not taken from the film since the authors have not developed a method to remove sufficient quantities from the electrode.

Figure 4, curve C, shows the u.v.-*vis*. spectrum of Ru(IV) in 4M NaOH. The molar absorptivity values should be within ±10%. The spectrum, though it resembles that of perruthenate, is quite distinctive. Besides differences in molar absorptivity and major band maximum positions, a small band maximum at 670 ± 10 nm is observed. The spectrum is that expected for an octahedrally coordinated $4d^4$ system (17). Thus,

disproportionation of ruthenate to perruthenate and ruthenium dioxide is not involved in the reaction. Interpretation of the spectrum extending into the infrared region will be reported in another paper.
