The Anodic Behavior of Lithium in Aqueous Lithium Hydroxide Solutions

John F. Cooper,* Pamela K. Hosmer, and Robert V. Homsy

Lawrence Livermore Laboratory, University of California, Livermore, California 94550

ABSTRACT

The anodic behavior of lithium in 3-5M LiOH was investigated at ambient temperatures under well-defined hydrodynamic conditions using a flow channel. The electrode showed a linear polarization behavior up to a mass-transfer limited anodic current density. The rate of the parallel chemical corrosion of lithium was determined over a range of current densities, flow rates, and concentrations using a gas coulometer to measure the total rate of hydrogen evolution. The corrosion rate approaches zero linearly as the current density approaches the diffusion-limited level. On the basis of electrode resistance and efficiency, the plane-parallel electrode configuration was judged suitable for batteries of the lithium-water type.

It is remarkable that the most reducing of the alkali metals, lithium, has been utilized in practical aqueous electrolyte batteries (1-3). In the lithium-water battery, lithium and water react to form lithium hydroxide and hydrogen gas. The hydrogen is evolved at an iron-screen cathode. The lithium-water cell is the prototype of a family of galvanic cells employing lithium anodes, aqueous electrolytes, and inert cathodes in combination with dissolved oxidizing agents. Analogous cells have been demonstrated using as oxidizing agents: oxygen (4), hydrogen peroxide (5), nitrite (6, 7), sulfite, hypochlorite, bromate, and iodate (7), and aqueous complexes of bromine or iodine (8).

The relative stability of lithium in the presence of water (compared to that of, *e.g.*, sodium) is the consequence of the properties of an adherent surface film which develops under certain conditions of polarization and electrolyte composition. In a manner which is not yet fully understood, the layer impedes the electron transport necessary for the reduction of water (and of other dissolved oxidizing agents), thereby preventing the catastrophic corrosion of the metal. The layer allows for the unusual cell configuration adopted for lithium-water batteries in which the anode and iron-mesh cathode are pressed together without the use of separator. Internal *IR* losses are thereby minimized while the layer prevents internal shorting of the electrodes.

The aqueous electrochemistry of lithium has been studied by Littauer and Tsai using experimental cells with internal anode-cathode contact, and both a transient and permanent passivation phenomena have been reported (3). Bennion and Littauer developed a mathematical model to describe battery discharge voltage, efficiency, and rate (9). The model, based on the assumption that the diffusion of water through the surface layer to the metal substrate is rate-determining, shows qualitative agreement with experiment. Egorov *et al.* have studied the dissolution of rotating-disk lithium electrodes in KOH solutions and have found the self-discharge of lithium to be proportional to the square root of rotation rate, suggesting that lithium dissolution is controlled by the solution-side mass transport (10). To date, no complete set of data has been reported for the rates of lithium dissolution and hydrogen evolution at the Li/LiOH(aq) electrode under well-defined conditions of hydrodynamics and current distribution.

The primary purpose of this study is to determine the effect of solution-side mass transport on the dissolution of lithium and on the reduction of water at the lithium electrode. For this we have used systems of simple geometry and well-defined hydrodynamics. Lithium polarization and coulombic efficiency of lithium dissolution at ambient temperatures have been measured as functions of flow rate, electrolyte concentration, and current density. A secondary purpose of this study is to evaluate the suitability of the closely spaced, plane-parallel electrode configuration, which has not been previously used in batteries of the lithium-water type.

Apparatus and Materials

The influence of electrolyte flow rate on the polarization of the lithium electrode was investigated using the flow channel shown schematically in Fig. 1. Electrodes of lithium and platinum, 9.8 mm square, were placed opposite each other, flush with the horizontal walls of a rectangular duct. The electrode separation was 3.2 mm, while the width of the channel (10.3 mm) just exceeded the electrode width. The channel entrance length, 650 mm, was chosen to assure fully developed laminar flow profiles in the vicinity of the electrodes. Electrolyte was forced through the channel at a steady rate with the use of a single stroke piston pump of 2.3 liter capacity. Pump and channel were constructed of Lucite; interconnecting tubes were of reinforced polyvinyl chloride. No metal or glass parts were allowed to come into contact with the electrolyte.

In the experiments with the flow channel, current was either held constant or programmed as a linear ramp, using a commercial programmable power supply

(Princeton Applied Research, Princeton, New Jersey, Models 173, 175, and 176). Electrode potential was measured relative to the reference electrode, Hg/HgO, 1M LiOH. Current and potential were recorded on a 1 MΩ X-Y recorder (Mosely, Pasadena, California, Model 2D2).

Shown in Fig. 2 is a removable section of the flow channel floor which contains both the lithium electrode and a reference electrode capillary opening. The 0.3 mm diam hole, drilled into this epoxy plug just 0.5 mm upstream of the lithium electrode, was connected by means of flexible tubing to a vessel containing the reference electrode. The lithium electrodes were prepared by extruding the metal into a rectangular cavity

in the plug. The surfaces were then gently ground flat against emery paper wetted with a methanol-water mixture.

Coulombic efficiency was determined from the total rate of evolution of hydrogen from anode and cathode, using the apparatus shown schematically in Fig. 3. The electrodes were contained in a closed Lucite vessel. Electrolyte was internally circulated by means of an impeller and allowed to impinge vertically onto the 100 mm^2 lithium disk imbedded in a removable plug. Electrode potential was measured as in the flow channel. The steady-state hydrogen gas evolution rate was determined from the rate at which the electrolyte was displaced into the pipette. The vertical position of the pipette was continually adjusted to maintain zero head and a constant (atmospheric) pressure within the vessel. Prior to experiments, the electrolyte was purged with hydrogen. In the gas coulometer, no metal or glass parts came in contact with the electrolyte.

Reagent grade lithium hydroxide was used in all experiments (G. Frederick Smith Chemical Company, Columbus, Ohio). The lithium was supplied by D. S. Goldsmith Chemical and Metal, Incorporated (Evanston, Illinois); it was analyzed in our laboratory and found to have the impurities listed in Table I.

Experimental Results

Current-voltage curves.—Typical polarization curves obtained with the flow channel are shown in Fig. 4.

Table I. Analysis of lithium electrodes

Impurities were detected by spectrochemical analysis and are given as ppm by weight.

Element	ppm
Si	35
Ca	14
Cu	14
Ag	10
Be	10
Al	3
Mg	3
Na	<100

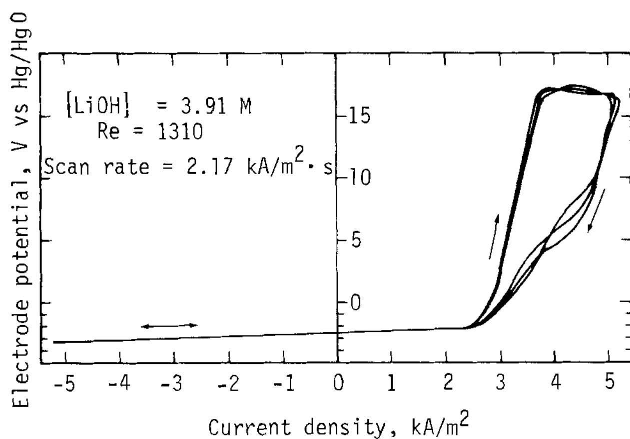

Fig. 4. Voltammetry of the Li/LiOH(aq) electrode. $T = 22°C$; galvanodynamic technique (triangular current wave applied to the electrode); begin anodic scan at zero current.

The applied current was cycled as a triangular waveform. The curves show a low potential, linear polarization behavior, and a high potential region occurring above a critical anodic current density. The resistance in the high potential region generally decreases with time. Consequently, the voltage for scans in the anodic direction may exceed those for the cathodic direction. This phenomenon probably indicates changes in the surface layer's microscopic structure or electronic properties rather than simple changes in electrode area. No gross changes in surface topography or area were observed for the duration of an experiment, the surface remaining smooth and flat.

A different behavior was noted for solutions close to the saturation concentration of 5.3M (see Fig. 5). Once passivated, the electrode would maintain its high resistance state for a time following current reversal. In saturated electrolytes, the passivation was permanent and not destroyed by cathodic polarization and the accompanying vigorous hydrogen evolution. The cathodic behavior was not further investigated.

Electrode resistance (*i.e.*, the differential of polarization with respect to current density in the linear polarization region) is reported in Table II. The range, $(0.5\text{-}1.8) \times 10^{-4}\ \Omega\text{-m}^2$, is comparable to that reported

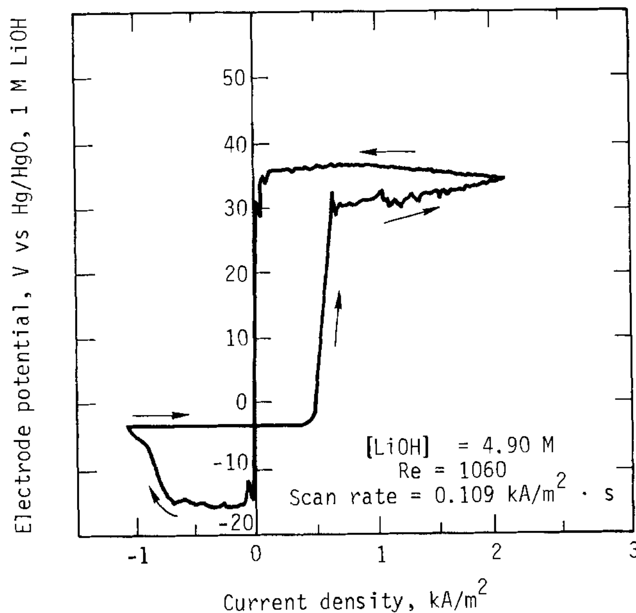

Fig. 5. Voltammetry of the Li/LiOH(aq) electrode near saturation concentrations. $T = 22°C$; galvanodynamic technique; begin anodic scan at zero current. The high voltages reflect high electrode resistances under passive conditions.

by Littauer and Tsai for cells with direct anode-cathode contact (3). In our work, no correction was made for *IR* drop between anode and capillary (an *IR* error of at most $0.2 \times 10^{-4}\ \Omega\text{-m}^2$), or for the enhanced current density near to the anode's leading edge. The values reported in Table II represent the average of three or more separate experiments. In all cases studied, the open-circuit potential, $E(O)$, was within 10 mV of -2.86V *vs.* Hg/HgO, 1M LiOH.

The critical anodic current density.—The critical anodic current density, i_k, which separates low and high potential regions of the current voltage curve, was determined for concentrations from 2.9M to saturation and for flow rates in the laminar flow regime. Typical scans are shown in Fig. 6. The scan rate, 100

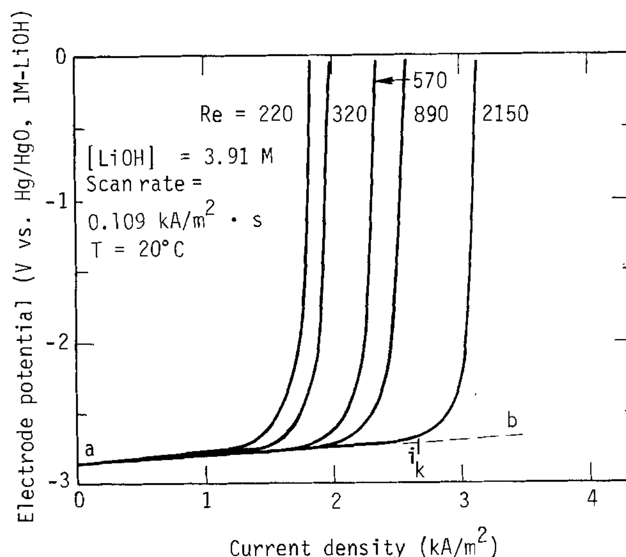

Fig. 6. Typical polarization curves for lithium dissolution at various flow rates. Critical current density, i_k, determined from extrapolation of the linear polarization region, a-b.

A/m²-sec, was sufficiently slow to assure a steady-state concentration profile in the diffusion layer and yielded values of i_k which were indistinguishable from those obtained from discrete galvanostatic experiments. For purposes of analysis, we have adopted a consistent, though somewhat arbitrary definition of i_k: at the critical current density, the electrode polarization $(E(i_k) - (E(O))$ exceeds that extrapolated from the linear region by 30%

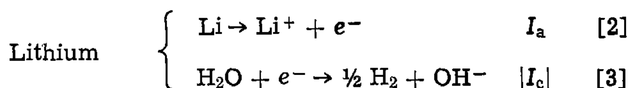
$$i_k \equiv \frac{E(i_k) - E(O)}{1.3\, dE/di} \quad [1]$$

Thus, i_k corresponds to a 30% increase in electrode polarization.

In Fig. 7, i_k is plotted against linear flow rate for various electrolyte concentrations. Two distinct groupings are evident in the plot. In one, i_k increases with flow rate and with dilution of the electrolyte. In the other, which is found at low flow rates or high concentrations, i_k does not vary with concentration or flow rate. Near the boundary of the two regions (*e.g.*, at [LiOH] = 4.44M, $<v>$ = 0.38 m/sec) a quasidiscontinuous change between the two kinds of behavior was observed.

Plots of i_k against flow rate to the one-third power are linear (Fig. 8). The relation between i_k and concentration is also approximately linear (Fig. 9). This behavior suggests that the critical current density corresponds to the mass-transfer limited flux of dissolved lithium hydroxide away from the anode surface. Proof of this concept requires knowledge of the rate of dissolution of lithium which, in general, exceeds that expected on the basis of the current applied to the cell because of the ongoing chemical corrosion of lithium.

Coulombic efficiency.—For the cell, Li/LiOH(aq)/Pt, electrode reactions and their rates expressed as currents may be written as follows



Lithium
$$Li \rightarrow Li^+ + e^- \quad I_a \quad [2]$$
$$H_2O + e^- \rightarrow \tfrac{1}{2} H_2 + OH^- \quad |I_c| \quad [3]$$

Platinum
$$H_2O + e^- \rightarrow \tfrac{1}{2} H_2 + OH^- \quad I_e \quad [4]$$

(By convention, I_a and I_e are positive quantities; I_c is negative.) Only I_e, the current in the external circuit, is directly measurable. Equating the rates of oxidation and reduction in the cell, we have

$$I_a = I_e + |I_c| \quad [5]$$

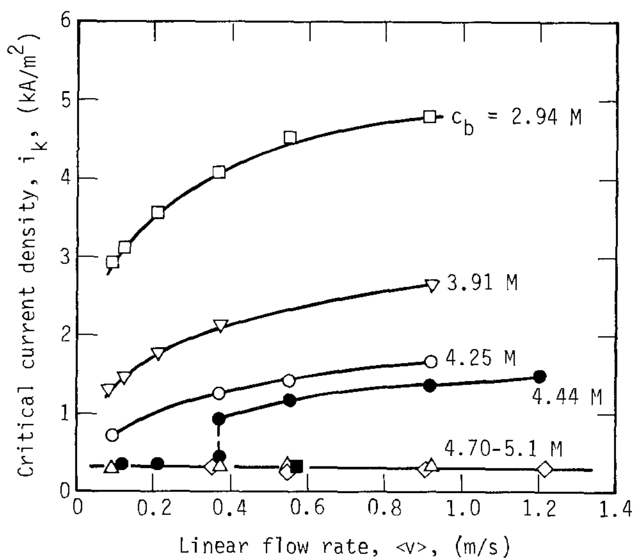


Fig. 7. Dependence of critical current density on flow rate (flow channel).

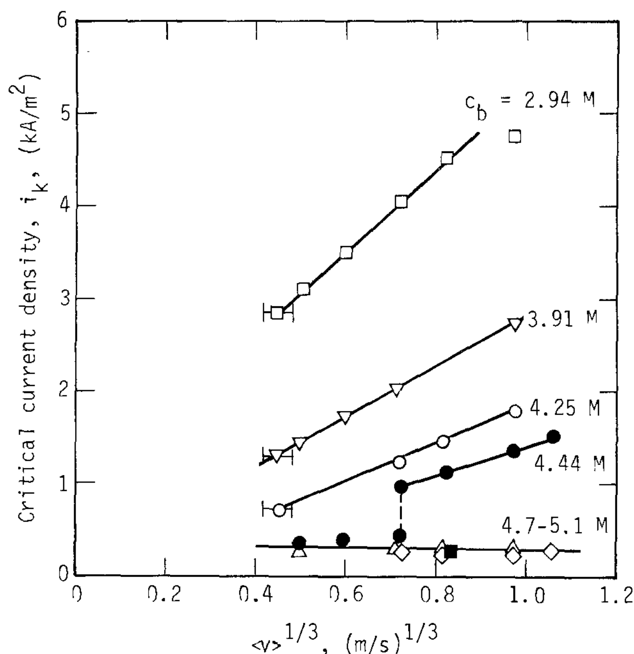

Fig. 8. Critical current density is proportional to $v^{1/3}$

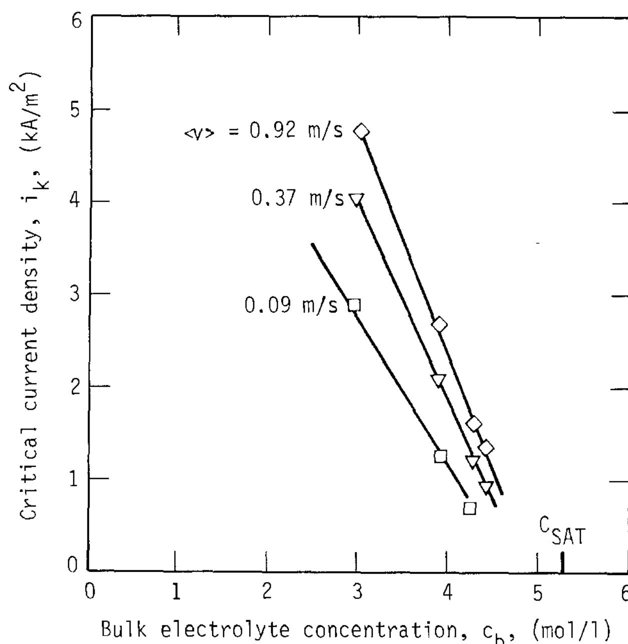

Fig. 9. Critical current density is proportional to electrolyte concentration. Saturation concentration of LiOH at ambient temperature is indicated.

We may define the coulombic efficiency of reaction [2] as

$$\epsilon \equiv I_e/I_a \quad [6]$$

Finally, we may calculate the coulombic efficiency from the total rate of hydrogen gas production using Eq. [5] and [6], Faraday's law, and the ideal gas law. Coulombic efficiency may then be expressed

$$\epsilon = \frac{I_e/2\mathbf{F}}{p_{H_2}\Delta V/RT\,\Delta t} \quad [7]$$

Here, p_{H_2} is the partial pressure of hydrogen gas above the lithium hydroxide solution, ΔV is the volume of gas evolved in the time interval, Δt, and T is the absolute temperature.

Experimentally determined coulombic efficiencies are plotted in Fig. 10 and 11. Typically, efficiency in-

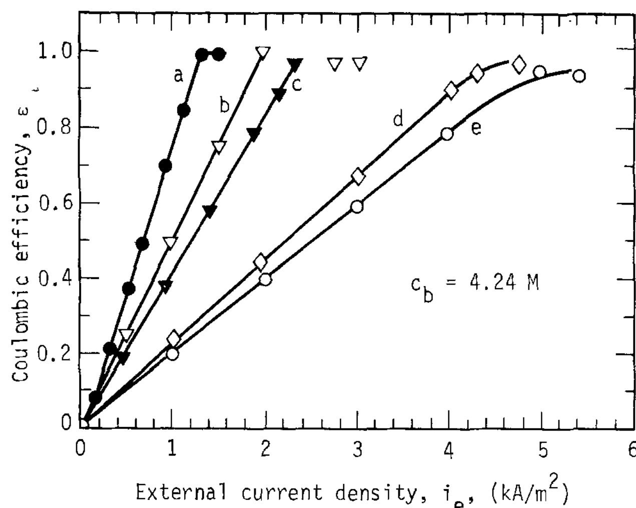

Fig. 10. Coulombic efficiency increases linearly with current density. Critical current density (kA/m²) = (a) 1.3; (b) 2.0; (c) 2.3 ± 0.1; (d) 4.2 ± 0.2; (e) 4.6 ± 0.3. Flow rate increases in the order, a-e.

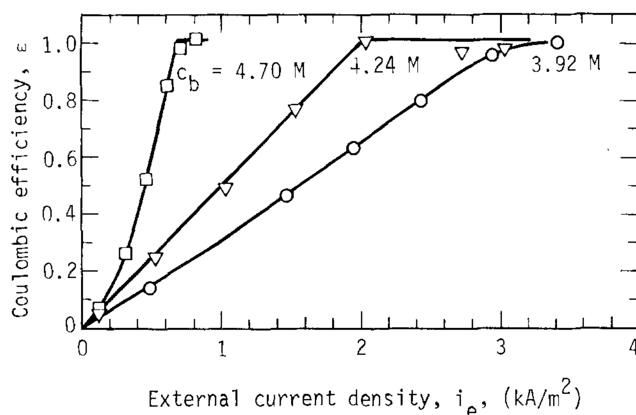

Fig. 11. Dependence of coulombic efficiency on current density at various concentrations.

creases linearly with current and approaches unity near the critical current density. The effects of increased mass transport rate (*i.e.*, increased flow rate) are shown in Fig. 10. As solution flow rate could not be easily measured in this apparatus, the experimentally determined critical current density was treated as an experimental parameter. Efficiencies were determined for flow conditions producing critical current densities up to five times the maximum obtained with the flow channel in the laminar regime.

Discussion of Results

The coulombic efficiencies of less than one indicate that the lithium is partially consumed in a corrosion reaction which contributes no net current to the external circuit. Consequently, the rate of dissolution of lithium will generally exceed the external current. In Fig. 12, the anodic current (I_a) and the corrosion current (I_c) are plotted against the current in the external circuit (I_e). These quantities are expressed as fractions of the external current at which $\epsilon = 1$. In general, the rate of dissolution of lithium is independent of the external current in the region of linear polarization, except at the lowest mass transport rates. Correspondingly, the corrosion current falls to zero as the external current is increased from zero to the critical level. At low flow rates, the corrosion current generally exceeds the critical current. This is most likely the result of enhanced mass transport resulting from the local stirring of the electrolyte during hydrogen gas evolution and from the local heating of the electrolyte caused by the corrosion reaction.

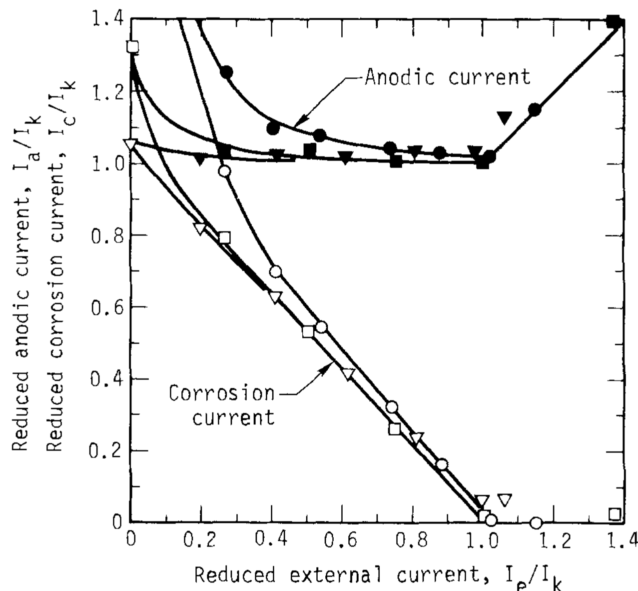

Fig. 12. Dependence of corrosion and anodic currents on external circuit current for various flow rates. $T = 21° \pm 1°C$; i_k (kA/m²) = (○) 1.3; (□) 2.0; (▽) 4.2 ± 0.2. Open symbols, corrosion current; closed symbols, lithium dissolution current.

As mentioned above, the dependences of i_k on flow rate and concentration suggest that the critical current density is determined by the rate of mass transfer of dissolved lithium hydroxide away from the lithium/electrolyte interface. When dissolution is forced to occur above this rate, by the use of an external power supply or by coupling the lithium with a cathode more oxidizing than water, a continuous accumulation of solid lithium hydroxide at the electrode will occur. The surface will be blocked and the electrode resistance will rise dramatically.

We may predict the limiting current density using the mass transfer equation for the region between two flat plates (11)

$$\langle Nu \rangle = 1.848 \, (Re \, Sc \, 2h/L)^{1/3} \qquad [8]$$

Evaluating this equation for the lithium hydroxide solution, the limiting current density may be expressed (see the Appendix)

$$\langle i_1 \rangle = \frac{1.467\mathbf{F}(c_{sat} - c_b) D^{2/3}}{(1 - t_+)(hL)^{1/3}} \langle v \rangle^{1/3} \qquad [9]$$

Here, the limiting concentration at the anode/electrolyte interface, c_{sat}, is taken as the saturation concentration of lithium hydroxide, 5.3M. Diffusion coefficient and transference number are evaluated at bulk electrolyte concentrations c_b. Calculated limiting current densities are shown in Table II.

In Fig. 13, experimental values of i_k are plotted against $\langle i_1 \rangle$ calculated using Eq. [9]. The calculated values exceed the experimental by a factor of about 1.6. The quantitative agreement is quite satisfactory considering the approximations involved in the application of Eq. [9] to our experimental system. In this analysis we have neglected the variation of transport properties within the diffusion boundary layer. (A closer agreement was obtained by evaluating [9] at an average concentration, $(c_b + c_{sat})/2$.) In addition, we have not considered "edge effects" caused by the restriction of electrolyte flow near the corners of the flow channel. While refinements of Eq. [9] are possible, they were judged unnecessary to support the conclusion that the critical current density is the mass-transport limited dissolution rate of solid lithium hydroxide.

Electrode polarizations obtained with the flow channel were as low or lower than those reported for cell

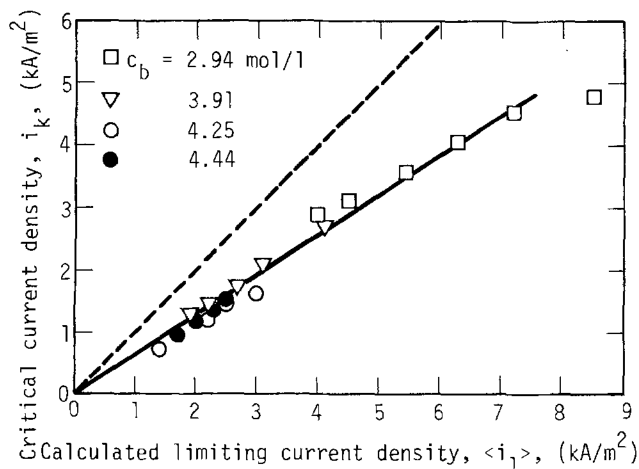

Fig. 13. Comparison of experimental critical current density with calculated diffusion-limited current density. Perfect agreement would be indicated by dashed line.

configurations with direct anode-to-cathode contact (3). More precise measurements of the complex impedance of the lithium electrode are planned. Nevertheless, it is evident that the low electrode polarizations and the high coulombic efficiencies obtained near to the limiting current density make the plane-parallel electrode configuration suitable for batteries of this type.

Conclusions

The lithium electrode sustains two electrochemical reactions: the anodic dissolution of lithium and the reduction of water (Eq. [3]). The rate of anodic dissolution appears to be controlled by the solution-side mass transport of dissolved lithium hydroxide. The rate of water reduction is controlled by the current flowing through the external circuit and is equal to the difference between dissolution and external currents. Consequently, the coulombic efficiency of lithium dissolution increases from 0 to 100% as the external current increases from zero to the mass-transport limited level. When the rate of dissolution is forced to occur above the mass-transport limited level, a net accumulation of solid lithium hydroxide occurs at the anode surface, rapidly blocking the electrode surface and causing the resistance to rise.

With the plane-parallel electrode configuration, the anode shows both a low polarization and a coulombic efficiency approaching 100% within the linear polarization region. Electrode polarizations are at least as low as those obtained with direct anode-cathode contact. The plane-parallel configuration therefore seems suitable for batteries of this type.

The model presented is consistent with experimental data reported here and elsewhere in the literature, but it is not necessarily a unique interpretation. A precise measurement of the electrode's complex impedance would help elucidate the nature of the anode surface film and its role in dissolution kinetics.

APPENDIX

To interpret the limiting current densities obtained with the flow channel, we will use the theory of mass transport of a binary electrolyte between two plane-parallel electrodes. The average diffusion-limited current density is given by the equation (11)

$$\langle i_l \rangle = \frac{1.467 n\mathbf{F} D^{2/3} (c_s - c_b)}{(1 - t_+)(hL)^{1/3}} \langle v \rangle^{1/3} \quad \text{[A-1]}$$

Here, D is the diffusion coefficient of the electrolyte, c_s and c_b are surface and bulk concentrations, t_+ is the cation transference number, and h and L are electrode separation and length in the direction of flow. We make the assumption that lithium hydroxide precipitates at the anode surface when the concentration reaches the saturation level, *i.e.*, $c_s = c_{sat}$.

The coefficient of $\langle v \rangle^{1/3}$ in Eq. [A-1]

$$F(c) = \frac{1.467 n\mathbf{F} D^{2/3} (c_{sat} - c_b)}{(1 - t_+)(hL)^{1/3}} \quad \text{[A-2]}$$

is given at the bulk electrolyte concentrations in Table III. Values of D and t_+ have been computed elsewhere (12) and are listed here along with reported values of specific viscosity (13). Specific viscosity and the diffusion coefficient show strong dependences on concentration, and the concentration of the electrolyte varies across the diffusion layer. This fact is neglected in the derivation of Eq. [A-1].

LIST OF SYMBOLS

A	projected anode area, mm²
c_b, c_s, c_{sat}	bulk electrolyte concentration, surface concentration, saturation concentration, mole/liter
D	diffusion coefficient of LiOH(aq), m²/sec

Thermodynamic Properties of the Intermetallic Systems Lithium-Antimony and Lithium-Bismuth

W. Weppner and R. A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

Galvanic cells of the type "LiAl," Al|LiCl-KCl(*e*), l|Li-X (X = Sb, Bi) were employed to determine the Gibbs free energy of formation ($\Delta G_f°$), and the corresponding enthalpies ($\Delta H_f°$), and entropies ($\Delta S_f°$) for the systems Li-Sb and Li-Bi as a function of composition from pure X to the Li-rich side of the Li_3X phases. The Li/X ratio was changed systematically by use of the coulometric titration technique. $\Delta G_f°$ values were obtained by integration of the coulometric titration curve from pure X to the composition of interest. Thermodynamic data have been determined for the trilithium compounds as a function of the stoichiometry. $\Delta S_f°$ and $\Delta H_f°$ were calculated from the temperature dependence of $\Delta G_f°$. Data were obtained over the temperature range 355°-600°C. At 400°C the following values were found for the standard Gibbs free energy of formation: -176.0 kJ mole^{-1} (Li_2Sb), -260.1 kJ mole^{-1} (Li_3Sb), -76.0 kJ mole^{-1} (LiBi), and -215.3 kJ mole^{-1} (Li_3Bi), all ± 0.1 kJ mole^{-1}. The standard enthalpies of formation are: -220.4 kJ mole^{-1} (Li_2Sb), -325.2 kJ mole^{-1} (Li_3Sb), -108.9 kJ mole^{-1} (LiBi), -293.5 kJ mole^{-1} (Li_3Bi), all ± 0.7 kJ mole^{-1}. The standard entropies of formation are: -66 J mole^{-1}K^{-1} (Li_2Sb), -97 J mole^{-1}K^{-1} (Li_3Sb), -49 J mole^{-1}K^{-1} (LiBi), and -116 J mole^{-1}K^{-1} (Li_3Bi), all ± 1 J mole^{-1}K^{-1}. The experimental results were also used to examine the phase diagrams for Li-Sb and Li-Bi. The range of stoichiometry of $Li_{3+\delta}Sb$ is very narrow ($\Delta\delta = 7 \times 10^{-3}$), whereas $Li_{3+\delta}Bi$ exhibits a large deviation from the ideal stoichiometry ($\Delta\delta = 0.22$), predominantly on the lithium-deficit side. Li_2Sb and LiBi have been found to be the only intermediate phases existing beside the trilithium phases in the temperature range investigated.

The voltage E of galvanic cells is a measure of the change of the Gibbs free energy ΔG due to the reaction which occurs upon a virtual current flux, $E = -\Delta G/nq$, where n is the number of elementary charges q necessary for one formula reaction. ΔG is the corresponding Gibbs free energy change at constant pressure and temperature. From the temperature dependence of E the changes of the enthalpy, ΔH, and the entropy, ΔS, may also be determined. Therefore, the application of electrochemical cells has become one of the standard techniques for the measurement of thermodynamic data with high accuracy (1).

Although the coulometric titration technique was introduced more than two decades ago (2) for systematically changing the composition of phases which are employed as electrodes in galvanic cells, this method has been used in only a small number of cases for the determination of thermodynamic properties as a function of the stoichiometry within individual phases [*e.g.*, (3, 4)]. Use of this technique can be especially valuable, however, in the case of phases with narrow composition ranges, as it can be employed to quantitatively produce very small, and reversible, compositional changes. By making measurements as a function of composition on a single sample, one can avoid errors which often occur in the preparation of a series of individual samples with different compositions.

Since the equilibrium potentials of galvanic cells with electrodes consisting of two adjacent phases of a binary system are independent of the over-all composition (according to Gibbs' phase rule) it is also possible to determine phase boundaries from measurements of the galvanic cell voltage as a function of the over-all composition in a binary system. Measurements at various temperatures can be used in this way to construct phase diagrams.

Key words: Gibbs free energy of formation, enthalpy of formation, entropy of formation, coulometric titration, galvanic cell method.

Experiments are reported here involving electrochemical measurements of the thermodynamic properties of the systems Li-Sb and Li-Bi in the temperature range between 355° and 600°C. The composition ranges investigated extended from the pure Va metals to the lithium-rich compositions within the phases "Li_3Sb" and "Li_3Bi" which coexist with lithium. Emphasis was given to the measurement of the thermodynamic properties of the phases "Li_3Sb" and "Li_3Bi" as a function of their stoichiometry.

Some fragmentary calorimetric measurements have been reported in these systems, both at room temperature and at high temperatures (5-11). Electrochemical methods have also been used at temperatures above 500°C over a limited range of concentration of Li in liquid Bi (11, 12).

The phase diagram of the system Li-Bi has been investigated by several authors, primarily by the use of nonelectrochemical techniques (13-16) Little is known, however, about the phases existing between Li and Sb; there have been some speculations about the existence of a phase Li_3Sb_2 (17-19) in addition to "Li_3Sb", and recently the phase Li_2Sb has been reported (20). This latter is a stoichiometry which has not been observed in other alkali metal-Va systems.

Aside from the considerable scientific interest in I-Va compounds related to their partially ionic and partially metallic character, the systems Li-Sb and Li-Bi are of special interest as potential electrodes in lithium batteries (21, 22) and also as photocathodes (23-25). It has been shown in previous investigations (26, 27) that "Li_3Sb" and "Li_3Bi" have quite different chemical diffusion coefficients, in spite of the similarity in the chemical properties of the Va constituents and the fact that they have the same crystal structure (15).

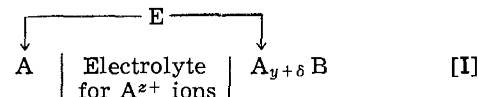
Basic Considerations

Galvanic cells have been used to determine thermodynamic data related to the formation of a number of compounds. One of the standard methods involves the use of polyphase electrodes selected to fix the activities of all the relevant species, according to the Gibbs phase rule (1, 28). The difference in the activity of the electroactive species in the two electrodes is determined from the cell voltage, using a suitable solid or liquid electrolyte. This voltage is then used to calculate the free energy change accompanying the cell reaction. Upon assuming simple stoichiometric relationships, this leads to the Gibbs free energy of formation of one phase from prior data on the others. In general, this technique is only precise if the solubilities of the components in each other and the compositional ranges of intermediate phases can be assumed to be negligible. In many cases, this implicit assumption of narrow intermediate phases has not been sufficiently recognized.

On the other hand, the method typically used to obtain integral molar properties, such as the Gibbs free energy, of terminal binary phases which exist over ranges of composition from experimentally determined partial molar data relating to one component is to use the Gibbs-Duhem relation to calculate the partial molar values of the second component as a function of the composition. This involves an integration, which is typically performed by fitting an empirical algebraic relation between the activity (or activity coefficient) of the first component and its concentration to the experimental data (11, 12, 29, 30). This procedure becomes quite messy when dealing with intermediate phases, in which, as illustrated in this work, the compositional dependence of the chemical potentials can be quite complex.

An alternative and more direct approach to the determination of the Gibbs free energy of formation that may be used if precise data relating the activity of the electroactive species and the composition are available, *e.g.*, from the use of a galvanic cell and the coulometric titration technique, is derived below. This method, which does not involve any assumptions about the partial molar quantity-composition relationship, is especially useful when dealing with intermediate phases with wide ranges of concentration. It does not require the commonly used assumption when dealing with one intermediate phase that the other phases are line compounds.

The following general galvanic cell is considered



$$A \;|\; \text{Electrolyte for } A^{z+} \text{ ions} \;|\; A_{y+\delta}B \qquad [I]$$

The left-hand side is assumed to be both a reservoir and a reference system for the component A, but may, of course, have a fixed activity different from unity. In such a case, this difference must be taken into account by an additional voltage term. The general formula $A_{y+\delta}B$ is used to denote a binary sample whose composition can be varied all the way from pure B to that which is in equilibrium with the activity $a_A = 1$ by charge transport through the galvanic cell.

Upon virtually passing $d\delta$ A^{z+} ions through the electrolyte (from the left-hand to the right-hand side), the stoichiometry of the electrode phase on the right-hand side is altered. The cell reaction is

$$A_{y+\delta}B + d\delta\, A = A_{y+\delta+d\delta}B \quad [\Delta G] \qquad [1]$$

In general, adding $d\delta$ A atoms to the sample can cause either a change in the stoichiometry of the existing phase or the nucleation and partial growth of a new phase. At constant pressure and temperature, the Gibbs free energy change ΔG accompanying reaction [1] corresponds to the electrical energy $z\, d\delta\, q\, E$ which is necessary to transport $d\delta$ A^{z+} ions from one side of the electrolyte to the other

$$\Delta G = -z\, d\delta\, q\, E \qquad [2]$$

where E is the emf of the galvanic cell [I].

For a more informative thermodynamic interpretation of the cell voltage, reaction [1] may be separated into a pair of successive partial reactions for the decomposition of $A_{y+\delta}B$, and the formation of $A_{y+\delta+d\delta}B$

$$A_{y+\delta}B = (y+\delta)\,A + B \quad [-\Delta G_f^\circ(A_{y+\delta}B)] \qquad [3]$$

and

$$(y+\delta+d\delta)A + B = A_{y+\delta+d\delta}B \quad [\Delta G_f^\circ(A_{y+\delta+d\delta}B)] \qquad [4]$$

Then, because of the additivity of the Gibbs free energies

$$\Delta G = \Delta G_f^\circ(A_{y+\delta+d\delta}B) - \Delta G_f^\circ(A_{y+\delta}B) \qquad [5]$$

and by combining Eq. [5] with Eq. [2], we have

$$E = -\frac{1}{zq}\,\frac{d[\Delta G_f^\circ(A_{y+\delta}B)]}{d\delta} \qquad [6]$$

The integration of this equation yields

$$\Delta G_f^\circ(A_{y+\delta}B) = -zq\int_{\delta_0}^{\delta} E\, d\delta + \Delta G_f^\circ(A_{y+\delta_0}B) \qquad [7]$$

The resultant Gibbs free energy of formation may, therefore, be determined for any stoichiometry $(y+\delta)$ from the area under the coulometric titration curve. Under the special circumstance of line phases being present, and negligible solubility of A in B, the integral may be replaced by the sum of the two-phase voltages times the respective changes of the stoichiometry.

If the integration is started when only the pure component B is present $(y+\delta=0)$, the integration constant $\Delta G_f^\circ(A_{y+\delta_0}B)$ is zero. By variation of the upper integration limit, ΔG_f° may be obtained as a function of the composition within any given phase, regardless of the composition ranges of the other phases present.

From the temperature and compositional dependences of the voltage of the galvanic cell [I] the entropy $\Delta S_f°$ and enthalpy $\Delta H_f°$ of formation of the composition $A_{y+\delta}B$ can be obtained with the help of the following equations

$$\Delta S_f°(A_{y+\delta}B) = -\frac{\partial \Delta G_f°(A_{y+\delta}B)}{\partial T} = zq \int_0^\delta \frac{\partial}{\partial T} E(\delta, T)\, d\delta \quad [8]$$

$$\Delta H_f°(A_{y+\delta}B) = \Delta G_f°(A_{y+\delta}B) + T\,\Delta S_f°(A_{y+\delta}B) = -zq \left\{ \int_0^\delta E\, d\delta - T \int_0^\delta \frac{\partial}{\partial T} E(\delta, T)\, d\delta \right\} \quad [9]$$

While the activity a_A of the species A is directly obtained as a function of the composition from the cell voltage E according to

$$\ln a_A(\delta) = -\frac{zq\, E(\delta)}{kT} \quad [10]$$

the activity of the second component, a_B, may be readily calculated as a function of composition from the data on the Gibbs free energy of formation of $A_{y+\delta}B$, rather than integrating the Gibbs-Duhem equation. Since $\Delta G_f°(A_{y+\delta}B)$ is given by the sum of $kT\,(y+\delta)\ln a_A$ and $kT \ln a_B$, we have from Eq. [10]

$$\ln a_B(\delta) = [(y+\delta)\, zq\, E(\delta) + \Delta G_f°(A_{y+\delta}B)]/kT \quad [11]$$

$$= \frac{zq}{kT}\left[(y+\delta)E(\delta) - \int_0^\delta E\, d\delta \right] \quad [12]$$

$$= \frac{zq}{kT}\left[(y+\delta)E(\delta) - \int_{\delta_0}^\delta E\, d\delta + \Delta G_f°(A_{y+\delta_0}B) \right] \quad [13]$$

Experimental Considerations

Pure antimony (> 99.99%), bismuth (> 99.999%), and lithium (> 99.9%) were used as the starting materials for the binary systems to be investigated. The antimony samples were machined into the form of dense polycrystalline pellets of about 1 mm thickness, with initial surface areas of 1-2 cm^2 ,whereas the bismuth was placed in a small molybdenum bucket, because it is molten (at low lithium contents) at the experimental temperatures. In this case, the surface area was 0.6 cm^2.

Both electrochemical titration and potential difference measurements were performed by use of a galvanic cell which can be represented as

"LiAl,"Al | LiCl-KCl (e), l | Li-Sb or LiBi [II]

The electrolyte was a spectrographically pure LiCl-KCl solution in the eutectic ratio, purchased from Anderson Physics Laboratories, Urbana, Illinois, which was carefully dried and pre-electrolyzed to assure the removal of any relevant impurities. By use of this molten salt excellent contact is provided between the electrolyte and the sample. The operating temperature was between the melting point of the salt at 352°C and ~600°C. Separate reference and (large) counterelectrodes were used, both being two-phase mixtures of Al and "LiAl." They were prepared previously by electrochemically titrating lithium into a high purity (> 99.9999%) aluminum wire, which was wound into a spiral, using molten lithium as the anode. The process of electrochemically introducing the lithium into the "LiAl" phase, which occurs by a highly selective solid-state diffusion process, serves to increase the effective purity of the lithium in the later experimental steps, in which this phase serves as the source of lithium. This same type of lithium purification mechanism also occurs again subsequently when the lithium is selectively diffused into the Li-Sb and Li-Bi phases. Thus, any metallic impurities brought in with the original lithium are of no consequence in the experimental results. For the same reasons, minor amounts of H_2O, N_2, O_2, or other gases present in the glove box are not important.

For the calculation of thermodynamic data the measured cell voltages were corrected for the voltage between the "LiAl," Al electrode, and pure lithium, which is about 300 mV at 400°C (26, 27, 31). The two-phase electrode is advantageous for this purpose, as it is solid, and has a lower lithium activity, thus avoiding problems with the thermodynamic stability of the LiCl-KCl(e) melt (32) in equilibrium with pure lithium, and considerably reducing the electronic leakage of the electrolyte (33). A similar experimental arrangement was used in a recently reported study of the Li-Si system (29).

The electronic leads for the galvanic cell were made from molybdenum wire, which proved to have excellent compatibility at all lithium activities. Alumina crucibles were used as containers for the molten salt, which was heated in a resistance furnace inside a recycling helium dry box. Temperatures were measured by means of Chromel-Alumel thermocouples, which were submerged in the melt inside closed stainless steel tubes. Additional checking thermocouples were also present immediately outside the crucible. Potentials, currents, and charge values were controlled and measured by use of a PAR Model 173 potentiostat/galvanostat and Model 179 digital coulometer.

The coulometric titration was performed by applying constant currents through the cell, typically 10-100 mA/cm^2 in the two-phase regions, and a factor of 10^{-2}-10^{-1} lower in the single phase regions. These relatively high current densities were possible because of the large values of the chemical diffusion coefficients in these systems (26, 27).

The thermodynamic data were calculated from values of the cell voltage that were observed to remain constant within ±1 mV over periods of several hours. In all cases, titrations were carried out in both the forward and backward directions. In addition to the time independence of the cell voltage, the presence of equilibrium was indicated by the attainment of the same voltage value (±1 mV) at any given composition after both adding and deleting lithium from the sample.

Because of the use of the "LiAl," Al electrode, a small voltage drift with time was only found at high lithium activities in the sample, corresponding to voltages less than about 150 mV *vs.* lithium. The reason for this is probably either an instability of LiCl-KCl(e) melts at high lithium activities (32), increased electronic partial conductivity of the electrolyte (33), which results in internal ion transport that is not measured by the current meter in the external circuit and a slight loss of lithium from the sample into the melt with corresponding evaporation of potassium (32), or a combination of these effects. At lower lithium activities the influence of these factors may be neglected.

Only a small number of other errors may limit the use of this general technique, and their presence would be easily detectable. One possibility might be solubility of lithium in the melt, the crucible, or the molybdenum leads, which could add to the current used to change the stoichiometry of the sample. Blind experiments without the sample in place were carried out, and the charge transport involved in going from essentially no initial lithium activity in the molybdenum electrode, to within 100 mV of pure Li (−200 mV *vs.* "LiAl," Al) was found to be negligible compared to the amount of lithium that was electrochemically titrated into the antimony and bismuth samples.

Results

In Fig. 1 and 2, the steady-state open-circuit cell voltages are plotted as a function of the composition, which was electrochemically changed *in situ* from pure Sb (or Bi) to a Li/Va metal ratio of more than 3, corresponding to the composition within the trilithium

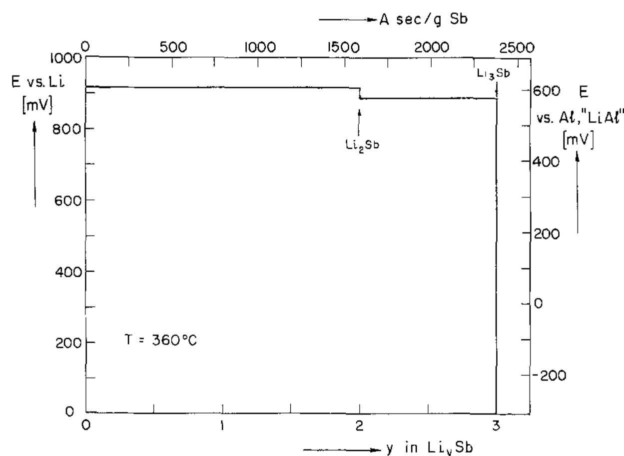


Fig. 1. The steady-state voltage of the galvanic cell with reference to pure lithium as a function of the amount of lithium electrochemically titrated into antimony (coulometric titration curve) at 360°C. The first horizontal part indicates the coexistence of Sb with Li_2Sb, the second one the two-phase region of Li_2Sb and "Li_3Sb."

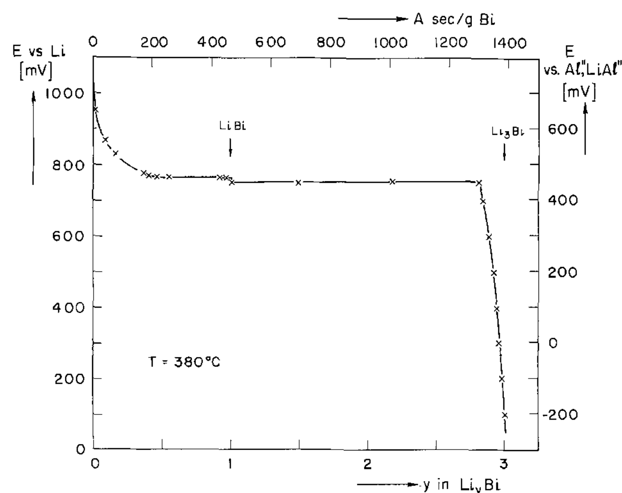

Fig. 2. The coulometric titration curve for the system Li-Bi at 380°C. A large range of solubility of lithium in bismuth is followed by the two-phase region of Bi in equilibrium with LiBi. The second plateau indicates the coexistence of LiBi with "Li_3Bi." The trilithium phase shows a large range of existence.

compounds in equilibrium with lithium. Though both systems are closely related chemically, the curves show significant differences. Antimony is solid in the experimental temperature range, whereas pure bismuth is a liquid. While the solubility of lithium in solid antimony is negligibly small, liquid bismuth dissolves approximately 30 atomic percent (a/o) lithium at 380°C. The extent of solubility and the activity of lithium in liquid bismuth may be determined from the coulometric titration curves, as shown in Fig. 3 for various temperatures. In that figure the voltage of the terminal bismuth-rich liquid solution *vs.* pure lithium is plotted as a function of composition, which was changed by current flux through the galvanic cell. The horizontal straight lines correspond to the coexistence of Bi (+ dissolved Li) with the adjacent binary phase.

The main voltage drops in Fig. 1 and 2, *i.e.,* changes of the activities of the components with composition, appear over the existence regions of the phases "Li_3Sb" and "Li_3Bi." As can be seen from Fig. 4 and 5, which show the coulometric titration curves in these phases in detail, the range of stability of "Li_3Sb" is very small ($\Delta\delta \approx 7 \times 10^{-3}$), whereas "$Li_3Bi$" exists over a much wider range of stoichiometry ($\Delta\delta \approx 0.22$). The composition values for the narrow "Li_3Sb" phase in Fig. 4 were shifted by a factor of about 10^{-4} in order to make

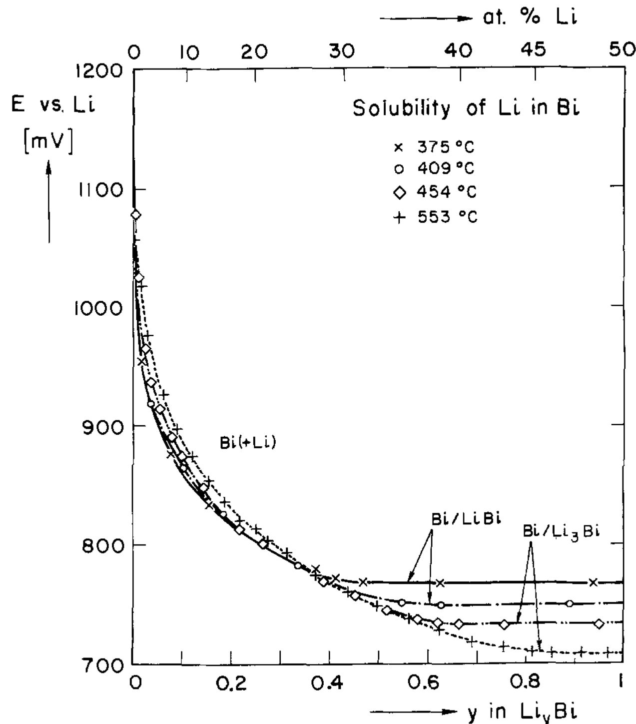

Fig. 3. The solubility of lithium in bismuth at different temperatures. The steady-state galvanic cell voltage *vs.* lithium is plotted as a function of the amount of lithium electrochemically titrated into liquid bismuth.

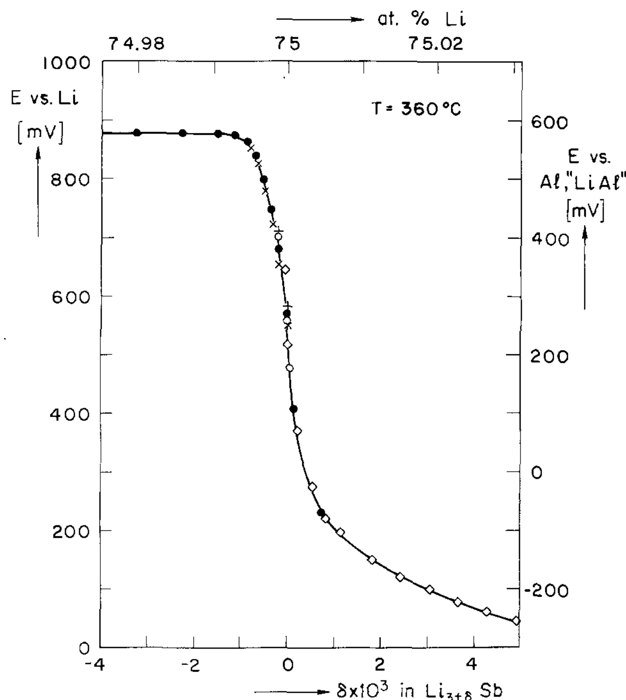

Fig. 4. The coulometric titration curve over the composition range of the single phase "Li_3Sb" at 360°C. The horizontal portion on the left side indicates coexistence with Li_2Sb. Five different symbols indicate data points taken from different experimental sequences, *i.e.,* Li pumped in or out. Their consistency indicates the extremely high resolution of this technique.

the inflection point occur at the ideal 3:1 stoichiometric composition, as that is what is expected from theoretical considerations (34). The results of several forward and backward titration runs are indicated by the use of different symbols. The precision of this technique is shown by their coincidence.

In both cases, only one intermediate phase of lower lithium content has been found. At 360°C neither LiSb

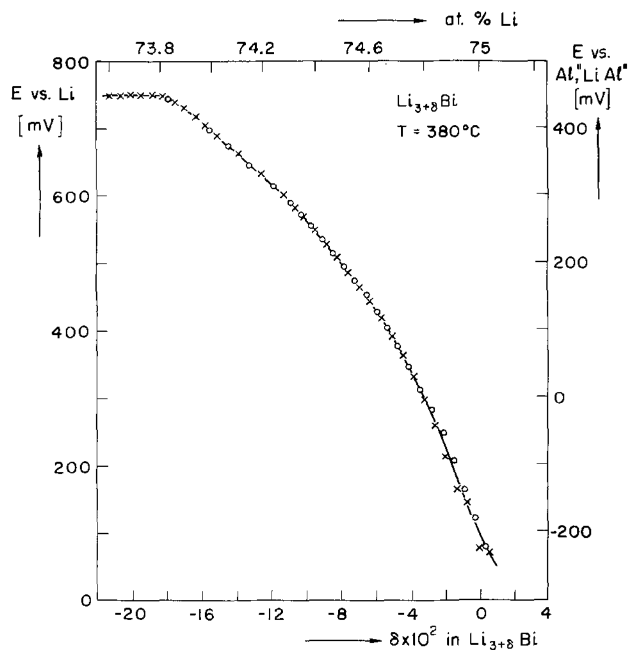

Fig. 5. The coulometric titration curve of the single phase "Li_3Bi" at 380°C. The different symbols indicate the results of two different titration experiments.

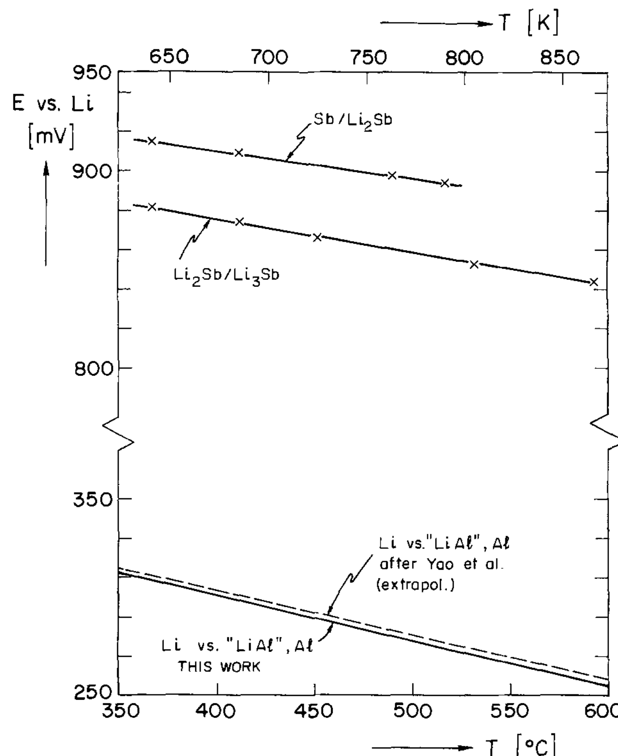

Fig. 6. The steady-state plateau voltages of the galvanic cell for the two-phase mixtures of the system Li-Sb as a function of the temperature with reference to pure lithium. The voltage of pure lithium vs. the actually applied "LiAl," Al electrode is also shown. For comparison, extrapolated literature data (31) are plotted.

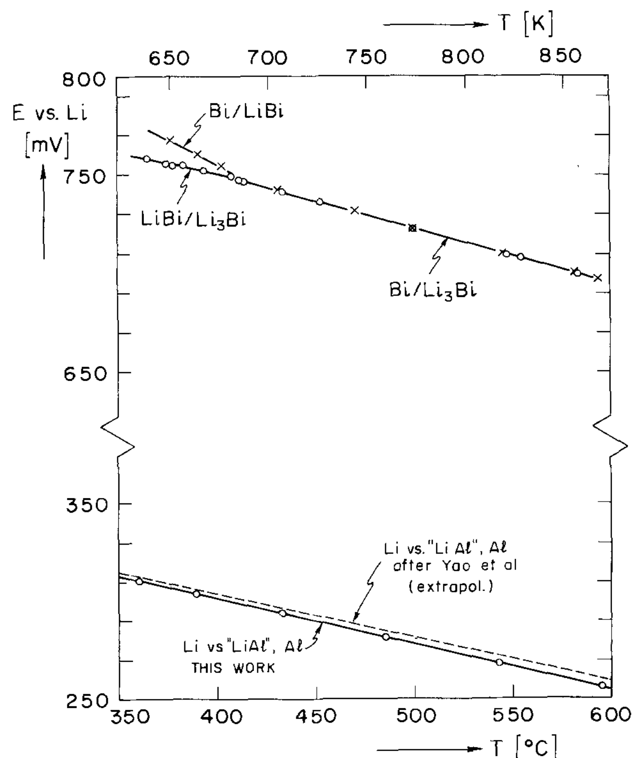

Fig. 7. The steady-state plateau voltages of the galvanic cell for the two-phase regions of the system Li-Bi as a function of the temperature with reference to pure lithium. At temperatures above 420°C only the trilithium phase exists. Below that temperature LiBi exists and the curve separates into two distinct plateau values. A small change of the slope is observed at the transition from the high temperature to the low temperature form of LiBi. The voltage of pure lithium vs. the actually applied "LiAl," Al electrode is also shown. Literature data (31) are plotted for comparison.

nor Li_3Sb_2, as supposed earlier, exists; only the compound Li_2Sb was observed. Extended anneals over periods of several days and repeated forward and backward titrations failed to produce any measurable voltage difference between that of Li-saturated Sb and Li_2Sb. In the system Li-Bi the existence of the phase LiBi was confirmed. Both of these intermediate phases have comparatively narrow ranges of stoichiometry and have very sluggish kinetics. The voltage drops over these phases are also very small, indicating only small changes of the lithium activity within their existence ranges.

Figures 6 and 7 present the composition-independent plateau voltages of the galvanic cell for the two-phase regions of the systems Li-Sb and Li-Bi, respectively, as a function of the temperature. The data were determined by using "LiAl," Al reference electrodes, but are plotted with reference to pure lithium, using the potentials between Li and "LiAl," Al, as also shown in the figures. The latter were determined in separate experiments. For comparison, extrapolated data from the literature (31) are also shown. From Fig. 7, it is seen that the formation of the intermediate phase LiBi can be easily detected below about 420°C. Also, a small change of the slopes of the voltages of "Li_3Bi" in equilibrium with the low temperature and the high temperature phase of LiBi is visible. By comparing Fig. 6 and 7 it is seen that lithium has an activity about one order of magnitude higher in the Li-Bi than in the Li-Sb system.

The phase diagram for the system Li-Bi can be deduced from data on the composition ranges of one and two phase regions determined from the shape of the coulometric titration curves at different temperatures. The general features agree well with those reported in the literature (13, 14, 16). However, they are different in detail, primarily with regard to the stoichiometric ranges of the single phases involved. The phase diagram of the system Li-Sb is relatively simple in the temperature range investigated, because the solubility of lithium in antimony and the stoichiometric ranges of Li_2Sb and Li_3Sb are very small. Therefore, this diagram contains vertical lines at the appropriate ideal compositions.

A special advantage of the use of galvanic cell coulometric titration techniques for the determination of thermodynamic values is the possibility of observing the influence of very small variations in composition

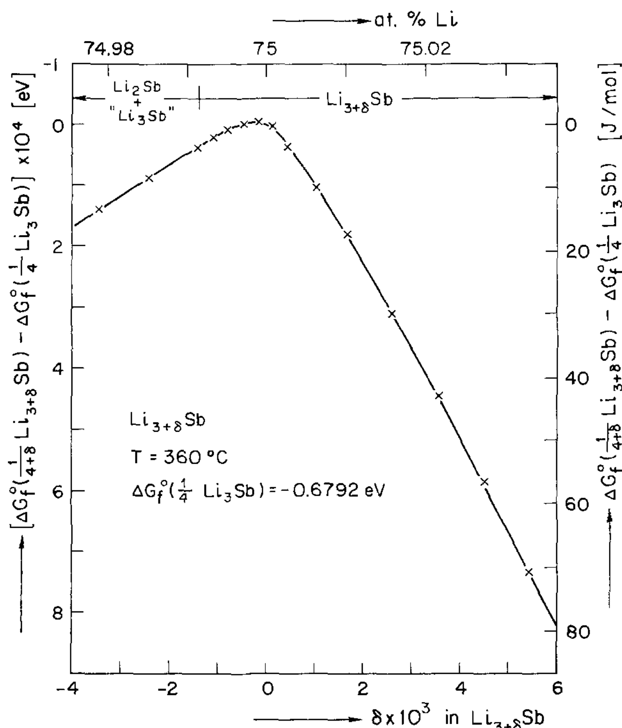

Fig. 8. The Gibbs formation energy of $Li_{3+\delta}Sb$ (per constituent) as a function of the stoichiometry of the single phase at 360°C. The data are plotted relative to the Gibbs formation energy of the compound with ideal stoichiometry, Li_3Sb.

within single phases. The precision obtainable in this way is much greater than that which can be achieved with conventional methods. In Fig. 8, the Gibbs free energy of formation of $Li_{3+\delta}Sb$ is shown as a function of the stoichiometry within the single phase region from $Li_{2.9985}Sb$ to $Li_{3.006}Sb$. The value of $\Delta G_f°$ of stoichiometric Li_3Sb is used for reference. It is seen that the resolution is better than 1 J/mole for these relative values. Their absolute magnitudes, however, are only correct to $\pm$ 100 J/mole. Further comments relating to the precision of this technique are included in the next section.

The corresponding curve for the $Li_{3+\delta}Bi$ phase, which exhibits a much larger range of stoichiometry, is shown in Fig. 9. These data are also given with reference to stoichiometric Li_3Bi. The lowest Gibbs formation energy per particle is observed for the composition having a lithium deficit of about 3%.

The variations of the molar Gibbs free energy of formation and the activities of both components as functions of the mole fraction Li within the phases "Li_3Sb" and "Li_3Bi" are presented in Tables I and II. Since this technique provides greater precision in the relative free energy values within the "Li_3Sb" and "Li_3Bi" phases than in their absolute values, due to the necessity for titration and integration over a wide composition range in the latter case, the values are indexed to those of the respective stoichiometric compositions.

0.752	-1.93×10^3	0.641	1.66×10^{-17}

Figure 10 shows the temperature dependence of the Gibbs free energy of formation of the phases existing in the Li-Sb and Li-Bi systems. In the latter case, the large range of solubility of lithium in bismuth had to be taken into consideration according to Eq. [7]. The data are related to the reaction of one lithium atom with the corresponding formula amount of the Va metal, and are compared with those previously calculated for the formation of "Li_3Bi" by Foster *et al.* (11). However, those authors did not take into consideration the large range of stoichiometry on the lithium-deficient side of that phase.

Entropy changes, $\Delta S_f°$, were calculated from the slopes of the straight lines. With $\Delta G_f°$ and $\Delta S_f°$ being known, values of the enthalpy of formation, $\Delta H_f°$, were also calculated using Eq. [9]. The results are presented in Table III.

Discussion

From the results presented here it is seen that the galvanic cell technique, combined with coulometric titration, can be used to obtain a large amount of thermodynamic information with very high precision. The cell voltage is a direct measure of the activity of the electroactive species, which is directly related to several thermodynamic quantities, and the composition can be reproducibly varied over a wide range.

It has been shown that one can utilize results obtained in this manner to directly calculate integral Gibbs free energy, enthalpy, and entropy data rather than using the common Gibbs-Duhem integration. This

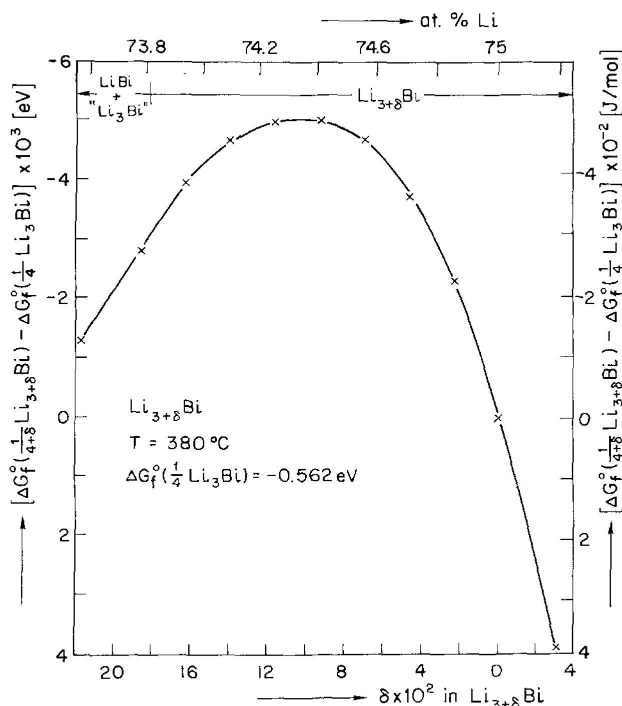

Fig. 9. The Gibbs formation energy of $Li_{3+\delta}Bi$ (per constituent) as a function of the stoichiometry of the single phase at 380°C. The data are plotted relative to the Gibbs formation energy of the compound with ideal stoichiometry, Li_3Bi.

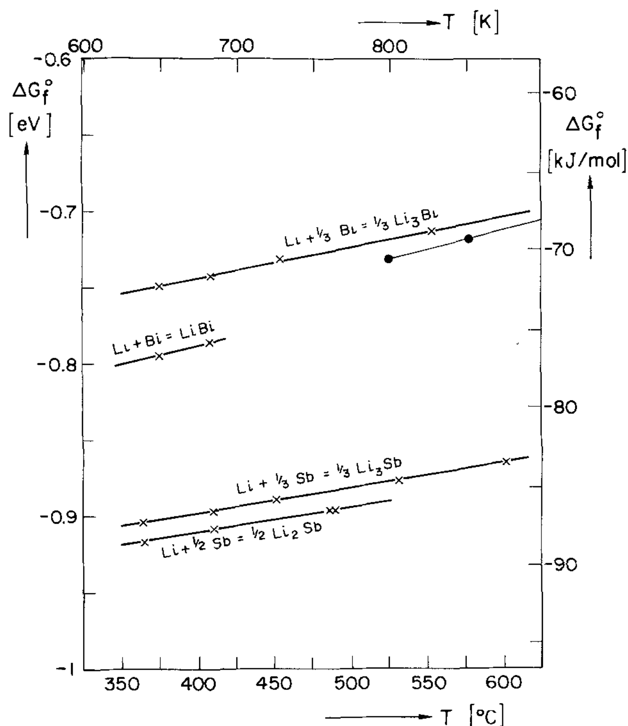

Fig. 10. The Gibbs formation energies of the compounds existing in the systems Li-Sb and Li-Bi as a function of the temperature. The negative slopes are the formation entropies of the compounds. Earlier data from Foster *et. al.* (11), which did not take into account the stoichiometric range of "Li_3Bi," are indicated by solid circles.

new method readily allows one to explicitly take into account the actual shape of the activity-composition relationship and finite composition ranges of other phases when calculating data for a given phase. As a result, greater precision can be obtained than by the use of traditional approaches, *e.g.*, the work of Foster *et al.* (11), who reported measurements on the liquid terminal solution of Li in Bi, and who calculated data on "Li_3Bi" on the assumption that this phase can be treated as a line compound. However, this work has shown that "Li_3Bi" has an appreciable range of composition on the lithium deficit side of the assumed stoichiometric value. As a result of their assumption of a 3/1 atomic ratio, their calculated values for the Gibbs free energy of formation have too great a magnitude.

The precision of the results reported here is unusually high for thermodynamic data, since electrical measurements can be made with high accuracy and the Li-Sb and Li-Bi systems reach equilibrium rapidly. There is negligible drift in the LiCl-KCl molten salt system if the purity is sufficiently high and the lithium activity is kept low enough.

The accuracy of the Gibbs free energy of formation data is due primarily to the good reproducibility of the cell voltages within the two-phase regions, which dominate the ranges of integration. The mean standard deviation was found to be less than ± 0.5 mV in these

Table III. Thermodynamic data for Li-Sb and Li-Bi Systems

Reaction	Temperature range (°C)	$\Delta G_f°$ (kJ mole^{-1}) (± 0.1)	$\Delta H_f°$ (kJ mole^{-1}) (± 0.7)	$\Delta S_f°$ (J mole^{-1} K^{-1}) (± 1)
2Li + Sb = Li_2Sb	355-500	$0.0319T - 197.3$	-197.3	-31.9
3Li + Sb = Li_3Sb	355-600	$0.0492T - 293.3$	-293.3	-49.2
Li + Bi = LiBi	355-420	$0.0245T - 92.6$	-92.6	-24.5
3Li + Bi = Li_3Bi	355-600	$0.0589T - 255.4$	-255.4	-58.9

T = absolute temperature (°K).

composition-independent regimes. This results in a precision of ± 100 J/mole in the free energy values.

The coulometric titration technique allows much greater compositional resolution than can be expected in cases in which one must prepare and analyze a series of separate samples. This is especially advantageous when one wishes to examine the compositional variation of properties within rather narrow phases. In cases such as these, with rapid equilibration and negligible drift, the compositional precision is only limited by the accuracy with which one can measure and control the current-time product. For example, a compositional change from $Li_{2.9985}Sb$ to $Li_{2.9990}Sb$ corresponds to a charge transfer of 1 A sec (*e.g.*, a current of 10 mA for 100 sec) per gram of sample. This is easy to both measure and control.

As a result of this high degree of compositional control, the variation in the relative values of thermodynamic parameters with composition within intermediate phases can be obtained with great accuracy. For example, the data in Fig. 4 show that a change in the stoichiometry of 1×10^{-4} corresponds to a change in cell voltage of about 100 mV. If we assume an error of 1 mV in the voltage, the corresponding error in the relative value of the Gibbs free energy of formation is only 4.8×10^{-3} J/mole.

Composition changes and phase transitions take place in both the Li-Sb and Li-Bi systems by insertion reactions with very high values of chemical diffusion coefficient (26, 27). This occurs by changes in the concentration and distribution of lithium atoms upon interstitial sites within the static Sb or Bi lattices, and thus produces only very minor changes in lattice parameter and sample shape.

In addition to the thermodynamic data already reported in this paper, other quantities may also be evaluated from these results. However, they may be dependent upon additional assumptions or information. For example, one may determine the intrinsic disorder concentration from the slope of the coulometric titration curve (34), if a specific disorder model can be assumed. Under the assumption of prevailing lithium vacancies in "Li_3Sb" at negative deviations from the ideal stoichiometry ($\delta < 0$), and either lithium interstitials or lithium atoms on antimony sites at lithium excess ($\delta > 0$) the mole fraction of intrinsic lithium vacancies at ideal stoichiometry was calculated from the slope at the inflection point to be $X_{V_{Li}} = 2 \times 10^{-5}$. For other disorder models different results would be obtained, but they will vary only slightly for most reasonable assumptions. The shape of the coulometric titration curve that is experimentally observed is very similar to that which is theoretically calculated (34) if one assumes lithium atoms on antimony sites at $\delta > 0$ and lithium vacancies at $\delta < 0$.

In addition to their fast kinetic behavior (26, 27)), it has been shown that the systems Li-Sb and Li-Bi exhibit thermodynamic properties which may make them of interest for possible use as cathodes in high energy- and power-density batteries. The maximum theoretical specific energies are 500 W-hr/kg for Li-Sb and 290 W-hr/kg for Li-Bi, respectively.

ABSTRACT

The performances of lithium cells based on Bi_2O_3 as a cathode have been evaluated. Because of the very high specific capacity of this compound, interesting values of energy densities were obtained at low discharge rates. A 12-electron discharge process is supposed to occur leading to the formation of Li_3Bi. Two steps were noticed, the first one giving rise to metallic Bi through a 6-electron reduction. Comparison is made of the performance of these cells with several lithium cells. In principle, Bi_2O_3 seems to be a very attractive material for cells of this type, encouraging further research on its practical utilization.

In the last few years lithium batteries with both solid and liquid electrolytes have come out of the stage of laboratory prototypes and their commercial development has started. In general, lithium cells seem to be particularly suitable in the field of microelectronics, where high values of specific energies and capacities (especially on a volume basis) are required at low current densities (a few $\mu A/cm^2$). Also in high rate applications nonaqueous cells are now emerging, especially with the Li/SO_2 (1) and the $Li/SOCl_2$ (2) systems.

A class of potentially useful cathode materials for organic electrolyte cells is a set of metal oxides, which seem to assure simultaneously, although to various extents, the characteristics of safety, economy, high energy density, and long life. Among others, CuO (3), MoO_3 (4), Mo_8O_{23} (5), and V_2O_5 (6) have proved to be suitable in this sense.

Key words: lithium batteries, Bi_2O_3, nonaqueous solvents, button organic cells.

During the search for other cathode materials, we observed that Bi_2O_3 has a surprisingly high specific capacity (*ca.* 0.7 A-hr/g) which could compensate for the relatively low cell voltage on load (1.5V at 0.5 mA/cm^2). Furthermore, the high density of this oxide (8.9 g/cm^3) can produce high values of volumetric capacities and energies.

In the open literature no report is given on the performance of cells (either aqueous or nonaqueous) based on Bi_2O_3; only the discharge characteristics in alkaline solutions of cathodes based on Bi_2O_3, Sb_2O_3, and As_2O_3 have been examined (7). In an American patent (8) the possibility of using Bi_2O_3 in lithium cells containing $LiPF_6$ or $LiBF_4$ in methyl acetate is mentioned, but no details on the electrochemical behavior of this oxide are given.

In the present paper the feasibility of Bi_2O_3 as a cathode for primary lithium cells is discussed and particular emphasis is given to the discharge process.

Experimental Aspects

Materials.—Bi_2O_3 was a reagent grade product used without any further treatment. The purification of the solvents [butyrolactone (BL), propylene carbonate (PC), tetrahydrofuran (THF), and methyl formate (MF)] and the preparation of the organic solutions have been described elsewhere (9). $BiPO_4$, Bi_2S_3, and $Bi(IO_3)_3$, which were also tested as cathodes, were prepared in this laboratory by metathetic reactions.

Apparatus and procedure.—Bi_2O_3 was usually mixed with 10% graphite in order to ensure electronic conductivity. This oxide is indeed a semiconductor (10) and a resistance of 1.4×10^6 Ω was measured for a pellet having a thickness of 0.12 cm. In spite of this value, cathodes not containing graphite can work at the current densities (around 0.5 mA/cm^2) used for these cells. A similar pattern was found with silver salts (9, 11) of high resistance. This effect is still obscure and worth a specific investigation. Of course, the use of graphite-free cathodes is welcomed in that higher specific energies may be obtained; furthermore, decomposition phenomena of the solutions were less probable in the absence of graphite (12).

The dry cathode material was pressed at 1600 kg/cm^2 onto a support of silver powder pressed at 550 kg/cm^2. Lower and higher pressures on Bi_2O_3 resulted in a less satisfactory performance. The cathode pellet was then put in a Teflon container having an internal diameter of 1.26 cm. The organic solutions were supported on a triple layer of glass fiber filter paper (Whatman 934 AH); the use of a higher or of a lower number of separators was not profitable. Both lithium and Bi_2O_3 on Ag were in contact with stainless steel terminals. The button-type cells had an internal volume of *ca.* 0.2 cm^3 (referred to the active components) and were maintained in a dry box under argon atmosphere during the constant current discharges obtained with ordinary galvanostats.

Polarization measurements for Bi_2O_3 cathodes in three solutions were made on fresh cells similar to those submitted to discharge. At each current value, the voltage was observed for 5 sec.

The x-ray diffraction pattern was obtained on cathodes discharged at a low rate in $LiAsF_6$-THF and $LiClO_4$-PC. The samples were analyzed under vacuum for 10 hr with the Debye-Scherrer method, using Cr-K_α radiation filtered by V.

The solubility of Bi_2O_3 in 1.5M $LiAsF_6$-THF was checked by polarographic analysis of the Bi^{+3} ion, after leaving Bi_2O_3 in contact with the above solution for 10 days. Blank experiments with a $LiAsF_6$-THF solution containing known amounts of $BiCl_3$ (which is fairly soluble in this solution) were also made.

Visual observations of $LiAsF_6$-THF and $LiAsF_6$-BL solutions containing Bi_2O_3 did not give evidence of unwelcomed reactions, because neither discoloration nor gassing were noticed.

Experimental Results

The OCV of cells of the type Li/organic electrolyte/Bi_2O_3 (with or without C at the cathode) exceeded 3V. However, even at low rates of discharge the potential dropped well below 2V, thus indicating that the observed OCV is not the thermodynamic value of the Li/Bi_2O_3 couple. Graphite could, in principle, be responsible for the high OCV through the formation of intercalation compounds, but even Ag pellets give the same OCV although the formation of lithium-silver compounds should give rise to potentials lower than 200 mV in these solutions (13). Also the presence of O_2 in the system cannot explain the OCV, since the emf of the Li/O_2 couple is equal to 2.9V. On the other hand, we observed that the OCV varied with the electrolyte used. The averages of several cells give values for $LiClO_4$-PC, $LiAsF_6$-BL, and $LiAsF_6$-THF of 3.0, 3.1, and 3.4V, respectively. Therefore, the initial OCV has to be related to the presence of electroactive impurities, mainly due to the solvents, incompletely eliminated by purification. For instance, THF contains peroxides (14) which can form a couple of high voltage with Li.

Table I. Performances of Li/Bi_2O_3 cells containing various electrolytes. 1.0V cutoff, 0.5 mA/cm^2

Electrolyte	$\chi \cdot 10^{-3}$ (Ω^{-1} cm^{-1})	Specific capacity A-hr/g	Specific capacity A-hr/cm^3	Mean discharge voltage (V)	Utilization (% based on 12*e*)
$LiAsF_6$-THF	16	0.380	3.38	1.49	55
$LiAsF_6$-BL	9.2	0.300	2.67	1.49	43
$LiClO_4$-BL	13	0.155	1.38	1.34	23
$LiClO_4$-PC	5.6	0.224	1.99	1.36	32
$LiAlCl_4$-BL	10	0.184	1.63	1.43	27
$LiClO_4$-MF/BL	27	0.100	0.89	1.39	10

Polarization curves for Bi_2O_3 in different solutions were measured. The rapid increase of the voltage drop with current indicates that this material can be useful only at low rate applications. In the range 0-3 mA/cm^2, the polarization decreases in the order $LiAsF_6$-THF, $LiAsF_6$-BL, and $LiClO_4$-PC. The same order has been found for the discharge behavior at 0.5 mA/cm^2, as shown in Table I where the results in three more solutions are also reported (the specific capacity is referred to Bi_2O_3 only). It can be seen that the performance of Bi_2O_3 cannot be connected to the specific conductivity of the solutions (values in the 2nd column), *i.e.*, mass transport phenomena have a minor effect on the electrode polarization. Gabano (12) has proposed a reaction scheme for cathodes not conducting and unable to form intercalation compounds, in which the locus of reduction is in the solution layers immediately near the cathodic surface. Obviously, the structure of these layers would be differently influenced by the various electrolytes through adsorption and solvation/dissolution phenomena.

In Fig. 1 the discharge curves in $LiAsF_6$-THF at different current densities are reported. An initial voltage delay is shown which was also present in all the other solutions. On the other hand, cathode materials such as Ag_2CrO_4 and Ag_3PO_4 do not exhibit such behavior in the same solutions (9), thus indicating that it may be connected with the low solubility of the cathode, *i.e.*, with its low concentration in the solution layers near the electrode (12).

The low solubility of Bi_2O_3 in $LiAsF_6$-THF was ascertained polarographically. A reduction wave of Bi^{+3} was not found with this material, whereas blank experiments with $BiCl_3$ revealed a well-defined reduction wave even at a concentration of 1×10^{-4}M. Obviously, a low solubility is desired in that it can give rise to a long service life. However, no data were obtained in this work on the storage capability of cells based on Bi_2O_3.

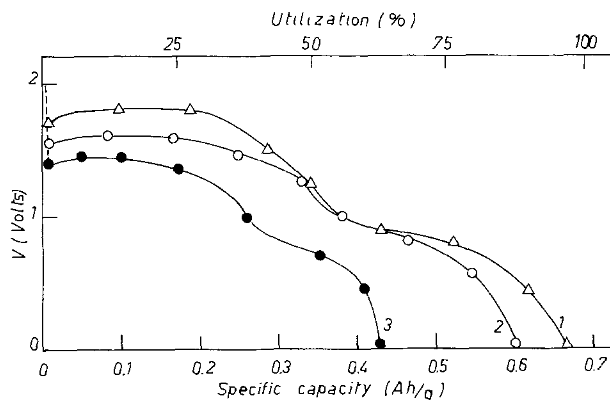

Fig. 1. Discharge curves of Li/Bi_2O_3 cells in $LiAsF_6$-THF at different rates. Curve 1, 0.25 mA/cm^2; curve 2, 0.50 mA/cm^2; curve 3, 1.00 mA/cm^2.

Table II. Influence of the temperature on the performances of $Li/LiAsF_6$-BL/Bi_2O_3 cells. 1.0V cutoff, 0.5 mA/cm^2

Temperature (°C)	Specific capacity A-hr/g	Specific capacity A-hr/cm^3	Mean discharge voltage (V)	Utilization (% based on 12e)
24	0.300	2.67	1.49	43
40	0.331	2.94	1.55	48
60	0.350	3.11	1.57	55

In Table II the influence of the temperature on $Li/LiAsF_6$-BL/Bi_2O_3, C cells is reported. BL was used as a solvent instead of THF, because of the difficulties that may be encountered with the latter at 60°C, since its boiling point is 64.5°C. Evidently, the positive effect of the temperature on solution conductivity and cathode polarization is not counterbalanced by an increase in cathode solubility, which would result in capacity losses. In particular, the result obtained at 40°C can be of some interest if these cells were to be used in cardiac pacemakers.

$BiPO_4$, Bi_2S_3, and $Bi(IO_3)_3$ were also tested. The first salt has a specific energy of 0.29 W-hr/g (which does not compare well with 0.57 W-hr/g obtained for Bi_2O_3), whereas the last two salts show poor discharge behaviors.

The performance of Bi_2O_3 (a two-step reduction process which corresponds to a high experimental capacity) was confirmed by the analogous Sb_2O_3. Also with this oxide good values of specific capacity and energy have been obtained (0.39 A-hr/g and 0.51 W-hr/g at 0.5 mA/cm^2 to 1.0V cutoff, respectively).

Discussion

The specific capacities to zero volt cutoff in $LiAsF_6$-THF (0.60 A-hr/g) and in $LiAsF_6$-BL (0.53 A-hr/g) are higher than the maximum calculated on the basis of the simple reduction of Bi_2O_3 to Bi (0.345 A-hr/g). These high capacities were rationalized through coulometric analysis at low rate, from which it was calculated that 12 electrons are involved in the discharge of each molecule of Bi_2O_3. The discharge has two steps (Fig. 1). The first one, ending a little below 1.0V, is calculated to involve 6 electrons to give the observed specific capacity (0.34 A-hr/g). A 12-electron process implies the formation of compounds in which Bi is in a negative oxidation state.

Indeed, As, Sb, and Bi are known to form with Li compounds of the Li_3Me type both chemically (10, 15) and electrochemically (16). On the basis of these observations and of the coulometric analysis, the discharge process may be written as follows

$$6Li + Bi_2O_3 \rightarrow 2Bi + 3Li_2O \qquad [1]$$

$$2Bi + 6Li \rightarrow 2Li_3Bi \qquad [2]$$

The net reaction is

$$12Li + Bi_2O_3 \rightarrow 2Li_3Bi + 3Li_2O \qquad [3]$$

The x-ray diffraction data (Table III) confirm the formation of Bi (especially with the lines having dÅ 2.38 and 2.27), whereas the presence of Li_2O is made uncertain by the coincidence of its principal lines with those of α-Bi_2O_3.

The possibility that the second step (occurring below 1V) could be connected with electrolyte decomposition (12) was greatly reduced by the fact that graphite-free cathodes were frequently used. Anyway, Li/Bi cells with or without graphite, when discharged in $LiAsF_6$-THF, showed very similar values of experimental specific capacity, which resulted near to the theoretical value for the formation of Li_3Bi (0.385 A-hr/g).

Reaction [1] has a ΔG of −283 kcal/mole and a theoretical E_o of 2.05V. This value is in agreement with the 2.0V OCV observed during the initial part of the first discharge plateau.

Table III. X-ray diffraction data for Bi_2O_3 discharged in $LiAsF_6$-THF

Experimental (dÅ)	Literature values (dÅ) α-Bi_2O_3	Bi	Li_2O
3.25 (VS)	3.23 (VS)	3.28 (VS)	2.66 (VS)
2.65 (S)	2.75 (W)	2.38 (M)	2.30 (W)
2.36 (S)	2.68 (S)	2.27 (M)	1.63 (M)

1.33 (M)	1.48 (MW)		
1.31 (M)	1.46 (MW)		
1.28 (W)	1.34 (M)		
1.18 (W)	1.32 (M)		
1.04 (W)	1.27 (MW)		
0.94 (W)	1.17 (MS)		

VS, very strong; S, strong; MS, medium strong; M, medium; MW, medium weak; W, weak.

No data for the free energy of formation are reported for Li_3Bi at room temperature. Extrapolation to 25°C of ΔG values obtained at high temperatures (17) gives $\Delta G = -56$ kcal/mole. Therefore, reaction [2] has a theoretical $E_o = 0.81V$. This potential is in agreement with an OCV of 0.8V experimentally found by us and by Eichinger (16) for Li/Bi cells.

With reaction [3] a theoretical energy density of 835 W-hr/kg was calculated. From a cell $Li/LiAsF_6$-THF/Bi_2O_3, having a capacity of 50 mA-hr and discharged at 0.5 mA/cm^2, an over-all energy density of 200 W-hr/kg was achieved on the basis of the weight of anode, cathode, solution, and separators. This figure is expected to be increased by working at lower rates and by optimizing the cell structure. Also the volumetric energy is expected to be quite high in view of the density of Bi_2O_3. In Table IV, the performance of several cathode materials tested in this laboratory are compared. The comparison is especially important with respect to MoO_3, Ag_2CrO_4, and Ag_3PO_4 which have been extensively studied also in other laboratories (11, 18) due to their practical interest. Parameters such as cell life and volume variations during discharge have to be carefully evaluated. The low solubility of Bi_2O_3 in organic solutions and the results of preliminary compatibility tests suggest a satisfactory cell life. The performance of Bi_2O_3 reported in the present paper is sufficiently promising that it calls for further research to ascertain the feasibility of practical cells.

The Effect of Noble Metal Additions upon the Corrosion of Copper: An Auger-Spectroscopic Study

J. Gniewek,[1] J. Pezy, B. G. Baker, and J. O'M. Bockris*

School of Physical Sciences, Flinders University of South Australia, Adelaide, Australia

ABSTRACT

Dissolution rates as a function of potential and the corrosion potentials for Cu and five Cu-Pd alloys with varying compositions in the range of (0-30%) Pd were measured. The Auger spectra of the alloy surface and fresh surfaces obtained by argon ion bombardment to a depth up to 30 nm were obtained. Cu dissolves from the alloy and the rate of dissolution of Pd is negligible. The Cu dissolution follows the same laws as from pure Cu. Below a certain critical potential, the initially observed dissolution current decayed towards zero. The electrode potential at zero current follows the surface composition. At zero current the bulk alloy composition was found to have been modified to a depth of about 20 nm. An approximate calculation of i_0 for Cu dissolution of the alloy as a function of composition showed that value is reduced by some ten orders of magnitude compared with that of pure Cu. Corrosion is reduced in a manner consistent with these i_0 reductions when the cathodic O_2 reaction is not rate controlling.

Knowledge of the theory of corrosion in electrode kinetic terms is now widespread (1). However, alloying elements can give rise to commercially interesting reductions in corrosion rate, often more marked than one would have expected according to simple theory. The influence of noble metal alloying upon corrosion protection has not hitherto received studies which contained information sufficient for the evaluation of the mechanism of this effect.

Auger electron spectroscopy (AES) provides information about the composition of alloy surfaces and the relative composition changes in the first few nanometers from the surface. Several earlier studies on AgAu (3) and CuAu (4-6) have established that, as the gold content of the alloy increases, the electrode potentials shift in the positive direction. However, in these studies physical analysis of changes occurring within the alloy has been limited to those corresponding to a high rate of dissolution under external anodic potential control, rather than under corrosion control. The copper-palladium alloy system was chosen for AES study of the corrosion region for the following reasons:

(*i*) Similarly to the AgAu and CuAu systems, there is a significant difference in the standard electrode potentials of the two elements, thereby favoring preferential dissolution of copper.

(*ii*) Copper and palladium form a complete solid solution series (although at low temperatures the β equilibrium phase forms at ~40 atomic percent (a/o) Pd) permitting study of corrosion behavior of the alloy over a wide composition range.

(*iii*) Cu and Pd provide favorable noninterfering Auger spectra.

(*iv*) The ion sputtering yields of Cu and Pd are nearly equal (7), simplifying interpretation of the composition-depth profile measurements obtained by AES studies combined with argon ion bombardment of surfaces arising from corrosion.

Experimental

Alloys were prepared from 99.999% Cu and 99.99% Pd by induction heating melting in boron nitride crucibles under pure argon. The material was held for 15 min at ~100°C above the melting point, solidified, and upon inverting the ingot, remelted for another 15 min. Weight change before and after melting was <0.01%, indicating negligible reaction with the crucible material. The ingots were then cold rolled to strips approximately 0.3 mm thick by 27 mm wide. After cutting into specimens for electrochemical and AES measurements the specimens were cleaned and vacuum annealed for

Key words: palladium, passivity, composition depth profile, dissolution rate.

16 hr at 920°C followed by rapid cooling to room temperature. In addition to alloys of 5, 10, 15, 20, 30 a/o Pd[2] pure Cu and alloys of 80/20 CuAu and 80/10/10 CuPdAu were also prepared.

Two types of specimens were used. Type A, which was used to establish the initial log *i-V* relationships, was circular with 14 mm diam. Prior to electrochemical measurements, the specimen surface was prepared by grinding with 600 grit paper and rinsing with distilled water and alcohol. To obtain meaningful composition depth-profiles, it was found necessary to polish the specimen to a mirror finish. Type B specimens (23 × 9 mm rectangular) which were used for subsequent electrochemical treatments and all AES measurements, were therefore further polished with diamond polishing paste prior to ultrasonic cleaning in distilled water and an alcohol rinse.

Electrochemical apparatus.—All investigations were conducted at room temperature in 0.5M Na_2SO_4-0.005M H_2SO_4 electrolyte. A calomel electrode was used as the reference cell. The potentials reported here are given on the standard hydrogen electrode (SHE) scale. Except where stated, the solution was deoxygenated by bubbling N_2 for several hours.

Initial log *i-V* measurements were obtained using Type A specimens in a standard electrochemical cell (8). Subsequent electrochemical measurements were performed on Type B specimens in an electrolyte flow system cell of similar design to that used by Damjanovic, Setty, and Bockris (9). The Teflon cell was machined with a thin Teflon perimeter ridge so that when held in compression against the specimen a liquid-tight seal was effected with the alloy specimen forming one wall of the cell. With the cell assembled, the volume between the specimen and the Pt counterelectrode was 0.3 cm^3. Electrolyte flow rates in the range of 0.01-0.1 ml/sec were used during electrochemical treatment. A valving arrangement permitted rapid electrolyte removal under N_2 gas followed by rinsing with distilled H_2O and drying in N_2 gas flow. The specimens were held in the N_2 ambient until ready for transfer to the vacuum system for AES measurements. Transfer between the electrochemical apparatus and the vacuum for the AES required exposure to the air ambient of less than 5 min.

Auger apparatus.—The AES equipment was constructed in this laboratory. A retarding grid electron energy analyzer with a post-monochromator after the design of Huchital and Rigden (10) was mounted in a Pyrex tube. A bakeable straight-through high vacuum valve connected the Auger analysis vacuum chamber to an auxiliary liquid nitrogen-trapped oil diffusion pumped vacuum chamber. Following removal from the electrochemical cell the sample was mounted on a stainless steel specimen holder which could be raised and lowered through a feed-through mounted on the auxiliary chamber. After evacuation of the auxiliary chamber to approximately 2×10^{-4} Torr, the sample was transferred to the Auger chamber via a straight-through valve, the transfer rod was withdrawn, and the high vacuum valve closed. AES analysis was begun when the vacuum reached the 10^{-8} Torr range. The auxiliary vacuum chamber and the electrochemical cell were designed so that the latter could be operated in the chamber with the sample being transferred to the Auger vacuum chamber without exposure to the air ambient. However this feature was not utilized in these experiments.

The axis of the energy analyzer was along a line normal to the sample. The axes of the energy analyzer, primary electron beam, and ion gun all lay in the same plane. A 2.4 kV primary electron beam was incident at an angle of ~25° (65° off normal) while the 1 kV argon ion beam was incident at an angle of 25° from the opposite direction. The primary electron beam of ~1.5 mm diam was operated in the center of the ion beam which was defocused to a diameter of 10 mm.

[2] All alloy compositions are reported as atomic percent.

The argon pressure during bombardment was kept between 2×10^{-5} and 5×10^{-5} Torr. The ion-beam current monitored at the specimen was used as a measure of the sputter removal rate. Ion bombardment and AES were performed sequentially, the ion beam being turned off during each AES measurement. The calibration of the sputter removal rate was made by measuring the time required to remove a 90 nm Cu film, which had been vacuum deposited over an evaporated film of Cr. The distance axis of the concentration profile graphs are labeled in angstroms utilizing this calibration result.

Auger analysis.—The dN/dE spectra were recorded utilizing a 7.5V p·p modulation voltage for the 330 eV Pd peak and an 18V p·p modulation voltage for the Cu 918 eV peak. The composition, reported as atomic fraction of palladium, X_{Pd}, was calculated from the measured peak-to-peak heights of the Pd and Cu peaks, by the formula (11)

$$X_{Pd} = \frac{A_{Pd}}{A_{Pd} + \alpha A_{Cu}} \quad [1]$$

While in principle the value of α can be obtained by direct comparison of spectra from the alloy and from pure copper, this method was found to be reliable only when very lightly sputtered samples are compared. Sputtering caused an increase in the copper peak from both alloy and pure copper, presumably due to the effect of surface roughening. Instead, taking the initial surface composition to be that of the bulk, the value of α was determined from Cu and Pd peak height. Measurements were made on 10, 20, and 30 a/o Pd alloys which were mechanically polished and very lightly ion bombarded to remove C contamination. Calculations made from the Cu and Pd peak heights before ion bombardment and correcting for the intensity absorption due to the contaminant overlay film support the assumption that little (*i.e.*, < 3 a/o Pd) surface composition change is caused by the ion bombardment. Measurements on the various alloy samples are reproducible within ±1 a/o Pd. Samples pretreated electrochemically had a lower surface contaminant level than those not so treated and representative surface composition measurements could be made prior to any ion bombardment without the need for intensity correction.

Surface composition determination with concentration gradient.—In cases where the composition changes significantly within distances comparable to the Auger electron mean free path (as found for electrochemically treated specimens), it is necessary to apply a correction factor to determine the true surface composition. For conditions where the concentration gradient can be approximated by an exponential function with characteristic length d, it can be shown that the true surface composition is given by (see Appendix)

$$X_{Pd,surf} = X_{Pd,bulk} + \left\{ \frac{X_{PM} - X_{Pd,bulk}}{d\left[\frac{1}{d + \lambda_{Pd}} - X_{PM}\left(\frac{1}{d + \lambda_{Pd}} - \frac{1}{d + \lambda_{Cu}}\right)\right]} \right\} \quad [2]$$

where λ_{Cu} and λ_{Pd} are the Auger electron mean free paths for copper (1.1 nm) and palladium (0.75 nm). $X_{Pd,bulk}$ = bulk concentration, X_{PM} = measured surface composition calculated from Eq. [1], and $X_{Pd,surf}$ = actual surface composition. Results obtained in this manner indicate that the actual surface compositions could be as much as 5-10 a/o Pd higher than the measured uncorrected determinations, depending upon the concentration gradient.

Results

Electrochemical results.—Steady-state rate potential relations.—The so-called steady-state log *i-V* curves

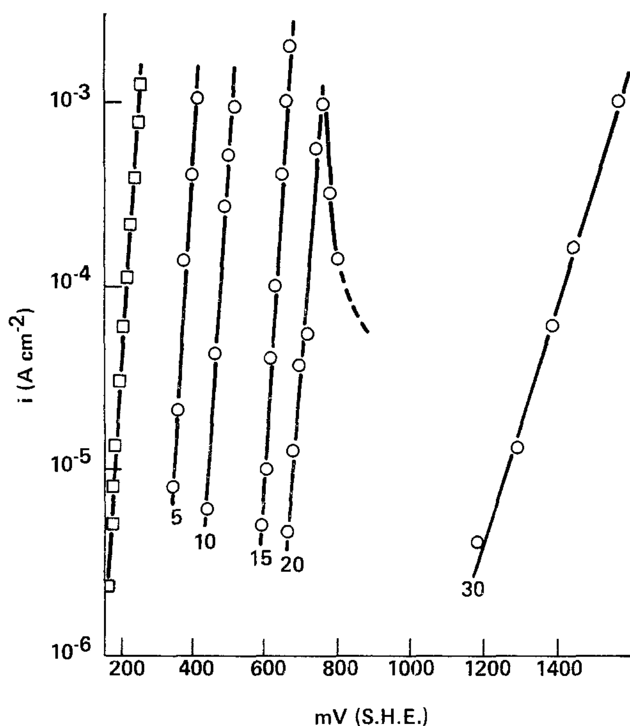

Fig. 1a. Log *i-V* relationship for Cu, Cu-5% Pd, Cu-10% Pd, Cu-15% Pd, Cu-20% Pd, Cu-30% Pd alloys.

for various alloy compositions are shown in Fig. 1a. The potential intercept where the current rises rapidly above 10^{-6} A/cm² can be termed the critical potential, E_c (5). These results were obtained on Type A specimens under potentiostatic control with the current read at 15 min intervals. In the potential range shown, below E_c, where there was no steady-state current, it was necessary to wait 1-2 hr before increasing the electrode potential, in 50 mV increments, to obtain well-defined values of E_c. For each alloy composition within the potential range shown, the results do not differ significantly from those obtained on Type B specimens in the flow cell. There were, however, appreciable differences between the two specimens in the current-time dependence at potentials, $E < E_c$; as discussed in the next section. In the higher current region ($\sim 10^{-4}$ A/cm²) the current on both specimens increased with time after an interval of less than 1 sec.

In Fig. 1a is shown the introduction of passivity at a potential of + 760 mV SHE for the 20% alloy. The result obtained for the 30% Pd alloy differs from the others with respect to the slope of the log *i*-potential relation. Oxygen was evolved under some conditions from this electrode. The results in the first five curves (Fig. 1a) represent the dissolution of copper (characteristic Tafel slope, $2RT/3\mathbf{F}$), while the result for the 30% alloy corresponds to oxygen evolution. For samples held at $\sim 2 \times 10^{-4}$ A/cm² dissolution current for 1 hr, significant grain boundary attack was observed for the 15 and 20% samples.

In Fig. 1b, a comparison of the log *i*-potential results obtained for 80/20 CuPd, 80/20 CuAu, and 80/10/10 CuPdAu is shown. The passivation which sets in for the 20% PdCu alloy is not seen for the gold-containing alloys.

Constant potential current-time relations.—Some initial work was done on log *i-V* curves on pure Cu, thus introducing some Cu^{++} into solution. Subsequent work with alloys was done at lower currents and shorter times than was the initial work with pure Cu. Such measurements lie at the basis of Fig. 1. This same electrolyte was used in all the flow cell measurements and so provides a constant reference for all potentials. In the flow cell, almost all of our work was done at or below the "critical potential," *i.e.*, the final resting current before the electrolyte was blown out

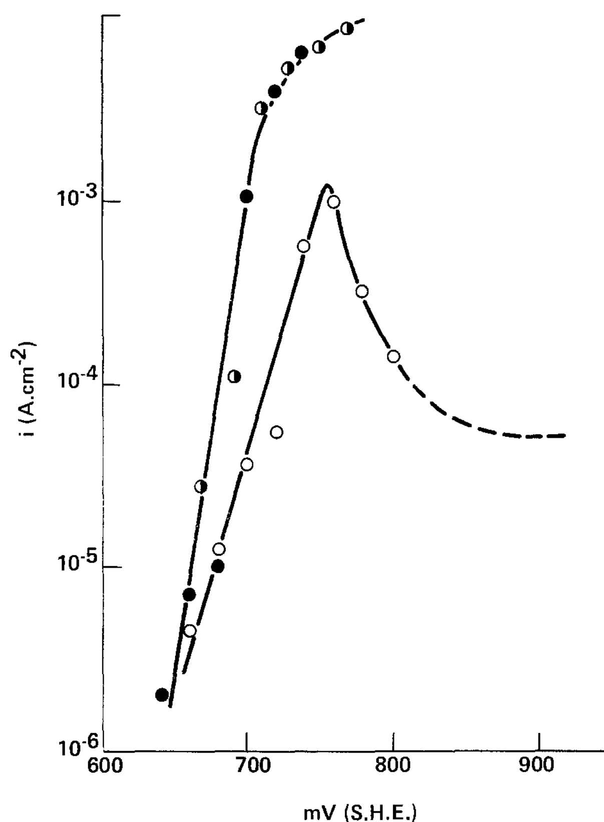

Fig. 1b. Log *i-V* relationship for ○—Cu-20% Pd, ●—Cu-20% Au, ◑—Cu-10% Au-10% Pd.

and the sample submitted for Auger analysis was very low, and, therefore, did not affect the Cu^{++} level of the solution flowing by.

In the potential region less positive than E_c, following a potential step increase, the current showed a step-like increase and subsequent decay. The current decay period was longer for Type A specimens, with current densities of a few microamp/cm² persisting after 2 hr. Except for potentials close to E_c, the current decreased to zero for Type B specimens. The total charge passed for a given potential jump increase could be as much as 5-10 times greater for Type A samples compared to Type B. The Auger data discussed apply to Type B (mechanically polished) samples.

The effect of applying successive 50 mV potential increases is shown in Fig. 2 for the alloy. Following a

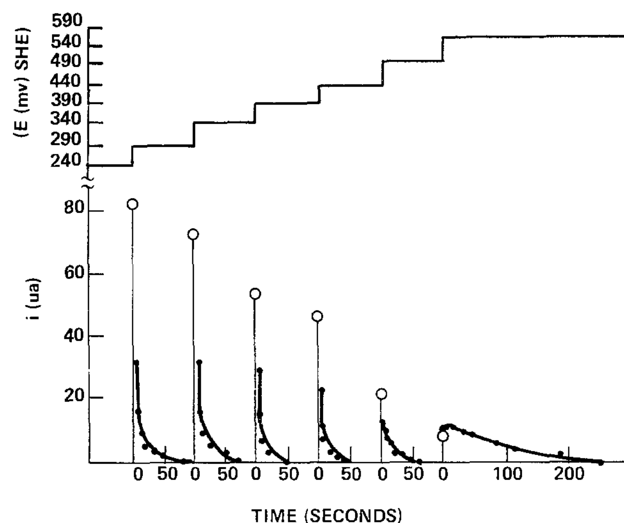

Fig. 2. Current-time behavior for successive 50 mV potentiostatic step increases for Cu-15% Pd alloy. ○ maximum current 15% Pd. Electrode potential shown in upper portion of diagram.

potential increase, the current was allowed to decrease to zero whereupon a second 50 mV potential increase was applied, the process being repeated until the critical potential was reached. As the electrode potential increases, there is a decrease in the maximum current attained for the same potential step increase. As the potential approaches E_c, the decay time increases.

Corrosion.—When the alloy was exposed to the electrolyte without being driven potentiostatically, the electrode potential changed to E_c in a time dependent upon the oxygen content of the electrolyte. The condition of holding the alloy potentiostatically and allowing the current to decay to zero corresponds to a corrosion situation near to the natural one. For set potentials at times when the net current falls to zero, the alloy was removed from the electrolyte and the surface composition measured by AES. The relationship between the corrosion potential and surface composition obtained is shown in Fig. 3 Figure 3 also contains points for the free corrosion situation and for the initial electrode potential measured when the alloy first contacts the electrolyte and before appreciable electrode potential drift has occurred.

AES results.—The Auger spectra from a 70/30 CuPd alloy are shown in Fig. 4. Palladium compositions were calculated utilizing the Pd(330 eV) and Cu(918 eV) peaks and Eq. [1]. The composition depth-profile results for different conditions of potentiostatic control are shown in Fig. 5-7. Surface enrichment by Pd is noted. Figure 5 demonstrates the results of potentiostatically controlling the potential of a 10% Pd alloy at +341 mV SHE for various times. In curve (a) the sample was removed after 480 sec when the current decreased to zero. In curve (b) the alloy was removed after 12 sec when the current had decreased to 4×10^{-5} A/cm^2. The latter case corresponds to ½ the total charge passed at this potential.

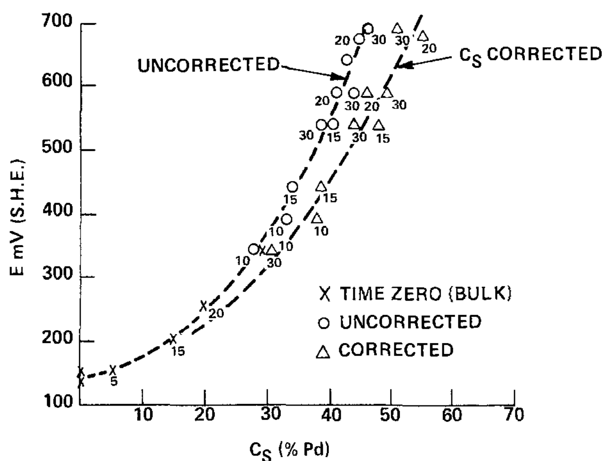

Fig. 3. Surface composition (%Pd) vs. electrode potential. Surface composition determined when net current decreased to zero. All potentials $E < E_c$ for all alloys. ○—C_s as measured; ΔC_s corrected for concentration gradient as described in text; X = initial electrode potential reading for different bulk alloys. Subscripts refer to Pd bulk alloy composition.

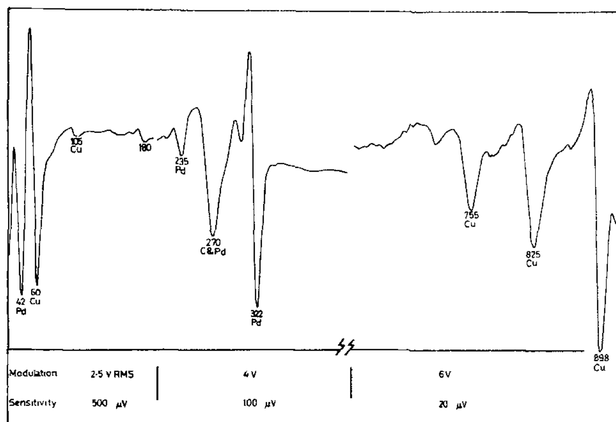

Fig. 4. Auger electron spectra for 70/30 CuPd alloy

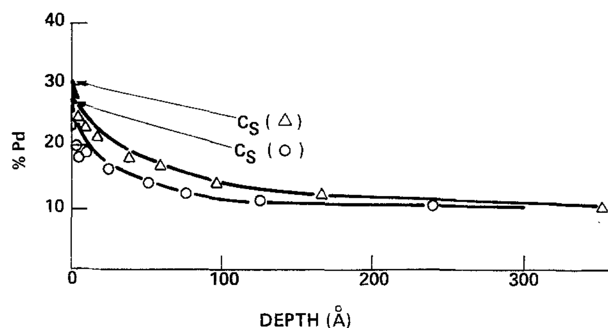

Fig. 5. Composition-depth profile; Cu-10% Pd alloy potentiostated to + 341 mV (SHE). △, t = 480 sec (i = 0); ○, t = 12 sec (i = 40 µa). ○, △; measured data points/full line; corrected composition as described in text.

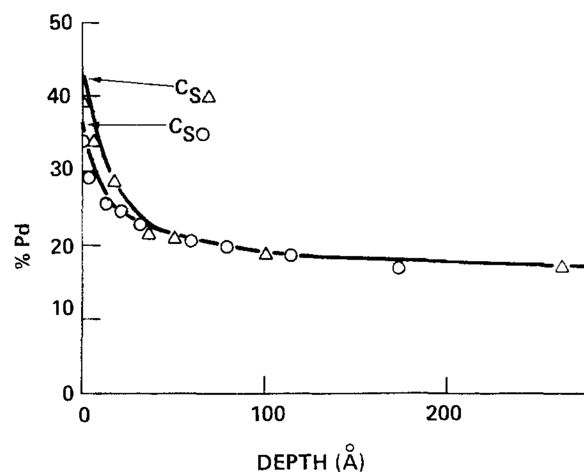

Fig. 6. Composition-depth profile; Cu-15% Pd alloy potentiostated to 441 mV (SHE)○ and 541 mV (SHE)△. ○, △; measured data points/full line; corrected composition as described in text.

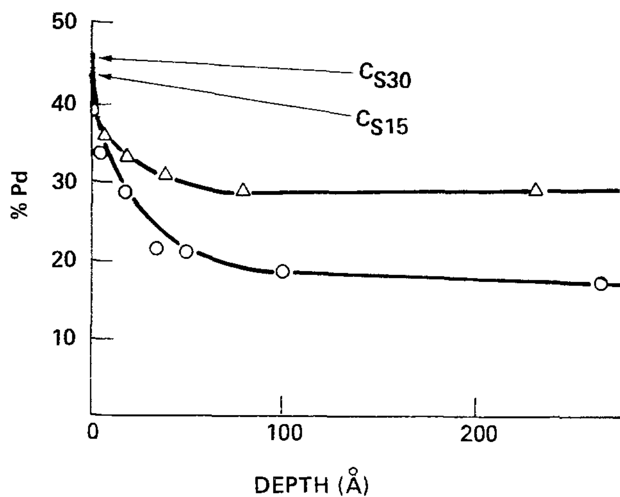

Fig. 7. Composition-depth profile for alloys potentiostated to 541 mV (SHE) △—30% Pd alloy. ○—15% Pd alloy. △, ○ measured points/full line; corrected composition as described in text.

Figure 6 illustrates the concentration profiles obtained after potentiostatic control of a 15% alloy to 441 and 541 mV. In both instances the alloy was removed when the net current decreased to zero, *i.e.*, when corrosion conditions pertain. Figure 7 illustrates the dif-

ference obtained in potentiostatically controlling a 20 and 30% alloy to 541 mV. The alloys were removed from the electrolyte when the current decreased to zero. A key factor to note is that the surface composition is nearly the same for a given set potential independent of the bulk alloy composition and that the concentration gradient is correspondingly steeper for the lower concentration alloy.

Discussion

Exchange current density: An order of magnitude estimate.—The positive shift in electrode potential required for the anodic dissolution of copper from copper-palladium alloys is similar to that observed for CuAu alloys (4-6). This potential shift is greater than that which can be attributed to changes in the reversible potential of Cu in the alloy due to the reduced activity of copper compared with that of pure Cu. The change in the reversible electrode potential, compared to pure copper, as a function of palladium content can be estimated from the thermodynamic data given by Hultgren *et al.* (12). With ΔG_{Cu} values calculated at 278°K from the tabulated values of ΔH_{Cu} and ΔS_{Cu}, the change in the reversible potential $2F(E_{rev}^{alloy} - E_{rev}^{Cu}) = -\Delta G_{Cu}$, is calculated as a function of alloy content with the results tabulated in Table I. As a result of the formation of ordered phases at lower temperatures, these values could be slightly underestimated, but it is improbable that the alteration compared with the calculated values of Table I would exceed 10 mV.

The fact that the measured electrode potential at zero current is nearly 500 mV more positive than E_{rev}^{Cu} for an alloy with a 50% Cu surface composition (Fig. 3) suggests that the electrode potential is a mixed potential arising from an anodic copper dissolution current and a cathodic oxygen reduction current. The positive shift in electrode potential compared with the reversible potential of Cu in the alloy (Table I) is consistent with a decrease in the exchange current density, i_o, for copper dissolution as the palladium content is increased. An estimate of i_o as a function of alloy composition can be obtained from the data in Fig. 1a and the estimated values of the alloy reversible potential. The Tafel slope for the 5-20% Pd alloys is the same as for pure copper. Extrapolation of the log i-V plot back to the reversible potential corresponding to the estimated surface composition allows an estimation of i_o for that composition. The surface composition is taken from Fig. 3 and corresponds to that at the critical potential for each particular value of bulk composition. The pertinent values are given in Table II.

These extremely low values of the exchange current density for the dissolution of Cu from the alloy are to be compared with the measured value of $i_o = 4 \times 10^{-6}$ A/cm^2 for pure copper for this Cu^{++} concentration. The latter value compares not unreasonably with a value of 0.9×10^{-6} A/cm^2 calculated from the data of Mattson and Bockris (13) by using the relationship, $i_o^{(1)}/i_o^{(2)} = (C_{Cu^{++}}^{(1)}/C_{Cu^{++}}^{(2)})^{3/2}$, where $C_{Cu^{++}}$ equals 0.15 M/l in the work of Mattson and Bockris and is 1.7×10^{-6} M/l in the present work. The interpretation of such low values of i_o and their implications for corrosion are discussed in a later section.

The critical potential, E_c.—As the electrode potential becomes more positive, the palladium concentration at the surface during dissolution increases. This occurs both for potentiostatic control and under freely corroding conditions. Potential drift experiments conducted at different oxygen partial pressures show that oxygen reduction ($O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$) is the cathodic reaction. Thus, the quicker rise of the electrode potential for the oxygen-saturated solution compared to a N_2 bubbled solution is shown in Fig. 8. The stable corrosion potential obtained under freely corroding conditions corresponds almost to the critical potential. If the alloy is potentiostatically controlled at potentials more positive than this, the current voltage relationship follows the Tafel line shown in Fig. 1a. Thus, for a given bulk alloy composition, there is an upper limit to the amount of the palladium enrichment which may be attained before copper is anodically dissolved from the alloy with the characteristic copper dissolution Tafel slope.

Gerischer and Rickert (4) proposed that the surface mobility of Au increases with potential, thereby permitting nucleation of Au-rich areas and leaving access to anodic dissolution of the underlying copper. Pickering and Wagner (5) and Pickering and Byrne (6) proposed that copper is supplied to the surface via a divacancy diffusion process (*cf.* Bockris *et al.*). The vacancy concentration is assumed to be potential dependent, and E_c corresponds to conditions where surface roughening commences.

The composition depth profile changes with time during dissolution and this is shown for a 10% Pd alloy potentiostated at +341 mV in Fig. 5. The curve obtained after 12 sec corresponds to 50% of the total charge passed before the current drops to 0 at 480 sec. The surface composition attains its final value when the current drops to zero. As the potential is increased for a given composition of bulk alloy the surface composition is further enriched with palladium (Fig. 6). For a given electrode potential, the surface composition is approximately the same, independent of the bulk concentration, and evidence for this interesting result is given in Fig. 7. Here the 15% alloy has been held at

~ 30 mV more negative than its critical potential. It is noted that the concentration gradient is steeper than that existing for the 30% alloy which is at a potential well below its critical potential. Thus, at this condition both alloys have the same surface composition and show zero net currents at this potential. Yet, if the electrode potential is raised another 50 mV, the 15% sample will experience anodic dissolution of copper while the 30% alloy remains stable. The difference in the two alloys a few tens of millivolts below the critical potential of the 15% alloy is the magnitude of the concentration gradient.

Corrosion.—The degree to which palladium additions reduce the corrosion rate of copper depends upon the corrosion environment. Although the effective exchange current density decreases by several orders of magnitude for as little as 5 or 10 a/o Pd, the corrosion rate will not necessarily be reduced by the same factor. When the cathodic process is diffusion limited, there will not be a reduction in the alloy corrosion rate compared to pure copper until the alloy i_o for copper dissolution is reduced sufficiently so that the anodic and cathodic currents intersect in the activation-controlled region of the cathodic process. This is illustrated in Fig. 9. Here, the cathodic curve (oxygen dissolution) has been obtained in an O_2 saturated solution for a 30% Pd alloy which was first allowed to corrode freely to a stable corrosion potential. The anodic curves for the various composition alloys are obtained in an N_2 bubbled solution from the data of Fig. 1a. Thus, in spite of the considerable diminution in i_o, the 5% Pd alloy corrodes at the same rate as pure copper, and it is not until the alloy composition reaches 15 a/o Pd that significant reductions in corrosion rate are obtained. The corrosion rate data for this condition are summarized in Table III. These values will change as the value of the cathodic limiting current is changed. The limiting current will be affected by O_2 pressure, stirring, and introduction of impurities which allow alternative cathodic processes, respectively.

Conclusions

Significant findings of this study are summarized below.

1. Passivity of CuPd alloys sets in at 20 a/o of Pd.
2. Composition-depth studies show enrichment of Pd by up to 30%.

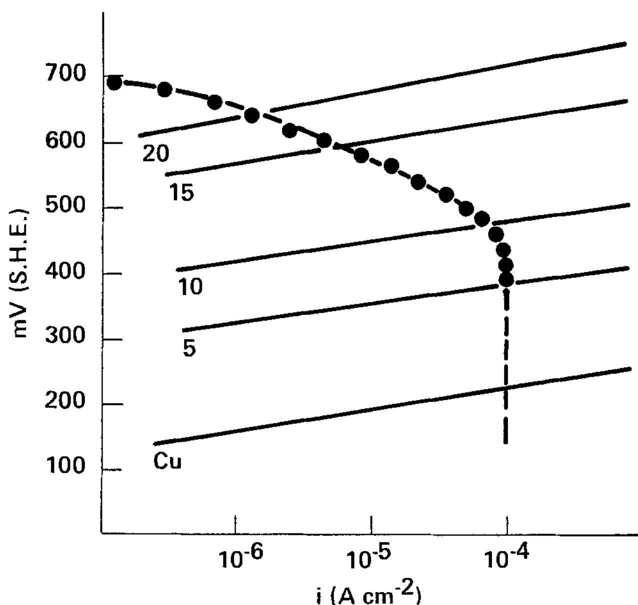

Fig. 9. Log *i-V* plot. Anodic curves for Cu, 5%, 10%, 15%, 20% Pd alloys obtained in N_2 bubbled solution. Oxygen reduction: ● cathodic curve obtained in oxygen-saturated solution for 30% Pd alloy.

Table III. Corrosion rate data for oxygen-saturated solution

C_b(Pd)	i_{corr} (μA/cm^2)	i_{Cu}/i_{alloy}	$V_{corrosion}$
0	100	1.0	215
0.05	100	1.0	380
0.10	72	1.4	475
0.15	5.4	18.5	595
0.20	1.15	87.0	642
0.30	0.3	333.0	680

3. The surface composition is the same under steady-state conditions, for a given potential and is independent of bulk composition.
4. Composition depth profiles are hence steeper for lower Pd concentrations.
5. Addition of Pd to Cu reduces the i_o for Cu dissolution by up to 10^{10} times for Pd concentrations of 20 a/o.

APPENDIX

Correction to Measured Composition Depth Profile for High Concentration Gradients

An expression is derived for the corrected surface composition assuming that the initial part of the concentration-depth profile can be approximated by an exponential function. For a homogeneous binary alloy, the Auger signal for component p is given by

$$I_p = K_p X_p \int_0^\infty \exp^{-Z/\lambda_p} dZ = K_p X_p \lambda_p \qquad [A-1]$$

where K_p is a constant incorporating ionization cross section, primary beam current, etc., z is distance into alloy measured from the surface, X_p = atom fraction of component P, and λ_p = Auger electron mean free path for component P.

Similarly $I_c = K_c(1 - X_p)\lambda_c$ for component C of a binary alloy. If X_p is calculated from

$$\frac{I_p}{I_p + \alpha I_c} \qquad [A-2]$$

then

$$\alpha = \frac{K_p \lambda_p}{K_c \lambda_c} \qquad [A-3]$$

Consider a composition gradient which can be approximated by an exponential function, $X_p = (X_{PS} - X_{PB}) \exp^{-z/d} + X_{PB}$, where X_{PB} and X_{PS} equal the bulk and surface compositions of component P, and d equals the exponential decay constant.

Then under this condition

$$I_p = K_p \int_0^\infty [X_{PB} + (X_{PS} - X_{PB}) \exp^{-z/d}] \exp^{-z/\lambda_p} dz$$

$$= K_p X_{PB} \lambda_p + K_p (X_{PS} - X_{PB}) \left(\frac{d\lambda_p}{d + \lambda_p} \right) \qquad [A-4]$$

Similarly

$$I_c = K_c(1 - X_{PB})\lambda_c + K_c(X_{PB} - X_{PS})\left(\frac{d\lambda_c}{d + \lambda_c}\right) \quad \text{[A-5]}$$

Then the measured composition, X_{PM}, calculated from Eq. [A-2] is given by

$$X_{PM} + \frac{\left[X_{PB} + (X_{PS} - X_{PB})\left(\frac{d}{d+\lambda_p}\right)\right]}{\left[X_{PB} + (X_{PS} - X_{PB})\left(\frac{d}{d+\lambda_p}\right)\right] + \left[(1 - X_{PB}) + (X_{PB} - X_{PS})\left(\frac{d}{d+\lambda_c}\right)\right]} \quad \text{[A-6]}$$

After rearranging and solving for X_{PS}, we obtain the surface composition, X_{PS}, in terms of the measured composition X_{PM}, the Auger electron mean free paths, λ_p and λ_c, and the composition-depth exponential decay constant d, which is obtained from the measured, uncorrected composition-depth profile

$$X_{PS} = X_{PB} + \frac{X_{PM} - X_{PB}}{d\left[\frac{1}{d+\lambda_p} - X_{PM}\left(\frac{1}{d+\lambda_p} - \frac{1}{d+\lambda_c}\right)\right]} \quad \text{[A-7]}$$

If d is $>>$ λ_p and λ_c the correction becomes negligibly small.

Reversible Optical Changes Within Anodic Oxide Films on Titanium and Niobium

C. K. Dyer[1] and J. S. L. Leach

Department of Metallurgy and Materials Science, University of Nottingham, University Park, Nottingham NG7 2RD, United Kingdom

ABSTRACT

During passage of cathodic current, large and reversible changes in ellipsometric parameters are interpreted in terms of changes in absorption and/or refractive index of surface anodic oxide films on Nb and Ti without significant change in thickness. A model based on dissolution and ionization of deposited hydrogen satisfactorily accounts for the slow reversible change in the optical absorption of films on Nb and for the impedance changes previously reported. More rapidly reversible changes in both absorption and refractive index occur in films on Ti. The decrease in refractive index is consistent with the reversible formation of TiOOH at negative potentials.

Decreases in electrode impedance of filmed Ti and Nb electrodes occur during cathodic polarization. On raising the electrode potential changes are largely reversible with only a small hysteresis in parallel resistance (R_p) and capacitance (C_p). A bulk mechanism was thought to be involved in which valency changes in the surface oxide films occurred (1). However, the size of the capacitance maximum in both cases was too small to confirm that a bulk faradaic reaction was occurring.

That hydrogen enters the anodic oxide films on Ti and Nb electrodes at low potentials has been demonstrated by measurement of coulombic capacities during potentiodynamic cycling (2). In the case of Nb electrodes the very low impedance at low potential was explained in terms of hydrogen doping of the surface oxide film (3) rather than as a result of a valency change (1). A similar mechanism was proposed to explain the impedance changes of anodic oxide films on Zr (4), and electrolytic rectification can also be explained in this way assuming a bulk oxide effect (2, 5).

Impedance measurements alone cannot justify a model based on bulk changes in the oxide films on Ti and Nb. Coulometric experiments are helpful (2) but the *in situ* optical changes presently reported confirm the bulk nature of the effects at low potentials on filmed Ti and Nb electrodes and support the proposed mechanisms.

Experimental

Specimens.—Spectroscopically pure Ti and Nb rod (Johnson Matthey Chemicals Limited, London) (Table I) was cut, milled, and abraded to reveal

[1] Present address: United Chemi-Con, Incorporated, West Springfield, Massachusetts 01089.

Key words: electrochromism, hydrogen, ellipsometry, impedance, electronic polarizability.

Table I. Spectrographic analysis of materials (impurity element in ppm)

Impurity element	Titanium	Niobium
Cu	40	—
Fe	20	40
Sn	20	—
Al	10	5
Ni	8	—
Si	5	30
Mn	4	—
Mg	<1	<1

a 0.33 cm^2 (Ti) or ~ 1 cm^2 (Nb) flat surface parallel to the rod axis. A Ti wire was permanently attached to the reverse surface and the specimen was anodized to ~200V in 3 weight percent (w/o) ammonium hydrogen tetraborate (99.99% pure) at 50 mA/cm^2 after degreasing in acetone.

After drying, the specimen and contact wire were coated with epoxy resin and hot-cured to give a leak-proof hard seal (6). Several coatings were applied and cured. To reduce the risk of surface beveling during subsequent polishing operations the specimen was mounted, flat surface downward, in thermosetting plastic in a standard metallurgical mounting press. The mounted specimen was abraded in a fixed position on a wheel until the metal surface emerged, which was finally polished also in a fixed position using alumina powder (5-30 nm particle diameter). Polished surfaces obtained in this way were satisfactorily flat. Surfaces were repolished before each anodic film growth.

Cell.—A cylinder, closed at one end, was machined from a block of clear Perspex to 6.3 cm (ID) × 7.6 cm (OD) × 6.5 cm (height). Holes were drilled in the sides to <2.5 cm diam so that their axes intersected at the center of the cylinder at an included angle of 140°. These holes were partly threaded to allow >2.5 cm diam annealed glass windows (F. Wiggins & Son, Sydenham) to be mounted against a PTFE washer, on an internal ledge, applying light pressure by turning a threaded pressure ring. In position, these windows were found to be almost free from strain birefringence and the resulting error was less than that of the ellipsometer itself (<0.015°).

The polished specimen surface was mounted vertically with a rigid clamping system having adjustments for rotation, tilt, and central positioning in the cell.

Ellipsometer.—An automatic ellipsometer with a maximum discrimination of 0.001° was used to follow optical changes during cathodic polarization of anodically filmed Ti and Nb electrodes. The instrument, designed and built by Matheson *et al.* (7), utilized a photoelectric detection system with faraday effect modulation. The light source was a water-cooled compact arc mercury lamp (Wotan HBO 100 W/2 Osram, West Germany). The collimated beam had a diameter of 2 mm and divergence of 0.2° at the specimen surface after passing through a modified Glan-Thompson polarizing prism and a modulator core (of dense SF 57 glass). After reflection from a test surface, the beam then passed through a second modulator core and analyzing prism before reaching the photodetection system. The azimuthal positions of the polarizing (P) and analyzing (A) prisms were measured by Moiré fringe counters to 0.001° and recorded digitally.

The retardation element was a three-reflection Fresnel rhomb (8) which allowed close to 90° retardation over the wavelength range available (from ~390 to ~610 nm). For operation at a single wavelength a quarter-wave mica retardation plate was used in conjunction with a narrow bandpass filter. The quarter-wave plate constants were then determined by four quadrant measurements.

The modulated signal arriving at the photomultiplier tube was electronically decoded and the error signals arising from the out-of-balance position of the polarizing and analyzing prisms were separated by two digital filters. The prisms were then automatically driven to balance positions at 1°/sec by servo motors in response to signals from the electronic decoding system.

The alignment procedure was to set the ellipsometer in the straight-through position and move the specimen surface to bisect the beam. The angle of tilt of the specimen surface was adjusted until, on reflection, there was no movement of the light beam image at the photomultiplier position at all angles of incidence (80°-40°). The sample position during this procedure was not altered since both arms of the ellipsometer were moved simultaneously. Using a dielectric mirror, the system was set so that the positions of the polarizer and analyzer were 0° and 90° ± 0.005° by the method of Forgacs (9). A full description and assessment of the system is published elsewhere (7).

Procedure.—Anodic films on polished Ti or Nb electrodes were grown galvanostatically at 1 mA/cm^2 in 3 w/o ammonium hydrogen tetraborate (99.99%) or 0.1M Na_2CO_3 + 0.1M $NaHCO_3$ buffer solution (AnalaR) both made up with doubly distilled water. From the automatically recorded P and A values tan ψ and Δ values (where tan ψ is the ratio of the resultant reflected amplitude in the plane of incidence and normal to this plane and Δ is the change in phase on reflection) were calculated (10) for a wide range of film thicknesses on each substrate. Polar plots (11) of the vector

$$\overline{Z} = \tan \psi \exp(i\Delta)$$

were compared with polar plots derived from hypothetical values of the film thickness, d, and constant complex refractive indexes of the metal substrate and surface film [$\overline{n}_s = n_s(1 - ik_s)$ and $\overline{n}_f = n_f(1 - ik_f)$, respectively] together with the refractive index of the electrolyte n_m (determined to 3 decimal places by Abbe refractometer). Experimental substrate constants n_s and k_s were determined by comparison of the experimental data with these theoretical polar plots and the assumption of a constant film refractive index (n_f variation <3%) and a zero absorption coefficient, k_f in the experimental data for different thicknesses (6). This is a more reasonable assumption than using "as polished" P and A values which led to calculated refractive indexes which increased with film thickness (6). Using these n_s and k_s values, film thickness, n_f and k_f were calculated using a standard computer program (11a).

During cathodic polarization a constant current was passed and P and A values were recorded together with the electrode potential. The cell was then open-circuited and the recovery of these parameters was followed as a function of time.

Impedance measurements.—Using a square-wave bridge technique described elsewhere (1), the parallel resistance (R_p) and capacitance (C_p) of the electrodes at 300 Hz were measured after the cell was open-circuited following cathodic polarization.

Results

Ti electrodes.—Application of a constant cathodic current density of 0.5 mA/cm^2 to anodically filmed electrodes resulted in rapid and large changes in P and A or Δ and ψ (Fig. 1). The cell was open-circuited at an electrode potential of ~ −1.15V (NHE)[2] which is the potential of the impedance minimum (1, 12) in the carbonate buffer solution (pH 9.7). P and A then returned rapidly to recover ~90% of the change in ~100 sec with complete recovery after 2 hr or on application of an anodic charge ~3 mC/cm^2. The electrode potential and impedance also recovered

[2] All potentials are referred to the normal hydrogen scale.

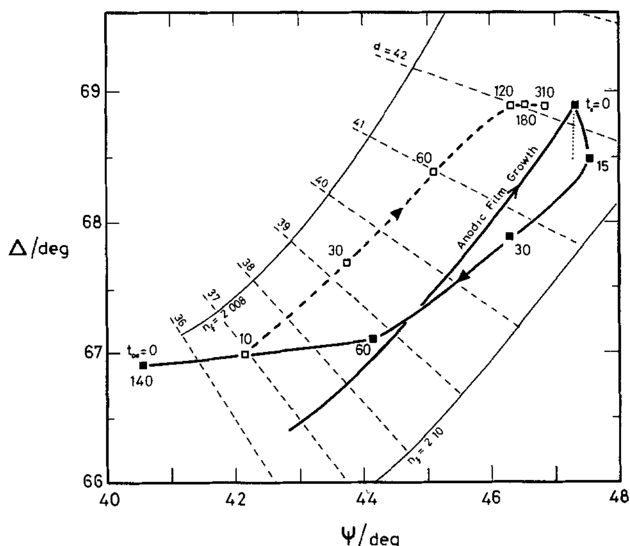

Fig. 1. Effect of a cathodic current (0.5 mA/cm^2) with time, t, on Δ and ψ of a filmed Ti electrode in carbonate buffer before and after open-circuiting at $E = -1.15V$ (NHE). λ = 546.1 nm, angle of incidence = 70°, n_m = 1.335. ■—■ with cathodic current, □- - -□ on open circuit (time in seconds is indicated during each stage). Also shown are calculated Δ/ψ relationships for constant n_f and k_f = 0 (——, variable d), constant d and k_f = 0 (– – – –, variable n_f), and constant d and n_f (. . . . . . ., increasing k_f) for n_s = 2.0, k_s = 2.7.

$\mu F \cdot cm^{-2}$, $\Delta R_p^{-1} = 7 \times 10^{-3} \Omega^{-1} \cdot cm^{-2}$, $\Delta n_f = 0.0115$, $\Delta k_f = 0.001$).

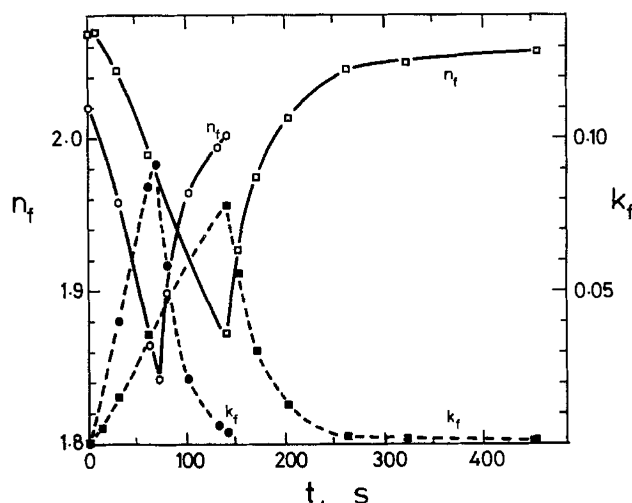

Fig. 2. Effect of a cathodic current (0.5 mA/cm^2) with time on optical parameters of anodic films on Ti before and after open-circuiting at $E = -1.15V$ (NHE): n_f (○), k_f (●) of 34.7 nm film (open circuit after 80 sec), and n_f (□), k_f (■) of 42.2 nm film (from Fig. 1 data) (open circuit after 140 sec) for n_s = 2.0, k_s = 2.7. λ = 546.1 nm, angle of incidence = 70°, n_m = 1.335.

rapidly on open circuit. If the change in ellipsometer readings was influenced wholly or partly by the formation of metallic hydride at the substrate, P and A readings would be irrecoverable on the observed time scale on open circuit because of the irreversibility of hydride formation (6, 12). The substrate was thus considered unaffected by this cathodic polarization.

To determine the effect of cathodic polarization on the thickness and optical properties of the surface film, a range of possible combinations of film thickness, d, refractive index, n_f, and absorption coefficient, k_f, were computed to fit the measured P and A combinations. Since there are only two measured parameters an assumption has to be made about one of the film parameters to determine uniquely the other two. The experimental Δ *vs.* ψ data (Fig. 1) show that the cathodic current does not simply cause film thinning, there is a movement, with time, of the data across lines of constant n_f and k_f. A constant film thickness during cathodic polarization was assumed because with the alternative assumptions that either n_f or k_f were constant, the measured P and A values could arise if the film underwent a large reversible change in thickness, *e.g.*, from 34.7 to 25.4 nm in the present case. It is unlikely that any significant amount of TiO_2 could be reduced to metallic Ti and then reoxidized reversibly and rapidly on open circuit to the original thickness even at the metal/oxide interface under the present conditions. Also reduction then oxidation of the substrate would change the optical constants significantly and irreversibly and thence the P and A readings, which was not the case.

Figure 2 shows that both n_f and k_f change with time during the passage of 0.5 mA/cm^2 cathodic current and on open-circuiting the cell. A constant film thickness is assumed throughout these experiments. For the thicker of the two surface films (42.2 nm) the changes were slower at the same current density.

n_f and k_f together with the electrode capacitance (C_p) and conductance (R_p^{-1}) are all related to time on open circuit, t, initially in a $t^{0.5}$ manner over the same period of time (Fig. 3 and 4). Recovery of C_p, R_p^{-1}, n_f, and k_f is not quite complete after 300 sec where there is a small net change ($\Delta C_p \simeq 19$

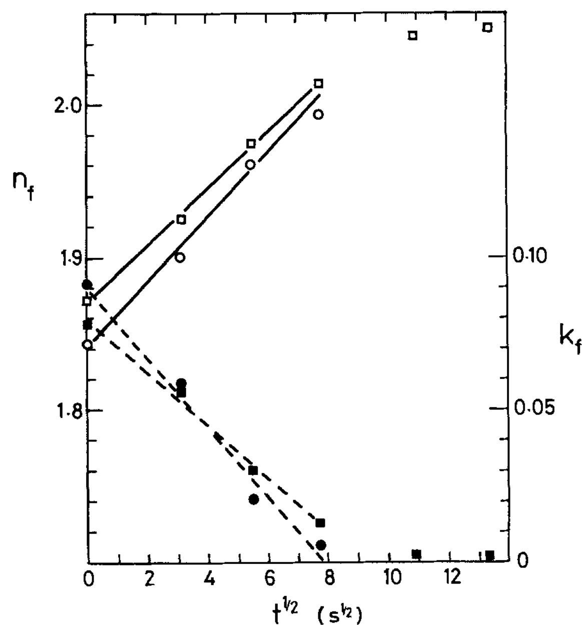

Fig. 3. Data from Fig. 2 plotted against (time on open circuit)$^{1/2}$

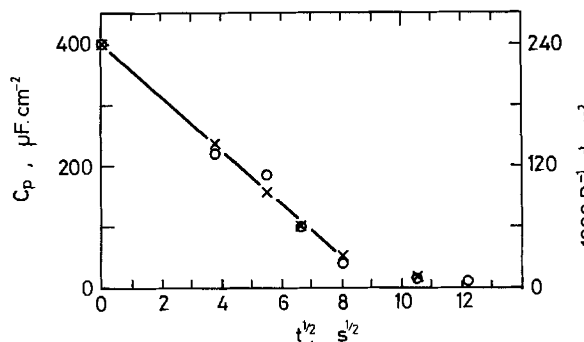

Fig. 4. Open-circuit decay from $E = -1.15V$ (NHE) of parallel electrode capacitance (X) and conductance (○) of Ti electrode filmed to 34.7 nm, in carbonate buffer solution.

Table II. Refractive indexes and derived polarizabilities at (i) −1.15V (NHE), (ii) the maximum change in n_f in carbonate buffer solution, for films (thickness, d) on Ti electrodes

	(i)		(ii)	
d (nm)	34.7	42.2	34.7	42.2
n_f (EXPTL)	1.8442	1.8678	1.7488	1.7577
$\alpha_{EXPTL} \div 10^{-23}$ cm³	0.451	0.447	0.413	0.405
TiOOH (%)	50.8	54.0	80.9	87.3

A more rapid change in n_f and k_f was found to accompany higher cathodic current densities on the same electrodes. After ~30 sec at 2.5 mA/cm², n_f and k_f became constant at values which were lower and higher, respectively, (Fig. 5, Table II) than at −1.15V (NHE) (Fig. 2). Increase in cathodic current density produced no further change. Recovery on open circuit was complete but slower (Fig. 5) than after less severe cathodic polarization (Fig. 3).

Nb electrodes.—The effect of cathodic current on Δ and ψ after anodic oxide growth on a Nb electrode is shown in Fig. 6. The data do not indicate simply film thinning. Recovery occurred on open-circuiting and was complete after long times or on passage of an anodic current [at fields too low for oxide film growth by ionic transport (2, 3)] (Fig. 6). It was thus considered unlikely that any significant film thinning occurred during passage of cathodic current since the observed reversibility of the phenomenon would require substantial film thickening under open-circuit conditions. The film thickness on Nb electrodes was assumed to be constant during cathodic polarization. Alteration of substrate optical constants by hydride formation in this case was again considered unlikely since the electrode showed complete recovery of *P* and *A* values on open circuit and the films had a low capacity for hydrogen (2). Surface hydride forms at very much higher cathodic current densities ~0.5 A/cm² (3) and its formation would be effectively irreversible during the time on open circuit.

Changes in n_f and k_f on passage of cathodic current were computed for films grown to 12.6, 28.7, and 51.9 nm on Nb electrodes. Changes in k_f comparable in magnitude and rate to those of the films on the Ti electrodes required much higher cathodic current densities (~10 mA/cm²) or thinner films (Fig. 7, 8, and 9). Recovery of k_f on open circuit was comparatively slow (Fig. 10) but faster following <10 mA/cm²

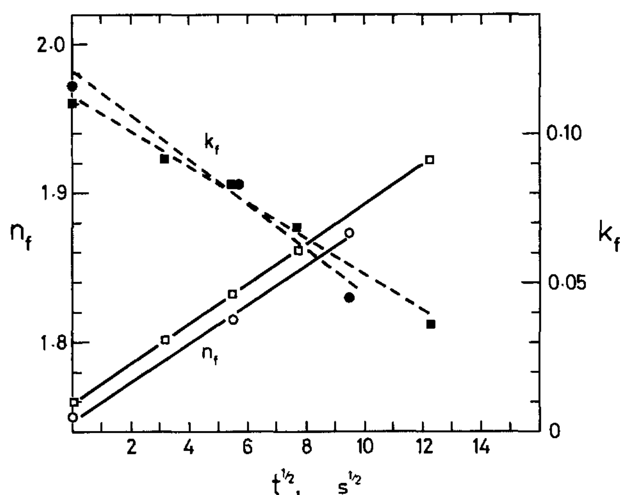

Fig. 5. Recovery of optical parameters of anodic films on Ti with (time on open circuit)$^{1/2}$ after 2.5 mA/cm² cathodic current for 45 sec (34.7 nm film; ○, ●) and 60 sec (42.2 nm film; □, ■).

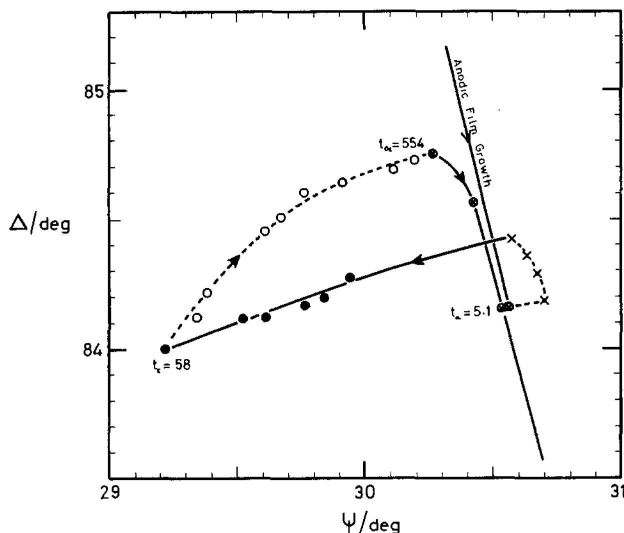

Fig. 6. Effect of cathodic current (10 mA/cm²) with time on Δ and ψ of a filmed Nb electrode. X---X open circuit after film growth, ●——● cathodic current, ○---○ open circuit, ⊗——⊗ anodic current (0.14 mA/cm²) (time in seconds indicated for each of these stages). λ = 546.1 nm, angle of incidence = 70°, n_m = 1.335.

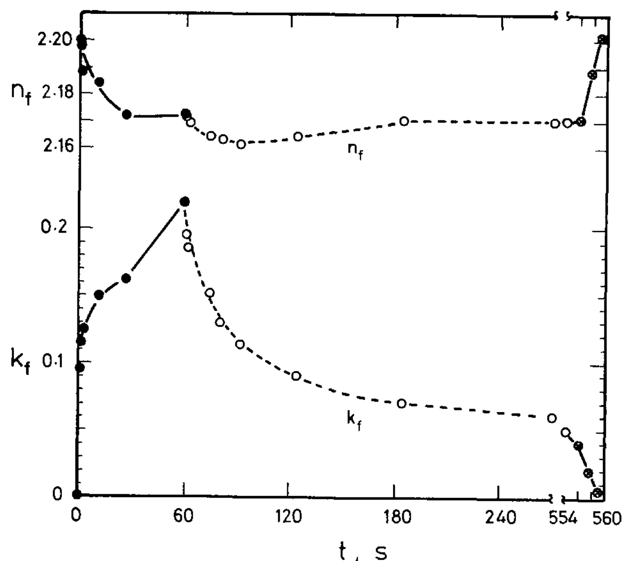

Fig. 7. Effect of cathodic current (10 mA/cm²) with time on optical parameters of 12.6 nm anodic oxide film on Nb electrode. Analysis of data from Fig. 6 with n_s = 2.85, k_s = 3.15.

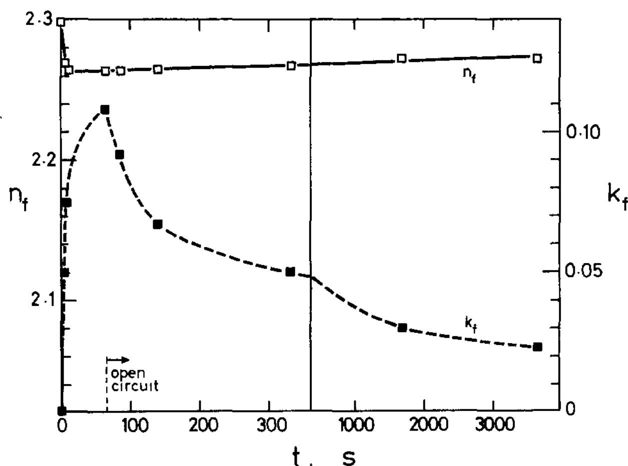

Fig. 8. Effect of cathodic current (10 mA/cm²) with time on optical parameters of 28.7 nm anodic oxide film on Nb electrode. λ = 405.0 nm, n_s = 2.7, n_m = 1.335, angle of incidence = 70°, k_s = 2.5.

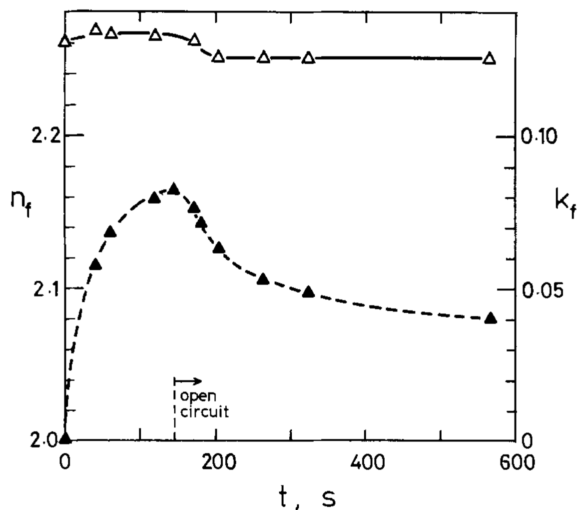

Fig. 9. Effect of cathodic current (10 mA/cm²) with time on optical properties of a 51.9 nm anodic oxide film on a Nb electrode. λ = 470 nm, n_s = 3.0, k_s = 2.9, n_m = 1.335, angle of incidence = 70°.

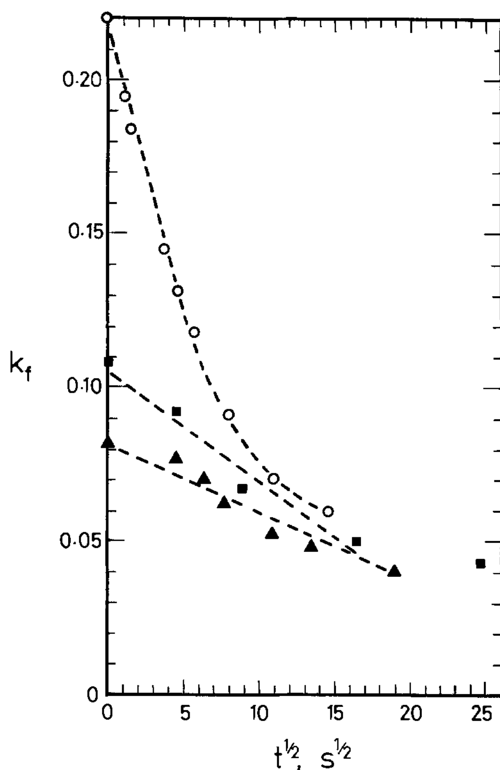

Fig. 10. Optical absorption data from Fig. 7-9 plotted against (time on open circuit)$^{1/2}$.

cathodic current density and was complete after $\geq$10 hr or on passage of a small anodic charge. Changes in n_f were small and slowly reversible in contrast to the behavior of the oxide films on Ti electrodes.

Discussion

The optical properties of oxide films on Ti and on Nb change reversibly during cathodic polarization and the results indicate that: (*i*) There is a significant difference between the optical behavior of the surface films on the two metals; (*ii*) the large changes in the optical parameters suggest that cathodic current flow modifies the bulk properties of the surface oxide films on both metals; and (*iii*) the speed of the decrease in n_f and/or increase in k_f is dependent on oxide thickness, cathodic current density, and the substrate metal. There is a difference in the rates of these changes between films on Ti and Nb electrodes.

Changes in k_f.—The impedance data for Ti electrodes show the same time dependence as n_f and k_f and have been shown previously to be characteristic of an effect in the bulk oxide rather than at the interfaces (metal/oxide or oxide/electrolyte) (12).

The recovery of k_f and of impedance for films on Nb electrodes on open circuit after cathodic polarization were at similar rates taking several hours (3).

Examined with variable wavelength (before cathodic polarization) absorption by anodic Ti oxide does not have a sharp "edge" but in common with other amorphous materials absorption was found to increase steeply (13) at $\lambda \sim 430$ nm corresponding to a bandgap of $\sim$2.88 eV. This value compares with that for the crystalline forms of TiO_2: anatase (3.04 eV) (14) and rutile (3.05 eV) (15). After cathodic polarization the absorption increase had moved to $\lambda \sim 415$ nm, *i.e.*, the bandgap increased to $\sim$2.99 eV but the absorption at longer wavelengths was still significant. Similar observations were reported on reduction of rutile or anatase which also showed an increase in bandgap of the same order of magnitude (14). This was interpreted in terms of donor sites (singly or doubly ionizable oxygen vacancies) in the oxide which, with increasing concentration, produce a "blurring" of the absorption "edge" effectively broadening the bandgap. The donor species in the present case would be hydrogen dissolved in the oxide films on Ti. The bandgap of anodic oxide film on Nb electrodes was $\sim$3.18 eV and the increase, after passage of cathodic current, was to energies corresponding to wavelengths below those available with the ellipsometer.

The proposed interpretation of the recovery in R_p and C_p of filmed Ti and Nb electrodes after cathodic polarization was in terms of the effects of the presence of hydrogen within the surface oxide films (3, 12). At negative potentials hydrogen was considered to act as a donor impurity in raising the conductivity of the surface oxide films [in addition to acting as a faradaic reactant in films on Ti electrodes (12)].

The ionization energy of hydrogen (=13.62 eV) is dependent on the dielectric constant, ϵ, of the medium. Assuming the electron can be considered to move in a coulombic field

$$E_D = E_H \cdot \frac{m_{ef}}{m} \cdot \frac{1}{\epsilon^2} \qquad [1]$$

where E_D is the least energy required to promote an electron from the donor hydrogen to the lowest level of the conduction band, E_H is the ionization energy for hydrogen, m_{ef} is the effective mass and, assuming this is approximately equal to m (electronic mass), $E_D \simeq 1.7 \times 10^{-2}$ eV for the surface films on Ti using $\epsilon \simeq 20$ (6) and $E_D \simeq 6.3 \times 10^{-5}$ eV in anodic films on Nb [$\epsilon \simeq 60$ (3)]. The value of ϵ for TiO_2 is significantly different from that for crystalline rutile but is not unexpected for "glassy" oxides as is the case for low voltage anodic TiO_2 (6). A significant proportion of electrons will be donated at room temperature ($kT \simeq 2.5 \times 10^{-2}$ eV) giving rise to the observed conductivity in addition to optical absorption at low photon energies ($h\nu < E_{bandgap}$).

The nearly complete recovery of k_f, R_p^{-1}, and C_p occur with the same time dependence during the same time interval (Fig. 3 and 4). Previously (3, 12), the frequency dependence of R_p and C_p at low frequencies (*e.g.* < 10 kHz) which are characteristic of the surface of the highly conducting film, was evidence for a reversible surface reaction (the hydrogen deposition reaction) dependent on diffusion in the oxide. The electrode potential, E, under these conditions is expected to be related to the diffusion of hydrogen to the oxide surface since E depends on surface concentration. The change in potential with hydrogen coverage θ_H, is $\partial \ln \theta_H / \partial E = -K$, where K is a constant. In the present case assuming that the change in surface coverage of hydrogen depends on diffusion in the bulk oxide and is proportional to $(Dt)^{-1/2}$

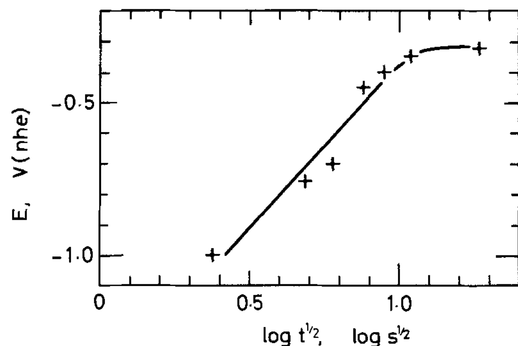

Fig. 11. Electrode potential, E, of a Ti electrode filmed to 34.7 nm as a function of time on open circuit after polarizing to $E = -1.15$V (NHE) at 0.5 mA/cm².

then $E \propto 1/2 \log t$. Figure 11 shows that this relationship is approximately followed on open-circuiting at $E = -1.15$V (NHE) over the same time interval as the (bulk) optical changes, verifying the dependence of the surface reaction on diffusion in the oxide.

The larger cathodic current requirement for significant k_f changes and the slower reversibility in films on Nb electrodes is consistent with the potentiodynamic behavior (2) which showed a lower susceptibility to hydrogen uptake and slower kinetics.

Changes in n_f.—The most remarkable effect of cathodic polarization is the influence on the real part of the refractive index, n_f, of films on Ti electrodes. The change in n_f is large and rapidly reversible with the same time dependence as k_f (Fig. 2, 3, and 5) and indicates an additional effect of the presence of hydrogen in the oxide film.

At negative potentials, coincident capacitance and conductance maxima appear. This is characteristic of a reversible electrochemical reaction (16). The capacitance maxima increased with increasing film thickness and there was no significant change in the surface area at different thicknesses. This indicated (12) that not only reaction at the surface was involved, but that a reaction such as

$$TiO_2 + H^+ + e^- \rightleftharpoons TiOOH \qquad [2]$$

was occurring in the bulk of the oxide film. The low magnitude of the capacitance maxima, however, was considered to be a result of the low reversibility of reaction on a time scale ~1 msec or less (12), as indicated by the broadness of the capacitance peak (16).

The observed n_f changes in TiO_2 could possibly be explained in terms of a very large reversible change in film density. However, at low fields (associated with the cathodic current) the electrostrictive effect is vanishingly small and a reversible and major change in the number of molecules in the oxide film at constant thickness is not likely. The reversible changes in n_f on a time scale of tens of seconds imply a reversible change in the electronic polarizability of the film molecules (α_m). The formation of TiOOH, as in Eq. [2] would be accompanied by a decrease in n_f since electronic polarizabilities of ions (α_i) are approximately additive (17) to give α_m, and $\alpha_{O^{2-}} > \alpha_{OH^-}$. Departures from simple additivity arise from a nonideal crystal state and overlapping of wave functions. To test for additivity in the case of TiO_2 the refractive indexes of the different crystalline forms will be considered using the Lorentz-Lorenz equation

$$\frac{n^2 - 1}{n^2 + 2} = \frac{4\pi}{3} \Sigma N_i \alpha_i \qquad [3]$$

where N_i is the number, per unit volume, of ions of polarizability α_i. Thus

$$\alpha_{TiO_2} = \frac{3}{4\pi} \frac{M}{N\rho} \frac{(n^2 - 1)}{(n^2 + 2)} \qquad [4]$$

where M = molecular weight of TiO_2, ρ = density, and N = Avogadro number. For comparison with the anodic film, each of the crystalline forms (anatase, brookite, and rutile) will be considered as randomly oriented microcrystals of single crystal density so that the average refractive indexes (at wavelength, λ = 588.9 nm) are: 2.5246, 2.6226, and 2.7545, respectively, with densities of 3.9, 4.13, and 4.23 g/cm³, respectively (18). Using these data in Eq. [4] the molecular polarizability of TiO_2 is remarkably similar for the widely different crystal forms, *viz.*, 0.522, 0.508, and 0.515×10^{-23} cm³, respectively, for anatase, brookite, and rutile. It is reasonable then to suppose that α_{TiO_2} for the anodic oxide is not dissimilar from an averaged value between the three crystal forms, which is 0.515×10^{-23} cm³. At the wavelength λ = 546.1 nm (Fig. 2, 3, and 5) the correction for optical dispersion is $\sim 0.001 \times 10^{-23}$ cm³ (6). This correction is smaller than the difference between the calculated α_{TiO_2} values of the different crystal structures and will be ignored.

Using $\alpha_{TiO_2} = 0.515 \times 10^{-23}$ cm³ in Eq. [4], the density of the 34.7 nm anodic film is 3.1214 g/cm³. This value of ρ together with M = 80 can be used at negative potentials where a change in the number of molecules or Ti ions is unlikely (Eq. [3]) for a constant film thickness (as already discussed). The amount of water in the film is not expected to change significantly and may contribute $< 0.01 \times 10^{-23}$ cm³ to the derived electronic polarizability.

Using Pauling's value (20) for $\alpha_{Ti^{4+}} \simeq 0.019 \times 10^{-23}$ cm³, the additivity relationship for α_{TiO_2} yields $\alpha_{O^{2-}} = 0.248 \times 10^{-23}$ cm³. With $\alpha_{OH^-} = 0.122 \times 10^{-23}$ cm³ (17) in Eq. [2] and assuming x is the fraction of molecules of TiO_2 converted to TiOOH, the average polarizability per molecule is then

$$\alpha_{Ti^{4+}} + \alpha_{O^{2-}} + (1 - x)\alpha_{O^{2-}} + x\alpha_{OH^-} = \alpha_{EXPTL}$$

so that

$$x = \frac{0.515 - \alpha_{EXPTL}}{0.126} \qquad [5]$$

In deriving Eq. [5] we have assumed that $\alpha_{Ti^{3+}} \simeq \alpha_{Ti^{4+}}$. We can find no published data for the electronic polarizability of Ti^{3+} but do not expect it to significantly alter calculated values of x.

At $E = -1.15$V (NHE), which is the potential of minimum electrode impedance [a phenomenon associated with a reversible or equilibrium potential (16)] the values of α_{EXPTL} derived from the measured n_f correspond to $x \simeq 0.5$ in Eq. [5] (Table II). (If $\alpha_{Ti^{3+}}$ were 50% higher than $\alpha_{Ti^{4+}}$, then values of x would be only ~8% higher.)

At the equilibrium potential of reaction [2] the effective concentrations of TiO_2 and TiOOH would be equal from thermodynamic considerations. The derived molecular composition of the anodic oxide films (Table II) at the reversible potential of the equilibrium reaction [2] (12) supports the concept of changes occurring in the bulk of the oxide film on Ti and the use of this equation to describe them. Below $E = -1.15$ (NHE) (at higher cathodic currents or after a longer time), the lowest refractive indexes found correspond with nearly complete conversion of TiO_2 to TiOOH.

Such large optical changes cannot readily be interpreted by models in which the changes in valency of the oxide occur only at surfaces of the oxide films.

There was more than sufficient cathodic charge passed to account for both n_f and k_f changes. ~35 mC of charge was passed by the 34.7 nm filmed Ti electrode before open-circuiting; this was ~5 times more than required to convert half of the TiO_2 molecules to TiOOH. Most of the hydrogen produced by this charge was released as gas in the hydrogen evolution reaction.

There is a small change in n_f with the passage of cathodic charge by filmed Nb electrodes and it de-

creases with increase in film thickness (Fig. 7-9). Using $\alpha_{Nb_2O_5} = 1.292 \times 10^{-23}$ cm^3 [from $\alpha_{O^{2-}} = 0.248 \times 10^{-23}$ cm^3 and $\alpha_{Nb^{5+}} = 0.026$ (19)] and arguments similar to those for films on Ti, the derived decreases in average polarizability per molecule ($\Delta\alpha_m$) on cathodic polarization are: 0.026, 0.020, and 0.009×10^{-23} cm^3 for the 12.6, 28.7, and 51.9 nm films, respectively. Assuming the formation of OH^- from O^{2-} ions in a reaction such as

$$Nb_2O_5 + 2H^+ + 2e^- \rightarrow Nb_2O_3(OH)_2 (\equiv 2NbO_2 \cdot H_2O) \quad [6]$$

the change in n_f corresponds to ~10% conversion of the 12.6 film. The decreasing change in n_f and α_m with increase in film thickness is characteristic of a surface effect, which, from the present figures, extends only to a few (3 to 5) (20) molecular layers of oxide.

Impedance measurements over a wide frequency range (3, 12) have also indicated a difference in the behavior of anodic oxide films on Ti and Nb at negative potentials. That the change in n_f on Nb electrodes is not characteristic of a reversible faradaic bulk reaction and is only slowly reversible is consistent with the absence of a distinct impedance minimum (3) at negative potentials. This model implies that the low impedance cathodic behavior of oxide covered Nb electrodes (3) arises mainly from conductivity changes in the bulk of the film and not from a reversible reaction in the bulk oxide. In this respect Nb differs from Ti where impedance changes (12) involve changes in conductivity and a reversible faradaic reaction in the bulk oxide film.

Rates of change of optical parameters.—Changes in the films during cathodic treatment and/or on open circuit are nonhomogeneous since the Δ/ψ data follow a different path during recovery of the electrodes on open circuit. Since hydrogen, deposited at the oxide/electrolyte interface, dissolves in the oxide films, the change in optical properties proceeds from this interface toward the metal/oxide interface. The films may approach homogeneity just after the open-circuit condition or during cathodic treatment to where there is no further change in the ellipsometric parameters at low potentials (Table II). At other conditions, where the parameters are rapidly changing, unambiguous analysis for regions of different optical properties within the oxide films cannot be done since the oxide must be considered multiphase, and two measured optical parameters are insufficient for a complete interpretation; under these conditions our calculated n_f and k_f values are approximations.

For both electrodes, rates of change of the calculated n_f and k_f on cathodic polarization were faster in thinner films (Fig. 2, 7, 8, and 9) as implied by the proposed model of hydrogen diffusion. Similarly on open-circuiting, initial changes were faster for the thinner films.

Calculation of the exact diffusion coefficient is, of course, complicated by the absence of data on the concentration gradient of hydrogen in the oxide, even though at −1.15V (NHE) films on Ti electrodes comprise ~50% TiOOH and TiO_2. Assuming a constant concentration of hydrogen at the surface and bulk concentrations similar for the two oxides, the relative diffusion coefficients for hydrogen in the films on Ti and Nb are $\sim 10^{-13}$ and $\sim 10^{-14}$ cm^2/sec, respectively. The assumption of a higher bulk concentration, which is more likely but unknown, would yield significantly faster rates of diffusion.

Summary

Cathodic polarization of filmed Nb electrodes involves large and reversible changes in the optical absorption due to solution and ionization of deposited hydrogen in the surface films. Only small changes in the refractive index occur.

Cathodic treatment of filmed Ti electrodes produces large and more rapidly reversible changes in both absorption and refractive index of the surface film. The change in electronic polarizability at the reversible potential of reaction [2] corresponds with the formation of ~50% TiOOH and the maximum change in refractive index corresponds with ~85% conversion of TiO_2 which occurs at more negative potentials where reaction [2] would go nearly to completion.

Examination of Aluminum Copper Films during Anodic Oxidation

I. Corrosion Studies

H.-H. Strehblow[1] and C. J. Doherty

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Aluminum copper films in the range of 1-70 atom percent (a/o) Cu prepared by vapor deposition were examined in buffer solutions of pH 5.0, 6.0, and 9.2. Films with a low copper content ($\leq$10 a/o) show similar corrosion properties as pure aluminum in weakly acid solutions. The formation of a layer of nonporous aluminum oxide leads to anodization up to a maximum potential of some 10V at which point the film is destroyed locally. For higher copper contents ($\geq$40 a/o) the oxygen evolution cannot be prevented and only brittle noncontinuous oxide films are formed. These metal films have similar corrosion properties to those of pure copper. At pH = 9.2 the polarization curves obtained are closely related to those of pure copper.

Aluminum films with additions of 1-5 weight percent (w/o) copper are widely used in integrated circuits. The copper alloying is used to reduce electromigration and thermal hillock formation and to facilitate chemical etching. However, the addition of copper is also known to accelerate aluminum corrosion in the presence of ionic contamination (1, 2) due to galvanic corrosion between the precipitated Al_2Cu θ phase and the pure aluminum matrix. To investigate the implications of this fact to the use of aluminum/copper metallizations for silicon-integrated circuits, the anodization conditions of evaporated alloy films have been investigated. Besides electrochemical examinations, transmission and scanning electron microscopy and ion backscattering were used to obtain information about the metal films and the anodic oxides.

Experimental

The films were deposited by electron gun evaporation from copper-aluminum melts. The films were deposited on sapphire, quartz, or oxidized silicon substrates. Prior to metal deposition the substrates were degreased with trichlorethylene and acetone followed by cleaning in a mixture of 1 part ammonium hydroxide, 1 part H_2O_2, and 4 parts of water at 80°C and were carefully rinsed with deionized water. Finally they were baked for 30 min at 500°C in air. After metal deposition, the specimens, which were about 1.5 cm^2 in surface area, were contacted electrically by a u-bent copper wire and conducting carbon paste. The whole contact area was covered by epoxy resin and the specimens were mounted to a glass tube.

Three different buffer solutions are used: phthalate buffer pH = 5.0, 0.023M KHPhth + 0.027M K_2Phth; citrate buffer pH = 6.0, 0.1M citric acid + 0.27M KOH; borax buffer pH = 9.2, 0.1M. All solutions were prepared from reagent grade chemical and triply distilled water.

The following reference electrodes were used: Hg|Hg_2SO_4|1N H_2SO_4 E_h = 0.68V; Hg|HgO|0.1M KOH E_h = 0.18V. All potential values are referred to the standard hydrogen electrode and are corrected for liquid junction potentials.

Results

Potentiodynamic examinations.—Aluminum copper films were examined under potentiodynamic conditions. Films of low copper content ($\leq$10 a/o) show, in weakly acid solutions and other metals forming non-behavior similar to pure aluminum with no apparent metal dissolution when passivation is achieved and no appreciable removal of the passive film within a few minutes at negative potentials (E_h = −0.8V) well below the potential of the hydrogen electrode in the same solution. In alkaline solutions like 0.1M borax (pH 9.2), however, the films showed a similar corrosion behavior to that of copper during subsequent potentiodynamic polarization. Apparently there is copper present on the film surface and as copper oxides and hydroxide show very low solubility at pH = 9.2, this metal is oxidized and reduced during subsequent runs. Figure 1 shows typical scans in borax buffer for 1.9 and 71.4 a/o copper films using scan rates of 0.1 V/sec and 0.1 V/min, respectively. The faster scan rate was required for the low copper sample, because the copper peak, corresponding to the surface concentration of this alloy addition, was very small and could not be detected at slower scan speeds. The same peaks are found for copper in the same buffer, as shown in Fig. 2, although with greater current density indicating that the surfaces of the alloy films are only partially covered by copper. The first peak is attributed to the formation of copper (I) oxide and the second to copper (II) oxide or hydroxide (3-5). Cathodic reduction peaks are found when the potential is changed in the negative direction,

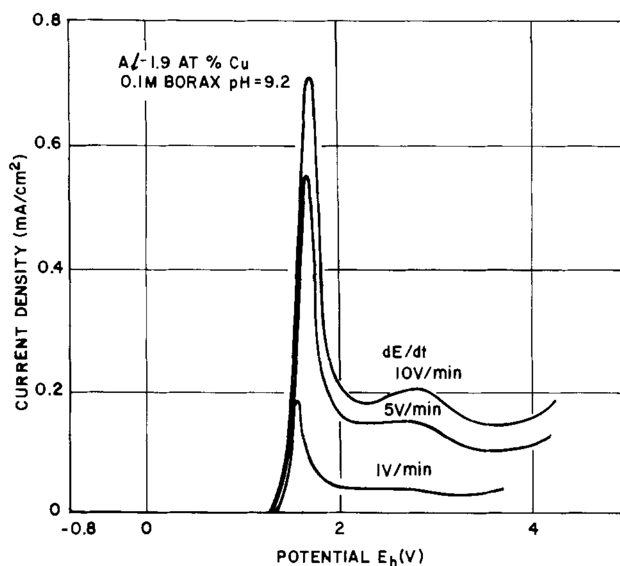

Fig. 5. Potentiodynamic polarization curve for Al-1.9 a/o Cu film in 0.1M borax pH = 9.2 up to some volts.

correspond to the results for pure copper, and are related to the reduction of the surface compounds which are formed during the anodic scan (Fig. 3).

Passivated specimens with a low copper content can be polarized in acid solutions to potentials several volts more positive than the standard hydrogen electrode without an appreciable increase in the current density. For subsequent potentiodynamic scans a current increase is observed only when the potential gets more positive than the run before resulting in a thickening of the anodic oxide (Fig. 4). This corresponds to the behavior of passive aluminum in weakly acid solutions and other metals forming non-electron-conducting poreless passive films (6-8). During repeated potentiodynamic examinations in 0.1M borax, however, a current peak at E_h = 1.6V appears which is attributed to oxygen evolution (Fig. 5). The reversible oxygen potential at a pH 9.2 is somewhat lower, the difference being presumably due to the overpotential typical for oxide-covered metals. The subsequent decrease in current density with increasing potential occurs because the surface becomes increasingly passivated by aluminum oxide and the local enrichment of copper or copper oxide is removed from the surface by dissolution or is covered by the aluminum oxide. In acid solutions (phthalate buffer or citrate buffer), this current peak is not observed for films with low copper content because copper cannot accumulate due to the solubility of its oxides in these solutions. Citrate solutions are especially effective in removing copper from the surface because of its complexing property. In consequence these solutions show higher corrosion current densities for copper and better passivating properties for low copper films.

12 a/o copper films behave similarly to the 1.9 a/o films described above, but 41 and 71 a/o Cu-films, however, show heavy oxygen evolution at potentials more positive than 1.2V and the gas evolution does not decrease at high potentials. The copper content is apparently too high for the formation of a continuous aluminum oxide film over the surface.

The potentiodynamic polarization curves show that the films with a copper content of less than 10 a/o are similar to pure aluminum. In weakly acid solutions passivity is observed and oxygen evolution is prevented up to E_h = 10V and more. These solutions are therefore the most suitable for the anodization of the metal films to high electrode potentials. Greater difficulty would be expected in 0.1M borax, mainly caused by the accumulated copper at the surface resulting in oxygen evolution. This would prevent the galvanostatic formation of thick films at high potentials especially at small current densities and copper concentrations of more than 2 a/o. In these cases, no continuous aluminum oxide film can cover the surface and oxygen evolution consumes a great part of the applied current density at the surface sites containing copper and the semiconducting copper oxide.

Galvanostatic examinations.—The citrate buffer (pH = 6.0) solution proved the most effective for film

anodization. In phthalate buffer (pH = 5.0), localized destruction of the metal film is observed at lower potentials than for the citrate solution; for example, the 1.9 a/o Cu film could be anodized to only 50V in phthalate but to 100V in citrate solution under equivalent conditions ($i = 1$ mA/cm²). In borax buffer galvanostatic experiments with current densities of $i < 500$ μA/cm² failed to reach high potentials. Characteristic corrosion structures appeared on the metal surface. These small stained areas are also found after potentiodynamic experiments in the borax buffer as mentioned above.

In 0.1M citrate solution galvanostatic anodization of the films with different copper content results in a nearly linear increase of the electrode potential with time (Fig. 6). This potential increase stops at a maximum value, potential oscillations and drops are observed, and characteristic local corrosion structures can be detected on the specimen surface (Fig. 7). Immediately before the maximum potential is reached the potential increase grows steeper; the exact potential at which it occurs is dependent on the composition of the film (Fig. 8).

Microscopic examination.—The maximum potential which can be applied to the films is limited by local breakdown. Figure 7 represents a part of the film which has lifted off the substrate forming a bubble. At the center of each bubble is a small area (1-5 μm diam) where the metal film is clearly corroded and appears to be perforated. Electron microprobe analysis of the corrosion product does not show a significantly increased copper concentration in this area. It is postulated that once local film corrosion and perforation have occurred, the electrolyte penetrates to the film/substrate interface and continued gas evolution causes the film to lose adhesion.

Figure 9 shows an Al-11.7 a/o Cu film which could be anodized to only 18 V_H. Continuing anodization at this potential results in the formation of a brittle surface film due to continuous passivation breakdown.

The grain structure of an Al 1.9 a/o Cu film was displayed using transmission electron microscopy. Sample preparation involved dissolving the silicon substrate, followed by ion milling the metal film. Figure 10a and 10b show the grain structure of the metallic and anodized portions of the film, respectively. A cross section of the film is shown in Fig. 10c which clearly shows the anodic oxide on top of the metal film.

Conclusion and Discussion

The following main results are obtained for the corrosion behavior of vapor-deposited aluminum copper films of various compositions.

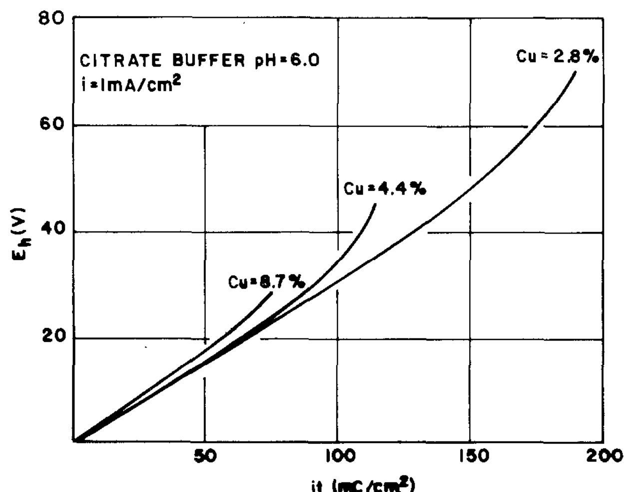

Fig. 6. Galvanostatic oxidation of aluminum-copper films of different composition up to film damage with $i = 1$ mA/cm² in 0.1M citrate pH = 6.0.

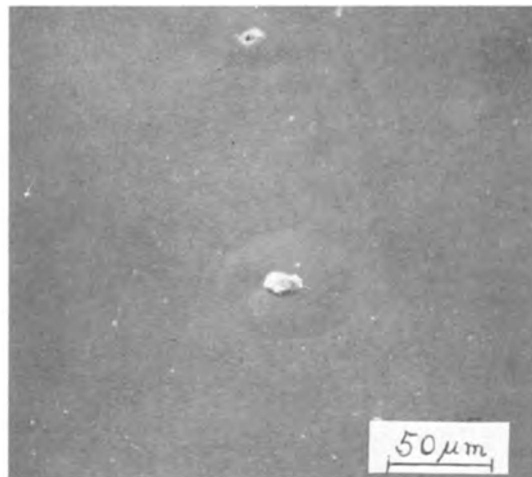

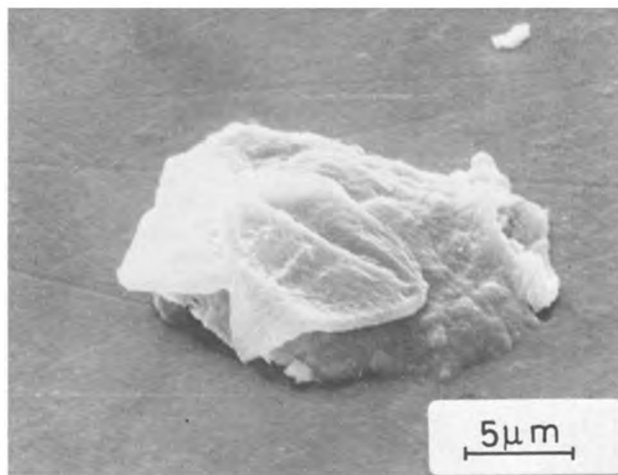

Fig. 7. Damage of an Al-4.3 a/o Cu film on a sapphire slide after oxidation to 70V_H in 0.1M citrate buffer pH = 6.0, with $i = 1$ mA/cm² for 5 min.

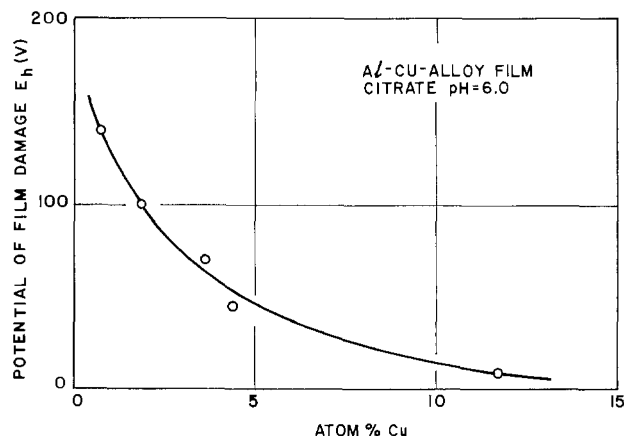

Fig. 8. Potential for film damage as a function of the copper content.

1. Passive behavior is observed in solutions in the range $pH = 5$-9.2. Films with a copper concentration up to about 10 a/o are protected by an anodic film to potentials of at least 10V. For high copper concentration (40 a/o, 70 a/o) oxygen evolution cannot be prevented as these films do not form a continuous film of the nonelectron-conducting aluminum oxide.

2. In 0.1M borax, which has a low solubility for copper oxides and hydroxide, copper is accumulated at the surface of the specimen during potentiodynamic examinations. The anodic and cathodic polarization curves

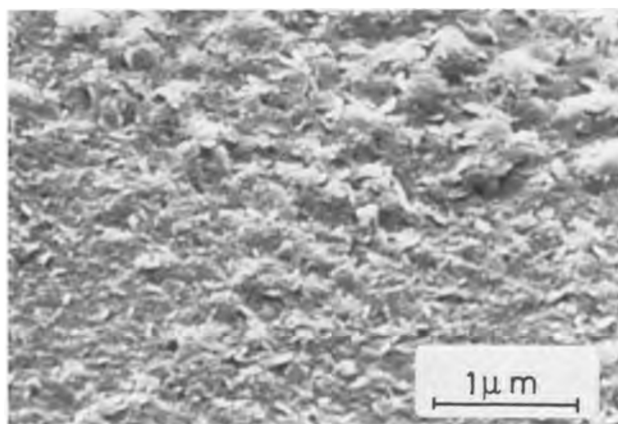

Fig. 9. Formation of noncontinuous brittle oxide on an Al-11.7 a/o Cu film on sapphire under galvanostatic conditions for 120 sec, $i = 3$ mA/cm^2, reached maximum potential $E_h = 18.6$V.

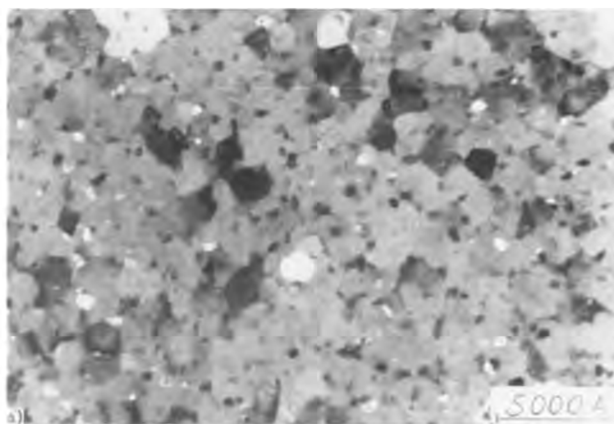
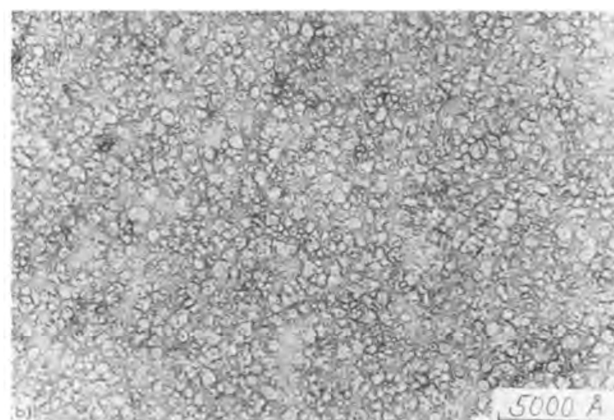
show a peak structure very similar to pure copper. The current densities decrease with the copper content of the film as the passivated aluminum-rich parts do not contribute to the electrochemical current. In acid solutions (pH = 5 or 6) only the copper-rich films (40 a/o, 70 a/o) show the peak structure of copper due to the greater solubility of the copper oxides and hydroxides at these pH values.

3. Optimum galvanostatic anodization is achieved in the citrate buffer. The maximum anodic potential and film thickness which can be obtained is controlled by film perforation and adhesion loss. This maximum potential decreases with increasing copper concentration of the film. Films of high copper content form only brittle discontinuous thick oxide films. Anodization in borax buffer, especially for high copper concentrations and small current densities, is not possible to high potentials as oxygen evolution cannot be prevented.

4. The metal phase consists of crystals of $\leq$1000Å diam. It will be shown elsewhere (9) that the oxide film does not contain any copper. Its failure during galvanostatic anodization at high potentials is closely related to an enrichment of copper at the metal-oxide interface.

5. Vapor-deposited aluminum films containing only a few atom percent of copper are protected against corrosion by the formation of an oxide film in a manner similar to films of pure aluminum. Care should be taken to avoid acid or alkaline environments to prevent the dissolution of the protective film. Anions with complexing properties for copper ions resulting in an increased solubility for copper oxide or hydroxide help to form a copper-free surface.





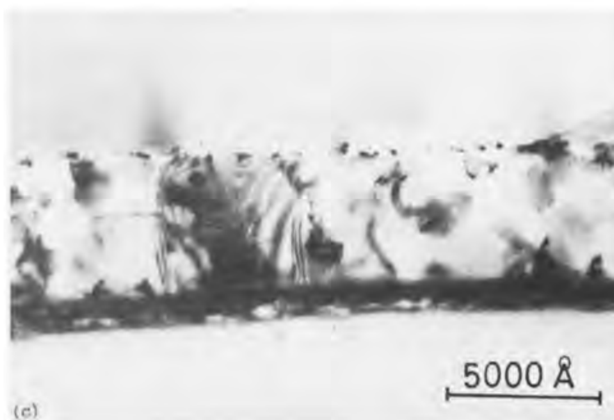


Fig. 10. TEM display of (a) metal phase; (b) anodic oxide; (c) cross section of an Al-1.9 a/o Cu film, anodized with $i = 1.4$ mA/cm^2 to $E_h = 100$V in 0.1M citrate $pH = 6.0$

The State of Tin in Tin-Anodized Aluminum

R. L. Cohen

Bell Laboratories, Murray Hill, New Jersey 07974

and Ch. J. Raub and T. Muramaki

Edelmetalle Forschungsinstitut, Schwäbisch Gmünd, Germany

ABSTRACT

We have used Mössbauer spectroscopy of Sn^{119} to determine the state of the tin in anodized aluminum surfaces which are colored brown by anodization in acidic stannous sulfate solutions. We conclude that the tin is present predominantly in the form of tin metal.

Aluminum alloys used for architectural and appearance applications are frequently dyed gold, bronze, or dark brown. One way to achieve these brown anodized surfaces is by a-c treatment of anodized aluminum in an electrolyte containing metal salts (1-3). By varying the electrolysis conditions various shades of color can be obtained. Some of the most widely used metal salts in electrolytes for generating bronze to brown colors are those of divalent tin, the effects of which were already well known in the 1930's (4). At that time it was speculated that the coloring might be caused by reduction products of the tin salt, *e.g.*, metallic tin. In the last years more work has been done to establish coloring mechanism. Läser (5) came to the conclusion that the coloring particles consist of metallic tin. A similar result was published in Ref. (6) and (7). This information was obtained by x-ray diffraction. Sheasby and Cooke (2) and Sandera (6) suggest that tin oxides are present in these layers too. Therefore some confusion exists on the nature of the tin compounds responsible for the coloring effect. This is primarily due to the small quantity and fine particle size of the tin-containing phase, and the difficulty of isolating it.

We have used the technique of Mössbauer spectroscopy (8) on Sn^{119} to study these layers, and the results of this work are presented here. Mössbauer spectroscopy is ideally suited for this study—it works well with thin layers of material, is sensitive only to the tin atoms in the layer, and is completely unaffected by the aluminum backing or aluminum oxide matrix. The identification of the tin phase in these experiments is by a "fingerprint" technique, in which the Mössbauer spectrum of the unknown (tin anodized) sample is compared with the spectra of known compounds. In general, the parameters determining the Mössbauer spectrum are insensitive to particle size or crystallinity. Particularly relevant to the problem we consider here, Akselrod *et al.* (9) have recently shown that for SnO with a grain size of ~20Å, the Mössbauer spectrum was indistinguishable from that of bulk SnO.

Experimental Details

Samples were prepared by anodizing both sides of the 0.2 mm thick aluminum sheets in 10% H_2SO_4 at a current of 1 A/dm^2 for the times shown in Table I. These sheets were then colored in a second electrolyte consisting of 20 g/liter $SnSO_4$ dissolved in 5% H_2SO_4, 4 min, at room temperature, 9V, 50 Hz a.c., using Pt as a second electrode. The samples were rinsed in water and allowed to dry in air at room temperature. Four pieces of sheet were stacked, making an absorber composed of 8 anodized layers for the measurements. All of the samples were dark bronze in color.

The Mössbauer spectra were taken with the samples at 78°K, using a source of $BaSnO_3$ at room temperature and a silicon detector for the gamma rays. A Pd critical absorber was used to filter out the Sn K x-rays.

Key words: Mossbauer, anodizing, tin, aluminum.

Data were taken using a multichannel analyzer in the up-down multiscaling mode (8). Spectra of the tin-anodized samples are shown in Fig. 1, along with spectra of stannic hydroxide (10) and tin metal.

The dominant line in the spectrum of the tin-anodized samples clearly corresponds to that of tin metal. Other obvious possible compounds can be conclusively excluded: Both SnO and hydrated SnO have well-resolved symmetric doublets for their Mössbauer spectra (11, 12), as indicated in Fig. 1. Stannic oxide has a broad line similar to that of stannic hydroxide. Stannous sulfate yields a barely resolved doublet centered at 4 mm/sec, while SnS yields a barely resolved doublet centered at 3.5 mm/sec (11). Thus, not only does the primary observed line correspond exactly to that of tin metal, but all of the other simple compounds containing tin, sulfur, oxygen, and hydrogen have obviously different spectra.

There is additional intensity in the spectra near zero velocity, and we attribute this to a small fraction of the tin being combined in the form of stannic oxide or hydroxide (Mössbauer spectra of these materials are almost indistinguishable).

The spectra of the tin-anodized layers have been least squares fitted to establish the relative quantities of the oxide/hydroxide and tin metal. This was accomplished using a constrained least squares fitting routine, which was given the shape, width, and position of lines for stannic hydroxide and for tin metal, and allowed only the intensities of the two lines (and the baseline) as degrees of freedom. The fine line running through the data points in Fig. 1 is the result of this least squares fitting procedure; it is obviously an excellent description of the experimental spectra. From the line intensities, the amount of tin metal present can be determined by comparison with spectra of tin samples of known thickness. For thin samples, the resonance intensity is proportional to the sample thickness. These results are shown in Table I. From the Mössbauer data, there is no way to determine if the oxide/hydroxide

Table I

Sample preparation and tin concentrations determined in these experiments. The relative accuracies of the tin metal determinations are ±5%, of the hydroxide phase, ±25%. The absolute accuracies are ±20% for the metal phase, and ±40% for the hydroxide phase, being limited by the complete line shapes and poorly established recoil-free fractions, f. In determining tin in the hydroxide phase, the value f_{hyd}/f_{metal} = 1.25 at 78°K was used, following results of Ref. (13).

Sample	Anodizing time (min)	Anodized layer thickness (μ)*	Sn (metal phase) (μg/cm²)	Sn (in hydroxide phase) (μg/cm²)
A	5	<1	35	4
B	15	5	40	4
C	30	10	35	4

* Determined by "Lichtschnittmikroskop" (light-section microscope).

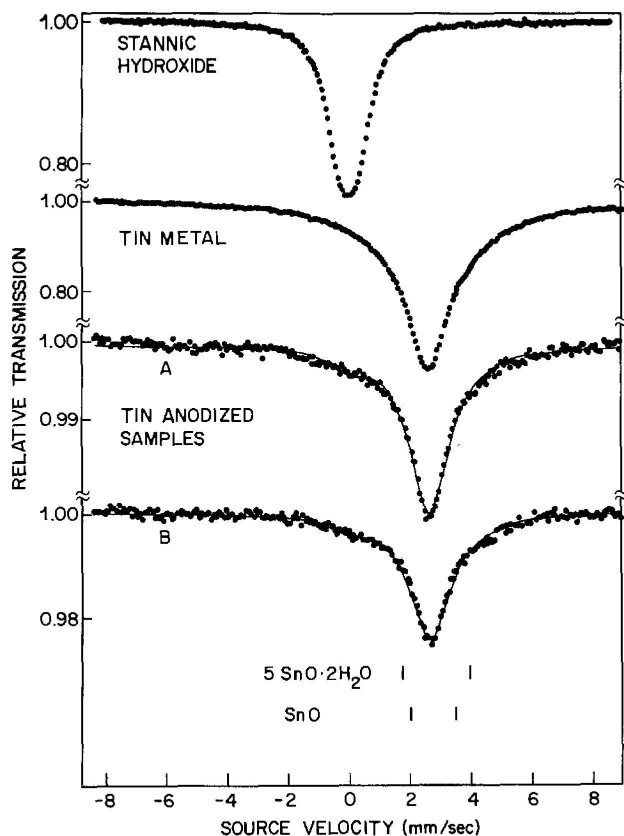

Fig. 1. Mössbauer spectra of the tin-anodized samples A and B along with spectra of stannic hydroxide and tin metal for comparison. The spectra are taken in transmission, so that the absorption lines are downward pointing "peaks." The energy scanning in Mössbauer spectroscopy is normally done by doppler shifting the gamma ray energy by moving the source, so the "source velocity" scale is effectively an energy scale. The spectra of SnO and hydrated SnO are doublets, with the line positions shown at the bottom of the figure. The least squares fit to the data (assuming the layer is composed only of tin metal and stannic hydroxide) is shown by the thin line.

phase is associated with the tin metal phase (*i.e.*, as a surface layer on tin particles) or is entirely independent. The most obvious source for the formation of a stannic hydroxide phase would be hydrolysis of Sn^{4+} ions as the surface *p*H is raised during the wash process (10). The high surface area of the anodized layer would serve as an ideal nucleation site for precipitation of the insoluble stannic hydroxide ions.

It is interesting to note that the amount of metallic tin does not depend on the thickness of the oxide layer, and even at rather small thicknesses (sample A) the same amount of tin is deposited under the conditions used. The quantities of tin shown in Table I are slightly smaller than those determined by Sautter *et al.* (6) for tin-dyed layers produced under slightly different conditions.

In the spectra of the tin-anodized samples shown in Fig. 1, there is a very weak absorption near 4 mm/sec, visible only by the minor departure of the data points from the least squares fit line. This presumably arises from traces of $SnSO_4$ (12) remaining in the porous anodized layer.

In conclusion, studies of the composition of anodized layers dyed by tin have shown that the tin is present primarily in the form of tin metal. The brown coloration of the layers presumably reflects the color of finely divided tin metal particles, dispersed in the aluminum oxide surface layer.

Investigation of Agitation Effects on Electroplated Copper in Multilayer Board Plated-Through Holes in a Forced-Flow Plating Cell

Werner Engelmaier* and Thomas Kessler[1]

Bell Laboratories, Whippany, New Jersey 07981

ABSTRACT

The effect of electrolyte agitation in plated-through holes (PTH's) of multilayer boards (MLB's) is investigated for high conductivity $CuSO_4/H_2SO_4$ electrolytes with and without brightener additives. The experiments were carried out in an 80 liter forced-flow plating system capable of agitation by air sparging also. PTH quality is assessed in terms of the PTH electrical resistance, the PTH deposit uniformity, and the deposit morphology. Correlations are made with plating current density, electrolyte velocity in the PTH's, and two dimensionless plating parameters, $\xi_{T\kappa}$ and $\bar{j}/\bar{j}_{lim}$. The results show that for additive-free plating, the agitation requirements to prevent mass transport-limited plating conditions increase rapidly with increasing current densities and decreasing cupric ion concentrations. At the current densities common in MLB production, the low levels of agitation produced by air sparging alone provide only for marginal plating conditions particularly at the board edges where the test coupons are located. The plating criteria for good PTH deposits, $\xi_{T\kappa} < 1$ and $\bar{j}/\bar{j}_{lim} < 0.25$ are confirmed by the experimental results. Plating with Cubath®M additives is shown to be considerably less sensitive to variations in the plating parameters which are likely to occur in production. The criteria for good PTH quality can be extended to $\xi_{T\kappa} < 2$ and $\bar{j}/\bar{j}_{lim} < 0.25$, which allows for more latitude for plating current density variations.

Among the many critical process steps that a multilayer printed wiring board (MLB) undergoes during its production, the electroplating of copper is one of the most important. MLB's contain plated-through holes (PTH's) which provide electrical connections between the various circuit layers of the MLB (see Fig. 1). During the electroplating step, copper is deposited in the drilled PTH's as well as on the outer MLB surfaces. Since the plating of PTH's in MLB's places much more complex demands on the plating process as compared to standard electroplated product, a better understanding of the plating process and its controlling parameters is necessary (1-3). Efforts have been reported which were designed to gain understanding either through analysis of the existing plating phenomenology (1, 5-12) or through analytical modeling (2-4, 13). Parameters were defined which provide a gauge for the relative importance of the three mechanisms (electrical characteristics of the plating solution, electrochemical kinetics of the plating reaction, and fluid dynamic conditions at the cathode) whose interaction determines the performance of an electroplating process. Different mechanisms become dominant for the copper distribution at the different scales important in the plating of MLB's: macroscale, miniscale, and microscale (3).

The macroscale is characteristic of plating of complete panels. Plating at this scale is dominated by the primary current distribution as long as sufficient electrolyte agitation at the cathode surface prevents the formation of significant gradients in the cupric ion concentration.

For the miniscale, characteristic of the region within and close to a PTH, current distribution, and thus the plating thickness distribution, is determined by the interaction of ohmic conduction, charge transfer kinetics, and mass transfer conditions. Criteria, involving dimensionless plating parameters $\xi_{T\kappa}$ and $\bar{j}/\bar{j}_{lim}$, developed by Kessler and Alkire (3) indicate which of the mechanisms dominates.

On the microscale, which encompasses effects on the scale of surface roughness, deposit thickness, and grain size, additives play a major role. Additives affect the microleveling capability of the plating solution and determine the deposit morphology. Thus, additives have a major effect on the properties of the plated copper.

Sufficient agitation is a common requirement to all three scales. The consequence of insufficient agitation is inadequate mass transport which in turn results in large ion concentration gradients at the cathodic surfaces. Mass transport limited plating results in poor quality deposits and the conditions at which the de-

posits occur at the cathode do not reflect the condition in the bulk of the plating solution.

For these reasons, agitation has always been an important aspect in the electroplating of copper. Most commonly, agitation is achieved by the discharging of air from sparging pipes located beneath the cathodic work pieces near the bottom of the plating tank. The most obvious effect of air sparging is a stirring of the electrolyte. The rising air bubbles impart velocity to the electrolyte close to the cathodic surfaces. Thus, the surface boundary layer is reduced and plating conditions are less likely to be mass transport limited. For the plating of planar vertical surfaces, the agitation provided by air sparging generally is sufficient for good quality plating.

However, for MLB's air sparging does not provide sufficient agitation in the PTH's in many instances. Therefore agitation by air sparging is sometimes supplemented by mechanical agitation. However, the level of agitation in PTH's resulting from these modes of agitation is exceedingly difficult to predict. The only practical method for the parametric evaluation of the effects of agitation on the electroplated deposit and of what agitation levels constitute sufficient mixing to prevent mass transport limited plating conditions appears to be a phenomenological study of PTH's plated at varying plating conditions. The results of such a study with parametric variations of current densities and forced-flow PTH electrolyte velocities are reported. Some experiments using only air agitation were performed also. The experiments were carried out using a high conductivity acid-copper sulfate plating solution with and without Cubatn®M proprietary organic additives (14).

Analysis

Plating parameters.—Since this study is primarily concerned with the plating inside of PTH's, miniscale considerations are the most important. For the miniscale, two-dimensionless criteria for good plating quality have been analytically determined (2)

$$\xi_{T\kappa} < 1 \quad [1]$$

is necessary for sufficient uniformity of plated copper thickness within PTH's, since it indicates that charge-transfer resistance rather than solution ohmic resistance predominates.

$$\bar{j}/\bar{j}_{\lim} < 0.25 \quad [2]$$

indicates sufficient electrolyte agitation, the absence of mass transport limitations, and smooth copper deposits with acceptable grain structure. From Ref. (2)

$$\xi_{T\kappa} = \frac{\alpha_c \mathbf{F} t_B^2}{2\kappa R_g T r_o} \bar{j} \quad [3]$$

and

$$\frac{\bar{j}}{\bar{j}_{\lim}} = \frac{2 s_i \Gamma(4/3)}{3n\mathbf{F} D_i c_\infty} \left(\frac{9 D_i r_o t_B}{4\bar{v}} \right)^{1/3} \bar{j} \quad [4]$$

For the conditions in this study ($c_\infty = 0.34 \rightarrow \kappa = 0.52\ \Omega^{-1}\ \text{cm}^{-1}$, $D_i = 0.55 \times 10^{-5}\ \text{cm}^2/\text{sec}$) (2)

$$\xi_{T\kappa} = 4.77 \times 10^{-5} \frac{t_B^2}{r_o} \bar{j} \quad [5]$$

and

$$\frac{\bar{j}}{\bar{j}_{\lim}} = 7.10 \times 10^{-4} \left(\frac{r_o t_B}{\bar{v}} \right)^{1/3} \bar{j} \quad [6]$$

From Eq. [5] and [6] and the sample dimensions (t_B = 123 mil, r_o = 23 mil), the plating criteria can be reduced to

$$\bar{j} < 32\ \text{mA/cm}^2 \quad [7]$$

and

$$\bar{v} > \frac{(\bar{j})^3}{15{,}500} \quad [8]$$

From the Eq. [4] and the second criterion minimum mean electrolyte velocities in the PTH's can be calculated and are presented in Table I. This electrolyte velocity is in the direction of the long axis of the PTH's and thus perpendicular to the MLB's (see Fig. 1 and 2). Minimum velocities are given for the cupric ion concentrations used in this study and the preliminary work discussed in Ref. (1).

Table I. Minimum mean PTH electrolyte velocities for electrolytes with different cupric ion concentrations

c_∞ (M/liter)	100	40	32	25	15	10	5	$\bar{j}$(mA/cm²)
0.27	129	8	4	2	0.44	0.13	0.016	$\bar{v}$(cm//sec)
0.34	65	4	2	1	0.22	0.065	0.008	$\bar{v}$(cm//sec)
0.375	48	3	1.6	0.75	0.16	0.05	0.006	$\bar{v}$(cm//sec)

The minimum mean electrolyte convection requirement of 4 cm/sec in PTH's determined in Ref. (2) is correct only for average plating current densities up to 32 mA/cm² at the cupric ion concentration of 0.27 M/liter used in Ref. (2). The level of minimum agitation required for good plating changes dramatically for different current densities and cupric ion concentrations.

Agitation levels.—With forced-flow agitation of the electrolyte, the mean electrolyte velocity in a PTH is easily determined. However, in practical production plating electrolyte agitation by air sparging and/or side-to-side MLB motion are the means employed to achieve electrolyte mixing. The flow fields generated by air sparging cannot be sufficiently described to determine the equivalent PTH electrolyte velocities. Clearly, the mass transfer in PTH's is enhanced by air sparging resulting from the random short duration pressure field variations creating localized pressure differences from one side of the MLB to the other as well as from mixing currents created by the bubble-wake eddies, however, the equivalent PTH velocities are obviously small as compared to either MLB motion or forced flow.

A simple model of the flow in a PTH resulting from the side-to-side MLB motion gives for a typical MLB (r_o = 23 mils, t_B = 123 mils) at a velocity of v_B = 10 cm/sec a mean PTH electrolyte velocity of $\bar{v}$ = 3.4 cm/sec. Decreasing MLB velocitites results in rapidly increasing the $v_B/\bar{v}$ ratios; thus, v_B = 1 cm/sec results in $\bar{v}$ = 0.075 cm/sec.

The level of agitation achievable by transverse motion of the MLB's has practical limitations. The maximum practical velocity in side-to-side agitation is about 10 cm/sec. This would mean that about 3.4 cm/sec is the maximum mean velocity of a near-sinusoidal velocity distribution and that during a considerable portion of the motion cycle the mean velocity falls below the minimum mean electrolyte convection established in Table I. However, these minimum agitation levels are established for steady-state fully developed laminar flow conditions (2, 3). There are a

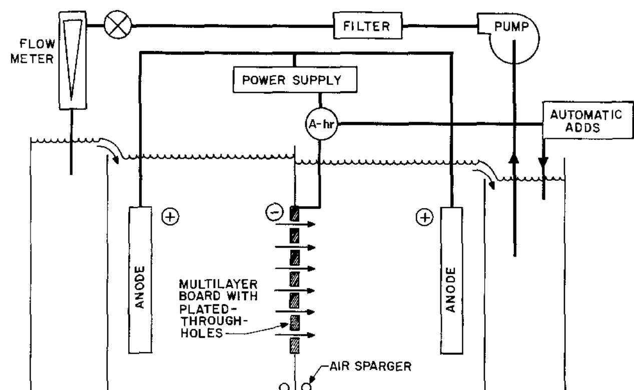

Fig. 2. 80 liter forced-flow electroplating system.

number of considerations, which indicate that fully developed laminar flow constitutes the conservative bound for the mixing in the mass diffusion layer at the PTH surface. Some of these considerations are:

1. The downstream distance from the mouth of the PTH, L_e, to establish fully developed laminar flow is a significant fraction of the total length of the PTH ($L_e = 116$ mils for $\bar{v} = 5$ cm/sec and a 46 mil PTH diam).
2. The oscillating flow field generates a phase shift between the flow in the PTH's and the MLB motion.
3. The sharp-edged PTH entrance and exit result in a *vena contracta* at the entrance and eddies at the exit.

The theoretical prediction of the electrolyte agitation at the PTH surface and the species concentration gradients is exceedingly difficult under these circumstances.

The results from forced-flow experiments, for which the electrolyte agitation is clearly defined, can establish the effects of varying levels of agitation on the quality of the electrodeposited copper. It also can serve as a standard from which effective agitation levels in PTH's resulting from air sparging and/or side-to-side MLB motion may be estimated.

In the determination of the level of agitation, an additional factor can play a significant role. The density of the electrolyte decreases as the cupric ion concentration decreases. Thus, the large ion concentration gradients generated under transport-limited plating conditions result in natural convection flow into and from PTH's.

Mirarefi and Alkire (15-17) have shown that at low flow velocities natural convection effects cause a deviation from the Lévêque equation flow. From the data in Ref. (15-17) and our data, which confirm this deviation, the level of agitation provided by natural convection is estimated to be equivalent to $\bar{v} = 1.7$ cm/sec. This result would indicate that agitation levels much below $\bar{v} = 1.7$ cm/sec cannot meaningfully be investigated and that plating at current densities below minimum values that can be estimated from Table I will be independent of additional external agitation provided. Natural convection appears to explain why air sparging produces good quality PTH's under plating conditions where air sparging alone provides insufficient agitation. Air sparging however is clearly desirable because it provides the bulk stirring necessary to provide at each PTH the bulk concentration of cupric ion.

Experiment

Plating apparatus.—The 80 liter forced-flow plating system, shown in Fig. 2, consists of four discrete chambers separated from each other by impermeable weirs. Suction and discharge chambers separate the spaces for solution pumping and discharge from the plating cells to eliminate spurious flow currents at the cathodic MLB samples. The electrolyte is pumped from the suction chamber by two Sethco Model ZDX-50A pumps, filtered through a 5 μm polypropylene filter, flows through a flow metering valve and a flow meter, and is discharged in the discharge chamber. The electrolyte flows over a weir from the discharge chamber into the upstream plating cell, from there through the PTH's in the MLB cathode into the downstream plating cell, and over a weir into the suction chamber. Each plating cell contained an anode 11 cm from the cathode and an air sparging pipe at the cathode weir close to the tank bottom. The air spargers were supplied with air from a Cyclonair Blower Model VFC201P-IT through a metering valve and a flow meter.

A Nova Tran Model 1221 Digi-Plate Pulse Plater with Model 6001 Ampere Time Controller served as the power supply. The MLB samples were connected to the power supply via an insulated wire and the anodes hung from standard titanium anode hooks. During plating with electrolyte containing brightener additives, a Rapid Electric Precision Solution Metering System Model MPAT-P-SMS in conjunction with a Fisher Volustat metering pump provided for the automatic maintenance of the additive balance. Additives were replenished at the rate of 1 ml every 120 A-min.

Electrolyte.—For the experiments a high conductivity acid-copper sulfate electrolyte containing 0.34M $CuSO_4$, 1.76M H_2SO_4, and 40 ppm Cl^- was used. Experiments were carried out with an additive-free plating bath and with the electrolyte containing the standard levels of Cubath®M proprietary organic additives (14).

MLB samples.—The MLB samples used are 9 × 9 cm in size, have a thickness of 123 mils, and have 46 mil diam PTH's on 125 mil centers. The samples contain 812 PTH's, except for the samples used for the high velocity experiments ($\bar{v} = 87$ cm/sec) where half the PTH's, and thus half the sample area, were masked with plating tape to make the high electrolyte velocities possible. The samples were electroless copper plated with a thin (~0.05 mil) conducting film.

Plating procedure.—To make electrical connection to the plating power supply 18 gauge bare copper wire was threaded through two PTH's on the top edge of the samples and crimped into place. The wire was then insulated with plating tape for its remaining length submerged in the plating solution. The following cleaning procedure was carried out for all samples: (*i*) Neutra-Clean soak of 30 sec at 50°C, (*ii*) DI water rinse for 2 min, (*iii*) etch in 10% sulfuric acid for 3 min, and (*iv*) DI water rinse for 2 min.

After the cleaning procedure, the samples were placed in the opening cut into the cathode weir (see Fig. 2) for this purpose and held in place by a holding frame. To prevent leakage flow of electrolyte from the upstream to the downstream plating cell all seams were sealed with plating tape.

Electrolyte velocities in the PTH's ranging from 0.17 to 87 cm/sec were obtained by varying the solution flow, the number of PTH's in the sample, and by permitting some known bypass flow. During the experiments with forced electrolyte flow, air sparging was not employed. No forced solution flow took place during the air sparging experiments. Experiments were carried out for two sparging rates: 0.25 and 1.0 liter/min-cm sparger length. These rates prevailed per unit length of the air spargers and were identical for the upstream and the downstream cell spargers. The lower sparging rate results in slight agitation of the electrolyte in the vicinity of the MLB samples, whereas the higher rate gives a very vigorous stirring and agitation of the electrolyte throughout the plating cells.

Experiments were carried out for plating current densities ranging from 5 to 100 mA/cm^2. The plating times for the experiments at different current densities were adjusted to plate every sample with the same number of coulombs and thus to yield identical average plating rates per unit total sample area. An automatic shutoff terminated each experiment when the predetermined number of ampere-minutes was attained. At the conclusion of the plating, the samples were removed from the plating tank, thoroughly rinsed with DI water, and dried in a forced air flow.

Sample preparation for analysis.—The MLB samples were visually inspected after the plating procedure and the quality of the deposit "read." A 0.5 × 0.75 in. coupon was cut from the center of each sample. The land areas surrounding each of the 15 PTH's on these coupons were electrically isolated from each other by cutting through the planar surface deposits between the PTH's on both sides of the MLB's. PTH electrical resistance measurements were made using a 4-point probe technique (18). After the resistance measurements, these coupons were cut in half, encapsulated, and the cross sections polished for metallographic examination.

Results and Discussion

Additive-free plating.—The results of the experiments employing additive-free electrolyte are illustrated in Fig. 3-8. In Fig. 3 the PTH resistance is cor-

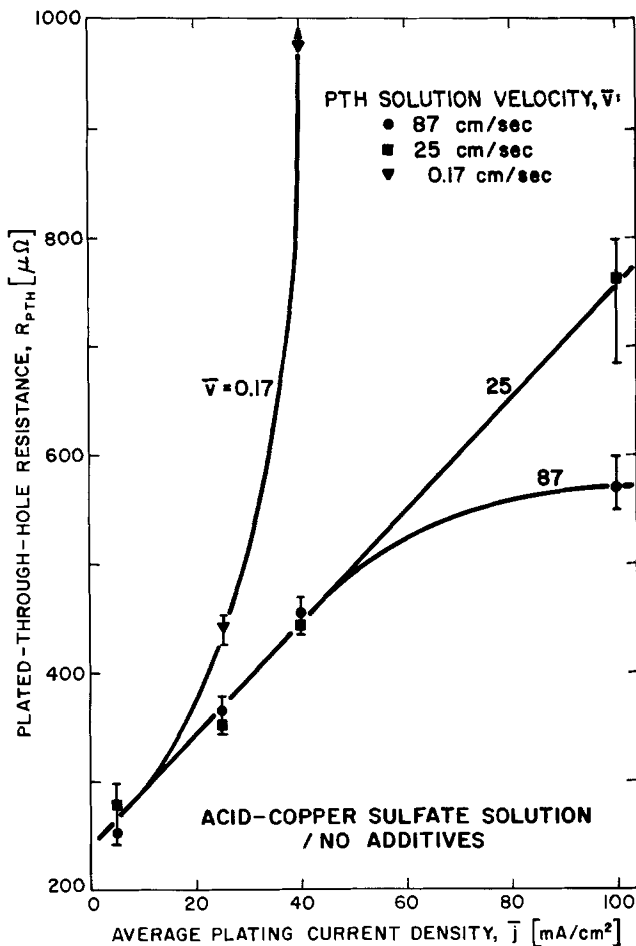

Fig. 3. Plated-through hole resistance as a function of plating current density and agitation velocity for additive-free plating.

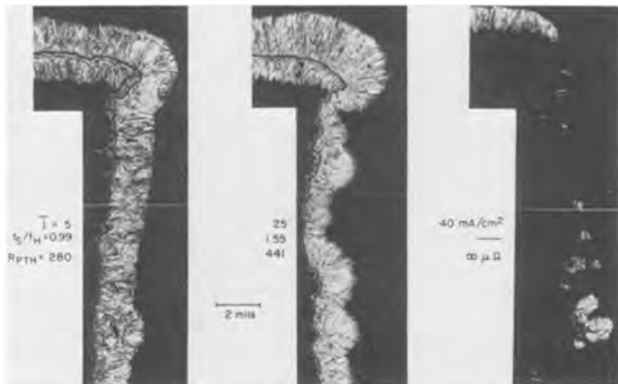

Fig. 4. Metallographic cross sections of plated-through holes plated at an electrolyte velocity $\bar{v}$ = 0.17 cm/sec and various current densities for additive-free plating.

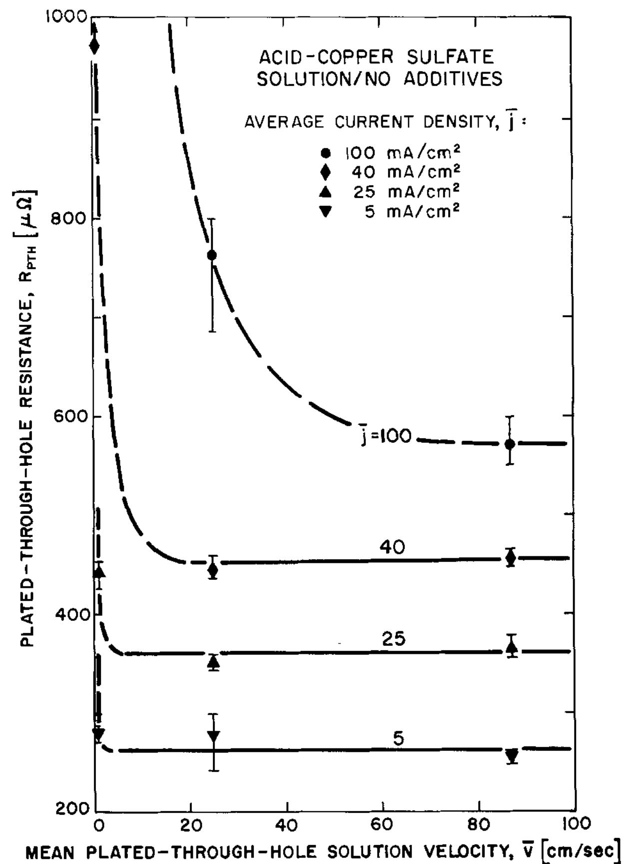

Fig. 5. Plated-through hole resistance as a function of agitation velocity and current density for additive-free plating.

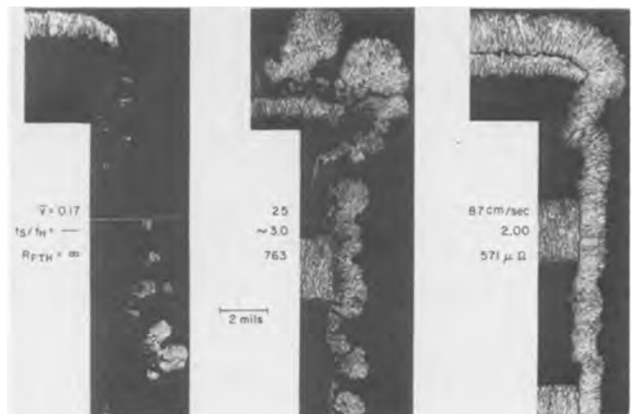

Fig. 6. Metallographic cross sections of plated-through holes plated at a current density of $\bar{j}$ = 100 mA/cm² and various agitation velocities for additive-free plating.

related with the average current density for three solution velocities in the PTH's. In all cases an increase in the plating current density results in a higher PTH resistance because of the deteriorating throwing power and changes in the macrocurrent distribution. The resulting PTH resistances at low current densities are the same for all agitation velocities; however, as the current density increases, the onset of mass transport-limited plating is clearly reflected in a more rapidly increasing PTH resistance for the lower agitation level conditions. These deviations, signaling the onset of mass transport-limited plating condition, are in good agreement with the calculated minimum mean PTH electrolyte velocities given in Table I.

Figure 4 illustrates the results shown in Fig. 3 with metallographic cross sections showing the changes in the copper deposit with increasing current density at a constant electrolyte velocity of 0.17 cm/sec. The deposit quality for 5 mA/cm² is very good. At 25 mA/cm² the deposit is rather rough and at 40 mA/cm² it is very rough and discontinuous.

In Fig. 5 the PTH resistance is plotted as a function of the mean PTH electrolyte velocity for current densities ranging from 5 to 100 mA/cm². It clearly shows that an increase in agitation beyond the level required to prevent mass transport-limited plating conditions does not improve the quality of the copper deposit in the PTH's. PTH resistances will decrease with increasing levels of agitation until mass transport-limited conditions no longer prevail and then will remain at a constant plateau. This also shows that even under optimum plating conditions, a minimum PTH resistance exists for each plating current density. These minimum resistances increase rapidly with increasing

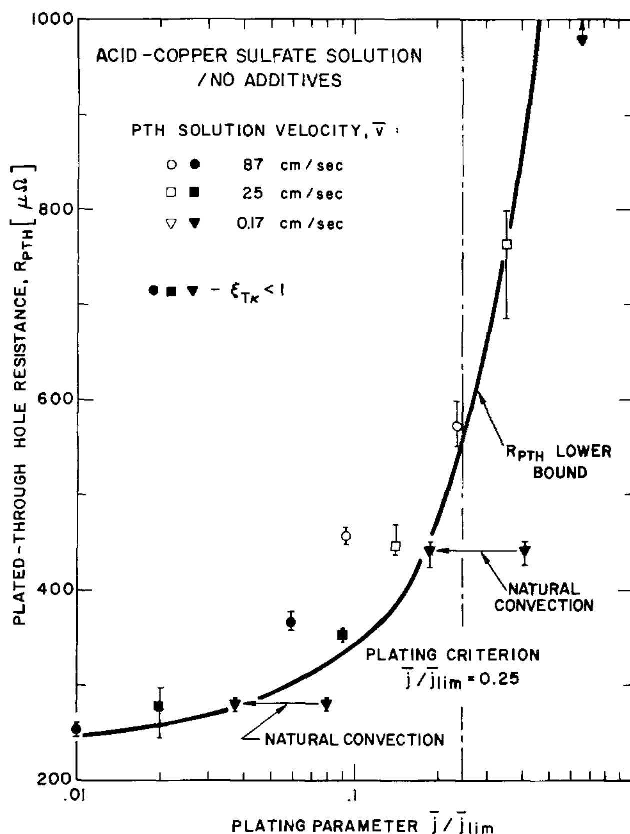

Fig. 7. Plated-through hole resistance as a function of $\bar{j}/\bar{j}_{lim}$ for additive-free plating. Natural convection corrections for low velocity data are indicated.

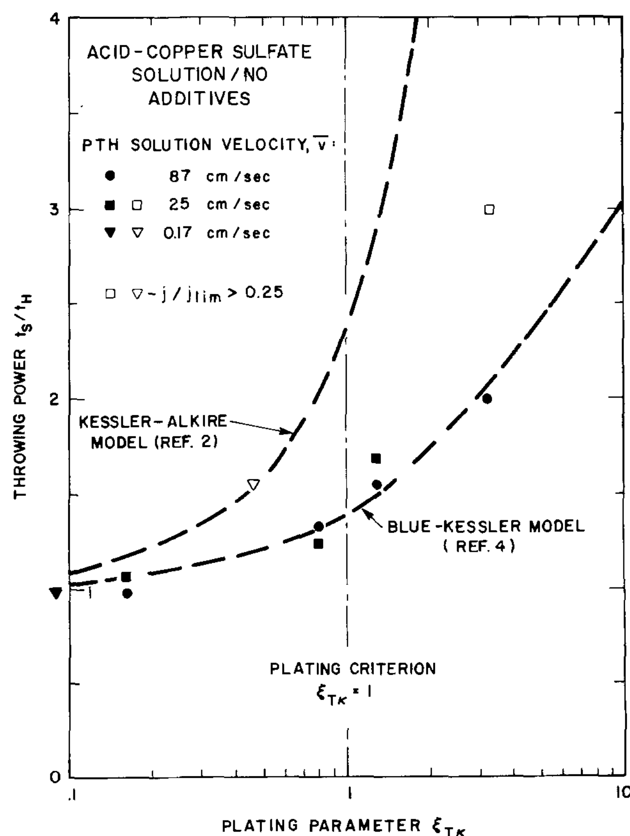

Fig. 8. Throwing power as a function of ξ_{TK} for additive-free plating with superimposed analytical model predictions.

current densities due to the throwing power characteristic for each current density.

Figure 6 exemplifies the results in Fig. 5. The photomicrographs show the PTH deposits for increasing electrolyte velocities at constant current densities of 100 mA/cm^2. The totally discontinuous deposit resulting from the low level of agitation provided by $\bar{v}$ = 0.17 cm/sec improves at $\bar{v}$ = 25 cm/sec to a still extremely rough deposit and changes to a good smooth deposit at a velocity of 87 cm/sec.

In Fig. 7 the PTH resistance is plotted as a function of the plating parameter $\bar{j}/\bar{j}_{lim}$. Since it is shown in Fig. 5 that increases in agitation beyond the minimum level required to prevent mass transport-limited plating conditions have no effect on R_{PTH}, correlation is expected only for results obtained with insufficient agitation. This correlation represents a lower bound for PTH resistances. The results for 25 and 87 cm/sec correlate rather well, but the PTH resistances for the samples plated at $\bar{v}$ = 0.17 cm/sec are much better than would be expected from the corresponding values of $\bar{j}/\bar{j}_{lim}$ and indicate a higher level of agitation. When the natural convection agitation effects are taken into consideration in the calculation of $\bar{j}/\bar{j}_{lim}$, the low velocity data correlate well with the high velocity results. The data plotted in Fig. 7 indicate that if both plating criteria Eq. [1] and [2] are met, PTH resistances of less than 450 $\mu\Omega$ result. Dendritic deposits form at values of $\bar{j}/\bar{j}_{lim} \geqq 0.3$ for the 0.34M $CuSO_4$ solution used.

In Fig. 8 the throwing power is correlated with the plating parameter ξ_{TK} and the results from two plating models (2, 4) are superimposed. The data show that the results from samples plated under conditions that meet the plating criterion Eq. [2] follow the Blue-Kessler (4) model prediction closely. This confirms the findings from a preliminary study (1), which concluded that the Kessler-Alkire model (2, 3) establishes a bound for limiting case behavior and that the Blue-Kessler model would give better predictions for well-controlled nominal conditions. The throwing power obtained under mass transport-limited plating conditions is significantly worse than the predicted optimum. From this plot it can be concluded that values of better than 1.5 for the PTH throwing power result from plating conditions meeting both plating criteria, Eq. [1] and [2].

Plating with Cubath®M additives.—The results of the experiments employing electrolyte with Cubath®M additives are illustrated in Fig. 9 through 13. In Fig. 9 the PTH resistance is shown as a function of the average plating current density for six solution velocities and two levels of air sparging. In contrast to the results for additive-free plating in Fig. 3, the PTH resistance is a much weaker function of the plating current density. Except for results from plating conditions with clearly inadequate agitation ($\bar{v}$ = 0.17 cm/sec and air sparging), the PTH resistance shows an increase with increasing current density only at values in excess of 40 mA/cm^2. In addition, the results for $\bar{v}$ = 25 and 43 cm/sec at $\bar{j}$ = 100 mA/cm^2 indicate a greater tolerance for agitation levels below the minimum electrolyte velocities established analytically (see Table I). On the other hand, at the low agitation levels provided by either forced flow at $\bar{v}$ = 0.17 cm/sec or by any level of air agitation, the rapid increase of the PTH resistance with increasing current density is indistinguishable from the results for additive-free plating. From these results it appears that the agitation provided by air sparging in the PTH's is roughly at the same level as the agitation provided by forced flow at $\bar{v}$ = 0.17 cm/sec.

In Fig. 10 the PTH resistance is correlated with the mean solution velocity in the PTH's. The results show even more vividly than the results for additive-free plating (Fig. 5) that an increase in agitation beyond the level necessary to prevent mass transport-limited plating does not further improve the PTH deposit quality. Compared to the results from additive-free plating the "band width" of possible PTH resistances

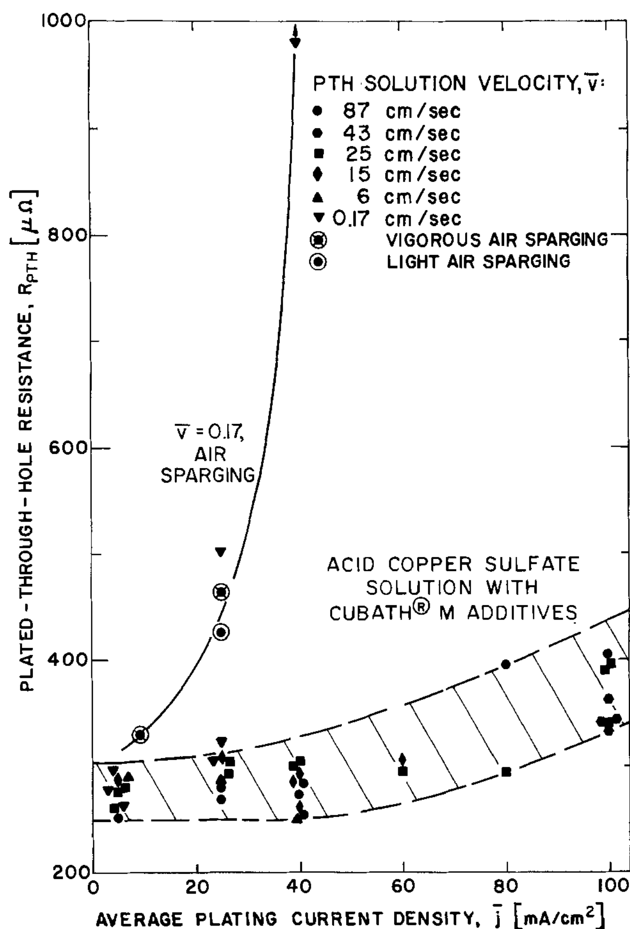

Fig. 9. Plated-through hole resistance as a function of plating current density and agitation velocity for plating with Cubath®M.

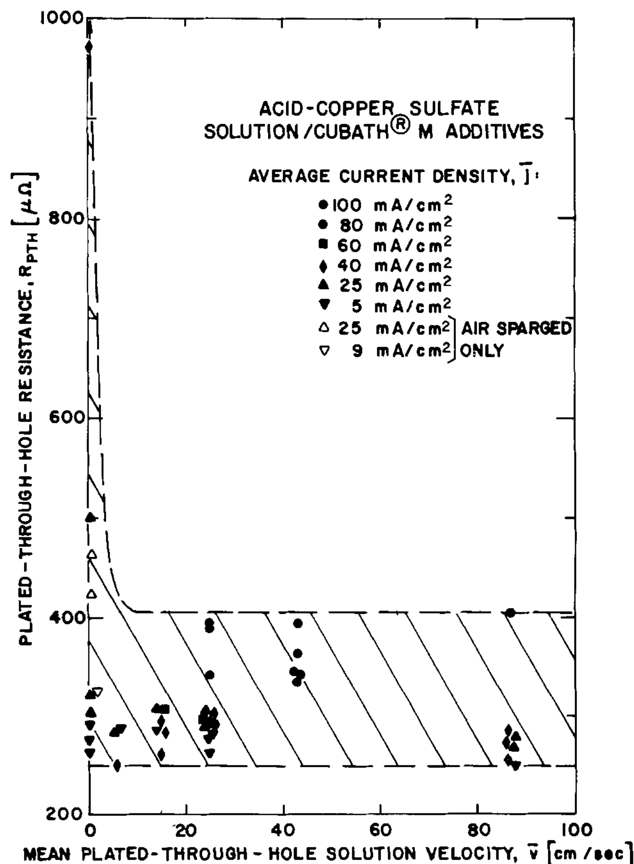

Fig. 10. Plated-through hole resistance as a function of agitation velocity and current density for plating with Cubath®M.

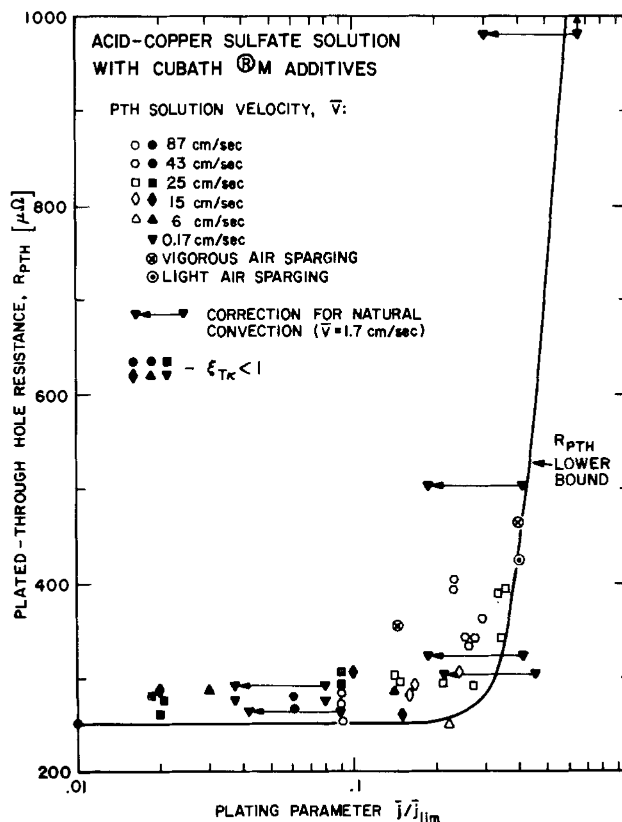

Fig. 11. Plated-through hole resistance as a function of $\bar{j}/\bar{j}_{lim}$ for plating with Cubath®M. Natural convection corrections for low velocity data are indicated.

for plating current densities ranging from 5 to 100 mA/cm² is much narrower for plating at adequate agitation. However, as for additive-free plating, but less pronounced, plating at higher current densities yields PTH's with higher resistances.

In Fig. 11 the PTH resistance is shown as a function of the plating parameter $\bar{j}/\bar{j}_{lim}$. As in Fig. 7, the lower bound for PTH resistances is indicated. Unlike the results for additive-free plating (see Fig. 7), the PTH resistance is virtually independent of $\bar{j}/\bar{j}_{lim}$ for values below the plating criterion $\bar{j}/\bar{j}_{lim} = 0.25$. For higher values of $\bar{j}/\bar{j}_{lim}$ however, the PTH resistance increases very rapidly. The results for very low agitation plating ($\bar{v} = 0.17$ cm/sec) show, as was the case for additive-free plating, improved correlation with the other results when the natural convection agitation effects are taken into consideration. However, for the very rough samples with $R_{PTH} > 300$ $\mu\Omega$, the natural convection is apparently impeded by the surface roughness in the PTH and thus a natural convection correction of $\bar{v} = 1.7$ cm/sec is too large.

An equivalent agitation velocity for both light and vigorous air sparging of $\bar{v} = 0.25$ cm/sec was estimated by fitting the PTH resistances for the air sparged MLB samples onto the lower bound curve in Fig. 11. The results from air sparging are plotted accordingly in Fig. 11. It also appears that natural convection may play a much less significant role in air sparging than for low level forced flow. It can be speculated that air sparging could disrupt natural convection sufficiently to prevent the resulting beneficial agitation effect.

The independence of the PTH deposit from variations in $\bar{j}/\bar{j}_{lim}$ for values of $\bar{j}/\bar{j}_{lim} < 0.25$ is further illustrated in Fig. 12a and 12b. In these figures photomicrographs of PTH's plated at consecutively larger values of $\bar{j}/\bar{j}_{lim}$ are shown. Samples (a)-(d), plated at $\bar{j}/\bar{j}_{lim}$ values ranging from 0.02 to 0.14 all show good, almost indistinguishable deposits with good leveling characteristics. However sample (e) plated at $\bar{j}/\bar{j}_{lim} = 0.41$ shows a

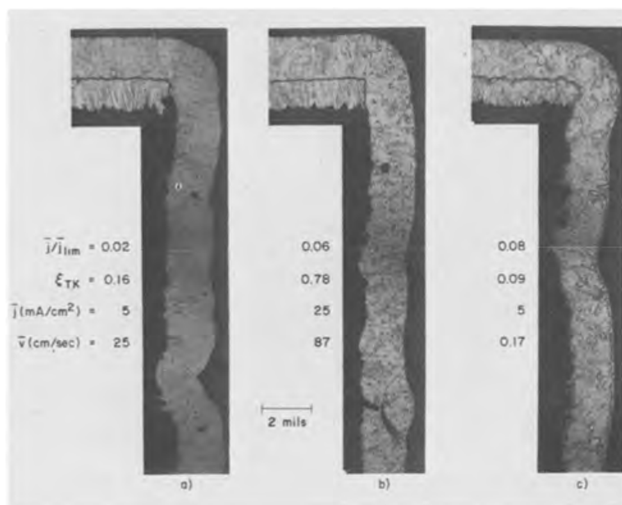

Fig. 12a. Metallographic cross sections of plated-through holes plated with Cubath®M at consecutively increasing values of $\bar{j}/\bar{j}_{lim}$.

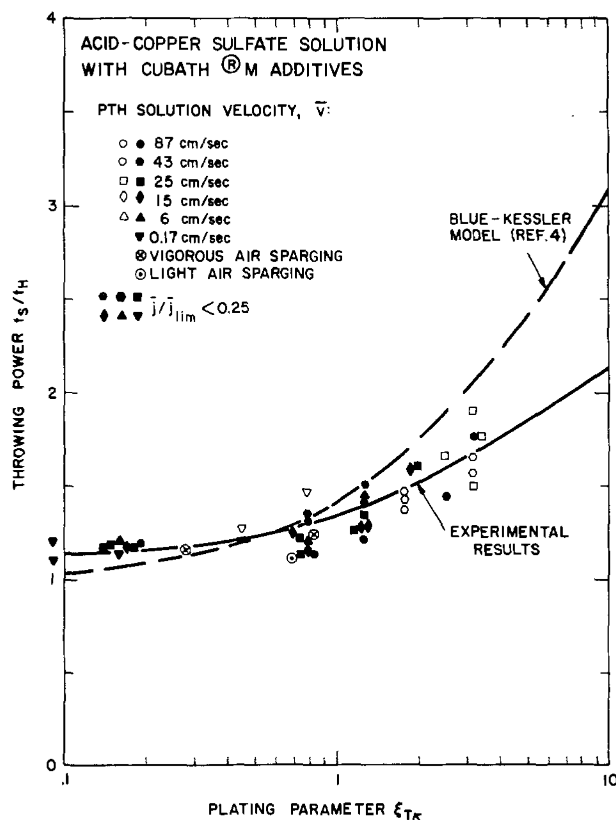

Fig. 13. Throwing power as a function of ξ_{TK} for plating with Cubath®M with superimposed analytical model predictions.

very rough, nonleveling deposit and for sample (f) plated at $\bar{j}/\bar{j}_{lim} = 0.66$ no copper has been deposited onto the electroless copper film and the electrodeposited copper formed isolated dendritic globules. The grain structure from deposits at very low current densities was columnar rather than fine as observed for deposits from higher current densities. Examination of samples (a) and (c), both plated at 5 mA/cm², show a much more pronounced grain structure than the other samples. Interestingly, sample (a) plated at a high level of agitation shows a columnar structure, whereas sample (c) plated at a very low level of agitation shows a large grained structure.

In Fig. 13 the throwing power is correlated with the plating parameter ξ_{TK} and the curve from the Blue-Kessler model (4) is superimposed. A curve is also fitted to the experimental data. Generally, the throwing power worsens as ξ_{TK} increases; however, this in-

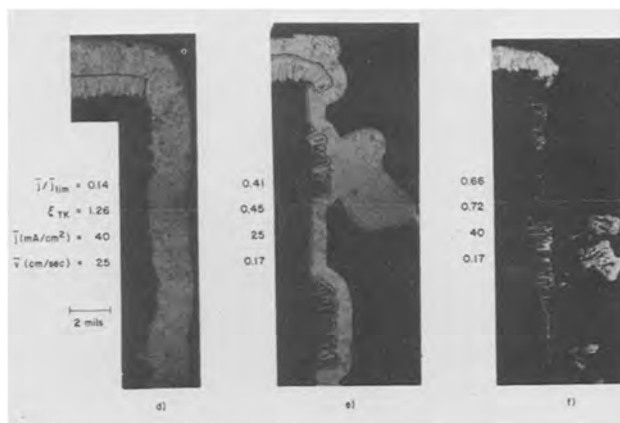

Fig. 12b. Metallographic cross sections of plated-through holes plated with Cubath®M at consecutively increasing values of $\bar{j}/\bar{j}_{lim}$.

crease is less than predicted by the Blue-Kessler model which correlated very well with the results from additive-free plating. This would indicate that Cubath®M additives make the plating quality less sensitive to changes in the plating parameters.

Summary and Conclusions

Additive-free acid-copper sulfate electrolyte.—The plating parameters developed in Ref. (2) correlate very well with the quality of the copper deposit in the PTH. The plating criteria established in Ref. (2) assure good quality PTH's with a throwing power t_S/t_H of better than 1.5. Plating for a given number of amperes-minute, lower plating current densities give lower PTH resistances and better throwing power. Increased levels of agitation improve the deposit quality dramatically up to the point of eliminating ion concentration gradients causing mass transport-limited plating conditions; further increases in the level of agitation, however, provide no further improvement in the PTH copper deposit. To prevent mass transport-limited plating conditions, agitation requirements increase rapidly with increasing current density and decreasing cupric ion concentration. For plating conditions meeting the plating criteria from Ref. (2), the Blue-Kessler model (4) predicts the throwing power into PTH's very well. The Kessler-Alkire model (2, 3), on the other hand, establishes limiting case behavior. Electrolyte agitation provided by natural convection has to be considered when only low levels of electrolyte agitation are provided by other means; an equivalent agitation velocity for natural convection of $\bar{v} = 1.7$ cm/sec has been determined from deviations from the Lévêque flow (15-17) and provides for excellent correlation of the low agitation results.

Acid-copper sulfate electrolyte with Cubath®M additives.—The findings for additive-free plating generally hold for plating with Cubath®M. However, Cubath®M plating is considerably less sensitive to changes in plating parameters such as current density and level of agitation. The dimensionless criteria for good plating (throwing power $t_S/t_H \leq 1.5$) of the miniscale can be relaxed to

$$\xi_{TK} < 2$$

and

$$\bar{j}/\bar{j}_{lim} < 0.25$$

The experimental results show a better deposit quality for higher values of ξ_{TK} than is predicted by the Blue-Kessler model (4). The assumption of negligible effects of additives on the miniscale plating (2, 3) used in the development of the Blue-Kessler model (4) cannot be maintained. This is indicated by the decreased sensitivity to plating parameter variations as well as the higher deposit quality (R_{PTH}, t_S/t_H) of PTH's plated in Cubath®M when compared to PTH's plated under the same conditions but in an additive-

free solution. From a comparison of the plated deposit, assuming no interaction between the sparging air and the brightener additives, it is estimated that air sparging provides electrolyte agitation in PTH's equivalent to $\bar{v} = 0.25$ cm/sec. It also appears that natural convection agitation effects benefiting low level forced flow agitation are impeded by air sparging. It is expected that this estimate is valid for additive-free plating also.

Auger Spectroscopic Evidence That Plasma Anodization Involves Mass Transfer from the Cathode to the Anode

J. D. Leslie and V. Keith[1]

ABSTRACT

Auger spectroscopic evidence is presented that cathode material is transported to the anode during plasma anodization, even when the anode is facing away from the cathode and is located on the back of a shield. In the preparation of the plasma oxide samples, anodes of Ta, Nb, and Cu and cathodes of Ta, Nb, Al, and C have been used in various combinations. The Auger spectroscopic results indicate that cathode material does not deposit on the anode unless the anode is passing a current and that the oxide on the anode formed by plasma anodization generally has two layers, with the outer layer consisting of oxide of the cathode material and the inner layer consisting of oxide of the anode material. Evidence is presented which suggests that the transfer of cathode material to the anode is an integral part of plasma anodization.

In this paper we would like to report on an Auger spectroscopic study of metal oxide films produced by plasma anodization. Auger spectroscopy (1) is a technique for identifying atomic elements and determining their percentage concentration on the surface of a sample. When combined with *in situ* ion etching, it allows one to determine the depth profile of the percentage concentrations of the atomic constituents of the sample (2).

In 1963, Miles and Smith (3) introduced a method of forming an oxide layer on a metal surface which they called plasma anodization. They utilized a d-c oxygen gas at a pressure of 0.05 Torr. The surface ring cathode held at -1000V in a bell jar filled with oxygen gas at a pressure of 0.05 Torr. The surface of the metal sample to be anodized was mounted so that it would not see the cathode directly, supposedly to eliminate direct sputtering of cathode material onto the metal sample surface. If a thin oxide layer was desired, the glow discharge was maintained for a short period of time: a few seconds to some tens of minutes. If a thicker oxide layer was desired, the metal sample was made positive with respect to the system ground by means of an external positive voltage applied to the sample by a direct electrical connection, thus making the sample the anode. They found that the oxide thickness increased linearly with the anode voltage applied and that for a fixed anode voltage the anode current decreased to zero as the limiting thickness associated with that voltage was reached. By comparing this behavior with the similar behavior of anodization in an aqueous electrolyte, they called their process plasma anodization and suggested that the oxygen plasma was playing the role of an electrolyte that supplies negative oxygen ions to the surface of the metal anode where the oxide growth occurs.

Since the pioneering work of Miles and Smith, there have been a number of investigations of the phenomenon of plasma anodization. [See the article by Dell'Oca, Pulfrey, and Young (4) for a review of the work up to 1971.] While many of these investigators have questioned the role of negative oxygen ions assumed by Miles and Smith, there have been only a few indirect tests of the effect of negative oxygen ions on plasma anodization. O'Hanlon and Pennebaker (5) by applying a combination of d-c and rf voltages to the anode claimed to have shown that anodization would not occur under conditions where the negative oxygen ion component of the anodizing current was zero. Olive *et al.* (6) questioned the conclusion of O'Hanlon and Pennebaker, in that they pointed out that the bias conditions employed would have prevented oxide growth whether or not negative oxygen ions from the plasma were needed for growth. Olive *et al.* repeated this d-c and rf biasing experiment, but utilized a constant d-c current, and claimed from the result of their experiment that negative oxygen ions in the plasma were not utilized in plasma anodization. However, this test is a very indirect one and, as Olive *et al.* pointed out, it depended on the validity of some of the theoretical equations assumed.

The role of the cathode in plasma anodization, apart from that of being the source of the oxygen plasma, has always been assumed to be that of a source of contamination via reactively sputtered cathode material (7, 8). It is for this reason that in the literature it is always advocated that the sample should face away from the cathode and be suitably shielded, so that the surface being anodized cannot see the cathode directly. However, Leslie and Knorr (9), in an earlier ellipsometric study of the plasma anodization of tantalum, showed that under certain conditions, even if the sample was facing the cathode, there was no direct sputtering contamination of the sample, in that the sample was not being coated with sputtered material independently of the growth of the oxide layer. However, as Knorr and Leslie (10) showed in this earlier work on the plasma anodization of niobium and tantalum, it is necessary to assume a model, *i.e.*, one layer or two, values of refractive indexes, to interpret the ellipsometric data. For this reason, it was decided that only a more direct technique such as Auger spectroscopy would be useful in the present study.

Experimental Procedures

The vacuum system and experimental arrangements for producing the plasma anodized samples were the same, in general, as those used in the earlier ellipsometric studies (9, 10). However, one significant difference was that the samples were mounted facing away from the cathode. An aluminum shield that was 5 cm wide by 10 cm high was positioned parallel to the cathode and 8 cm away and was isolated electrically from the rest of the vacuum chamber. The samples were 0.1 mm foil and were mounted between mica sheets on the side of the shield away from the

[1] Present address: Department of Physics, Queen's University, Kingston, Ontario, Canada.

cathode. The top mica sheet had a hole 0.5 × 1.0 cm that defined the active area of the sample. The samples had a wire spotwelded to them, so that the anodization current could be supplied, and the wire was insulated over its entire length in the vacuum space to prevent leakage current.

Because of the location of the sample facing away from the cathode, it was not possible to make ellipsometric measurements during the growth of the oxide. The thickness of the oxide layer was estimated during growth from the change in the sample voltage at fixed anode current, which was compared to similar plots that had been calibrated in earlier ellipsometric studies.

Before mounting the samples, we had cleaned them by heating the foils to a red heat in a pressure of 10^{-8} Torr for a few minutes. The samples were all polycrystalline foil, and the material was Marz grade Ta and Nb foil purchased from Materials Research Corporation. After the cleaned sample was mounted in the vacuum chamber where the plasma anodization would take place, the system was pumped down to less than 10^{-7} Torr. Then research grade oxygen gas was admitted to the vacuum chamber through a leak valve while a mechanical pump connected to the chamber through a sorption trap kept the pressure in the vacuum chamber at 0.05-0.07 Torr under flow conditions. Once the pressure was stable, the glow discharge was initiated by applying −800V to the cathode. The anodizing current applied to the sample was typically 2 mA, and the samples were anodized for periods of 2-6 hr. A number of different cathode and anode material combinations were used. We used cathodes of Ta, Al, and C, which all measured 4 × 10 cm and a Nb cathode which measured 2.5 × 8 cm.

The Auger spectrometer used in this study was manufactured by Physical Electronics Industries and consisted of a stainless steel vacuum system (Model 12-100) with ion pumps and titanium sublimation pump, a cylindrical mirror analyzer (Model 10-150) with an integral 5 keV electron gun, a 2 keV sputter ion gun (Model 04-161), a carousel specimen manipulator (Model 10-502), and associated electronics. The plasma anodized samples were mounted on the carousel specimen manipulator, which could accommodate 12 samples at one time. After the vacuum system had been pumped down to 10^{-9} Torr, the ion pumps were turned off and the system was backfilled to a pressure of 5×10^{-5} Torr of krypton so that the ion etching could take place. Although the sputter ion gun had a maximum ion voltage of 2 keV, the normal conditions used in these experiments were a 1 keV etching voltage and a constant etching current. Auger spectra were obtained in two ways: First, complete Auger spectra (Auger signal *vs.* electron energy) were taken after different amounts of etching. In this way it was possible to examine the surface of the sample after a specified thickness of the sample had been removed. In particular, this was useful for determining all the elements of particular interest in a plasma oxide associated with a particular combination of cathode and anode materials. Second, through the use of a multiplexer, it was possible to scan the Auger signal occurring within up to eight separate electron voltage ranges. In this way it was possible to pick a voltage range for each multiplexer channel associated with a particular Auger peak identifying a particular element. By scanning cyclically through these voltage ranges and displaying the Auger signal *vs.* ion etching time, it was possible to see directly the variation of the concentration of the different elements as we etched through the sample. Thus we could arrive at an Auger depth profile of the atomic element concentrations throughout the thickness of the plasma oxide layer. The "depths" in these depth profiles are initially in terms of etching time, but by performing subsidiary ion etching experiments, it is possible to find the appropriate factors for converting etching times into thicknesses in angstroms.

These subsidiary experiments consisted of the following: A fairly thick (approximately 2000Å) layer of the plasma oxide, whose etch rate was to be determined, was formed on the anode sample in the standard way, but a cathode of the same metal was used. Then a stainless steel mask with a 2 mm hole in it was placed over the anode sample, which was then mounted in the Auger system. The anodic oxide layer was etched away using the constant current beam of krypton ions of specified voltage, until the oxygen Auger signal had dropped to half its initial constant value. The total etching time for this was noted and the etch was discontinued. The sample was removed from the Auger system and the depth of the resulting circular hole in the plasma oxide layer was measured using a Talysurf 4 depth profile measurer and/or a Gaertner interference microscope. By dividing the measured depth in angstroms by the measured etching time in seconds, one can arrive at the etching rate in angstroms per second for that plasma oxide for the constant current of Kr ions of the specified voltage. This procedure was checked by growing a known thickness of anodic oxide on Ta or Nb in an electrolyte. The thickness was determined from the anode voltage used and the known anodization constant. The resulting anodic oxide layer was then masked, ion etched, and the thickness measured in the same way as for the plasma oxide samples. The thickness measurements so found were within 5% of those given by the anodization constants and the anode voltages, and so we estimate that the thicknesses of the plasma oxide layers were determined within 5%.

Experimental Results

Ta anode and Nb cathode.—The first system that we studied was the plasma anodization of Ta using a Nb cathode. Figure 1 shows the complete Auger spectrum for the surface "as is" of a Ta sample, which we estimated to have a plasma oxide of approximately 1750Å on its surface. The largest peak at 510 eV is associated with oxygen, as are the smaller peaks between 460 and 510 eV. The low energy peaks between 150 and 200 eV are associated with Nb, except for the one peak at 180 eV which is associated with Cl. All the peaks between 1600 and 2000 eV are also associated with Nb. The peaks at 260, 380, and 660 eV are associated with C, N, and F, respectively. The most interesting thing about this spectrum is that there is absolutely no indication of Ta on the surface of the

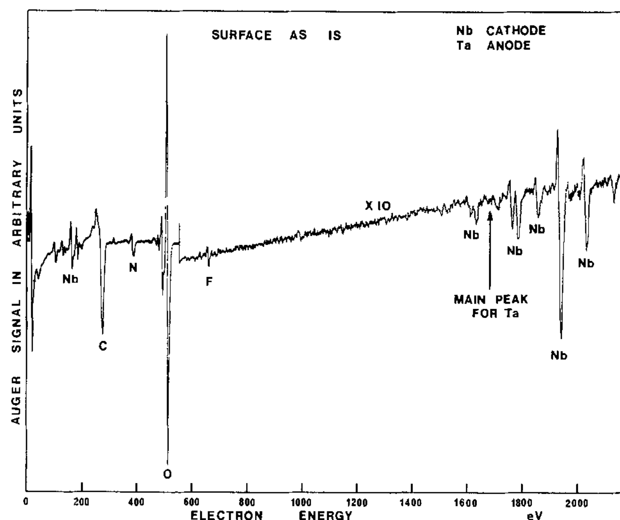

Fig. 1. Complete Auger spectrum of the surface of a plasma anodized Ta foil. Experimental conditions of the anodization: Nb cathode, cathode voltage −800V, oxygen pressure 0.06 Torr, sample area 50 mm², anode current 2 mA for 2 hr.

sample. The arrow in Fig. 1 at 1680 eV indicates the position of the main line for Ta which is at least as strong as the main line for Nb at 1944 eV. In Fig. 1, there is an increase of signal sensitivity of a factor of 10 for the region with electron energy greater than 550 eV. By using the multiplexer, and establishing appropriate channels, *e.g.*, 250-300 eV for C, 490-520 eV for O, 1650-1710 eV for Ta, 1920-1960 eV for Nb, etc., it was possible to monitor the Auger depth profile of the atomic constituents of the plasma oxide layer. We chose to observe the higher energy peaks of Ta (1680) and Nb (1944) rather than the stronger low energy peaks, because the Ta and Nb peaks overlap at low energy.

Figure 2 shows the plot of the Auger signals for Nb, Ta, and O *vs.* etching time in seconds. The Auger signals are plotted in arbitrary units, although it would be possible to process the data to give surface percentages. The Auger peaks associated with Cl, C, N, and F disappeared within 100 sec of etching, so they are associated just with surface contamination of the plasma oxide sample from the laboratory environment during the transfer to the Auger system. The etching was performed with a beam of 1 keV krypton ions. In separate etching experiments, the etching rate of such a beam was established to be 1 Å/sec for Ta oxide and 0.8 Å/sec for Nb oxide.

Figure 2 shows that there is no indication of Ta for at least 1000 sec of etching. The Auger signals for Nb and O are large and constant for the first 1000 sec (apart from the initial 100 sec of surface contamination). Although Auger spectroscopy cannot establish the chemical state that the atomic constituents are in, the constant Nb and O Auger signals and the known reactivity of Nb indicates that the Nb is present as an oxide. We can estimate the thickness of the Nb oxide layer in the following way. If we take the time at which the Nb Auger signal falls to half its initial constant value as an indication of the thickness of the Nb oxide, we see that this is 1520 sec. If we take the half-height of the O Auger signal as a measure of the total oxide thickness, we see that this is 1850 sec. We see that over the time between 1520 and 1850 sec the Ta signal is rising sharply, so we can attribute 1520 sec of etch time to Nb oxide and 330 sec, *i.e.*, 1850 − 1520, to Ta oxide. Using the etch rates of 0.8 Å/sec for Nb oxide and 1 Å/sec for Ta oxide, we find that the plasma oxide consists of a top layer of 1220Å of Nb oxide and a bottom layer of 330Å of Ta oxide. These thickness estimates may be in error from two sources. First, we are neglecting the mixing effect of the Ta and Nb, in that we are using the etching rate for Nb oxide to convert the etching time into a thickness, even though the last few hundred seconds involve an increasing component of Ta oxide. Second, the Ta oxide layer actually produced during the plasma oxidation process will certainly be less than our estimate here, because as soon as the clean Ta surface is exposed to oxygen, a surface layer of oxide will form immediately, even without a plasma.

The interface between Nb oxide and Ta oxide is quite thick, in that the Nb Auger signal drops from 90 to 10% of its initial value over 420 sec of etching time, which corresponds to a thickness of 336Å. The corresponding 10-90% of the final value for the Ta Auger signal yields a width of 640 sec, which would translate into 640Å, if we use the Ta oxide etching rate. However this figure is not as meaningful as that for Nb, since, if there is a 330Å layer of Ta oxide, we would expect the Auger Ta signal to increase to a plateau through the oxide region and then increase again as we reach pure Ta. There is a suggestion in Fig. 2 that this is occurring, so we should really take 90% of this plateau value, which appears to be 130, and 90% yields 117. Therefore the appropriate Ta oxide interface thickness is 320Å; *i.e.*, (1660 − 1340) sec × 1 Å/sec. Thus this simple analysis suggests that there is a cross-over or transition region of Nb oxide to Ta oxide of approximately 320-340Å. The mean escape depth of the Auger electrons in this energy range is 20Å, so this cannot account for such a broad transition region. It may be a real effect of the oxide formation or it may be caused by the polycrystalline foils that we are using, which have very small grain size. The resulting grain boundaries might affect the results in two ways. First, diffusion along grain boundaries is known to occur much faster than through the bulk, and this may be producing a greater mixing distance of the species during the oxidation process. Second, it is possible that the ion etching rate may be greater at the grain boundaries than through the bulk, and thus the etching would expose material farther into the sample along the grain boundaries. This would cause an apparent broadening of the transition region. The magnitude of both of these effects is unknown. Obviously, repeating these experiments on single crystal anodes would eliminate these possible problems and show whether the large transition regions that we obtain in these experiments are intrinsic to the plasma oxidation process. It is for this same experimental reason that we have adopted a rather simple approach to analyzing the plasma oxide into two layers, and we have not worried about the details of what is occurring in the interface region between the layers.

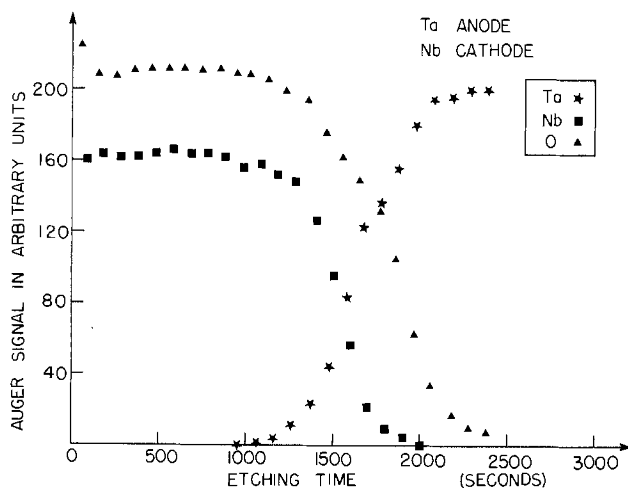

Fig. 2. Auger depth profile of the atomic constituents of the plasma oxide on the Ta anode of Fig. 1. Etching time is a measure of the thickness of the oxide layer that has been etched away, and the Auger signal gives the relative concentration of the atomic constituents on the surface of the layer remaining.

Figure 3 shows the Auger depth profile of the atomic constituents of another plasma oxide layer produced on a Ta anode using a Nb cathode. The experimental conditions of cathode voltage, anode current, and oxygen pressure were similar to those for the sample of Fig. 2, the only major difference between the two being that the plasma oxide in Fig. 3 was grown for a longer time. The most striking feature of Fig. 3 is that once again, as in Fig. 2, there is no indication of any Ta until the sample has been etched for 1500 sec. Let us use the half-heights of the Auger signals for Nb and O to indicate the thickness of the Nb oxide and the total oxide thickness, respectively, *i.e.*, the same procedure as in Fig. 2. We find that the Nb oxide has an etching time of 2220 sec which corresponds to a thickness of 1780Å. The total etching time for the oxide is 2500 sec. Therefore the Ta oxide thickness is 280Å, *i.e.*, (2500 − 2220) sec × 1 Å/sec. The main point to note is that the Nb oxide in Fig. 3 is 560Å thicker than in Fig. 2, whereas the Ta oxide layer is almost the same thickness for the two samples. The other striking feature of Fig. 3 is that there is no indication of a shoulder associated with a plateau in the Ta Auger signal. The thickness of the transition region is hard to establish

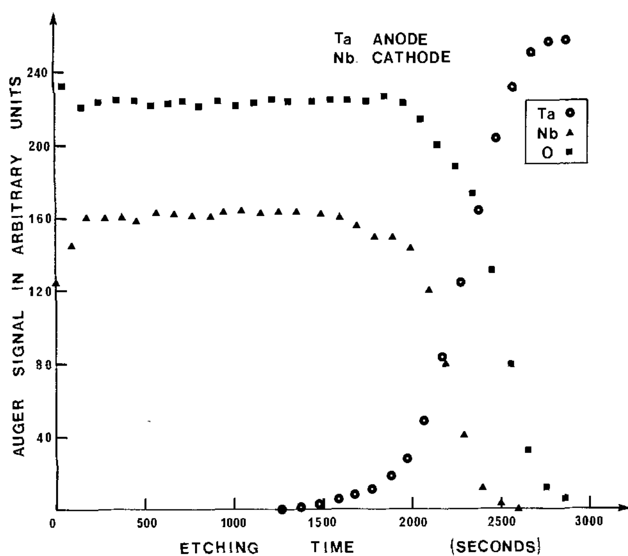

Fig. 3. Auger depth profile of the atomic constituents of the plasma oxide on a Ta anode. Experimental conditions of the anodization: Nb cathode, cathode voltage −800V, oxygen pressure 0.05 Torr, sample area 50 mm^2, anode current 2 mA for 3 hr.

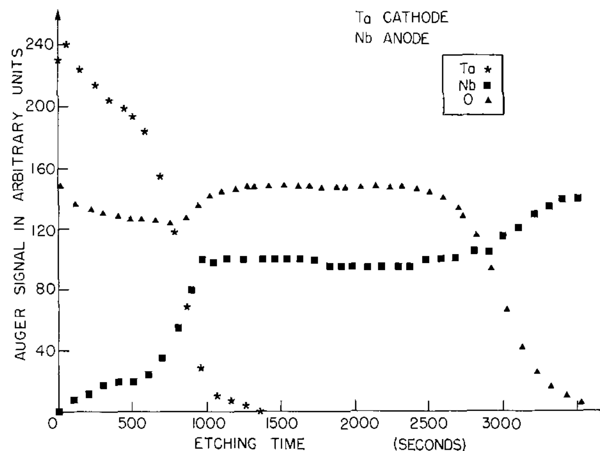

Fig. 4. Auger depth profile of the atomic constituents of the plasma oxide on a Nb anode. Experimental condition of the anodization: Ta cathode, cathode voltage −800V, oxygen pressure 0.06 Torr, sample area 50 mm^2, anode current 2 mA for 4 hr.

because of this fact and also the fact that the Nb Auger signal starts to fall slowly for 500 sec, between 1500 and 2000 sec before descending sharply. If we take the sharp descent as the indication of the interface, then the 90-10% Nb Auger transition region occurs over 400 sec of etching time between 2060 and 2460 sec. This translates into a 320Å Nb oxide transition width which is almost identical to what was found for Fig. 2. However, there is some indication of a slightly longer tail in the Ta distribution into the Nb oxide. The total sample thickness is 1780Å Nb oxide + 320Å Ta oxide for a total thickness of 2100Å.

Now, from the results of Fig. 2 and 3, one might suspect that all that is happening is that cathode material is being sputtered onto the anode sample and contaminating it. However, we must point out, most emphatically, that if no voltage is applied to the anode sample then less than 100Å of cathode oxide is formed on the sample regardless of the length of time that the sample is left in the glow discharge. Ta samples were processed in exactly the same way as those of Fig. 2 and 3 and were exposed to the plasma for the same times as those samples, with the exception that no anode current was supplied. The samples were analyzed in the Auger system, and the Nb oxide on the surface etched away in less than 100 sec. This initial buildup of less than 80Å of Nb oxide can be understood in terms of an effective voltage on the sample due to a difference in potential between the plasma and the sample.

Nb anode and Ta cathode.—Next we studied the growth of a plasma oxide on a Nb anode using a Ta cathode. The experimental conditions of cathode voltage, anode current, and oxygen pressure were similar to the earlier samples. Figure 4 shows the Auger depth profile of the atomic constituents of a plasma oxide layer produced on a Nb anode with a Ta cathode. The most striking feature of Fig. 4 is that a Nb oxide layer has been formed under the Ta oxide layer on the surface. Using the half-heights of the Ta and O Auger signals to determine the etching time through the Ta oxide and the total oxide thickness, we arrive at etching times of 820 sec for the Ta oxide and 2980 − 820 = 2160 sec for the Nb oxide. Using the etching rates of 1 Å/sec for Ta oxide and 0.8 Å/sec for Nb oxide, we arrive at 820Å of Ta oxide as the outer layer and 1730Å of Nb oxide as the inner layer for a total thickness of 2550Å. Other interesting things to note about Fig. 4 are that a low concentration of Nb penetrates through the Ta oxide layer almost to the surface of the sample and the Ta concentration drops throughout the outer oxide layer. So we probably have some mixing going on in this outer layer, with the outer surface being entirely Ta oxide and the concentration of Nb oxide increasing throughout this layer. Using the 90-10% drop in Auger signal for Ta to define the thickness of the Ta oxide interface region, and using the value of the Auger signal at 600 sec, *i.e.*, 186, we find that the interface thickness of the Ta oxide is 320 sec, which translates into 320Å, which is exactly the same as what was found for the samples of Fig. 2 and 3. Since there is this large penetration of Nb oxide into the Ta oxide, it is a little harder to define an interface thickness for the Nb oxide, but if we take 10-90% of the jump between the plateau at 20 and the final value of 100, we find an etching thickness of 310 sec, which is very close to the time for Ta oxide, but using a conversion of 0.8 Å/sec this translates into a thickness of 248Å. The O peak drops off more slowly as we approach the end of the oxide, and the interface region is 640 sec thick, which corresponds to 512Å.

Nb anode and Al cathode.—Many studies of plasma oxidation have used aluminum as the cathode material, consequently, we thought that we should see what effect this would have on the growth of the plasma oxide on Nb and Ta anodes. The experimental conditions of cathode voltage, anode current, and oxygen pressure were similar to the earlier samples. Figure 5 shows the Auger depth profile of the atomic constituents of the plasma oxide obtained for a Nb sample plasma oxidized using an Al cathode. Once again, the most striking feature of Fig. 5 is that the plasma oxide consists of an outer layer of Al oxide and an inner layer of Nb oxide. Using the half-heights of the Al and O Auger signals to determine the etching time through the Al oxide and Nb oxide, we arrive at etching times of 590 sec for the Al oxide and 1820 − 590 = 1230 sec for the Nb oxide. The etching rate for Nb oxide is 0.8 Å/sec and the etching rate for Al oxide is also 0.8 Å/sec, thus, the Al oxide outer layer is 470Å thick and the Nb oxide inner layer is 980Å thick. The 10-90% thickness of the Al oxide interface is 360 sec which corresponds to 290Å. Quite a pronounced dip in the O Auger signal is seen at the interface of the Al oxide and Nb oxide in Fig. 5. It can also be seen to a lesser extent in Fig. 4 at the interface between the Ta oxide and the Nb oxide.

Ta anode and Al cathode.—Figure 6 shows the Auger depth profile of the atomic constituents of the plasma oxide obtained with a Ta anode and an Al cathode. The experimental conditions of cathode voltage, anode

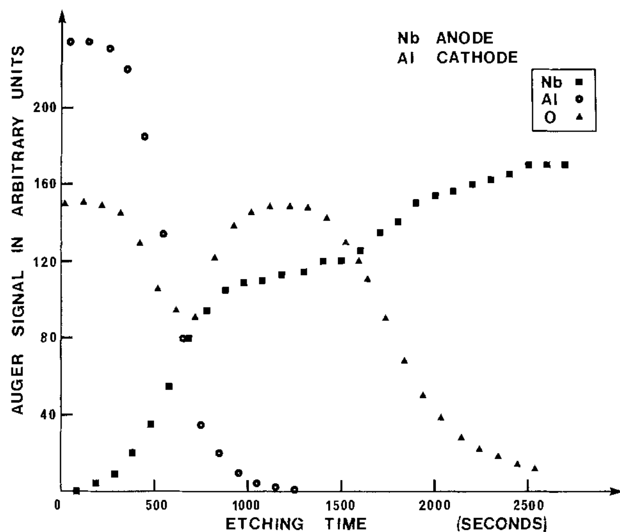

Fig. 5. Auger depth profile of the atomic constituents of the plasma oxide on a Nb anode. Experimental conditions of the anodization: Al cathode, cathode voltage —800V, oxygen pressure 0.06 Torr, sample area 50 mm^2, anode current 2 mA for 4 hr.

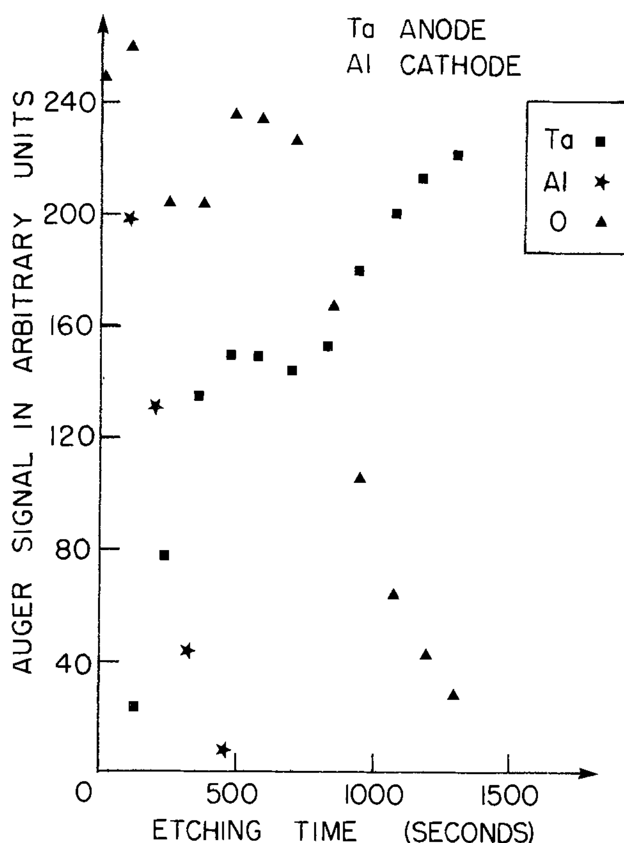

Fig. 6. Auger depth profile of the atomic constituents of the plasma oxide on a Ta anode. Experimental conditions of the anodization: Al cathode, cathode voltage —800V, oxygen pressure 0.07 Torr, sample area 50 mm^2, anode current 2 mA for 3 hr.

current, and oxygen pressure were similar to those for the other samples. Although Fig. 6 shows a much thinner plasma oxide layer than some of the other samples, the general feature of an outer oxide of cathode material and an inner oxide of the anode material can be clearly seen. Using the half-height Auger signals for Al and O to denote the thicknesses of the outer layer and of the outer plus inner layers, respectively, we find that the etching time for the Al oxide layer is 240 sec and for the Ta oxide layer is 930 − 240 ≃ 690 sec. Using the etching rates of 0.8 Å/sec for Al oxide and 1 Å/sec for Ta oxide, the Al oxide has a thickness of 190Å and the Ta oxide has a thickness of 690Å. The transition width (defined as the etching time to go from 10 to 90% of the Auger peak) is 280 sec for both the Al peak and the Ta peak and 590 sec for the O peak.

Cu anode and Ta cathode.—Since all the anode materials that we had tried up to this point were substances that oxidized reasonably well, *i.e.*, Ta and Nb, we thought that it might be interesting to try as an anode material a substance that did not oxidize as readily. We therefore decided to try an anode of Cu foil. We thought that this might give some information on the importance of the oxidation ability of the anode in this plasma anodization process. Figure 7 shows the depth profile of the atomic constituents of the resulting plasma oxide on a Cu anode due to a Ta cathode. Figure 7 shows that a layer of Ta oxide was formed on the surface of the Cu during the plasma anodization process, but there is no evidence of oxidation of the Cu. This can be seen from the fact that the O and Ta Auger signals drop to zero together, and there is no appreciable shift as is evident in the earlier samples (see Fig. 2-6). Using the half-height of the Ta Auger signal, we find that the etching time for the Ta oxide layer is 730 sec which corresponds to a Ta oxide thickness of 730Å. A very small Cu Auger signal was discernible throughout most of the Ta oxide layer, but it only started to increase appreciably at a depth of 700Å into the Ta oxide layer. One other feature that is notable in Fig. 7 is the presence of a sizable C Auger signal throughout the Ta oxide layer. In all the other systems studied, the C Auger signal dropped quickly to zero after the etching commenced, indicating that the C was present just as surface contamination. Whether the presence of this C is important to the formation of the Ta oxide layer is unknown at this time, but the C was present in all samples of this type.

Cu anode and Al cathode.—Having succeeded in forming a Ta oxide layer on the surface of a copper anode using plasma anodization, we thought that it might be interesting to repeat this experiment with an Al cathode. Figure 8 shows the depth profile of the atomic constituents of the resulting oxide. The experimental conditions of cathode voltage, anode current, and oxygen pressure were similar to those for all other samples. While growing this oxide, we noted that the anode voltage was not changing with time as occurred with all the other samples. We con-

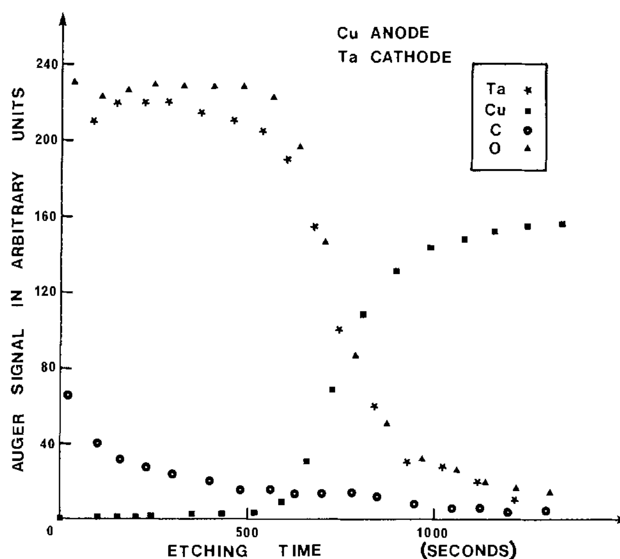

Fig. 7. Auger depth profile of the atomic constituents of the plasma oxide on a Cu anode. Experimental conditions of the anodization: Ta cathode, cathode voltage —800V, oxygen pressure 0.07 Torr, sample area 50 mm^2, anode current 2 mA for 4 hr.

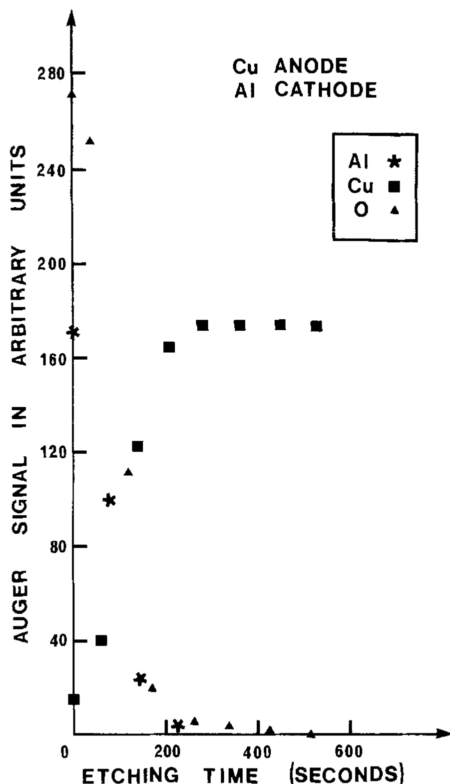

Fig. 8. Auger depth profile of the atomic constituents of the plasma oxide on a Cu anode. Experimental conditions of the anodization: Al cathode, cathode voltage —800V, oxygen pressure 0.06 Torr, sample area 50 mm^2, anode current 2 mA for 6 hr.

tinued the experimental run for 6 hr, whereas all other runs took between 2 and 4 hr. Figure 8 shows that there is at most 100 sec of Al oxide on the surface of the copper and that there is no appreciable indication of oxidation of the Cu. The Cu Auger signal is observable at the surface of the sample and starts to increase as soon as the ion etching commences. The C Auger signal quickly drops to zero within 50 sec of etching, unlike the situation with the Ta cathode, and indicates that C is present only as a surface layer.

C cathode.—All the data that has been presented in Fig. 1-8 involved the use of cathodes such as Nb, Ta, and Al which form stable oxides. If the only thing that is important about the cathode is that it should have a low sputtering rate, then it should be possible to do plasma anodization using a carbon cathode. Carbon has as low a sputtering rate as Ta and Nb and lower than Al. We tried using a graphite cathode and successively anodes of Nb, Ta, and Cu. The experimental conditions of cathode voltage, anode current, and oxygen pressure were similar to those for the other systems. In each case we observed the following two things. First, the anode voltage did not increase with time, although some of the experimental runs lasted for several hours. Second, the plasma was a different color, *i.e.*, a deep blue rather than the greenish white that occurred with the other metallic cathodes. When we observed the anode samples with the Auger system after several hours of trying to form a plasma oxide, we found that there was no evidence of oxidation of the anode metals, apart from the approximately 100Å surface layer of anode oxide that resulted from exposure of the clean anode surfaces to oxygen.

Discussion of Results

Let us commence by enumerating the facts that have been established by this Auger spectroscopic study of plasma anodization:

1. There is clear evidence of transport of cathode material to the anode during plasma anodization, even when the anode is facing away from the cathode and is located on the back of a shield.
2. Deposition of cathode material on the anode does not occur unless a current is passing through the anode.
3. Cathode material is present in the form of an oxide on the anode.
4. The oxide on the anode formed by plasma oxidation is generally composed of two layers, with the outer layer being composed of oxide of the cathode material and the inner layer being composed of oxide of the anode material. The point to note is that the cathode oxide is always found as an outer layer.
5. The cathode oxide thickness can be a significant fraction of the total oxide thickness, but the fraction depends on what materials were used for the anode and cathode.
6. In certain cases, it appears to be impossible to form substantial amounts of cathode oxide on the anode. For example, it appears to be impossible to grow more than 100Å of Al oxide on Cu, but it is possible to form 730Å of Ta oxide on Cu in a comparable amount of time.
7. It is impossible to plasma oxidize Ta, Nb, or Cu using a C cathode.

With the information that is available from these Auger spectroscopy experiments, we cannot arrive at a complete theory of what is occurring in plasma anodization. But we can take the first step toward a theory by considering different possible models that are consistent with the facts revealed in these Auger experiments. In arriving at such models, the best that we can do at this stage is to ask questions and give the most plausible answers consistent with the facts.

The Auger results show that cathode material reaches the anode and is present there as an oxide. Is this cathode material reaching the anode in elemental form or as an oxide molecule? Is the cathode material charged or neutral as it reaches the anode? We feel that it is most likely that the cathode material is reaching the anode in the form of a negatively charged oxide molecule of the cathode material. We feel that the cathode material has to be oxidized, because what is taking place is reactive sputtering of the cathode. We feel that the cathode material has to be charged, because, if it were neutral, what would cause it to reach the anode only when the anode is passing a current? The charging of the cathode oxide molecules could occur during the sputtering, *i.e.*, a certain percentage of the molecules sputtered off the cathode would be charged, or within the plasma by electron attachment.

Is the cathode oxide formed on the anode just a "dirt" effect or is it an integral part of the plasma oxidation process? The usual approach in the literature is to assume that sputtering from the cathode is just a dirt effect that can cause contamination of the growing oxide. The proposed solution is to turn the anode away from the cathode so that the anode sample cannot see the cathode directly. However, the assumption in this approach is that any material sputtered from the cathode will travel in a straight line of sight and stick to the first thing that it hits. At the pressures of 0.05-0.07 Torr used in these studies, the mean free path is so short that any sputtered material is going to make many collisions with gas molecules while traveling from the cathode to the anode, and thus be scattered throughout the volume of the gas. This sputtered cathode material is not sticking to the first surface that it hits, as is assumed, because substantial amounts of cathode material, *i.e.*, more than 100Å, are not found on the anode surface unless the anode is passing a current. Finally, if the cathode oxide is just a dirt effect and the oxide growth is by some other means, *e.g.*, negative oxygen ions, why is not the cathode oxide incorporated into the anode oxide in a uniform manner throughout the whole thickness of the oxide layer on the anode? Instead, we always find that the cathode oxide

occurs as a well-defined layer on the outside of any oxide of the anode material.

Can we suggest a model to explain the observed two-layer structure of the oxides produced by plasma anodization? One possible model is the following: The outer oxide layer is formed by absorption of charged cathode oxide molecules, which have been attracted to the anode surface by the electric field at the surface of the outer oxide. The oxygen for the growth of the inner oxide layer, *i.e.*, the anode oxide layer, comes from the oxygen in the outer oxide layer. Thus the relative reactivity of the anode and cathode materials would be important in determining the relative thicknesses of the inner and outer oxide layers. In this way, one could explain why little Ta oxide forms under the Nb oxide in the Ta anode and Nb cathode situation, whereas lots of Nb oxide forms under the Ta oxide in the Nb anode and Ta cathode situation, if the Nb is more reactive than the Ta and the Nb oxide has a much larger binding energy than the Ta oxide. In this model, no oxygen would have to come directly from the plasma in the form of negative oxygen ions. The absence of oxide growth observed when a carbon cathode is used in the plasma anodization experiment supports this model. The carbon sputtered off the cathode is probably in the form of CO or CO_2 molecules. The binding energies of these molecules are large and it is not possible to form a layer of CO or CO_2 on the surface of the anode. Therefore, we get no layer of cathode oxide which can be a source of oxygen for the growth of the underlying layer of anode oxide.

The only other model that we could have to explain the two-layer nature of the oxides produced in the plasma anodization process is the following: The outer oxide is formed by deposition of the cathode oxide material on the anode surface or by reaction of cathode material and oxygen ions on the anode surface. However, as soon as this outer cathode oxide is formed on the anode surface it is then inactive, and the growth of the underlying anode oxide is due to oxygen ions moving through the outer layer to reach the anode metal underneath. This might be called the cathode dirt model, in that the sputtering of cathode material is given the role of just producing a layer of cathode oxide dirt on the surface of the anode and another mechanism has to be invoked for the growth of the underlying anode oxide. However, such a model has a number of problems. How can it explain the fact that Ta oxide does not grow appreciably under the Nb oxide layer whereas Nb oxide does grow appreciably under a Ta oxide layer? How can it explain the fact that anode materials do not oxidize when a carbon cathode is used? Since C has as low a sputtering rate as Ta and Nb, if we invoke the presence of oxygen ions as the oxidizing agent in the case of Ta or Nb cathodes, it is difficult to see why there would not be oxygen ions present also in the case of a C cathode and we would, consequently, expect some oxidation of the anode materials in contrast to what is observed.

It must be emphasized that the results of the ellipsometric studies (9, 10) mentioned earlier are consistent with the present Auger spectroscopic studies. For example, the ellipsometric study of the plasma oxidation of tantalum (9) showed that there was no direct sputtering contamination of the sample, in that the sample was not being coated with sputtered material independent of the growth of the film. Exactly the same result is observed in this Auger spectroscopic study, in that no appreciable, *i.e.*, more than 100Å, deposition of cathode oxide occurred regardless of the length of time that the sample was exposed to the plasma as long as no anodizing current was supplied to the sample. Of course we can even understand this initial buildup of 100Å of cathode oxide in terms of an effective voltage on the sample due to a difference in potential between the plasma and the sample. The fact that the ellipsometric results for the plasma anodization of Ta could be fitted with a single Ta oxide layer model with a refractive index of 2.21 is not at variance with the general behavior revealed by these Auger spectroscopic studies of a two-layer model, consisting of an outer layer of cathode oxide and an inner layer of anode oxide. In those ellipsometric studies of plasma anodization of Ta and Nb (9, 10), the cathode material used was Ta. Thus in the plasma anodization of Ta, the cathode oxide and the anode oxide would both be Ta oxide and a single layer model could be expected to be an excellent fit. Even in the case of the plasma anodization of Nb, the ellipsometric results could be fitted with a single Nb oxide layer model with a refractive index of 2.30. The Auger spectroscopic results of Fig. 4 for the Nb anode and Ta cathode case suggest that the plasma oxide consisted of an outer layer of Ta oxide comprising 32% of the total thickness of the film and an inner layer of Nb oxide comprising 68% of the total thickness of the film. If the true index of refraction of the Nb oxide layer were slightly higher than 2.30, *e.g.*, 2.37 (4), it is not surprising that a single layer model with an index of refraction of 2.30 might fit quite well to an actual situation consisting of two layers with indexes of refraction of 2.21 and 2.37 with the lower index for 32% of the film thickness and the higher index for 68% of the film thickness.

These Auger spectroscopic results also help us to understand the earlier ellipsometric studies of plasma anodization of Ta and Nb by Lee *et al.* (11). They found that they could fit their ellipsometric results only with a two-layer model for the plasma oxide on Ta or Nb, although Knorr and Leslie (10) showed later that this two-layer fit was not unique since the ellipsometry data could be fitted equally well by a single oxide layer possessing some absorption. However, apart from the problems of interpretation, there are definite differences between the ellipsometry data of Lee *et al.* and that of Knorr and Leslie on the plasma anodization of Nb and Ta. The present Auger spectroscopic study suggests the reason for these differences. In the case of Knorr and Leslie, a Ta cathode was used, while in the case of Lee *et al.*, an Al cathode was used in the plasma anodization process. Figure 5 suggests that their plasma oxide layer on Nb might have consisted of an outer layer of Al oxide forming 32% of the total film thickness and an inner layer of Nb oxide forming 68% of the total film thickness. Figure 6 suggests that their plasma oxide layer on Ta might have consisted of an outer layer of Al oxide forming 22% of the total film thickness and an inner layer of Ta oxide forming 78% of the total film thickness. The index of refraction of Al oxide is 1.62 (12) and is thus very different from the index of refraction of Ta oxide or Nb oxide, which are 2.21 and 2.37, respectively. Thus it is not surprising that Lee *et al.* could not fit their ellipsometry data with a single layer model with a real index of refraction.

Conclusion

These Auger spectroscopic studies of plasma oxides indicate clearly that mass transfer from a cathode to the anode is occurring in the plasma anodization procedure. They show that in general the plasma oxide consists of two layers, with an outer layer consisting of oxide of cathode material and an inner layer consisting of oxide of the anode material. Evidence is presented which suggests that the transfer of cathode material to the anode may be an integral part of the plasma anodization procedure, in that the oxygen for the oxidation of the anode material may come from the outer layer of cathode oxide rather than directly from oxygen ions in the plasma. Obviously, such a suggestion needs further experimental testing before one can conclude that this is the dominant mechanism in plasma anodization. Work is continuing on this aspect of the problem, but perhaps the results so far will focus more attention

on the exact role of the cathode in the plasma anodization process, rather than the current assumption in the literature that the cathode is needed just to produce the oxygen plasma and that any sputtering of cathode material is an unwanted side effect.

On the Influence of Sensitization of the Electron Transfer Through the Interface Zinc Oxide/Electrolyte by Salt Additions

U. Bode and K. Hauffe*

Institut für Physikalische Chemie der Universität Göttingen, Göttingen, Germany

ABSTRACT

To study the mechanism of the spectral sensitization with the electrochemical cell

$$+ \text{ In/ZnO-single crystal/dye} + \text{electrolyte/Pt} -$$

measurements of the photocurrent influenced by salt additions to the electrolyte were performed. The ZnO-semiconductor-anode operates as a probe for excited states of dyes acting as sensitizer for the charge transfer through the interface zinc oxide/electrolyte. By addition of Br^-, J^-, SCN^-, and $SeCN^-$ ions to the dye-containing electrolyte a significant increase of the sensitized photocurrent was generated. This enhancement can either be attributed to a change of the dye adsorption on zinc oxide or be explained by the fluorescence quenching of the adsorbed sensitizer in the presence of halide ions. With this quenching, radical anions $\overline{F^{\cdot}}$ or excited triplet states $^3F^*$ of the dyes are produced which are responsible for the increase of the photocurrent. The possible single steps of this reaction are discussed.

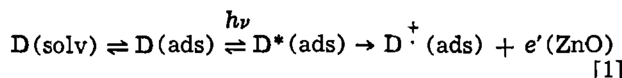
The electrochemical photosensitization of the electron transfer through semiconductor interfaces has been studied extensively because of its importance for photographic and electrophotographic processes (1-4). Recently, it has also gained interest with regard to possible application to direct solar energy conversion into electrical energy (5). Proposals for such solar cells have been made (6), however their technical usability must be tested critically for every system. One of the main difficulties of photoconductor-electrolyte cells is the insufficient photochemical stability of the semiconductor electrode, as well as of the electrolyte at continuous operation, a problem which still has to be cleared, although attempts have been made in this field (7).

The first experiments with zinc oxide single crystals as the electrode in an electrochemical cell were carried out by Dewald (8). This technique permits the investigation in more detail of the sensitized charge transfer caused by dyes and dye mixtures which are dissolved in the electrolyte. Zinc oxide belongs to the group of n-type semiconductors because of the presence of an excess of zinc existing as zinc ions in interstitial positions accompanied by an equivalent number of free electrons. With anodic polarization an exhaustion boundary layer is generated owing to a decrease of the concentration of free electrons in zinc oxide near the ZnO/electrolyte interface which results in a bending up of the bandedges. Consequently, by this formation of a blocking barrier layer the inhibited anodic current amounts only to 10^{-11}-10^{-10} A/cm² (V = 1-3V *vs.* Ag/AgCl/0.1*N* KCl) compared to 10^{-6}-10^{-5} A/cm² with cathodic polarization ($V = -1$ to -2V *vs.* Ag/AgCl/0.1*N* KCl) of the zinc oxide crystal.

Illumination with a wavelength of $\lambda = 385$ nm, corresponding to the distance of the bandedges of $E_G = 3.2$ eV (9), causes a photoconductivity. A photocurrent can also be produced if dye molecules adsorbed at the surface are illuminated and inject electrons into the conduction band of zinc oxide. Generally, such a process occurs by electronically excited molecules, generated either by a chemical reaction (10) or by optical excitation. The charge carriers increase the

* Electrochemical Society Active Member.
Key words: dye sensitization, photosensitization, ZnO/electrolyte interface, electrochemical cell, reducing fluorescence quenching, dye adsorption.

anodic current by several orders of magnitude attaining values of $i_{photo} = 10^{-8}$-10^{-7} A/cm^2. The electronic transfer reaction by means of a dye D can proceed in the following way



$$D(solv) \rightleftharpoons D(ads) \overset{h\nu}{\rightleftharpoons} D^*(ads) \rightarrow D^{\overset{+}{\cdot}}(ads) + e'(ZnO) \quad [1]$$

In previous investigations (11), it was demonstrated that an enhancement of the sensitized photocurrent appears if halides are added to the dye-containing electrolyte. This process was explained by the fluorescence quenching of the excited dye, particularly rhodamine B, giving rise to the tentative assumption that the halides react by an electron exchange with the dye. Therefore, the yield of fluorescence and thus the corresponding yield of the photocurrent should depend on the redox potential of the added halides as discussed by Baur (12) as well as by Weiss and Fischgold (13). This reducing fluorescence quenching described by Förster (14) effects a permanent regeneration of the injecting sensitizer. In the absence of the quenching anions, the oxidized dye radicals which are formed according to Eq. [1] can bleach photochemically much more easily and are no longer available for a repeated sensitizing reaction. Under this aspect, it was of interest to study the correlation between the decrease in the fluorescence of the sensitizer and the observed increase in the quantum yield of the sensitized photocurrent. These measurements were performed with the following electrochemical cell

$$+ \text{In} \mid \text{ZnO} \mid \text{dye} + \text{electrolyte} \mid \text{Pt} -$$

The anodically polarized ZnO electrode is a probe for the detection of excited states of the adsorbed dye molecules. In contrast to a metal electrode an electron transfer to the semiconductor anode is only possible via energetically high dye levels which can be occupied by optical excitation. In the following experiments, rhodamine B (RHB) was used as sensitizer because of its good sensitizing efficiency. In order to clarify the adsorption of RHB, zinc oxide powder was employed since the amounts of the dye adsorbed on a ZnO single crystal are too small. By these experiments, particularly the question had to be clarified to what extent an increase of the photocurrent is related to an enhanced dye adsorption by addition of salts. Necessarily, a current flowing through the electrochemical cell requires a charge exchange through the interface ZnO/electrolyte. Furthermore, an increase of the anodic photocurrent under constant potentiostatic conditions corresponds to a larger electron injection into the conduction band of ZnO. By means of anodic polarization experiments, the discharge kinetics of the space-charge layer was measured after switching off the external voltage source. The capacity of the space-charge layer will be discharged owing to an uptake of electrons by the positively polarized ZnO crystal which are released due to an oxidation of the adsorbed sensitizer molecules.

As is demonstrated in this paper, under certain conditions measurements in the electrochemical cell represent model experiments for the discharge of electrophotographic layers.

Experimental

Photocurrent measurements.—The experimental setup including the circuit with the electrochemical cell is schematically represented in Fig. 1. An extensive description was published earlier (1). The undoped ZnO single crystal was with its (0001) face (= Zn^{2+} face) in contact with the electrolyte. It was polarized potentiostatically with a voltage of +1.5V *vs.* a Ag/AgCl/0.1*N* KCl reference electrode. The cathode consisted of a platinized platinum net with a sufficiently large area. The illumination was carried out with a xenon high pressure lamp XBO 75W/2 of Osram and a Farrand grating monochromator through the rear of the crystal. The used light was irradiated

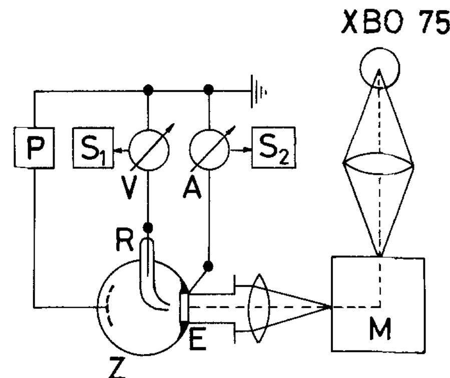


Fig. 1. Electrical circuit and optical arrangement of the experimental setup. P, potentiostat; Z, electrochemical cell; S_1, S_2, recorder; M, monochromator; V, electrometer; E, ZnO-single crystal; A, picoammeter; R, reference electrode.

in the optical absorption maximum of the dye (= RHB) amounting to $\lambda = 555$ nm. The density of the photon flux had a value of 3×10^{14} photons/cm^2 sec at 550 nm and was measured by means of a RCA photodiode SD 100. The action spectra of the photocurrents have been corrected to this photon flux.

The current and the voltage were recorded with a Keithley picoammeter 417 and a Keithley electrometer 610 R, respectively. The aqueous electrolyte with a volume of 15 ml consisted of an acetic acid-sodium acetate buffer of 0.1 mole/liter yielding a *p*H of 4.6. An addition of a conducting salt was not necessary. For the removal of oxygen in the electrolyte, the cell was flushed with purified nitrogen 15 min before every measurement.

Polarization measurements.—In addition to photocurrent measurements discharge experiments were carried out in the electrochemical cell at the ZnO single crystal polarized anodically with 4V. After switching off the external voltage source, the time slope of the discharge of the space-charge layer in the crystal and the electric double layer at the interface ZnO/electrolyte was recorded by potential measurements. These experiments were performed in the presence of various salts in the electrolyte at an open external circuit both in the dark and under illumination.

Discharge experiments with ZnO-resin layers.—In order to study the influence of salt additions to a ZnO-resin layer on the speed of the sensitized discharge under illumination, suitable ZnO-resin layers were charged up under a corona operating at about 12,000V. Then they were exposed to light of a defined photon flux and wavelength in a closed chamber with a revolving plate and a translucent probe for potential measurements. The exact experimental details have been published (15).

For this purpose a dispersion consisting of a RHB[1] doped zinc oxide powder[2] in a toluene-resin solution[3] with and without a salt admixture was coated on an aluminum foil as conductive support. Subsequently, the layer which had generally a thickness of 20μ, was dried at 80°C for 60 min. To obtain constant and reproducible conditions, the preparation of the dispersion and the technique for coating remained unchanged. Finally, the sample was mounted on the revolving plate in the measuring chamber and charged up with a corona. The change of the voltage with time was measured by a probe in connection with a Keithley electrometer and a recorder for the graphs. By this technique we were able to determine the value of the charge of the electrophotographic layer and its charge decay. For a good quality of an electrophotographic copy, this charge decay should proceed slowly in the dark and fast under illumination.

[3] Sinolac 602 S.

Optical measurements.—The photocurrent measurements of the respective dye solution were compared with its optical spectrum. These two spectra often are identical, in some cases, however, a significant shift of the absorption maximum was detected. The extinction spectra were recorded by a spectral photometer DMR 21 of Zeiss. Complementarily, emission spectra were measured by means of a fluorescence equipment ZFM 4. It is then when the apparatus operates as a one-single beam spectral photometer. The yield of fluorescence was converted into a relative intensity. As an excitation irradiation was emitted, light of a wavelength of 436 nm separated from the line spectrum of a mercury lamp by a monochromatic filter. In order to prevent a reabsorption of the fluorescence light, the cuvette of 1 cm thickness was brought into a sloping position. In combination with the spectral photometer and its remission equipment, remission spectra of the dye adsorbed on zinc oxide were determined. By means of this technique, the scattered remission of a dull surface could be analyzed. For these experiments, zinc oxide powder was mixed with a dye solution and filtered after 30 min stirring. Afterward, the dyed zinc oxide was washed with small amounts of distilled water and finally dried in air at 50°C for 1 hr in a drying chamber. As a white standard a pressed tablet of undyed ZnO "Fotosiegel K1" was used. The relative remission compared to this white standard was measured.

Adsorption measurements.—Furthermore, adsorption measurements on zinc oxide powder were performed. For these experiments 1g ZnO powder was added to a 20 ml dye solution of a defined concentration. The slurry was stirred as long as the adsorption equilibrium was adjusted (about 30-60 min). After centrifuging the dispersion, the concentration of the dye remaining in the solution was determined photometrically. To prevent a bleaching of the adsorbed dye, all adsorption experiments were carried out under red light or in the dark. For the interpretation of the photocurrent measurements it was important to study the influence of salt additions on the extent of the dye adsorption.

Experimental Results and Discussion

In previous experiments it was observed that additions of suitable salts to the electrolyte of the electrochemical cell influence considerably the sensitizing ability of RHB concerning the anodic photocurrent (11). While several ions decrease the sensitized photocurrent (*e.g.*, JO_3^-, JO_4^-) and other ones have no influence (*e.g.*, NO_3^-, SO_4^{2-}), the photocurrent is significantly increased in the presence of halide ions in the sequence Cl^-, Br^-, and J^-. Particularly, high photocurrent yields have also been obtained in the presence of SCN^- and $SeCN^-$ ions while NO_2^- and $S_2O_3^{2-}$ ions exhibit only a poor action. The dependence of the RHB sensitized photocurrents on the salt concentration are represented in Fig. 2. As can be seen, the enhancement of the current is elevated in the sequence $Cl^- < Br^- < J^-$. The rise of the photocurrent with an addition of thiocyanate can be detected at low concentrations and nearly attains the maximum value at 0.1 mole/liter. Selenium cyanate ions cause an extraordinarily strong increase. At a concentration of 0.05 mole/liter the photocurrent will be enlarged to a factor of about 20 of its initial value. Due to a precipitation of selenium at higher *p*H values and higher salt concentrations the current decreases at $c >$ 0.05 mole/liter. In a similar way with thiosulfate a decomposition occurs accompanied by a precipitation of sulfur, the current attaining again its initial value. According to the time slope of the currents in Fig. 3, a slow exponential decay occurs after a steep initial rise. Depending on the salt concentration, the photocurrent can fall back again to the half and only then remain constant.

An entirely different course of the photocurrent can be obtained with thiocyanate and selenium cyanate ions. With SCN^- ions the photocurrent mounts continuously and attains a plateau with an insignificant decay during a long time period. A conspicuous bathochromic shift of 15-20 nm, depending on the salt concentration, has been found in the action spectrum of the photocurrent in the presence of SCN^- and $SeCN^-$ ions. This shift can be gathered from Fig. 4. The photocurrent is plotted *vs.* the wavelength using electrolytes containing RHB and NaSCN of various concentrations, represented by curves 1 and 2. Corresponding curves are plotted with electrolytes satu-

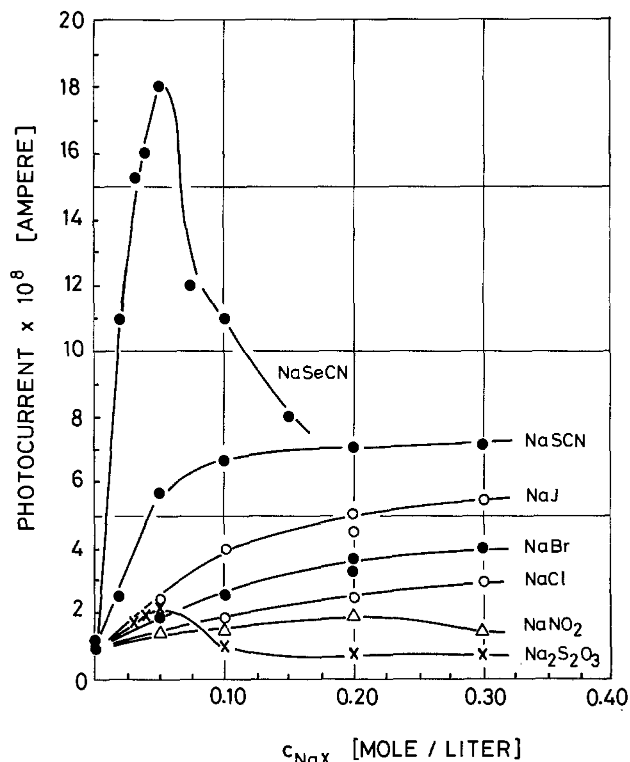

Fig. 2. Sensitized photocurrents of rhodamine B (= RHB) as a function of salt additions: $C_{RHB} = 10^{-4}$ mole/liter, *p*H = 4.6 (sodium acetate buffer), $\lambda = 555$ nm.

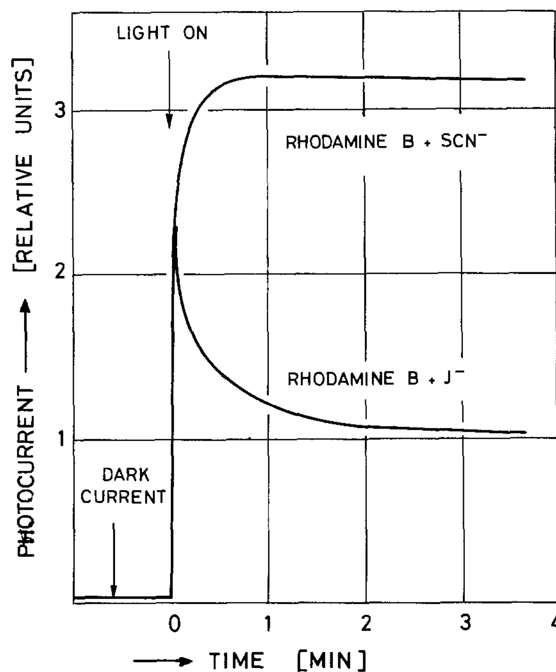

Fig. 3. Time slope of the photocurrent with RHB and NaSCN ($\lambda = 575$ nm) and NaJ ($\lambda = 555$ nm) additions, respectively, during illumination.

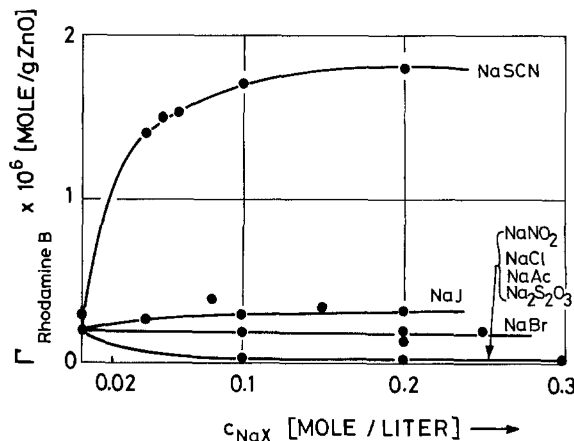

Fig. 6. Change of the RHB adsorption on zinc oxide by addition of various salts, $T = 23°C$.

rated with RHB (curve 3) and with a RHB concentration of 2×10^{-4} mole/liter (curve 4). The band of the spectrum of curve 4 at 555 nm does agree with the optical absorption of a dye solution of the same concentration. The maximum of the photocurrent of curve 1, however, is shifted at larger wavelengths to 575 nm. Since a saturated RHB solution without NaSCN addition exhibits the same shift, we may assume a salt-out effect. Obviously, the adsorption of the dye on the ZnO anode is intensified by the salt addition detectable by the large increase of the photocurrent and by its kinetic (Fig. 3). We may assume an aggregation of the dye which seems also to be responsible for an increased dimer formation. A term scheme for the dimer formation of RHB has been described by Krüger and Memming (16). The S_1 term of the dye is split up into two levels which correspond to the dimer bands. For the longer wavelength main band, an energetic shift of 0.06 eV is outlined. This value corresponds rather well to the experimentally observed shift of 15-20 nm found in the maximum of the action spectrum of the photocurrent with sensitization using the system RHB/SCN^- as well as highly concentrated or saturated RHB solutions.

Further information is obtained from the remission spectra represented in Fig. 5. Because of the increase of adsorption of RHB in the presence of SCN^- ions the remission at $\lambda = 555$ nm is decreased. However, the adsorption of the dye is not so high that the maximum of the remission spectrum is shifted. Therefore an aggregation of the dye does not occur. If the sample tablets are exposed to the daylight, then the dye is bleached. Compared to curve 1, which represents the spectrum of a new sample, both the intensity of remission and on a lower scale the position of the band maximum are changed. Due to the increased dye adsorption by the salt-out effect of NaSCN, a bleaching of the sample, curve 2a, cannot be detected. The extent of the influence of the adsorption of RHB on zinc oxide by anions which influence the photocurrent in

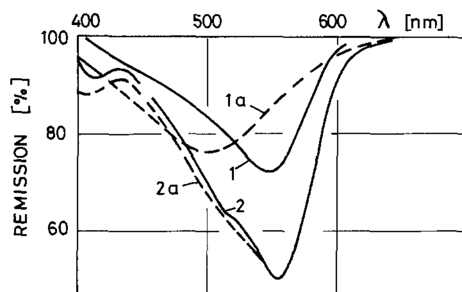

Fig. 5. Remission spectra of RHB with NaSCN addition adsorbed on zinc oxide. RHB, just after the preparation, curve 1; RHB, bleached, curve 1a; RHB + NaSCN, just after the preparation, curve 2; RHB + NaSCN, bleached, curve 2a.

the electrochemical cell was measured on ZnO powder. In Fig. 6, the adsorbed amount of the dye is plotted *vs.* the salt concentration. While NO_2^-, CH_3COO^-, $S_2O_3^{2-}$, and Cl^- ions decrease the adsorption of the dye, Br^- ions have no influence on it and J^- ions cause an insignificant increase. The measurements demonstrate undoubtedly that the rise of the sensitization by the halide ions as well as $S_2O_3^{2-}$ and NO_2^- ions cannot be attributed to adsorption effects. A salt-in effect by halides intensifies the solubility of an organic compound according to the sequence $Cl^- < Br^- < J^-$ (17) and consequently lowers the sensitization because of the decreasing adsorption. Then especially, the well-known salt-out by the sulfate ions should increase the sensitized photocurrent, but no influence is observed. An addition of NaSCN to the electrolyte results in a remarkable enhancement of the adsorption of RHB. With a salt concentration of 0.2 mole/liter the amount of the adsorbed dye is increased about one order of magnitude. As can be seen from the change with time of the photocurrent, the remission spectra and the band shift in the sensitization spectrum in accordance with the adsorption measurements with ZnO powder; the considerable rise of the sensitization with the system RHB/SCN^- is the consequence of an increase of the dye adsorption. A similar mechanism can be assumed with the $SeCN^-$ ions. Adsorption measurements could not be performed because in the presence of the dye selenium is precipitated at low concentration of $SeCN^-$

As may be concluded, the anions in the electrolyte may react electronically with the adsorbed dye molecules whose redox potential is changed during illumination favoring the reaction and, therefore, increasing the speed of electron injection into the conduction band of zinc oxide. The electron injected from the dye molecule into ZnO cannot return to the ground state because it has already been filled up by an electron of the anion. This mechanism has been discussed earlier by other authors (2, 3) assuming a mere redox process. During these redox steps a short-lived intermediate dye radical appears, for example, as a semireduced sensitizer. Allylthiourea (ATU) and hydroquinone (H_2Q) were often employed in these experiments as effective reducing agents.

Recently, it has been demonstrated with an oxazine dye (oxonine) that ATU not only operated as a mere redox species but also took part in a bimolecular quenching reaction with the excited singlet state of the dye (28). This singlet quenching process involves a rise of the intersystem crossing rate and hence leads to an increase of the triplet yield. In a consecutive step via the triplet state a semireduced dye radical and an oxidized ATU radical, $ATU^{\overset{+}{\cdot}}$, are formed. Preliminary experiments carried out by these authors show that with this dye the halides Br^- and J^- cause in a similar way an enhanced triplet formation. In the

same manner as ATU, H_2Q also increases the photocurrent spectrally sensitized by RHB at an n-CdS single crystal operating as anode in an electrochemical cell (27). Here, also, the correlation between cosensitization and fluorescence quenching was discussed. This relation has been stated in a previous paper (11) in which the influence of the viscosity of the electrolyte on the cosensitized current was presented. With increasing viscosity of the solvent the singlet quenching decreases (14). Since the rise of the photocurrent can be traced back to this reaction, consequently the current too should be reduced with growing viscosity. This expectation was confirmed by experiments. In Fig. 7 the results showing the influence of halides on the fluorescence yield of RHB were plotted in a Stern-Volmer relationship. The dependence on the fluorescence efficiency on the salt concentration is described by the following expression.

$$\phi_0/\phi = 1 + k_q\tau[Q^-] \qquad [2]$$

In this equation ϕ denotes the intensity of the fluorescence in the presence and ϕ_0 in the absence of the quenching anion, $[Q^-]$ the concentration of the quencher, and τ the singlet-state lifetime. The experimentally obtained slope $k_q\tau$ of the Stern-Volmer plot is in the case of J^- in approximate agreement with the data published by Wawilow (29). The values with SCN^-, Br^-, and Cl^- are a little larger than those quoted by Majumdar (20). The fluorescence quenching grows in the same sequence $NO_2^- < Cl^- < Br^- < SCN^- < J^- < SeCN^-$ as the sensitized photocurrent in the electrochemical cell except for SCN^- ions. This series of the (pseudo)halide ions has been found by other authors by quenching experiments with hydrocarbons (19) and with dyes belonging to the group of acridine and xanthene compounds (20). Förster (14) has discussed redox reactions for the mechanism of the fluorescence quenching assuming an intensive electronic interaction between excited dye molecule and quencher.

McKay and Hillson (21) have found from photometric investigations with rhodamine 6 G and other dyes that, depending on the concentration and the type of the solvent, the dye ions and their counterions are not separated by solvent molecules. The counterion is incorporated particularly at higher concentrations in the solvating envelope of the dye resulting in corresponding ion pairs. Furthermore, since the action spectrum of the sensitized photocurrent agrees with the optical spectrum of the dye solution except for the systems RHB/SCN^- and $RHB/SeCN^-$, we may assume that the solvating envelope of the dye ion will survive during the adsorption and the sensitization steps. In the case of the pseudo halides, an increase of the dye adsorption has been found which presumably causes a simultaneous formation of aggregates and, therefore, a bathochromic change in the spectrum of the photocurrent.[4] The particularly strong rise of the measured photocurrent could be attributed to a static quenching which appears at an associate formation of two or more molecules according to Förster (14) besides an increased adsorption and a reducing quenching of the fluorescence.

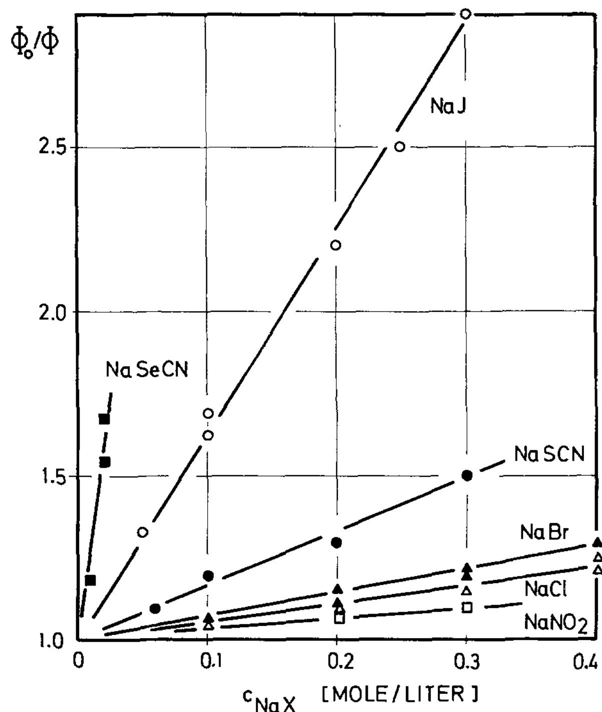

Fig. 7. Stern-Volmer plot of the fluorescence quenching of an aqueous RHB solution depending on the salt concentration, $\lambda_{ex} = 436$ nm, $T = 28°C$, $C_{RHB} = 10^{-4}$ mole/liter, pH 4.6 (sodium acetate buffer), N_2 flushing.

For the halide ions it is obvious to assume a dynamic quenching mechanism which occurs in the transition state via a complex formation of the dye cation and the halide. This very short-lived charge-transfer state and its reaction have often been discussed (19, 23, 24). This reaction is characterized by the fact that only after the formation of the encounter complex with the excited singlet state the specific activated quenching step occurs according to

$${}^1D^* + Q^- \rightleftharpoons ({}^1D^*\text{-}Q^-) \rightarrow \text{quenching} \qquad [3]$$

Leonhardt and Weller (24) were the first to supply proofs by spectroscopic methods for a charge transfer during the fluorescence quenching of aromatic hydrocarbons, for example, perylene, etc. It results in a reduction of the excited singlet state under formation of a radical anion at simultaneous oxidation of the quenching molecule. The effectiveness of the quenching anion occurs parallel to the change of the redox potential of $Q\cdot/Q^-$

$$({}^1D^*\text{-}Q^-) \rightarrow \bar{D\cdot} + Q\cdot \qquad [4]$$

These results, found particularly at aromatic hydrocarbons with amines as quenchers, cannot be transferred arbitrarily to other systems.

Further experiments of the fluorescence quenching with the strongly effective halides demonstrated that besides the radical anion generated according to step [3] also excited triplet molecules are observed whose formation in some cases is mainly responsible for the quenching process (25, 28)

$$({}^1D^*\text{-}Q^-) \rightarrow ({}^3D^*\text{-}Q^-) \rightarrow {}^3D^* + Q^- \qquad [5]$$

Here, the singlet quenching does not occur by an electron transfer but by an intersystem crossing reaction of the singlet to the triplet state during the lifetime of the encounter complex. It depends primarily on the type of the quenching molecule whether radical ions or triplet states are formed predominantly.

The mechanisms of the fluorescence quenching admit an interpretation of the spectral sensitization reaction and its modulation by anionic quenchers. If radical anions are formed by reduction of the dye then the probability of the electron injection from these species is significantly increased because the deactivation generally occurring as competition reaction is no longer possible. The ground state of the dye molecules is already filled up and a regeneration can occur only by delivery of an electron. During the total reaction, the dye will not be changed and is available for repeated sensitization steps. This, however, is not the case if the electronic interaction with the quencher delivers a larger yield of triplet states. Under these circumstances, the increase of the sensitized photocurrent in the electrochemical cell can be attributed also to the longer lifetime of the triplet states. After the electron

[4] Similar results have been obtained by Killesreiter (22) who was able to demonstrate that with RHB a solvate chromic shift in the optical absorption spectrum also occurs in the sensitization spectrum.

injection, the dye is present as a radical cation so that a regeneration cannot occur in a primary step. The sequence of the single steps can be stated as follows

$$\mathrm{D(solv)} \rightleftharpoons \mathrm{D(ads)} \qquad K\mathrm{(ads)} \qquad [6]$$

$$\mathrm{D(ads)} + h\nu \rightarrow {}^1\mathrm{D^*(ads)} \qquad k_1 I \qquad [7]$$

where I = light intensity. The adsorption equilibrium is given in Eq. [6]. Furthermore, it may be assumed that with steady-state conditions the dye diffusion toward the electrode from the solution occurs rapidly enough and thus despite consecutive reactions the concentration of the adsorbed sensitizer D(ads) can be considered constant. Especially, the desorption of products being formed by photochemical bleaching should proceed quickly. This condition is better fulfilled the lower the pH value of the electrolyte, and in an acid environment a constant dissolution of the zinc oxide takes place. The surface of the single crystal will then be etched and therefore renewed continuously. Besides the electrochemical step, the anodic oxidation of the excited and adsorbed dye molecules, the singlet and triplet states, too, are deactivated. In the absence of a quencher the equations can be specified as below

$${}^1\mathrm{D^*} \rightarrow \mathrm{D}^{\dot{+}} + e'(\mathrm{ZnO}) \qquad k_{21} \qquad [8a]$$

$${}^1\mathrm{D^*} \rightsquigarrow \mathrm{D} \qquad k_{22} \qquad [8b]$$

$${}^1\mathrm{D^*} \rightarrow {}^3\mathrm{D^*} \qquad k_{\mathrm{isc}} \qquad [8c]$$

$${}^3\mathrm{D^*} \rightarrow \mathrm{D}^{\dot{+}} + e'(\mathrm{ZnO}) \qquad k_{31} \qquad [9a]$$

$${}^3\mathrm{D^*} \rightsquigarrow \mathrm{D} \qquad k_{32} \qquad [9b]$$

$$k_2 = k_{21} + k_{22} + k_{\mathrm{isc}}$$

$$k_2' = k_{22} + k_{\mathrm{isc}}$$

To simplify the above and following equations the adsorbed state of RHB was not marked. It results from the fluorescence lifetime of τ = 4.3 nsec (in aethanol) (30) for k_2' a value of 2.3×10^8 sec^{-1}. That means for an effective electron injection via S_1 according to Eq. [8a] k_{21} must be greater or at least comparable to k_2'. With optical excitation an intersystem crossing process populates the triplet state T_1 [8c]. The rate constant k_{32} amounts to $k_{32} \sim 2.5 \times 10^3$ sec^{-1} given by the triplet lifetime of $\tau \sim 0.4$ msec thus being higher by several orders of magnitude compared to the singlet lifetime. This suggests a considerable share of the electron injection via T_1 according to Eq. [9a]. Here, too, the deactivation in Eq. [8b] and [8c] is found as a competitive step. Further consideration shall demonstrate the influence of a quenching anion on the fluorescence and on the cosensitized photocurrent. Given the excited singlet state S_1 the quenching is described as below

$${}^1\mathrm{D^*} + Q^- \rightarrow ({}^1\mathrm{D^*}\text{-}Q^-) \qquad k_4 \qquad [10]$$

$$({}^1\mathrm{D^*}\text{-}Q^-) \rightarrow \mathrm{D}^{\dot{-}} + Q \qquad k_{51} \qquad [11a]$$

$$({}^1\mathrm{D^*}\text{-}Q^-) \rightarrow {}^3\mathrm{D^*} + Q^- \qquad k_{52} \qquad [11b]$$

$$({}^1\mathrm{D^*}\text{-}Q^-) \rightarrow \mathrm{D} + Q^- \qquad k_{53} \qquad [11c]$$

$$({}^1\mathrm{D^*}\text{-}Q^-) = \mathrm{D}Q$$

$$k_5 = k_{51} + k_{52} + k_{53}$$

$$k_5' = k_{51} + k_{52}$$

First, according to Eq. [10] an encounter complex DQ is formed by collision with a high rate of formation. During the short lifetime of the complex the electronic interactions between the singlet RHB cation and the added anion take place. The subsequent dissociation leads to a dye radical [11a], to a dye triplet [11b], and to a molecule in the ground state [11c]. In principle, the rate constants of the above single steps are to be accessible by photoflash experiments carried out with dye solutions. The results available at present regarding certain dye-quencher systems (28) show that the intersystem crossing is mainly responsible for the singlet quenching. So, the electron injection in Eq. [12a] and [12b] can occur as the consecutive process of Eq. [11a] and [11b], these leading to an increased photocurrent with participation of the added halides

$$\mathrm{D}^{\dot{-}} \rightarrow \mathrm{D} + e'(\mathrm{ZnO}) \qquad [12a]$$

$${}^3\mathrm{D^*} \rightarrow \mathrm{D}^{\dot{+}} + e'(\mathrm{ZnO}) \qquad [12b]$$

One should notice that even the excited triplet can be quenched by anions, either the quencher being oxidized or only the $T_1 \rightarrow S_0$ transition being promoted.

Since, under continuous illumination, the cosensitized current remains roughly constant the relation between current and quencher concentration is given by a steady-state treatment. The kinetics of the formation and the decay of the encounter complex DQ, as well as of the excited singlet, read

$$d[\mathrm{D}Q]/dt = k_1 I[\mathrm{D(ads)}] - (k_2 + k_4[Q^-])[{}^1\mathrm{D^*}] \qquad [13]$$

$$d[{}^1\mathrm{D^*}]/dt = k_4[{}^1\mathrm{D^*}]\,[Q^-] - k_5[\mathrm{D}Q] \qquad [14]$$

According to Eq. [12a] and [12b] and taking [11a] and [11b], respectively, into consideration, the cosensitized current I_{cos} can be stated as

$$I_{\mathrm{cos}} = k_5'[\mathrm{D}Q] \qquad [15]$$

Substituting and rearranging Eq. [13], [14], and [15]

$$I_{\mathrm{cos}} = k_5'\,k_4[Q^-] \times k_1 I[\mathrm{D(ads)}]/k_5(k_2 + k_4[Q^-]) \qquad [16]$$

$$A = k_5 k_2/k_5' k_4 k_1 I[\mathrm{D(ads)}] = \text{constant} \qquad [17]$$

$$B = k_5/k_5' k_1 I[\mathrm{D(ads)}] = \text{constant} \qquad [18]$$

$$1/I_{\mathrm{cos}} = \mathrm{A} + \mathrm{B}/[Q^-] \qquad [19]$$

A linear function should be obtained if the reciprocal cosensitized photocurrent $1/I_{\mathrm{cos}}$ will be plotted $vs.$ the reciprocal value of the quencher concentration $1/[Q^-] = 1/C_{\mathrm{NaX}}$. This correlation is represented in Fig. 8 and is indeed realized for $\mathrm{Cl^-}$, $\mathrm{Br^-}$, and $\mathrm{J^-}$ additions.

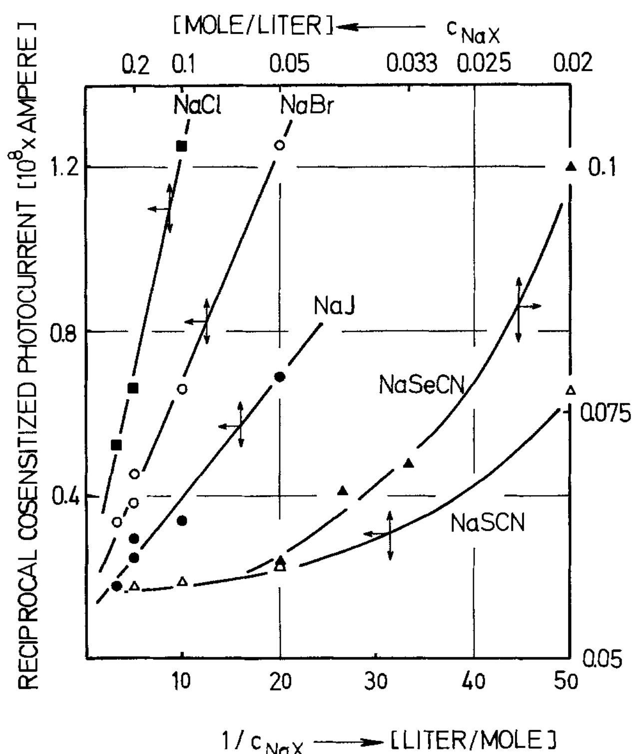

Fig. 8. Reciprocal cosensitized photocurrent as a function of $1/C_{\mathrm{NaX}}$. Data calculated from Fig. 2.

However, it must be noted that the actual concentration of the quenching anion at the electrode surface is higher by specific adsorption at zinc oxide than the bulk concentration in the electrolyte (31). Therefore, the relation between the fluorescence quenching (Fig. 7) and the change of the photocurrent (Fig. 8) can be given only qualitatively at present. Using the halides as quenchers the kinetic model is confirmed but deviations have been found with SCN^- and $SeCN^-$ ions. This result is not surprising since the SCN^- ions influence the adsorption equilibrium of the dye before the sensitization step, so that the increase of sensitization is mainly determined by the enhancement of the dye concentration on the surface. A similar behavior may be assumed for the $SeCN^-$ ions.

In order to demonstrate the effectiveness of salt additions on the sensitization of electrophotographic layers we performed the following model experiments in the electrochemical cell by a 4V anodic polarization of the ZnO crystal. This previously used technique (26) can be compared with charging and discharging experiments with ZnO-resin layers. In Fig. 9 the course of the dark and photodecay after the external voltage is switched off is represented. One can recognize clearly that the sensitized voltage decay is accelerated by the various salts, if the illumination takes place in the optical absorption maximum of the dye causing an electron injection into the ZnO crystal responsible for the avoidance of the barrier effect. The sequence of the effectiveness of the cosensitizing ability of the salts in these experiments is identical to that in the sensitized photoconductivity. The same results have been obtained with discharging experiments employing ZnO-resin layers charged up to about —300V. As can be seen from Fig. 10, where the photodischarge is recorded, a salt addition to the electrophotographic layer accelerates the voltage decay in the same sequence of the salts as was found for the polarization experiments with the ZnO crystal in the electrochemical cell. With too large salt additions, however, the conductivity of the electrophotographic layer becomes too high, so that the charge acceptance becomes too small. Therefore, the optimum concentration of salt and dye must be elaborated for practical purposes. The resin employed for the preparation of the layer undertakes the role of the electrolyte since it acts as

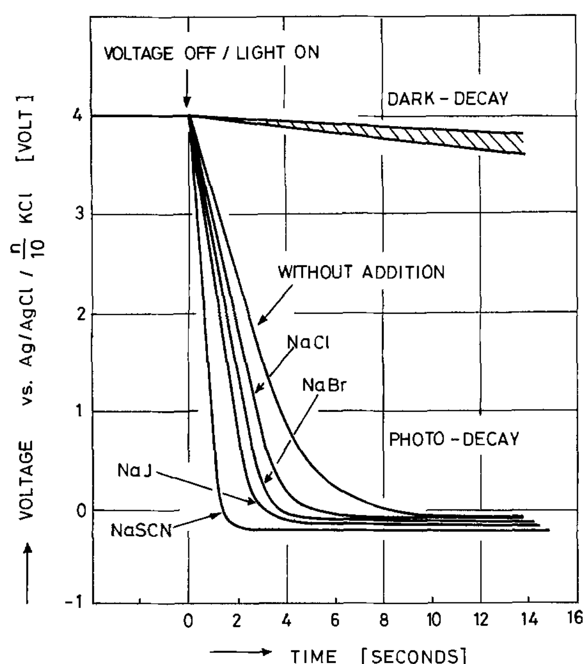

Fig. 9. Time slope of the photo- and dark decay at the anodically polarized ZnO-electrode (u = 4V vs. Ag/AgCl/0.1N KCl) with different salt additions. C_{RHB} = 10^{-4} mole/liter, C_{SALT} = 0.1 mole/liter, λ = 555 nm.

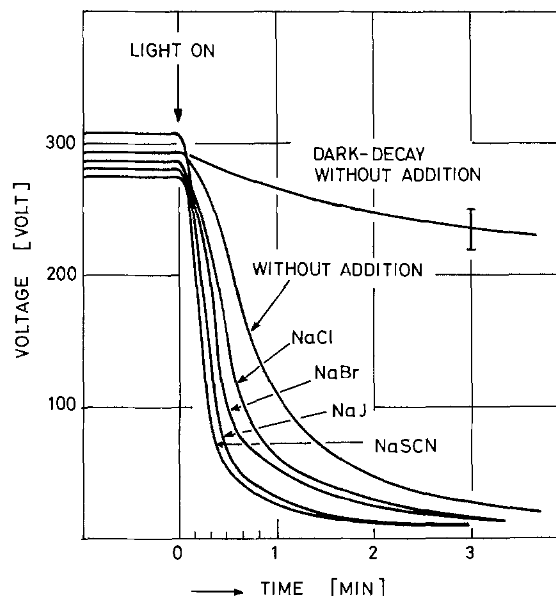

Fig. 10. Time slope of the photo- and dark decay of a ZnO-resin layer with addition of various salts (respectively, 10^{-3} mole NaX per 20g ZnO).

solvent for the dye and the salts. It is well known that the type of the used resin determines also the quality of the electrophotographic layer, presumedly due to the different influence on the solubility and the adsorption of the sensitizer on zinc oxide.

Unfortunately, the results obtained with the electrochemical cell technique based on aqueous electrolytes cannot be transferred for the evaluation of electrophotographic discharging experiments in any case. Therefore, it is desirable to carry out investigations on the sensitization with dyes dissolved in nonpolar solvents, *e.g.*, toluene. Such experiments, which also allow the study of the influence of the resin on the sensitization, are planned.

The Effect of Electrode Placement and Finite Matrix Conductivity on the Performance of Flow-Through Porous Electrodes

James A. Trainham*[1] and John Newman*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A one-dimensional model for flow-through porous electrodes is used to predict the effluent concentration as a function of matrix conductivity and electrode length for upstream and downstream placement of the counterelectrode and current collector relative to the fluid inlet to the working electrode. Two chemical systems are considered: (*i*) the removal of copper from sulfate solutions, and (*ii*) the removal of silver from thiosulfate solutions. For an infinite matrix conductivity, the lowest effluent concentration is achieved when the counterelectrode is placed upstream to the fluid inlet of the working electrode. When the matrix conductivity is small, the lowest effluent concentration is still achieved for upstream placement of the counterelectrode; however, the optimum placement of the current collector depends on the chemical system and the value of the matrix conductivity that can be achieved in practice. Calculations show that for downstream placement of the counterelectrode a limiting current distribution cannot be achieved (for electrode lengths of interest here). The most undesirable configuration for achieving a low effluent concentration when the matrix conductivity is low is when both the counterelectrode and current collector are placed downstream of the fluid inlet. Distribution of potential, reaction rate, and electric driving force are presented for four different configurations: (*i*) upstream counterelectrode, downstream current collector, (*ii*) downstream counterelectrode, upstream current collector, (*iii*) upstream counterelectrode, upstream current collector, and (*iv*) downstream counterelectrode, downstream current collector.

The model used in calculating the effects of counterelectrode placement and current collector placement (when the matrix conductivity is moderate) on the performance of flow-through porous electrodes was developed in a previous paper by the authors (1); however, results were presented only for the effective matrix conductivity σ much greater than the effective solution conductivity κ. To date, previous models for flow-through porous electrodes (2-6) have considered only an infinite matrix conductivity, and no comparisons have been made on the performance of these electrochemical reactors as a function of counterelectrode placement.

The purpose of this paper is to suggest the optimum electrode configuration for two cases: (*i*) when $\sigma >> \kappa$ we are concerned only with the upstream and downstream placement of the counterelectrode and (*ii*) when $\sigma \approx \kappa$, placement of not only the counterelectrode is important but also the current collector placement must be considered. At least four geometric configurations are possible: (*i*) upstream counterelectrode, downstream current collector (UD); (*ii*) downstream counterelectrode, upstream current collector

Key words: current distribution, potential distribution, mass transfer, axial dispersion, side reaction, copper deposition, silver deposition.

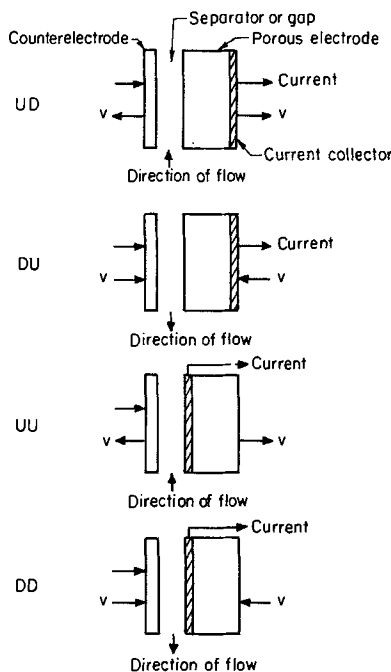

Fig. 1. Various configurations of counterelectrode placement and current collector placement relative to the direction of the fluid flow.

(DU); (*iii*) upstream counterelectrode, upstream current collector (UU); and (*iv*) downstream counterelectrode, downstream current collector (DD); and are shown schematically in Fig. 1. It should be noted that the direction of fluid flow through the counterelectrode is unimportant to the analysis to be considered as long as the products do not enter the electrode of interest.

Analysis

As mentioned earlier, calculations presented here are a direct application of a model for flow-through porous electrodes developed by the authors in a previous paper (1), and, therefore, detailed derivation of the governing equations are not presented here.

For the removal of metal ions from dilute streams, the behavior of a flow-through porous electrode with parallel current and fluid flow as shown in Fig. 1 can be described by two ordinary differential equations: one equation which describes the conservation of the metal-ion reactant

$$\frac{d\theta}{dy} = D' \frac{d^2\theta}{dy^2} - \frac{\theta - P_1 \exp\left[(\alpha_{aR}/\alpha_{cR} + 1)\eta'\right]}{1 + \exp(\eta')} \quad [1]$$

and one charge balance equation

$$\frac{d^2\eta'}{dy^2} = P_2 \left\{ P_3 \exp(-\alpha_{cS}\eta'/\alpha_{cR}) \left[1 - P_4 \exp\left(\frac{\alpha_{aS} + \alpha_{cS}}{\alpha_{cR}}\eta'\right)\right] + \frac{\theta - P_1 \exp\left[(\alpha_{aR}/\alpha_{cR} + 1)\eta'\right]}{1 + \exp(\eta')} \right\} \quad [2]$$

where θ is the reactant concentration divided by its value upstream in the feed, η' is the dimensionless local overpotential defined by

$$\exp(\eta') = -\frac{n\mathbf{F}k_m c_{Rf}}{s_R i_{oR,ref}} \exp(\alpha_{cR}\mathbf{F}\eta/RT) \quad [3]$$

and the reactor coordinate x was made dimensionless by

$$y = xak_m/v = x\alpha \quad [4]$$

Equation [1] describes the conservation of the metal-ion reactant and states that convection is balanced by axial diffusion and dispersion and by the rate of disappearance of the metal ions due to electrochemical reaction at the matrix-solution interface. Mass transfer limitations are included by introducing an average mass-transfer coefficient k_m (see dimensionless parameter defined below) and eliminating the wall concentration of the metal-ion reactant.

The charge balance equation utilizes Ohm's law in both the matrix and solution phases and states that a change in the total current at any point within the electrode ($d^2\eta'/dy^2$) is due to the rates of the side reaction and the main reaction. The term for the rate of the main reaction is the same in Eq. [1] and [2]. The side reaction is characterized by its rate at the half-wave potential of the main reaction.

The dimensionless parameters in Eq. [1] and [2] are defined as follows (1)

$$D' = (D_R + D_a)ak_m/v^2$$

$$P_1 = \left(-\frac{s_R i_{oR,ref}}{n\mathbf{F}k_m c_{Rf}}\right)^{1+\alpha_{aR}/\alpha_{cR}}$$

$$P_2 = \frac{\alpha_{cR} n\mathbf{F}^2 v^2 c_{Rf}}{s_R a k_m RT}\left(\frac{1}{\kappa} + \frac{1}{\sigma}\right)$$

$$P_3 = -\frac{s_R i_{oS,ref}}{n\mathbf{F}k_m c_{Rf}} e^{\alpha_{cS}\mathbf{F}\Delta U/RT}\left(-\frac{n\mathbf{F}k_m c_{Rf}}{s_R i_{oR,ref}}\right)^{\alpha_{cS}/\alpha_{cR}}$$

$$P_4 = \left(-\frac{s_R i_{oR,ref}}{n\mathbf{F}k_m c_{Rf}}\right)^{\frac{\alpha_{aS} + \alpha_{cS}}{\alpha_{cR}}} \exp\left[-(\alpha_{aS} + \alpha_{cS})\Delta U\mathbf{F}/RT\right] \quad [5]$$

Boundary conditions.—Before Eq. [1] and [2] can be solved simultaneously for θ and η', four boundary conditions are required for each electrode configuration shown in Fig. 1. For θ the following conditions were used

$$\theta - D'\frac{d\theta}{dy} = 1 \text{ at } y = 0$$

and

$$\frac{d\theta}{dy} = 0 \text{ at } y = \alpha L \quad [6]$$

which are the Danckwerts (7), Wehner-Wilhelm (8) conditions when axial diffusion and dispersion are included. The conditions on η' depend on electrode configuration and may be determined from Ohm's law

$$\frac{d\eta}{dx} = \frac{d(\Phi_1 - \Phi_2)}{dx} = -\frac{i_1}{\sigma} + \frac{i_2}{\kappa} \quad [7]$$

and are tabulated in Table I. The dimensionless parameters P_5 and P_6 which arise in the analysis are related to P_2

$$P_5 = -\frac{\sigma P_2}{\sigma + \kappa}$$

and

$$P_6 = -\frac{\kappa P_2}{\sigma + \kappa} \quad [8]$$

so that

$$-P_2 = P_5 + P_6 \quad [9]$$

The total current density i to the reactor was made dimensionless with the limiting current density that would exist if all the reactant in the feed were completely reacted

$$I^* = \frac{s_R i}{n\mathbf{F}vc_{Rf}} \quad [10]$$

Now that all the boundary conditions for each electrode configuration have been specified, Eq. [1] and [2]

Table I. Current and potential boundary conditions for various electrode configurations

Electrode configuration	$i_1(0)$	$i_1(L)$	$i_2(0)$	$i_2(L)$	$d\eta/dx\|_{x=0}$	$d\eta/dx\|_{x=L}$	$d\eta'/dy\|_{y=0}$	$d\eta'//dy\|_{y=\epsilon L}$
UD	0	$-i$	$-i$	0	$-i/\kappa$	i/σ	$P_5 I^*$	$-P_6 I^*$
DU	i	0	0	i	$-i/\sigma$	i/κ	$P_6 I^*$	$-P_5 I^*$
UU	i	0	$-i$	0	$-i\left(\frac{1}{\sigma}+\frac{1}{\kappa}\right)$	0	$-P_2 I^*$	0
DD	0	$-i$	0	i	0	$i\left(\frac{1}{\sigma}+\frac{1}{\kappa}\right)$	0	$P_2 I^*$

can be solved simultaneously for θ and η' using Newman's method (9).

The potential distribution in each phase $\Theta_1(x)$ and $\Phi_2(x)$ can then be obtained by solving Eq. [3] for η using the known distribution for η', along with the conservation of charge condition

$$\frac{di_1}{dx} = -\frac{di_2}{dx} \quad [11]$$

and substituting this condition into the derivative of Eq. [7]

$$\frac{d^2\eta}{dx^2} = -\left(\frac{\kappa+\sigma}{\kappa\sigma}\right)\frac{di_1}{dx} \quad [12]$$

then finally substituting the derivative of Ohm's law for the matrix phase into Eq. [12] to yield

$$\frac{d^2\eta}{dx^2} = \frac{\kappa+\sigma}{\kappa}\frac{d^2\Phi_1}{dx^2} \quad [13]$$

Equation [13] may be integrated twice to yield an expression for Φ_1

$$\Phi_1 = \frac{\kappa}{\kappa+\sigma}(\eta + C_1 x + C_2) \quad [14]$$

The value of C_1 for the various configurations is obtained from the derivative of Eq. [14] using the values of i_1 and $d\eta/dx$ at the boundaries found in Table I. The value of C_2 is then obtained by specifying $\Phi_1 = 0$ at the current collector and using a known value of η at the appropriate boundary. Table II summarizes the results for $\Phi_1(x)$ for the various configuration; $\Phi_2(x)$ is simply obtained by subtracting $\eta(x)$ from $\Phi_1(x)$.

Chemical systems.—For the calculations to be presented, two different chemical systems [copper removal from sulfate solutions (11) and silver removal from thiosulfate solutions (10)] are used to illustrate the effects of counterelectrode placement and current collector placement (when the matrix conductivity is finite) on electrode performance. The purpose of presenting results for two different chemical systems is to obtain reasonable values for the model parameters so that a valid comparison of electrode performance can be made when the side reaction is substantial [as for silver removal from thiosulfate solutions (10)] and when it is small [as for the copper recovery process (11)].

Figure 2 compares model calculations to the data of Van Zee and Newman (10) for silver removal from thiosulfate solutions using a porous carbon electrode. The quantities I and VOP are the total current to the reactor and the potential of the cathode current collector relative to a saturated calomel reference electrode placed in the effluent stream, respectively. The experimental effluent silver concentration (in milligrams per liter) are shown as the numbers below each curve corresponding to the open circles 0. The numbers above each curve correspond to the solid dots ● and are the calculated values of the effluent silver concentration (in milligrams per liter).

A similar model fit to the data of Bennion and Newman (11) for copper removal can be found in Ref. (1). Values of the parameters used to fit the data in Ref. (1) and in Fig. 2 are given in Table III.

Four parameters were adjusted to obtain agreement between calculated and experimental values in Fig. 2: one value of the exchange current density for the main reaction (silver deposition from thiosulfate solutions), assumed to be the electrode reaction (12)

$$Ag(S_2O_3)_2^{3-} + e^- \rightarrow Ag + 2S_2O_3^{2-} \quad [15]$$

and has a standard electrode potential (12) $U^0_{Ag/Ag(S_2O_3)_2^{3-}} = 0.0164V$; one value of the exchange current density for the side reaction (the reduction of thiosulfate), which was assumed to be the following reaction (10)

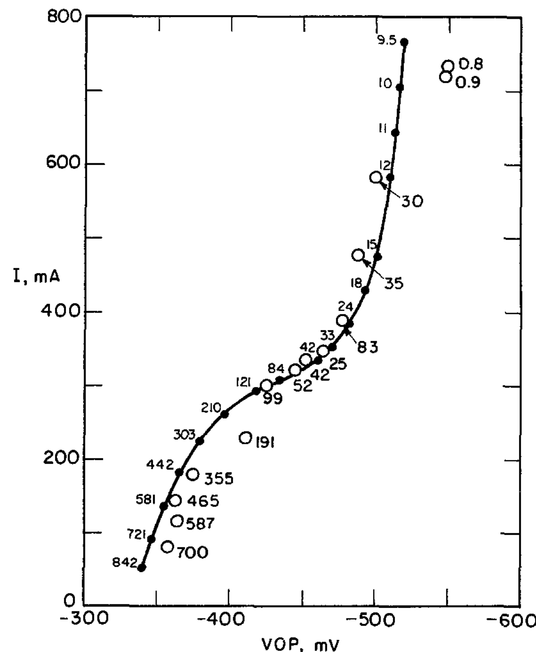

Fig. 2. Current-potential curve for an electrode 5.5 cm deep and superficial electrode area of 61 cm², packed with carbon flakes and chips. Flow rate = 22 cm³/min and the feed concentration = 1000 mg Ag/liter. Numbers below curve corresponding to the open circles 0 are experimental effluent concentrations (in milligrams per liter). The small numbers above the curve corresponding to the solid dots ● are calculated effluent concentrations (in milligrams/liter). *VOP* is the potential of the current collector with respect to a saturated calomel reference electrode placed in the dilute product stream.

P_4	5.863×10^{-8}	6.341×10^{-46}
P_5	3.254	3.738
P_6	9.089×10^{-11} to 3.254	3.777×10^{-15} to 3.738
D'	0.1217	0.1168

$$S_2O_3^{2-} + 8e^- + 8H^+ \rightarrow 2HS^- + 3H_2O \qquad [16]$$

where the standard electrode potential can be calculated (13, 14) to be $U^\theta_{HS^-/S_2O_3^{2-}} = 0.221V$; one value each for the transfer coefficients for the side reaction α_{aS} and α_{cS}, which were assumed to sum to four. The freedom to assign arbitrary values to α_{aS} and α_{cS} is allowed in the model since the composition dependence of the polarization equation for the side reaction is neglected.

The value of the mass transfer coefficient k_m used in fitting the data was that obtained in fitting the data of Bennion and Newman (11), which was correlated to be (1)

$$\frac{\epsilon k_m}{aD_o} = 0.07054 \left(\frac{v}{aD_o}\right)^{0.5454} \qquad [17]$$

In obtaining the fit to the silver removal data in Fig. 2, it should not be interpreted that there is anything fundamental about the values of the fitted dimensional parameters found in Table III, because not only are the data insufficient, but also the electrode is operating with a highly nonuniform current density and mass-transport limitations dominate in certain regions.

The model predictions of the current-potential behavior in Fig. 2 are in satisfactory agreement with experimental data between 50 and 500 mA total current. However, at higher currents (above 500 mA), the data indicate the beginning of an additional limiting-current plateau, and agreement of the model calculations cannot be expected for the following reasons: (*i*) The postulated side reaction (10) (Eq. [16]) for the reduction of thiosulfate could be incorrect and there appears to be no fundamental kinetic information on this reaction, and (*ii*) if the limiting reactant species for the higher plateau were known, the model used here would not be sufficient since the concentration dependence for the side reaction was neglected and a more general model such as the one proposed by Alkire and Gould (4) would be more appropriate.

Agreement between model predictions for the silver effluent concentration and the experimental values shown in Fig. 2 are satisfactory near the limiting current. This is because the model parameters were chosen so as to fit the data in this region. However, agreement should not be expected over the entire current-potential range because the data exhibit unexplained anomalies (10): (*i*) current efficiencies above 100%, and (*ii*) a minimum in the silver effluent concentration with increasing values of *VOP*.

A comparison of the dimensionless parameters in Table III between the two chemical systems suggests that the parameters P_1 and P_3 account primarily for the difference in behavior of these systems. The parameters P_1 and P_3 represent the relative importance of the backward rate of the main reaction and the forward rate of the side reaction and are 10^4 and 4.3 times greater, respectively, for the silver system than for the copper system. As is observed later a low effluent concentration cannot be achieved for the silver system and this is due to the combined effect of the parameters P_1 and P_3.

The magnitude of the side reaction is substantial for the silver system and this shields the back of the electrode (in the case of an upstream counterelectrode) from having a large electric driving force which results in a very small rate for the deposition of silver in this region. This is accentuated by the fact that P_1 is large, which causes the backward rate of the deposition reaction to be of the same order on the forward rate and the reactor can become thermodynamically limited.

Results and Discussion

As a unifying concept here, let us consider how we can achieve a very high conversion or, equivalently, a very low effluent concentration of the limiting reactant while, at the same time, operating the reactor at as high a flow rate as possible. Toward these ends, we can consider variations of electrode current density and length, flow rate, configuration, and matrix conductivity. By means of the computer program, we have the means to investigate in detail how the presence of a side reaction places limitations on the attainment of these goals.

Effect of electrode length.—For the case of a very high matrix conductivity, Fig. 3 shows the effect of electrode length and current density on the effluent concentration for the copper system. We see, first of all, that we must operate at or above the limiting current in order to reach a really low effluent concentration. If we operate at $I^* = 0.9501$, we cannot expect to remove more than 95% of the copper even if we have very high current efficiencies and substantial electrode lengths.

The curve on Fig. 3 for an upstream counterelectrode and $I^* = 1.038$ shows essentially a limiting-current condition, the effluent concentration decreases almost exponentially with electrode length. [See, for example, the analysis of Bennion and Newman (11) and that of Newman and Tiedemann (15) when axial diffusion and dispersion are included.] However, for downstream placement of the counterelectrode, a limiting-current distribution cannot be maintained except for electrode lengths less than 2 cm, and a truly low effluent concentration cannot be attained at all with this electrode configuration (at this flow rate). The current efficiency must necessarily be somewhat lower, and the extent of the side reaction somewhat higher, with the downstream counterelectrode.

Figures 4 and 5 introduce the effect of a finite matrix conductivity σ. Now, according to Fig. 1, four different

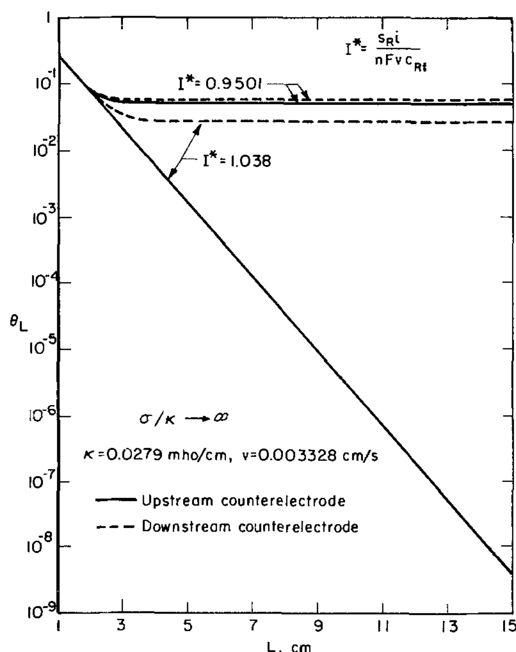

Fig. 3. Effluent copper concentration as a function of electrode length for $c_{Rf} = 0.0105M$.

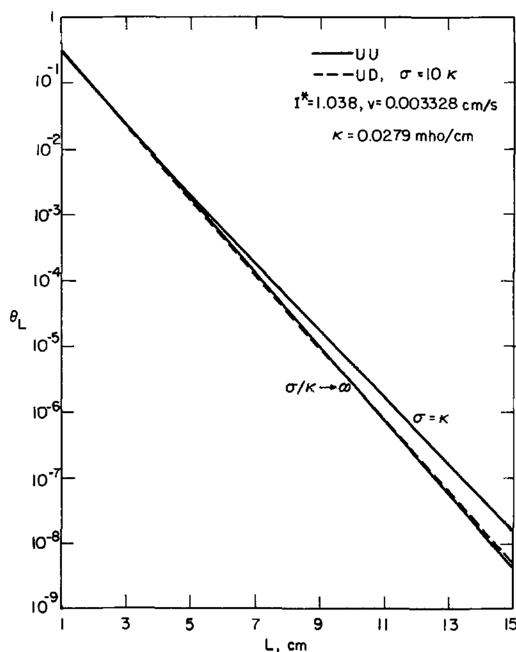

Fig. 4. Effluent copper concentration as a function of electrode length.

configurations are relevant since the placement of the current collector must also be considered. Figure 4 shows that the UU configuration retains the exponential decrease of θ_L with L, although performance is slightly degraded by the additional ohmic potential drop compared to the case of the infinite matrix conductivity. (The curve for $\sigma = 10\kappa$ is discussed later in connection with the optimum matrix conductivity.) Figure 5 shows the relatively poor performance achievable with the other configurations. In these cases, the ohmic potential drop in the matrix and solution phases prevents the entire reactor from being operated at a limiting-current condition, as is discussed in more detail later.

Figure 6 displays the silver effluent concentration as a function of electrode length for the various electrode configurations for cases where $\sigma >> \kappa$ and $\sigma = \kappa$. The results show that none of the electrode configurations yields an exponental decrease in θ_L with electrode

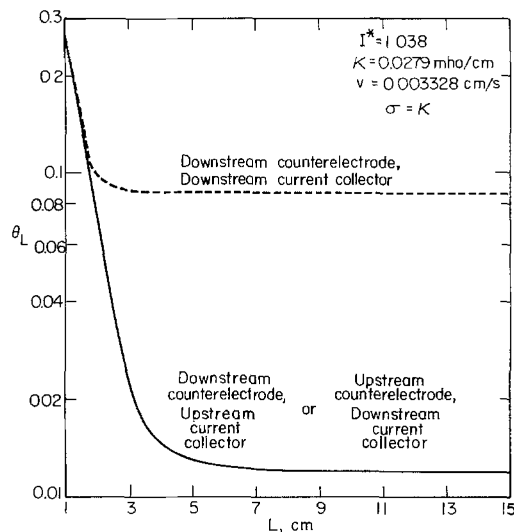

Fig. 5. Effluent copper concentration as a function of electrode length.

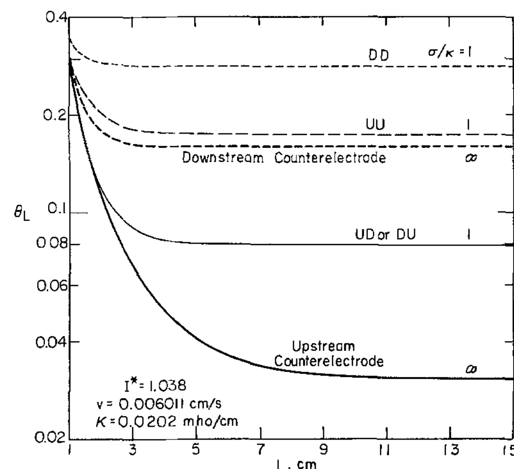

Fig. 6. Effluent silver concentration as a function of electrode length for $c_{Rf} = 0.00927M$.

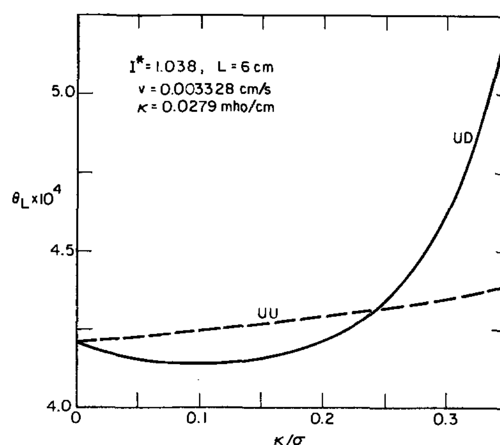

Fig. 7. Dependence of the copper effluent concentration on the matrix resistivity.

length; thus a limiting-current distribution cannot be achieved in any of the geometries due to extensive interference by the side reaction.

Effect of matrix conductivity.—Figures 7 and 8 show the dependence of the effluent copper concentration on the matrix resistivity ($1/\sigma$). Figure 9 shows similar results for the silver system. Calculations for a DD placement are not presented here since this configuration does not allow a low effluent concentration, in

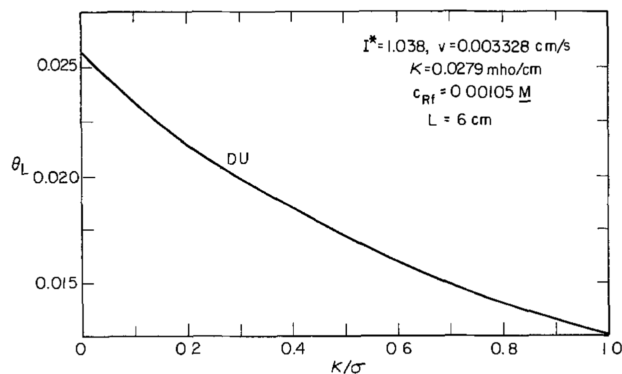

Fig. 8. Dependence of the copper effluent concentration on the matrix resistivity.

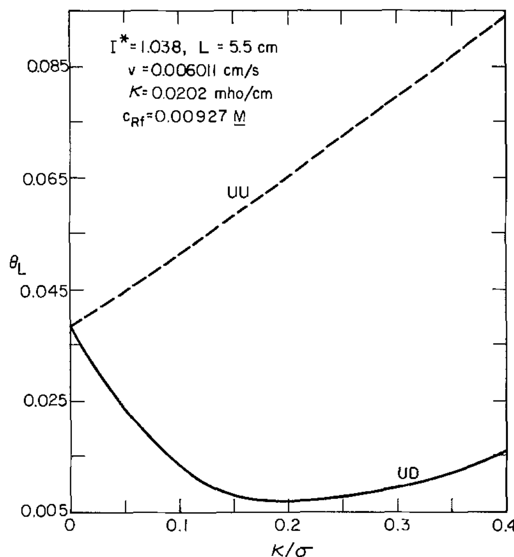

Fig. 9. Dependence of the silver effluent concentration on the matrix resistivity.

comparison to the other configurations when the matrix conductivity is small.

In Fig. 7 and 9, we observe that the UD configuration exhibits a minimum with matrix resistivity and, therefore, has an optimum value for σ (about equal to 0.1κ for the copper system). On the other hand, for the UU configuration, θ_L increases monotonically with increasing matrix resistivity. The DU configuration on Fig. 8 would also show a minimum at values of κ/σ substantially greater than unity. This is of less interest than the minima for the UD configuration because matrix resistivities are usually much less than solution-phase resistivities and because the effluent concentrations are inherently large with the DU configuration. For example, the DU and UD configurations give the same effluent concentration when $\sigma = \kappa$ (see Fig. 5) but at this point, the value of θ_L has risen to 0.0125 from a minimum of 4.14×10^{-4} on Fig. 7. At $\sigma = \kappa$, the UU configuration is still able to attain a value of θ_L of 6.08×10^{-4} (see Fig. 4). (Note, however, that the DU configuration performs better than the UU configuration for $\sigma = \kappa$ in the silver system, as displayed on Fig. 6.)

Return for a moment to the dashed curve on Fig. 4. For this curve, $\sigma = 10\kappa$, which corresponds to the minimum for the UD configuration shown in Fig. 7, and an exponential dependence of θ_L on L can evidently be maintained. The performance is superior to the high matrix-conductivity case for L less than about 10 cm, after which it becomes somewhat inferior. The optimum ratio of κ/σ depends on electrode length, for example, for an electrode 4 cm in length the optimum ratio is approximately 0.17, for an electrode 8 cm long the optimum ratio is approximately 0.07. Note that we get a markedly different view of the effect of configuration and matrix resistivity if we confine our attention to the cases $\sigma >> \kappa$ and $\sigma = \kappa$ on Fig. 3, 4, and 5 from what we get if we include the variation of σ and the optimum value of σ. The UD configuration is totally unsatisfactory at $\sigma = \kappa$ but excellent at $\sigma = 10\kappa$.

For the silver system, other calculations show that, even at the optimum ratio of $\kappa/\sigma = 0.2$ shown on Fig. 9 for the UD configuration, a limiting-current distribution and an exponential dependence of θ_L on L cannot be achieved. Similar results for the copper system can be obtained by increasing the flow rate to somewhat less than three times the value used in calculating Fig. 3, 4, and 5.

Bennion and Newman (11) and more recently Wenger and Bennion (16) have formulated design considerations for achieving a low effluent concentration while operating at as high a flow rate as possible. First, the electric driving force within the electrode must be maintained high enough to attain a limiting-current condition throughout the reactor. The electric driving force must also be maintained low enough to avoid excessive side reactions. These two conditions thus define a limited range of potentials allowable within the reactor. Since the electrode must be of substantial length in order to achieve a given effluent concentration, there is an upper limit on the flow rate above which these constraints cannot be satisfied simultaneously.

The effect of the side reaction is not one which can be compensated for by using a longer electrode or a higher current, even if one is willing to pay the price of a lower current efficiency and a higher cell potential. It is a characteristic of porous electrodes, leading to their inherently nonuniform reaction rate distributions, that substantial current densities flowing over substantial distances in either the matrix or solution phases make it impossible to maintain a uniform electric driving force (for the reactions) throughout the electrode.

On the basis of these considerations, an important quantity is the difference between the minimum electric driving force η_{min} and the maximum electric driving force η_{max} that prevail within the reactor. Figure 10 displays this quantity as a function of the conduc-

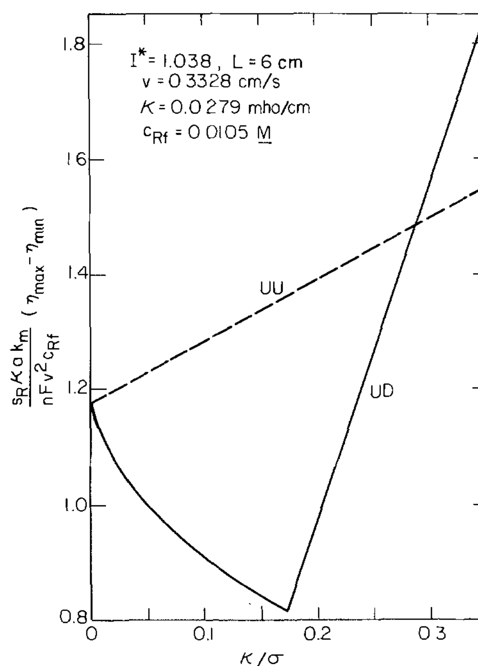

Fig. 10. Variation in the difference between the maximum and minimum driving force for copper deposition with the matrix resistivity.

tivity ratio for the copper system and corresponds directly with the conditions of Fig. 7. The ordinate, made dimensionless with $nFv^2c_{Rf}/s_R\kappa ak_m$, will have a magnitude on the order of unity if the current density is distributed like that for the limiting current for the main reaction (11, 15). A graph similar to Fig. 10 is given by Newman and Tiedemann (15) for the case where the current densities are calculated according to the limiting-current distribution for the main reaction. The computer program used here permits analysis above and below the limiting current and in the presence of a side reaction.

The fact that the ordinate values on Fig. 10 are of order unity illustrates how the constraints on the flow-through porous electrode can better be satisfied by operation at lower flow rates.

There is a correspondence between the shapes of the curves on Fig. 7 and 10. Conditions which lead to an inherently smaller value of $|\eta_{max} - \eta_{min}|$ make it possible to achieve a limiting-current condition through a larger portion of the reactor, without extensive side reaction. For the UD configuration, the maximum electric driving force occurs at the fluid inlet for $\kappa/\sigma < 0.175$. The position of the maximum electric driving force then shifts to the fluid outlet for $\kappa/\sigma > 0.175$. This leads to the sharp minimum for the UD configuration in Fig. 10.

Detailed distributions.—The behavior of these systems can be understood better by consideration of the calculated current, potential, and electric driving force distributions within the electrode. These are illustrated for the copper system with an electrode 6 cm long and by a 5.5 cm electrode for the silver system.

For the copper system with an infinite matrix conductivity, Fig. 11 shows the relative rates of reaction for both the main and side reactions for both upstream and downstream placement of the counterelectrode. Figure 12 shows the corresponding distributions of potential in the matrix and pore solution. The total current density to the electrode was chosen close to the limiting current ($I^* = 1.038$) for the deposition of copper. For upstream placement of the counterelectrode, the main reaction rate decreases almost exponentially

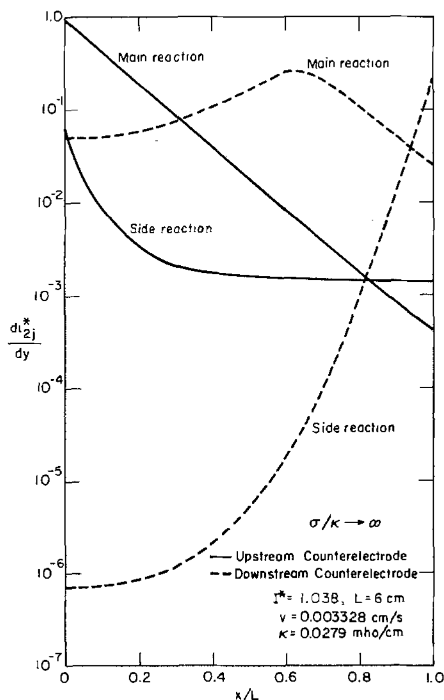

Fig. 11. Current distributions for deposition of copper and generation of dissolved hydrogen within a porous electrode. Calculated for $c_{Rf} = 0.0105M$.

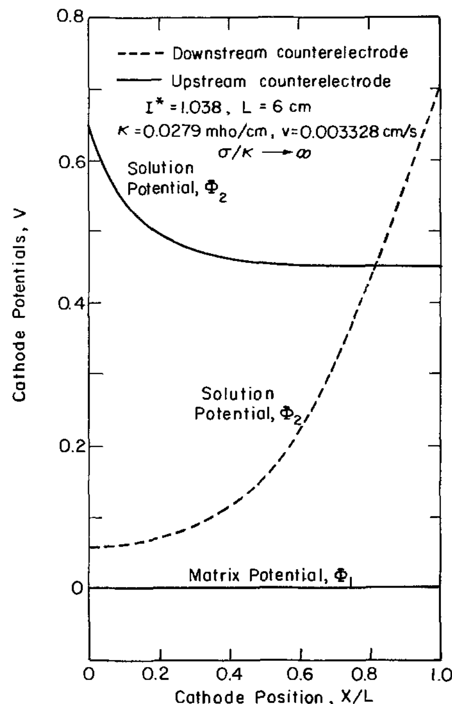

Fig. 12. Calculated solution phase and solid matrix phase potential distributions for the deposition of copper and simultaneous formation of dissolved hydrogen.

with distance through the electrode [as predicted by the limiting-current analyses in Ref. (11) and (15)]. At the same time, the side reaction follows the electric driving force (see Fig. 12), which is high at the fluid inlet and decreases toward a uniform value near the fluid outlet.

On the other hand, for the downstream placement of the counterelectrode, the main reaction rate does not show an exponential dependence on distance. Figure 12 shows that the electric driving force is very large at the outlet but too low at the inlet. Consequently, a limiting-current condition is not maintained near the front. At about 65% of the distance through the electrode, the electric driving force has become large enough to assure a limiting-current condition, and subsequently an exponential dependence on distance is exhibited. However, failure to utilize effectively the front part of the electrode makes it impossible to achieve a truly low effluent concentration, and increasing the electrode length would not help (see Fig. 3). The resulting reaction-rate distribution now has a maximum; as the electric driving force increases toward the back of the electrode, the reaction rate goes up, and copper is depleted from the solution to the extent that the mass-transfer driving force becomes small. The reaction rate exhibits a maximum and then decreases with distance. [Similar reaction-rate distributions have been reported by Alkire and Gould (4). These are examples of a general phenomenon (17-20) resulting from the competition of electric and mass-transfer driving forces.] The side reaction has a distribution in Fig. 11 that again follows that of the electric driving force in Fig. 12. Because of the somewhat lower rate of the main reaction, in comparison to the upstream placement of the counterelectrode, the side reaction now occurs at a somewhat higher rate on the average. For these comparisons at a constant total current ($I^* = 1.038$), an increase in the effluent concentration from one electrode to another is accompanied by a corresponding decrease in the current efficiency.

As in porous electrodes in general, the reaction rate distributions and ohmic potential drop shield the more remote parts of the reactor from having an adequate

electric driving force. In this particular situation, the contrast between the cases of upstream and downstream placement of the counterelectrode arises in the following way. In order for there to be a high conversion, there must be a high reaction rate (generating high current densities in the solution) near the fluid inlet. Since the solution-phase conductivity κ is not high, potential variations in the solution phase can be minimized if the current flows out of the electrode at the nearest possible point, namely, to a counterelectrode placed upstream. If the counterelectrode is placed downstream, the large currents which should be generated near the fluid inlet must flow in the solution through most of the thickness of the electrode, and this necessarily leads to large variations of potential. A similar explanation applies in the more complex cases to follow, where the matrix conductivity is also finite.

Figure 13 shows the reaction-rate distributions for the main and side reactions for the copper system where $\sigma = \kappa$. The corresponding potential distributions are shown in Fig. 14. Because of the complexity of Fig. 14, the distributions of electric driving force are also shown in Fig. 15.

The reaction-rate and electric driving force distributions for the UD and DU configurations happen to be identical when $\sigma = \kappa$ since the boundary conditions given in Table III are then identical. However, the potential distributions in each phase will be different, as seen in Fig. 14. In these configurations, the counterelectrode and the current collector are not at the same end of the reactor. Consequently, the current flows in the same direction in the matrix as in the solution, and to a certain extent the potential drop in the matrix can match in the solution (see Fig. 14). This makes it possible, in some cases, to reduce the variation of the electric driving force within the reactor (see Fig. 10). It also means that the extreme values of the electric driving force occur at the ends of the reactor, with the minimum value occurring somewhere between (see Fig. 15), and the side reaction follows this distribution (see Fig. 13).

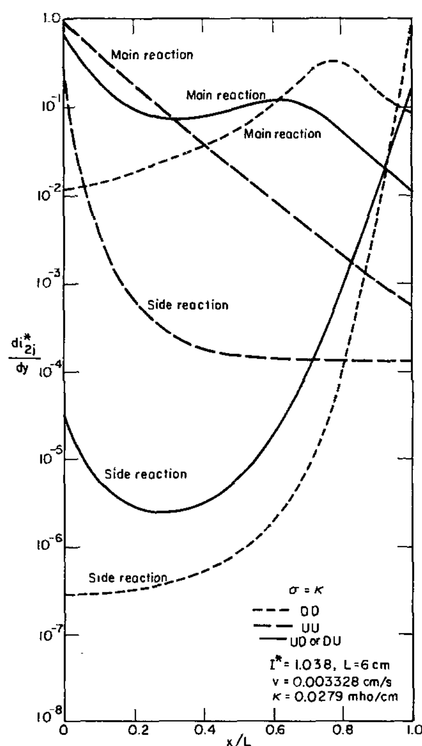

Fig. 13. Current distributions for deposition of copper and generation of dissolved hydrogen within a porous electrode. Calculated for $c_{Rf} = 0.0105M$.

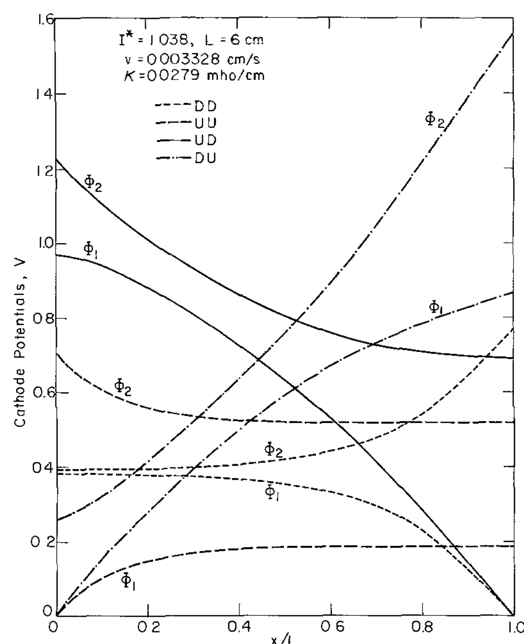

Fig. 14. Calculated solution phase and solid matrix phase potential distributions when $\sigma = \kappa$ for the depositions of copper and simultaneous formation of dissolved hydrogen.

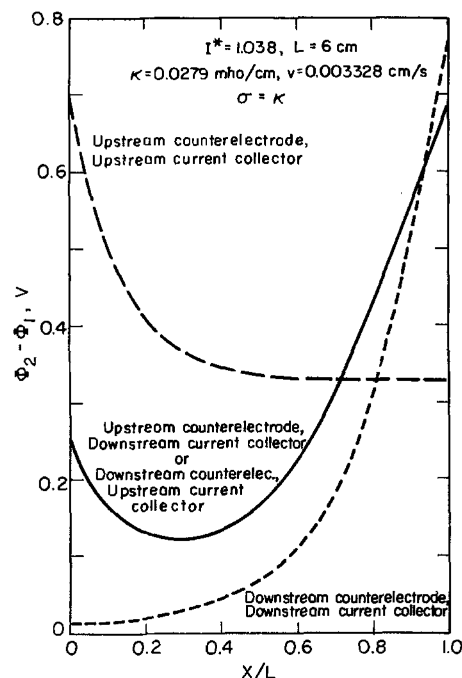

Fig. 15. Electrical driving force distributions for the potential distributions shown in Fig. 14.

For the UU configuration, the maximum electric driving force occurs at the inlet, and the minimum at the outlet, and conversely for the DD configuration. For the main reaction, only the UU configuration shows an exponential dependence of rate on distance (see Fig. 13). For the other configurations, the main reaction is below the limiting current for a substantial (DD) or moderate (UD or DU) region near the inlet, and consequently the effluent concentration cannot be reduced to a truly low value. Only in the UU configuration are the current densities in both the solution and matrix phases small near the back of the electrode. In this region the electric driving force varies little (as is the case also for the upstream counterelectrode case in Fig. 12, where $\sigma >> \kappa$), and measurement of $\Phi_1 - \Phi_2$ at $x = L$ can lead to a lower

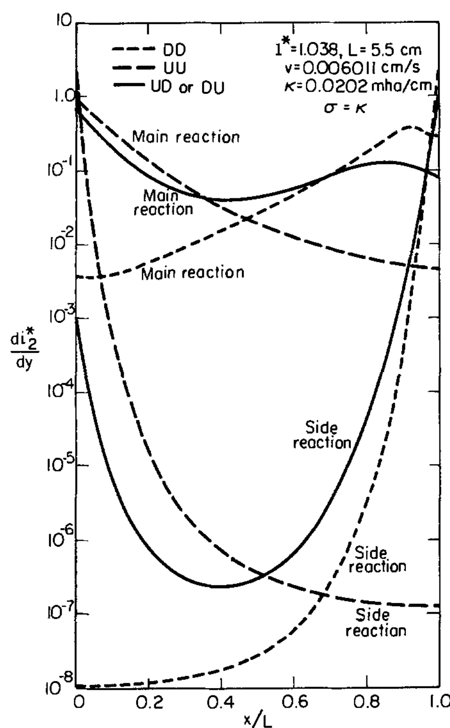

Fig. 16. Current distributions for silver deposition and reduction of thiosulfate within a porous electrode. Calculated for $c_{Rf} = 0.00927M$ and $L = 5.5$ cm.

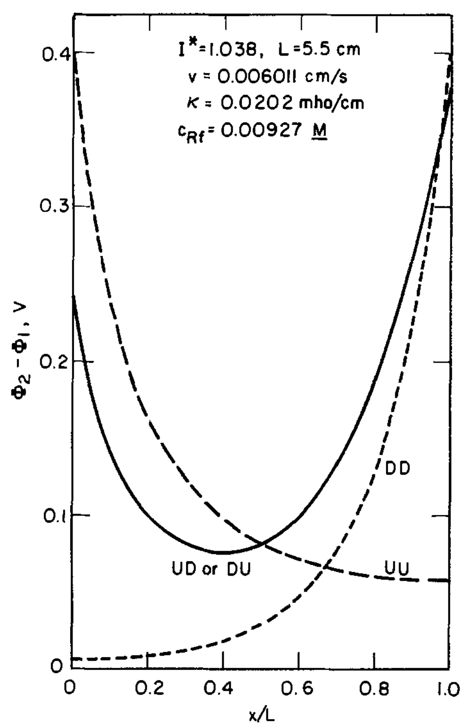

Fig. 17. Electrical driving force distributions for the deposition of silver from thiosulfate solutions.

bound thermodynamic estimate of the minimum attainable concentration in a flow-through porous electrode (12).

Figures 16 and 17 show the reaction-rate and electric driving force distributions for the silver system. A limiting-current distribution is not achieved for any electrode configuration, due to extensive interference by the side reaction, as indeed, it is not, even for an infinite matrix conductivity (see Fig. 6). As for the copper system, the electric driving force for the DD configuration is small at the front of the electrode and, for the UD and DU configurations it is small in the middle and only moderately large at the front. Under these conditions, the front and middle regions of the reactor are not effectively utilized, and a low effluent concentration cannot be achieved even though a limiting-current condition is maintained near the rear. However, for the UU configuration, the lowest electric driving force occurs at the rear of the reactor, and the rate of the main reaction does not decrease exponentially with distance. In fact, with the higher value of P_1 for the silver system, the effluent concentration is very close to the thermodynamic limit determined by the electric driving force prevailing at the fluid outlet (12).

Effect of configuration.—The preceding discussion has permitted a comparison of several configurations under a variety of operating conditions. It is important to recognize that the lowest effluent concentration is achieved for upstream placement of the counterelectrode (see Fig. 3 through 6). For downstream placement of the counterelectrode, a limiting-current distribution cannot be obtained (see Fig. 11 and 13), principally because the current in the solution must flow through most of the length of the electrode, and this leads to a large ohmic potential drop.

For the DU configuration shown in Fig. 8. θ_L decreases with increasing values of matrix resistivity. For a downstream counterelectrode, a situation is created where the ohmic potential drop in the solution is working against the favorable mass-transfer condition near the fluid inlet. Increasing the matrix resistivity increases the electric driving force near the fluid inlet because the matrix current must leave through the current collector placed there. This causes the rate of the main reaction at the front of the electrode to increase from about 0.05 when $1/\sigma \to 0$ (in Fig. 11) to 0.67 when $\sigma = \kappa$ (in Fig. 13).

As mentioned earlier, the DD configuration is the least efficient of the configurations shown in Fig. 1. If the matrix resistivity is increased from zero, the electric driving force is further reduced near the fluid inlet, while it increases somewhat near the fluid outlet (compare Fig. 14 and 15 with Fig. 12). This causes the rate of the main reaction near the front to decrease from about 0.05 when $1/\sigma \to 0$ to 0.012 when $\sigma = \kappa$ (see Fig. 11 and 13). Since the rear of the electrode was already at a limiting current, the increase in the electric driving force in this region is of little benefit; the rate of the main reaction is higher than with $1/\sigma \to 0$ because the flowing stream was not depleted as much in the upstream region, not because the electric driving force is larger. The integrated reaction rate is 6.3% lower when $\sigma = \kappa$, and the rest of the current goes into the side reaction, driven by the higher electric driving force near the rear.

For upstream placement of the counterelectrode, conditions are already more favorable when the matrix resistivity is small. For the UU configuration, increase of $1/\sigma$ decreases the electric driving force in the rear region and causes the current locally to drop below the limiting value. Consequently, σ_L increases, as shown in Fig. 7 and 9. For the UD configuration, the electric driving force decreases near the inlet and increases near the outlet as $1/\sigma$ increases. This is favorable until the reaction rate drops below the limiting value near the inlet, and this leads to the minimum in the curve of θ_L *vs.* κ/σ. The choice between the UD and UU configurations is dependent on the chemical system and the matrix conductivity. However, the UD configuration will display a minimum in the effluent concentration as a function of κ/σ and is therefore the best configuration if this electrode could be built in practice.

Conclusions and Summary

A theoretical model for flow-through porous electrodes (1) has been used to evaluate the effects of

electrode placement relative to the fluid inlet and finite matrix conductivity on the performance of flow-through porous electrodes. If a low effluent concentration is desired, the electrode must be operated at a superficial current density sufficiently high so that the main reaction may achieve a limiting-current distribution. Calculations show that a limiting-current distribution can only be achieved for upstream placement of the counterelectrode and not for a downstream counterelectrode. However, if interference by the side reaction is substantial, as is the case for silver removal from thiosulfate solutions or for the copper system if the superficial velocity is too high, a limiting-current distribution cannot be achieved for any electrode configuration at any matrix conductivity.

For an upstream counterelectrode when the matrix conductivity is not large, the choice between upstream or downstream placement of the current collector depends on the chemical system and what matrix conductivity can be achieved in practice.

Below the limiting current, the performance is only slightly better for an upstream counterelectrode than for downstream placement of the counterelectrode.

Calculations for a small matrix conductivity show that the DD configuration should probably never be built.

It is evident from the results that simple limiting-current calculations are inadequate for describing the behavior of flow-through porous electrodes. Thus, the ability to calculate distributions of current, potential, and concentration in the presence of side reaction above and below the limiting current makes it possible to choose the optimum electrode configuration so as to design and optimize an electrode system for the most economical removal of metal ions.

Extension of Spectral Response of p-Type Gallium Phosphide Electrodes by Metal Adatoms

Hiroshi Yoneyama, Shuichi Mayumi, and Hideo Tamura

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka, Japan

ABSTRACT

The spectral response of p-type GaP electrodes was successfully extended to longer wavelengths by depositing a monolayer of any of several kinds of metal such as gold, silver, palladium, or copper onto the electrode surface and then cathodically polarizing the electrode under illumination. The shape, but not the magnitude, of the developed photocurrent spectra, which covered wavelengths between 600 and 1400 nm, were independent of the kind of metal chosen. Impregnated hydrogen seemed to be responsible for the enhanced photocurrent spectra.

p-type GaP is useful as a photocathode of a water photolysis cell (1, 2). Although it dissolves anodically, no appreciable cathodic decomposition has been found (3, 4). It is found that the quantum yield of the hydrogen evolution reaction (HER) on p-type GaP electrodes exceeded unity if the electrode had an appropriate carrier concentration (5). Although no definite mechanism for this phenomenon has been proposed, we have speculated that surface states are responsible for it. A recent report on cathodic polarization characteristics of p-type GaP covered with a small amount of metal also suggested with more clarity the contribution of surface states to the HER (6).

It was first proposed by Memming *et al.* that surface states played an important role in the cathodic reduction of several oxydizing agents such as hexacyanoferrate and persulfate (3, 4). However, rather ambiguous results were presented by them for the role of the surface states in the HER. Therefore, clear evidence for the contribution of the surface states to the HER seems to be required now.

For that purpose, we have investigated the spectral response of the electrode with and without metal adatoms as a function of the cathodic polarization time and have discovered that the photoresponse of the electrode is extended to wavelengths longer than the threshold of the intrinsic absorption of GaP by cathodically polarizing the electrode at potentials to cause hydrogen evolution. In this paper, several results on this subject are presented.

Experimental

p-type GaP wafers having the acceptor concentration of $4 \times 10^{17}/cm^3$, supplied by Sanyo Electric Company Limited, were used as the electrode. The (111) face was chosen as the electrode surface. The wafer was etched with hot aqua regia to give a shiny surface before being mounted in a glass tube with epoxy resin. Just before the electrodeposition, the electrode was dipped in aqua regia at room temperature, followed by washing with deionized water. The electrodeposition of several kinds of metal was made potentiostatically onto the illuminated electrode in the conditions given in Table I. The deposition potential was selected in such a manner that at that potential not the hydrogen evolution but the metal deposition preferentially proceeded under a fixed band bending of the electrode in all the electrolytes chosen; *i.e.*, the deposition potential was shifted cathodically by 60 mV with an increase in unit *p*H of the electrolyte. Thermodynamically, copper cannot be deposited at the potential selected. However, the deposition was possible at the illuminated electrode, since the deposition reaction proceeded as a photosensitized reaction.

Key words: photoelectrochemistry, semiconductor electrode, gallium phosphide, metal adatoms, surface states.

The number of surface sites equivalent to the monolayer coverage was assumed to be $2.4 \times 10^{15}/cm^2$ of apparent surface area by taking the roughness factor into consideration. The assumption of the number of surface sites is not critical to this study, as is shown in a later section. The deposition was made by employing an electronic coulometer (Nichia Keiki, Model N-CR 404). The current for deposition was automatically interrupted by an action of an electronic relay of the coulometer when the charge amounted to the set value. The deposition was usually completed within several seconds at the longest when the monolayer was deposited. If the metal deposition was made with the charge equivalent to the monolayer coverage, the prepared electrode is represented in this paper as $M(\theta = 1)/$p-GaP. After the metal deposition, the electrode was washed in a stream of deionized water for over 1 hr.

When it was necessary to use the wasted electrodes again, the metal-deposited electrodes were usually dipped in aqua regia at room temperature for 5 min before use with the objectives of both removal of the deposited metal and surface pretreatment, if they still retained the shiny surface. The removal proceeded very rapidly, judging from the fact that metals deposited so much as to show their characteristic color completely lost the color within several seconds after immersion in the aqua regia. On the other hand, no appreciable etching of GaP seemed to proceed in a comparable time. Therefore, we believe that the etching proceeded fairly homogeneously throughout the entire surface by the 5 min dipping even when the deposited metal was distributed in patches on the surface.

Table I. Conditions for metal deposition

Metal	Potential (*vs.* SCE)	Composition of electrolyte (g/liter)	*p*H
Pd	−0.27	$PdCl_2 \cdot 2H_2O$ 16, NH_4Cl 30, NH_4OH 30	10.36
Ag	−0.40	$KAg(CN)_2$ 100, K_2CO_3 45	12.51
Au	−0.23	$KAu(CN)_2$ 170, Na_2HPC_4 5	9.60
Cu	0.29	$CuSO_4$ 200, H_2SO_4 50	0.90
Pb	−0.05	$Pb(BF_4)_2$ 200, HBF_4 20, H_3BO_3 20	1.5

The techniques of ion microprobe mass analysis were employed to obtain information on the distribution profiles of the deposited metal on the surface. A focused Ar^+ beam of 1×10^{-7}A with a 4 μm diameter was scanned on the sample surface with a suitable choice of energy selection of the mass spectrometer of an ion microanalyzer (Hitachi, Model IMA-2). The surface distribution pattern of the deposited metal was obtained as a specific ion image by observing the objective metal ions produced only when the Ar^+ beam struck the deposited metal. This technique has been used by other investigators (7, 8). The in-depth analysis of the surface composition was made in a manner similar to that reported by Evans *et al.* (9) by bombarding an Ar^+ beam of 0.5 μA with a 0.47 mm diameter onto a fixed position of the sample surface, and the signal intensity of the objective element was measured as a function of the sputtering time.

The monochromatic light of various wavelengths was obtained by a prism monochrometer. A 500W xenon lamp was used as a light source. A rather large slit width of 2 mm or more was used in order to obtain high illumination intensity of the monochromatic light. The purity of the monochromatic light was, therefore, not high especially in long wavelengths. The number of incident photons at 450 nm, determined by ferrioxalate actinometry, was usually around 2×10^{14}/cm^2sec for the monochromatic light obtained in this manner. Owing to poor purity of the monochromatic light, a photocurrent spectrum obtained is thought to contain undefined errors. As far as discussion in this paper is concerned, however, the purity of light does not cause a serious problem, because we do not discuss fine structure of the spectrum. A sequence of measurements was done with the same experimental setup, so that the irradiation intensity is believed to have been kept constant during the measurements.

In order to develop photoresponse to light of wavelengths longer than that corresponding to the bandgap energy, the electrode was polarized for a fixed period of time usually in 0.5M Na_2SO_4 at -2.0V under illumination with a focused light from the 500W xenon lamp. The light intensity was around 1.2 W/cm^2, as determined by a laser power meter (Coherent Radiation, Model 201). Then, the electrode was set in an electrolytic cell for measurements of photoresponse. After being set in the cell, the electrode was repeatedly subjected to potential sweep polarization at 1 V/min in the dark in a potential range between -1.0 and the potential at which the cathodic current commenced, until stable current-potential curves were obtained.

The polarization curves were measured by using a potentiostat having high input resistance of $10^{11}\Omega$ (Hokuto Denko, Model HA 104). The electrode potentials cited in this paper are referred to SCE. The differential capacitances of electrodes were measured by means of a Wheatstone bridge assembly (1).

Results and Discussion

Appearance and disappearance of response to monochromatic light of 1000 nm.—When an Au ($\theta = 1$)/p-GaP electrode was cathodically polarized in 0.5M Na_2SO_4 at -2.0V under illumination, a noticeable response to monochromatic light of 1000 nm gradually developed with polarization time; when the electrode was not intentionally subjected to the cathodic polarization, it was insensitive to this wavelength. Figure 1 shows typical results. The measurements of current-potential curves were made not in 0.5M Na_2SO_4 but in 0.5M H_2SO_4, because a higher response was observed in the latter electrolyte than in the former (see Fig. 3). The electrode having no adatoms also showed response to 1000 nm light, although very weak, when it was subjected to the same cathodic polarization treatment as stated above. Trials to characterize the deposited metal layers are presented in a later section.

The initial surface etching with hot aqua regia to give a shiny surface seemed to be essential for the electrode to develop the response to 1000 nm light. The initial etching with HCl, for example, brought about quite different electrode behavior. In this case, the development of photoresponse to 1000 nm light was usually negligible, and a relatively high anodic current was observed at potentials anodic to around -0.5V, even after the electrode was cathodically prepolarized in the above-mentioned manner. The instability of p-type GaP as a photocathode, which was reported previously (1) and drew a contradiction from Bockris and Uosaki (10), was also improved by the pretreatment of the electrode with hot aqua regia.

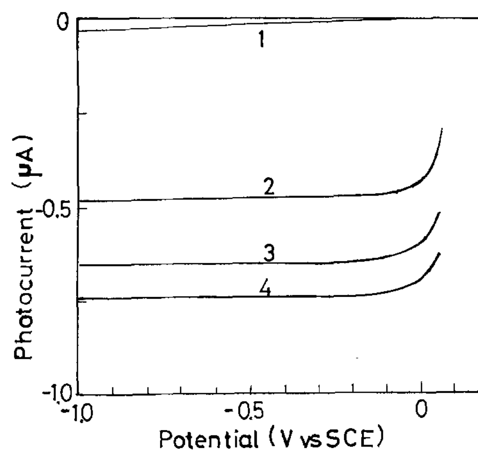

Fig. 1. Increase in photocurrent at 1000 nm with polarization time for an Au($\theta = 1$)/p-GaP electrode polarized at -2.0V in 0.5M H_2SO_4 while under illumination with a 500W xenon lamp. Measuring solution = 0.5M H_2SO_4 and sweep rate = 1 V/min. The cathodic polarization was successively conducted in the order: Curve 1, before the polarization; curve 2, 10 min; curve 3, 20 min; and curve 4, 30 min.

The developed response became weak and finally disappeared if the electrode showing the response was left to stand in the solution under the open-circuit condition or taken out from the solution. Typical examples are given in Fig. 2.

Considering that the minimum bandgap of GaP is 2.38 eV (11), one should recognize that the response to 1000 nm light is caused not by the band-band transitions of electrons but by band-surface state transitions. Then, it seems reasonable to assume that these surface states must have been formed during the 1 hr cathodic polarization and that they disappear after interruption of the cathodic polarization. The cathodic treatment to create the surface states is, therefore, termed here "the activation treatment," and the electrode showing the developed response, "the activated electrode."

The developed response of the activated Au($\theta = 1$)/p-GaP was higher when measurements were made in an acid solution such as 0.5M H_2SO_4 than in a neutral or in an alkaline solution, as Fig. 3 shows. Therefore, measurements of the developed response were usually

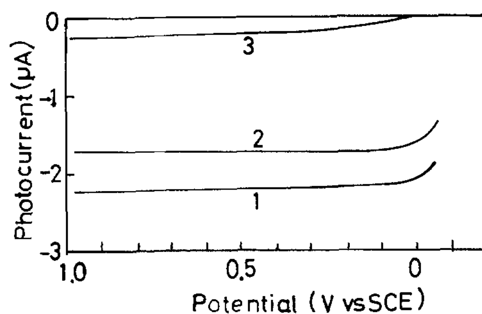

Fig. 2. Decrease in photocurrent at 1000 nm for an activated Au($\theta = 1$)/p-GaP electrode. Measuring solution = 0.5M H_2SO_4 and sweep rate = 1 V/min. Curve 1, immediately after the cathodic polarization for 1 hr under the same condition as given in Fig. 1; curve 2, subsequent to drying for 10 min; and curve 3, subsequent to standing in 0.5M H_2SO_4 for 2 days.

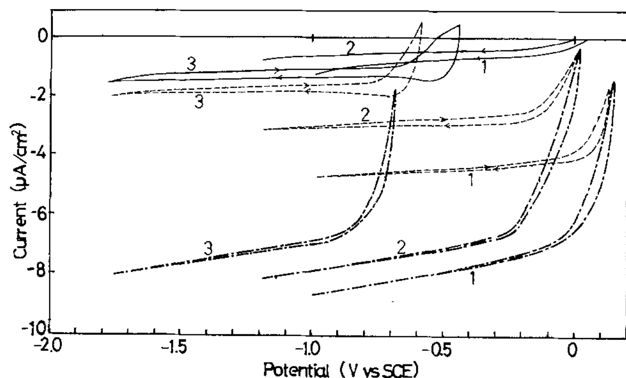

Fig. 3. Current-potential curves for an activated Au(θ = 1)/p-GaP electrode in: Curve 1, 0.5M H_2SO_4; curve 2, 0.5M Na_2SO_4; and curve 3, 0.5M NaOH. (—) In darkness, (- - -) λ = 1000 nm, (· — ·) λ = 440 nm.

made in 0.5M H_2SO_4. On the other hand, the response due to the band-band transition of electrons was not influenced by the nature of the electrolyte used in the measurements.

Activation treatment.—The photocurrent spectra given in Fig. 4 show how the response of an Au(θ = 1)/p-GaP electrode changed with the time of the activation treatment. Notice that in this case in contrast to the conditions of Fig. 1 and 3, the activation treatment was conducted in 0.5M H_2SO_4 at −0.35V. Nevertheless, response appeared at wavelengths longer than 550 nm. This fact, together with a result obtained in 1M NaOH at −2.0V, indicates that the nature of the electrolyte used in the activation treatment is not critical for developing the photoresponse. Also noticeable is the fact that no rigid condition seemed to be required for the polarization potential in the activation treatment. By comparing the potential chosen in the activation treatment of Fig. 4 with that of Fig. 1 and 3, it is recognized that any potential seems to be sufficient to develop the response, providing it is in such a potential region as to give saturated photocurrent under illumination with focused light from the xenon lamp. It follows from these results that there are a variety of activation treatment conditions. However, we usually performed the treatment in 0.5M Na_2SO_4 at −2.0V for 1 hr. The results presented below are for electrodes subjected to this treatment unless otherwise noted.

Figure 4 indicates that the development of response was accompanied with a decrease in the photocurrent owing to the band-band transition of electrons. However, the rate of decrease was quite low compared with the rate of increase in photocurrent in the developed spectrum. The spectral response of p-type GaP could be extended by the activation treatment even when the electrode had no adatoms on it, although the effect was very small.

Effects of the amount of deposited metal on the development of response.—The results given in Fig. 5 show that deposition of one or two monolayers of gold was sufficient to improve the response of p-type GaP. One-half a monolayer was too little and three layers were too much. A similar relation between the amount of deposited metal and the magnitude of photocurrent was also found in the cases of silver and copper deposition. The results on Ag/p-GaP are given in Fig. 6.

These results suggest that the degree of coverage may have a critical role in the improvement of re-

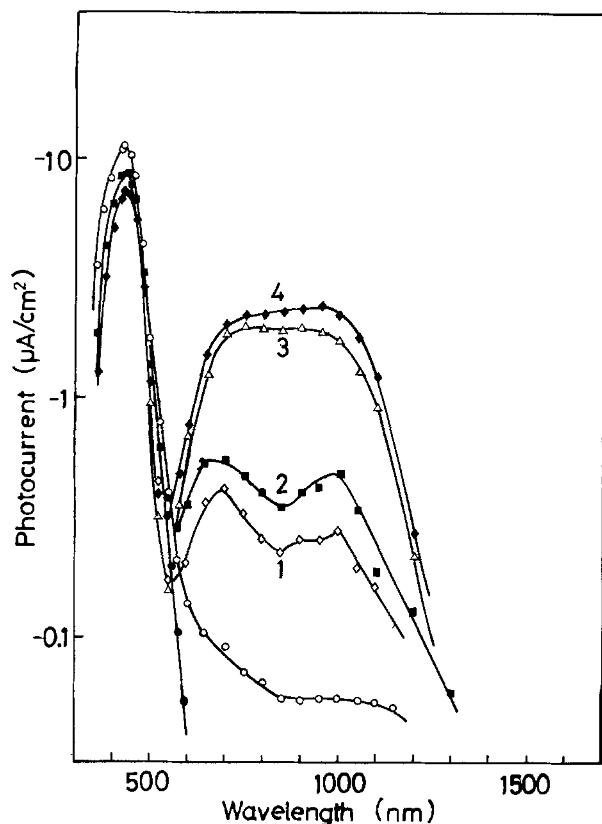

Fig. 4. Development of photoresponse at Au(θ = 1)/p-GaP by the activation treatment in 0.5M H_2SO_4 at −0.35V. Measurements were made with the same condition as in the activation treatment which was successively conducted in the order: Curve 1, 20 min and curve 2, 20 min, both in the dark, and curve 3, 20 min and curve 4, 10 min, both under illumination with a 500W xenon lamp. (—○—) For p-type GaP having no adatom after the activation treatment under illumination for 1 hr, (—●—) for "as chemically pretreated" p-type GaP.

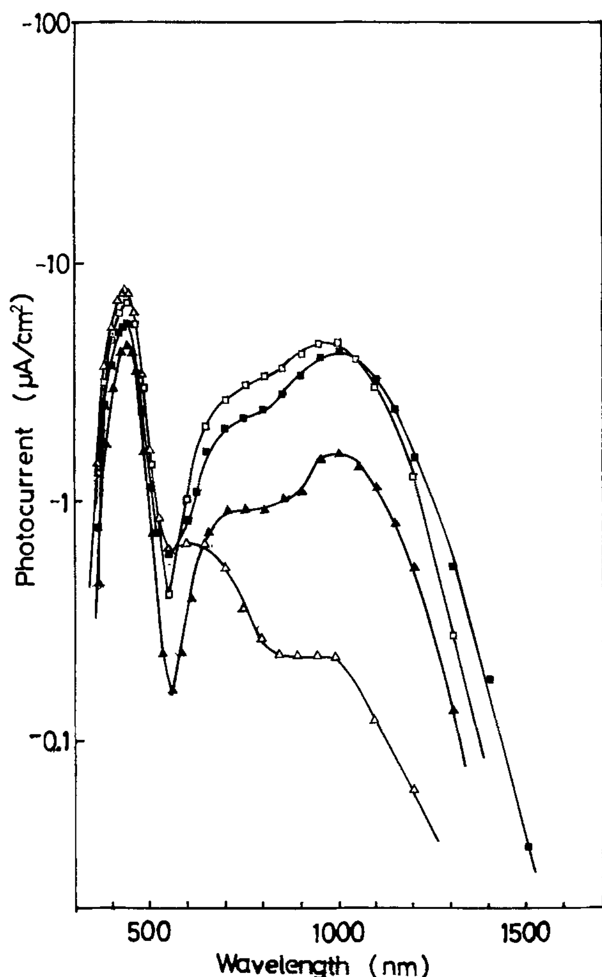

Fig. 6. As in Fig. 5, but for Ag deposition. (—△—) $\theta = 0.5$, (—□—) $\theta = 1$, (—■—) $\theta = 2$, and (—▲—) $\theta = 3$.

sponse. Specific ion image patterns of gold obtained for Au/p-GaP showed, however, that the deposited gold did not cover the entire surface even when the amount corresponding to twenty monolayers was deposited. Therefore, no definite conclusion can be drawn on whether or not the most favorable coverage was attained at the optimum amount of deposition observed and what the optimum coverage is, if any. Figures 4-6 show that the photocurrent spectra of the activated electrodes covered a wide spectral region ranging from 600 to 1400 nm.

Nature of the developed photocurrent.—In order to get information on the nature of the developed spectra, a constant potential electrolysis was conducted in 0.5M H_2SO_4 by using the activated Au($\theta = 1$)/p-GaP electrode. The polarization potential was set at −0.35V, and the electrode was illuminated with a focused light having longer wavelengths than 600 nm which was obtained by setting a colored glass filter (Toshiba, Vr-60) between the xenon lamp and the electrolytic cell. The cathodic current flow of 300 $\mu A/cm^2$ was caused by light irradiation of 0.5 W/cm^2, and gas bubbles were observed to stick to the electrode surface. After the electrolysis for 2.5 hr, the evolved gas was analyzed by a gas chromatograph using a molecular sieve 5A column and was identified to be hydrogen. After the electrolysis no appreciable change was noticed in the electrode surface condition.

Deposited metals as shallow surface states of the electrode.—The monolayer amount of metal deposition did not cover the entire surface of the electrode, but was restricted to areas distributed in patches, as stated above. The activation treatment did not make any change in the ion image pattern obtained. The in-depth analysis of gold, however, showed that the time required for the deposited gold to be sputtered out was

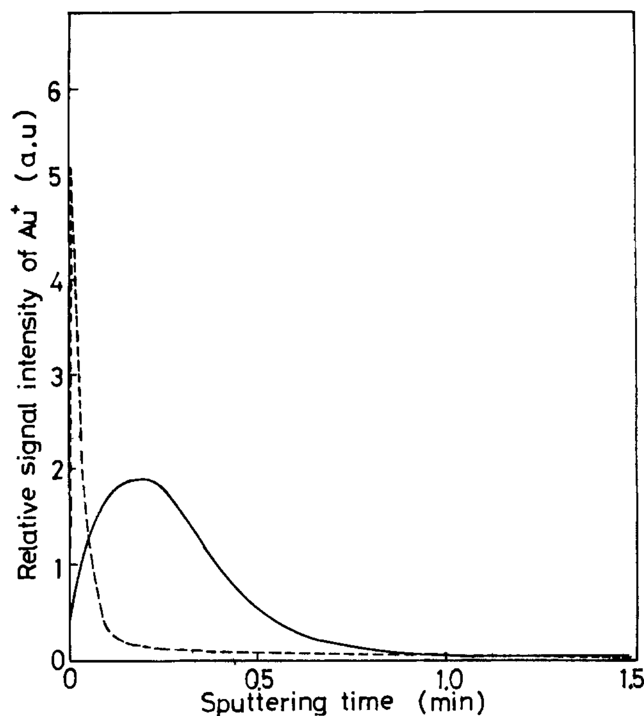

Fig. 7. In-depth distribution profiles for Au($\theta = 1$)/p-GaP before (- - -) and after(—) the activation treatment.

changed and prolonged by the activation treatment (Fig. 7). A simple interpretation may be made that the deposited metal was forced into the electrode surface by the activation treatment. However, this interpretation may draw criticism, since the secondary ion yield for Au will be affected by a change in the bond strength between the adatoms and GaP (12). If the prolongation of sputtering time observed is ascribable to an increase in the bond strength, then one may be able to conclude that the deposited layers became dense by the activation treatment. Any discussion on coarseness of the deposited layers as was done on n-type GaP coated with metal films (6), however, will not be so effective since the deposited layers were distributed in patches. In any case, the deposited gold seems to have no direct relation with the appearance of response at wavelengths longer than 550 nm, because the activated electrode, as mounted in the sample chamber of the ion microanalyzer, had already lost its developed response by the time the ion microprobe mass analysis was made.

The results obtained on CdS and ZnO having metal adatoms also eliminate the possibility for direct participation of deposited metals in the development of photoresponse. According to the results obtained by Gerischer *et al.* (13, 14), the direct optical electron transfer from the adatoms to the conduction band, observed in the anode process, takes place with a very low probability because an electron is required to move in position from the energetic level in the metal adatoms to a place inside the electrode during the course of the optical excitation. A quite analogous situation will be met in the cathode process at p-type GaP having metal adatoms. The optical electron transfer from the valence band to the energetic levels in the metal adatoms, which may lead to the hydrogen evolution, must also proceed with a very low probability even if it would occur.

Formation of deep surface states by the activation treatment.—The above discussion indicates that we have to seek another origin for the development of photoresponse. The results shown in Fig. 1 and 4 suggest that the formation of surface states is a slow process. This is important information for evaluating the origin of surface states. Another important finding is that the shapes of the photocurrent spectra of M(θ=1)/p-GaP are independent of the kind of metal M (Fig. 8). This result suggests that the surface states

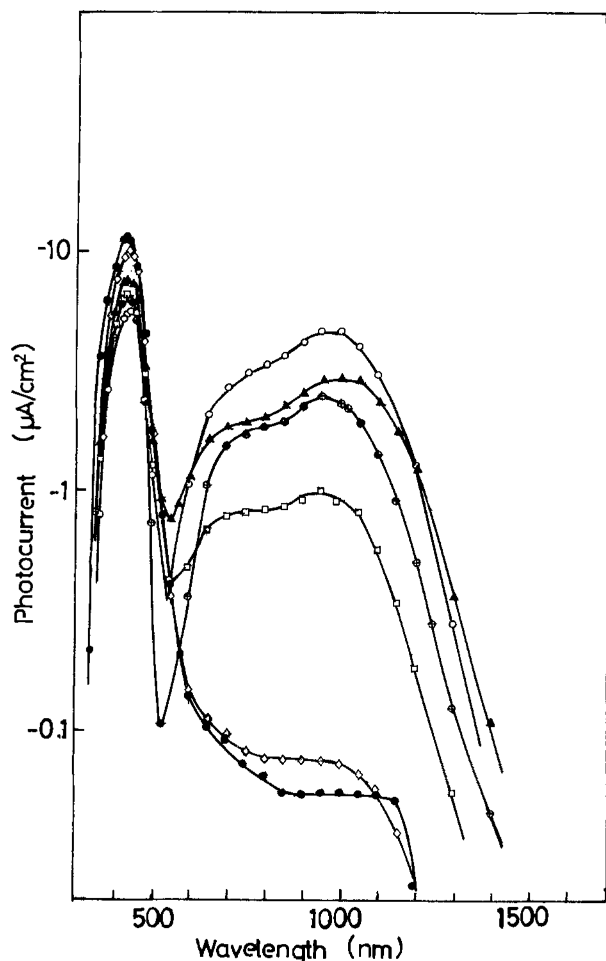

Fig. 8. Photocurrent spectra of activated GaP having the monolayer amount of various metals. (○) Ag, (—▲—) Pd, (—⊕—) Au, (—□—) Cu, (—◇—) Pb, and (—●—) none. Solution = 0.5M H_2SO_4, E = −0.35V.

formed have the same origin. Then, hydrogen impregnation evolves as the most probable cause for the formation of surface states, although we have no definite knowledge of the impregnated condition.

It is well known that the cathodic evolution of hydrogen causes hydride formation for Ge (15) and leads to its decomposition. In the case of compound semiconductors, such as GaAs (16) and InP (17), the nonmetallic elements are removed from the semiconductor surface as hydrides during the course of hydrogen evolution. Compared with these semiconductors, GaP seems to be suitable for the hydrogen evolution, so that it can accommodate the impregnated hydrogen in the electrode surface region.

It was noticed that the activation treatment for 1 hr was enough to develop photoresponse at wavelengths longer than 550 nm and that further activation treatment brought about no appreciable effect. This finding also supports the premise that hydrogen impregnation is closely related to the formation of surface states. The impregnation proceeds toward the interior of the electrode during the course of the activation treatment, and the formed surface states can trap photoexcited electrons with energies smaller than the bandgap energy. If the assumption is made that photoexcited electrons from the valence band to levels of the formed surface states are responsible for the developed cathodic photocurrent, then the magnitude of the developed photocurrent must depend on the trapping probability of photoexcited electrons as well as on irradiation intensity. The dependence of the developed photocurrent on illumination intensity is given in Fig. 9. The trapping probability will become saturated if the formation of surface states extends into the interior for a distance

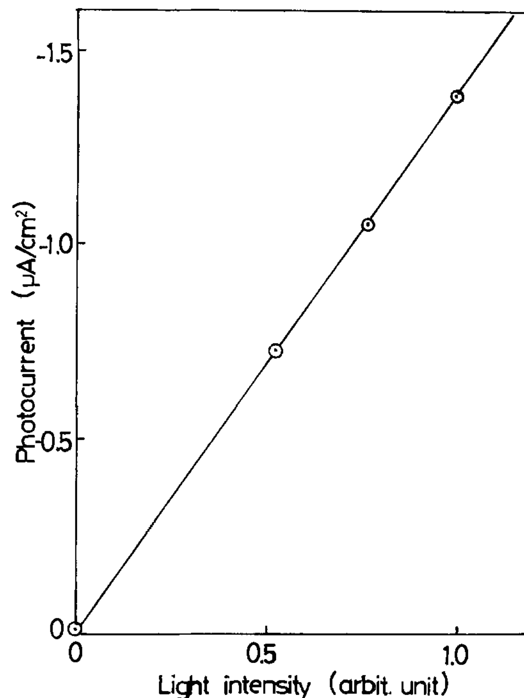

Fig. 9. Photocurrent via the formed surface states as a function of illumination intensity. λ = 1000 nm, solution = 0.5M H_2SO_4, electrode = activated Au(θ = 1)/p-GaP.

comparable to the penetration depth of the illuminated light. The experimental results show that such a condition was almost realized by the activation treatment for 1 hr.

As shown in photocurrent spectra of M(θ=1)/p-GaP, growth of the developed spectrum was usually accompanied by depression in the photocurrent at wavelengths of the intrinsic absorption of GaP. This phenomenon possibly reflects that some of the electrons photoexcited into the conduction band were trapped by the formed surface states.

Energy levels of surface states.—It is possible to determine the energy levels of the surface states from the photocurrent spectra obtained. In the case of Au(θ = 1)/p-GaP, they are distributed from about 0.9 to 2.3 eV above the upper edge of the valence band with a high density between 1.4 and 1.8 eV, although no rigid determination was possible in the present study owing to poor resolving power of the monochrometer as used. It is evident that almost the same distribution profile holds for electrodes having other kinds of deposited metals. From a knowledge of the flatband potential of the electrode, which is given below, relative positions of the energy levels of the surface states to that of the hydrogen electrode can be pictured as shown in Fig. 10. This figure is given for the case when the electrode was polarized at −0.35V in 0.5M H_2SO_4. If one takes into consideration the distribution function of unoccupied electron states in the hydrogen electrode (18, 19), hydronium ions must find a distribution probability in the energies equal to or higher than the lowest level of the surface states. Therefore, the electron transfer from the surface states to hydronium ions in the electrolyte must occur in the energy region covering the entire surface state. Furthermore, this transfer seems to be more feasible than that via the conduction band since the energy levels of the surface states, rather than those of the conduction band, are closer to the energy of the hydrogen electrode.

Memming *et al.* found participation of surface states in the reduction of several oxidizing agents at p-type GaP electrodes (3, 4). It is noteworthy that the energy region covered by the surface states discovered by them is in good agreement with that found in the present study, although their results showed negligible par-

ticipation of the surface states in the hydrogen evolution reaction.

Flatband potentials.—Figures 11 and 12 show Schottky-Mott plots of differential capacitance of p-type GaP and Au(θ = 1)/p-GaP electrodes, respectively, before and after the activation treatment. As the figures show, the potentials obtained by extrapolation of the plots to $1/C^2 = 0$ were independent of the measured frequency. It is then possible to determine the flatband potential in a straightforward manner (20). The flatband potentials of M(θ=1)/p-GaP electrodes determined in this manner are presented in Table II. It will be noticed that the flatband potential of the electrode was shifted negatively by the activation treatment regardless of whether or not the electrode had metal adatoms.

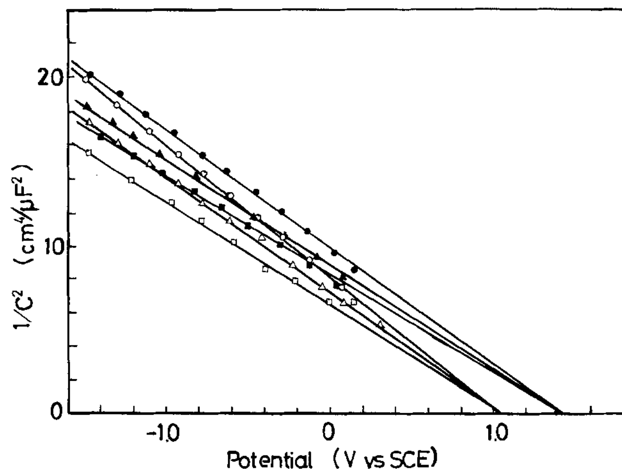

Fig. 12. As in Fig. 11, but for Au(θ = 1)/p-GaP

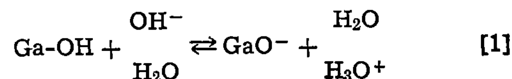
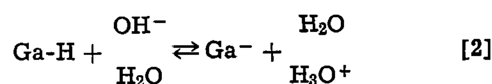
In the case of Ge electrodes, the cathodic polarization brings about a change in the surface condition from a hydroxyl to a hydride nature, so that the flatband potential is shifted in a negative direction. This phenomenon could successfully be elucidated only when a rapid measurement technique was employed (21, 22). A quite analogous situation is expected on GaP electrodes.

The surface Ga sites of GaP are believed to be responsible for formation of hydroxide and hydride, according to the following equations



$$\text{Ga-OH} + \underset{H_2O}{\overset{OH^-}{\rightleftarrows}} \text{GaO}^- + \underset{H_3O^+}{\overset{H_2O}{}} \quad [1]$$



$$\text{Ga-H} + \underset{H_2O}{\overset{OH^-}{\rightleftarrows}} \text{Ga}^- + \underset{H_3O^+}{\overset{H_2O}{}} \quad [2]$$

The surface Ga-H will be too unstable to be detected by a slow measurement technique of differential capacitance such as by employing a Wheatstone bridge assembly, because gallium is an sp metal and cannot retain adsorbed hydrogen (23). In the case when hydrogen is impregnated, however, a different situation may hold, and surface gallium may behave as if it retains adsorbed hydrogen. This is a plausible explanation for the negative shift of the flatband potential of the electrode by the activation treatment.

The values of the flatband potentials were affected by the kind of metals chosen, as Table II shows. An argument similar to that made for CdS electrodes having various kind of metal adatoms (13) would hold here also. Unfortunately, however, a linear relation has not yet been established between the flatband potential of M(θ=1)/p-GaP and the work function of the deposited metals, possibly because of scarcity of experimental results.

It is shown in Fig. 3 that the photocurrent caused by illumination with monochromatic light of 1000 nm was affected by the nature of the electrolyte. A plausible explanation for this is as follows. By changing *p*H values of the electrolyte, the number of the surface hydride sites will be changed according to Eq. [2]. The continuity of the surface-state energy levels from the surface into the interior is then affected, and there will

Table II. Flatband potentials of M(θ = 1)/p-GaP electrodes measured in 0.5M H_2SO_4

	Flatband potential (V *vs.*SCE)	
M	Nonactivated	Activated
Au	1.20	1.02

Cu	0.90	0.86
Pb	0.94	0.80
None	0.95	0.73

be a large tendency in a high pH solution for the continuity to be broken down and thus for the photocurrent to be suppressed.

Conclusion

Extension to longer wavelengths of the photocurrent response of p-type GaP electrodes for the hydrogen evolution reaction was successfully achieved by depositing a monolayer of any of several kinds of metals onto the electrode surface and then cathodically polarizing the resulting electrode under illumination. The cathodic polarization must be related to surface-state formation, and the impregnated hydrogen seems to be the most probable cause for this. The developed response was high enough to have practical significance for solar energy utilization at least in the following two points: First, the activated electrode responds in a wide wavelength region below 1400 nm, so that a large part of the solar spectrum can be utilized. Second, while the activated electrode is being used as a photocathode, there seems to be no problem in the stability of the metal adatoms; thus a long life duration of the activated electrode is to be expected. From a scientific point of view, however, some questions remain on the development of the response to be elucidated, especially on the mechanism of the appearance of the developed response, and on the role of the deposited metals. On the latter point, the catalytic activity of the metals for the hydrogen evolution may have some relation to the development of the response, since deposition of Pb did not give any apprciable effect.

Manuscript submitted July 7, 1977; revised manuscript received Aug. 30, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Homomolecular Oxygen Exchange and the Electrochemical Reduction of Oxygen on Semiconducting Oxides

D. B. Hibbert* and A. C. C. Tseung*

Department of Chemistry, The City University, London EC1V 4PB, United Kingdom

ABSTRACT

The activation energies of the reversible electrochemical reduction of oxygen on $La_{0.5}Sr_{0.5}CoO_3$ and lithiated nickel oxide were shown to correlate with those of the gas phase exchange reaction between $^{16}O_2$ and $^{18}O_2$ on these catalysts. This result suggests that the rate-determining step of the reversible oxygen reduction is the dissociative chemisorption of an oxygen molecule, in agreement with the "joint pseudosplitting/dissociative chemisorption" mechanism. The electrochemical reduction and isotopic exchange reaction on high and low surface area lithiated nickel oxide showed that only above the Neel temperature could oxygen be chemisorbed as $2\,O^-$. The effect of particle size distribution, leading to a mixed potential, may account for the fact that high surface area lithiated nickel oxide is reversible only above 150°C.

Research into the mechanism of the electrochemical reduction of oxygen has stemmed from the quest for a reversible oxygen electrode. Work by Tseung, Hobbs, and Tantram (1) and Bevan and Tseung (2, 3) has shown the importance of the magnetic properties of semiconducting oxide electrocatalysts.

In this paper, the concepts developed in the earlier work are discussed and further evidence from isotopic exchange experiments is reported which clarifies the nature of the rate-determining step of the reaction.

The Theory of Electrochemical Oxygen Reduction

The reduction at an oxygen cathode in alkaline solution may take two paths

$$O_2 + 2H_2O + 4e = 4\,OH^- \quad [1]$$

$$O_2 + H_2O + 2e = HO_2^- + {}^-OH \quad [2]$$

* Electrochemical Society Active Member.

Key words: electrocatalysis, lanthanum cobalt oxide, magnetic properties, lithiated NiO, isotopic exchange.

A possible scheme for the four-electron process (Eq. [1]) involves the so-called "joint pseudosplitting/dissociative adsorption" mechanism (2, 4). "Side-on" adsorption of an oxygen molecule followed by partial electron transfer at the catalyst surface and hydrogen bonding to adjacent adsorbed hydroxyl ions leads to a low energy pathway for the cleavage of the oxygen molecular bond. The scheme is depicted in Fig. 1(a)-(d). The initial adsorption is seen as an interaction between the π^* electrons of O_2 and partially filled d orbitals of two adjacent transition metal ions of the semiconducting oxide electrode. This is essentially the "bridge model" discussed by Yeager (5).

If the conditions for side-on adsorption are not favorable bonding may occur through just one oxygen atom leading to "end-on" adsorption and the pathway of Eq. [2] (6). The participation of both reactions at the cathode leads to a mixed potential and irreversible behavior.

By this theory, therefore, an efficient material for a reversible oxygen electrode should be able to chemisorb oxygen in the side-on position. Tseung and Bevan have argued that side-on adsorption of oxygen (a paramagnetic molecule) will be facilitated by the presence of parallel electron spins in the surface of the electrocatalyst. Thus the requirement for the catalyst is that it, too, should be paramagnetic at the temperature of operation of the electrode.

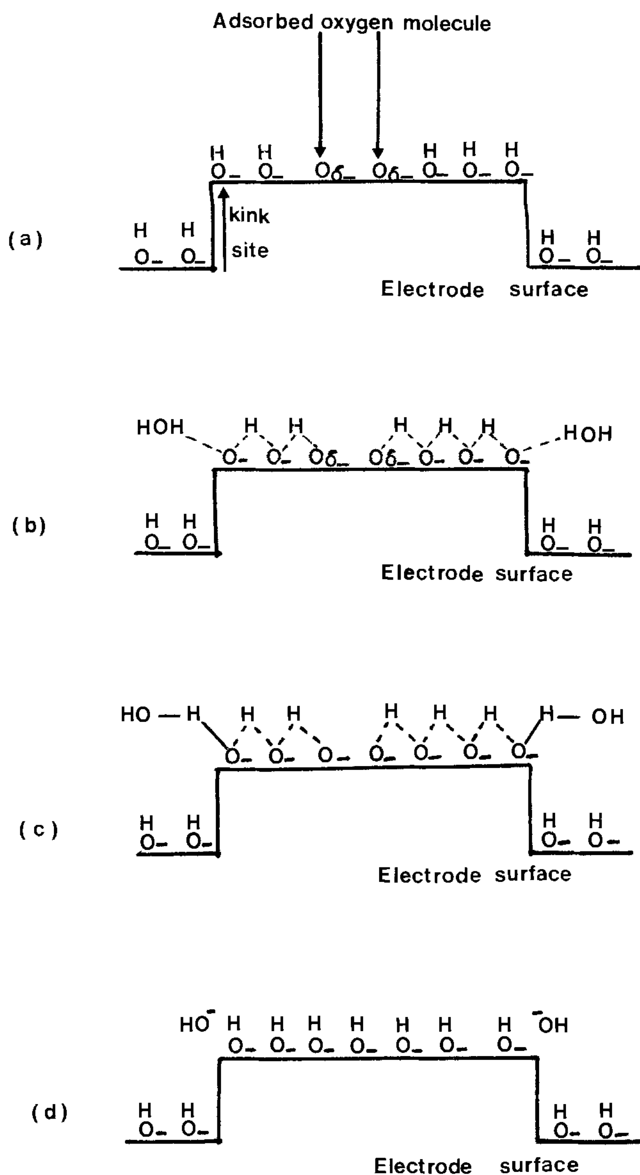

Fig. 1. Stages in pseudosplitting. (a) Partial electron transfer, (b) hydrogen bonding, (c) completion of electron transfer, (d) reorientation. Over-all reaction: $O_2 + 2H_2O + 4e \rightarrow 4\ OH^-$.

Yeager (5), in a recent review, distinguishes two modes of side-on adsorption involving one, or two catalyst sites. A one-site adsorption, the Griffiths model (7), although leading to a weakening of the oxygen molecular bond, does not require a particular magnetic state, in contrast to the two-site (bridge) model discussed above.

In addition, correct spacing of the metal ions is a prerequisite of the bridge model.

Two classes of oxides have been shown to reduce oxygen in alkaline solution via the four-electron path of Eq. [1]; perovskite oxides based on $LaCoO_3$ (3) and lithiated nickel oxide (2). $La_{0.5}Sr_{0.5}CoO_3$ is ferromagnetic at room temperature. Nickel oxide is antiferromagnetic with a Neel temperature (for massive nickel oxide) of 247°C. The apparent Neel point is extremely sensitive to particle size and is reduced to room temperature for nickel oxide of mean particle size diameter of 130Å (8).

Experimental

Preparation of oxide catalyst.—Low surface area lithiated nickel oxide [5 atom percent (a/o) Li^+] was prepared by the freeze drying technique (9) with a reduced volume of nickel acetate and lithium acetate (200 ml for 5g catalyst). $La_{0.5}Sr_{0.5}CoO_3$ was prepared using the same method from a solution of mixed nitrates following the procedure of Tseung and Bevan (3).

High surface area lithiated nickel oxide was prepared by the method given by Teichner (10) in which nickel hydroxide, precipitated by ammonium hydroxide from a solution of nickel nitrate, was wetted with a saturated solution of lithium hydroxide. After agitation for 1 hr in an ultrasonic bath, the resulting slurry was dried and decomposed under vacuum (10^{-3} Torr) at 200°C. High surface area nickel oxide was prepared by the same method.

Catalyst characterization.—The surface area of each catalyst was measured by the BET method from the adsorption of nitrogen at 77°K. The conductivity of the catalyst was measured in a specially designed steel die containing a fixed amount of catalyst powder compressed at a fixed pressure by a Wayne-Kerr a-c bridge (1592 Hz).

The composition of the catalysts was checked by atomic absorption of a solution produced by dissolving a known weight of the catalyst in nitric acid. For the samples of high surface area lithiated nickel oxide, a leach with water was performed to determine the amount of lithium oxide which had remained unreacted on the surface of the nickel oxide.

X-ray powder photographs of $La_{0.5}Sr_{0.5}CoO_3$ (a Phillips machine with molybdenum targets and zirconium filter to select $K\alpha$ radiation) revealed the correct perovskite structure. Table I gives details of the physical properties of the catalysts used.

All the powders used for the isotopic exchange experiments were examined by transmission electron microscopy (by a JEOL, JEM 100B microscope, accelerating voltage 100 kV). Samples were sprayed onto a grid from a dispersion in water. Maximum magnification available was 50,000× which allowed the resolution of particles of 40Å diameter. From this it was possible to obtain a particle size distribution of the powders.

Electrode preparation.—Teflon bonded (1) porous electrodes were fabricated to test the electrocatalyst powders. A slurry of 10 mg catalyst and 3 mg 60% PTFE dispersion in water was ultrasonically dispersed for 10 min, then painted onto a preweighed, degreased, and etched 100 mesh Ni grid. The electrode was cured at 300°C for 1 hr, then spot welded onto a gold strip attached to a gold wire.

Table I. Physical characteristics of the electrocatalysts

Catalyst	Preparation technique*	Surface area (m^2/g)	Conductance** (Ω^{-1} cm^{-1})	X-ray analysis	Experimental investigations

* f.d. = freeze drying, h.p. = hydroxide precipitation.
** n.d. = not determined.

Electrochemical testing.—The cell used was a modification of the floating electrode cell of Giner and Parry (11). Electrodes of 1 cm^2 area were used in an electrolyte of 45 weight percent (w/o) KOH up to 140°C and 75 w/o KOH between 140° and 230°C. A Witton Model EC108L transistorized 1A potentiostat was used. A platinized platinum electrode was used as a dynamic hydrogen reference electrode (DHE), which was periodically standardized against a reversible hydrogen electrode (RHE). The *i-R* drop between Luggin and electrode surface was determined by the interruptor technique. A 20 cm^2 platinum gauze was used as the counterelectrode.

Isotopic oxygen exchange experiments.—The apparatus used to follow the equilibration of an $^{16}O_2/^{18}O_2$ mixture is essentially similar to that used by Winter (12) and is depicted in Fig. 2. The capillary leak joining mass spectrometer to reaction vessel was such as to allow a pressure of 10^{-5} Torr in the spectrometer for a pressure of 100 Torr in the reaction vessel. The volume of the reactor was 200 cm^3 and for a total pressure of gases of 100 Torr the leak rate to the mass spectrometer caused less than a 2% change in this pressure during the course of an experiment.

The mass spectrometer, an AEI MS10, scanned m/e (mass: electron ratio) 36, 34, and 32 with a sensitivity of 28 μA $Torr^{-1}$ allowing the detection of about 0.1% of any isotope in 10 Torr oxygen in the reaction vessel. "White spot" nitrogen was dried over silica gel. Oxygen containing 63.6% ^{18}O was supplied by British Oxygen Company, Special Gases Division.

In order to observe homomolecular exchange, the catalyst (~1g) was preequilibrated overnight at the temperature of the experiment with the $^{16}O_2/^{18}O_2$ mixture. The system was then evacuated to 10^{-3} Torr and filled with nitrogen to 100 Torr. To start the experiment 5 ml of labeled oxygen mixture was introduced into the reactor (giving a pressure of about 10 Torr). The ion currents of m/e 32, 34, and 36 were recorded at intervals for 400-600 min.

The accuracy of this method is limited by the rate of change of the m/e 36:34 ratio. The results were not considered if this ratio changed by less than 1% in 300 min. Practically, the lowest temperature which could give this rate for the catalysts investigated was between 100° and 150°C.

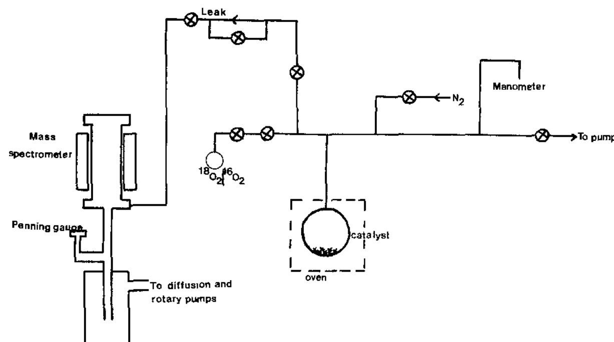

Fig. 2. Apparatus to measure the rate of oxygen exchange on a catalyst surface.

Results

Electrochemical testing.—Current-voltage relations for $La_{0.5}Sr_{0.5}CoO_3$ and lithiated nickel oxide have been published by Tseung and Bevan (2, 3), and Bevan (13).

Low surface area (12 m^2g^{-1}) lithiated nickel oxide electrodes showed reversible behavior (correct OCV, $i \propto p_{O_2}^{1/2}$, no change in slope of *i/V* curves through OCV) above 240°C, but below 220°C the reduction of oxygen was irreversible. For a high area sample (180 m^2g^{-1}) reversibility was shown above 150°C. In the case of $La_{0.5}Sr_{0.5}CoO_3$ the electrodes were reversible at room temperature.

To express the electrochemical rate of oxygen reduction in terms of the number of oxygen molecules reacting per second per square centimeter of true catalyst surface (Ƶ), the value of i_o was calculated from the *i-V* data. For all reversible electrodes the *i-V* curves were linear within 50 mV of the OCV. i_o was therefore calculated from the linear approximation to the Butler-Volmer equation given by Bockris and Reddy (14)

$$i_o = \frac{\Delta i}{\Delta \eta} \frac{\nu RT}{n\mathbf{F}} \quad [3]$$

($\Delta i/\Delta\eta$) is the slope of current density-overpotential line; ν is the stoichiometric number (taken as 2 for reaction [2]); n is the number of electrons associated with the reaction (here 4); and R, T, and $\mathbf{F}$ have their usual meanings. From i_o the rate of reaction, corrected for an atmosphere of 10 Torr oxygen ($i_o p_{O_2}^{0.5}$) may be calculated

$$Ƶ = (Ni_o/4A\mathbf{F})\,(1.32/p_{O_2})^{1/2}$$

where N is Avogadro's number, A is the true surface of the catalyst per square centimeter of electrode, and p_{O_2} is the partial pressure of oxygen used in the experiment expressed as a percentage (10 Torr is 1.32% of 760 Torr).

Figure 3 shows an Arrhenius plot of the results of $La_{0.5}Sr_{0.5}CoO_3$ and 10 a/o Li^+/NiO (ssa 180 m^2/g). These lines give: $La_{0.5}Sr_{0.5}CoO_3$ $Z = 10^{17.56}$ exp ($-13.0/RT$ kcal/mole); lithiated nickel oxide $Z = 10^{12.26}$ exp ($-4.3/RT$ kcal/mole).

The open-circuit voltage (OCV) of nickel oxide electrodes made from both high and low surface area oxide were measured at room temperature. At 25°C hydrophobic nickel oxide electrodes (ssa 135 m^2/g) gave more than 1.063V *vs.* DHE (in 100% oxygen). Attempts to purify the KOH solution by electrolysis (15) resulted in no significant change. Increasing the temperature to 70°C gave the expected decrease in OCV. Low surface area nickel oxide (ssa 38 m^2/g) had an OCV of 1.053V *vs.* DHE in air.

No attempt to measure current voltage curves was made due to the high resistivity of nickel oxide [$10^6\Omega$ cm (1)].

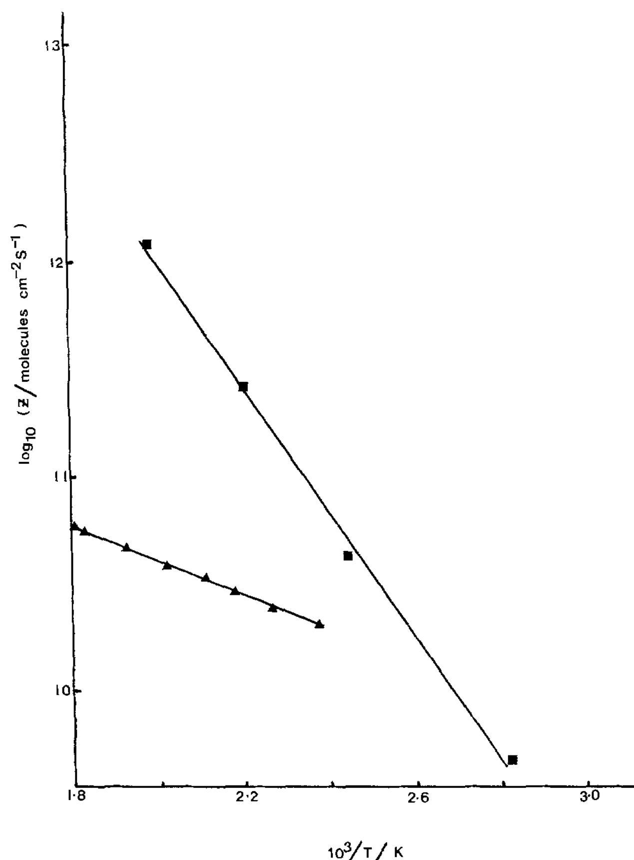

Fig. 3. The rate of the electrochemical reduction of oxygen calculated from i_0 measurements, as a function of temperature. ■ $La_{0.5}Sr_{0.5}CoO_3$, ssa 38 m^2/g; ▲ 10 a/o Li/NiO, ssa 180 m^2/g.

Isotopic exchange studies.—According to Boreskov (16) the rate of exchange of oxygen on a catalyst which has been equilibrated with an isotopic gas mixture is given by

$$\ln \frac{C^{\infty} - C^{0}}{C^{\infty} - C^{t}} = kt \qquad [4]$$

where C^t is the fraction of $^{16}O^{18}O$ molecules at time t, and k is the rate constant for the homomolecular exchange reaction

$$^{16}O + {}^{18}O \rightleftarrows {}^{16}O^{18}O \qquad [5]$$

Values of the rate constant k, were determined from Eq. [4] at temperatures between 150° and 300°C for $La_{0.5}Sr_{0.5}CoO_3$, 5 a/o Li^+/NiO (ssa 150 m^2/g and 2.5 m^2/g) and for NiO (ssa 135 m^2/g) at 160°C. k is related to the number of molecules reacting per second per unit surface area (Z) by

$$Z = \frac{N_A k}{A} \qquad [6]$$

where N_A is the total number of oxygen molecules in the reactor and A is the surface area of the catalyst.

Figure 4 is an Arrhenius plot of $\log_{10} Z$ *vs.* $1/T$ for the different catalysts. The rates for $La_{0.5}Sr_{0.5}CoO_3$ and high ssa lithiated NiO are described by

$$Z = 10^{17.2} \exp(-15.8/RT \text{ kcal/mole})$$

$$Z = 10^{10.3} \exp(-4.7/RT \text{ kcal/mole})$$

respectively.

It is noted that the single determination of Z for NiO (ssa 135 m^2/g) at 160° also falls on the lithiated nickel oxide curve.

The line for the low surface area 5 a/o Li^+/NiO shows a distinct change in shape between 220° and 240°C which encompasses the Neel temperature for this oxide.

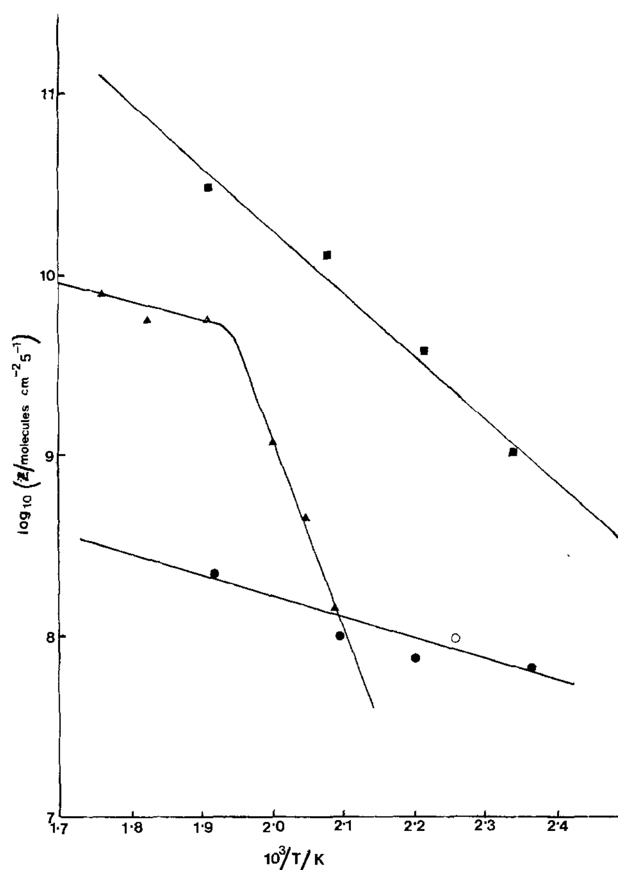

Fig. 4. The rate of homomolecular exchange of oxygen as a function of temperature. ■ $La_{0.5}Sr_{0.5}CoO_3$, ssa 30 m^2/g; ● 5 a/o Li/NiO, ssa 150 m^2/g; ▲ 5 a/o Li/NiO, ssa 2.5 m^2/g; ○ NiO, ssa 135 m^2/g.

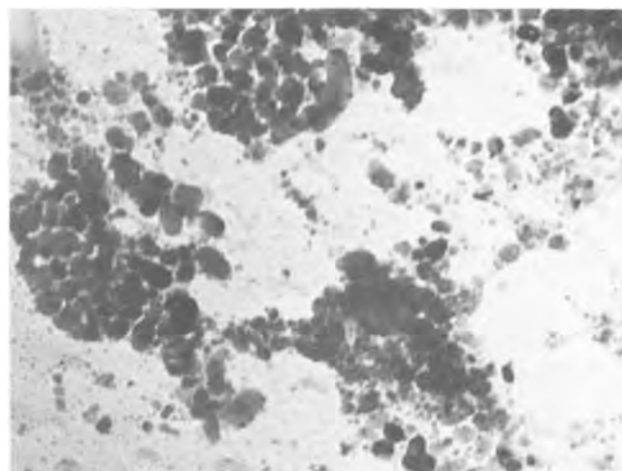

Fig. 5. Electron micrograph of 5 a/o Li/NiO ssa 150 m^2/g, showing crystallite size distribution. Original magnification 50,000X.

Particle size distribution.—Figure 5 gives a transmission electron micrograph of a lithiated nickel oxide sample of ssa 135 m^2/g. A count of the distribution of particle sizes leads to a mean particle size diameter (PSD) of approximately 100Å. That this is larger than is predicted from the BET measurement (67Å) indicates the presence of particles smaller than were resolved by the microscope (40Å). Of interest is that about 5% of the particles counted were of diameter greater than 200Å and particles greater than 600Å diameter were observed.

It is also of interest to note that low surface area lithiated nickel oxide powders showed a much smaller distribution of diameters.

Discussion

The comparison of chemical and electrochemical rates.—In comparing chemical and electrochemical rates of reaction it must be noted that the electrochemical rate determined from i_o will contain not only an element due to the chemical step (here the chemisorption of oxygen), but also to the added effect of potential. However if the rate-determining step is essentially a chemical adsorption of oxygen it would be expected that the slopes of the Arrhenius plots would be a measure of the activation energy of the process for both chemical and electrochemical reactions. It is seen immediately from a comparison of Fig. 3 and 4 that the activation energies for gas phase oxygen exchange and reversible elecrochemical reduction of oxygen on $La_{0.5}Sr_{0.5}CoO_3$ and high ssa lithiated nickel oxide have similar values ($La_{0.5}Sr_{0.5}CoO_3$: 15.8 kcal mole^{-1} and 13.0 kcal mole^{-1}; lithiated NiO: 4.7 kcal mole^{-1} and 4.3 kcal mole^{-1}, respectively). These results support the theory that the rate-determining step in each reaction is the dissociative adsorption of oxygen, which, in the case of electrochemical reduction of oxygen, is the first step in the joint pseudosplitting/dissociative adsorption mechanism.

The effect of particle size on the reversibility of lithiated nickel oxide electrodes.—In accord with their theory that semiconducting oxide electrodes should be reversible above the Neel temperature, Tseung and Bevan (3) found that $La_{0.5}Sr_{0.5}CoO_3$ [$LaCoO_3$ shows antiferro magnetic behavior below 100°K (17)] was reversible at room temperature, and that lithiated nickel oxide of ssa 12 m^2g^{-1} was reversible above 220°C. However, when high surface area (ssa 180 m^2g^{-1}) lithiated nickel oxide was tested, reversibility was shown only at 150°C although the apparent Neel point of nickel oxide of ssa 180 m^2g^{-1} is, according to Richardson and Milligan (8), less than 120°K. The predominance of peroxide production from massive lithiated nickel oxide cathodes at room temperature has also been noted by Yeager's group (18).

There is some dispute concerning the effect of particle size on the Neel temperature of nickel oxide. Richardson and Milligan (8), while finding that the position of the maximum in the susceptibility *vs.* temperature curve moved to lower temperatures with decreasing average particle size, concluded from neutron diffraction studies that the true Neel point of NiO was not changed and that the data could be explained by a change in magnetic environment for small crystallites. Later work by Cohen *et al.* (19) and Kawada and Kawai (20) agreed with the experimental results but attributed these to a shifting Neel point. Neel himself (21) explained the magnetic behavior of small particles of nickel oxide in terms of "superparamagnetism" and "superantiferromagnetism."

Of significance to the present work is that small particles ($<$100Å) of nickel oxide will show paramagnetism at room temperature. The average particle size diameter (PSD) of nickel oxide of ssa 180 m^2g^{-1} is 60Å and so it is necessary to explain why reversibility was not shown at room temperature in our experiments.

On examination of the distribution of particle sizes of the 180 m^2g^{-1} sample (Fig. 5) approximately 5% of the particles were of diameter greater than 200Å. A crystallite of this size will show the normal antiferromagnetic behavior of massive nickel oxide and would not be expected to facilitate side-on adsorption of oxygen at room temperature. Gross magnetic determinations and the isotopic exchange reactions will be relatively unaffected by these particles. In the electrochemical environment, however, the presence of particles which may only allow oxygen reduction to the peroxide via end-on [Pauling (22)] adsorption given by Eq. [2], will give rise to a mixed potential which will be less than a truly reversible potential from the four-electron reaction.

Isotopic exchange on low ssa lithiated nickel oxide.—The break in the Arrhenius plot for low surface area lithiated nickel oxide is explained by the antiferromagnetic-paramagnetic transition at the Neel temperature. Below 240°C the isotopic exchange rate falls and soon becomes unmeasurable. These findings agree with Winter (12) who suggested that adsorption on nickel oxide occurred as 2 O^- above the Neel point but O_2^- below this temperature. That the rate does not fall immediately to zero below the Neel point, but shows an exponential decline (Fig. 4), may again be related to the particle size distribution (see previous section). As crystallite diameter will be distributed normally about the mean particle size, the number of paramagnetic particles will exponentially decrease below the Neel point.

Conclusion

Gas phase and electrochemical data support the conclusion that the rate-determining step in the electrochemical reduction of oxygen in alkaline medium via reaction [2] is the dissociative adsorption of an oxygen molecule. This is in agreement with the joint pseudosplitting/dissociative adsorption theory of Goldstein and Tseung (6).

The effects of particle size on the Neel temperature and the reversibility of an electrode suggest that the electrochemical reduction of oxygen is more sensitive to the presence of large crystallites which will lead to a mixed potential and over-all irreversibility.

Ring Electrodes

Peter Pierini*[,1] **and John Newman***

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The primary and secondary current distributions and the primary resistance for ring electrodes are presented. Current distributions, including mass transfer effects, for various potential dependent heterogeneous kinetics are computed for a representative set of rotating-ring electrode geometries.

Rotating-ring electrodes are a common and useful device for the study of electrochemical systems. They have appeared individually and in conjunction with disks, spheres, and other rings. Ring electrodes have very thin concentration boundary layers at the inner or upstream edge of the electrode, so the limiting current densities are high in that region and infinite at the edge. The primary and secondary current distributions have large densities close to both the inner and outer edges; the primary distribution has infinite values at both edges. The ring electrode thus behaves very much like a short plane electrode in the wall of a wide flow channel, and in the limit of zero ring thickness becomes exactly such a plane electrode. Very thick rings demonstrate characteristics of disk electrodes, and in the limit of zero inner radius are exactly disk electrodes.

A rotating-ring electrode can simulate two of the classic tools used by electrochemical experimenters. A ring electrode can be fitted to practically any rotator used for disks, thus enabling an experimental investigation of processes that were previously studied in flow channels, which are more expensive and specialized pieces of equipment. The problems associated with end effects at the walls of the flow channel do not occur with the ring electrode. The current distributions on rings used as collectors in ring-disk, ring-sphere, and ring-ring systems are not radically different from that on solitary rings, so a detailed study of ring electrodes yields basic information which can be applied qualitatively to all the systems involving ring electrodes.

The asymptotic behavior of thick ring electrodes was experimentally investigated by Gregory and Riddiford (1,2) when they reported the effects of blocking off the center of a disk. Levich (3) provided an expression for the limiting current density distribution on ring electrodes, which was extended to show the average limiting current in a discussion of Gregory and Riddiford's work by Ibl (4). Dagunet (5) first and then Kornienko and Kishinevskii (6) used ring electrodes to study the effect of turbulence on the limiting current. Deslouis and Keddam (7) also measured limiting currents on rings in laminar, transitional, and turbulent flows, and compared their results favorably to the Levich equation for rings. The effect of adding a drag-reducing agent, Polyox, was examined by Deslouis *et al.* (8) with rotating-ring electrodes by the change in limiting current. Shabrang and Bruckenstein (9) experimentally determined the resistance of several ring electrodes by applying alternating current modulation techniques, and they also computed primary resistances by finite differences. Several theoretical studies on ring electrodes have been made of highly reversible heterogeneous reactions possessing potential independent kinetics. Rosner (10) presented calculations for kinetics which included the effect of the reactant concentration only, and he considered ring electrodes as partially blocked disks. Redox kinetics, which included both product and reactant, were analyzed by Albery and Bruckenstein (11) for the case of very thin rings. Matsuda (12) showed a method to compute current distributions for redox reactions on rings of any thickness. Similar work (13,14) can be found in the literature on ring-ring electrodes for rapid heterogeneous reactions where the inner ring is decoupled from the outer ring since the kinetics are not considered to be potential dependent.

Primary Current and Potential Distribution

The primary current distribution for a ring electrode can be easily computed following the method outlined by Miksis and Newman (15) for ring-disk electrodes. The technique involves the solution of Laplace's equation which Newman (16) reduced to an extremely useful (17) integral equation

$$\Phi_0(r) = \frac{2}{\pi\kappa_\infty}\int_{r_0}^{r_1} i(r')K\left(\frac{4rr'}{(r+r')^2}\right)\frac{r'dr'}{r+r'} \quad [1]$$

where Φ_0 is the ohmic potential drop between the surface of the ring electrode and a large counterelectrode which is far enough away from the working electrode so that it does not influence the current distribution, i is the normal component of the current density, K is an elliptic integral of the first kind (18). The use of Eq. [1] implies that the electric conductivity κ_∞ is constant and there are no concentration gradients in the region. The primary current distribution assumes Φ_0 to be constant and allows no kinetic effects. Figure 1 shows the primary current distributions for several values of the geometric parameter r_0/r_1. As r_0/r_1 approaches unity, the current distribution begins to look like the primary current on a plane electrode which was given by Wagner (19) and displayed in Fig. 3 of Parrish and Newman (20)

$$\frac{i}{i_{avg}} = \frac{1}{\pi}\left[\frac{x}{L} - \left(\frac{x}{L}\right)^2\right]^{-1/2} \quad [2]$$

where x is the distance along the plane electrode and L is the length of the electrode. When the geometric parameter tends to zero, the ring assumes essentially the same primary distribution as a disk (21) with the exception of an infinite current density at the inner edge of the ring. The primary resistance of the ring electrode R_r is given in Fig. 2. The solid curve is the result of our calculations. The dashed curve and the bracketed data points are from Shabrang and Bruckenstein (9). The ordinate of Fig. 2 was chosen by applying the criteria used in reporting thermodynamic data such as activity coefficients which have large changes in value with relatively small changes in concentration (22). This allows the ring resistance to be interpolated from the plot for thin rings easily. The abscissa was chosen to show the asymptotic behavior of a ring resistance as it approaches a disk. The rela-

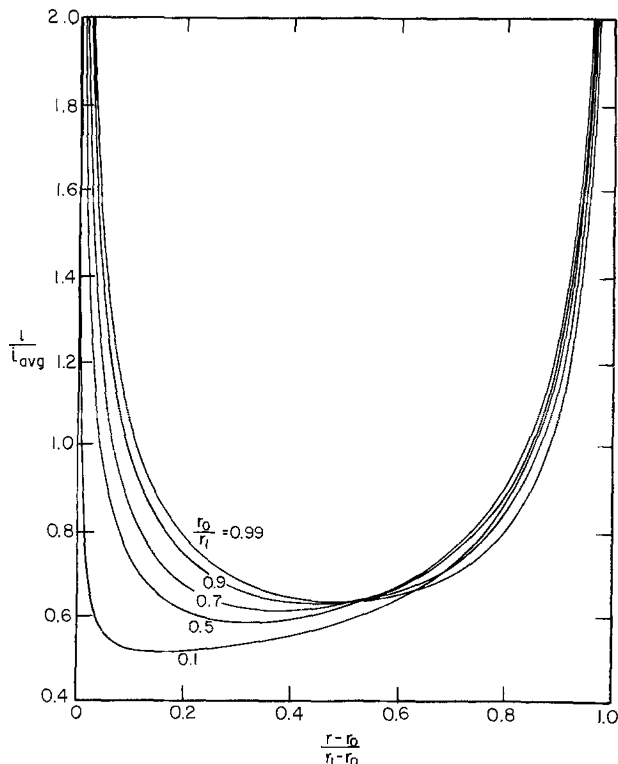

Fig. 1. The primary current distribution on ring electrodes

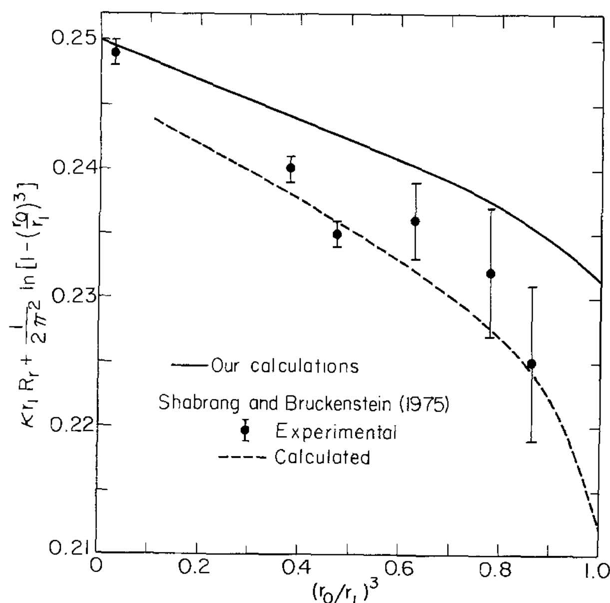

Fig. 2. Resistance of current flow to a ring electrode with a primary current distribution.

tive difference between the data points and the finite difference calculations (9) and our calculations are exaggerated by the ordinate. However it is difficult to approach a primary distribution using alternating current techniques unless frequencies can be extrapolated to infinity. The small effect of a large laboratory-size cell rather than the infinitely dimensioned cell used in computing the resistance could also resolve some of the difference between the data and our calculations. The same sort of difficulty in getting good agreement between the Levich limiting current and measured limiting currents for thin rings was encountered by Deslouis and Keddam (7). We feel that the method of embedding essential singularities as employed in the method of Miksis and Newman (15) is superior to a finite difference approximation. The resistance varies from that of a disk electrode to large values for very thin rings, which is given by (15)

$$\kappa_\infty r_1 R_r + \frac{1}{2\pi^2} \ln\left(1 - \left(\frac{r_o}{r_1}\right)^3\right) = \frac{\ln 96}{2\pi^2} = 0.2312 \quad [3]$$

Equation [3] is the asymptotic value of the ring resistance as the ring width goes to zero, and is the value of the ordinate variable of the solid curve at the right-hand side of Fig. 2 (See Appendix I for the analytical development of Eq. [3].) Equation [1] is also used to compute the variation in the ohmic drop extrapolated to the surface of the ring for nonuniform potential distributions, in the same manner as for ring disks (17).

The Concentration Boundary Layer

A high Schmidt-number formulation of the convective diffusion equation appropriate for binary electrolytes and minor reacting components in a solution with an excess of supporting electrolyte, where migration effects can be safely ignored, has been used in most of the previous studies involving potential independent heterogeneous kinetics (10, 12-14). An integral equation has proven useful for computing analytic and numerical results. The same equations and approach for the concentration boundary layers which were recently applied by Pierini and Newman (17) to ring-disk electrodes are used here for computing the surface concentration when ohmic effects and potential dependent kinetics are included. The results of Levich (3) are easily reproduced with the integral equation to yield

$$\left.\frac{\partial c_R}{\partial y}\right|_{y=0} = \frac{r}{\Gamma(4/3)}\left(\frac{a\nu}{3D_R}\right)^{1/3}\left(\frac{\Omega}{\nu}\right)^{1/2}\frac{c_{R,\infty} - c_{R,0}}{(r^3 - r_o^3)^{1/3}} \quad [4]$$

Figure 3 shows limiting current distributions for rings of various thicknesses computed with Eq. [4]. The thin rings are similar to the limiting current for plane electrodes shown in Fig. 3 of Parrish and Newman (20) while the thick rings have fairly uniform distributions except in the central regions.

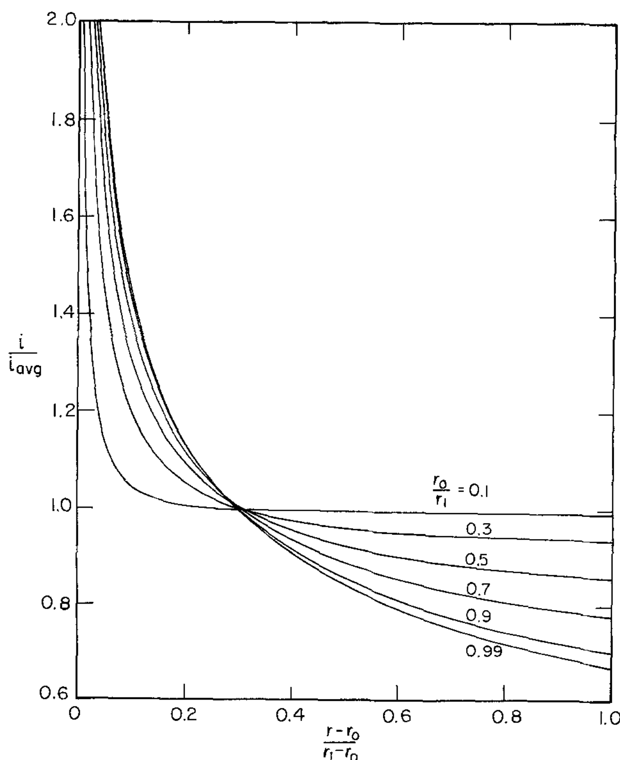

Fig. 3. The limiting current distribution on ring electrodes

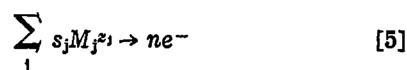
Kinetics

A single electrode reaction



$$\sum_j s_j M_j^{z_j} \rightarrow ne^- \qquad [5]$$

is chosen as the basis for the potential dependent heterogeneous kinetics to demonstrate the manner in which the current distribution varies between the ohmically limited (Fig. 1) and the mass transfer-controlled (Fig. 3) distributions. The applied voltage V can be decomposed (23) as follows

$$V = \Phi_o + U + \eta_s + \eta_c \qquad [6]$$

where Φ_o is the local ohmic potential drop extrapolated to the ring surface and U is the open-circuit potential calculated with the bulk concentrations. The surface overpotential η_s is given implicitly by the kinetic expression

$$i = i_{o,\infty} \prod_j \left(\frac{c_{j,0}}{c_{j,\infty}}\right)^{\gamma_j} \left[\exp\left(\frac{\alpha Z F}{RT}\eta_s\right) - \exp\left(\frac{-\beta Z F}{RT}\eta_s\right)\right] \qquad [7]$$

and the concentration overpotential takes the form (24)

$$\eta_c = \frac{-RT}{ZF}\left[\sum_j \ln\left(\frac{c_{j,\infty}}{c_{j,0}}\right) - t\left(1 - \frac{c_{R,0}}{c_{R,\infty}}\right)\right] \qquad [8]$$

This basic equation covers a variety of situations, such as deposition from a binary electrolyte and redox and deposition reactions with supporting electrolyte.

Results

The problem as stated can be solved numerically (17, 20, 21) with the basic parameters r_o/r_1, α, β, λ_i, t, Z, D_i/D_R

$$J = \frac{i_{o,\infty} r_1 Z F}{RT \kappa_\infty} \qquad [9]$$

$$N = -\left(\frac{r_1^2 \Omega}{\nu}\right)^{1/2}\left(\frac{a\nu}{3D_R}\right)^{1/3} \frac{nZF^2 D_R c_{R,\infty}}{s_R R T (1-t)} \qquad [10]$$

$$\delta = |i_{avg}| \frac{r_1 Z F}{RT} \qquad [11]$$

where the limiting reactant has been subscripted as R. J can be thought of as a dimensionless exchange current density, and N is the dimensionless stirring rate. The concentration boundary layer grows thinner as N gets larger; when N is infinite the boundary layer has zero thickness and the concentrations at the surface of the electrode are uniform and equal to the bulk concentrations.

For examples, three ring geometries are chosen. The cases in which r_o/r_1 is respectively 0.5 and 0.7 represent situations that characteristically behave like rings, that is, they do not tend to simulate either a disk or a plane electrode. The case of r_o/r_1 equal to 0.9 can be easily compared to plane electrodes.

Secondary current distribution.—When N is infinite and the concentration effects may be ignored, the secondary current distribution is achieved. For small surface overpotentials Eq. [7] is linearized to read

$$i = (\alpha + \beta) J \frac{\kappa_\infty}{r_1} \eta_s \qquad [12]$$

The average current density is much smaller than the characteristic exchange current density in this case. Figure 4 shows how a ring with r_o/r_1 equal to 0.5 behaves over a range of kinetic parameters. The distribution varies from a basically uniform current when kinetics control, to the primary distribution when ohmic effects dominate.

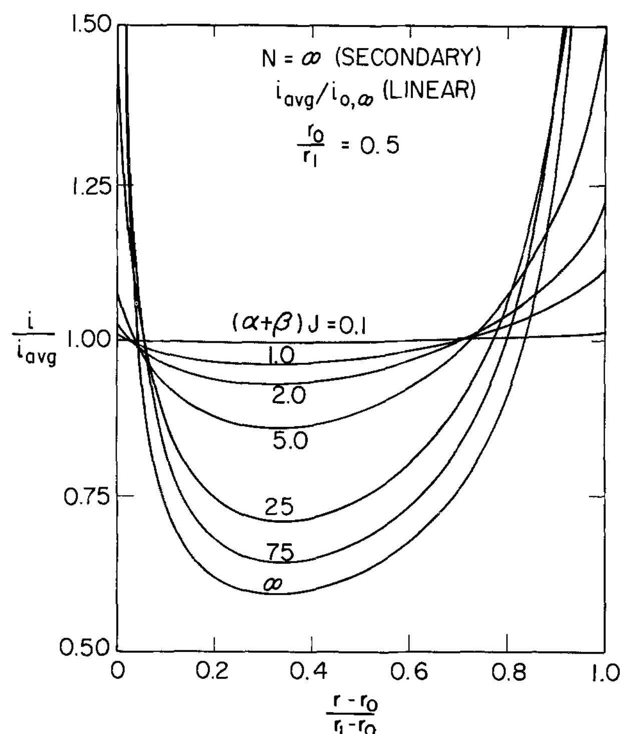


Fig. 4. Secondary current distribution on a ring electrode for linear kinetics. $|i_{avg}|i_o$ is equal to zero.

Tafel polarization occurs when one of the exponential terms in Eq. [4] is small enough to be dropped. Then for a cathodic process the polarization equation may be written

$$\eta_s = -\frac{RT}{\beta ZF}[\ln(-i) - \ln(i_{o,\infty})] \qquad [13]$$

and the characteristic parameter is

$$\beta\delta = \frac{\beta ZF}{RT}\frac{r_1|i_{avg}|}{\kappa_\infty} \qquad [14]$$

The current distribution now depends only on the magnitude of the average current density, and the exchange current density has no effect. Figure 5 for Tafel kinetics is similar to Fig. 4. The change in the shape of the curves is principally due to the difference in the geometric ratio r_o/r_1. Both cases go to a primary distribution as the kinetic parameter goes to infinity, and the effect of the radii ratio can be clearly seen in Fig. 1 for the primary distributions.

Concentration and kinetic effects.—Mass transfer effects must be taken into account for finite values of the dimensionless stirring rate N. Again the situation in which the average current density is much greater than the exchange current density is examined in Fig. 6, where one of the exponential terms in Eq. [7] may be neglected. The reaction is very slow as characterized by the zero value of J, and is considered to have Tafel kinetics but with concentration dependence in contrast to the Tafel kinetics described by Eq. [13] and shown in Fig. 5. The effect of the concentration boundary layer begins to dominate as the controlling factor as the fraction of the limiting current is increased. The behavior of the current distribution at the outer edge of the ring is very similar to that of both disk electrodes (23) and plane electrodes (20) in exhibiting a maximum.

Curves for deposition kinetics in which both terms of Eq. [7] make a contribution but where there is no back-reaction are shown in Fig. 7. This particular reaction, with $J = 1$, would still be considered slow, but

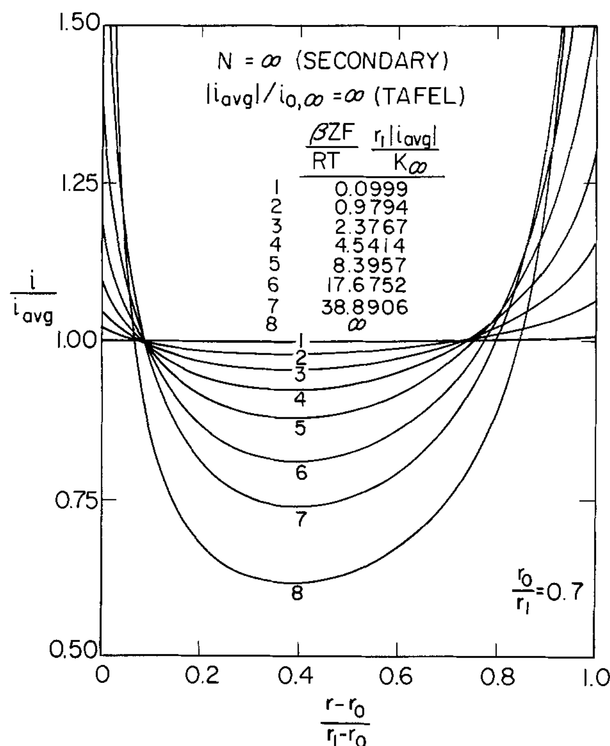

Fig. 5. Secondary current distribution on a ring electrode for Tafel kinetics.

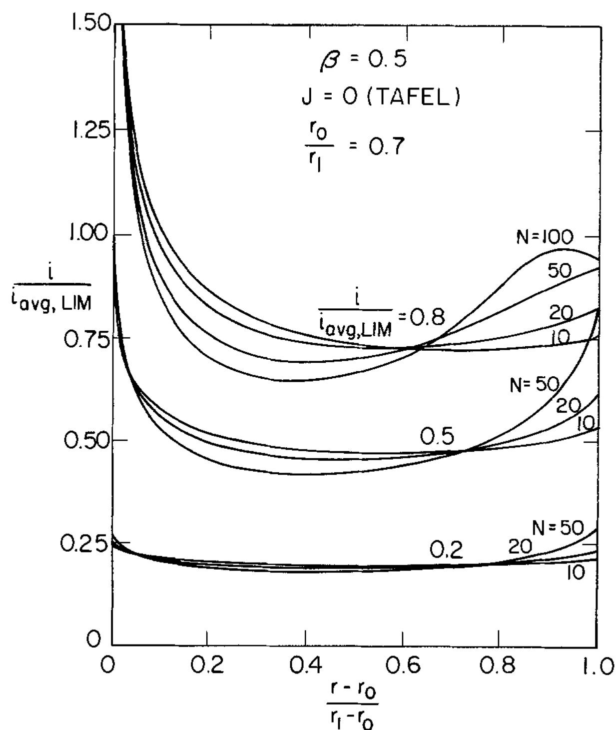

Fig. 6. Current distribution on a ring electrode for Tafel kinetics where $|i_{avg}| >> i_{o,\infty}$ but N is finite and mass transfer effects must be taken into account.

it is more reversible than the previous example as indicated by a larger value of J. The distributions appear to be more disk-like, primarily due to the smaller r_o/r_1, while the differences between the maxima and minimum in the distribution are enhanced by the kinetics.

As a final example, a very fast redox reaction was chosen in conjunction with a very thin ring. The interesting feature of Fig. 8 is the comparison to the limiting current curve (dashed line). The mass transfer is dominant over a wide range of currents influencing the shape of the curves. Also the local cur-

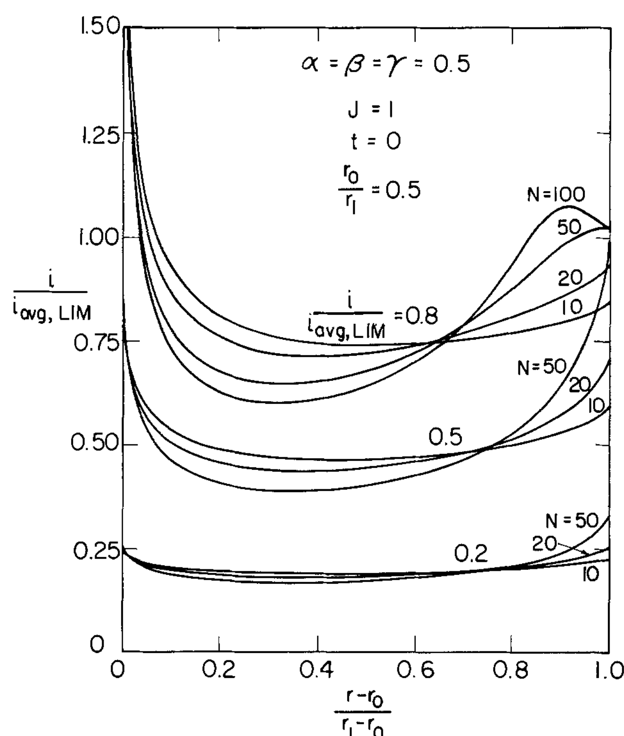

Fig. 7. Current distribution on a ring electrode for product-independent or deposition kinetics with an excess of supporting electrolyte and with mass transfer effects.

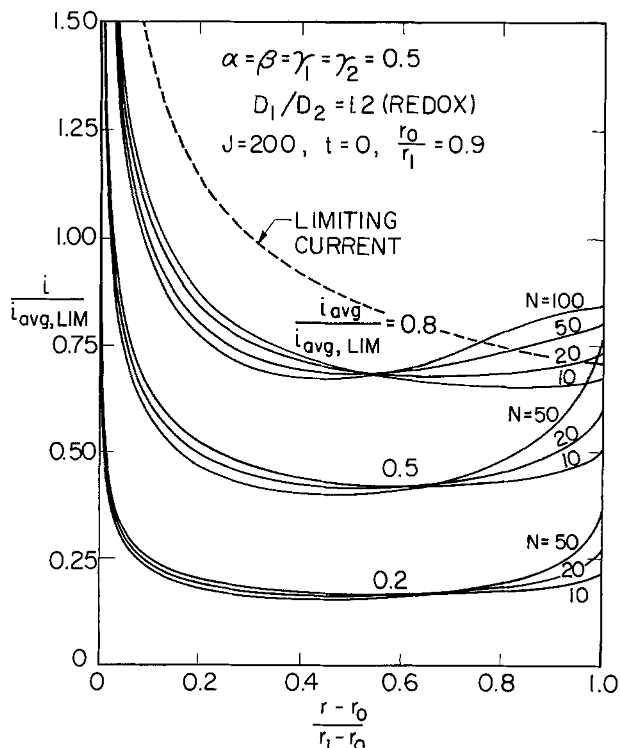

Fig. 8. Current distribution on a ring electrode for product-dependent or redox-type kinetics with an excess of supporting electrolyte with mass transfer effects. Dashed line is the limiting current.

rent densities near the trailing edge of the ring are driven above the local limiting current densities, a situation which is similar to disks (23) and planes (20). Since the ring is very thin, the distributions can be compared to those of Fig. 4 of Parrish and Newman (20), which is a plane electrode with Tafel kinetics.

Landolt, Mueller, and Tobias (25) assessed the design considerations for a cell to study electrochemical

machining processes. The rotating disk electrode and concentric rotating cylinders were deemed unfeasible due to the difficulty in maintaining reasonable cell voltages and because of the radial dependence of resistance and characteristic length. A flow channel was shown to have a primary voltage drop of 50V with a 100 A/cm^2 current for a solution with a specific conductance of 0.1 Ω/cm and an interelectrode gap of 0.5 mm. An equivalent primary voltage with the same solution and operating conditions can be obtained with a ring electrode having an inner radius of 0.2480 cm and a width of 0.0275 cm, dimensions well within practical machining considerations. This particular design required r_o/r_1 to be 0.9, which is the geometric ratio used for the redox reaction shown in Fig. 4. Alternatively the resistance and one length could be specified; Fig. 2 would then provide the remaining length, thus enabing the characteristic length to be varied and the resistance to be fixed. Turbulent flow can be maintained with most commercially available rotators by keeping the inner ring radius greater than 1 cm for common electrochemical machining solutions. Ring electrodes seem feasible to study high current density processes with a smaller capital investment than a thin gap flow channel.

APPENDIX

The Asymptotic Value of the Primary Resistance of Thin Ring Electrodes

The asymptotic value of the primary resistance of ring electrodes as the geometric parameter r_o/r_1 goes to unity can be determined analytically. An order of magnitude analysis of Laplaces' equation shows that the terms associated with the effect of curvature in the radial direction are small. This means that the physical situation to be analyzed is an analog of the finite width plane electrode embedded in an insulator treated by Wagner (19). Therefore the detailed variation of the current density can be expressed as

$$i(r) = \frac{r_1 - r_o}{2\sqrt{(r_1 - r)(r - r_o)}} \quad \text{[A-1]}$$

where the total current to the ring is

$$I_r = 2\pi \int_{r_o}^{r_1} i(r) r dr = \frac{2\pi}{2}(r_1 - r_o)(r_1 + r_o) \quad \text{[A-2]}$$

The potential drop for the current I_r to the ring is then computed by integrating Eq. [A-1] with Eq. [1] making use of the property of the complete elliptic integral of the first kind that

$$K\left(\frac{4rr'}{(r+r')^2}\right) \rightarrow -\frac{1}{2}\ln\left(\frac{r-r'}{r+r'}\right)^2 \Big/ 16 \quad \text{[A-3]}$$

as

$$\frac{4rr'}{(r+r')^2} \rightarrow 1 \quad \text{[A-4]}$$

This yields after manipulation

$$\Phi_o(r) = -\frac{r_2 - r_1}{4\pi\kappa} \int_{-1}^{1} \ln\left[\frac{(z-z')^2}{64}\left(\frac{r_1 - r_o}{r_1 + r_o}\right)^2\right]\frac{dz'}{\sqrt{1-z'^2}} + \frac{r_2 - r_1}{\pi\kappa}\int_{-1}^{1}\left[\frac{r'}{r+r'}K\left(\frac{4rr'}{r+r'}\right) + \frac{1}{4}\ln\left(\frac{z-z'}{8}\frac{r_1 - r_o}{r_1 + r_o}\right)^2\right]\frac{dz'}{\sqrt{1-z'^2}} \quad \text{[A-5]}$$

where the variables r and y are related by

$$z = \frac{2r - r_1 - r_o}{r_2 - r_1} \quad \text{[A-6]}$$

Because this is the primary distribution, this potential must actually be constant across the ring, and evaluation gives

$$\Phi_o(r) \approx \frac{r_1 - r_o}{2\kappa}\ln\frac{16(r_1 + r_o)}{r_1 - r_o} \quad \text{[A-7]}$$

and the resistance of thin rings is then given by

$$\kappa r_1 R_r + \frac{1}{2\pi^2}\ln\frac{r_1 - r_o}{r_1} = \frac{\ln 32}{2\pi^2} \quad \text{[A-8]}$$

This equation shows explicitly the manner in which the value of R_r increases to infinity as the ring width goes to zero. After transformation to the variable plotted in Fig. 2 is made, the right side of Eq. [A-8] yields the ordinate value of the solid curve at the right side of Fig. 2.

Variational Approximations to Current Distribution Problems

II. Rectilinear Electrodes and Baffles

S. H. Glarum

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Current distribution problems for the flat-strip electrode and the rectangular electrolytic cell with an arbitrary distribution of cathodic elements in a plane are analyzed using a previously formulated variational integral. High impedance baffles permitting the control of macrocurrent distributions are described, equations for their design derived, and several elementary examples analyzed.

In a preceding paper we discussed the use of variational approximations for the analysis of current distribution problems at the rotating-disk electrode (1). The present discussion focuses upon the application of the variational function previously derived to rectilinear geometries, more closely akin to practical electroplating configurations. We treat first the case of an isolated flat-strip electrode, and find a solution for the current density distribution in terms of a superposition of orthogonal polynomials. Next we consider the more general problem of a rectangular electrolytic cell with an arbitrary electrode distribution in a cathodic plane and insulating sidewalls or periodic boundary conditions. Finally, we address the very practical problem of controlling current distributions on a macroscopic scale. High impedance baffles appear to be attractive structures for achieving this objective. General design equations are derived, and several low order baffle designs are analyzed.

The Flat-Strip Electrode

The problem to be solved is depicted in Fig. 1. A flat-strip electrode with width 2a is flushly embedded in an infinite insulating plane. The strip is either sufficiently long or boundary conditions in the y direction are such that the potential is independent of y. A surface $s(x, z)$ to be defined, in the half-space containing electrolyte lies at zero potential, while the electrode is at a potential ϕ_0. This problem has been previously analyzed by Wagner, using a different approach (2).

We begin, as in our treatment of the rotating-disk electrode, with the coordinate transformation

$$z = a\xi\eta$$
$$x^2 = a^2(1 + \xi^2)(1 - \eta^2) \quad [1]$$

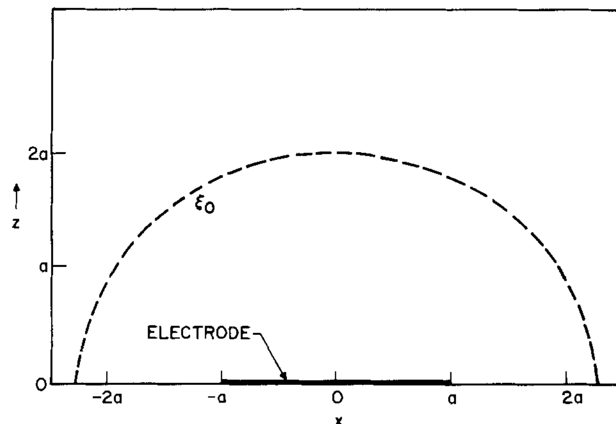

Fig. 1. The flat-strip electrode

Key words: current distribution, high impedance baffles, variational analysis.

Within the electrolyte $\nabla^2\phi = 0$, and Laplace's equation becomes

$$\left[(1-\eta^2)\frac{\partial^2\phi}{\partial\eta^2} - \eta\frac{\partial\phi}{\partial\eta} \right] + \left[(1+\xi^2)\frac{\partial^2\phi}{\partial\xi^2} + \xi\frac{\partial\phi}{\partial\xi} \right] = 0 \quad [2]$$

Letting

$$\phi = F(\eta)G(\xi) \quad [3]$$

a separation of variables gives

$$(1-\eta^2)\frac{\partial^2 F}{\partial\eta^2} - \eta\frac{\partial F}{\partial\eta} + n^2F = 0$$

$$(1+\xi^2)\frac{\partial^2 G}{\partial\xi^2} + \xi\frac{\partial G}{\partial\xi} - n^2G = 0 \quad [4]$$

where n^2 is the constant of separation. The further substitutions

$$\eta = \cos\alpha$$

$$\xi = \sinh\beta \quad [5]$$

reduce these equations to

$$\frac{\partial^2 F}{\partial\alpha^2} + n^2F = 0$$

$$\frac{\partial^2 G}{\partial\beta^2} - n^2G = 0 \quad [6]$$

The boundary condition at the insulating surface

$$\left(\frac{\partial F}{\partial\eta}\right)_{\eta=0} = 0 \quad [7]$$

requires that n be an even integer. At the surface defined by $\xi = \xi_o$ we shall assume ϕ vanishes (Fig. 1). The resulting solution for ϕ is therefore

$$\phi^{(n)} = c_nT_n(\eta)\frac{\sinh[n(\sinh^{-1}\xi_o - \sinh^{-1}\xi)]}{\sinh[n\sinh^{-1}\xi_o]} \quad [8]$$

where

$$T_n(\eta) = \cos[n\cos^{-1}\eta] \quad [9]$$

is a Chebyshev polynomial of even order and c_n is a constant. The general solution for the strip electrode is thus

$$\phi = \sum_{n=0,2,4\ldots} c_nT_n(\eta)\frac{\sinh[n(\sinh^{-1}\xi_o - \sinh\xi)]}{\sinh[n\sinh^{-1}\xi_o]} \quad [10]$$

This function satisfies Laplace's equation in the bulk, and meets all boundary conditions except those at the electrode surface, which remain to be specified.

The linear coefficients may be evaluated by variational analysis. Our general variational function is (1)

$$W = \kappa_o\int d\tau\nabla\phi\cdot\nabla\phi + 2\int dsf(s)\int_o^{\phi_o-\phi} d\theta F(\theta) \quad [11]$$

where κ_o is the bulk electrolyte conductivity, $F(\theta)$ is an overpotential function, the first integral is over the electrolyte volume, and the second is over its bounding surface. The function $f(s)$ vanishes on insulating surfaces, and may be set equal to unity when the overpotential depends only upon local current density. If bulk concentration gradients are significant, $f(s)$ must be found from the simultaneous solution of hydrodynamic and electrical expressions.

For the particular case of linear polarization

$$F(\theta) = \theta/z \quad [12]$$

z being the surface impedance of the electrode in units Ω-cm². Because $\nabla^2\phi = 0$ and the normal derivative $\partial\phi/\partial n$ vanishes on the insulating boundary, the variational function reduces to an integral over the electrode surface

$$W = 2a\int_o^1 \frac{\eta d\eta}{(1-\eta^2)^{1/2}}\left[\kappa_o\phi\frac{\partial\phi}{\partial n} + \frac{1}{z}(\phi_o-\phi)^2\right] \quad [13]$$

The coefficients c_n are found by setting

$$\partial W/\partial c_n = 0 \quad [14]$$

This results in the set of linear equations

$$\Gamma g_nc_n + \sum_{n'} K_{nn'}c_{n'} = K_{On}\phi_o \quad [15]$$

where

$$\Gamma = \pi\kappa_o z/4a$$

$$g_n = n(1+\delta_{n,O})\coth[n\,\text{sech}^{-1}\xi_o]$$

$$K_{nn'} = \int_O^1 d\eta\,\eta(1-n^2)^{-1/2}T_n(\eta)T_{n'}(\eta) \quad [16]$$

Finally, the current density distribution over the strip is given by

$$\vartheta(\eta) = (1/z)[\phi_o - \Sigma c_nT_n(\eta)] \quad [17]$$

Equations [15]-[17] are equivalent to those previously derived for the rotating-disk electrode. The dimensionless parameter Γ is again the ratio of the characteristic throwing distance of the electrolyte-electrode combination, $\kappa_o z$, to the electrode's dimension. When Γ is large the current distribution becomes uniform, and when small it approaches the primary distribution. The matrix $K_{nn'}$, which couples the basis functions, also involves integrals of a set of orthogonal basis functions. In this instance, however, they are Chebyshev instead of Legendre polynomials.

The expressions for the flat-strip and rotating-disk electrodes are sufficiently similar to make further detailed discussion repetitious. By analogy with disk calculations, a low order polynomial accurately describes the current distribution when current variations are small (<10%). Wagner has derived a logarithmic expression also accurate in this regime (2). If larger variations are encountered, both the procedure described by Wagner and that presented here require more extensive numerical computations. Newman's disk results indicate that 10 or more polynomial terms are needed to approximate a primary distribution (3), while Wagner's approach requires the solution of a like number of simultaneous linear equations.

The Rectangular Electrolytic Cell

We shall next examine the rectangular electrolytic cell (Fig. 2). Bounding planes at $x = \pm a$ and $y = \pm b$ are insulating, and plane $z = l_o$ is taken to be an equipotential surface of zero potential. An arbitrary cathodic surface distribution, $f(x,y)$, is assumed for the plane $z = 0$. The insulating planes may represent either real surfaces or planes partitioning a large

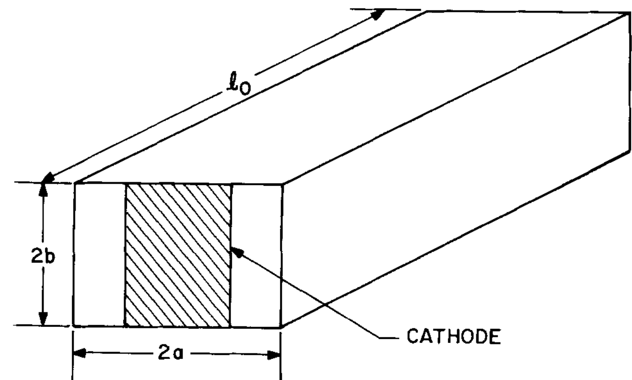

Fig. 2. The rectangular electrolytic cell

assembly of parallel cells. We shall, for convenience only, assume $f(x,y)$ to be symmetric in x and y.

A particular solution for ϕ satisfying all requirements except those at the cathodic plane is

$$\phi^{(m,n)} = \cos\left(\frac{m\pi x}{a}\right)\cos\left(\frac{n\pi y}{b}\right)\frac{\sinh[\lambda(l_o - z)]}{\sinh(\lambda l_o)} \quad [18]$$

where

$$\lambda = \left[\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2\right]^{1/2} \quad [19]$$

and m and n are integers. A general solution is given by a linear combination of these solutions with coefficients c_{mn}. Since ϕ satisfies Laplace's equation in the bulk and all boundary conditions except those at the cathodic plane, the variational function reduces to an integral over this plane. The coefficients c_{mn} correspond to the Fourier components of the current density distribution function. If $f(x,y) = f(x)$ only $(n = 0)$, and a linear polarization function is assumed (Eq. [12]), use of the variational integral yields the set of linear equations

$$\Gamma g_m c_m + \sum_{m'} K_{mm'} c_{m'} = K_{0m}\phi_o \quad [20]$$

with

$$\Gamma = \pi\kappa_0 z/2a$$

$$g_m = (1 + \delta_{m,0})\, m \coth(m\pi l_o/a)$$

$$K_{mm'} = \frac{1}{2a}\int_{-a}^{a} dx\, f(x)\cos\left(\frac{m\pi x}{a}\right)\cos\left(\frac{m'\pi x}{a}\right) \quad [21]$$

The similarity of these equations with the rotating-disk and flat-strip expressions reveals how certain obvious limiting cases follow. Thus, if $f(x) = 1$, the matrix $K_{mm'}$ is diagonal and $c_m = 0$ for $m \neq 0$, giving a uniform current distribution. A uniform distribution is also achieved by making the diagonal elements large, *i.e.*, by increasing the throwing distance of the bath, $\kappa_0 z$, or decreasing the anode-cathode separation, l_o.

The Baffled Rectangular Cell

The control of current distributions, either to obtain more uniform electrodeposits or to plate selectively upon cathodic surfaces, is a high priority technological problem. One approach is through the use of baffles composed of chemically inert, insulating material to direct current flow. An important class of baffling problems can be treated by compounding two rectangular electrolytic cells (Fig. 3). The geometry and boundary conditions are those of the previous problem except that at a distance l from the cathodic plane a baffle with a spatially varying conductance function is interposed. A perforated panel, immersed in electrolyte, with holes of varying density and/or radii would be one realization of such a baffle.

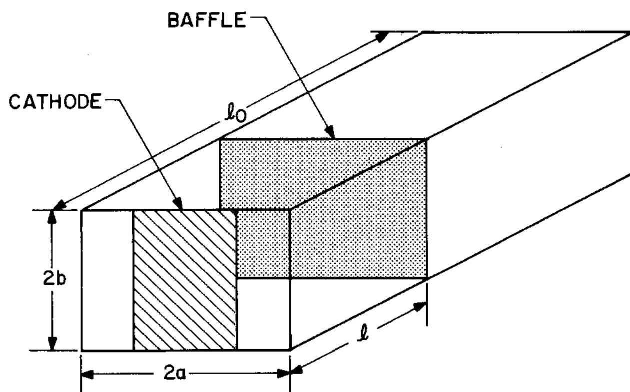

Fig. 3. The baffled rectangular cell

For convenience we shall again neglect variations in the y direction. The potential in the anodic compartment may be expressed as

$$\phi_A = \sum a_m \cos\left(\frac{m\pi x}{a}\right)\frac{\sinh\frac{m\pi}{a}(l_o - z)}{\sinh\frac{m\pi}{a}(l_o - l)} \quad [22]$$

while in the cathodic compartment

$$\phi_C = \sum b_m \cos\left(\frac{m\pi x}{a}\right)\frac{\sinh(m\pi z/a)}{\sinh(m\pi l/a)} + \sum c_m \cos\left(\frac{m\pi x}{a}\right)\frac{\sinh\frac{m\pi}{a}(l - z)}{\sinh(m\pi l/a)} \quad [23]$$

The coefficients have been chosen so that

$$\phi_A(z = l_o) = 0$$

$$\phi_A(z = l) = \sum a_m \cos(m\pi x/a)$$

$$\phi_C(z = l) = \sum b_m \cos(m\pi x/a)$$

$$\phi_C(z = 0) = \sum c_m \cos(m\pi x/a) \quad [24]$$

Implicitly the baffle is of zero thickness, but mathematically we require only that the normal current distributions on each baffle face be identical.

Let us first construct the variational function for the anodic compartment

$$W_A = \int_{-a}^{a} dx \left\{ \kappa_0\phi_A\frac{\partial\phi_A}{\partial n} + \kappa(x)[\phi_A - \phi_C]^2 \right\}_{z=l} \quad [25]$$

where κ_0 is the electrolyte conductivity and $\kappa(x)$ is the baffle conductance function. This expression is to be minimized with respect to variations of ϕ_A only, that is the coefficients a_m. The required conditions are

$$f_m a_m + \sum B_{mm'}(a_{m'} - b_{m'}) = 0 \quad [26]$$

where

$$f_m = (1 + \delta_{m,0})\left(\frac{m\pi}{2a}\right)\coth\left[\frac{m\pi}{a}(l_o - l)\right]$$

$$B_{mm'} = \frac{1}{2a}\int_{-a}^{a} dx\frac{\kappa(x)}{\kappa_0}\cos(m\pi x/a)\cos(m'\pi x/a) \quad [27]$$

For the cathodic compartment

$$W_C = \int_{-a}^{a} dx\left\{\kappa_0\phi_C\frac{\partial\phi_C}{\partial n} + \kappa(x)[\phi_A - \phi_C]^2\right\}_{z=l} + \int_{-a}^{a} dx\left\{\kappa_0\phi_C\frac{\partial\phi_C}{\partial n} + (1/z)f(x)[\phi_o - \phi_C]^2\right\}_{z=0} \quad [28]$$

A linear overpotential function has been assumed and $f(x)$ is again a distribution function for cathodic elements. Setting the variations of W_C with respect to b_m and c_m equal to zero yields

$$g_m b_m - h_m c_m - \sum B_{mm'}(a_{m'} - b_{m'}) = 0$$

$$-\gamma h_m b_m + \gamma g_m c_m + \sum K_{mm'} c_{m'} = K_{0m}\phi_o \quad [29]$$

with

$$\gamma = \kappa_0 z$$
$$g_m = (1 + \delta_{m,0}) \left(\frac{m\pi}{2a} \right) \coth(m\pi l/a)$$
$$h_m = (1 + \delta_{m,0}) \left(\frac{m\pi}{2a} \right) \operatorname{csch}(m\pi l/a)$$
$$K_{mm'} = \frac{1}{2a} \int_{-a}^{a} dx\, f(x) \cos(m\pi x/a) \cos(m'\pi x/a) \quad [30]$$

In matrix notation the equations when solved for c_m give

$$\left(\gamma g + \underline{\underline{K}} - \gamma \left(\frac{hf}{f+g} \right) \left(\frac{fg}{f+g} + \underline{\underline{B}} \right)^{-1} (f + \underline{\underline{B}}) \left(\frac{h}{f} \right) \right) \underset{\sim}{c} = \underline{\underline{K}} \underset{\sim}{\phi_0} \quad [31]$$

where f, g, and h are diagonal, $\underline{\underline{B}}$ and $\underline{\underline{K}}$ are symmetric matrices, and $\underset{\sim}{c}$ and ϕ_0 are column vectors, *i.e.*

$$\underset{\sim}{c} = \begin{pmatrix} c_0 \\ c_1 \\ c_2 \\ \cdot \\ \cdot \\ \cdot \end{pmatrix} \quad \underset{\sim}{\phi_0} = \begin{pmatrix} \phi_0 \\ 0 \\ 0 \\ \cdot \\ \cdot \\ \cdot \end{pmatrix} \quad [32]$$

In the limit $\underline{\underline{B}} \to \infty$, it may be verified that Eq. [20] and [21] are recovered. Given $\underline{\underline{B}}$ and $\underline{\underline{K}}$, numerical solution for $\underset{\sim}{c}$ is straightforward using standard computer routines.

For many practical problems high impedance baffles are an important consideration, and in this limit

$$\left(\frac{fg}{f+g} + \underline{\underline{B}} \right)^{-1} = \left(\frac{f+g}{fg} \right) - \left(\frac{f+g}{fg} \right) \underline{\underline{B}} \left(\frac{f+g}{fg} \right) + \ldots \quad [33]$$

where the expansion has been carried to linear terms in the baffling matrix. This approximation then gives

$$\left(\gamma g \left(1 - \frac{h^2}{g^2} \right) + \underline{\underline{K}} + \gamma (h/g) \underline{\underline{B}} (h/g) \right) \underset{\sim}{c} = \underline{\underline{K}} \underset{\sim}{\phi_0} \quad [34]$$

or equivalently

$$\gamma(1 + \delta_{m,0}) \left(\frac{m\pi}{2a} \right) \tanh \left(\frac{m\pi l}{a} \right) c_m + \sum \left[K_{mm'} + \gamma \operatorname{sech} \left(\frac{m\pi l}{a} \right) \operatorname{sech} \left(\frac{m'\pi l}{a} \right) B_{mm'} \right] c_{m'} = K_{0m} \phi_0 \quad [35]$$

It may be seen by examining the appropriate determinants that when

$$B_{0m}/B_{00} = \cosh \left(\frac{m\pi l}{a} \right) \frac{K_{0m}}{K_{00}}, \quad m = 1, 2, \ldots, n \quad [36]$$

the coefficients $c_1, c_2, \ldots, c_n$ vanish in an nth order calculation, yielding a uniform current density. For a zero-order baffle with $\kappa(x) \propto f(x)$ the current distribution is uniform when $l = 0$. This configuration is, of course, not realizable in practice. More generally we shall define the order of a baffle as the order of the calculation giving a uniform distribution. Thus for a first-order baffle $m = 1$, for a second-order baffle $m = 1, 2$, etc.

To conclude, it may be observed that

$$\kappa(x) \propto \operatorname{Re} f(x + il) \quad [37]$$

is an analytical solution for the baffle distribution giving a uniform current distribution. For passive baffles $\kappa(x)$ is necessarily positive, and for all but the most trivial examples no physical solution exists when $l \neq 0$.

Baffle Designs

The preceding discussion has been somewhat abstract, and it is appropriate to pause and offer a brief explanation of the operation of a high impedance baffle. It is a well-known proposition that the throwing power of a bath is proportional to the electrode surface impedance. This impedance is set by the cathodic current-voltage curve and is fixed within practical limits by the chemical nature of the electrode reaction. Placing a high impedance baffle near the electrode artificially increases the surface impedance seen by the bath to a level where the bath has sufficient throwing power to give a controlled current distribution.

Implementation of the baffle design equations is best illustrated working through several elementary examples. We shall assume for a sample problem

$$\begin{aligned} a &= 20 \text{ cm} \\ f(x) &= 1, |x| < 10 \text{ cm} \\ &= 0, |x| > 10 \text{ cm} \\ \gamma &= 1.0 \text{ cm} \\ B_{00} &= 0.1\, K_{00} \text{ cm}^{-1} \end{aligned} \quad [38]$$

Thus we are dealing with a 20 cm wide panel in a 40 cm wide cell. The value chosen for γ is typical for commercial plating baths.

We shall calculate current distributions to second-order using the high impedance approximation, and the $\underline{\underline{K}}$ matrix in (Eq. [30])

$$\underline{\underline{K}} = \begin{bmatrix} 1/2 & 1/\pi & 0 \\ 1/\pi & 1/4 & 1/3\pi \\ 0 & 1/3\pi & 1/4 \end{bmatrix} \quad [39]$$

For a zero-order baffle

$$\underline{\underline{B}} = 0.1 \underline{\underline{K}} \text{ cm}^{-1} \quad [40]$$

All parameters in Eq. [35] are given, and the three simultaneous equations may be solved for c_0, c_1, and c_2. Normalized current distributions are plotted in Fig. 4 for several baffle-cathode distances. As $l \to \infty$, the current distribution approaches a primary distribution, except near the edge where the current density must remain finite. For $l = 0$ the distribution is necessarily uniform, and for separations less than 3 cm it remains adequately uniform for most applications.

Next let us design a first-order baffle. A variety of baffle distribution functions can be tried. The simplest is given by adjusting the width of the zero-order baffle to compensate for a finite baffle-cathode separation. If the total width of the baffle is $2w$, Eq. [36] indicates

$$\left(\frac{a}{\pi w} \right) \sin \left(\frac{\pi w}{a} \right) = \frac{2}{\pi} \cosh \left(\frac{\pi l}{a} \right) \quad [41]$$

The maximum value of the left-hand term of Eq. [41] is unity ($w \to 0$), corresponding to $l = 6.5$ cm. A first-order baffle solution exists only for separations less than this distance. Current density distributions are shown in Fig. 5. Limiting slit baffle functions have been used for separations greater than 6.5 cm. The distributions in the matched region show a maximum directly beneath the baffle opening and a slight rise at the electrode edge. Within this region current density distributions are uniform to ±20%.

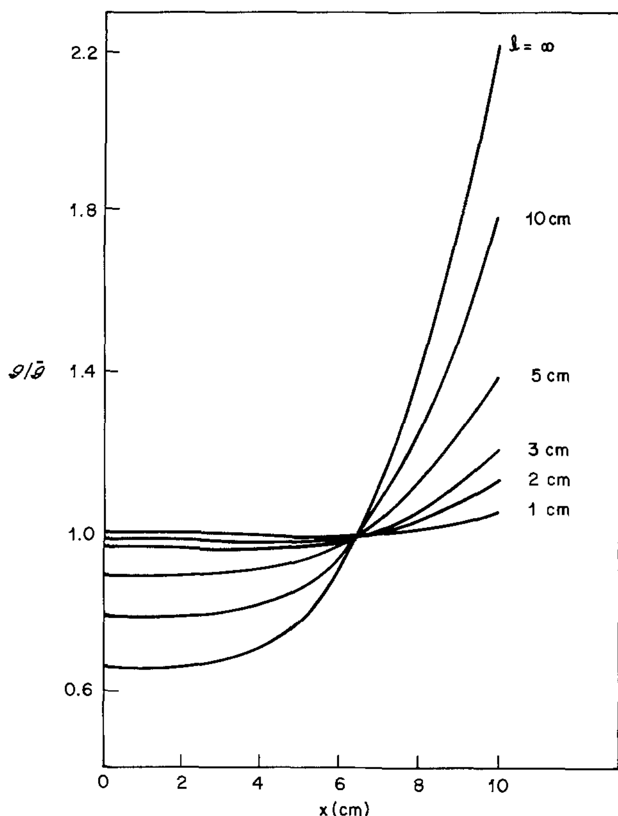

Fig. 4. Normalized current distributions using a zero-order baffle at various baffle-cathode distances.

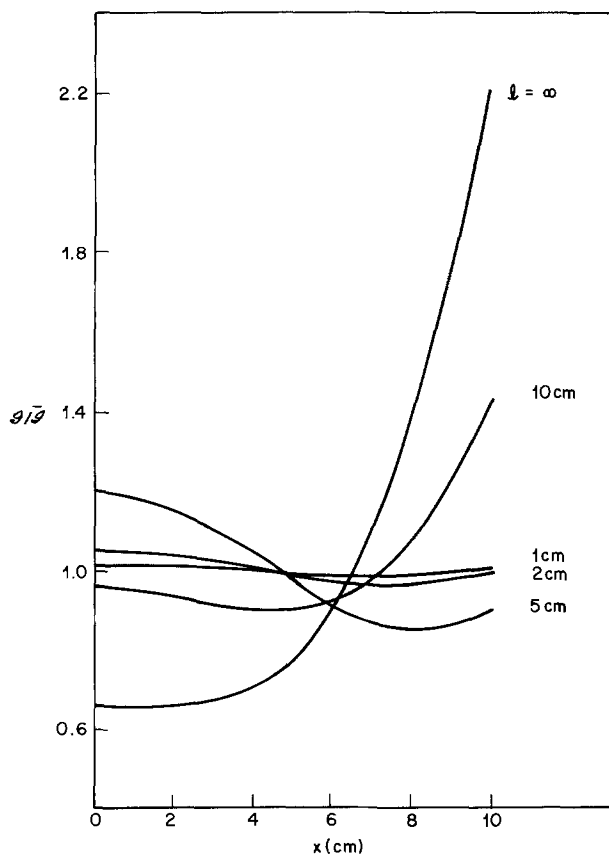

Fig. 5. Normalized current distributions using a first-order baffle at various baffle-cathode separations.

Design of a second-order baffle requires $B_{O2} = 0$. This condition is satisfied when the baffle impedance function is symmetric about $|x| = 5$ cm. The simplest design consists of a pair of variable width slits centered at these positions. Then (Eq. [30])

$$\left(\frac{a}{\pi w}\right) \sin\left(\frac{\pi w}{a}\right) = \frac{\sqrt{8}}{\pi} \cosh\left(\frac{\pi l}{a}\right) \quad [42]$$

Physical solutions exist for $l < 2.97$ cm. Results are given in Fig. 6. Over the matched region the distribution is necessarily uniform, for we are using a second-order calculation of current density. Higher order computations are required to evaluate the residual structure which should reveal maxima beneath the baffle openings.

There are obviously more sophisticated baffle functions to be tried. Smoothing the step functions used should help suppress residual wiggles. More detailed calculations are best reserved for specific design applications. In the final design stages one should solve Eq. [31] using a sufficiently large basis to insure that all approximations made are in fact valid.

Discussion

High impedance baffles have both advantages and disadvantages. The latter include problems of energy loss and mass transport. The baffle impedance should be sufficiently large to spread the current distribution over the baffle's surface. Control over a distance of 100 cm in an electrolyte with $\kappa_0 = 0.5\ \Omega^{-1}\ \text{cm}^{-1}$ requires a nominal surface impedance of 200 Ω cm^2. At a plating current density of 25 mA/cm^2, a 5.0V potential drop across the baffle follows. This is perhaps an extreme case, and proportionately smaller drops are needed to exercise control over smaller distances.

To function properly the baffle must lie within several centimeters of the cathode and will hinder the transfer of fresh electrolyte to the surface. Ideally the baffle should span the entire bath, but it is essential that it extend sufficiently far beyond the cathode to minimize leakage currents.

The primary advantage of high impedance baffles is their ability to control macrocurrent distributions in plating large panels or arrays of smaller compo-

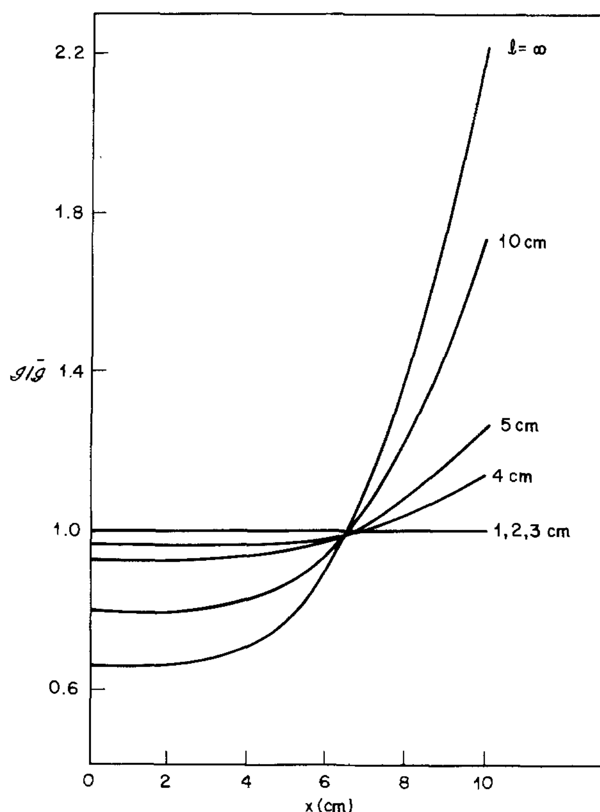

Fig. 6. Normalized current distributions using a second-order baffle at various baffle-cathode separations.

nents. "Burned" edges can be avoided, material savings effected, and, mass transfer permitting, higher plating rates can be maintained without exceeding a maximum current density. In certain applications optimum designs could require higher plating current densities in certain regions, for example where higher local densities of plated-through holes exist, or lower densities in regions serving no useful function. Tailored baffles may accommodate both situations. Further, the baffle effectively isolates the anodic and cathodic compartments, and the current distribution is insensitive to the anodic configuration. Failures due to faulty anode connections or contamination by anodic chemical products can be minimized.

An additional advantage is that baffle design is a straightforward proposition and need not require extensive trial-and-error testing. For a uniform deposit the baffle attempts to construct a uniform potential over the cathode surface. Design is independent of the explicit overpotential function and the operating point of the bath. The design conditions (Eq. [36]) are independent of material properties and involve only geometric parameters.

In summary, high impedance baffles can provide a useful addition to electroplating technology when macroscopic current distribution problems are encountered. The present analysis furnishes a format through which designs can be tested and optimized prior to physical construction.

Mass Transfer of Dissolved Chlorine to a Rotating-Zinc Hemisphere in $ZnCl_2$ Solution

Jung Taek Kim* and Jacob Jorné**

Department of Chemical Engineering, Wayne State University, Detroit, Michigan 48202

ABSTRACT

The chemical reaction of a rotating-zinc hemisphere with dissolved Cl_2 is mass transfer limited. The diffusion coefficients of dissolved Cl_2 in various $ZnCl_2$ aqueous solutions at 25°C were calculated from the weight loss of the rotating Zn hemisphere at various rotational speeds. The Stokes-Einstein equation was confirmed, $(D\mu/T) = 4.42 \times 10^{-10}$ g cm/sec^2 °K and can be used to estimate diffusion coefficients of total dissolved Cl_2 in various $ZnCl_2$ solutions. The average Cl_2 Stokes radius in $ZnCl_2$ solution is calculated to be 1.64Å. The dissolution rate follows the Levich equation for convection diffusion. Surface roughness is of major importance, and the dissolution rate of Zn increases rapidly at moderate Reynolds number. Spiral markings can be observed on the corroding Zn hemisphere due to instability of the three-dimensional boundary layer, as a result of the increasing surface roughness.

The zinc-chlorine battery is a secondary battery which incorporates zinc and chlorine electrodes and a flowing aqueous $ZnCl_2$ electrolyte (1). The battery is currently being developed for load-leveling and electric car applications.

The chemical reaction which occurs in the battery is straightforward

$$Zn + Cl_2 \rightleftarrows ZnCl_2\ (aq.)$$

During charge zinc is deposited at the cathode and chlorine gas is evolved at the anode. The flowing $ZnCl_2$ electrolyte replenishes $ZnCl_2$ and removes the evolving chlorine. On discharge, the flowing electrolyte removes the electrode reaction products, aqueous $ZnCl_2$, and supplies chlorine to the chlorine electrode. The chlorine storage system is cold water, which forms a clathrate compound with chlorine.

One of the main problems facing the use of Zn-Cl_2 battery as a load-leveling device is that of achieving a high coulombic efficiency while maintaining a high voltaic efficiency. The main reason for the coulombic inefficiency in the Zn-Cl_2 battery is the spontaneous reaction between dissolved chlorine and the zinc electrode upon charging. It is expected that the limiting step for this chemical reaction is the mass transfer of dissolved chlorine to the zinc surface. If this is the case, then hydrodynamic conditions and convective effects might be the dominant factors in the design to reduce the coulombic inefficiency during charging.

The effect of hydrodynamic conditions on the mass transfer and consequent reaction of dissolved chlorine with the zinc electrode can be investigated using a rotating-Zn hemisphere is a $ZnCl_2$ solution partially saturated with Cl_2. The rate of the reaction is followed from the weight loss of the rotating Zn hemisphere, and if the rate of weight loss is proportional to the square root of the angular velocity, according to the Levich equations (2), then the process is mass transfer limited and the diffusion coefficient of dissolved chlorine in $ZnCl_2$ solution can be calculated from the slope.

According to Levich (2) the diffusion layer thickness for the laminar flow on a disk electrode is given by

$$\delta = \alpha D^{1/3} \nu^{1/6} \omega^{-1/2} \qquad [1]$$

where D is the diffusion coefficient of dissolved Cl_2, ν is the kinematic viscosity, ω is the rotational velocity, and α is a constant which is equal to 1.62 for a disk and 2.109 for a hemisphere (3). Hemispherical electrode is preferred in the present case because the

Key words: zinc, chlorine, battery, rotating hemisphere, diffusion coefficient.

system's geometry remains unchanged. The hemisphere's limiting current, controlled by diffusion, has been corrected by Newman (4)

$$I_l = n\mathbf{F}DC_bA/\delta = 0.451\, n\mathbf{F}C_bD^{2/3}\nu^{-1/6}\omega^{1/2}A \quad [2]$$

$n\mathbf{F}$ is the number of coulombs per mole, C_b is the bulk concentration, and A is the electrode's area.

The dissolution of Zn is controlled by the diffusion of dissolved chlorine, therefore, the limiting current can be expressed by the weight loss

$$I_l = \frac{\Delta W n\mathbf{F}}{Mt} \quad [3]$$

where ΔW is the weight loss of the Zn hemispherical electrode, t is the time of the experiment, and M is the molecular weight of Zn. The mass transfer coefficient, k_c, is given by

$$k_c = \frac{\Delta W}{MAC_bt} = 0.451\nu^{-1/6}D^{2/3}\omega^{1/2} \quad [4]$$

From the plot of $\Delta W/MAC_bt$ *vs.* $\omega^{1/2}$, the diffusion coefficient of dissolved Cl_2 can be calculated.

At very high rotational speed, the flow becomes turbulent, and the Levich equation for convective diffusion does not hold; however, it is expected that earlier transition to turbulence is initiated due to surface roughness and secondary flow patterns.

The dissolution of Cl_2 in chloride aqueous solution is accompanied by the formation of dissolved molecular Cl_2, hypochlorous acid HOCl, and trichloride ion Cl_3^-. The reaction of dissolved Cl_2 with Zn is governed by the mass transfer of these three species and therefore the diffusion coefficients in the present investigation have an average meaning. The concentrations of the various species are estimated in the discussion section, and the Stokes-Einstein products $D\mu/T$ are interpreted as a function of the chloride concentration and the pH.

Experimental

The rotating-zinc hemisphere consists of a Teflon support rod and a replaceable Zn hemispherical head (Fig. 1). The Teflon support was 1.9 cm diam rod. A zinc hemisphere (99.999% New Jersey Zinc) was embedded in the Teflon rod. The diameter of the Zn hemispheres varied from 0.700 to 0.872 cm. At the center of the support there was a 0.396 cm hole in the central stainless steel shaft. The stainless steel shaft contained a 6-32 female thread to accommodate the Zn hemisphere. The other end of the Teflon support rod was attached to a stainless steel collet which was machined to fit a high speed rotator. The rotator was a Pine Instrument ASR rotator with a range of 0-10,000 rpm.

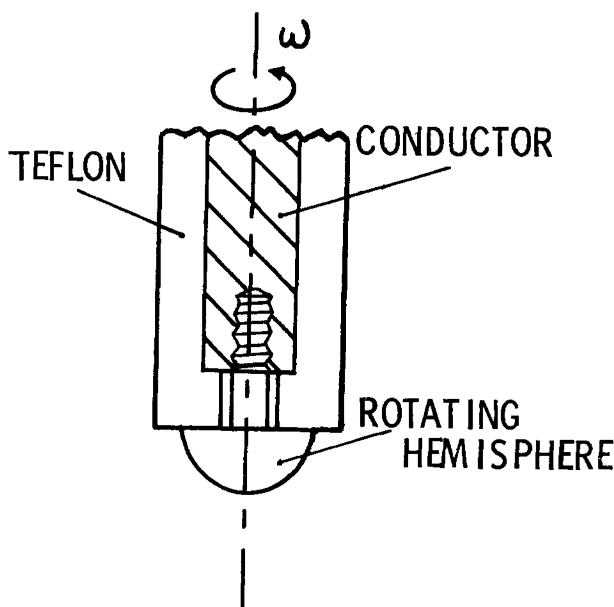

Fig. 1. Rotating Zn hemisphere

A 6-32 Zn screw having a hemispherically shaped head was used as the replaceable hemisphere. The surface of the electrode was polished with waterproof Al_2O_3 paper (grid number 600) and degreased with spectroscopic grade pentane. The Zn hemisphere was weighed on a Mettler Balance and transferred into the cell. After the experiment, the Cl_2-etched Zn hemisphere was rinsed with double distilled water, washed with pentane, and weighed.

A 1000 ml Pyrex vessel fitted with Teflon cover was used as the cell container. It was equipped with Cl_2 gas expenser. The $ZnCl_2$ 37% wt solution was obtained from EDA, Incorporated where the solution was prepared by direct recombination of pure Zn rods with dissolved Cl_2 gas. The $ZnCl_2$ concentrations were measured by hydrometer following the specific gravity data of $ZnCl_2$ (5). Viscosity data was obtained from (6) and the pH of the solution was recorded with Beckman pH meter.

The dissolved Cl_2 concentration was measured by standard titration method using 1/100 normal $Na_2S_2O_3 \cdot 5H_2O$. The solution was deaerated by bubbling nitrogen gas over a 30 min period. Cl_2-N_2 gas mixture was then bubbled for additional 30 min, and continuously bubbled throughout the experiment. Various Cl_2 concentrations were obtained by varying the composition of the Cl_2-N_2 mixture. The flow rates of Cl_2 and N_2 were controlled by needle valves and measured by calibrated rotameters.

Results and Discussion

Chlorinated $ZnCl_2$ solutions.—Table I summarizes the experimental data of the weight losses of Zn hemispheres in chlorinated 37, 22, and 17% wt $ZnCl_2$ solutions and in acidified 26% $ZnCl_2$ solution (pH = 1.0). Figure 2 shows the mass transfer coefficient of chlorine to the Zn hemisphere in chlorinated $ZnCl_2$ solutions *vs.* the square root of the rotational speed. The lines were obtained by a least square method not including the origin. The Levich equation for convective diffusion (2) is satisfied and the diffusion coefficients of dissolved Cl_2 can be determined, using Eq. [4], from the slope of the plot of $\Delta W/MtA(C_b)_{Cl_2}$ *vs.* $\omega^{1/2}$. The obtained diffusion coefficients of dissolved chlorine are shown in Table II. The corrosion of Zn due to H_2 evolution was measured by conducting weight loss measurements without Cl_2 at the same pH range. The weight loss due to H_2 evolution was negligible (<1%).

The value $D_{Cl_2} = 0.633 \times 10^{-5}$ cm^2/sec for 37% $ZnCl_2$ solution is in agreement with the value obtained from limiting current measurements of Cl_2 on a rotating nonporous graphite-disk electrode ($D = 0.664 \times 10^{-5}$ cm^2/sec) (7).

Table II also shows the calculated Stokes-Einstein product $D\mu/T$ for dissolved Cl_2 in the four $ZnCl_2$ solutions. The Stokes-Einstein product was found to be constant and the average value, $(D\mu/T)_{avg} = 4.42 \times 10^{-10}$ g cm/sec^2 °K, can be used to estimate the diffusion coefficients of dissolved Cl_2 at various $ZnCl_2$ solutions. This value is in general agreement with the chronopotentiometry data of Chao (16). The calculated Stokes radii for dissolved Cl_2 are shown in Table II and the average value is $(r_{Cl_2})_{avg} = 1.64$Å.

The present diffusion coefficient data are in good agreement with a value $D_{Cl_2} = 1.22 \times 10^{-5}$ cm^2/sec in H_2O at 20°C (8). The viscosity of pure water at 20°C is 1.0050×10^{-2} poise, and the Stokes-Einstein product is 4.185×10^{-10} g cm/sec^2 °K, in agreement with the present data.

The dissolution of Cl_2 in $ZnCl_2$ solution is governed by the formation of molecular Cl_2, HOCl, and Cl_3^-. The corrosion of Zn is therefore the result of the mass transfer and equilibria of the three species and

* Denotes spiral markings observed on Zn hemisphere.

the measured diffusion coefficients have an average meaning. In the following section the hydrolysis and equilibria of Cl_2 solution are analyzed. The true diffusion coefficient and the Stokes-Einstein product of dissolved molecular Cl_2 are measured in $HClO_4$ + HCl solution and in acidified $ZnSO_4$ solution, and compared to the average values in the $ZnCl_2$ solutions.

The hydrolysis and equilibria of dissolved chlorine.—The dissolved chlorine exists in chloride aqueous solution partly in the form of free molecular chlorine Cl_2, partly in its hydrolized form hypochlorous acid HOCl, and the remainder in the form of the complex trichloride ion Cl_3^-.

Table II. Diffusion coefficients, Stokes-Einstein products and Stokes radii of dissolved Cl_2 in various $ZnCl_2$ solutions

$ZnCl_2$ M	pH	T, °C	D (cm²/sec) ×10⁵	$D\mu/T$ (g cm/sec² °K) ×10¹⁰	$r_{\Sigma Cl_2}$ A
1.44	2.3	21.3	0.969	4.46	1.64
1.95	2.5	22.0	0.808	4.49	1.63
3.74	3.2	25.0	0.633	4.46	1.64
2.38	1.0	25.0	0.718	4.28	1.70

$(D\mu/T)_{avg} = 4.42 \times 10^{-10}$ g cm/sec² °K
$(r_{Cl_2})_{avg} = 1.64$A

The hydrolysis of chlorine is governed by the following two equilibria with K's at 25°C (14-16)

$$Cl_2 + H_2O \rightleftarrows HOCl + H^+ + Cl^- \quad K_1 = 3.94 \times 10^{-4} \qquad [5]$$

$$Cl_2 + Cl^- \rightleftarrows Cl_3^- \quad K_2 = 0.191 \qquad [6]$$

The hydrolysis of dissolved Cl_2 depends strongly on the pH.

The dissociation constant of hypochlorous acid to hypochlorite (15)

$$HOCl \rightleftarrows H^+ + OCl^- \quad K = 3 \div 4 \times 10^{-8}$$

is very small and in the present acidic solution hypochlorite is not present.

Although the $ZnCl_2$ solutions in the present work are acidic and the dissolved Cl_2 is the predominant species, the concentrations of HOCl and Cl_3^- can be estimated from the equilibrium constants

$$(HOCl)^2 = K_1 \frac{(\Sigma Cl_2) - (HOCl) - (Cl_3^-)}{(Cl^-)\gamma_{HCl}} \qquad [7]$$

$$(Cl_3^-) = K_2[(\Sigma Cl_2) - (HOCl) - (Cl_3^-)](Cl^-) \qquad [8]$$

where ΣCl_2 is the total dissolved Cl_2.

In the following calculations it was assumed that $\gamma_{Cl_2}\gamma_{H_2O}$ cancelled γ_{HOCl} to a good approximation (14), and that $\gamma_{Cl_3^-} \approx \gamma_{Cl^-}$ (15). The initial H^+ concentration can be neglected in comparison to the final H^+ concentration. The activity coefficient of HCl, γ_{HCl}, in $ZnCl_2$ solution was approximated from the available activity coefficient data of HCl in $BaCl_2$ (17).

Table III. Estimated concentration of Cl_2, HOCl, and Cl_3^- in chlorinated $ZnCl_2$, $ZnSO_4$, and $HClO_4$ + HCl solutions

$ZnSO_4$	8.74×10^{-3}	1.0	1.0	2.0	1.29	0.71	—
	8.74×10^{-3}	2.5	2.5	2.0	0.25	1.75	—
$HClO_4$+ HCl	0.975M 0.025M	0.02	0.02	2.0	2.0	—	—

Table III presents the calculated concentrations of the various species Cl_2, HOCl, and Cl_3^- in typical 2×10^{-2}M total-dissolved Cl_2 solutions. It appears that for a typical $ZnCl_2$ solution 50 ± 10% of the dissolved chlorine remains as molecular Cl_2, while 50 ± 10% and 5 ± 5% are converted to Cl_3^- and HOCl, respectively. The decrease in the pH upon chlorination is due to the partial hydrolysis of dissolved Cl_2 to HOCl and HCl, according to the first equilibrium (Eq. [5]). The obtained diffusion coefficients of dissolved Cl_2, the calculated Stokes-Einstein product, and the Stokes radius represent an average of the three diffusing species Cl_2, HOCl, and Cl_3^-.

Figure 3 shows the mass transfer coefficient as a function of the square root of the rotational speed in chlorinated acidified 8.74×10^{-3}M $ZnSO_4$ (pH = 1.0), acidified 26% wt $ZnCl_2$ solution (pH = 1.0), and in 0.975M $HClO_4$ + 0.025M HCl chlorinated solution.

In H_2SO_4-acidified $ZnSO_4$ solution (pH = 2.5), most of the dissolved Cl_2, 87.5%, is hydrolyzed to HOCl and therefore, the diffusion coefficient which was calculated from the slope $D = 1.451 \times 10^{-5}$ cm²/sec is the approximate value for HOCl. In the 26% weight $ZnCl_2$ solution (pH = 1.0), HOCl is not present and about 47.5% of the total dissolved Cl_2 is converted to Cl_3^-. The obtained diffusion coefficient $D = 0.718 \times 10^{-5}$ cm²/sec represents an average value for Cl_2 and Cl_3^-.

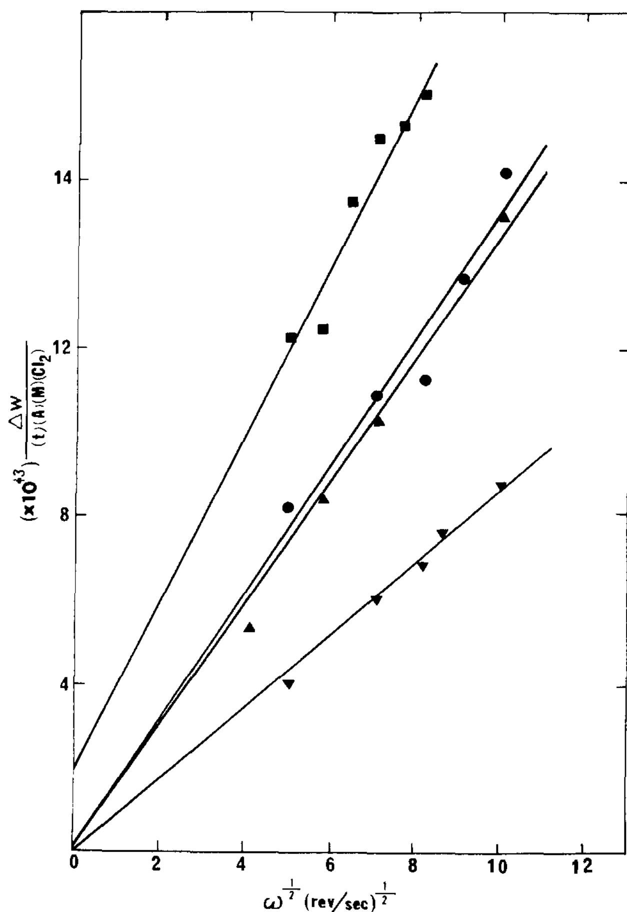

Fig. 3. Zn weight loss vs. the square root of the rotational velocity. 8.74×10^{-3}M $ZnSO_4$; ● pH = 1.0; ▲ pH = 2.5; ■ 0.975M $HClO_4$ + 0.025M HCl; ▼ 26% (pH = 1) $ZnCl_2$.

Similar weight-loss experiments were performed in chlorinated 0.975M $HClO_4$ + 0.025M HCl solution. In this solution all the dissolved Cl_2 remains as molecular Cl_2 and therefore the diffusion coefficient $D_{Cl_2} = 2.14 \times 10^{-5}$ cm²/sec is the true value for Cl_2. In this experiment the weight loss due to H_2 evolution was estimated from a weight loss experiment in the absence of Cl_2 and from the intercept at $\omega = 0$ in Fig. 3. The viscosity of the $HClO_4$ + HCl solution was measured at 28° in our laboratory, $\mu = 8.23 \times 10^{-3}$ g/cm sec, using an Ostwald viscometer.

The Stokes-Einstein products and the Stokes radii of dissolved Cl_2 in acidified $ZnSO_4$ solutions and $HClO_4$ + HCl solution are shown in Table IV. The $ZnSO_4$ pH = 2.5 values can be regarded as an approximation for HOCl

$$(D\mu/T)_{HOCl} \cong 4.45 \times 10^{-10} \text{ g cm/sec}^2\ {}^\circ\text{K}$$

$$r_{HOCl} \cong 1.67\text{Å}$$

The HOCl concentration was quite low in all the experiments, except in the $ZnSO_4$ solutions. The diffusion coefficient of Cl_3^- is expected to be the lowest, followed by HOCl and Cl_2. In $ZnSO_4$ solution at low pH, the diffusion coefficient is higher (Table IV) due to the higher concentration of molecular Cl_2, in agreement with Chao (16).

In the $HClO_4$ + HCl solution, the Stokes-Einstein product is the highest because of the expected high diffusion coefficient of dissolved molecular Cl_2, which is the predominant species. The data from the $HClO_4$ + HCl solution can be regarded as the true values for Cl_2

$$(D\mu/T)_{Cl_2} = 5.85 \times 10^{-10} \text{ g cm/sec}^2\ {}^\circ\text{K}$$

$$r_{Cl_2} = 1.25\text{Å}$$

A Cl_2 bond length of 1.98Å is given by Pauling (13).

Hydrodynamic effects.—Above a rotational speed of about 100 rps, the Levich equation is not satisfied (see Fig. 2), and the weight loss is much higher than expected for laminar flow. The empty data points in Fig. 2 represent experiments where spiral vortex shape markings were observed on the Zn hemisphere at the end of the experiment. The higher weight losses of the Zn hemisphere under these conditions can be explained by an earlier transition to turbulent flow and the appearance of secondary flow pattern near the surface which enhances the mass transfer of dissolved Cl_2 to the Zn surface.

During the Zn dissolution the Zn surface becomes rough. This surface roughness changes the nature of the flow, and transition to turbulence appears earlier than expected for a smooth surface. Levich (2) discusses convective diffusion to a rough surface and relates the size of the protrusions to the thickness of the hydrodynamic boundary layer. If the size of the protrusion is larger than the hydrodynamic boundary layer, then transition occurs earlier. The thickness of the hydrodynamic boundary layer depends on

Table IV. Diffusion coefficients, Stokes-Einstein products and Stokes radii for dissolved Cl_2 in $ZnSO_4$ solution and $HClO_4$ + HCl solution

Electrolyte (M)		pH	T, °C	D (cm²/sec) × 10^5	$D\mu/T$ (g cm/sec² °K) × 10^{10}	r, A
$ZnSO_4$	8.74×10^{-3}	1.0	25	1.517	4.57	1.60
$ZnSO_4$	8.74×10^{-3}	2.5	25	1.451	4.38	1.67
$HClO_4$ HCl	0.975 0.025	0.02	28	2.14	5.85	1.25

$r_{Cl_2} = 1.25$A $r_{HOCl} \cong 1.67$A

the rotational speed through the Reynolds number ($Re = \omega r^2/\nu$). As the rotational speed increases (6000-8000 rpm) the thickness of the boundary layer decreases and reaches the same order of magnitude of the rough surfaces. Secondary flow of small vortexes is initiated, which enhances the mass transfer of dissolved Cl_2 to the surface.

In all the electrodes which exhibited higher weight loss than expected, the corroded surface showed spiral shape patterns of dissolution. Typical spiral markings are shown in Fig. 4 where the rotational speed is high (8000 rpm). The formation of spiral markings on a rotating-disk electrode has been shown (9, 10) to be caused by the formation of wakes behind small protrusions and the formation of secondary flow is due to instability of the three-dimensional boundary layer on the rotating disk or hemisphere. Figure 5 shows the surface of Zn hemisphere after Cl_2 corrosion at lower rotational speed ($Re = 4.37 \times 10^3$). Spiral markings are absent and the grain boundaries can be observed clearly. Ibl (18) explains the formation of the spirals during metal deposition on a rotating-disk electrode by the relative size of the surface protrusions and the mass transfer boundary layer thickness.

Fig. 4. Zn hemisphere after reaction with dissolved Cl_2. $\omega = 8000$ rpm; radius $= 0.436$ cm; $[Cl_2] = 1.96 \times 10^{-2}M$; time $= 31$ min; $Re = 9.2 \times 10^3$; 37% $ZnCl_2$.

Fig. 5. Zn hemisphere after reaction with dissolved Cl_2. $\omega = 4390$ rpm; radius $= 0.406$ cm; $[Cl_2] = 0.35 \times 10^{-2}M$; time $= 60$ min; $Re = 4.37 \times 10^3$; 37% $ZnCl_2$.

The transition flow appears at a Reynolds number of about

$$Re = \frac{\omega r^2}{\nu} = \frac{2\pi(121)(0.4)^2}{1.72 \times 10^{-2}} = 7 \times 10^3$$

which is below the transition Reynolds number of 1.5×10^4 obtained experimentally for a smooth rotating hemisphere (12). The flow near a hemisphere is less stable than near a rotating disk, and the present value for a hemisphere is lower than 10^5, as predicted from linear stability analysis of a flow near a rotating disk (10, 11). The earlier transition in the present case is due to the surface roughness during the corrosion of the zinc surface by the dissolved Cl_2.

In conclusion, it has been shown that the chemical reaction of dissolved chlorine with zinc in $ZnCl_2$ aqueous solution is mass transfer limited. The Zn surface roughness initiates a secondary flow and increases the mass transfer of dissolved Cl_2 to the surface. At low pH the dissolved Cl_2 is in the form of dissolved molecular Cl_2 and trichloride ion, Cl_3^-. At higher pH, the presence of hypochlorous acid, HOCl, is significant.

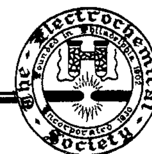
Technical Notes



Dynamic-Foamed Electrolyte Hydrogen Electrode

Jacob Jorné*

Department of Chemical and Metallurgical Engineering, Wayne State University, Detroit, Michigan 48202

The potentially advantageous use of foamed electrolyte in fuel cell has been suggested by Nanis and McLarnon (1). They suspended a Pt electrode just above H_2SO_4 or NaOH solution which contained a small amount of surfactant and bubbled the fuel gas (H_2 or O_2) through the solution creating a foam which rose and covered the electrode. The foam contained the fuel gas (H_2) and the bubble walls acted as a thin film when in contact with the electrode's surface. The most significant finding of Nanis and McLarnon's work was that when using a flat platinum electrode the anodic limiting current in the foamed electrolyte was an order of magnitude larger than the limiting current when the electrode was completely immersed in the liquid electrolyte. From the limiting currents they were able to estimate the apparent diffusion boundary layer thickness, using the following equation

$$\delta_D = n\mathbf{F}DC_b/I_l \qquad [1]$$

Where C_b is the bulk concentration of dissolved H_2, D its diffusion coefficient, and I_l is the anodic limiting current. The obtained diffusion boundary layer thickness was on the order of 3-4μ, and Nanis and McLarnon (1) explained it in terms of a thin film of electrolyte covering the electrode when it is in the foam. However, no attempt was made to compare quantitatively the calculated apparent diffusion boundary layer thickness with the average thickness of the foam's wall.

In the present work limiting currents were measured for the anodic reaction

$$H_2 \rightarrow 2H^+ + 2e^-$$

using a dynamic foamed electrolyte where the foam flowed continuously over a platinum electrode. The apparent diffusion boundary layer thickness was calculated using Eq. [1]. The average thickness of the foam's wall δ_F was calculated from the measured average bubble diameter $\bar{d}$ and f, the foam wetness (7, 8)

$$\delta_F = f\bar{d}/6 \qquad [2]$$

The two values are in general agreement which substantiates quantitatively the assumption that the thin walls of foam present the major resistance to mass transfer of the dissolved gaseous fuel to the electrode surface.

The importance of thin films in gas electrodes have been noticed by several researchers (2-6). When a gas electrode is partially withdrawn from liquid electrolyte into the gas atmosphere the current increases and the local current density is higher at the thin film covering the electrode surface.

Experimental

The apparatus consisted of a circulatory foam column; the working anode and the countercathode were located at the middle section of the foam column (see Fig. 1). The foam column is similar to the one used in foam separation technique by Rubin and Jorné (7). Hydrogen gas was passed through a rotameter and prehumidifier and bubbled through a glass frit dispersion tube located in the bottom of a 4 liter flask where the electrolyte was initially placed. The column consisted of a 36 cm long 2.8 cm ID Pyrex tube. The upper part of the column was bent to form an angle of about 45° to direct the foam into the rotating foam breaker (7). Near the midpoint of the column the two platinum electrodes were located. The working electrode was a Fisher Scientific Company electrode (Cat. No. 13-639-102) located in a Pyrex cylinder, and the active area of the circular electrode was 0.785 cm^2. The counterelectrode was a 1 cm^2 bright platinum foil attached to a platinum wire. The Luggin capillary tip was introduced below the working electrode and the capillary was connected to the reference electrode container where a standard calomel electrode was placed.

The constant current was maintained by a power supply (Electronic Measurements Model C-613) and the potential between the anode and the reference electrode was measured with a Keithley 600A electrometer. A flat glass window (1 cm diam) was located below the electrode where close-up pictures of the flowing foam were taken in order to measure the average bubble diameter (7, 8)

$$\bar{d} = \frac{\sum_i n_i d_i^3}{\sum_i n_i d_i^2} \qquad [3]$$

* Electrochemical Society Active Member.

Key words: foam, hydrogen, fuel cell, bubbles, mass transfer, limiting current.

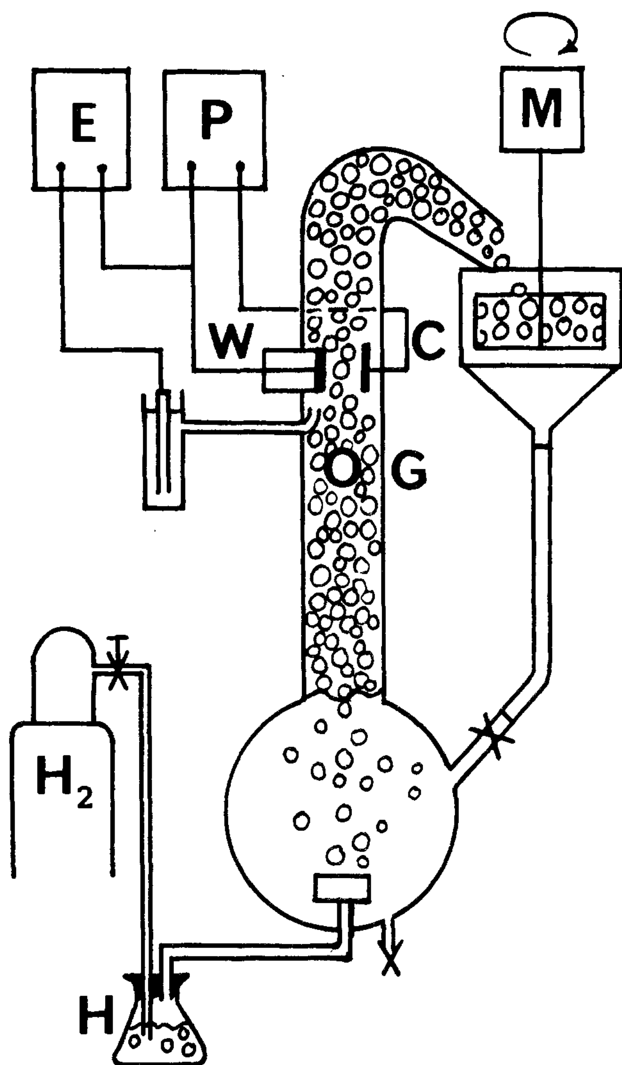


Fig. 1. Circulatory foam column and electrodes arrangement. W, C, R—working, counter, and reference electrode, respectively. P, power supply; E, electrometer; M, motor; G, flat window; H, prehumidifier.

The electrolyte consisted of 4*N* sulfuric acid containing 0.1% wt carboxane TW-100, Textilana Corporation, Hawthorne, California. This surfactant was found to be inert in the potential range (1).

The experiment began by filling the lower flask with 4 liters of the electrolyte. Hydrogen gas was bubbled into the electrolyte-surfactant solution through a fritted glass dispersion tube. The hydrogen bubbles, as they emerged from the electrolyte solution, formed the foamed electrolyte. The foam flowed up the column past the electrodes and was circulated back into the flask after being broken by the rotating foam breaker. The foam wetness f was calculated by measuring the flow rate of the foamate (the broken foam) and the flow rate of the foam in the column. The foamate flow rate was measured by accumulating it over a period of 90 sec. The foam flow rate was measured from the upward velocity of the foam's plug-flow in the 2.8 cm. ID column. The foam wetness f is calculated from

$$f = \frac{\text{foamate flow rate}}{\text{foam flow rate}} \quad [4]$$

and represents the liquid fraction in the foam.

Limiting current data were obtained by increasing galvanostatically the current between the two Pt electrodes and recording simultaneously the overpotential between the working and reference electrode. The limiting currents were measured for various foam velocities. The foam remained stable in all the experiments and the room temperature was around 25°C.

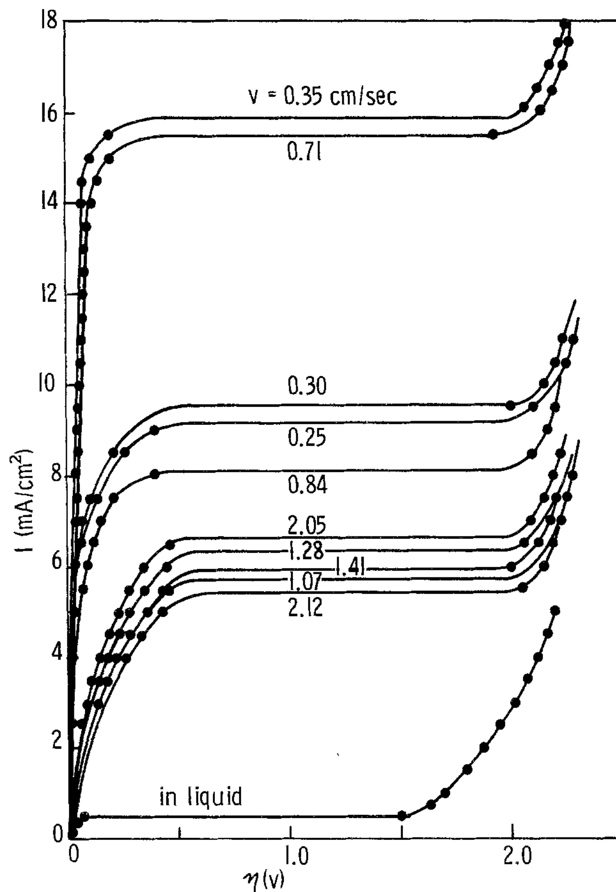

Fig. 2. Current density vs. anode overpotential for H_2 electrode at various foam's upward velocities. 4*N* H_2SO_4, 0.1 w/o carboxane TW-100; $P = 1$ atm; $T \sim 25°C$.

Results and Discussion

Anodic polarization curves for H_2 oxidation in the foamed 4*N* H_2SO_4 electrolyte are shown in Fig. 2. The limiting currents correspond to various foam upward velocities, and can be compared to the lower polarization curve which was measured in the liquid solution where the hydrogen electrode was totally submerged. Table I presents the data for the limiting currents as well as the foam's physical properties: average bubble diameter, foam velocity, and foam wetness. The bias potential between the anode and the calomel reference electrode was about 260 mV, in excellent agreement with the Nernst equation. The missing data in Table I and consequently in Table II are due to the failure of the camera in one case, and the lack of foamate flow rate data in the other.

A comparison between the effective diffusion boundary layer thickness and the average wall thickness of the foam is shown in Table II. The diffusion bound-

ary layer thickness δ_D and the average wall thickness δ_F were calculated from Eq. [1] and [2], respectively. Hydrogen diffusion coefficient and solubility data were obtained from Ruetschi (9). $D_{H_2} = 3.7 \times 10^{-5}$ cm²/sec, $C_{H_2} = 0.58 \times 10^{-3}M$ (uncorrected from 30°C).

A general agreement can be found between δ_D and δ_F as can be seen from Fig. 3, indicating that the thin walls of the foam bubble represent the diffusion path for the diffusion of H_2 from the bubbles to the electrode's surface. The deviations of δ_D from δ_F, especially at small δ_F, can be attributed to the error in determining the average bubble diameter $\bar{d}$ (Eq. [3]). The error in determining the average bubble diameter is quite large and can reach 100% for a dry foam where the bubbles are not spherical and δ_F should be larger than estimated from Eq. [2]. This explains that the deviation of δ_D from δ_F in Fig. 3 is largest for small δ_F and generally positive for small δ_F. The obtained limiting currents and effective boundary layer thicknesses are in agreement with Nanis and McLarnon's results (1), where the foam was accumulated above the solution. Figure 4 shows the behavior of the limiting current *vs.* the upward foam velocity. The maximum occurs at about 0.5 cm/sec. The foam velocity determines the foam wetness. At very slow upward velocities the foam drainage is complete and the foam is very dry. However the gas flow rate also determines the average bubble diameter; at low flow rate the average bubble diameter is high. Thus as the gas flow rate increases, the two effects, the foam wetness and average bubble diameter, compete in determining the trend of the

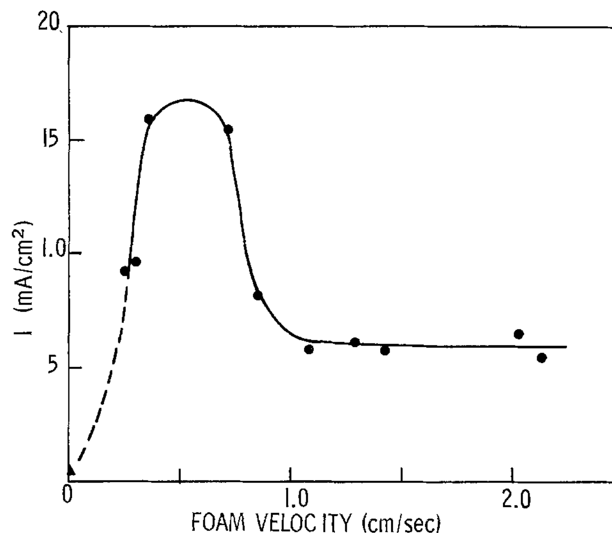

Fig. 4. The anodic limiting current *vs.* the foam's upward velocity. Δ, in liquid.

average wall thickness (according to Eq. [2]) and the optimal upward velocity of the foam corresponds to the formation of a thin film.

Summary

The hydrogen electrode was investigated in a flowing foamed electrolyte. The improved mass transfer effect reported previously by Nanis and McLarnon has been confirmed. A correlation was established between the anodic limiting current and the dynamic properties of the foam. A general agreement was found between the calculated effective mass transfer boundary layer and the measured foam's average wall thickness. These results confirm that the thin walls of the foam represent the resistive path for the diffusion of hydrogen from the bubbles to the surface of the electrode.

The Reactivity of Metals with Mixtures of Carbon Tetrachloride and Alcohols

James R. Kuppers

Chemistry Department, The University of North Carolina at Charlotte, Charlotte, North Carolina 28223

Al reacts directly with the lower aliphatic alcohols only under anhydrous conditions at elevated temperatures or when amalgamated (1), or when highly stressed surfaces are freshly exposed (2). The reaction of Mg metal with moist ethanol at reflux is accelerated with the addition of small amounts of iodine or an aliphatic halogen compound such as chloroform or CCl_4. Al and its alloys, brasses, bronzes, and iron alloys are subject to corrosion under some stringent conditions such as mechanical stress, high temperatures, or amalgamation (5-9). Some Al alloys undergo a rapid, autocatalytic reaction with CCl_4-methanol mixtures, initiated at room temperature and leading to complete dissolution of the metal (10). The corrosion of metals in halogenated hydrocarbons is currently under intensive study by Heitz and Kyriazis (11).

My interest in this subject stems from reports of corrosion problems encountered in a brass thermal diffusion cell containing CCl_4-alcohol mixtures (12, 13). I report some novel features of this class of reactions.

Experimental

Reactions in sealed tubes.—Separate 125 mg samples of Cu, Zn, Ag, Pt, and Au (each at least 99% pure) were sealed in NMR tubes with 500 mg of CCl_4-methanol mixture (40% CCl_4, air not excluded) and held at 25°C. Zn metal was decomposed overnight leaving a white solid and a colorless solution. Cu metal was consumed after two weeks leaving a yellow-brown solution and no solid residue. Ag metal was faintly discolored after two weeks but otherwise unaffected.

Pt and Au remained bright with no visible indication of reaction. The course of the reaction with Zn and Cu was monitored with proton magnetic resonance spectra. Although the methyl and hydroxy proton signals were progressively shifted downfield (approximately 0.3 ppm in all) no new proton signal developed.

In particular, nothing was seen which would indicate the formation of halohydrocarbons, aldehydes, or compounds containing methylene protons. The methyl and the hydroxy proton signals in the Cu tube were significantly broadened at the end of the reaction. When ethanol, 2-propanol, or 1-butanol were substituted for methanol, the reaction with Zn in sealed tubes was progressively more sluggish in order of increasing molecular weight of the alcohol and NMR spectra revealed no new proton signals which were not present at the beginning of the reaction.

The induction period.—The time required for the initiation of a vigorous, autocatalytic reaction of Zn with CCl_4-methanol mixtures in open containers was sensitive to the composition of the mixture as well as to the presence of certain chemical initiators. This reaction was self-initiated at 25°C over a range of concentrations from 0.60 to 0.98 mole fraction of methanol. The minimum induction period, 2 hr, corresponded to a methanol concentration of approximately 0.90 mole fraction when used with 30 mesh Fisher Reagent Grade Zn powder. The induction period was completely eliminated by adding traces of soluble salts of some less active metals, *e.g.*, $CuCl_2$, $HgCl_2$, and $CrBr_3$. Al and Mg, unlike Zn, required no induction period under any circumstances. Nevertheless, reactions proceeded more vigorously in the presence of the previously mentioned salts.

Key words: corrosion, organic solvents, water.

Reactivity of various metals.—Mg, Al, Si, Ti, Cr, Mn, Fe, Co, Ni, Cu, Zn, Ga, Ag, Cd, Sn, Pt, Au, and Hg were immersed for two weeks at 25°C in CCl_4-methanol mixtures containing 0.90 mole fraction of methanol. Rapid, autocatalytic dissolution of Mg, Al, and Zn occurred. The reaction of Cu and Cr was slow but eventually resulted in complete dissolution of the metals. All the other metals were nonreactive in the sense that whatever reaction occurred was halted by the immediate formation of passive coatings.

Water as a quenching agent.—Reactions of Mg, Al, and Zn with CCl_4-methanol mixtures were quenched with small additions of water. Since there was no induction period for Mg and Al and since Mg reacts with anhydrous methanol at 25°C, even in the absence of CCl_4, these two metals were convenient for a quantitative study of the water-quenched reactions. To the metals immersed in anhydrous methanol, small successive additions of CCl_4 and water were made. The amount of CCl_4 needed to reinitiate the rapid reaction at specified water concentrations were recorded (Fig. 1). Mg did not react with ethanol containing 5.0% water in the presence of CCl_4 at 25°C, but the reaction pro-

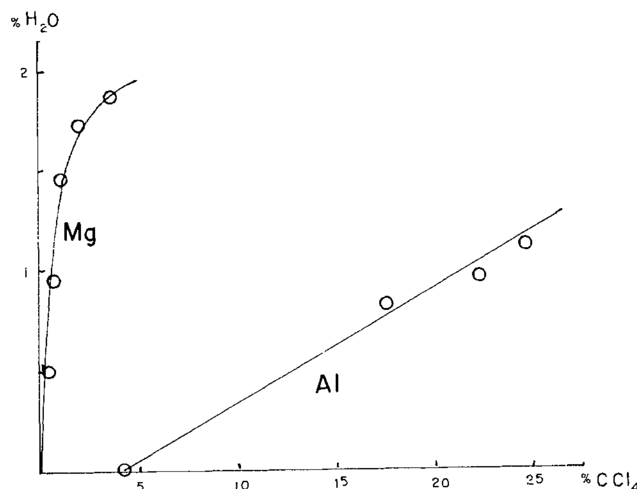

Fig. 1. The concentration of water needed to quench the reaction of Al and Mg and CCl_4-methanol mixtures and its dependence upon the CCl_4 concentration. Concentraotions are expressed in weight percentages in the liquid mixture.

ceeded vigorously with mixtures of CCl_4 and ethanol containing 0.1% water.

Products of the reaction.—The gaseous products of the Zn reactions were swept, in sequence, through a 0° trap and a liquid N_2 trap. Infrared spectral comparisons showed the gas frozen out in the second trap contained methane. The liquid N_2 trap permits the passage of H_2 gas which, of course, is a possible product of the reaction. However, gas density measurements on the gas passing the 0° trap suggested that it was predominantly methane. This conclusion was confirmed by a chromatographic separation on Molecular Sieve "5A" which achieved a good separation of H_2, O_2, N_2, and CH_4 at a column temperature of 80°. Moreover, it was demonstrated that CH_4 was the dominant gaseous product of the reaction of Zn with CCl_4-acetic acid, $CHCl_3$-acetic acid, CH_2Cl_2-acetic acid, and CF_3CCl_3-acetic acid mixtures (the latter three reactions were initiated by adding a trace of CCl_4). It was shown, on the other hand, that H_2 gas was dominant in the Mg and Al reactions with CCl_4-methanol mixtures. The largest yield of gas from any of these reactions was 0.25 mole of gas per mole of metal.

I recovered 1.5g of C_2Cl_6 from a reaction mixture containing 3g Zn, 40g methanol, and 16g CCl_4 which represents 0.15 moles of C_2Cl_6 per mole of metal. The recovery of C_2Cl_6 was performed by distilling away about half of the excess liquid, adding water to precipitate the C_2Cl_6, then subliming the residue at 187°C. Vacuum drying of the residue at 110° left a solid which, on the basis of weight relations and chloride content, was predominantly the oxychloride of Zn with a small amount of waxy material, probably chlorocarbon polymers. The mole ratio of chloride to Zn was 1.03. A mole ratio of CCl_4 to Zn of at least one was required for the complete dissolution of Zn.

Much less C_2Cl_6 was formed with Mg and the mole ratio of chloride to Mg was 0.57. Vacuum drying of reaction products from Al and Cr produced vitreous solids which were very hygroscopic and otherwise were not examined in detail.

Discussion

The reaction of several metals with CCl_4-alcohol mixtures at room temperature occurs in the absence of any electrochemical process. If these oxidation-reduction reactions are coupled with electrochemical reactions, such as those to be expected with alloys, the range of complexity of the reaction may be far more complex.

No aldehydes, acetals, or chloroform were detected in my experiments. I propose that such products, reported previously but not observed in these experiments, appear only with secondary reactions which may occur in the presence of alloys. Proposed mechanisms for this class of reactions (7, 8, 10) may need revision.

The most striking result of this preliminary study was the observation of CH_4 rather than H_2 gas in the Zn reaction and the potential violence of this and related reactions. Such autocatalytic processes could create previously unsuspected hazards in the laboratory and in industrial operations. The results also suggest that CH_4 is formed from the halocarbon compounds, in which case the stoichiometry corresponds to 1/4 mole of CH_4 per mole of Zn when CCl_4 is the halocarbon.

Story and Turner (13) suggested that the yellow color which developed in a thermal diffusion cell containing CCl_4-alcohol mixtures resulted from the reaction with Hg. It is more likely that this color was associated with brass corrosion products in solution. Their experience, along with that of Beyerlein (12), should stress the importance of taking into account the reactivity of CCl_4-alcohol mixtures when designing enclosures for such systems.

Optical Absorption as a Control Test for Plasma Silicon Nitride Deposition

Myron J. Rand* and David R. Wonsidler

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

The composition (Si/N) and properties of glow discharge-deposited silicon nitride films are sensitive to variations in many apparatus parameters. A rapid and simple test for film composition is needed to monitor and control production equipment. The position of a defined optical absorption edge in the near ultraviolet and visible ranges serves this purpose over a Si/N atomic ratio range of 0.8-1.5. Film thickness is determined at the same time. The procedure and a typical calibration curve are given; computation is simple. The existence of relatively low energy optical absorption is considered evidence for a highly distorted and irregular structure compared with that of pyrolytic Si_3N_4.

Plasma-deposited silicon nitride has been gaining popularity as a final encapsulation film for integrated circuit chips. This hard, adherent dielectric provides scratch and particle protection during mounting and bonding operations; it also helps to protect the metallization from corrosion and provides some measure of resistance to sodium ion penetration. This nitride is usually deposited with the substrate at 250°-350°C, a temperature which is well tolerated by aluminum metallization.

Plasma nitride deposition is actually a low pressure chemical vapor deposition reaction aided by a radio frequency glow discharge. The mechanism of the reaction is unquestionably complex. The film contains substantial residual bonded hydrogen from the silane and ammonia reactants, and it would be best described as a polysilazane, $Si_xH_yN_z$. Unlike 1 atm pyrolytic silicon nitride, it has no fixed stoichiometry. We have analyzed films with Si/N atomic ratios ranging from 0.7 to 1.5.

As with most plasma reactions, experience has shown that the course of the polymerization and the properties of the resulting film are sensitive to many deposition parameters. Plasma power and pressure, electrode separation, wafer temperature, total flow rate, reactant concentrations, the carrier gas used: these are only some of the variables we have found to be important. Furthermore, interactions among these are common, so that it may be impossible to generalize on the influence of an individual variable. Close control of the deposition machine is required to produce a film with good properties, and control wafers should be included along with device wafers in every run.

For thin film insulators, common control tests include thickness (usually by some optical method), fluoride etch rate, refractive index, flaw density, and film stress. Unfortunately we have not found any of these to be reliable indicators of reproducibility of nitride film composition, and it is composition which largely determines film properties and which responds sensitively to many deposition variables.

* Electrochemical Society Active Member.
Key words: plasma polymerization, thin films.

We believe the best criteria for plasma nitride control are the Si/N ratio of the film (oxygen being absent) and the uniformity of thickness over the batch of wafers. For the latter there are conventional methods. For composition, however, the most unequivocal determination is electron microprobe analysis, which is far too complex for a routine control test. Refractive index, as measured by ellipsometer, was found to correlate only roughly with composition, and furthermore the correlation seems to be somewhat different for different reactors. The films are probably too thick and too nonuniform for ellipsometric work; in addition, there is significant absorption at the measuring wavelength (546 nm), especially for the higher Si/N films. Nomographs or computer programs for refractive index which assume a transparent film give too high a result under this condition, and the error is increasingly serious the thicker the film and the more the absorption.

The presence of optical absorption in the visible range is a clue to another possibility for composition monitoring. Stoichiometric (pyrolytic) Si_3N_4 films have an absorption edge near 225 nm (1), whereas plasma silicon nitride films can have absorption edges well into the visible range and vary in appearance from colorless to deep amber. The latter are silicon-rich, by analysis. The extra absorption could be due to structural disorder, causing band broadening and "tailing" at the edges, or, alternatively, some bonding which is not present in Si_3N_4. Since neither SiH_4 nor NH_3 absorbs strongly in the 200-400 nm range, the absorption is unlikely to be caused by Si-H or N-H bonds, leaving only Si-Si as a reasonable possibility. If excess silicon were present in units as large as two or three bond lengths, the film would begin to show some of the optical properties of pure Si (2), including strong absorption in the near ultraviolet.

Either explanation, disorder or Si-Si bonding, suggests a correlation between composition and absorption or absorption edge. We report here an investigation of this correlation and show that a simple spectrophotometer scan can contain information on both thickness and chemical composition of plasma nitride films. Only an approximate refractive index is required. The answers

are easy to extract, and the method is therefore suitable for controlling deposition machine operation.

Experimental

Plasma nitride films 0.5-1.5 μm thick were deposited from SiH_4 and NH_3 in three different radial-flow reactors of the type first described by Reinberg (3). A 13.6 MHz glow discharge was maintained between two horizontal plates in a capacitor configuration, with substrate wafers resting on the lower (heated) electrode. Reactants entered the discharge around the periphery of the wafer table and were exhausted at the center. By varying plasma power, pressure, and reactant ratios the gamut of plasma nitride compositions could be produced.

For the purposes of this study the films were deposited on 22 mm square Corning microscope cover glasses. These are transparent down to 300 nm, so the more costly vitreous fused silica or sapphire is not really necessary. A 1/4 in. square in the center was defined by a cardboard mask and transmission measured with a Perkin-Elmer Model 202 ultraviolet-visible spectrophotometer. It is an advantage to have a readout directly in absorbance ($\log I_0/I$) units. Either an uncoated glass or an attenuator may be used in the reference beam.

The transmission level fluctuates with wavelength even in the absence of absorption because of interference effects. With a transparent film on a transparent substrate of lower index, maximum transmission is the same as that for the substrate alone. Consequently, for comparability of spectra the maximum transmission in the minimally absorbing 600-750 nm range was set at 100% using the instrument adjustment for this purpose.

After absorbance measurement, the same area of the sample was analyzed with the MAC 400 electron probe microanalyzer (4). CVD pyrolytic Si_3N_4 about 8000Å thick was used as the standard for both Si and N. To minimize surface charging, a 500Å film of carbon was evaporated onto the samples and standard. A new standard specimen was coated along with each group of samples to assure uniform carbon thickness. Some analyses were performed after evaporation of ~300Å of aluminum, with equally satisfactory results.

The microprobe uses wavelength-dispersive Johanson-type spectrometers with flow-proportional x-ray detectors. A Tousimis Research Corporation universal x-ray detector with a Nitrolucid® window was used for nitrogen. The accelerating potential was usually 5.5 keV with an effective penetration depth of ~0.37 μm in plasma SiN if a density of 2.3 is assumed and ~0.27 μm in the Si_3N_4 standard ($d = 3.1$). The analyses on Al-coated films were performed at 7.0 keV with essentially identical results and with standard deviation halved.

Si-Kα and N-Kα x-ray intensities were measured for 20 sec counting periods on samples and standards, taking at least 12 locations at random on each. Averaged background intensities above and below characteristic wavelength positions were subtracted from peak intensities. Intensities were converted to weight percentages utilizing MAGIC IV (5).

In ten of the first eleven samples analyzed, the sum of Si and N weight percentages was 100 ± 2%. The Si data were more reproducible, had smaller 2σ limits, and were less subject to noise than the N counts. Thereafter it was decided to analyze only for Si and calculate N by difference; all the Si:N atomic ratios reported here were obtained this way. In all samples oxygen was at or below the detection limit of ~0.2%.

Before a film may be characterized by its absorbance, variations in thickness among films must be taken into account. According to the Beer-Lambert law, absorbance is directly proportional to absorption path. Thus, readings may be normalized by dividing the absorbance by the film thickness. To make this more convenient for the operator, we have arbitrarily defined the absorption edge as the wavelength λ_a at which this ratio is unity when thickness is in micrometers. In other

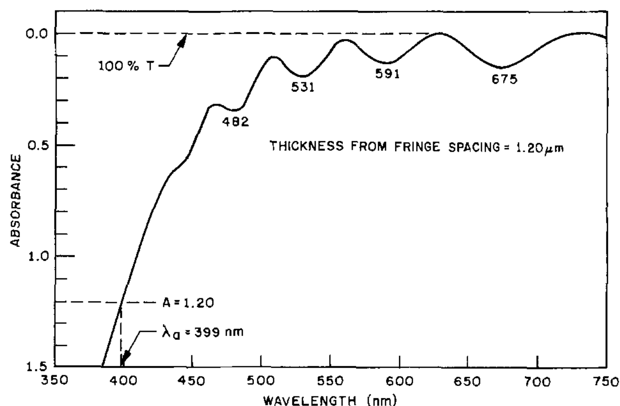

Fig. 1. Typical transmission curve for plasma nitride film on glass, illustrating the method for locating λ_a.

words, λ_a is the wavelength at which the absorption coefficient is $10^4/e$ cm^{-1}. For example, for a 1.25 μm thick film λ_a is where $A = \log I_0/I = 1.25$, or the transmission is down to about 5%. For a film of the same optical properties but only 0.8 μm thick, an absorbance of 0.8 should be found at the same λ_a.

Figure 1 shows a typical spectrophotometer scan and the method for determining λ_a.

The advantage of this procedure lies in the fact that the transmission curve yields thickness as well as absorbance. There is enough difference in index of refraction between plasma SiN, $n > 1.9$, and the glass substrate, $n = 1.51$, to produce interference fringes in the transmission spectrum. A satisfactory approximation for film thickness d in this normal incidence case is

$$d = \frac{N\lambda_2\lambda_1}{2n(\lambda_2 - \lambda_1)}$$

where λ_2 and λ_1 are wavelengths of transmission minima ($\lambda_2 > \lambda_1$), N the order difference, *i.e.*, the number of complete cycles between λ_1 and λ_2, and n the refractive index. The ellipsometer result may be used for the index; Fig. 1 shows that the absorption edge is so sharp that λ_a is not very sensitive to thickness. A 10% error in thickness results in ~3% error in Si/N ratio.

Results and Discussion

In Fig. 2 the results for composition are plotted *vs.* λ_a. Error bars shown are for 2σ limits. It is evident that the wavelength of the absorption edge, as defined here, is indeed a good index of plasma nitride film Si/N ratio, at least in the range of deposition conditions which we used.

Because of the variety of deposition parameters which can influence film composition, we would caution

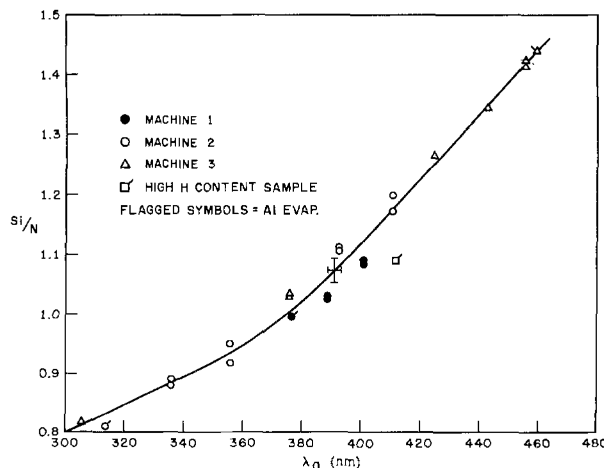

Fig. 2. Correlation of electron microprobe analyses and optical absorption edge. 2σ error bars are shown.

against accepting Fig. 2 as a calibration curve until it is confirmed that it is valid for the particular equipment. Figure 2 covers a wide range of compositions made with some variations in power as well, but there can be no guarantee that it is perfectly general. We believe, however, that for any mode of operation one can establish a Si/N *vs.* λ_a curve as we describe. Note that the one point departing considerably from the Fig. 2 curve represents a sample made under conditions quite different from the normal ones, *i.e.*, five times the SiH_4 concentration, 1/4 the pressure, and twice the deposition rate. Infrared spectra have established that this film contained roughly 50% more hydrogen than usual. Since neither Si-H nor N-H bonding is expected to absorb at >250 nm, the result of having less excess elemental Si, *i.e.*, fewer Si-Si bonds, than usual for a film of given Si/N should be less absorption. This reasoning is evidently naive, since the sample clearly has greater absorption than would be expected for Si/N = 1.1.

The point is emphasized by Fig. 3. Here we show absorption curves for amorphous silicon (6), pyrolytic Si_3N_4 (1), and four typical intermediate plasma nitride compositions. The calculated curve for Si/N = 1.25 [H. R. Philipp, (1)] is based on the statistical probability of each of the allowable types of Si tetrahedral bonding for that composition. The assumption is made that there are no N-N bonds and that all absorption at <5 eV is due to Si-Si bonding. Since the absorption curve for amorphous 100% Si is known, this "bond-counting" approach provides a prediction for the absorption of any composition between the two extremes of Si and stoichiometric Si_3N_4. Any success of such a model, *e.g.*, for SiO_x (2, 6), is evidence that intermediate compounds are not simple mixtures of the extremes of the range but rather an atomic-scale blending or polymer. The absorption curves for plasma nitrides do indeed occupy a position intermediate between those of Si and Si_3N_4; however, agreement with the random bonding model is not very good. In all cases, the plasma

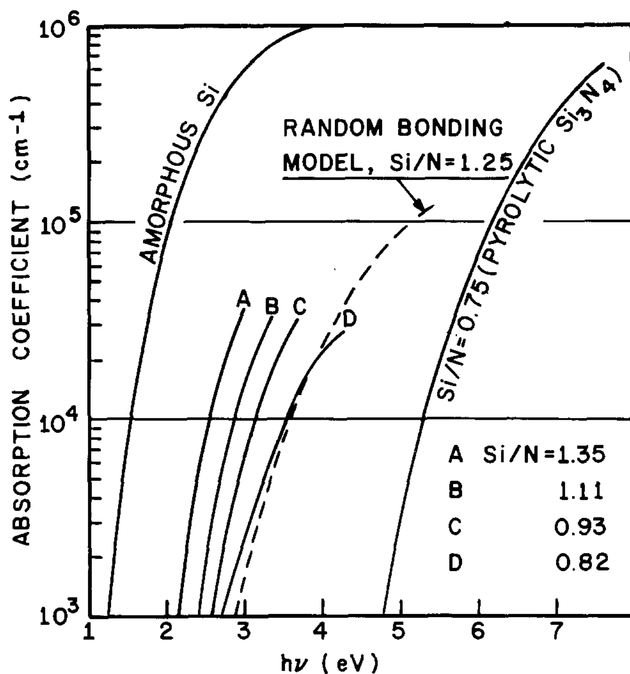

Fig. 3. Optical absorption of various compositions in the range between amorphous Si and stoichiometric Si_3N_4. A, B, C, and D are curves for plasma SiN films from this work.

nitrides have too much absorption for their Si/N ratios. Curve D (Si/N = 0.82) is rather far removed from the curve for Si/N = 0.75, and obviously pyrolytic Si_3N_4 would never fit on the curve of Fig. 2. The calculated curve for Si/N = 1.25 actually fits a plasma nitride curve for Si/N = 0.8.

It is beyond the scope of this report to investigate the optical properties of plasma nitride films in any fundamental or systematic fashion. It seems certain that something more than excess silicon is responsible for absorption in the near ultraviolet region. The most likely cause is severe distortion of the structure, in terms of bond distances and angles. This would shift the edges of the absorption band markedly. A 20% energy difference is not excessive for changing from rings of tetrahedra (Si_3N_4) to the random three-dimensional atomic network which might very well represent this plasma polymer. Furthermore, the presence of hydrogen as a major component (7) can only serve to increase the extent of dislocation and strain the structure even further. Our results support what has been amply demonstrated by now: that plasma-polymerized "silicon nitride" bears little resemblance in structure and properties to pyrolytically deposited Si_3N_4 and should, therefore, be evaluated as a unique material.

Summary

The composition and properties of plasma silicon nitride are sensitive to variations in many deposition parameters. A rapid and simple control test to measure or infer film composition is needed. The position of a defined optical absorption edge in the near ultraviolet and visible meets this requirement over a quite broad Si/N ratio range. A typical calibration curve and the procedure are given; film thickness is determined at the same time. With a rough refractive index available, a commercial spectrophotometer is the only instrument required, and computations are simple. The existence of relatively low energy optical absorption is considered evidence for a highly distorted and irregular structure compared with that of pyrolytic Si_3N_4.

The Preparation and Low Energy Electron (LEE) Excitation of SnO_2:Eu Powder Phosphor

T. Matsuoka, Y. Kasahara, M. Tsuchiya, T. Nitta,* and S. Hayakawa

Matsushita Electric Industrial Company Limited, Materials Research Laboratories, 1006 Kadoma, Osaka, Japan

ABSTRACT

We carried out an investigation on preparation and low energy electron (LEE) luminescence of SnO_2:Eu powder phosphors. Solid powder mixing, hydroxide coprecipitation, and oxalate coprecipitation methods were examined for preparation. The oxalate method was found to give best results. SnO_2:Eu powder phosphors made with 0.5 atomic percent (a/o) and more Eu contained $Eu_2Sn_2O_7$ as separate phase. No change of the lattice parameters could be observed up to 8 a/o of added Eu. The amount of Eu actually dissolved in the SnO_2 lattice is estimated to be between 0.05 and 0.5 a/o of Eu/Sn. Cathodoluminescence of SnO_2:Eu phosphors was examined at high and at low excitation voltage. Measured emission spectra did not show green and blue emission lines due to transitions from $^5D_1$ and higher states, in contrast to observations on single crystals by Crabtree. SnO_2:Eu phosphors show orange-red emission without any charge-up effect when excited by electrons as low as 10V. The luminous efficiency was about 0.2-1 lumens/W for various excitation voltages and pulse duties.

Stannic oxide, SnO_2, is widely used as a metal oxide resistor in electronic applications, for transparent electrically conducting coatings on glass, and as u.v. sensor utilizing its photoconducting properties. However, studies of SnO_2 as a phosphor host material are comparatively rare.

Hall *et al.* (1) observed cathodoluminescent emission bands due to Ti and W at ~565 and 440 nm, respectively, in zoned cassiterites of hydrothermal origin. The cathodoluminescence of SnO_2 single crystals doped with Eu and Tb was studied in detail by Crabtree (2, 3). He used crystals grown by vapor phase transport and then doped with Eu or Tb. The emission spectrum contained a broad band of the host material, and lines due to the presence of Eu^{3+} and Tb^{3+} ions. He also studied photo-, cathodo-, and thermoluminescence of Tb-doped SnO_2 crystals containing Li, H, or P as charge compensation and of SnO_2 crystals doped with various amounts of Eu without or with interstitial Li^+ as charge compensation (4-6). Although there are several other reports on SnO_2 phosphors more or less similar to the ones above, we are not aware of studies on low energy electron excitation of these materials.

ZnO phosphors are known for LEE excitation (7-9) and have recently been studied as display tube phosphors excited by LEE from a gas plasma (10, 11). In fact, ZnO is widely used for α-numeric display devices (pocket calculators, etc.) because of its low dead voltage and high efficiency under LEE excitation. However, the emission color of ZnO is restricted to bluish-green. A search for phosphors emitting in other colors with reasonably high efficiencies under LEE excitation had been fruitless (12).

A phosphor suitable for LEE excitation must have low dead voltage and either low electrical dark resistivity or some photoconduction. Most common phosphors do not meet these requirements. Even if they have low dead voltage, they are highly electrically insulating and charge up very rapidly under LEE excitation because of a secondary-electron emission coefficient below unity at low voltage. The resistivity of a phosphor for LEE application must be low to prevent the phosphor screen from charging up negatively.

The present study was done to work out the preparation conditions of SnO_2:Eu powder phosphors and to study their cathodoluminescence. The emission under LEE excitation is affected by the semi- and photoconductive properties of the SnO_2. We have established that SnO_2:Eu phosphors emit a steady reddish-orange emission under excitation by LEE as low as 10V.

Experimental Procedures

Preparation of powder phosphors.—A representative experimental procedure is as follows. 1/5 mole of $SnCl_2 \cdot 2H_2O$ and europium chloride in the concentrations of 0, 0.05, 0.5, 1, 3, and 8 a/o were dissolved in 400 cm^3 ethyl alcohol. 35g of $(NH_4)_2C_2O_4 \cdot H_2O$ were dissolved in 750 cm^3 water at 60°C. The chloride solution was then added to the oxalate solution while vigorously stirring. The suspension was kept at 60°C for about 5 min after which the precipitate was filtered, washed, and dried. The dry powders were fired in vitreous quartz boats in oxygen for 2 hr at 1000°-1300°C.

Two other methods of oxalate precipitation were tested. One of them is to use 0.1*N* HCl in water as a solvent of $SnCl_2 \cdot 2H_2O$ and europium chloride, and a solution of $H_2C_2O_4 \cdot 2H_2O$ in water. The precipitation was carried out at room temperature in this case. Another method used a solution of CH_3COOH in water as solvent for the $SnCl_2 \cdot 2H_2O$ and the europium chloride, and $(NH_4)_2C_2O_4 \cdot H_2O$ dissolved in water. The precipitate in this case was held at 80°C for 30 min while stirring. The *p*H of this mixed solution was kept at about 3-4 by the buffer action of the CH_3COONH_4-CH_3COOH system. Both methods were found to give the same final phosphors as the alcohol method. The latter is preferred nevertheless because of the low solubility of the oxalate.

Two different preparation methods of solid powder mixing and hydroxide coprecipitation were also examined. The solid powder mixing method was found to be poorly reproducible and the resulting phosphors were not bright. The oxalate methods were found to give better precipitates of larger particle sizes, better stability at drying, higher activity during subsequent firing, and generally easier preparation and handling than the hydroxide method.

Measurements.—DTA and TGA measurements, electron microscope, and x-ray powder diffraction were carried out to examine the properties of the powders at various stages of preparation.

The cathodoluminescence of the completed phosphors was tested at 10 kV excitation voltage. Dry phosphor layers in a copper tray were bombarded

Key words: SnO_2:Eu powder phosphor, LEE excitation, oxalate coprecipitation methods.

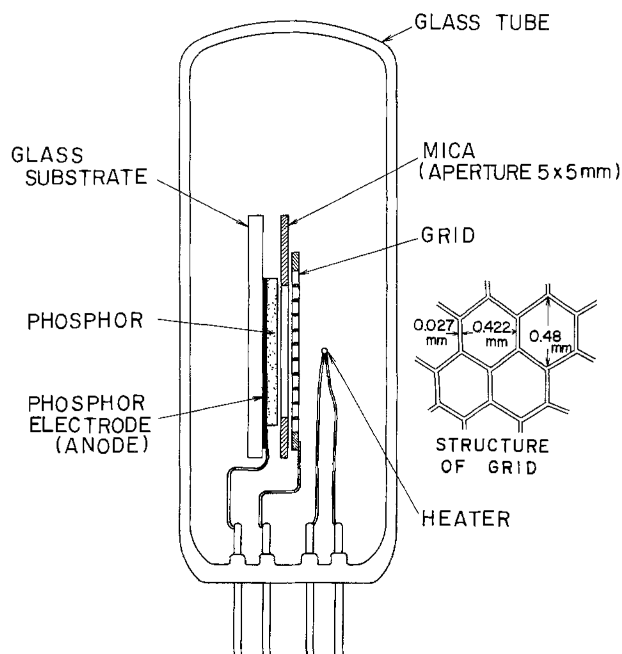

Fig. 1. Schematic of the device used to measure LEE cathodoluminescence.

with d-c electrons from a modified TV-gun at room temperature with a current density of 2.8 $\mu A/cm^2$. A grating spectrometer with 0.1 mm slits and a S-10 photomultiplier were used for emission spectrum measurements.

A schematic diagram of the device to study LEE excitation is shown in Fig. 1. The phosphor was coated at a density of 3 mg/cm^2 on a glass plate coated with a conducting SnO_2 electrode using a centrifugal settling method (3000 rpm) with pure water as dispersing agent. No binder was used. The region actually bombarded with electrons is an aperture area of 5 $\times$ 5 mm size. The grid in front of the phosphor layer is made of stainless steel 60 μm thick and has a honeycomb-like structure as shown in Fig. 1.

The glass substrate coated with the phosphor, the mica aperture, and the grid were annealed at 350°C for 30 min in an atmosphere of 10% H_2 + 90% N_2 at 1 atm pressure. This structure and the heater were then mounted to the electrodes in a glass stem of a TV cathode ray tube. The stem was covered with a glass cap and fused together. The tube was exhausted to below 10^{-6} Torr while heating to 200°C, then the heater coated with $BaCO_3$, $SrCO_3$, and $MgCO_3$ was activated by heating, causing decomposition of the carbonates to the oxides. The tube finally was sealed and the getter operated.

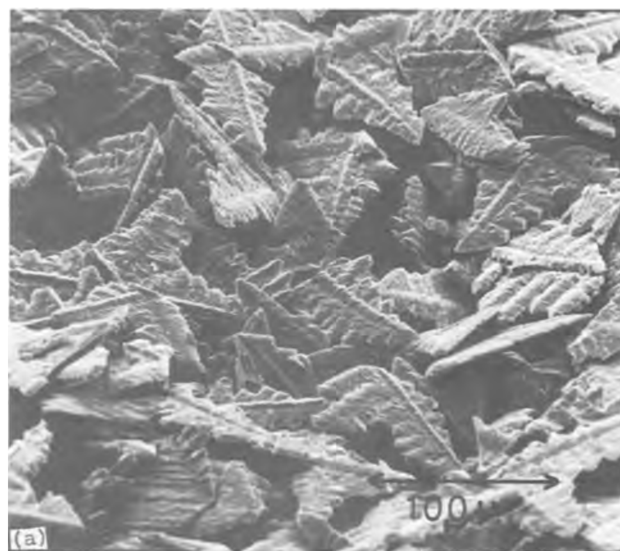
Results and Discussion

Preparational characteristics.—DTA and TGA of thermal decomposition of 36.8 mg of pure SnC_2O_4 in air at a heating rate of 600°C/hr were examined to establish the lowest permissible firing temperature. A decomposition starts gradually at about 245°C accompanied by a broad endothermic peak. More rapid decomposition between 322° and 360°C is indicated by two large exothermic peaks and a strong reduction in weight. The latter is complete already at 345°C and is only 10.8 mg which is smaller than the theoretical decrease of 12.8 mg of a reaction $SnC_2O_4 \rightarrow SnO + CO_2 + CO$ probably because of an oxidation reaction $SnO + \frac{1}{2} O_2 \rightarrow SnO_2$ taking place simultaneously. The two large exothermic peaks are believed to be the result of a superposition of the endothermic reaction of the decomposition of the oxalate and the exothermic reaction of the combustion of CO produced by the oxalate. Also the exothermic reaction of the oxidation of SnO to SnO_2 probably is involved because of the small rapid increase in weight just after 345°C. The latter reaction apparently is still incomplete and is completed only at increasingly higher temperature because of a broad exothermic peak around 500°C and the slow increase in weight above 360°C. The over-all weight decrease up to 655°C is 10.3 mg, coinciding with the theoretical weight loss in the reaction $SnC_2O_4 \rightarrow SnO_2$.

Also an oxalate precipitate containing 8 a/o of Eu in a sample weight of 20 mg was examined by DTA and TGA. A new small endothermic peak was observed at about 210°C and the starting and completion temperatures of the decomposition and oxidation reaction were 311° and 331°C, respectively, both lower than those in case of pure SnC_2O_4. No other difference was observed.

These oxalate precipitations showed a uniform reddish-orange luminescence under u.v. and under electron excitation after firing at 1000°C for 2 hr in oxygen. The actual phosphors were fired at 1300°C, however. When an alumina boat was used for the firing, the boat was destroyed by the thermal shock of the vigorous exothermal reaction. Therefore these samples were fired in quartz boats.

Particles of an oxalate precipitate containing 1 a/o Eu are shown in Fig. 2(a). Each particle has leaf-like shape approximately 60 μm long, 30 μm wide, and 7-8 μm thick. Generally, increasing Eu concentra-



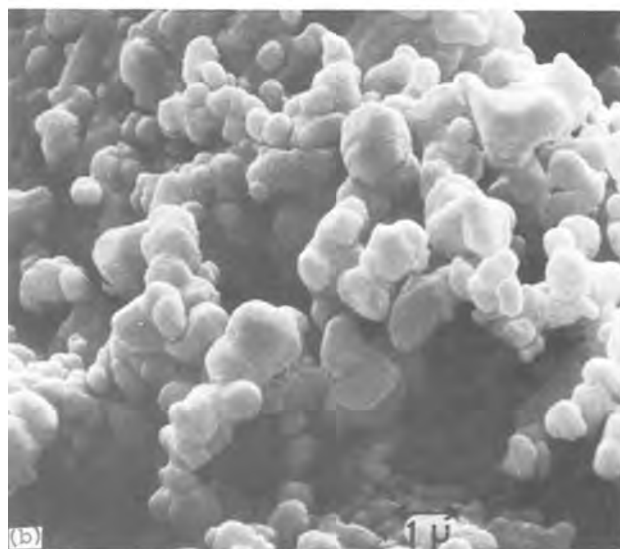


Fig. 2. Particles of precipitated SnC_2O_4:Eu(1%), (a) and particles after firing in oxygen for 2 hr at 1300°C(b).

tion caused smaller particles of more irregular shapes. Particles of the same material, containing 1 a/o Eu after firing for 2 hr at 1300° in oxygen are shown in Fig. 2(b). The particle size from 0.5 to 1.5 μm of this phosphor is smaller than that of the oxalate before firing.

X-ray powder diffraction spectra were taken of all precipitates. The weak diffraction peaks of pure SnC_2O_4 become still weaker with increasing Eu concentration but no change of the d value could be observed up to 8 a/o Eu. However, a new peak at $d = 6.06Å$ was observed at 8 a/o Eu. We believe that Eu is incorporated up to about 3 a/o in the SnC_2O_4 but cannot explain the absence of any shift of the d value with increasing Eu concentration in the diffraction patterns.

Results of similar x-ray powder diffraction measurements of completed phosphors are summarized in Table I. All samples containing 0.5 a/o and more Eu show pyrochlore-type $Eu_2Sn_2O_7$ as minor phase. No change of the lattice parameters with increasing Eu was observed. We conclude that Eu is soluble in SnO_2 to a concentration between 0.05 and 0.5 a/o.

High energy electron excitation.—Studies of cathodoluminescence were restricted to phosphors prepared by the oxalate method. All these phosphors were fired for 2 hr at 1300°C in oxygen.

Figure 3 shows an emission spectrum of pure SnO_2. It extends from about 350 nm in the ultraviolet to about 750 nm in the infrared with a maximum at about 500-520 nm. Its whitish-blue color agrees with that reported by Crabtree on single crystals (2) although Crabtree mentions an intensity maximum at about 600 nm.

An emission spectrum of SnO_2:0.05% Eu is shown in Fig. 4. The emission of pure SnO_2 is completely suppressed now in agreement with Crabtree's observation on single crystals. The most intense emission corresponds to $^5D_0$-$^7F_1$ transitions. Emission contributions due to $^5D_0$-$^7F_0$, $^5D_0$-$^7F_2$, and $^5D_1$-$^7F_4$ transitions are much weaker. No appreciable emission was observed at shorter wavelengths below 580 nm.

The emission spectrum does not appreciably change with increase of the added Eu concentration up to 8 a/o. Only the emission due to $^5D_0$-$^7F_0$ transition increases somewhat relative to the others. For instance, the intensity ratio of $^5D_0$-$^7F_0$ compared to $^5D_0$-$^7F_1$ emission was about doubled at 8% Eu compared to 0.05% Eu. No shorter wavelength emission from $^5D_1$ or higher energy states was observed, in contrast to Crabtree's observations on single crystals. The second phase, $Eu_2Sn_2O_7$ of pyrochlore structure, observed at higher Eu concentrations did not contribute to any visible emission.

Figure 5 shows the voltage dependence of the brightness of cathodoluminescence. This characteristic is different for different Eu additions. The phosphor containing 0.05 a/o Eu increases linearly in brightness up to about 15 kV and saturates above this voltage. The highest brightness was observed on a phosphor containing 1 a/o of added Eu; still higher Eu concentrations cause lower brightnesses. The saturation voltage decreases with increasing Eu concentration. Since the phosphors containing 0.5% and more Eu contain $Eu_2Sn_2O_7$ as separate phase (Table I), some influence of this phase on brightness and saturation voltage can certainly be expected. The decrease of saturation voltage with increase of Eu is considered to be due to lowering of second unity intercept (second crossover voltage) of the secondary-emission ratio *vs.* voltage curves by the coexistence of $Eu_2Sn_2O_7$ where phosphors normally saturate because of negative charge-up in still higher voltage. It is difficult to consider the dead core in each phosphor particle since the saturation voltage rather decreases with increasing of Eu. It is hard to explain all details.

The linear portions of all brightness-voltage curves extrapolate to finite brightnesses. This follows to

Table I. Results of x-ray powder diffraction analysis of SnO_2:Eu phosphors prepared by firing oxalate precipitates in oxygen for 2 hr at 1300°C

No.	Amount of Eu (a/o)	Phases observed	Lattice constant a (A)	c (A)

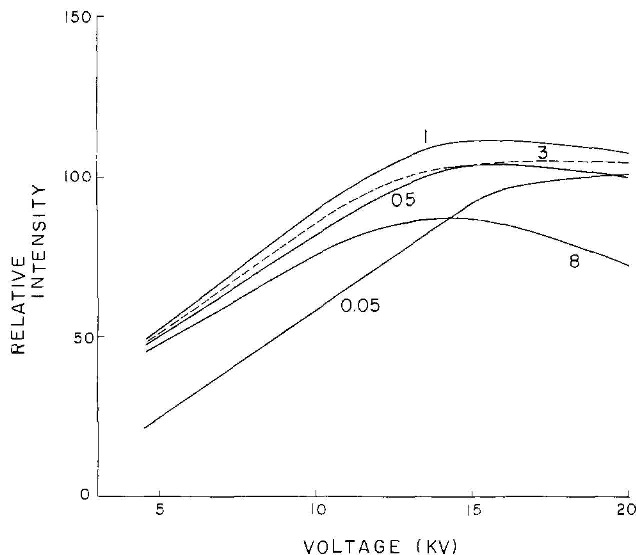

Fig. 5. Brightness-voltage dependence of cathodoluminescence of SnO_2:Eu phosphors. Numbers denote a/o Eu/Sn.

the surface-sensitive particles of the phosphors corresponding to the nonuniform structure particularly at shallow surface region (<0.09 μm from Terrill's equation) as expected from voltage less than 5 kV, but we have no reliable proof supporting this assumption.

The visible brightness of SnO_2:Eu containing 1 a/o of added Eu was compared to that of a commercial Y_2O_2S:5% Eu phosphor and found to be about 20% of the latter at 2.5 kV and 16% at 5 kV. The energy efficiency is somewhat lower, about 10% of that of Y_2O_2S:Eu, because of the different emission spectra.

Low energy electron excitation.—This study was limited to an SnO_2:0.05% Eu phosphor containing no $Eu_2Sn_2O_7$ as separate phase. Its luminescence characteristics under LEE excitation are shown in Fig. 6 as function of V_A (anode voltage) or V_G (grid voltage). Anode and grid were connected so that $V_A = V_G$. The three different duty cycles are excitation by 16.7 μsec pulses repeated every 267 μsec; (duty 1/16, left-hand curves), every 16.7 msec; (duty 1/1000, center curves), and every 167 msec; (duty 1/10,000, right-hand curves). Anode current, I_A, and grid current, I_G, are the currents during the 16.7 μsec pulses, B is the brightness, and η is the luminous efficiency in lumens/W. A heater voltage of 0.9 to 1.0V was used.

The phosphor showed a brightness of 7.5 f-L and an efficiency of 0.3 lumens/W at $V_A = V_G = 50V$, $I_A = 2$ mA, and the duty 1/16. A commercial ZnO:Zn phosphor familiar for LEE excitation applications gave 45 f-L and 2 lumens/W under the same conditions of excitation. When the exciting voltage was raised to 100V and the duty decreased to 1/1000, the SnO_2:Eu phosphor gave $B = 1.8$ f-L, $I_A = 5$ mA, and $\eta = 0.97$ lumens/W. For comparison again the ZnO:Zn phosphor excited under these same conditions gave $B = 4.2$ f-L, $I_A = 5$ mA, and $\eta = 2$ lumens/W. The efficiency of the SnO_2:Eu phosphor became about half of that of the ZnO:Zn phosphor. D.c. excitation of the SnO_2:Eu phosphor gave 60 f-L brightness and 0.18 lumens/W efficiency at $V_A = V_G = 75V$ and $I_A = 1.2$ mA.

The decay time (to 10%) of the luminescence following excitation by 16.7 μsec pulses depends on the excitation voltage (Fig. 7). It is fairly long, about 10 msec, at low voltage but decreases rapidly with increasing voltage above about 300V. The reason for this unexpected long afterglow is not clear. ZnO:Zn does not show a similar dependence of its afterglow on the excitation voltage. However, we believe the long decay of the SnO_2:Eu phosphor to be involved in the increase of the efficiency at 100V when going from duty 1/16 to duty 1/1000 (Fig. 6). Details are not understood.

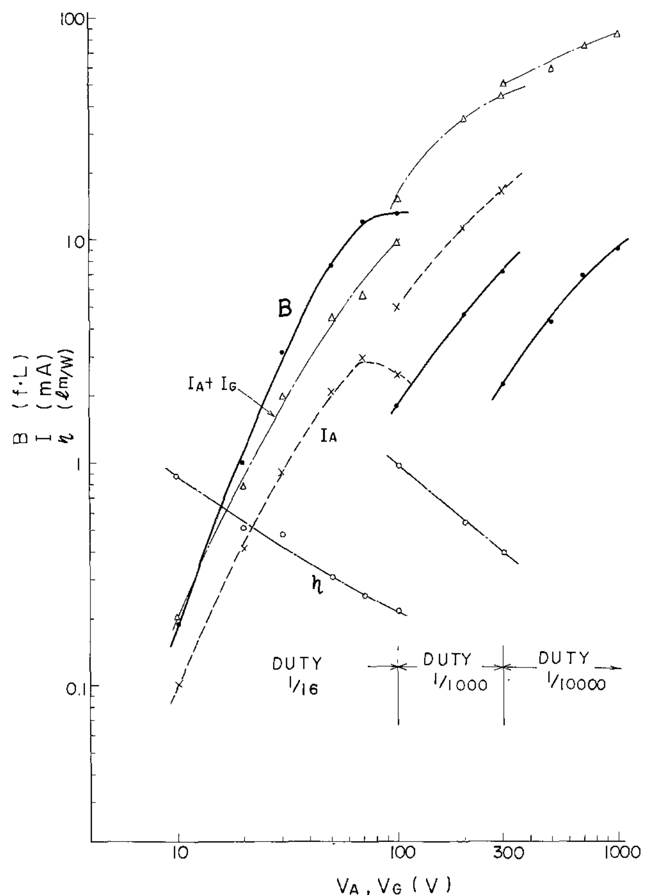

Fig. 6. Cathodoluminescent properties of SnO_2:Eu(0.05%) excited by low energy electrons.

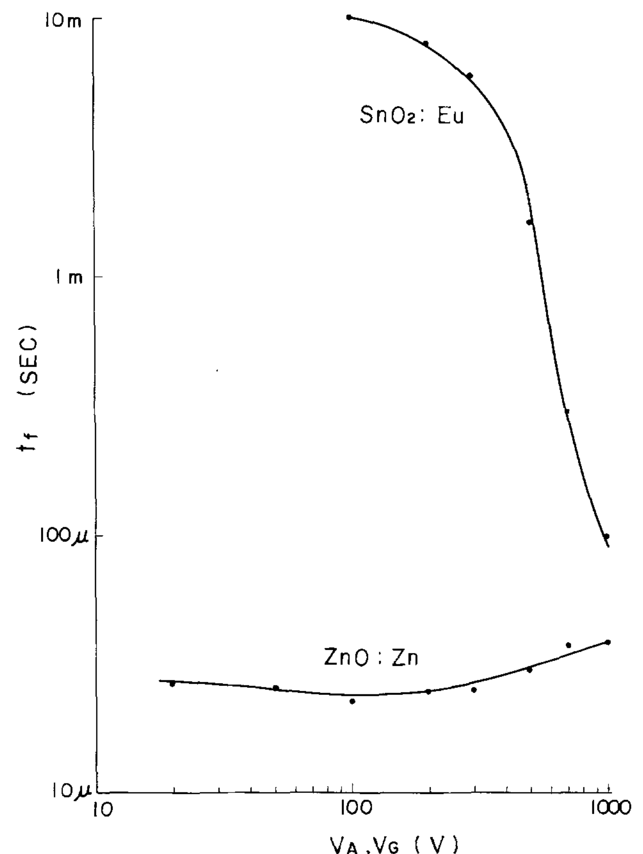

Fig. 7. Afterglow times of SnO_2:Eu(0.05%) and of ZnO:Zn

Summary and Conclusions

The most useful preparation technique of SnO_2:Eu phosphor is by coprecipitation as the oxalate followed by firing at high temperature. The higher the firing temperature, the longer the firing time, and the slower the cooling rate after firing, the more efficient is the final phosphor. In practice, firing for 2 hr at 1300°C in oxygen is sufficient. The maximum Eu concentration under these conditions incorporated in the SnO_2 lattice is between 0.05 and 0.5 a/o.

Cathodoluminescence of pure SnO_2 shows bluish-white emission of a very broad band extending from about 350 to 750 nm. SnO_2:Eu shows only the europium emission, most of it occurring in lines corresponding to $^5D_0$-$^7F_1$ transitions. This implies centrosymmetrical site symmetry such as D_{2h} or C_{2h}. Emission at shorter wavelengths corresponding to transitions from $^5D_1$ or other levels were not observed. The brightness of cathodoluminescence appears to saturate with increasingly high excitation voltage above about 15 kV, depending somewhat on the added europium amount. The energy efficiency of the SnO_2:Eu phosphor performing best under high energy excitation, a material containing 1% of Eu, is estimated to be about 1/10 of that of a commercial Y_2O_2S:Eu phosphor.

SnO_2:Eu phosphors can be excited to steady luminescence by LEE as low as 10V without any charge-up phenomenon. Its luminous efficiency so far is roughly 15-50% of that of ZnO:Zn, the only other phosphor known before suitable for LEE excitation. An SnO_2:Eu phosphor containing 0.05 a/o Eu/Sn shows long afterglow, about 10 msec to 10%, after excitation by electron pulses of 100V; this afterglow shortens considerably with increasingly higher voltage.

SnO_2:Eu phosphors appear to be useful for various applications where excitation by LEE is required as in a He-gas plasma described by Kazan, for instance (9). We provide an additional color, reddish-orange, besides the blue-green of ZnO:Zn. Some improvements can still be expected with further developments. Points under investigation are the optimization of the Eu-concentration, selection of a flux for better particle growth up to 6 ~ 7 μm, addition of sensitizers and charge compensators, and other refinements.

ABSTRACT

The thermodynamic equilibria established in oxidation atmospheres in polycrystalline silicon tubes operated at 1000°C are analyzed. Silicon oxidation tubes made by chemical vapor deposition through hydrogen reduction of pure trichlorosilane have very low sodium content (about 10 ppb or 1000 times less sodium than in transparent fused silica oxidation tubes). Due to the low sodium content in new oxidation tubes, clean (low alkali content) thermal oxide films can be grown on silicon wafers. However, tube contamination developed during semiconductor processing operations imposes the need for appropriate periodic tube cleaning to maintain sodium contamination in the oxidation atmosphere within acceptable levels. Tube cleaning reactions taking place at oxidation temperature are discussed showing that the quality of thermal oxide films is influenced by tube cleaning efficiency.

Preparation of thermally grown clean oxide films on silicon wafers has great technological impact on successful microelectronic device fabrication. Although the understanding of the role played by alkali ions in such films is not complete, especially concerning the behavior of electrically "active" and "inactive" contamination (1), the presence of alkali species in thermally grown silicon dioxide films has been ex-

Key words: alkali contamination, clean SiO_2 film, microelectronic device preparation, MOS structures.

perimentally demonstrated to cause ionic conductivity and consequently instabilities in metal-oxide semiconductor (MOS) devices (2-5). The presence of sodium and other alkali species in thermally grown oxide films used for semiconductor device preparation has been extensively investigated (6-8). Sources of alkali contamination have also been investigated in processing materials (9-13), in oxidation furnace refractories (14), and in evaporated gate metal films (15). Addition of about 5% chlorine or hydrogen-chloride to the oxidation atmosphere has been reported to enhance the electrical stability of Si-SiO_2 structures, both through cleaning and passivating effects (16-22). HCl diluted in an inert gas carrier (concentration up to 10%) is used for periods of several hours immediately before oxidations to produce low mobile-ion content thermal oxide films for MOS device fabrication.

In a recent paper (23) the development of sodium contamination in oxidation atmospheres contained in transparent fused silica tubes operated at 1000°C was analyzed thermodynamically in terms of the impurity content primarily included in fused silica bulk resulting from the tube manufacturing process. Transparent fused silica tubes currently used in most semiconductor processing furnaces contain about 10 ppm sodium (24-25). *In situ* cleaning of fused silica tubes at 1300°K results in removal of material from the inner tube wall surface creating a sodium-depleted layer. This in turn reduces the sodium content in the oxidation ambient, allowing the thermal growth of cleaner oxide films on silicon wafers. However, due to its high diffusivity in SiO_2 [$D = 2 \times 10^{-6}$ cm²/sec at 1000°C (26)] sodium from furnace refractories or from the room atmosphere around the oxidation tube may be incorporated into the fused silica wall contributing to the maintenance of its contamination level. When fused silica oxidation tubes are replaced by silicon tubes, the conditions established in the oxidation ambient are expected to be more favorable for growing clean thermal oxide films on silicon wafers. This is caused by the low sodium content in silicon tubes fabricated by chemical vapor deposition through hydrogen reduction of trichlorosilane. This process produces high purity polysilicon with only 10 ppb sodium contamination, 1000 times less sodium content than in fused silica tubes (28). However, due to external contamination sources (*i.e.*, sodium from refractories and room ambient), periodic *in situ* cleaning of the tube is necessary to maintain appropriate conditions in the oxidation atmosphere. The cleaning interval for both fused silica or silicon tubes is determined by the boundary conditions at the tube wall outer surface and the diffusion of sodium in the tube wall. The diffusion coefficient of sodium in polycrystalline silicon is higher than in single crystal silicon due to grain boundary effects. At 1000°C the latter is $D = 3 \times 10^{-6}$ cm²/sec (26). Similar effects were reported on the diffusion of boron in silicon at 1050°C (27).

The work presented here is an extension of the previous analysis on the behavior of fused silica oxidation tubes at 1000°C (23).[1] Silicon oxidation tube behavior resembles the fused silica tube behavior except for the initial low sodium content when the tube is new. The effects of HCl cleaning on these tubes are also analyzed.

Oxidation of Silicon Wafers in Silicon Oxidation Tubes

The kinetics of silicon oxidation have been extensively studied by different authors for a number of temperatures in the range of 800°-1200°C and for several oxidation atmosphere compositions contained in fused silica tubes [most early work on this subject is listed in bibliographic compilations on MOS technology (9, 30)]. It was shown that the addition of trace amounts of water to the oxidation ambient causes a significant increase of silicon oxidation rate for all silicon orientations (31). It has also been shown that the equilibrium sodium density in oxidation atmospheres at 1300°K significantly increases when a few ppm water are added to the oxidation atmosphere (23). From these results it can be stated that the preparation of clean, low mobile ion content oxide films on silicon wafers is controlled primarily by four parameters: the oxidation temperature, the amount of sodium (in general, alkali) contamination in the tube wall bulk, the amount of water content in the oxidation atmosphere, and the furnace environment. The use of strictly controlled hydrocarbon-free dry oxygen in addition to alkali-free oxidation tubes operated at high temperatures (above 1000°C) may result in clean thermal oxide preparations if appropriate care is taken concerning clean room environments around oxidation facilities. For high temperature (close to 1200°C) processes where devitrification of fused silica may produce serious problems, silicon tubes are preferred due to their better mechanical behavior and low sodium contamination level.

In the present work, the equilibrium atmosphere established at 1300°K in a silicon oxidation tube was studied theoretically for a number of cases of practical interest.[2] Table I shows the equilibrium atmo-

[1] For these thermodynamic calculations data at 1300°K are used.
[2] The scheme for these calculations is outlined in the appendix of Ref. 23. Because of errors and approximations involved in thermodynamic data used to evaluate the equilibrium results, an absolute error of ±50% could be expected in these calculations. The relative error is much smaller.

* Rapid formation of a silica film on the silicon tube.

sphere resulting in a typical silicon oxidation tube operated at 1300°K using pure oxygen at 1 atm plus 100 ppm water. Sodium in the tube wall might be assumed to be sodium metasilicate [$Na_2O \cdot SiO_2(c)$] and sodium silicate [$Na_2O \cdot 2SiO_2(c)$]. Measurements of sodium vaporization from silica glasses (32) indicate that sodium metasilicate might be dominant; deviations of the value $\Delta H°_{f298} = -376.8$ kcal/mole calculated for $Na_2O \cdot SiO_2(c)$ from the JANAF value (33) is ascribed to solution effects of $Na_2O \cdot xSiO_2$ species. Silicon and water react to form $SiO_2(c)$ (equilibrium reaction constant $K = 1.33 \times 10^{13}$). Sodium metasilicate is incorporated in the oxide film developed on the tube wall and evaporates to build up in the oxidation chamber an atmosphere containing about 10^8 sodium atoms/cm^3, including both atomic and molecular species; NaOH is the most abundant compound. If no water is present in the oxidation ambient, the sodium content is negligible [$P(Na_2O) = 7.9 \times 10^{-28}$ atm]. This condition prevails as long as the sodium level in silicon bulk is only 10 ppb.

Oxidation Tube Cleaning

Periodic *in situ* cleaning at oxidation temperature is required to keep silicon oxidation tubes clean under operative conditions. Dilute hydrogen chloride is generally used for rather long periods in the oxidation chamber to assure proper cleaning of the wall. Assuming 100 ppm water (10^{-4} atm) in addition to 10% HCl in a silicon tube operated at 1300°K, the relevant reactions occurring are shown in Table II. Sodium chloride is formed from the interaction with sodium glasses contained in the silica film formed on the silicon tube wall. At equilibrium, the sodium number density in the atmosphere is 3.66×10^{15} atoms/cm^3. This is 10^7 times larger than the equilibrium sodium density normally present in the oxidation ambient. It should be emphasized that these results refer to equilibrium conditions. Although most reactions proceed rapidly at the inner tube wall surface, diffusion effects in the bulk may limit to some extent the applicability of this analysis. However, the enhanced sodium diffusion in polysilicon will reduce this limitation. The density of the resulting species at the surface could be lower, thus reducing the amount of sodium (or other species) actually removed. No attempts are made here to explore the kinetics of these reactions although it can be seen that hydrogen chloride cleaning is predicted to be very effective in agreement with current empirical observation.

The use of dry chlorine as a cleaning agent of silicon tubes should be avoided because of the risk involved due to its high reactivity with silicon. Table III shows that the tube could be severely damaged by chlorine if the protective silica film deposited on the inner tube wall has pinholes through which chlorine may come in contact with silicon to produce quantities of $SiCl_4(g)$, $SiCl_3(g)$, and $SiCl_2(g)$. However, if water is present in the system, hydrogen chloride is generated, moderating the aggressive behavior of dry chlorine.

Oxidation Tube Conditioning

The silica film formed on the tube wall can be removed by hydrogen at oxidation temperature. The formation of water generated through the hydrogen silica interaction contributes to the leaching of sodium from the tube bulk. Table IV shows the relevant reactions taking place in the tube when 100 ppm water (10^{-4} atm) is present in the hydrogen atmosphere. Sodium compounds such as NaO, Na_2O, NaOH, and $Na_2(OH)_2$ are formed in addition to atomic sodium. The total sodium equilibrium pressure in the tube atmosphere is 1.82×10^{-8} atm resulting in a number density of 1.03×10^{11} atoms/cm^3 where the atomic species is the most abundant one due to the reducing action of hydrogen. Although the use of hydrogen around an oxidation facility involves risks and difficulties which may make it impractical, it is of value to observe that the use of diluted (less than 4%) hydrogen in an inert gas carrier could make this procedure feasible by eliminating the risk of forming an explosive air-hydrogen mixture. If such an atmosphere is maintained in silicon oxidation tubes when they are

[1] ΔH°_{f298} = standard enthalpy of formation.
[2] $(G^\circ_T = H^\circ_{298})/T$ = Gibbs energy function in the standard state at 1300°K.
[3] The value of ΔH°_{f298} for $Na_2O \cdot SiO_2$ (in SiO_2) was calculated using the equilibrium constant from reaction $Na_2O \cdot SiO_2$ (in SiO_2) $\rightarrow 2Na(g) + ½\,O_2(g) + SiO_2(c)$, $K = 2.5 \times 10^{-19}$ [see Ref. (32)]. The free energy function was assumed to be that of $Na_2O \cdot SiO_2$ (gls) given by the JANAF tables.
[4] The Na_2O data were estimated from various lithium, sodium, and potassium oxides data given in the JANAF tables.
[5] The heats of formation were calculated from bond energies as outlined in Ref. (36). The thermodynamic functions were obtained by interpolation of the values given there.

not being used for semiconductor processing, the sodium impurity from the tube wall bulk and the silica film on the tube are constantly removed from the hot zone. The enhanced sodium diffusion in polysilicon increases the sodium migration into the silica film which is being removed by the hydrogen reducing action. This tube conditioning would reduce the need for periodic HCl cleaning and consequently minimize the incidence of other species (such as chlorine) in the oxidation chamber. Experimental evidence shows that chlorine is incorporated into oxide films thermally grown on silicon wafers processed in oxidation tubes previously cleaned with HCl (34). This has proved to be detrimental for radiation-hard devices resulting in electrical instabilities (35).

Conclusions

The above results show that the dominant factor in the preparation of clean thermal oxides is the purity of the oxidation tube wall if other process steps are kept under strict control. Such processes involve the wafer cleaning and handling prior to oxidation and metallization immediately after oxidation. When recently installed, new silicon tubes have a low sodium content and thus constitute an excellent material to enclose the oxidation atmosphere. This is due to the tube fabrication process (chemical vapor deposition) employing highly purified (low alkali) materials (28). Preparation of clean low mobile ion content thermal oxide films by wet oxidation of silicon wafers is in principle possible if silicon oxidation tubes are used, provided that the tube environment is clean enough to avoid inclusion of ambient contamination in the tube. However, a silicon oxidation tube will tend to develop alkali contamination during normal operation unless special care is taken to isolate it from external contamination. These conditions are hard to maintain even in clean production-oriented facilities, so periodic *in situ* tube cleaning is required. At oxidation temperatures sodium deposited on the exterior of the tube diffuses through the wall into the oxidation atmosphere contaminating the thermal oxide films grown on silicon wafers. The contamination process may be originated by the furnace refractories impurity, the room ambient, and other factors external to the tube. The main advantage of employing silicon oxidation tubes lies in the possibility of using temperatures higher than tolerated by fused silica tubes.

Mechanism of CVD Thin Film SnO_2 Formation

R. N. Ghoshtagore*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

The kinetic mechanism of CVD SnO_2 deposition has been studied for (*i*) $SnCl_4 + O_2$ reaction at 675°-940°C for $p_{SnCl_4} = 1.67 \times 10^{-5}$ to 5.3×10^{-4} atm and $p_{O_2} \geqq 1.04 \times 10^{-3}$ atm, (*ii*) $SnCl_4 + H_2O$ reaction at 400°-807°C for $p_{SnCl_4} = 2.63 \times 10^{-5}$ to 4.2×10^{-4} atm and $p_{H_2O} = 5.2 \times 10^{-5}$ to 4.17×10^{-3} atm, and (*iii*) $Sn(CH_3)_4$ (TMT) + O_2 reaction at 425°-578°C for $p_{TMT} = 3.5 \times 10^{-5}$ to 1.17×10^{-3} atm and $p_{O_2} \geqq 1 \times 10^{-3}$ atm. In combination with the available literature data, the results of the present investigation have been interpreted to show atomic oxygen as the adsorbed species and tin-containing gas as the gaseous reactant in both the direct oxidation reactions (Rideal-Eley mechanism). The hydrolysis reaction is the only thermally unactivated one in the group and proceeds by the collision of $SnCl_4$ molecules on four adsorbed (symmetrically) water molecules on the surface. The open tube cold wall horizontal reactor has been established as an ideal equipment for the kinetic mechanism delineation of all CVD reactions.

The vast influence of solid surfaces on reaction kinetics has been the subject of catalysis for more than a century. But a detailed understanding of the molecular mechanism of such interactions requires a knowledge of chemical reaction equilibria and kinetics, vapor pressures of all the participating species, fluid dynamics of the system, and the adsorption and desorption characteristics (including surface diffusion) of all the chemical entities. So few of these quantities are known for most systems that a complete theoretical and/or experimental analysis of most chemical vapor deposition reactions becomes almost impossible. However, several guidelines are available in this direction (1).

Chemical vapor deposition under large supersaturations or chemical driving force is controlled by growth, producing a fine-grained, roughly random deposit with growth rates tending to approach a maximum as fixed by the slowest (rate-determining) process. Under low supersaturations (fixed by vapor-phase mass transport) nucleation can be rate controlling, preferred-orientation deposits can form (epitaxy or oriented growth), and growth rates can be less than the maximum.

Stannic oxide thin films are currently actively investigated since their high transparency (in the 0.4-1.2μ range) and electrical conductivity would be of unique value in numerous optoelectronic applications (solar cells, MOS sensors, etc.). Although a majority of these films are being formed by CVD, little or no information exists on their heterogeneous deposition kinetics. The kinetics of polycrystalline SnO_2 CVD film deposition explored in this study include O_2 or H_2O vapor reaction of two basic tin sources: (*i*) $SnCl_4$ and (*ii*) tetramethyl tin. The experiments utilize these chemical reactions on a heated amorphous SiO_2 substrate in a conventional horizontal "cold wall" quartz tube reactor at atmospheric pressure. The methodology of the present study has been reported earlier (2).

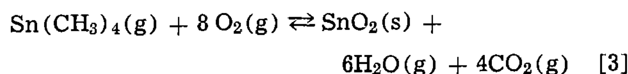
* Electrochemical Society Active Member.

Experimental Technique

Ultrahigh purity stannic chloride or tetramethyl tin (TMT) (Ventron Corporation) in thermostat-held quartz bottles was used as a tin source bubbler through which a carrier gas of ultrapure oxygen or nitrogen was passed at a controlled rate. This gas (saturated with tin source vapor) was then mixed with additional ultrapure oxygen or water vapor (from a quartz bubbler held at 25° ± 0.5°C) and/or nitrogen through a set of calibrated flowmeters, liquid traps, and filters, and the mixture was reacted on a quartz encapsulated high purity graphite susceptor heated by rf induction. The saturation transport of all liquid reactants in this study was carefully checked for the maximum carrier gas flow used by observing growth rate changes as a function of bubbler bath length change (in a multiple bubbler system). The quartz tube reactor used in this study was of 92 mm ID, with the susceptor being 20 × 65 × 320 mm externally. The over-all reactions employed in this work can be described by

$$SnCl_4(g) + O_2(g) \rightleftarrows SnO_2(s) + 2Cl_2(g) \quad [1]$$

$$SnCl_4 + 2H_2O(g) \rightleftarrows SnO_2(s) + 4HCl(g) \quad [2]$$



$$Sn(CH_3)_4(g) + 8\,O_2(g) \rightleftarrows SnO_2(s) + 6H_2O(g) + 4CO_2(g) \quad [3]$$

The free energy changes at different temperatures for reactions [1] and [2] have been calculated (3), whereas that for reaction [3] cannot be calculated due to the unavailability of the thermodynamic data for TMT. The vapor pressure of TMT was obtained from the compilation by Dub (4).

Of the three reactions listed above, the direct oxidation of stannic chloride (Eq. [1]) is the highest temperature reaction examined in the present work. It has also been used here for the CVD SnO_2 film growth for the first time. On the other hand, the high temperature hydrolysis of stannic chloride spray (Eq. [2]) is the classic technique of "Nesa" glass coating. A controlled version of this reaction was reported by Aboaf *et al.* (5) for CVD thin film SnO_2 formation on oxidized silicon. Their films were basically reproduced in this study with added emphasis on the surface reaction kinetics. The direct oxidation of TMT (Eq. [3]) on glass slides and deposited SiO_2 (in a hot wall reactor) was recently studied (6) as a means of producing chlorine-free SnO_2 films. The kinetic data in that work was not optimized for mechanism delineation, however.

The substrates used in this work were uniformly (111), 20-30 Ωcm, 9 ± 1 mil single crystal silicon wafers pyrogenically oxidized at 1100°C to 900 ± 5Å. In most experiments the deposited SnO_2 thickness was ~ 1000Å. Film thicknesses were determined by reference to an ellipsometrically calibrated SiO_2 color chart, assuming an effective deposited film refractive index of 2.0 (see later). All the liquid bubblers were maintained at 25° ± 0.5°C and that of the substrates to ± 5°C (with a calibrated IR pyrometer). All experiments were conducted at the atmospheric pressure. All the films grown were randomly oriented polycrystalline (by electron diffraction) with an average grain size of 0.1-0.3 μm.

Results

Flow rate relationships.—In any kinetic investigation of heterogeneous reactions in a flow system, the examination of the dependence of the rate of formation of the solid reaction product on the flow rates of each of the reactants (while the others are kept constant) is the primary order of business. This information provides the fluid dynamic relationships of the particular experimental system and helps to delineate the surface reaction-controlled region from the mass-transfer controlled region (2, 7). In the absence of a nucleation barrier, at low flow rates the reaction rate is controlled by the gas-phase mass-transfer rate. In this region, the CVD deposition rate is proportional to the half-power of the gas flow rate or the average gas velocity (2, 8) and the reaction is not strongly activated. With increasing flow rates (at constant reactant partial pressure), the boundary layer thickness attains a limiting value, and the Reynolds number and the gas-phase mass-transfer coefficient increase to a value where the reaction is controlled by the chemical surface reaction rate constant. Growth rates are no longer dependent on the flow rates and the reaction becomes highly activated.

The dependence of the tin oxide growth rates on the gas velocities were examined and the surface reaction-controlled activated region determined for all the reactions studied in this work. However, no attempt was made to delineate the mass-transfer controlled region in detail. As expected (2), at all temperatures and rate-determining species partial pressures the measured SnO_2 film growth rates attained a constant value at high flow rates. Boundary layer theory predicts that under such circumstances the gas-phase mass-transfer coefficient is much higher than the surface-reaction rate constant and the reaction kinetics is controlled by an activated process (adsorption, desorption, surface reaction, or nucleation). Within the range of reaction temperatures and stannic chloride partial pressures used, the direct oxidation reaction (Eq. [1]) was established to be flow rate independent at average gas velocities (calculated from volume flow rates) over 10 cm/sec. To be safely beyond the mass-transfer-controlled region, all the kinetic mechanism delineation experiments were conducted at 11.3 cm/sec. The stannic chloride hydrolysis reaction (Eq. [2]) was established to be total flow rate independent at gas velocities over 6 cm/sec in the entire range of reaction temperatures and $SnCl_4$ partial pressures used in this study. All the kinetic data for this reaction were accumulated at an average velocity of 7.2 cm/sec. Finally, the direct oxidation of TMT (Eq. [3]) was flow rate independent at gas velocities above 2 cm/sec, and all the kinetic data were obtained at 2.4 cm/sec.

Reactant partial pressure relationships.—$SnCl_4$ + O_2 reaction.—In the surface reaction-controlled region under 873°C, the deposition rate of SnO_2 was an increasing function of oxygen concentration for any fixed $SnCl_4$ concentration. As shown in Fig. 1, at low oxygen concentrations the reaction is of one-half order, but becomes zero order above a minimum p_{O_2} whose value increases with increasing p_{SnCl_4}, but is independent of temperature. This behavior is identical to that of the direct oxidation of $TiCl_4$ (2). Since the saturated growth rates (Fig. 1) at any two temperatures are disproportional to the corresponding enhancement of tin chloride diffusion rates through the boundary layer

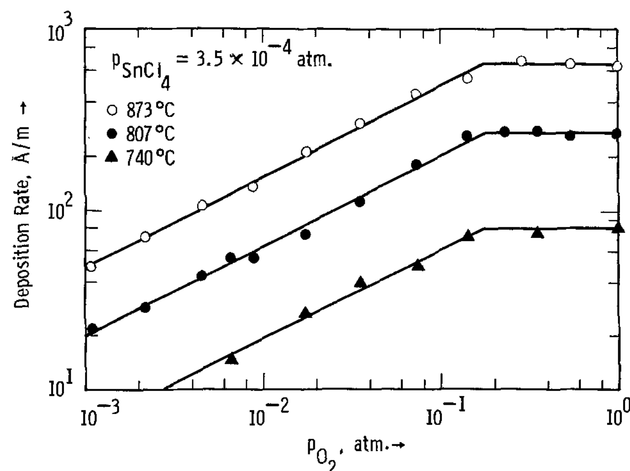


Fig. 1. Oxygen partial pressure dependence of SnO_2 deposition at different temperatures for the $SnCl_4$ + O_2 reaction.

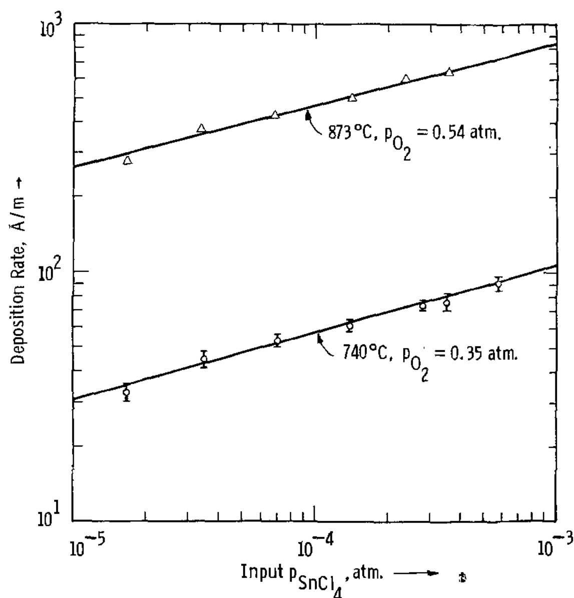

Fig. 2. SnO_2 deposition rate as a function of stannic chloride partial pressure in the p_{O_2} independent range.

(9) and the onset of saturation is not a function of p_{O_2}, it can be concluded that the complete consumption of tin chloride species at the substrate surface is not involved in these experiments.

Figure 2 shows the linear dependence of the SnO_2 deposition rate on the partial pressure of tin chloride at two temperatures and fixed oxygen gas phase concentrations. Since the oxygen partial pressure was fixed high enough in these experiments for the reaction to be of zero order (with respect to oxygen) for the highest p_{SnCl_4} used, no depletion of oxygen is expected in each of these series of experiments. Both at 740° and 873°C, the reaction order is seen to be 0.26 ± 0.01 with respect to $SnCl_4$.

$SnCl_4$ + H_2O reaction.—Figure 3 shows the behavior of the surface deposition rate as a function of water vapor concentration at different p_{SnCl_4}. In the entire range of temperature studied (400°-807°C), the deposition rate increases monotonically with p_{H_2O} to a saturated value at each p_{SnCl_4}. Figure 4 shows the first-order relationship of the surface reaction rate on the stannic chloride concentration. The fixed water vapor concentration (4.17 × 10^{-3} atm) in these experiments was high enough for reaction [2] to be independent of p_{H_2O} (Fig. 3). The data of both Fig. 3 and 4 show no effect of the deposition rate on the substrate temperature. This is further pointed out in Fig. 5, where the minimum water vapor partial pressure required for zero-order SnO_2 deposition (with respect to H_2O) is plotted against the corresponding p_{SnCl_4} at all temperatures studied. In the flow-independent range, the ratio of p_{H_2O} to p_{SnCl_4} is always found to be four.

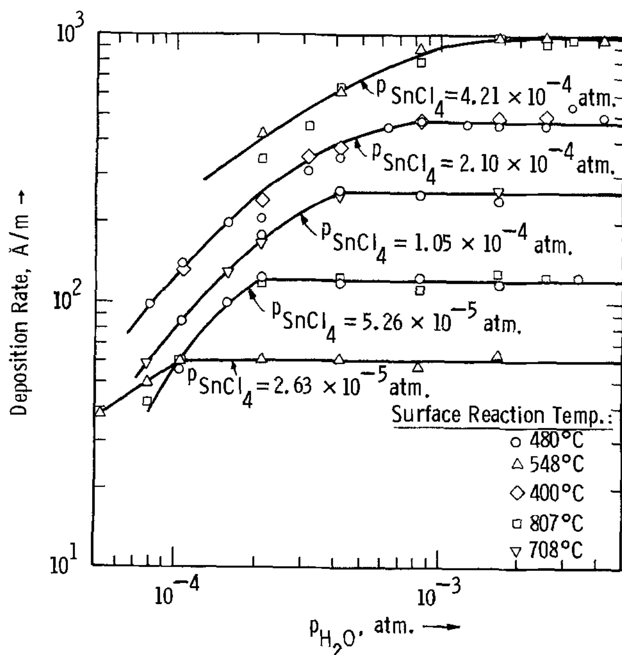

Fig. 3. Deposition rates of SnO_2 films as a function of water vapor and $SnCl_4$ concentration for the $SnCl_4$ + H_2O reaction (at different temperatures).

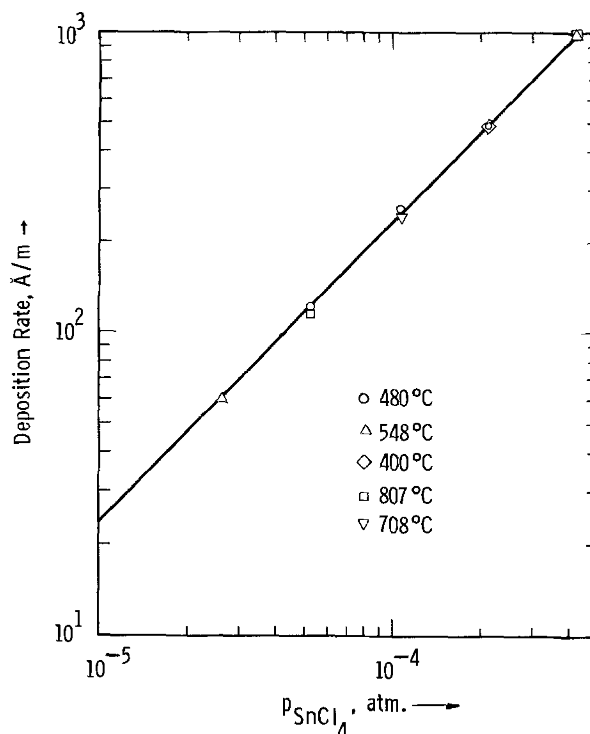

Fig. 4. Stannic chloride concentration dependence on the deposition rate of SnO_2 at p_{H_2O} = 4.17 × 10^{-3} atm.

$Sn(CH_3)_4$ + O_2 reaction.—As has already been demonstrated (6), the direct oxidation of TMT (Eq. [3]) is a very favorable route of SnO_2 CVD film formation. However, the partial pressure relationships of the reactants are not known so far. Figure 6 shows a typical SnO_2 film deposition rate dependence on p_{O_2} at a fixed p_{TMT} at low temperatures. As in the direct oxidation

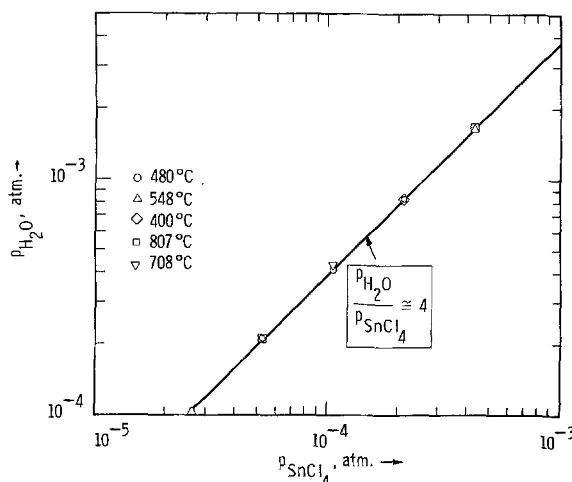

Fig. 5. Minimum water vapor partial pressure required for zero order (with respect to H_2O) SnO_2 deposition at different stannic chloride concentrations.

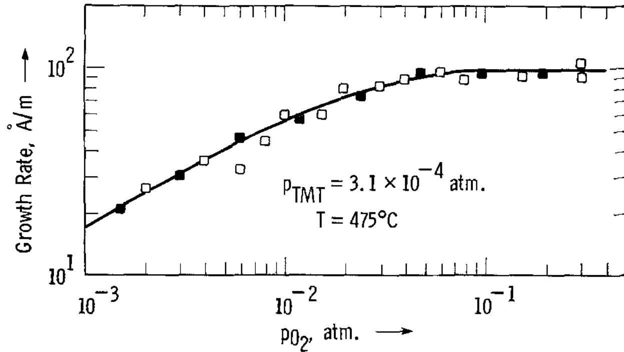

Fig. 6. Growth rate data as a function of oxygen concentration at a temperature where volume reaction is negligible. Open symbols indicate data from the first ~ 1000Å of the film and closed symbols are those from the second ~ 1000Å of the film.

of $SnCl_4$ (Fig. 1) the growth rate is one-half order with respect to oxygen at low p_{O_2} and saturates at higher p_{O_2}. The open symbols indicate macroscopic growth rate data from the first ~ 1000Å of the film and the closed symbols are those from the second ~ 1000Å of the film. The significance of the latter is illustrated in Fig. 7, where these two types of growth rate data differ significantly at higher temperatures. It should also be noted that at low partial pressures the reaction order is no longer one-half with respect to oxygen and goes higher at higher temperatures. Moreover, the growth rate clearly peaks out at higher oxygen pressures for the second kÅ film at both the high temperatures and for the first kÅ of the film at the highest (578°C) temperature shown. As will be seen later, this temperature dependence of p_{O_2} relationship of the growth rate in the surface reaction-controlled region of Eq. [3] is directly related to the high temperature non-Arrhenius behavior of the apparent surface reaction rate. Figure 8 shows the TMT concentration dependence of the growth rate at a so-called "low" and "high" temperature. The fixed oxygen pressure at both these temperatures was maintained high enough for the reaction either to be saturated with respect to oxygen (Fig. 6) or to be beyond the apparent peak (Fig. 7). The deposition rate data of Fig. 8 was obtained macroscopically from the first kÅ of the film. It is clear that the reaction is apparently of first order with respect to TMT at both these temperatures.

Temperature coefficients of CVD SnO_2 formation.—The temperature dependence of a chemical reaction in the activated region provides insight into both the molecular mechanism of the reaction and the sensitivity of the process to temperature variation in the system. Figure 9 shows the Arrhenius behavior of the SnO_2 film formation rate on SiO_2 (by Eq. [1]) at two $SnCl_4$ concentrations up to a maximum temperature of 873°C. Above that temperature the behavior is nonideal. Both sets of data in Fig. 9 were obtained with a fixed p_{O_2} of 0.9975 atm ($\simeq$ 1 atm), well in the region of zero-order dependence of the surface reaction rate with respect to oxygen. Between 675° and 873°C, the surface reaction rate constants can be calculated from the data of Fig. 9 using a relation of the type

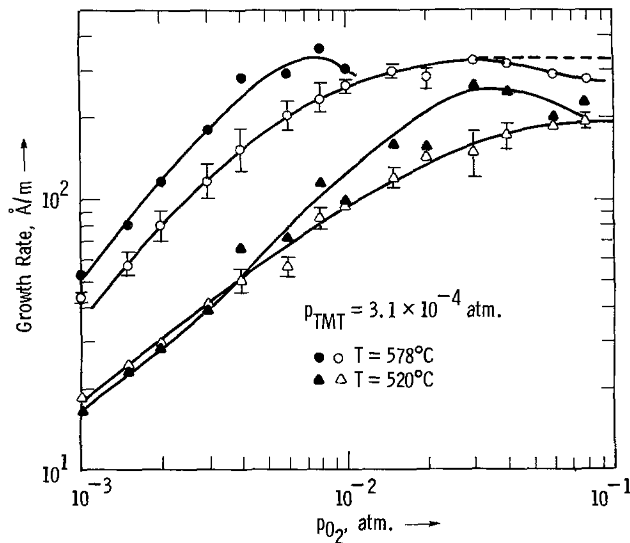

Fig. 7. Growth rate of SnO_2 film from TMT as a function of oxygen concentration. Closed and open symbols have the same significance as in Fig. 6.

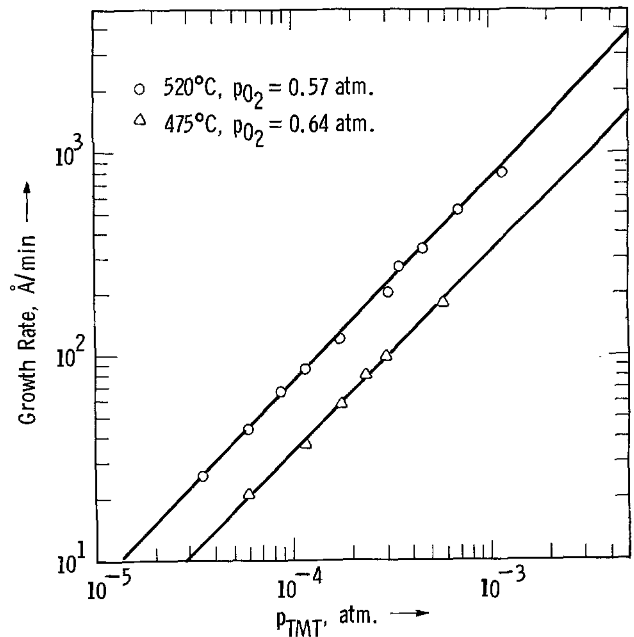

Fig. 8. TMT-produced SnO_2 film growth rate as a function of TMT concentration in the oxygen-saturated region.

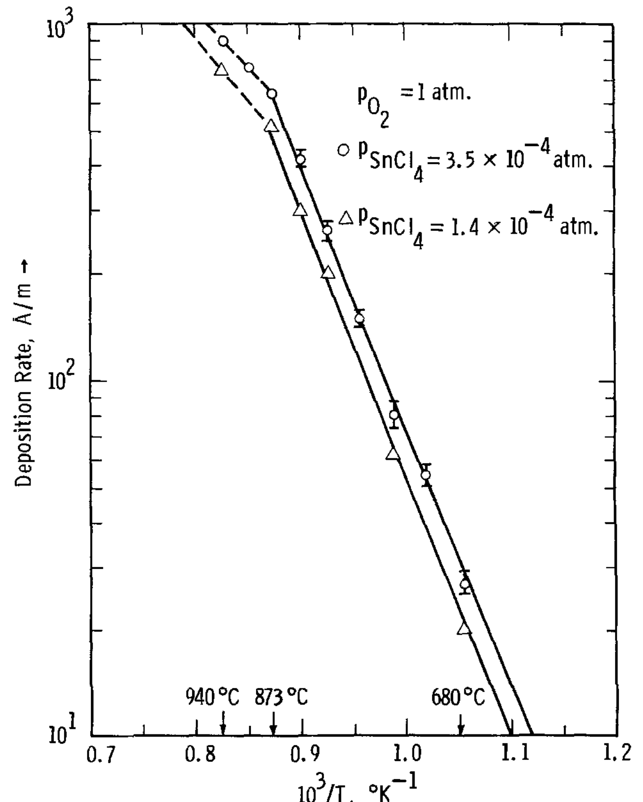

Fig. 9. Temperature dependence of SnO_2 deposition rate by the $SnCl_4 + O_2$ reaction.

$$G = \frac{C_G}{N} k_s \quad [4]$$

where G is the growth rate, C_G is the gas phase $SnCl_4$ concentration, N is the number of SnO_2 molecules per unit volume of the film, and k_s is the surface reaction rate constant. The activation energy of the surface reaction rate is seen to be ~ 1.5 eV from Fig. 9. It should be noted that the normalization of the observed partial pressure relationships of the deposition rate for both the reactants of Eq. [1] (shown in Fig. 1, 2, and 9) at all temperatures below 873°C would result in a single Arrhenius plot for either the specific growth rate or the surface reaction rate constant (2). However, this is not the case in the higher temperature non-Arrhenius region and both these fundamental parameters are directly proportional to the concentration of the rate-determining species (*i.e.*, $SnCl_4$).

In contrast to the direct oxidation of $SnCl_4$ (Eq. [1]), the high temperature hydrolysis of $SnCl_4$ (Eq. [2]) is seen to be thermally nonactivated (Fig. 3-5) even in the so-called flow-independent activated region of the surface reaction. An attempt to explain this phenomenon is made in the Discussion section.

The temperature dependence of the direct oxidation of TMT (Eq. [3]) shown in Fig. 10 is seen to be very similar to that of $SnCl_4$. Below ~ 490°C, the relationship is Arrhenius with an indicated activation energy of ~ 1.8 eV. The growth rate data, shown in Fig. 10, are macroscopic values obtained from the first ~ 1000Å of the film. As has been described before, below 490°C a single Arrhenius plot can be obtained for either the specific growth rate or the surface reaction rate constant of Eq. [3] from Fig. 6, 8, and 10. The non-Arrhenius regions of Fig. 9 and 10 are seen to be very similar.

Microscopic growth characteristics.—For an accurate assertion of the molecular mechanism of a CVD film growth, it is imperative to establish that the macroscopic kinetic data are valid from the microscopic point of view. In the Arrhenius region, deposition rates were determined as a function of film thickness or time for both the reactions involving $SnCl_4$ (Eq. [1] and [2]) at some selected temperature and partial pressure conditions. Within the range of experimental error, film thicknesses (in the range ~ 200 to ~ 2000Å) were found to be linearly proportional to the deposition time with no detectable incubation period. The situation has not been found to be so with Eq. [3]. Figure 11 shows the microscopic growth data for a set of SnO_2 films grown by the direct oxidation of TMT at the highest temperature of the Arrhenius region (Fig. 10). The oxygen pressure was maintained at the onset of the growth rate saturation (Fig. 6) that is independent of temperature (Fig. 1) for similar surface reaction-controlled oxidation reactions (2). The films were ellipsometrically analyzed for individual thickness and refractive index. Both the growth rates and the refractive index attain a constant value after about 400Å of the film have been grown. Since the thin samples did appear to be of low refractive index, one of the thicker samples (1428Å) was argon ion-milled to remove the outer portion of the film to test if the film first deposited was of low refractive index. ψ, Δ values obtained after milling for 1 min and again after a further 35 sec milling fitted the 2.053 refractive index curve well with no indication of lower refractive index for the remaining films of 775 and 183Å, respectively. (Apparently, the first 60 sec milling removed 750Å for a 750Å/min rate; the second 35 sec removed 592Å for a 1015 Å/min rate. Whether this increase in milling rate under identical conditions is significant is unclear.) No evidence of any significant optical adsorption at 546 nM wavelength was discovered. Although the data of Fig. 11 indicate an incubation period of about a minute, no attempt was made either to incorporate it into the macroscopic growth data shown in Fig. 6, 7, 8, and 10 or to delineate its temperature and reactant concentration dependence. Its effect on the kinetic data of TMT oxidation is considered to be small.

Figure 12 shows the resistivity of the same films as a function of the film thickness. Films under 400Å must be defective enough to produce both very low resistivity and refractive index (Fig. 11). However, unlike the refractive index, the resistivity of the thicker films does not saturate above 400Å. That could originate either in mobility or in carrier concentration variation across its thickness.

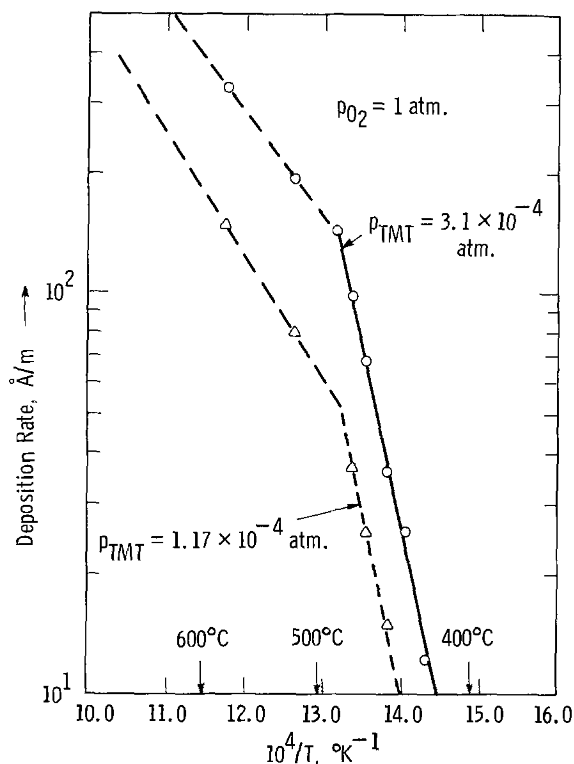

Fig. 10. Temperature coefficient of TMT-produced SnO_2 film growth rate.

Discussion

In general, a heterogeneous reaction involving one or more gaseous species on a solid surface involves the following steps: (*i*) diffusion of reactants to the surface, (*ii*) adsorption of at least one reactant on the surface, (*iii*) formation of critical nuclei by surface reaction preceded by surface diffusion and formation of activated complex, (*iv*) desorption of gaseous products with or without some surface migration, and (*v*) diffusion of products away from the surface. When the

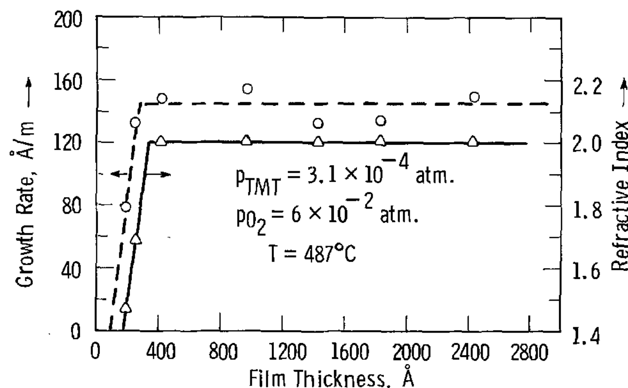

Fig. 11. Over-all growth rate and refractive index of SnO_2 film from TMT as a function of film thickness or growth time in the oxygen-saturated region.

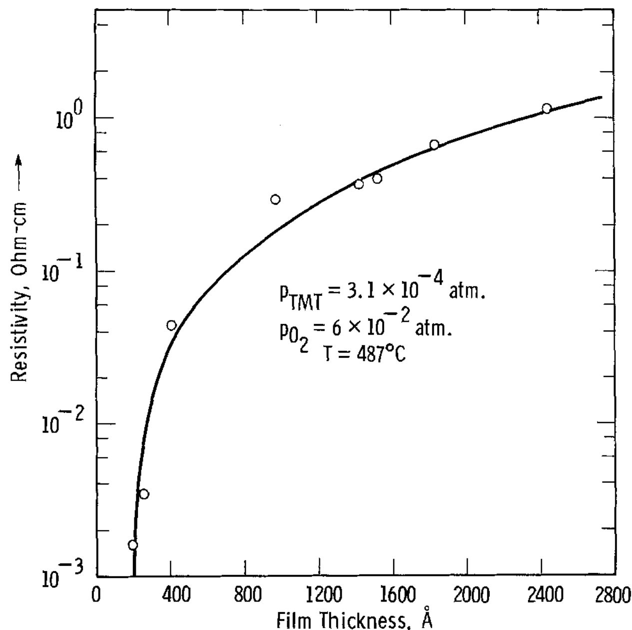

Fig. 12. Resistivity of the same TMT oxidized SnO_2 films as a function of film thickness.

heterogeneous CVD reaction is conducted in the flow-independent activated region (as has been done in this study), steps (*i*) and (*v*) are not rate controlling. Each of the CVD reactions studied in this work (Eq. [1]-[3]) will now be examined in light of step (*ii*), (*iii*), or (*iv*) rate control. It should, however, be noted that there are two basic mechanisms of reactant adsorption-controlled CVD reactions:

(*a*) In the Langmuir-Hinshelwood mechanism the reaction occurs between both the species adsorbed on adjacent sites. This may lead to considerable competition for the adsorption sites as a function of temperature and reactant concentration ratios.

(*b*) In the Rideal-Eley mechanism the CVD reaction is between an adsorbed species and a gaseous species without any competition between them.

The major distinguishing feature of these two mechanisms is that in the former the rate (*R*) will pass through a maximum as the partial pressure of either reactant is varied, whereas in the latter the rate will reach a limiting value when the partial pressure of one of the reactants is varied (which is the one that is adsorbed).

The direct oxidation of $SnCl_4$ shows

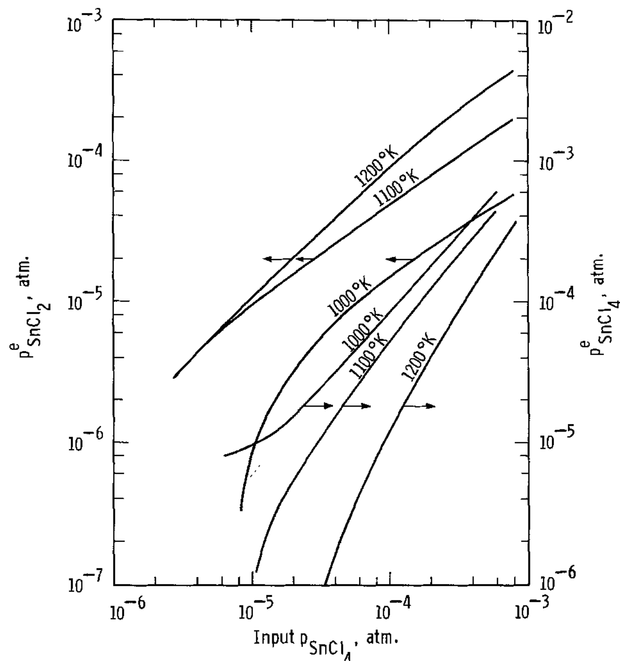
$$R \propto (p_{O_2})^{1/2}(p_{SnCl_4})^{0.26\pm0.01} \quad [5]$$

at low p_{O_2} and all p_{SnCl_4}, whereas

$$R \propto (p_{SnCl_4})^{0.26\pm0.01} \quad [6]$$

at high p_{O_2} (depending on p_{SnCl_4}) and all p_{SnCl_4}. Since the surface reaction rate is proportional to the adsorption density of the species involved, it appears that Rideal-Eley mechanism is operating for Eq. [1] with atomic oxygen as the most probable chemisorbed species and some molecular form of tin chloride colliding on the surface from the gas phase. Similar to the direct oxidation of $TiCl_4$ to produce TiO_2 (2), the saturation of surface adsorption of atomic oxygen occurs at the same p_{O_2} at all temperatures. An alternative interpretation of the Eq. [5] p_{O_2} dependence is the partial surface coverage by adsorbed oxygen (10). The value of the exponent of p_{O_2} should then increase with temperature. This is in contradiction to the experimental findings (Fig. 1).

The absence of a maximum in the deposition rate as a function of both p_{O_2} and p_{SnCl_4} (Fig. 1 and 2) indicates the strong possibility that the tin-containing species is not involved in adsorption on the substrate, *i.e.*, it is a gas phase diffusing species. The $p_{SnCl_4}{}^{0.26\pm0.01}$ dependence of the surface deposition rate (Eq. [5] and [6]) is also indicative of the fact that the rate-determining tin species is not the input stannic chloride. Thermodynamic calculations of the major equilibrium tin species in the $SnCl_4$-N_2 system were performed at 1000°-1200°K to check the possibility of a clear connection of the observed p_{SnCl_4} dependence of the deposition rate with the intermediate $SnCl_2$ species. This is shown in Fig. 13(*a*) and (*b*). For any input p_{SnCl_4},



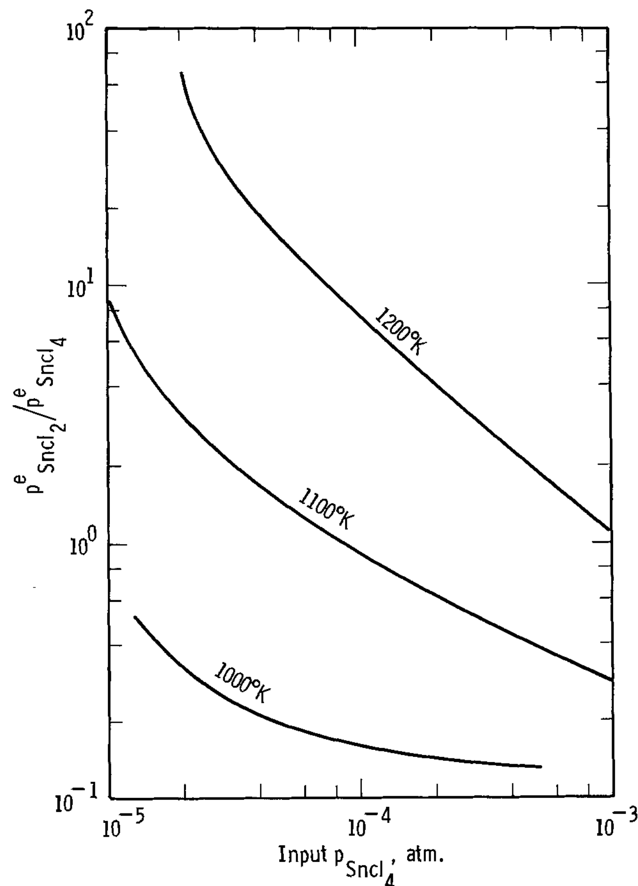


Fig. 13. Calculated equilibrium distributions of $SnCl_2$ and $SnCl_4$ as a function input p_{SnCl_4} at atmospheric pressure. Courtesy of P. Rai-Choudhury.

the equilibrium partial pressure of $SnCl_4$ ($p^e{}_{SnCl_4}$) decreases and that of $SnCl_2$ ($p^e{}_{SnCl_2}$) increases with increasing temperature [Fig. 13(a)]. Alternatively, the ratio of $p^e{}_{SnCl_2}$ to $p^e{}_{SnCl_4}$ always decreases with increasing p_{SnCl_4} in the experimental temperature and input p_{SnCl_4} range [Fig. 13(b)]. Since this is contrary to the experimental findings (Fig. 2), $SnCl_2$ is not the rate-determining species. The major effect of rising p_{SnCl_4} on the surface reaction rate must therefore be of $p^e{}_{SnCl_4}$ with possibly some poisoning effect from the liberated chlorine and/or gas phase oxygen. In Eq. [1] the reverse reaction is fairly active at ~1000°C. As a result, the net reaction rate (obtained from the deposition rate) is the difference between the forward and reverse reactions with reverse being proportional to $p_{Cl_2}{}^2$ or ¼ $p_{SnCl_2}{}^2$. Without an independent determination of the etch rate of SnO_2 films by chlorine, it is, therefore, not possible to identify the $p_{SnCl_4}{}^{0.26\pm0.01}$ dependence of the deposition rate to any single species in the $SnCl_4$-$SnCl_2$-Cl_2-Cl-O_2-O system.

The activation energy of the sufrace reaction process (~1.5 eV), shown in Fig. 9, in the oxygen-saturated region, is too high for the desorption of product chlorine [step (*iv*)] to be rate controlling. At the same time since no incubation period has been detected in the microscopic growth rate studies, the reaction is probably not nucleation controlled. The surface reaction control of this reaction above ~873°C becomes apparently non-Arrhenius due to the significant onset of volume reaction-produced depletion of the rate-determining tin species. It is interesting to compare the fortuitous agreement of this transition temperature of 873°C with that of ~875°C calculated by Tabata (3) where the free energy of reaction [1] becomes positive and thus no longer favored heterogeneously.

As shown in Fig. 6-8, the direct oxidation of TMT below ~490°C is a close analog to that of $SnCl_4$ with the surface deposition rate (R) being expressed by

$$R \propto (p_{O_2})^{1/2}(p_{TMT}) \qquad [7]$$

at low p_{O_2} and all p_{TMT}, whereas

$$R \propto p_{TMT} \qquad [8]$$

at high p_{O_2} (depending on p_{TMT}) and all p_{TMT}. Over and above, there is detectable nucleation-induced(?) incubation period of growth (Fig. 11). Consequently, following the previous logic, it can be inferred that atomic oxygen is also the adsorbed species here with TMT as the virtually undissociated gaseous (unadsorbed) reaction species. The initial nucleation-induced rate limitation presumably has no impact on the equilibrium growth kinetics limited by the surface reaction (under oxygen saturation conditions). The higher activation energy of the surface reaction rate constant, shown in Fig. 10 (~1.8 eV), compared to that of the similar mechanism SnO_2 formation from $SnCl_4$ (~1.5 eV), may originate from the larger activation energy of the surface diffusion of a bigger activated complex (involving methyl groups) in this case. The non-Arrhenius behavior of this surface reaction above ~490°C (Fig. 10) also has the same origin, *i.e.*, volume-reaction induced depletion of the TMT in the gas phase. This fact is further illustrated by the growth rate data above 490°C in Fig. 7. Compared to that in Fig. 6, the p_{O_2} dependence in this region is more than one-half order and the apparent reaction order increases with the temperature (particularly for the second kÅ). This growth enhancement presumably originates from the increasing incorporation of the volume-reacted material in the growing film (at low p_{O_2}). The volume reaction rate, being proportional to p_{O_2}, increases faster than the surface reaction rate at higher p_{O_2}. But at fixed flow rates the fraction of the volume-reacted material collected by the growing film is the same. Consequently, at higher p_{O_2} the gas phase would be homogeneously depleted of TMT and the growth rate would actually drop (instead of saturation) as seen in Fig. 7. This situation apparently gets more severe at longer times of growth (*i.e.*, second kÅ of the film). The apparent enhancement of reaction order at temperatures where significant volume reaction occurs has also been observed in CVD TiO_2 film growth rates (2).

The high temperature hydrolysis reaction (Eq. [2]) is the most interesting process studied. As shown in Fig. 3 and 4, in the entire range of temperature studied (400°-807°C), the surface depositon rate can be expressed by

$$R \propto (p_{H_2O})(p_{SnCl_4}) \qquad [9]$$

at low p_{H_2O} and all p_{SnCl_4}, whereas

$$R \propto p_{SnCl_4} \qquad [10]$$

at high p_{H_2O} (depending on p_{SnCl_4}) and all p_{SnCl_4}. These rate dependences immediately identify H_2O as the undissociated adsorbed species and $SnCl_4$ as the gaseous reactant. Since no growth rate saturation or maximum is achieved with increasing stannic chloride concentration, Langmuir-Hinshelwood mechanism of surface reaction by two adjacently adsorbed species is ruled out. This reaction then appears to be another classic case of Rideal-Eley mechanism where gaseous $SnCl_4$ reacts at the surface with adsorbed H_2O molecules (without any competition for the adsorption sites). The data in Fig. 5 (obtained from Fig. 3) indicate the requirement of four (symmetric?) H_2O molecule adsorptions on oxygen sites (around a tin site) of the rutile lattice for the $SnCl_4$ collision reaction at the surface to be successful in SnO_2 formation at all temperatures. This fact is interestingly in violation of the stoichiometric relation shown in Eq. [2]. From the facts that the calculated free energy change of reaction [2] is less than −10 kcal/molecule (3) and that the net energy change of a catalyzed heterogeneous reaction is the difference between that of homogeneous reaction and adsorption or desorption of the rate-determining species (2) (which is zero for this unactivated reaction in the activated region), it can be concluded that the adsorption energy of H_2O on SnO_2 closely compensates for the energy of reaction [2] in the entire temperature range studied.

Summary and Conclusions

The kinetics of three heterogeneous CVD reactions for SnO_2 thin film formations were studied in this work. Using a horizontal cold-wall reactor, it was demonstrated again (2) that it is possible to reasonably delineate the kinetic mechanism of all such surface reactions. The kinetics of both stannic chloride and tetramethyl tin surface oxidations were found to proceed by the collision of the gas-phase tin species with the adsorbed atomic oxygen. In the case of high temperature hydrolysis of stannic chloride, four adjacent symmetrically adsorbed water molecules are required for every colliding gaseous tin chloride species to be successfully reacted at the surface. The requirement of no activation energy in this case is due to the close balance of the free energies of water adsorption (on SnO_2) and homogeneous volume reaction. Furthermore, in the entire range of temperatures (400°-807°C) and stannic chloride partial pressures (0.26-4.17 $\times$ 10^{-4} atm) examined in this work, no evidence of the homogeneous gas-phase volume reaction has been found. In contrast, this homogeneous reaction becomes very important for stannic chloride oxidation above ~875°C and for TMT oxidation above ~490°C. It should be noted that volume reaction is highly undesirable in all CVD processes. The fractional order kinetics of stannic chloride surface oxidation on its concentration could not be quantitatively explained on any single species.

The Role of Energy Levels in Semiconductor-Electrolyte Solar Cells

R. Memming

Philips GmbH Forschungslaboratorium Hamburg, 2000 Hamburg 54, Germany

ABSTRACT

The transfer of minority carriers across the semiconductor-electrolyte interface during illumination has been studied. In particular the parameters which determine the competition between pure redox processes and hydrogen evolution at p-type or anodic dissolution at n-type material have been investigated. In the first case the electron transfer between p-type electrodes and the redox system can simply be interpreted on the basis of an energy scheme. In the case of hole transfer from n-type electrodes across the interface the competition of a pure redox process and anodic dissolution is more complex. It is mainly determined by kinetic parameters. The results obtained with CdS and various III-V compounds are discussed in view of application of n- and p-type semiconductors in solar energy conversion systems.

During the last few years photoelectrochemical processes at semiconductor-electrolyte interfaces found new interest because of their possible application in solar energy conversion systems. Originally the research was mainly devoted to the direct electrolytic decomposition of water which is principally possible with semiconductor electrodes. Corresponding systems have been realized with TiO_2 (1-5), titanates (6), and tantalates (7). In these cases, however, the efficiency of solar energy is very low because of the large bandgaps (>3 eV) of these materials. There are several other semiconductor electrodes of low bandgaps which show large photoeffects. These electrodes, however, are not stable, *i.e.*, instead of oxygen formation electrochemical dissolution occurs.

It has also been suggested to construct self-regenerating photocells containing at least one semiconductor electrode for conversion of solar energy directly into electrical energy. Corresponding cells have been realized consisting of an n-type CdS and a Pt counterelectrode and $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ (8) or $S/S^{=}$ (9) as redox systems. Several aspects make these electrochemical photocells quite attractive in comparison to ordinary solid-state devices such as pn junctions and metal/semiconductor interface. There are three main advantages: (*i*) no complicated technology is required for making electrolyte/semiconductor contacts; (*ii*) the light can easily pass the electrolyte and reach the space charge region without essential losses; (*iii*) several semiconductor electrodes of different bandgap can be combined in one cell.

Key words: charge transfer, redox systems, anodic dissolution, semiconductor photoelectrolysis.

On the other hand problems arise with semiconductors in electrolytic cells as far as the stability of these compounds are concerned (10), although in the two CdS cells mentioned above the corrosion could be reduced to very low levels. However, the bandgap of CdS is still relatively large (2.5 eV) and other semiconducting electrodes of lower bandgaps are required for a high solar energy conversion efficiency. The stability problem arises insofar as holes produced by light excitation in n-type material may not only be transferred to the occupied energy levels of a redox system such as $[Fe(CN)_6]^{4-}$ or $S^{=}$, but could also be consumed for the anodic dissolution of the semiconductor.

The conversion efficiency cannot only be increased by semiconductors of a smaller bandgap but also by choosing a combination of an n-type electrode/redox system in which the difference of flatband and redox potentials is larger than in the case of CdS/$[Fe(CN)_6]^{3-/4-}$. Principally this can be realized by combining n-CdS with a redox system of a more positive normal potential or by using a semiconductor such as n-GaP with energy bands at rather negative energy values (Fig. 1) [negative flatband potential (11)].

For all combinations, however, the stability problem arises (30). It is the purpose of this paper to investigate the parameters which determine the competition between redox process and anodic dissolution during illumination. Moreover, the possibility of combining p-type electrodes with redox systems is investigated in order to avoid the problem of anodic dissolution.

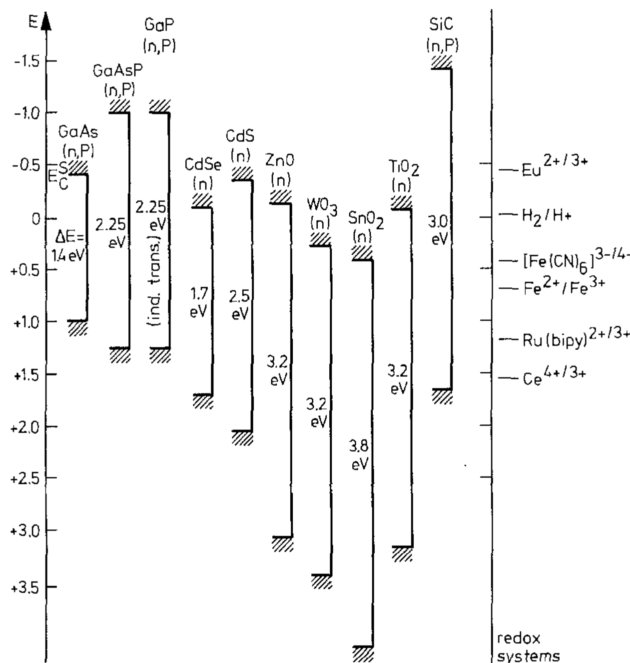

Fig. 1. Energy band at semiconductor-electrolyte interface at pH 1

Experimental

Most experiments were performed with single crystals of CdS, GaP, GaAs, and GaAsP. Their surfaces were carefully polished. In some cases epitaxial layers of GaP and GaAsP on GaP-substrates were investigated too. In order to distinguish between anodic dissolution and pure redox process rotating ring-disk electrodes were used consisting of a semiconductor disk and platinum ring. The semiconductor was illuminated by chopped light. If any charge transfer between semiconductor and redox system occurs during illumination then the oxidized species passed the Pt-ring during rotation where it was reduced back to its original state. The method has been described in detail elsewhere (12). The collection factor was determined by a pure platinum ring-disk electrode of the same dimensions. We obtained $\gamma = (i_{\mathrm{Ring}}/i_{\mathrm{disk}}) = 0.14$.

The current-potential curves were measured under potentiostatic conditions. The potentials refer to the standard calomel electrode if not otherwise indicated. The photo- and ring currents were measured by a lock-in amplifier or displayed on an oscilloscope (signal averager).

Results

Current-potential behavior.—Typical current-potential curves have been obtained with n-type electrodes. The surface preparation or the use of epitaxially grown layers did not have any influence on the value of the anodic limiting current. In the case of cathodic processes at n-type materials it has been observed that the H_2 evolution at epitaxial layers occurs at somewhat more cathodic potentials. As far as p-type electrodes are concerned the treatment of the electrode surface plays an important role. Only for well-polished surfaces or epitaxial layers could the cathodic limiting current be kept at a very low level over a large potential range (>3V).

The doping of the semiconducting material seems only to be important for GaAs as demonstrated at first by Hollan and Tranchart (13). In this case the anodic and cathodic limiting currents remain at a low value only for donor or acceptor densities below 10^{15} cm^{-3}. For higher doping levels the anodic current for n-type and the cathodic current for p-type GaAs increase at certain potentials. The authors (13) interpreted this result as avalanche processes.

As far as the spectral distribution of the photosensitivity is concerned it should be emphasized that

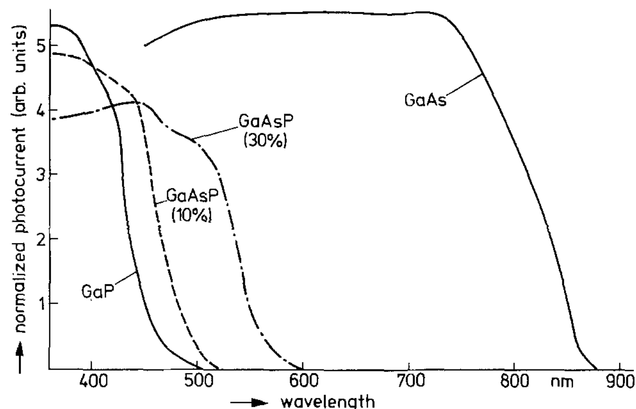

Fig. 2. Spectral distribution of photocurrent at pH 7

the corresponding photocurrent obtained with GaP sets in below 500 nm (2.5 eV) (Fig. 2). *i.e.*, at an energy being much larger than the bandgap of 2.25 eV and comparable with that of CdS. This result is due to the fact that the bandgap of 2.25 eV corresponds to an indirect transition (14), which generally has a lower absorption coefficient ($\alpha \leq 10^3$ cm^{-1}). Since the diffusion length is much smaller ($L = 10^{-4}$ cm) greater photocurrents can only be obtained in the range of direct transitions. The absorption of GaP can be shifted towards longer wavelengths in crystals of GaAsP containing only 10-30% As (90-70% P). In the case of 30% As the direct transition of GaAsP occurs at the energy of the indirect transition of pure GaP.

Redox processes during illumination.—The ring(Pt)-disk (semiconductor) electrode arrangement has been used for studying charge-transfer processes between redox systems and semiconductor during illumination (12). A typical example obtained with the ring-disk electrode using a CdS disk and $[Fe(CN)_6]^{4-}$ as a redox system is shown in Fig. 3. The anodic photocurrent immediately follows the light pulses. The ring current, corresponding to the reduction of Fe(III) formed at CdS during light excitation back into Fe(II), rises and decays rather slowly depending on the speed of the angular rotation. Using the collection factor $\gamma = 0.14$ one obtains for the current i_{ox} equiva-

lent to the oxidation of Fe(II) in the anodic process at the semiconductor electrode

$$\frac{i_{ox}}{i_{ph}} = \frac{i_R}{\gamma i_{ph}} \quad [11]$$

For instance in the case of $[Fe(CN)_6]^{4-}$ we obtained $(i_{ox}/i_{ph}) = 1$ at pH = 6.5. Various other semiconductors and redox systems have been investigated; the results are given in Table I. In some cases also the pH dependence has been determined as given in Fig. 4. It is interesting to note that not only in the case of CdS but also for GaP the oxidation of $[Fe(CN)_6]^{4-}$ is faster than the anodic dissolution. In the latter case, however, the redox process can only sufficiently compete with the dissolution in a pH range between 6.5 and 10. With GaAs and also with GaAsP (30% As) the i_{ox}/i_{ph} ratio was always much lower even in neutral solutions (Fig. 4, Table I). The ratio did not depend on the electrode potential of the semiconductor.

It should be emphasized that large i_{ox}/i_{ph} values have only been obtained with very well-polished surfaces or epitaxial layers. Especially in the case of GaP, GaAsP, and GaAs any deterioration of the surface led to a decrease of the i_{ox}/i_{ph} ratio.

Similar investigations have also been performed with p-type GaP and GaAs. Here the corresponding redox process (reduction) has to compete with the hydrogen evolution. The best results have been obtained with quinone, Eu^{3+} and Fe(III)EDTA. In all cases the ratio i_{red}/i_{ph} was equal to 1, *i.e.*, the redox process competes well with the hydrogen formation. No pH dependence has been found in the range of $6 \leq pH \leq 0$. It should be emphasized that ring currents could only be detected if oxygen was excluded from the electrolyte. Obviously oxygen easily reoxidized the reduction products. The surface pretreatment did not seem to be as important for cathodic processes as for n-type electrodes in the anodic range. The surface roughness should only be sufficiently low in order to keep the dark current at a low value.

It should be mentioned that in some cases information about the cathodic reduction of a redox system such as $Eu^{3+/2+}$ can also be obtained directly from a current-potential curve as determined with an n-type electrode. For instance with an n-type GaAsP electrode the reduction of Eu^{3+} yields higher cathodic currents than that of H^+/H_2 (Fig. 5). This result, however, has only been obtained with epitaxial layers and not with ordinary crystals.

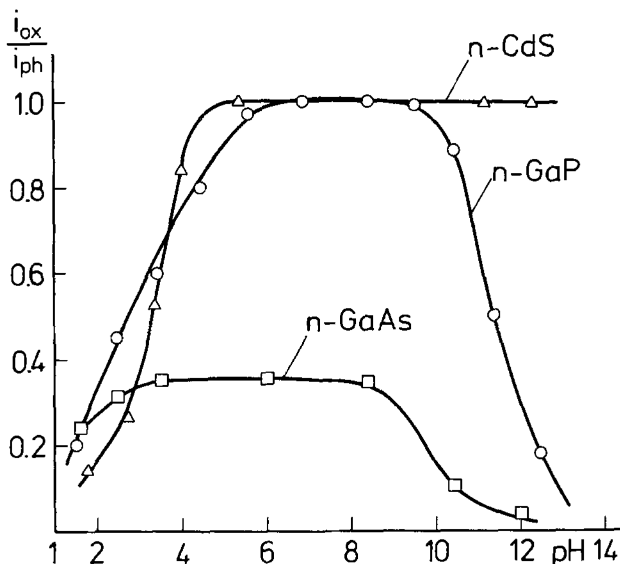

Fig. 4. i_{ox}/i_{photo} vs. pH for $[Fe(CN)_6]^{4-}$

Discussion

The results presented in the previous section show that some redox processes at semiconductor electrodes can occur during illumination without having any anodic dissolution or hydrogen evolution. The question arises, however, which factors are of importance in determining whether a redox process can really compete with the anodic dissolution at n-type and with hydrogen evolution at p-type electrodes. The two cases will be treated separately.

Hole transfer at n-type electrodes.—In the case of n-type electrodes the anodic current is limited to a very low value since no holes are available at the surface. Light excitation leads to the creation of electron-hole pairs. The holes are pushed towards the surface by the electrical field across the space-charge region and consumed for an anodic charge transfer process. In some cases such as SnO_2 (15), TiO_2 (2, 7, 15), and WO_3 (16) the corresponding anodic reaction is oxygen evolution. The semiconductor electrodes such as CdS (17), GaP (18), GaAsP, and GaAs (19, 20) discussed here only show anodic dissolution. Taking GaP as an

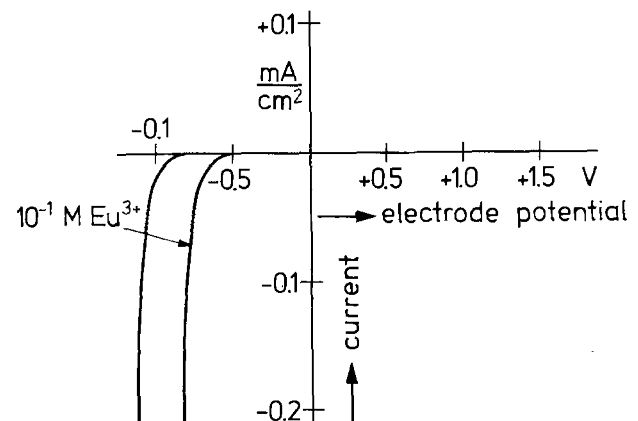

Fig. 5. *I-U* dependence for n-GaAsP (epitaxial layer on GaP) in 0.1*N* H_2SO_4.

example this reaction can be described as (18)

$$GaP + 6H_2O + 6p^+ \rightarrow Ga(OH)_3 + H_3PO_3 + 6H^+ \quad [2]$$

In the case of an oxidation of a redox system which also consumes holes the competing process is given by

$$Red + p^+ \rightarrow Ox \quad [3]$$

It seems to be useful to consider these two competing processes in view of thermodynamic data from which a theoretical value of the potential at which anodic dissolution is expected can be calculated. In order to relate such a value to the normal hydrogen potential we also used the equation

$$3H_2 + 6p^+ \rightarrow 6H^+ \quad [4]$$

Subtracting Eq. [2] and [4] one obtains

$$GaP + 5H_2O \rightleftarrows Ga(OH)_3 + H_3PO_3 + 3H_2 \quad [5]$$

Free energy values of $Ga(OH)_3$ and H_3PO_3 are tabled in Ref. (21). Some uncertainty exists about the value for GaP (22). We used $\Delta G_{GaP} = -23$ kcal. The free energy of the total reaction (5) is $\Delta G = +40.6$ kcal/mole. The corresponding potential calculated from this ΔG value is given in Fig. 6 for $pH = 7$. In the same way also the potential for the dissolution of GaAs has been determined (Fig. 6). The latter value differs from that already calculated by Harvey (20) who used only an estimated ΔG_{GaAs} value.

According to the thermodynamic data dissolution should be the process preferred over charge-transfer processes with redox systems such as $[Fe(CN)_6]^{4-/3-}$, $Fe^{2+/3+}$, etc. The situation is quite similar for various other semiconductors such as CdS (23), CdSe, and ZnO (Table II). It must be emphasized, however, that thermodynamic data only describe the general tendency of the material and do not take into account the existence of energy bands in the semiconductor, shown in Fig. 6.

An electron transfer across the interface only occurs if energy levels exist at the same energy on both sides of the interface assuming weak interaction between electrode and reactant. Consequently, the most effective hole transfer is expected if the occupied levels D_{red} of a redox couple overlap with the valence band. In order to fulfill this condition one should select a redox system of a sufficiently large normal potential. Taking $[Fe(CN)_6]^{4-/3-}$ as an example the corresponding energy levels of this redox system are given in Fig. 7 assuming a value of the reorientation energy of $\lambda = 0.5$ eV (24, 25). The position of the energy bands at the surface of a few semiconductors are also plotted in this figure for $pH = 7$. Comparing the three semiconductors GaAs, GaP, and CdS the largest density of states of the redox system occurs at the upper edge of the GaP valence band whereas it is much lower at the valence band of CdS. According to this energy scheme one should also expect that a hole transfer across a CdS electrode surface would preferably work (with respect to the dissolution) with a redox system of a higher normal potential such as, *e.g.*, $Fe^{2+/3+}$.

The experimental results indicate, however, that this model is not sufficient. The investigations with the rotating ring-disk electrodes have definitely shown that the oxidation of $[Fe(CN)_6]^{4-}$ at CdS can compete well with the anodic dissolution. In the case of GaP it

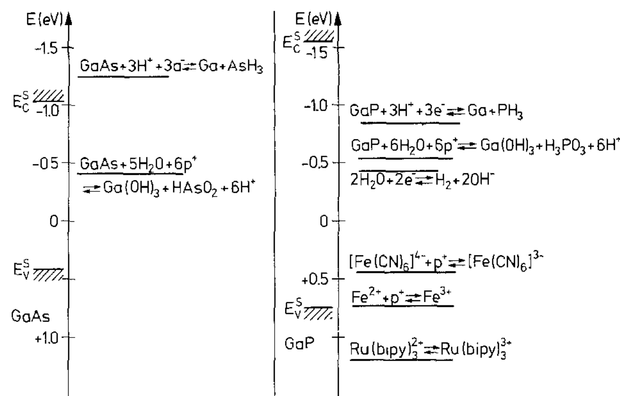

Fig. 6. Thermodynamic data for GaAs and GaP

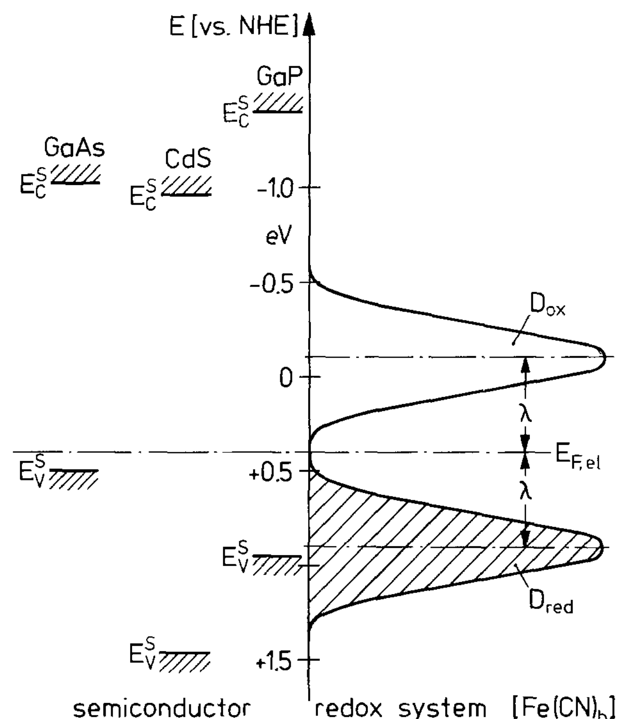

Fig. 7. Energy scheme of semiconductor/$[Fe(CN)_6]^{4-/3-}$ at *p*H 7.

is already critical. The strong pH dependence found with this electrode (Fig. 4) cannot be explained only by a corresponding shift (18) of the energy bands with pH. Moreover, it is not clear from this picture why GaAs and GaAsP dissolve (Table I).

A pure thermodynamic picture is also insufficient because it would never explain any effective hole transfer from one of these semiconductor electrodes to a redox system such as $[Fe(CN)_6]^{4-/3-}$.

Another possibility to interpret the efficient hole transfer from CdS or GaP to $[Fe(CN)_6]^{4-}$ is the assumption that this complex is better adsorbed at the surface than, for instance, Fe^{2+} ions surrounded by a strong solvation shell. Adsorption, however, cannot be the dominant factor in this process because no hole

SnO_2	3.8	$SnO_2 + 4HCl + 4p^+ \rightleftarrows SnCl_4 + O_2 + 4H^+$	+1.05

transfer from GaP or CdS to $Ru(bipy)_3^{2+}$ has been detected between pH 1 and 8 although this complex is partly adsorbed at the surface and its redox potential (U_{Redox} = 1.2V) is much larger.

It is interesting to note that besides $[Fe(CN)_6]^{4-}$, hydroquinone (Table I) and polysulfide (9) can effectively compete with the anodic dissolution process too. Both latter systems have rather low normal potentials. In all three cases the density of the corresponding energy levels (D_{red}) is certainly not very large at the upper edge of the CdS valence band. These results lead to the assumption that the essential charge transfer occurs mainly via surface states as shown in Fig. 9. Such a process seems to be reasonable because anodic dissolution occurs also partly via surface states. In most cases several reaction steps are involved in the dissolution process and surface states are formed as intermediate states [see *e.g.*, (10)] The complete dissolution of a surface group can obviously be avoided by a fast electron transfer from a redox system into surface states. This model is supported by recent results obtained by Chang *et al.* (26) who studied the charge transfer between n-GaAs electrodes and a selenide redox system. In this case the standard potential of the redox system is rather negative and the occupied levels of the redox system can only reasonably overlap with surface states within the bandgap of GaAs. The authors found that at high (~1M) selenide concentrations the GaAs surface remains completely stable during illumination.

The *p*H dependence in Fig. 4 is not yet fully understood. It may be partly due to a relative shift of energy levels but it seems to be mainly determined by the change of surface groups (dissociation) which influence strongly the rate of anodic dissolution.

Electron transfer at p-type electrodes.—Transfer of excited electrons from the conduction band to a redox system seems to be much easier, since most redox systems selected on the basis of the normal energy scheme

work even with GaAs (i_{red}/i_{ph} = 1, Table I). Taking Eu^{2+}/Eu^{3+} as an example the corresponding energy diagram of the interface is presented in Fig. 8. The reorientation energy was estimated to be $\lambda \approx 1$ eV, a value being similar to that of Fe^{2+}/Fe^{3+} (24). The unoccupied levels of Eu^{2+}/Eu^{3+} overlap well with the conduction band of several semiconductors. We did not plot any levels of the H_2/H_3O^+ system because it is not known whether it can be treated as a simple redox system or whether other surface reactions are involved (strong interaction). According to the experimental results, however, the reduction of some systems can efficiently compete with the hydrogen evolution. The density of occupied states of $Eu^{2+/3+}$ must be very low at the lower edge of the conduction band because the electron transfer from Eu^{2+} into the conduction band of, *e.g.*, n-GaAs is hard to detect. The corresponding anodic current must be less than $2 \cdot 10^{-7}$ Acm^{-2} (Fig. 10).

It is interesting to note that the photoinduced electron transfer to quinone can also compete with the hydrogen evolution although the normal potential of Q/QH_2 is +0.7V [NHE]. This is due to the fact that two electrons are involved in the redox process of quinones and the normal potential of Q/QH occurs at much more negative values as derived from current-doubling effects observed with p-GaP electrodes (27).

Solar cells.—According to the results obtained with p-type electrodes it would be quite interesting to construct photocells with p-GaAs as a semiconductor and $Eu^{2+/3+}$ as a redox system because p-GaAs should show strong band bending under equilibrium conditions as shown in Fig. 11. In this case a large photopotential of more than 1V is expected. We performed some preliminary experiments with a corresponding cell. As a counterelectrode we used an amalgamated

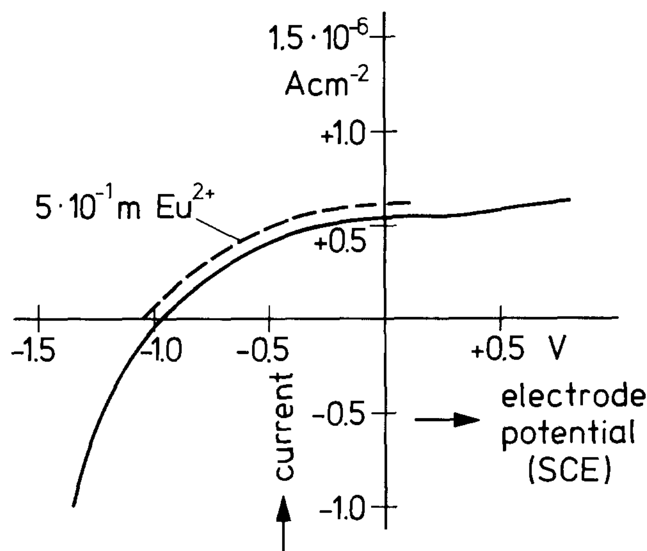

Fig. 10. *I-U* characteristic for n-GaAs in 1*N* H_2SO_4

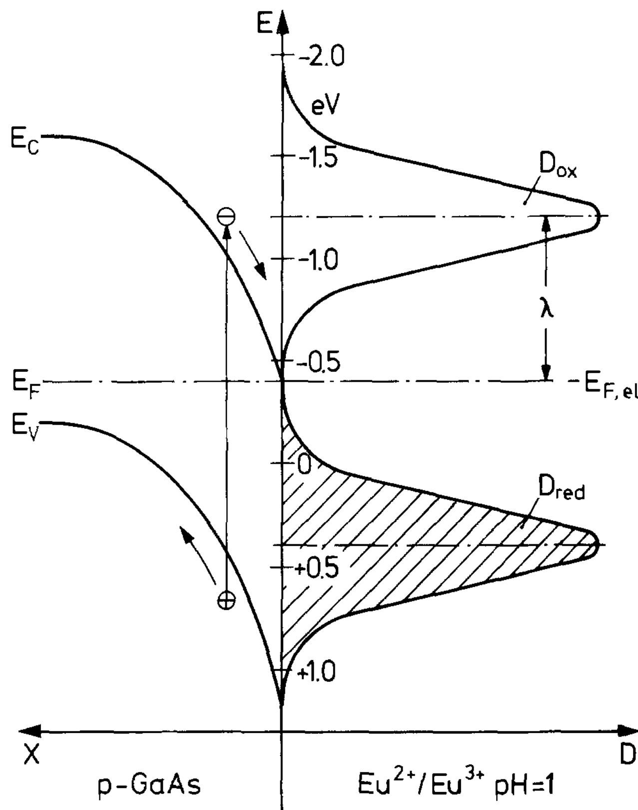

Fig. 11. Energy scheme of p-GaAs/$Eu^{2+/3+}$ at pH 1

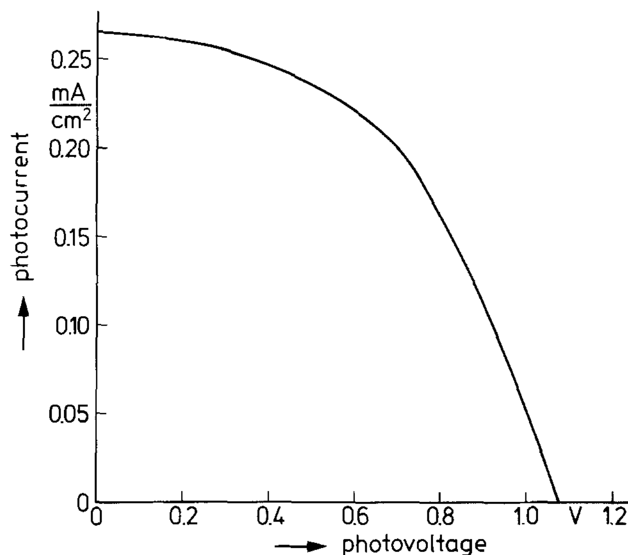

Fig. 12. i_{ph}-U_{ph} for p-GaP/Hg(Au) solar cell with 10^{-1}M Eu^{3+}/2 · 10^{-2}M Eu^{3+} at pH 1.

Au electrode since its large H_2 overpotential defines the potential well. We obtained relatively large photocurrents and a photopotential of 0.7V; the i_{ph}-U_{ph} characteristic, however, was rather poor. This has to be studied in more detail. A better cell performance has been obtained with a cell containing a p-GaP electrode (Fig. 12). The open-circuit photovoltage was 1.07V. The intensity of the incident white light (Xe lamp) was ~6 mW.

In general it seems to be rather easy to find suitable redox systems to be combined with p-type electrodes. The selection is limited, however, by the fact that the energy bands of most semiconductors which can be made p-type are located at relatively high energies (Fig. 1). On the other hand it has been shown by several authors that the light-induced anodic dissolution at n-type electrodes can be avoided by selecting a redox system of which the occupied levels overlap with surface states of the semiconductor. In this case, however, the Fermi level is located at the interface near the middle of the forbidden zone. The maximum value of the photovoltage is given by the difference of the redox potential U_{Redox} and the flatband potential U_{fb} according to

$$U_{ph} \leqq U_{Redox} - U_{fb}$$

Consequently, the photopotential U_{ph} is always much lower than that of the bandgap Eg/e. In most cases one should expect a value of $U_{ph} \approx 0.5$ Eg/e. Accordingly, the maximum quantum efficiency for solar energy conversion in systems containing n-type semiconductors will not be more than half of the theoretical value.

In connection with this problem the question arises whether the sensitivity in the red can be increased by strong doping of the material so that excitation of electrons from acceptor levels into the conduction band also contributes to the photocurrent. Such effects are well known in CdS photoconductors doped with Cu, with which sensitivities up to 700 nm have been found (28). We have tested corresponding CdS(Cu) layers in electrochemical cells but did not find any extrinsic photocurrent. WO_3 is the only material known so far where excitation via interstates causes an anodic photocurrent (16).

It would be quite tempting to combine n- and p-electrodes of different bandgaps in one cell, as it has been suggested by Nozik (28) for the direct decomposition of H_2O. According to the results presented above certainly a self-generating cell can be constructed. One would expect on the first sight that the combination of n- and p-type electrodes which also have different bandgaps would lead to a considerable increase of the efficiency. Such a cell, however, would only show a reasonable characteristic if the anodic and cathodic photocurrents at the n-and p-type electrodes, respectively, are equal. The two currents can be balanced by using electrodes of different surface areas. This is a rather tricky method and we did not test such a system.

Acknowledgments

Fujitsu Laboratories Limited, 1015 Kamikodanaka, Nakahara-ku, Kawasaki, Japan

ABSTRACT

The phase diagram of the In-Ga-As-P quaternary system has been determined experimentally for several As isoconcentration sections at 600° and 650°C. The liquidus data were obtained by the seed dissolution technique, and the solidus data were determined from liquid phase epitaxial layers grown on InP(111)B substrates by using EPMA. Lattice constants of the quaternary solid solutions were measured by an x-ray diffraction technique. The LPE growth conditions of exactly lattice-matched $In_{1-x}Ga_xAs_{1-y}P_y$ ($0 \leq x \leq 0.35$, $0.3 \leq y \leq 1.0$) layers on InP substrates were found from the results of the phase diagram and lattice constant measurements. The phase diagram was also calculated by using a simple solution model and was compared with experimental results.

It has been reported that lasers or LED's emitting in the 1.1-1.3 μm region would provide optimum performance in communication systems using fused silica fibers (1, 2). The InGaAsP quaternary system has received considerable attention because of the advantage that exactly lattice-matched layers can be grown by liquid phase epitaxy (LPE) on InP substrates (3, 4) for such devices giving emission in the wavelength range from 0.9 to 1.6 μm. Recently, Hsieh *et al.* (5) reported that stripe-geometry InGaAsP/InP DH diode lasers operate continuously at room temperature with emission at 1.15 μm.

For producing these InGaAsP/InP quaternary diodes by LPE growth, the accurate In-Ga-As-P equilibrium phase diagram is desired. Antypas *et al.* (6, 7) reported this phase diagram first, however, it did not supply sufficient information required for the growth of lattice-matched quaternary layers giving various emission wavelengths. Sankaran *et al.* (8) measured the Ga and As content in the solid for layers lattice-matched to InP as a function of the Ga and As in the liquid at 650°C.

In this paper, the experimental equilibrium phase diagram of In-Ga-As-P system to facilitate the preparation of closely lattice-matched InGaAsP/InP heterostructure diodes is described. We report 600° and 650°C phase diagram data. These temperatures were selected to permit the LPE growth of the quaternary layers under reasonable conditions. The LPE growth conditions of exactly lattice-matched $In_{1-x}Ga_xAs_{1-y}P_y$ ($0 \leq x \leq 0.35$, $0.3 \leq y \leq 1.0$) layers are also described. The phase diagram calculated by using a simple solution model is compared with experimental results.

Key words: III-V semiconductors, light emitting materials, phase equilibrium, heterojunctions.

Experimental Procedure and Results

Liquidus.—The seed dissolution technique (9-11) was used to determine the 600° and 650°C liquidus isotherms. A ternary undersaturated In-Ga-As solution (the As concentration in the solution was always below the solubility limit) was saturated with P at the fixed temperature by bringing the melt into contact with an InP seed. The melt and the seed were kept in contact at temperature for an hour. The liquidus composition was determined from the weight loss of the seed after removal from the melt. In this work, the materials used were semiconductor grade In, InP, InAs, and GaAs. The experimental apparatus consisted of a horizontal furnace system and a conventional sliding graphite boat.

The experimental 600° and 650°C liquidus results are listed in Table I and II, respectively. Figure 1 shows the 600°C liquidus isotherms at $X_{As}^l = 0.0$ and 0.030, where X_i^l represents the atomic fraction of the element i in the liquid. Figure 2 shows the 650°C liquidus isotherms at $X_{As}^l = 0.030$ and 0.050. These figures indicate that the main effect of the addition of Ga to the melt is to appreciably decrease the solubility of P in the liquid, while the presence of As

has a less pronounced effect in this range. The 650°C liquidus data at $X_{As}^{l} = 0.0145$ by Antypas and Moon (6) shown in Fig. 2 are found to be consistent with this work. Broken lines in these figures are drawn through our experimental points.

Solidus.—The 600° and 650°C solidus isotherms were determined by electron microprobe analysis performed on surfaces of $In_{1-x}Ga_xAs_{1-y}P_y$ epitaxial layers grown on Sn-doped InP(111)B substrates from quaternary solutions. The apparatus used was the same as that used for the saturation experiments. Prior to growth the undersaturated In-Ga-As solutions were held on InP sources for an hour to achieve saturation and then were moved over the substrates while simultaneously the cooling cycle was started. A constant cooling rate of 0.5°C/min was used starting from an initial temperature of 600° ± 0.5°C or 650° ± 0.5°C. Cooling intervals adopted were 25°C at 600°C and 16°C at 650°C. Thicknesses of the layers were in a range of ~2.5 to ~4.0 μm.

Electron microprobe analysis, employing wavelength dispersive x-ray detection, was used to determine the intensities of the Ga-K_α, As-K_α, and P-K_α lines from the sample and from GaP and InAs standards. An electron beam energy of 25 keV was used. The measured intensities were converted to concentrations by performing the atomic number, absorption, and fluorescence corrections.

The experimental 600° and 650°C solidus results are also listed in Tables I and II, respectively. The solidus isotherms in equilibrium with the quaternary liquids containing $X_{Ga}^{l} < 0.016$ and $X_{As}^{l} = 0.005$,

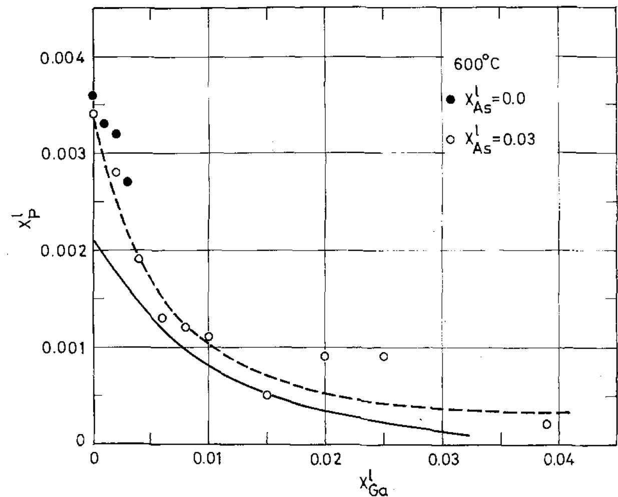

Fig. 1. 600°C liquidus isotherms in the In-Ga-As-P system at $X_{As}^{l} = 0.0$ and 0.030 determined by the seed dissolution technique. ●, $X_{As}^{l} = 0.0$; ○, $X_{As}^{l} = 0.030$. ---- drawn through experimental points at $X_{As}^{l} = 0.030$. —— Represents the calculated liquidus at $X_{As}^{l} = 0.030$.

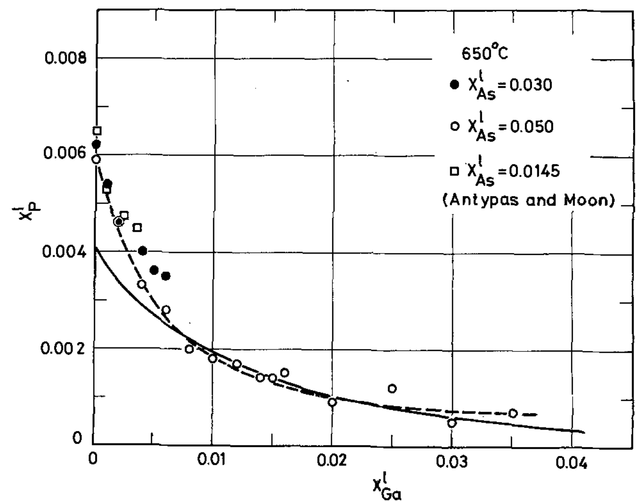

Fig. 2. 650°C liquidus isotherms in the In-Ga-As-P system at $X_{As}^{l} = 0.030$ and 0.050 determined by the seed dissolution technique. ●, $X_{As}^{l} = 0.030$; ○, $X_{As}^{l} = 0.050$, □, $X_{As}^{l} = 0.0145$ by Antypas and Moon (6). ---- Is drawn through experimental points at $X_{As}^{l} = 0.050$. —— Represents the calculated liquidus at $X_{As}^{l} = 0.050$.

0.010, 0.015, 0.020, 0.030, 0.040, and 0.050 were determined. These As compositions and temperatures were selected to permit the LPE growth of $In_{1-x}Ga_xAs_{1-y}P_y$ ($0 \leq x \leq 0.35$, $0.3 \leq y \leq 1.0$) lattice-matched layers on InP substrates under reasonable conditions. Figures 3 and 4 show the solid solubility isotherms for Ga into the quaternary solid solutions at 600° and 650°C, respectively. These solidus isotherms indicate that the distribution coefficient for Ga increases with decreasing growth temperature and/or X_{As}^1. Figures 5 and 6 show the solid solubility isotherms for P into the quaternary solids at 600° and 650°C, respectively. These isotherms indicate that the distribution coefficient for P increases with decreasing X_{As}^1. The 650°C solidus data at $X_{As}^1 = 0.00565$ by Antypas and Moon (6) are also included in Fig. 4 and 6. Present results of the solid solubility for Ga are a little higher than the data reported by them, as shown in Fig. 4.

Lattice constant.—Lattice constants of the quaternary solid solutions were measured by an x-ray diffraction technique. A double crystal x-ray diffraction technique was used for nearly lattice-matched samples. Samples used were 1.5-3 μm thick epitaxial layers on InP(111)B substrates.

The results at 600° and 650°C are shown in Fig. 7 and 8, respectively. The lattice constant is displayed as a function of X_{Ga}^1 at several X_{As}^1. The dashed line represents the lattice constant of InP. The exactly

lattice-matched layer can be easily grown by using these results. Figure 9 shows the compositions of the lattice-matched quaternary solids. The solid line is the calculated result on the basis of Vegard's law. The experimental points are in good agreement with the calculated line. The broken line is the calculated room temperature bandgap energy of the lattice-matched solid using Moon *et al.*'s expression (13).

Solidus isoconcentration curve.—Figures 10 and 11 show solidus isoconcentration curves of Ga and P at 600° and 650°C, respectively. These curves were obtained by interpolation of the results of solidus isotherms shown in Fig. 3, 4, 5, and 6. The broken line shows the composition of the quaternary liquid ($X_{Ga}{}^l$ and $X_{As}{}^l$) required for the LPE growth of the lattice-matched layer at each temperature. They were derived from the results of lattice constant measurements shown in Fig. 7 and 8. The Ga and As content in the solid for layers lattice-matched to InP measured by Sankaran *et al.* (8) at 650°C are in exact agreement with the results shown in Fig. 11.

Discussion

The experimental phase diagram shows that, in the InP-rich end at constant $X_{As}{}^l$, the solubility of Ga in the quaternary solid is almost linearly dependent on $X_{Ga}{}^l$, and the atomic ratio of P to As in the solid is nearly independent of $X_{Ga}{}^l$. Antypas and Moon (6) reported the same results, *i.e.*, changing Ga in the liquid changed only the Ga in the solid and did not affect the P or As in the solid. Such

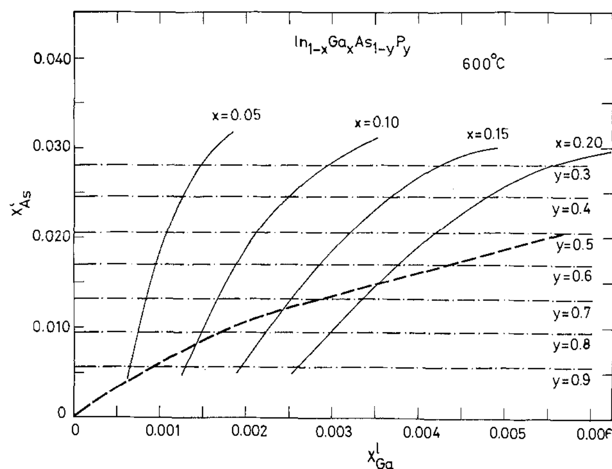

Fig. 10. Solidus isoconcentration curves of Ga and P at 600°C. ---- Represents the composition of the In-Ga-As-P quaternary liquid required for the LPE growth of the lattice-matched layer at 600°C.

phenomena were also observed in other quaternary systems, such as Al-Ga-As-Sb (16), In-Ga-As-Sb (17), and Al-Ga-In-As (18). Therefore, in the In-Ga-As-P system, the lattice constant of the quaternary solid in the InP-rich end is linearly dependent on $X_{Ga}{}^l$ at constant $X_{As}{}^l$ as shown in Fig. 7 and 8. By using the information contained in the phase diagram and the lattice constant measurements, the LPE growth conditions for lattice matching on InP substrates can be easily known.

The In-Ga-As-P phase diagram was calculated by treating the quaternary liquid and solid as simple solutions (14, 15), similar to our previous work (18). Calculation methods to predict the III_A-III_B-V_C-V_D type phase diagram have been derived by Huber (19), Ilegems and Panish (20), and Stringfellow (26). Jordan and Ilegems (27) presented the most rigorous thermodynamic treatment of solid-liquid equilibria in this type of quaternary system. Therefore, we adopted Jordan and Ilegems's model for calculation of the In-Ga-As-P phase diagram. The reasonable values found in the literature were used as the interaction parameters necessary for the calculation. These values are listed in Table III. The calculated results represented by solid lines in Fig. 1-6, however, did not agree well with the experimental ones.

Exact reasons for the disagreement are not known, but it seems that one of the reasons may be the unsuitability of the interaction parameters used for calculation. These parameters have been derived from

Table III. Thermodynamic input data for the In-Ga-As-P phase diagram calculation

T_{AB}^F and ΔS_{AB}^F are the temperature and entropy of fusion of the AB compound, respectively. Ω^l and Ω^s are the interaction parameters in the liquid and solid, respectively.

Input data	
T_{GaP}^F = 1738°K (21)	T_{GaAs}^F = 1511°K (21)
T_{InP}^F = 1343°K (22)	T_{InAs}^F = 1215°K (23)
ΔS_{GaP}^F = 16.8 cal/mole °K (15)	ΔS_{GaAs}^F = 16.64 cal/mole °K (24)
ΔS_{InP}^F = 14.0 cal/mole °K (15)	ΔS_{InAs}^F = 14.52 cal/mole °K (24)
Ω_{GaP}^l = 2800 − 4.8T cal/mole (15)	Ω_{GaAs}^l = 5160 − 9.16T cal/mole (25)
Ω_{InP}^l = 4500 − 4.0T cal/mole (15)	Ω_{InAs}^l = 3860 − 10.0T cal/mole (15)
Ω_{GaIn}^l = 1060 cal/mole (15)	Ω_{AsP}^l = 1500 cal/mole (15)
$\Omega_{GaP-GaAs}^s$ = 400 cal/mole (15)	$\Omega_{InP-InAs}^s$ = 400 cal/mole (15)
$\Omega_{GaP-InP}^s$ = 3500 cal/mole (15)	$\Omega_{GaAs-InAs}^s$ = 3000 cal/mole (15)

curve-fitting with the binary or ternary experimental phase diagrams, but most of them have not been determined at such low temperature as 600° or 650°C. Therefore, it is difficult to entirely fit the calculated results with the experimental data presented in this paper. For obtaining reasonable agreement, values of several parameters need to be changed. This seems to suggest that the departure from regularity in the thermodynamic property of the In-Ga-As-P system cannot be neglected. That is, the interaction parameters may be functions of temperature and composition in the strict sense. For example, Osamura and Murakami (28) reported that the partially associated solution model successfully explains the asymmetric III-V binary phase diagrams of the AlSb, InP, GaP, and InAs systems whose compounds have relatively large ionicity (29). Such an idea gives us a hint for the development of a thermodynamic model which can explain every III-V phase diagram data quite satisfactorily.

Summary

The In-Ga-As-P quaternary equilibrium phase diagram was experimentally determined at 600° and 650°C. From this investigation of the phase diagram and lattice constant measurements, we have found the LPE growth conditions of exactly lattice-matched $In_{1-x}Ga_xAs_{1-y}P_y$ ($0 \leq x \leq 0.35$, $0.3 \leq y \leq 1.0$) layers on InP substrates and also found that the $In_{1-x}Ga_xAs_{1-y}P_y$ quaternary solid solutions obey Vegard's law.

High Temperature Annealing Behavior of Oxygen in Silicon

H. J. Ruiz and G. P. Pollack*

Texas Instruments Incorporated, Semiconductor Research and Engineering Laboratories, Dallas, Texas 75222

ABSTRACT

It is well known that the Czochralski-grown silicon commonly used in manufacture of electronic devices contains, as a major impurity, oxygen in excess of 1×10^{18} atoms/cm^3. At typical device-processing temperatures (900°-1300°C) this oxygen is quite mobile and has been shown to interact in a complex manner both with the silicon lattice and the dopant species used to form active regions in the device (1, 2). In this report, the effect of high temperature annealing on the state of oxygen near the surface of silicon wafers is examined. It is shown that, after high temperature annealing, a considerable number of oxygen donors can still be generated at 450°C except in the region near the surface where the oxygen donor concentration is reduced in a manner which suggests out-diffusion of oxygen from the silicon lattice.

Experimental

The substrates used in this study were 2 in. diam <111> silicon wafers, sliced from adjacent sites in the top portion of a Czochralski-grown crystal and mechanically polished on one side to a thickness of 15 mil. The crystal was phosphorus doped with an average resistivity of 5 Ω-cm ±10% in the region selected. The interstitial oxygen concentration, as measured by the 9 μm absorption band in silicon, was 1.4×10^{18} atoms/ cm^3 (3). In addition, several similarly prepared slices were obtained from the top portion of a phosphorus-doped 4 Ω-cm <111> crystal grown by the float-zone method. The oxygen concentration in this crystal was found to be less than 5×10^{15} atoms/cm^3.

The wafers were subjected to various high temperature diffusion, oxidation, and annealing cycles which were designed to simulate the type of environment typically encountered during device processing. The wafers then received a 100 hr 450°C nitrogen anneal in an attempt to form electrically active oxygen donors from those with oxygen still present in its original interstitial state. Spreading resistance measurements were then made on angle-polished samples taken from the center of each wafer. The spreading resistance apparatus consisted of an in-house built spreading resistance probe interfaced to a computer-controlled data acquisition system. This allowed the spreading resistance data to be automatically translated and plotted as resistivity *vs.* depth for each of the samples.

Results and Discussion

As an initial experiment a float-zone and a Czochralski grown-wafer were given a 1 hr deposition from a boron nitride source at 1050°C followed by a 1150°C diffusion cycle consisting of 15 min in O_2 and 2 hr in N_2. The spreading resistance profile obtained on a sample taken from the float-zone wafer is shown in Fig. 1. In this case, no change in the bulk resistivity was observed after the 450°C heat-treatment which indicates that no electrically active oxygen was present in the sample. The spreading resistance profile obtained before and after the 450°C heat-treatment on samples taken from the Czochralski-grown wafer are shown in Fig. 2. Note that, even after considerable high temperature processing, a significant number of oxygen donors were generated by the 450°C heat-treatment as evidenced by the decrease in the bulk resistivity from 5 Ω-cm to approximately 0.55 Ω-cm after heat-treatment. Of particular interest, however, is the increase in the bulk resistivity that is observed in the heat-treated sample in the region near the boron-diffused junction. This surface resistivity gradient has also been observed in the nondiffused surface regions of oxide-patterned Czochralski-grown wafers after 450°C heat-treatment. Thus, this apparent decrease in oxygen donor activity near the surface of Czochralski-grown wafers is not associated with the presence of the boron-diffused junction.

The results suggest that oxygen has outdiffused from the wafer surface during the high temperature processing, thus reducing the amount of oxygen available for donor formation in the region near the surface. The

Key words: oxygen donors, oxygen diffusion, silicon wafer processing, spreading resistance.

driving force for this outdiffusion is assumed to be the lower oxygen solubility at these processing temperatures. In order to test this hypothesis, a number of Czochralski-grown wafers were annealed in nitrogen at 1100°C for times ranging from 1-100 hr. At 1100°C the solid solubility of oxygen in silicon is almost an order of magnitude below the measured value of 1.4×10^{18} atoms/cm^3 in these samples (4). The spreading resistance profiles obtained after the 450°C anneal for samples annealed for 1, 9, and 25 hr at 1100°C are shown in Fig. 3. Note that, as the annealing times are increased, the bulk resistivity value is reached asymptotically at increasing depth below the surface. For annealing times greater than approximately 36 hr, the bulk resistivity was found to slowly increase from its minimum range of 0.6-0.7 Ω-cm to 5 Ω-cm, until after 100 hr at 1100°C no change in the bulk resistivity was observed after the 450°C anneal.

These results suggest that, for annealing times less than 36 hr, the center region of the 15 mil thick wafer can be treated as a semi-infinite source of oxygen. A solution of the diffusion equation subject to this boundary condition yields the following expression for the distribution of oxygen in the wafer

$$C = C_F + (C_O - C_F)\ \mathrm{erfc}\left(\frac{\chi}{2\sqrt{Dt}}\right) \quad [1]$$

where C_F is the solid solubility of oxygen in silicon at 1100°C, and C_O is the initial oxygen concentration in the wafer. The relationship between the oxygen donor concentration is believed to follow a power law dependence (1). Since there is some question as to the exact form of this dependence, it will be assumed, for simplicity, that Eq. [1] also reasonably approximates the oxygen donor distribution in the samples. The resistivity distribution in the wafer is then given by the relation

$$\frac{1}{\rho} = \frac{1}{\rho_S} + \frac{1}{\rho_B}\ \mathrm{erf}\left(\frac{\chi}{2\sqrt{Dt}}\right) \quad [2]$$

where ρ_S is the resistivity at the wafer surface, *i.e.*, $x = 0$, and ρ_B is the net decrease in resistivity produced by the oxygen donor formation. The surface resistivity ρ_S can be expressed as

$$\frac{1}{\rho_S} = e\mu_n(N_D - N_A + N_F) \quad [3]$$

where $N_D - N_A$ is the net impurity density other than oxygen donors, N_F is the oxygen donor density at the surface, e is the electronic charge, and μ_n is the electron mobility. The decrease in resistivity produced by oxygen donors, ρ_B, can be expressed as

$$\frac{1}{\rho_B} = e\mu_n(N_o - N_F) \quad [4]$$

where N_o is the oxygen donor density in the semi-infinite bulk region of the wafer.

A curve fit of Eq. [2] to the results shown in Fig. 3, while not exact, has been found to be reasonably good. Average values for ρ_S and ρ_B obtained from the results shown in Fig. 3 are $\rho_S = 4.5$ Ω-cm and $\rho_B = 0.65$ Ω-cm. If, for convenience, $\chi/2\sqrt{Dt}$ is assigned a value of 0.6, Eq. [2] can be solved and yields a value of $\rho = 0.91$ Ω-cm. Values of χ obtained from the spreading resistance plots at $\rho = 0.91$ Ω-cm are shown in Fig. 4 plotted as a function of the square root of the annealing time. As predicted by Eq. [2], a linear dependence between χ and $\sqrt{t}$ is observed. A fit of the expression

$$\chi = 1.2\sqrt{Dt} \quad [5]$$

to the results shown in Fig. 4 yields a value of $D = 1.3 \times 10^{-10}$ cm^2/sec for the diffusion coefficient of oxygen in silicon at 1100C. This is in good agreement with the most recently published value for the diffusion coefficient of oxygen in silicon of $D = 1.4 \times 10^{-10}$ cm^2/sec obtained by Takano and Maki (4).

As a final result, it was found that diode test structures fabricated in this material exhibited no measurable degradation in the form of enhanced reverse leakage after heat-treatment at 450°C. The only measurable change exhibited by these structures was a decrease in both breakdown voltage and reverse leakage as a result of the decreased resistivity in the region of the junction. This low leakage is presumably due to the shallow nature of the oxygen donor levels in silicon, ~0.13 eV, which prevent the oxygen donor from acting as an efficient generation-recombination center.

In summary, it has been shown that even after considerable high temperature processing, a large number of oxygen donors can still be generated in Czochralski-grown silicon wafers after heat-treatment at 450°C. However, in the region near the wafer surface, this oxygen donor activity is considerably reduced due to the effect of oxygen outdiffusion. No change in junction properties is produced by this annealing other than those effects resulting from an increase in donor density.

Properties of Liquid Phase Epitaxial $In_{1-x}Ga_xAs$ ($x \cong 0.5$) on InP Substrate

Yoshikazu Takeda, Akio Sasaki, Yujiro Imamura, and Toshinori Takagi

Department of Electronics, Kyoto University, Kyoto, Japan

ABSTRACT

Undoped $In_{1-x}Ga_xAs$ ($x \cong 0.5$) crystal films with very homogeneous composition were grown on InP substrates by liquid phase epitaxy. Study was made on physical, electrical, and optical properties of this mixed crystal. The growth temperature was varied between 550° and 750°C. All the crystals were n-type. The electron mobility was found to vary from 5240 to 8500 cm^2 V^{-1} sec^{-1} and the electron concentration from 6.3×10^{16} to 1.3×10^{16} cm^{-3} at 300°K. Etch pit density and half-width of photoluminescence spectra decreased with increasing growth temperature. High quality crystals were grown at around 700°C.

Much interest has been recently focused on $In_{1-x}Ga_xAs$ mixed crystal because of its applications to optical sources (1-3) and detectors (4) in the 1.06 μm low loss region of optical fibers (5). Efficient light-emitting diodes and room temperature laser diodes were fabricated with this material. Another potential application of this mixed crystal is for high frequency devices (6).

The mixed crystal can be designed to have larger bandgaps than InAs and higher mobilities than GaAs. Near middle composition the bandgap, E_g, is about 0.75 eV at which the extrinsic carrier concentration ($>10^{15}$ cm^{-3}) is not affected by the temperature variations of the intrinsic carrier concentration ($\sim 10^{11}$ cm^{-3}) around room temperature. Further, the energy separation, ΔE, between the central and the satellite valleys in the conduction band becomes wider with the increase of the InAs mole fraction. Near $x \cong 0.5$, E_g is expected to equal ΔE. This does not make the electron velocity decreased by the transferred electron effect. Thus, $In_{1-x}Ga_xAs$ ($x \cong 0.5$) can be considered better suited for high frequency field-effect transistors and high speed switching devices than GaAs or InP (6).

The $In_{1-x}Ga_xAs$ epitaxial films of around middle composition ($x \cong 0.5$) have been grown by vapor phase epitaxy on GaAs (7-8) and Al_2O_3 (9) substrates. Fairly high electron mobilities and the electron scattering analysis were reported by Glicksman *et al.* (10) for $In_{1-x}Ga_xAs$ ($0.75 \leqq x \leqq 1$). However, the mobilities around 6000 cm^2 V^{-1} sec^{-1} are not higher than those of GaAs. Bulk $In_{1-x}Ga_xAs$ crystals have shown very high mobilities (11-12) as compared with epitaxial mixed crystals of around middle composition, but it is difficult to grow single crystals uniform in composition. The difficulty is attributed to large difference between the liquidus and solidus. Single crystals with nonuniform composition are not suitable for most device applications.

A uniform and good crystalline $In_{1-x}Ga_xAs$ can be grown on GaAs by using stepwise (2) or continuous (14-15) compositional grading to take up the lattice mismatch between the substrate and the desired composition layers. However, with the grading process it is not easy to reach $In_{1-x}Ga_xAs$ ($x \cong 0.5$) from GaAs substrate nor is it suitable for mass production. The lattice constant of InP lies in the middle of the lattice constants of InAs and GaAs, matching with that of $In_{0.53}Ga_{0.47}As$, when Vegard's law is applied to $In_{1-x}Ga_xAs$. Moreover, semi-insulating InP substrates, although not yet developed enough, are available which facilitate electrical evaluation of the grown layers and device applications. It has been reported by Sasaki *et al.* (16) that $In_{1-x}Ga_xAs$ ($x \cong 0.5$) can be grown directly on InP by liquid phase epitaxy. Recently, the conditions for LPE growth of $In_{0.53}Ga_{0.47}As$ have been discussed by Sankaran *et al.* (17). Electron mobility and energy gap of LPE $In_{0.53}Ga_{0.47}As$ on InP have been reported by Takeda *et al.* (18).

In this paper, we describe a study on the properties of $In_{1-x}Ga_xAs$ ($x \cong 0.5$) grown on InP from a melt with a theoretical solidus composition of $x = 0.5$ at each growth temperature. Single crystals of $x \cong 0.5$ are grown on semi-insulating InP substrates by liquid phase epitaxy. The growth temperature (the initial temperature at which the melt is brought over the substrate is called the growth temperature in this paper, since the temperature is lowered in this growth process) is varied from 500° to 800°C keeping the other conditions, such as the melt-baking temperature and interval, the cooling rate and interval, and the substrate orientation, the same. Thickness, surface morphology, etch pit density, composition, photoluminescence, electron mobility, and electron concentration of the grown layers are examined.

Experimental Procedures

Crystal growth.—Liquid phase epitaxial growth is carried out in a horizontal graphite boat and slider assembly in a Pd-diffused flowing hydrogen ambient. All the mixed crystals are grown on the Cr-doped ($\rho > 10^3$ Ωcm), (111)B-oriented InP substrates. Growth temperatures are chosen at 50°C intervals from 500° to 800°C. The cooling rate is 0.15°C/min, and the cooling interval is about 10°C at each growth temperature.

Starting materials are six 9's pure In, seven 9's pure Ga (Mitsubishi Metal Mining Company, Limited),

Key words: InGaAs, LPE, heteroepitaxy, InP substrate.

and undoped polycrystalline InAs ($n = 1 \sim 3 \times 10^{16}$ cm^{-3} and $\mu = 20{,}000 \sim 23{,}000$ cm^2 V^{-1} sec^{-1}) (Sumitomo Electric Industries, Limited). The Ga is not etched, but the In is etched with a 5% $HCl{:}H_2O_2$ solution, and the InAs with a 1% Br:methanol solution just prior to loading. Polished InP substrates are etched with a 1% Br:methanol solution for 2 min. The melts are about 2g, and a slight excess of InAs is added to ensure As saturation in the melt. The substrate dimensions are $10 \times 5 \times 0.4$ mm^3.

Prior to growth, In and Ga are baked in a flowing hydrogen ambient at 800°C for 3 hr to mix the In atoms and Ga atoms. In order to minimize the thermal etching of the substrate surface and to avoid the deviation of the melt composition due to the loss of As during the baking treatment at a high temperature, the substrate and the InAs are introduced to the furnace after cooling the melt to room temperature. The substrate is placed in a recess of the boat and is covered with the slider to minimize thermal etching during the saturation time of the melt.

The phase diagram was calculated according to Wu and Pearson's model (19), and the ternary melt having a solidus composition of $In_{0.50}Ga_{0.50}As$ is used at each growth temperature. The melt compositions are given in Table I.

Composition.—The composition is determined by x-ray diffraction of the Cu-$K_{\alpha 1}$ radiation using Vegard's law which can be applied to this mixed crystal (20). At high diffraction angles such as for (333) or (444) reflections, both reflections from the epitaxial layer and the substrate are detected. Since the diffraction angle of the InP substrate is known, the precise diffraction angle of the mixed crystal is determined from (333) or (444) reflection using the substrate reflection as an internal standard.

Photoluminescence (PL).—The photoluminescence excited by a He-Ne laser (6328Å) is detected by a PbS photoconductive diode cooled with a Dry Ice: ethanol solution. A conventional lock-in technique is used. The spectral response of the total system is in the range from 1.4 to 2.3 μm (at half-responses). After being lightly etched with a 1% Br:methanol solution, the sample is attached to a copper jig and immersed in liquid nitrogen contained in a double wall Dewar. All the samples are angle-lapped at 3° to examine the spectral variations along the thickness of the grown layers. The sample is moved parallel to the angle-lapped surface by a manipulator to which the copper jig is attached.

Resistivity and Hall coefficient measurement.—The method of van der Pauw (21) is used to determine the resistivity and the Hall coefficient. Typical sample dimensions for the measurements are 4×4 mm^2 and the thickness of the epitaxial layers varied from 3 to 24 μm. Pure indium dots (usually about 300 μm in diameter) are alloyed for contact electrodes at the corners of the grown layers in a flowing hydrogen ambient at 450°C for 1 min. Prior to the alloying, the surface is lightly etched with a 1% Br:methanol solution.

The sample temperature is varied from 77°K (immersed in liquid nitrogen) to 300°K and controlled to be stable within ±0.5°K. The source current is 20 or 100 μA, and the magnetic field for the Hall coefficient measurement is 5 kG.

Table I. Calculated weight of Ga and InAs per gram of In of melt for solidus $In_{0.50}Ga_{0.50}As$

T_G (°C)	In (g)	Ga (mg)	InAs (mg)
500	1.000	10.27	13.80
550	1.000	13.84	29.94
600	1.000	18.08	58.55
650	1.000	23.14	104.67
700	1.000	29.27	174.12
750	1.000	36.82	275.32
800	1.000	46.58	423.96

Results and Discussion

Thermal etching of InP substrate surface.—Examples of the substrate (111)B-surface baked at 500° and 750°C for 1 hr in a flowing hydrogen ambient are shown in Fig. 1, (a) and (b), respectively. The substrates are placed in a recess of the boat and covered with the slider during the heat-treatment. The substrate surface shows evidence of thermal etching. Small droplets remain on the surface at a lower temperature, and larger droplets at a higher temperature. A large droplet is seen to be due the coalescence of small droplets. The droplets are identified to be In by the electron probe microanalyzer (EPMA), and this thermal etching is due to the thermal decomposition of InP at a high temperature. Similar observations have been reported by Pak *et al.* (22). This etching effect influences the thickness and the surface morphology of the grown layer as is shown next.

Thickness and surface morphology.—As-grown surfaces and cleaved cross sections of the epitaxial layers grown at 500° and 700°C are shown in Fig. 2 (a) and (b), respectively. The as-grown surface at 700°C is the smoothest among those grown in the range from 500° to 800°C. At temperatures below 650°C, the surface becomes rough. Melt droplets are left on the as-grown surface during wiping due to the surface roughness. The thickness of epitaxial layer decreases exponentially with decreasing growth temperature. At 500°C no layer is grown, and this can be attributed to the low solubility of As at 500°C. At temperatures above 750°C, the as-grown surface is also rough. This is confirmed to be caused by the roughness of the substrate surface as a result of the thermal etching. At 800°C the melt remains almost over the entire surface after wiping. However, a uniform layer would be grown if the problem of the thermal etching is overcome by keeping the phosphorus over-pressure

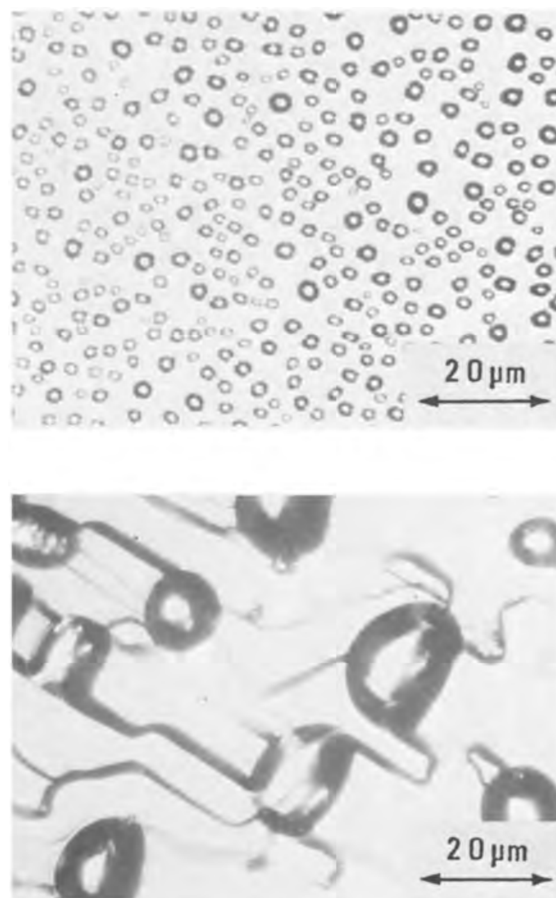

Fig. 1. Examples of the thermal etching of InP substrate surface after 1 hr baking at 550°C (a, top) and 750°C (b, bottom) in a flowing hydrogen ambient.

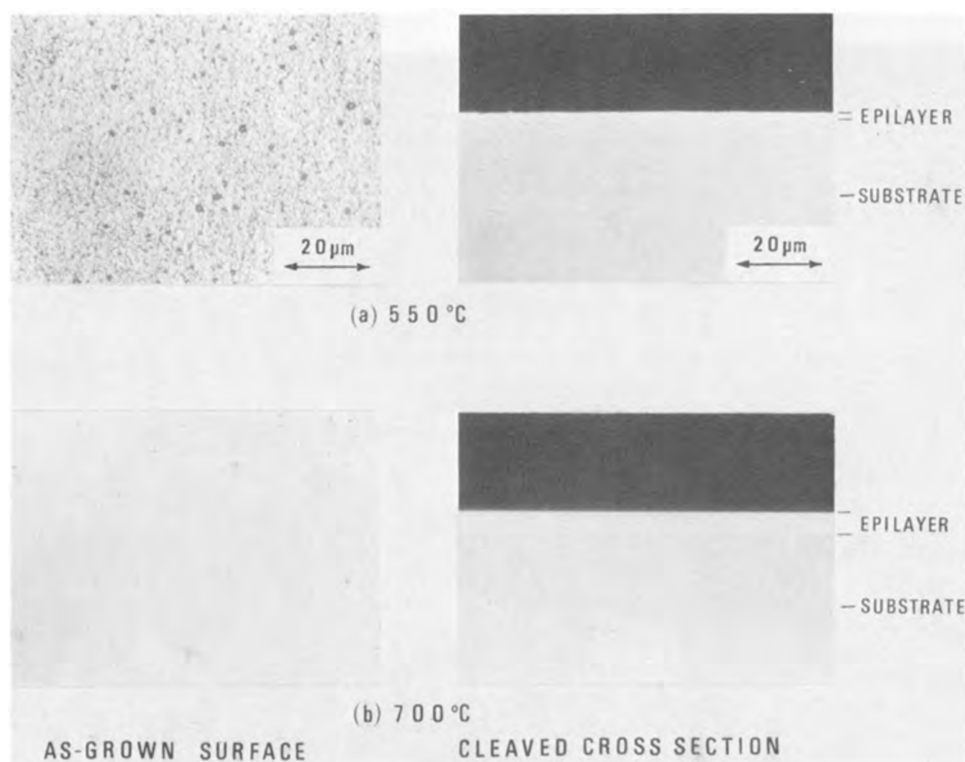

Fig. 2. As-grown surfaces and as-cleaved cross sections of the epitaxial layers grown at 550°C (a) and 700°C (b). Small spots are droplets of melts remaining on rough surface. No inclusions are found in cleaved sections.

or by etching back the InP surface. In the experiments all the mixed crystals grown at 800°C are excluded from the measurements.

In Fig. 3 the temperature dependence of the layer thickness normalized with the In weight in the melt (W_{In}) and the cooling interval (T_c) is shown. Between 550° and 700°C, the curve follows qualitatively the temperature dependence of the As fraction in the melt. The abrupt decrease at 750°C could be explained as follows. A fair amount of In remains on the substrate surface due to the thermal etching, as shown in Fig. 2. The melt when contacted with the substrate is diluted by this In and undersaturated at the interface. Therefore, the initial cooling period is spent in re-equilibration and resaturation and the layer thickness is small. No In inclusions are found at the interface of the layers, indicating that all the In droplets are taken into the contacted melt before the growth begins.

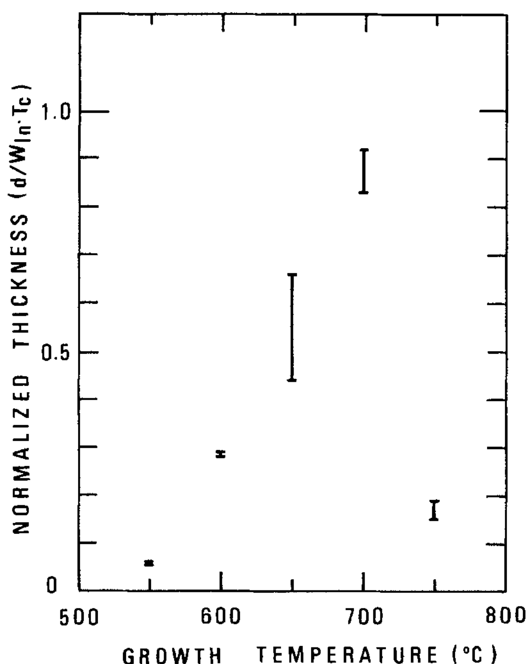

Fig. 3. Layer thickness as a function of growth temperature. The thickness is normalized to In weight (W_{In}) and cooling interval (T_c). The bar length corresponds to variation from sample to sample.

Etch pit density (EPD).—Etch pits in the grown layers are revealed by etching with an A-B solution (23) for 10-30 sec at room temperature. The average density at each growth temperature is listed in Table II. In the sample grown at 550°C the EPD is too high to count, far beyond 10^6 cm^{-2}. This high EPD may be in part due to the relatively large lattice mismatch between the substrate and the layer as is shown in Fig. 4. Better crystals could be grown even at temperatures below 650°C by precisely matching the lattice constant. About 1×10^5 cm^{-2} may be the lower limit of the EPD, because the Cr-doped InP substrate has approximately the same density of etch pits as revealed by etching with an R-C solution (24) for 10 min at 60°C.

Composition.—The composition *vs.* growth temperature is shown in Fig. 4. Although the In-Ga-As solution with the solidus composition of $In_{0.50}Ga_{0.50}As$ at each growth temperature is used, the composition of the mixed crystals grown at temperatures between 650° and 750°C is $In_{0.53}Ga_{0.47}As$ at which the lattice constant of the grown layer matches with that of InP. Below 650°C, the mismatch becomes greater with decreasing temperature.

As pointed out by Wu and Pearson (19) the accuracy of the solidus data in their experiment is ±3 mole percent. In our experiments at 600° and 550°C the deviation is over this range. It is possible that the lower Ga composition obtained at these temperatures is due to the inaccuracy of the Wu and Pearson phase diagram. Only a few experimental

Table II. Average EPD of mixed crystals at each growth temperature

Growth temperature (°C)	Average EPD (cm^{-2})
550	$>>1 \times 10^6$
600	$>1 \times 10^6$
650	$>5 \times 10^5$
700	$\sim 5 \times 10^5$
750	$\sim 1 \times 10^5$

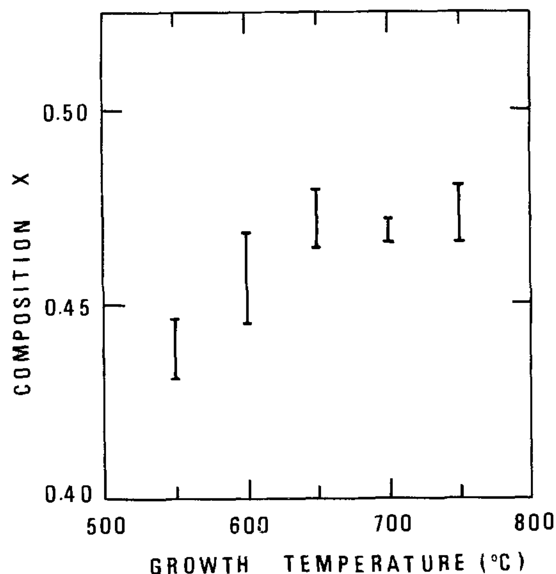

Fig. 4. Composition vs. growth temperature. The In-Ga-As solution of solidus composition $x = 0.5$ is used at each growth temperature.

data were examined in their phase diagram calculation at these lower temperatures.

Between 650° and 750°C the compositions of the grown layers are within the accuracy of the phase diagram and almost lattice-matched ($x \sim 0.47$) to the InP substrate. It could be considered that at these temperatures lattice-matched layers are obtained at the lower limit 0.47 (=0.50-0.03) of the accuracy of the phase diagram, but there may be another possibility that the lattice-matched layer is forcibly grown by the composition latching in the growth of InGaAs on InP in a certain range of composition as was observed by Stringfellow (25) in the LPE growth of InGaP on GaAs. Further investigations are being carried out on these phenomena and on the determination of the optimum melt composition for lattice matching at each growth temperature.

Continuous layers are obtained from melts of slightly deviated composition from 0.50, but from melts of 0.40 and 0.70 at 700°C only island growth, shown in Fig. 5, is observed as reported by Sankaran *et al.* (17).

An example of the (444) reflections is shown in Fig. 6. The reflections from the epitaxial layer and the substrate are detected at this high angle, and from these peaks a mismatch of 6.6×10^{-4} is calculated. The $K_{\alpha 1}$ and $K_{\alpha 2}$ peaks are clearly resolved, indicating good homogeneity of this mixed crystal which is grown at 750°C. The half-width of the peak from the epitaxial layer increases with decreasing growth temperature.

Photoluminescence.—Emission spectra of two epitaxial layer surfaces grown at different temperatures

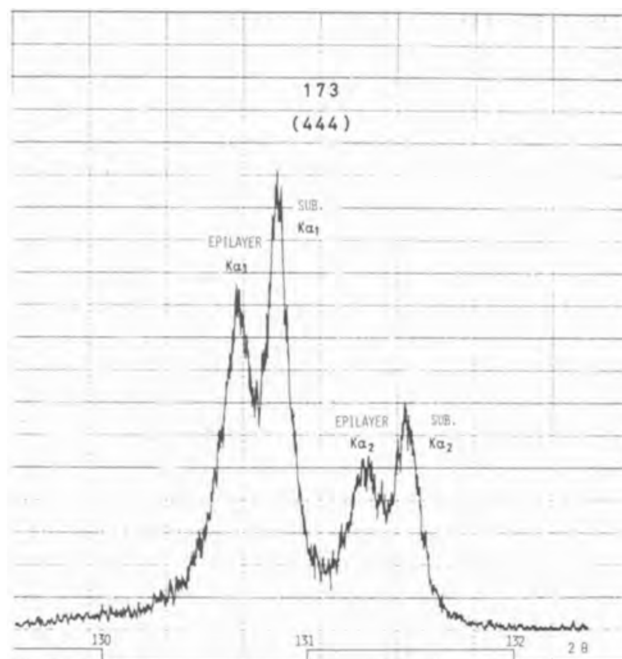

Fig. 6. An example of (444) x-ray reflections from the $In_{1-x}Ga_xAs$ layer and the InP substrate. $K_{\alpha 1}$ and $K_{\alpha 2}$ peaks from both crystals are clearly resolved.

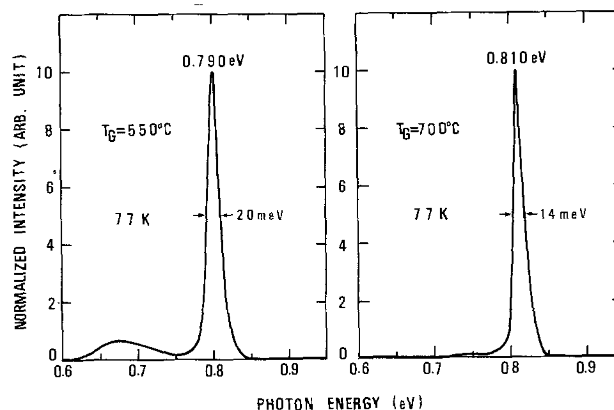

Fig. 7. Photoluminescence spectra (77°K) of two epitaxial layers grown at 550°C (a) and 700°C (b).

are compared in Fig. 7. There are two distinctions in the spectra: the photon energy at peak intensity and the half-width. The compositions determined by the photon energies at peak intensities are close to those in Fig. 4 obtained by x-ray diffraction. A good fit to the photon energy ($h\nu$) *vs.* composition (x), in the region $0.43 < x < 0.48$ and at $x = 0$, InAs, and $x = 1$, GaAs, at 77°K is given by

$$h\nu(\text{eV}) = 0.404 + 0.649x + 0.457x^2$$

The curve gives quite the same values as those by Wu and Pearson at 77°K (19).

The full width at half-maximum (FWHM) of the spectra decreases linearly with the increase of the growth temperature, *i.e.*, from ~20 meV at 550°C to ~14 meV at 750°C. This dependence is not based on the composition variation across the grown layer within the penetration depth of the He-Ne laser beam. Such a composition variation can be expected from the phase diagram (19); however, the lower the growth temperature, the smaller the composition variation for a cooling interval of 10°C at $x \cong 0.5$. Furthermore, in the experiments, the composition variation from near the interface to the surface is measured to be within ±1% by the EPMA and the photoluminescence. Moreover, the penetration depth of the

laser beam is less than 1 μm. Along with the growth temperature dependence of the half-width of x-ray reflection peak, it is understood that mixed crystals of better composition homogeneity are grown at higher temperature.

The variation of the photon energy at peak intensity, the intensity, and the FWHM along the angle-lapped grown layer are shown in Fig. 8 for sample 153 as an example. Constant photon energy indicates the uniformity in the composition, and very small variations of the intensity and the FWHM show a homogeneous crystal quality across the grown layer. Similar results are obtained in every sample at different growth temperatures. A relatively low intensity near the interface is due to the finite diameter of the laser beam (~50 μm), *i.e.*, at distance 0 μm, most of the laser spot irradiates the substrate and at about 3 μm (corresponding to about 50 μm in a layer angle-lapped by 3°) the whole spot is on the grown layer.

Electrical properties.—The highest electron mobilities at different growth temperatures are listed in Table III along with electron concentrations and compositions. In the table, the data of GaAs grown in the same growth system at 800°C are shown for comparison. All the grown mixed crystals are n-type with excess carrier concentrations of the order of 10^{16} cm^{-3}. Our experiments indicate the general tendency that the mobility increases while the concentration decreases with increasing growth temperature. An observation similar to this has been made in the case of InP grown at temperatures between 540°

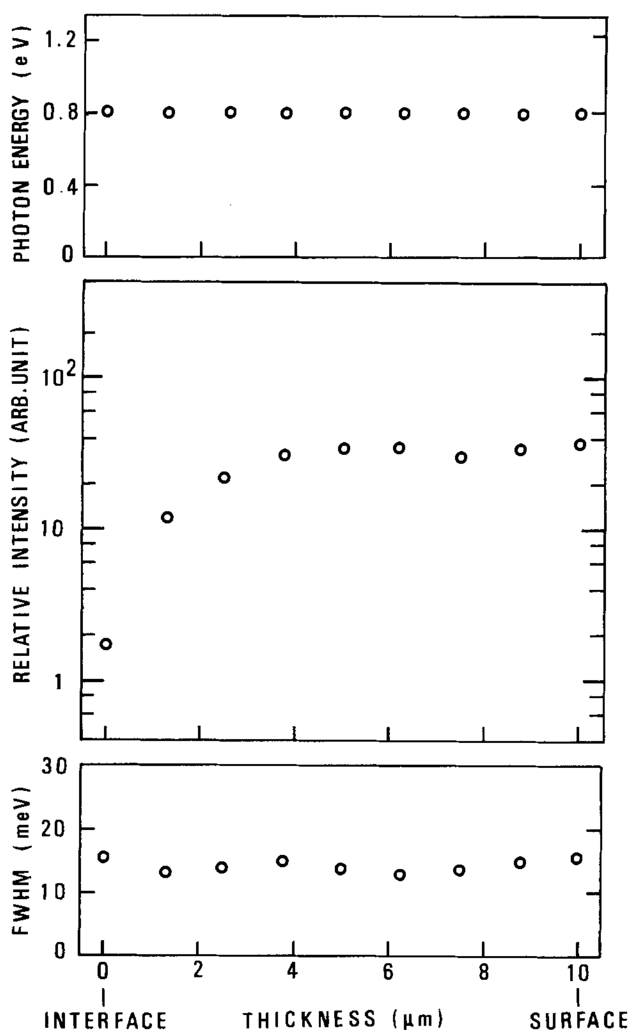

Fig. 8. Variations of the photon energy at peak intensity, the intensity, and the FWHM along the angle-lapped cross section in sample 153, showing good composition homogeneity and uniform crystal quality.

Table III. Composition and electrical properties of mixed crystals and GaAs

* μ (cm^2 V^{-1} sec^{-1}), n (cm^{-3}).

and 780°C by LPE on InP (26). It seems from Table III that better mixed crystals (with higher mobility and lower concentration) can be grown at higher temperatures. But the epitaxial layer is nonuniform at high temperatures due to the thermal etching of the substrate surface. Invariably, the mobility of the mixed crystals increases with decreasing lattice temperature in contrast to Conrad's (7) and Baliga's (8) data. Both 8500 cm^2 V^{-1} sec^{-1} at 300°K and 22,100 cm^2 V^{-1} sec^{-1} at 77°K of sample 173 are significantly high in the epitaxial $In_{1-x}Ga_xAs$ ($x \cong 0.5$) (7-8, 14) and comparable to those of bulk grown mixed crystals (11-13).

Recently, Sankaran *et al.* (17) have reported mobility values of 10,030 cm^2 V^{-1} sec^{-1} at 300°K and 34,620 cm^2 V^{-1} sec^{-1} at 77°K in $In_{0.53}Ga_{0.47}As$ grown at 650°C by LPE on InP substrate, using the In, Ga, and As for the melt which was baked at 725°C for 22 hr. With the In, Ga, and InAs as melt constituents they have obtained 5540 cm^2 V^{-1} sec^{-1} at 300°K and 8430 cm^2 V^{-1} sec^{-1} at 77°K. Using almost the same purity In, Ga, and InAs, we have obtained mobility values of about 8000 cm^2 V^{-1} sec^{-1} at 300°K in the $In_{0.53}Ga_{0.47}As$ grown between 650° and 750°C by baking the In and Ga at 800°C for only 3 hr.

There has been a distinct difference in the value of the mobility between an epitaxial and a bulk $In_{1-x}Ga_xAs$ ($x \cong 0.5$), *i.e.*, the former has been lower and the latter similar to or higher than that of GaAs. Although Conrad *et al.* (7) suspected that the mixed crystal formation *per se* might be responsible in part for the low mobility and its temperature dependence, our results contradict this conclusion. The low mobility of the epitaxial layer grown previously can be considered to be due to a large internal strain and a large number of defects in the layer caused by the lattice mismatch with the substrate.

The electron concentration is calculated from the Hall coefficient using the relation

$$n = 1/eR_H$$

where e is the electron charge and R_H is the Hall coefficient. The Hall factor is assumed to be 1 for simplicity as is usually done. Figure 9 shows the electron concentration *vs.* inverse absolute temperature for three samples. The curve of a low concentration sample 173 shows two distinct regions suggesting two impurity levels at least; a shallow level for $T <$ 200°K and a deeper level for $T >$ 200°K. The distinction is not clear in the higher concentration samples. To find the donor and acceptor concentrations, a wider range of the temperature dependence of the electron concentration has to be measured and analyzed. However, it is evident from the temperature dependence of the mobilities that the impurity concentrations are not very high and the impurity scattering cannot be dominant at room temperature.

Conclusions

Undoped $In_{1-x}Ga_xAs$ ($x \cong 0.5$) films were grown on the InP substrates by liquid phase epitaxy at temperatures between 550° and 750°C by the present growth process. Etch pit density, half-width of the

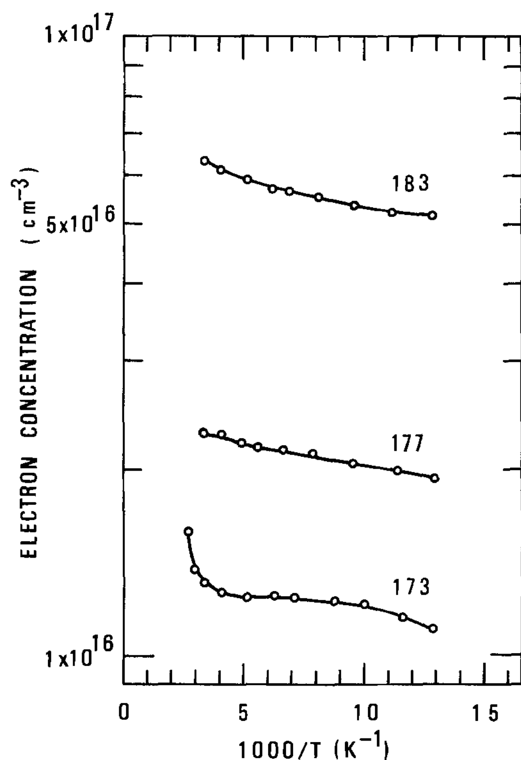

Fig. 9. The electron concentration as a function of inverse absolute temperature. In sample 173, there are at least two impurity levels.

PL spectra, and electron concentration decrease, while the electron mobilities at room temperature and at 77°K increase with increasing growth temperature. Composition and crystal quality are very uniform across the grown layer. The electron mobility is as high as 8500 cm^2 V^{-1} sec^{-1} at 300°K and increases on cooling from 300°K to 77°K in all samples. Although the crystal quality and the electrical properties seem to be better at high growth temperatures, the thermal decomposition of the InP substrate makes it difficult to obtain a uniform growth of the mixed crystal on the substrate. High quality crystals are grown at around 700°C.

Acknowledgment

We are grateful to Dr. Shigeo Fujita for valuable discussions and experimental facilities and to Professor Tanaka's laboratory for x-ray diffractometer. It is a pleasure to acknowledge Mr. Yukio Naito for his assistance in the electrical measurements. This work was supported in part by the Grant-in-Aid for the specified subject "Crystal Growth" from Scientific Research of the Ministry of Education in Japan.

Manuscript submitted Aug. 16, 1976; revised manuscript received Aug. 22, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Polishing of Sapphire with Colloidal Silica

Henry W. Gutsche and Jerry W. Moody

Monsanto Company, Electronic Products Division, St. Peters, Missouri 63376

ABSTRACT

The polishing of sapphire with colloidal silica has been studied. Stock removal rates have been found to vary with the solids content in the polishing fluid and the temperature on the polishing pad. The pH of the polishing fluid has also been found to be a factor influencing removal rate. Because concentrated silica solutions are unstable at high temperatures, a compromise between temperature and concentration must be made. Still, practical removal rates over 25 μ/hr have been achieved. Work damage, an important factor in polishing operations, has been found to extend about 1.0-1.5 mils into the surface of commercially available sawn or ground sapphire blanks. When all embedded diamond from the slicing and grinding operations is removed prior to polishing, a scratch-free, featureless surface is produced on which high quality, epitaxial silicon films can be deposited. C-MOS devices built into the films without the use of any specific processing technique to minimize the effect of the Al_2O_3-Si interface showed n-channel leakage of 1×10^{-10} A/mil with negligible wafer-to-wafer variations (1). The polishing of sapphire by colloidal silica is believed to follow a chemical reaction leading to aluminum silicate dihydrate as described in previous literature. For the reaction

$$Al_2O_3 + 2SiO_2 + 2H_2O \rightarrow Al_2Si_2O_7 \cdot 2H_2O \quad [1]$$

an activation energy of 14.6 kcal/mole has been calculated from the temperature dependency of the removal rate.

Sapphire, *i.e.*, αAl_2O_3, is used to advantage as a dielectric substrate under thin silicon films for integrated circuits and microwave devices with highly desirable features which are difficult or impossible to achieve on bulk silicon. Nonetheless, high material cost and difficulties with leakage currents have limited silicon-on-sapphire electronics to special applications only. The high material cost is related partly to the present low level of production and need not concern us here. The leakage currents, however, are our concern. One source of leakage currents is the Si/Al_2O_3 interface where lattice mismatch is often aggravated by the use of substrate material with mechanically polished surfaces.

Mechanical polishing produces mirror surfaces on the macroscopic scale only. "Semiconductor" polishing, *i.e.*, preparing material for electronic device work, must produce a surface which is whole, flat, and clean on the microscopic scale, better yet, on the atomic scale. Ideally, semiconductor surface preparation should produce a substrate that is enveloped by a natural, low energy, low index crystal plane that contains no remnant work damage and is covered by a well-defined usable or easily removable protective film.

In the case of silicon, polishing with colloidal SiO_2 has gained a reputation for producing a nearly perfect substrate surface for even the most critical integrated circuit application. Polishing with colloidal SiO_2 was patented in 1963 by Walsh and Herzog (2) as a mechanical process, and in 1966 as mechanical-chemical by Lachapelle (3), who found that the alkalinity of the polishing fluid drastically affected the removal rate.

Silicon surfaces polished with colloidal SiO_2 have been investigated by several authors (4-7). Techniques ranging from Sirtl etching before or after oxidation and epitaxial film growth to x-ray diffraction and ion backscattering have been applied. In all cases SiO_2 polished surfaces have been found to be free of damage, free of contour, and free of contamination. As a consequence semiconductor polishing with colloidal SiO_2 is now the worldwide accepted standard method for silicon substrate preparation. Colloidal SiO_2 also works on many other substances: metals and glasses, for example. It is particularly useful for polishing garnets (8).

Because of the success with garnets and silicon, it was therefore tempting to investigate whether colloidal SiO_2 could produce a similar surface on sapphire substrate. At first look such an endeavor seems obviously futile. When polishing silicon, with colloidal SiO_2 the particles may crystallize and reach a hardness sufficient to provide some degree of gentle molecular abrasion (9). Also, the alkalinity of the solution may be sufficient to chemically dissolve the substrate where friction generates enough heat on the surface of silicon. Surfaces of α-aluminum oxide, on the other hand, are extremely hard (Mohs' > 9) and allow even reactive melts at temperatures over 1000°C to dissolve only a few microns per hour (10). It was therefore rather surprising to find that colloidal SiO_2, in the complete absence of diamond particles, does indeed polish sapphire and produce a damage-free surface which is suitable for the growth of thin silicon epitaxial films for device work.

Before SiO_2 polishing of silicon, one physical imperfection in particular has been blamed for many device failures: remnant surface damage, that is to say, work damage left in mechanically shaped slices after inadequate polishing or etching. Especially in epitaxial wafers, surface damage in the substrate has been related to severe crystal disorder in the deposited film, often rendering the material useless for device work. Similarly remnant surface damage in sapphire substrate under thin epitaxial silicon films must make it next to impossible to prepare a good silicon-on-sapphire device. To date little has been published on processes for the preparation of a damage-free, flat, and clean sapphire-polished slices. Authors usually acknowledge the existence of "work" damage in the diamond-polished substrate surfaces they work with but rely then on "healing by annealing" for a remedy.

In silicon-on-silicon epitaxy only a slight lattice mismatch exists between the usually heavily doped substrate and the usually lightly doped film. It still leads to measurable tensile strain in n-on-p wafers however. In silicon-on-sapphire epitaxy, in addition to a considerable lattice mismatch [6% for {100} Si on $(1\bar{1}02)$ sapphire] (11), the large difference in their respective coefficients of thermal expansion cause the silicon film to sustain 8×10^9 dyne/cm^2 strain when grown at 1000°C and cooled to room temperature.

Therefore, for the preparation of usable epitaxial silicon films on sapphire, absence of damage in the substrate surface becomes an extremely important factor.

Experimental Results

Crystals.—The slices used were sawed from 2 in. diam sapphire crystals purchased from Union Carbide, San Diego, California, and from Crystal Systems, Salem, Massachusetts. The slice surfaces were oriented to within ±2° of the $(\bar{1}\bar{1}02)$ plane by Laue back-reflection. Sawing was done on a Silicon Technology saw, Silicon Technology Corporation, Oakland, New Jersey, equipped with a rotating ingot holder.

Slice preparation.—After sawing, the slices are 20 mils thick. They were fine ground to 14 mils on a Mueller grinder, Kugel-Mueller, Nurenberg, Germany, equipped with a 230 grit diamond wheel. To achieve complete absence of diamond which is necessary for scratch-free polish and to minimize bow after polishing, the ground slices are annealed in O_2 at 1100°C for 2-4 hr.

Polishing.—The polishing step was carried out on an Elgin 1-20 machine, Elgin Tool Company, Whitehall, Michigan, equipped with an oscillating pressure arm. A PR-30 polishing cloth, Process Research Products, Pennington, New Jersey, was found suitable, but non-perforated Pellon and Buehler Microcloth was also useful, albeit quick to wear out. Stock removal rate was calculated by measuring the thickness with a dial micrometer at 5 points on the wafer periodically during polishing. The fluid was Syton HT-40, Monsanto Company, St. Louis, Missouri.

It was found that the thin, heavily damaged layer of a freshly ground wafer was removed at stock removal rates of well over 50 μ/hr. The removal rates listed in the following tables and figures were measured after this heavily damaged layer was removed and when the rate became independent of total stock removal. Therefore, the removal rates given are believed to be characteristic of the undamaged $(\bar{1}\bar{1}02)$ sapphire plane under the conditions described.

The influence of various process variables on the speed of polishing expressed as rate of stock removal is shown in Tables I-III. Table I indicates that increasing the solids content of the colloidal SiO_2 solution from about 4 to 25% almost triples the removal rate from 6 to 17 μ/hr. Further increase in solids content does not seem to help matters much, probably because SiO_2 solutions with solid contents over 16% become rather unstable under polishing conditions. The SiO_2 particles agglomerate, precipitate, and finally crystallize thereby reducing the effective concentration of the solution. Therefore, practical removal rates do not exceed 12 μ/hr in strongly basic solutions.

Fortunately, as Table II shows, the speed of polishing is also influenced by the *p*H of the fluid which can be adjusted by carefully adding 0.5*N* HCl. Maximal removal rates occur at *p*H values between 7 and 8. In this manner 10% solid solutions which remove 11-12 μ/hr at *p*H 10.5 will "cut" at 19-20 μ/hr at *p*H 8.

When polishing sapphire with colloidal SiO_2, abrasion can be ruled out as cause for stock removal because sapphire is harder than the SiO_2. Stock removal must occur because of chemical reaction, and it comes

Table II. Removal rate vs. pH of fluid

as no surprise that the removal rate is also dependent on the temperature at the surface of the polishing pad as shown in Table III. This temperature, as monitored using a Fenwal-Spartan 2040 LTF infrared thermometer, is adjustable by varying the pressure of the polishing arm and the flow and temperature of the polishing fluid onto the turntable. We found that 82°C is about the highest operating temperature compatible with the stability of both the polishing fluid and the pad adhesive. Table III shows that the removal rate increased with temperature up to the maximum temperature employed. For practical, routine work a 16% solids, *p*H 8 fluid is recommended at 82°C pad temperature. This will "cut" the $(\bar{1}102)$ plane sapphire at rates ≧25 μ/hr.

Reaction Mechanism

The surprising fact that SiO_2 reacts at all with the extremely hard and nearly inert sapphire can be explained in part by the thermodynamics of the tripartite system $Al_2O_3/SiO_2/H_2O$. In the simplest case $Al_2O_3 + SiO_2 \rightarrow Al_2SiO_5$ such common, naturally occurring aluminum silicates as kyanite, andalusite, or mullite may form. All three reactions are thermodynamically possible, the mullite formation being the most likely of the three at 400°K, which is about the temperature on the surface of the sapphire during the polishing process. The free energies of these reactions are (T = 400°K): $\Delta\mathbf{F}$ (kyanite) = −18 cal/mole; $\Delta\mathbf{F}$ (andalusite) = −55 cal/mole; and $\Delta\mathbf{F}$ (mullite) = −377 cal/mole calculated from enthalpy and entropy data published by the Bureau of Mines (12). The reaction Al_2O_3 (alpha-alumina) + $SiO_2 \rightarrow Al_2SiO_5$ (mullite) is endothermic as might be expected and requires an enthalpy change of +5100 cal/mole at 400°K.

Naturally these data merely indicate that Al_2O_3 and SiO_2 may react at temperatures only slightly above the boiling point of water. However, what actually happens during polishing probably has been described by Schwartz and Brenner (13) who found that "in a neutral $Al_2O_3/SiO_2/H_2O$ system the stable compound $Al_2Si_2O_7 \cdot 2H_2O$ with a structure identical or very similar to natural kaolin is capable of forming," and, "it is uninfluenced by the presence of an excess of silica. It is formed with particular readiness when at least 6 moles of SiO_2 are present for each mole of Al_2O_3." Since we are observing in our polishing system maximal stock removal rates at *p*H values between 7 and 8, we suggest that the formation of $Al_2Si_2O_7 \cdot 2H_2O$ as described by Schwartz and Brenner can indeed explain the chemistry of polishing sap-

phire with colloidal silica at or near the boiling point of water. Indeed, a slight loss of weight can be measured when rough sapphire blanks are simply immersed in a boiling silica solution of pH 7-8.

To proceed with measurable speed the reaction must have available three conditions: (*i*) Heat must be supplied to support the reaction; (*ii*) the reaction product must be continually removed from the sapphire surface; and (*iii*) the reactants must be forced into intimate contact at all times. All three conditions are met during the polishing process. The sapphire surface is pressed against a fast-rotating high friction polishing cloth. The polishing cloth serves as vehicle and heater for the polishing fluid and by moving the Syton particles over the surface of the sapphire under pressure, continuously "shaves off" the reaction product thereby constantly exposing fresh sapphire surface to the SiO_2 in the polishing fluid. The reaction product can sometimes be observed under the electron microscope in the form of triangular, apparently oriented, precipitates ~1000Å in diameter which wipe off with a moist cotton swab (Fig. 1).

Stock removal in Syton polishing of αAl_2O_3 is therefore entirely chemical. No abrasive, fracturing, or otherwise mechanical action removes lattice constituents in the system described. Therefore, this system will not produce a flat, featureless surface as long as damage exists in that surface, simply because a damaged surface element will always polish faster than any damage-free surface element next to it. Since good phase-contrast optics make visible adjacent height differences as shallow as 30-50Å, microscopic examination of clean Syton-polished surfaces constitutes a sensitive test for absence of remnant surface damage. In fact, x-ray rocking curves showed absence of damage, indicating strain in all samples that were polished until their surface appeared featureless at 100× and maximum phase contrast position of the Nomarski attachment to a Reichert microscope.

C-MOS devices built into the films without the use of any specific processing technique to minimize the effect of the Al_2O_3-Si interface showed n-channel leakage of 1×10^{-10} A/mil with negligible wafer-to-wafer variations (11).

The activation energy for the polishing reaction was determined from the temperature dependency of the reaction rate as shown in Fig. 2. From the slope of the line the activation energy was calculated as 14.5 kcal/mole.

Conclusions

Silica solutions have been found to be an effective agent for polishing sapphire wafers for S-O-S device work. Under proper conditions of pH and temperature,

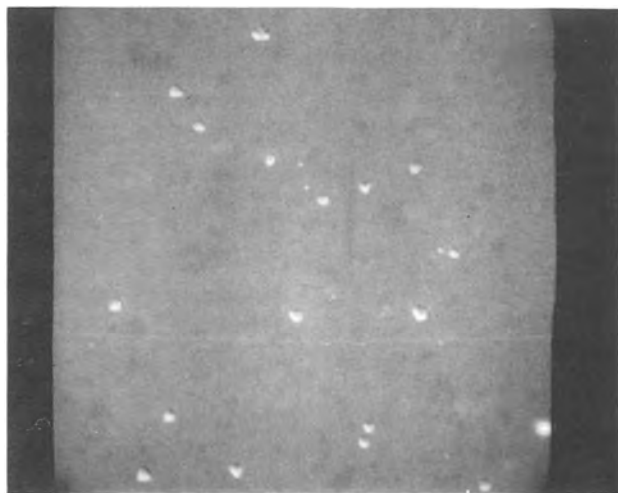

Fig. 1. Reaction products on sapphire surface; electronic microscope 10,000×.

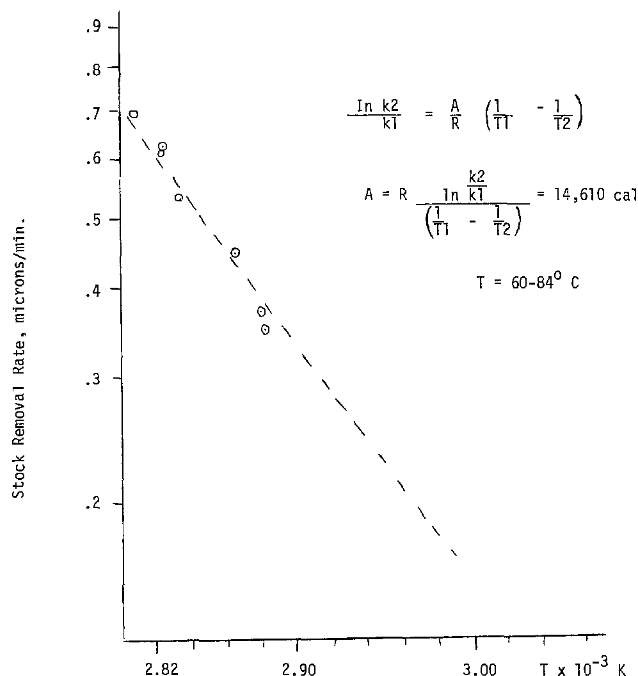

Fig. 2. Removal rate vs. temperature.

stock removal rates ≧25 μ/hr can be realized. It is believed that the polishing results from a chemical reaction between the sapphire and the silica particles in which alumina silicates are formed. Since abrasion can be ruled out completely and a chemical reaction is involved, this polishing procedure produces a surface which must be free of all remnant work damage.

Acknowledgments

The authors wish to thank Mrs. Brenda Schulte for her patience and help with carrying out the experiments. Thanks also go to Drs. J. Fayring and D. Dohm of the Physical Science Center of Monsanto for their valuable EM and x-ray work on the polished-sapphire surface. We also appreciate very much the device work performed by Dr. H. Hawkins of Hughes Aircraft Company to evaluate the influence of the Al_2O_3-Si interface on the electrical characteristics of C-MOS structures.

Physicochemical Properties of Chemical Vapor-Deposited Silicon Oxynitride from a SiH_4-CO_2-NH_3-H_2 System

A. K. Gaind* and E. W. Hearn

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The physicochemical properties of amorphous silicon oxynitride ($Si_lO_mN_p$) films deposited from a SiH_4-CO_2-NH_3-H_2 system have been investigated. The properties of CVD Si_3N_4 and SiO_2 deposited from SiH_4-NH_3-H_2 and SiH_4-CO_2-H_2, respectively, were also investigated, wherever appropriate, to determine the end points of the $Si_lO_mN_p$ series. The film stress is a continuous, approximately parabolic function of silicon oxynitride composition. The $Si_lO_mN_p$ composition also determines its resistance to oxidation in steam (950°-1100°C). It is shown that a ~500Å thick film with the composition of Si_2ON_2 is an adequate barrier to steam oxidation for 6 hr at 1000°C. The etch rate of $Si_lO_mN_p$ films is a function of composition in 7:1 BHF. In refluxing H_3PO_4, a peak in etch rate exists at a film composition of ~64% equivalent Si_3N_4. $Si_lO_mN_p$ films deposited between 900° and 1000°C densify 2-3% after "heat-treatment" at 1000°C for 2 hr and their etch rates decrease by ~50%; whereas the stress increases (more tensile) as a result of heat-treatment.

Silicon oxynitride ($Si_lO_mN_p$) films have been chemical vapor deposited from various chemical systems (1-6), and the resulting properties have been reported (1-8). It was shown earlier by Gaind *et al.* (9) that the SiH_4-CO_2-NH_3-H_2 chemical system results in better process control, especially in forming Si_3N_4-rich oxynitride films; *e.g.*, $Si_lO_mN_p$ films with refractive index $\geqq 1.73$ can be formed with NH_3:CO_2 ratio of ~6 at 900°C, whereas for other chemical systems, the NH_3:oxidant ratio must be at least 50, usually ~5000 depending upon the oxidant (1-5).

It is our purpose to show the similarity between the silicon oxynitrides produced by the above system and those reported in the literature. This is done by comparing physicochemical properties wherever possible with the existing data in the literature. We will at the same time be filling in gaps in the knowledge of physicochemical properties of silicon oxynitride, especially those which are important in the processing of devices (bipolar, FET, etc.) which require wet etching, *e.g.*, the oxidation barrier of oxynitrides to steam and the etch rate in refluxing phosphoric acid. There are no available data in the literature regarding these physicochemical properties.

From a device-processing point of view, the importance of the effect of postdeposition "heat-treatment" (which simulates processes like diffusion or oxidation) on physicochemical properties of these dielectric films cannot be overemphasized. Thus we have investigated the effect of heat-treatment on $Si_lO_mN_p$ film stress, etch rate, and changes in density (thickness). We have also investigated the effect of the deposition temperature on $Si_lO_mN_p$ physicochemical properties by investigating these at two deposition temperatures, 900° and 1000°C.

Experimental

The details of the reactor used (10), the sample preparation, thickness measurement procedures, and typical deposition conditions have been described elsewhere (9). During this study, 1000-1500Å films were used for the determination of most properties, except for stress measurements for which film thicknesses ranged between ~600-8000Å. The details of experimental techniques used to measure stress, etch rates, and other properties are given in the results section of this paper.

Key words: silicon nitride, silicon dioxide, barrier to oxidation, film stress.

Results

The dependence of refractive index of $Si_lO_mN_p$ films on NH_3:CO_2 ratio and the relationship of infrared absorption maxima with the refractive index have been previously established (9). Throughout this paper we have reported the physicochemical properties in terms of the composition of $Si_lO_mN_p$ films rather than their refractive indexes. The composition was calculated from the $Si_lO_mN_p$ refractive index, either (*i*) weight fraction averaging, *i.e.*, Lorentz-Lorenz theory (11-13) or (*ii*) mole fraction averaging techniques. The values used here are the mean of the results obtained by either method. If silicon oxynitride were to be represented as $x \cdot SiO_2 y \cdot Si_3N_4$, then "equivalent" SiO_2 (or Si_3N_4) can be calculated by Lorentz-Lorenz theory using Eq. [1]-[3], *i.e.*

$$n_{on}^2 = \frac{\dfrac{a_{ox} n_{ox}^2 W_{ox}}{\rho_{ox}} + \dfrac{a_n n_n^2 W_N}{\rho_N}}{\dfrac{a_{ox} W_{ox}}{\rho_{ox}} + \dfrac{a_n W_n}{\rho_N}} \qquad [1]$$

where

$$a_{ox} = (n_{ox}^2 + 2)^{-1} \quad \text{and} \quad a_n = (n_n^2 + 2)^{-1}$$

and w_{ox} and w_N are weight fractions of equivalent SiO_2 and Si_3N_4. Using n_{ox} (refractive index of SiO_2) = 1.45[1] and n_n (refractive index of Si_3N_4) = 2.025[1], ρ_{ox} = 2.15[1], and ρ_n = 3.09[1] are SiO_2 and Si_3N_4 densities, respectively. Rearranging Eq. [1] and substituting $W_N = 1 - W_{ox}$, we have

$$W_{ox} = \frac{0.217 - 0.053 \cdot n_{on}^2}{0.0605 n_{on}^2 - 0.021} \qquad [2]$$

where n_{on} is the refractive index of $Si_lO_mN_p$. The mole fraction of equivalent SiO_2 in silicon oxynitride is then given by

$$x = \frac{140\ W_{ox}}{60 + 80\ W_{ox}} \qquad [3]$$

Alternately, using the mole fraction averaging technique we have

$$n_{on} = x n_{ox} + y n_n \qquad [4]$$

and substituting $y = 1 - x$ and the values of n_{ox} and n_n we have

$$x = \frac{2.025 - n_{on}}{0.575} \qquad [5]$$

[1] Experimentally determined.

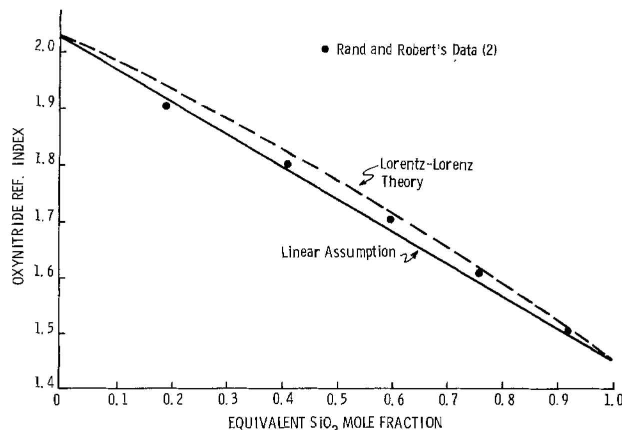

Fig. 1. Silicon oxynitride refractive index vs. equivalent SiO_2 mole fraction in $Si_lO_mN_p$ (composition) showing applicability of Lorentz-Lorenz theory and mole fraction averaging.

Equivalent SiO_2 mole fractions in silicon oxynitride films are plotted against these refractive indexes in Fig. 1. The experimental data of Rand and Roberts (2) is provided as a comparison.

Stress measurement.—The stresses in the films were calculated from measurements of elastic bending of the substrate film combination. In this technique, the substrate of thickness, t_s, is bent to a radius of curvature R by the forces at one surface. If the film thickness $t_f << t_s$, the average stress in the film is given by Eq. [6] (7, 14, 15)

$$\sigma_f = \frac{1}{6}\frac{E_s}{1-\gamma_s}\frac{t_s^2}{t_f}\left(\frac{1}{R_f}-\frac{1}{R_o}\right) \quad [6]$$

where E_s and γ_s are Young's modulus and the Poisson ratio of the substrate, respectively, and R_f and R_o are the radii of curvature of substrate with and without the film. For (100) oriented substrates $E_s/(1 - \gamma_s) = 1.8 \times 10^{12}$ dynes/cm^2 (16, 17).

The radius of curvature was measured by the use of Fe K_α radiation in a double crystal diffractometer. The x-ray beam is Bragg diffracted from (440) planes of [100] silicon monochromator. The diffracted beam is directed onto the sample whose radius of curvature is to be measured. Note that the sample is also (100) Si crystal with or without dielectric films (CVD SiO_2, Si_3N_4, or $Si_lO_mN_p$). If the sample is bent, the resulting topograph of the twice diffracted beam is a narrow vertical line. The sample is then rotated a small amount and another line is diffracted parallel and displaced from the first line on the topograph. (This procedure is schematically shown in Fig. 2.) Such a composite topograph is called a "zebra topograph" (18). In the case where the sample curvature is too small to yield a "zebra" pattern (thus producing overlapping intensities), a pair of pinhole slits is introduced between the monochromator and the sample crystal. The sample crystal is rotated to maximize the intensity of the diffracted beam from the two different diffracting positions and the x-ray films are replaced by an electronic detector which allows separation of overlapping intensities. Thus the radius of curvature is given by $l/\Delta\theta$, where l is the distance between the pinholes or the distance along the film in the zebra topographs, and $\Delta\theta$ is the measured angular distance resulting in separation l. With the above described techniques, the curvatures from a few seconds of arc up to a few degrees of arc can be measured. Several samples were measured with the film and then the film was stripped by etching in 49% HF and the radius of curvature measured again. In all cases $R_o >> R_f$ and therefore $1/R_o$ was neglected in Eq. [6] for all stress calculations.

Stress in Si_3N_4 (as-deposited).—The radius of curvature of samples with an Si_3N_4 film thickness of ~800-

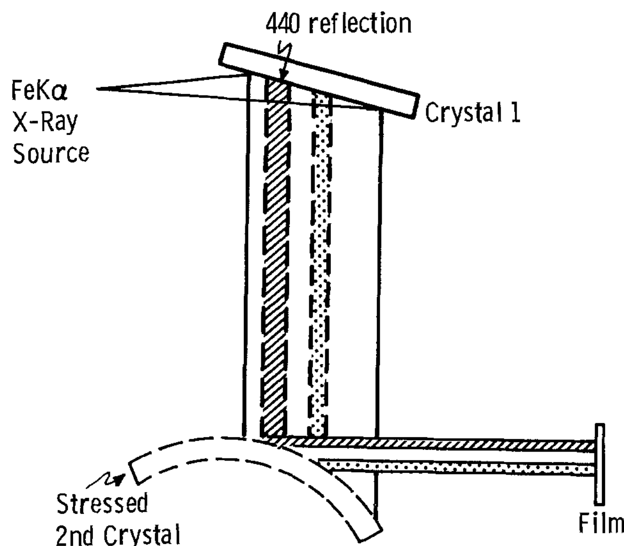

Fig. 2. Schematic of double crystal stress measurement technique

6000Å was measured. The stress in the Si_3N_4 is tensile and independent of film thickness and deposition rate. However, stress is a function of deposition temperature, *i.e.*, stress increases with decreasing deposition temperature. Shown in Table I are the Si_3N_4 refractive index, density, and stress of Si_3N_4 as a function of deposition temperature. The Si_3N_4 stress values reported here are in good agreement with literature values (2, 15).

Stress in SiO_2 (as-deposited).—The SiO_2 films deposited from SiH_4-CO_2-H_2 are under compression. Once again, the stress in CVD SiO_2 is not a function of thickness (~600-6000Å) or deposition rate. However, the stress decreases (*i.e.*, becomes less compressive) as the deposition temperature is decreased; *i.e.*, stress in 1000°C films is ~ 1.3×10^9 dynes/cm^2, where at 900°C it is only ~ 0.8×10^9 dynes/cm^2. These trends are consistent with the trends reported for thermally grown oxides [*e.g.*, (19, 20)]. The magnitude of stress in SiO_2 films deposited at 900°C are in good agreement with the value reported by Rand and Roberts (2).

Stress in silicon oxynitride (as-deposited).—The stress in silicon oxynitride films as a function of the equivalent Si_3N_4 mole fraction is shown in Fig. 3 at two deposition temperatures. The film thicknesses were varied from ~600 to ~8000Å. Consistent with CVD SiO_2 and Si_3N_4, the stress in oxynitride films was independent of film thickness and deposition rate. The strong influence of deposition temperature can be seen in Fig. 3. A 100°C drop in deposition temperature causes the film stress to become more tensile by ~ 2×10^9 dynes/cm^2 in the entire range of composition from near SiO_2 to near Si_3N_4. The stress in silicon oxynitride films does not increase as a linear function of equivalent Si_3N_4 mole fraction. However, stress does appear to be

Table I. Some properties of Si_3N_4 as a function of deposition temperature

Deposition temp. (°C)	RI[a]	Density[b] (g/cm^3)	Stress × 10^9 [c] (dynes/cm^2)
1000	2.025	3.09	8.5 (±1)
950	2.025	—	10.5 (±1)
900	2.023	3.09	11.1 (±1.5)
850	1.981	—	10.7 (±2.0)

[a] Median values shown in table. Distribution is skewed, minimum and maximum value of RI for 900°-1000°C range from 2.005 to 2.03 and for 850°C from 1.97 to 1.99.
[b] Density by weight loss method. The values given are mean values. Sample-to-stample variation ±0.1.
[c] Values in parentheses are twice the standard deviation. The stress in Si_3N_4 is tensile.

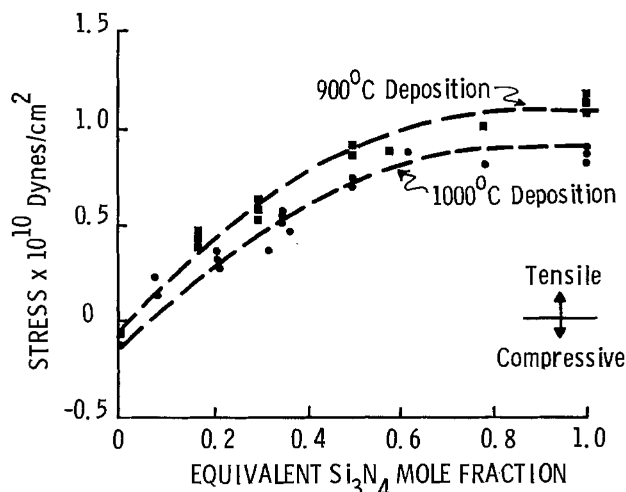

Fig. 3. Film stress as a function of composition and two deposition temperatures.

a continuous function of composition as shown by the broken curves. Unlike Rand and Roberts (2) we did not observe the discontinuity in stress *vs.* composition curve. This discrepancy is due to the fact that Rand and Roberts produced low refractive index silicon oxynitrides (for which they reported stress values) by SiH_4-NO processes and not by SiH_4-NO-NH_3 processes. These authors also attribute this discontinuity to the use of two different chemical systems for the deposition of silicon oxynitride films (2).

Relative oxidation barrier.—Si_3N_4 is known to be a barrier to oxidation in steam. The question then arises as to how this property varies as a function of silicon oxynitride composition. Si_3N_4 and $Si_lO_mN_p$ films (~1000Å on Si) were subjected to steam at 950°C (9.5 hr), 1000°C (6 hr), and 1100 C (2.5 hr). At these temperatures and respective times, ~ 1.15μ of SiO_2 grows on bare (100) Si wafers. The refractive index of Si_3N_4 or $Si_lO_mN_p$ films was measured before and after oxidation. The films were subsequently etched in 7:1 buffered HF and the refractive index measured at 5 sec intervals of etching. This process of etching and ellipsometric measurement was continued until the refractive index stabilized (*i.e.*, reached a constant value very nearly equal to the initial value). Thickness corresponding to stabilized refractive index was thus the thickness of unoxidized $Si_lO_mN_p$ (or Si_3N_4). A typical example of this process is graphically shown in Fig. 4 (initial RI = 1.788). The ratio of the thickness of oxidized Si_3N_4 to the thickness of oxidized $Si_lO_mN_p$ is called the relative oxidation barrier and is a function of $Si_lO_mN_p$ composition at the three temperatures as shown in Fig. 5. The effect of deposition temperature

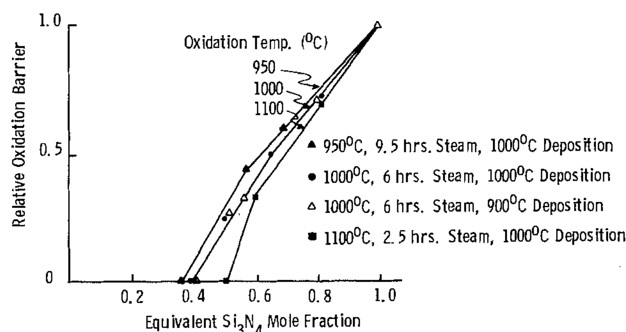

Fig. 5. Relative oxidation barrier of silicon oxynitride as a function of composition at three oxidation temperatures.

was investigated and no significant differences were found between 900° and 1000°C (Fig. 5). Zero oxidation barrier compositions were those which allowed ≧ 8000Å SiO_2 to grow on the film side of the silicon substrate. In other words, when none of the original silicon oxynitride remained on silicon after exposure to steam, the film was completely converted to SiO_2 and additional SiO_2 grew in the usual manner. Thus the minimum equivalent Si_3N_4 required for the film to act as a barrier to oxidation increases from 0.38 (at 950°C) to 0.5 (at 1100°C) when ~ 1.15μ of SiO_2 is grown on silicon. The effect of time on percentage oxidation of the film is shown in Fig. 6. Note that up to ~ 0.6 mole fraction of Si_3N_4, the percentage oxidation is nearly linear with a subsequent steep rise to 100% oxidation at 0.3-0.4 mole fraction of equivalent Si_3N_4. Thus the oxidation barrier study indicates that silicon oxynitride films with composition of ≧ 0.6 equivalent Si_3N_4 behave more like Si_3N_4, whereas films with equivalent Si_3N_4 ≦ 0.3 mole fractions behave like SiO_2. The region from 0.3 to 0.6 mole fraction can be considered a transition region, where the films can be completely oxidized in reasonably short time at 1000°C.

Etch rates.—The etch rates were measured on films of ~ 1000Å thickness. The film thickness was measured by ellipsometry and the sample then etched for fixed amount of time in a given etchant. The thickness was then measured again. This procedure was usually repeated a few times and the etch rate values reported here are an average of these measurements.

Etch rate of Si_3N_4 (as-deposited).—The etch rate of Si_3N_4 was determined in three etchants; *viz,* 49% HF (23° ± 2°C), refluxing H_3PO_4 acid at 180°C, and 7:1 buffered HF at 23° ± 2°C. The values obtained are

[3] Number in parentheses is twice the standard deviation.
[4] Deposition temperature of 880°C.

shown in Table II. Available data from the literature are also shown (1, 2, 21). Note that our Si_3N_4 etch rates in 49% HF are considerably lower than the data reported by Brown *et al.* (1). The etch rates in 7:1 BHF are comparable with the data reported by Rand and Roberts and our Si_3N_4 appears to etch more slowly in refluxing phosphoric acid than that of Van Gelder and Hauser (21).

From Table II it can be seen that the increase in etch rate due to decreasing temperature in as-deposited films is not exclusively due to decrease in density as suggested by Chu *et al.* (22), especially in the temperature range of 900°-1000°C. At these two temperatures, the measured densities, refractive indexes, and infrared absorption spectra are very nearly identical within the error of measurement. The reason for the significantly higher etch rate for 850°C deposited Si_3N_4 appears to be the decrease in refractive index between 900° and 850 C, which may be due to a change in either the density or composition, or both.

Etch rates of silicon oxynitride (as-deposited).—The etch rates of silicon oxynitride as a function of composition in 7:1 buffered HF are shown in Fig. 7 (Rand and Roberts' data are included for comparison). Figure 7 also includes data for oxynitride etch rates after annealing for 2 hr in N_2 at 1000 C. These data are discussed later under annealing. From Fig. 7, the etch rate of as-deposited films is a function of deposition temperature at a fixed composition, *i.e.*, higher etch rates are obtained for 900°C than for 1000°C deposited films. This is consistent with what we found for Si_3N_4 films. Films of identical refractive index and composition (*i.e.*, infrared spectra), deposited at 900° and 1000°C must also have identical density. This can be seen from Lorentz-Lorenz theory (11), which relates density of any material with its refractive index as shown in Eq. [7]

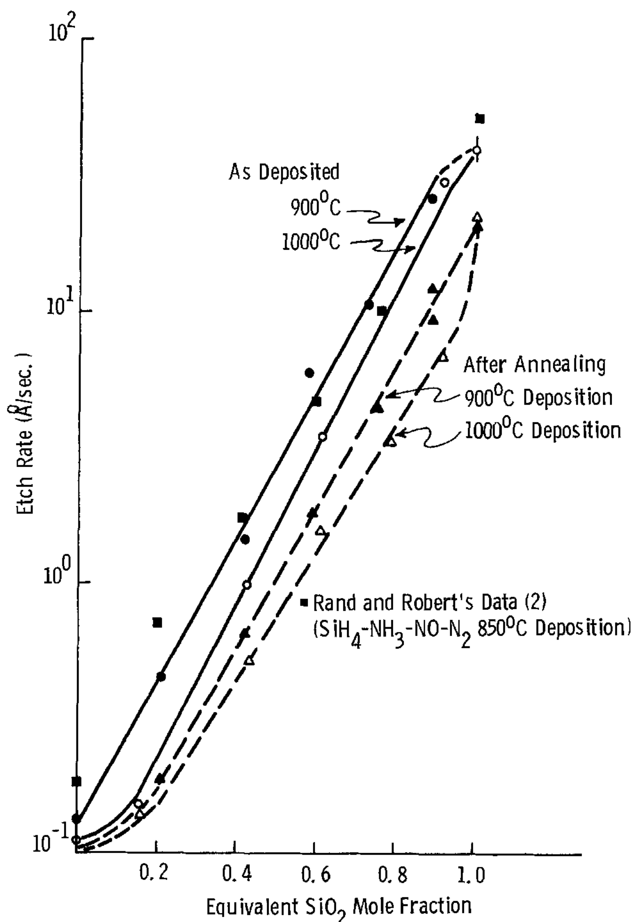

Fig. 7. Etch rate of silicon oxynitride in 7:1 BHF as a function of composition at two deposition temperatures, as-deposited, and after annealing in N_2 at 1000°C for 2 hr.

$$\rho = \frac{M}{A} \frac{n^2 - 1}{n^2 + 2} \quad [7]$$

where M is the molecular weight, n the refractive index, and A the molar refractivity. Since molar refractivity and molecular weight are a constant for a given material (11) the density is a function of the refractive index only (9). Therefore the difference in silicon oxynitride etch rates at two deposition temperatures (*i.e.*, 900° and 1000°C) for films with identical refractive indexes and composition (*i.e.*, infrared spectra) cannot be due to the difference in density.

The etch rates of silicon oxynitride films in refluxing H_3PO_4 (180°C) are presented in Fig. 8. Data are presented for 900° and 1000°C deposited films. Limited data are also shown for samples which were annealed in N_2 for 2 hr at 1000°C (this is discussed under Annealing). From the literature (2) we expected to find a linear relationship between etch rate and composition. This is not the case (Fig. 8). However, these data are consistent with earlier observations that films deposited at 1000°C etch at a slower rate than those deposited at 900°C.

The increase in etch rate with decreasing nitrogen content from 1 to 0.64 mole fraction of equivalent Si_3N_4 suggests that the presence of oxygen aids the dissolution of silicon nitride. This is consistent with the proposed mechanism of attack by hot H_3PO_4 acid on Si_3N_4 in the presence of H_2O (21). That is, if H_2O hydrolyzes (oxidizes) the Si_3N_4 to some form of hydrous silica and ammonia, the ammonia remaining in solution as ammonium phosphate, then the presence of oxygen in nitride films would increase the etch rate in hot phosphoric acid because it has partially accomplished what H_2O is supposed to achieve in the first place. However, as silicon oxynitride approaches pure SiO_2, the etch rate drops to approximately the etch rate of SiO_2 in refluxing H_3PO_4. Therefore the nonlinearity of etch rates as a function of composition can be explained by the mechanism proposed by Van Gelder and Hauser (21).

Etch rates of SiO_2 (as-deposited).—The etch rates of SiO_2 deposited from SiH_4-CO_2-H_2 in 7:1 BHF (23° ± 2°C) are shown in Fig. 7. The etch rate of these films was between 36 and 43 Å/sec independent of the deposition temperature in 900°-1000°C range. The measured density of these films was 2.15 ± 0.15 for 1000°C deposition and 2.15 ± 0.2 for 900°C deposition. The infrared spectra of these films was also identical within the error of measurement.

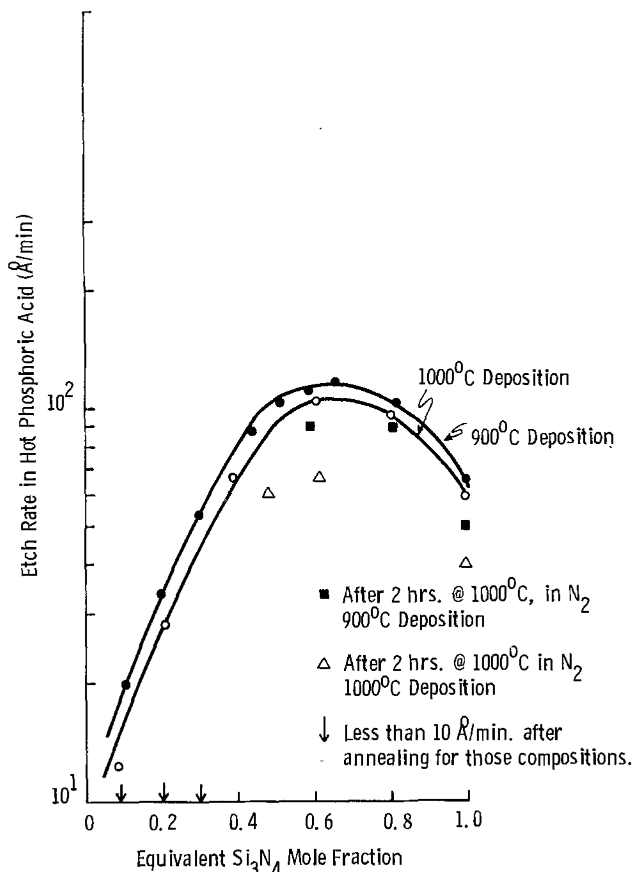

Fig. 8. Silicon oxynitride etch rate in hot refluxing phosphoric acid (180°C) as a function of composition at two deposition temperatures. Also shown is the etch rate after 2 hr annealing at 1000°C for 2 hr in N_2.

Effect of annealing.—The reason for undertaking the investigation of annealing on properties of $Si_lO_mN_p$ films was the experimental observation that the final refractive index (Fig. 4), during the oxidation barrier study, was always somewhat higher (*i.e.*, ~ 0.006 for most $Si_lO_mN_p$ films and ~ 0.008 for Si_3N_4) than the initial value. To determine whether the change in refractive index (and other properties) results from the oxidation or annealing, we carried out the investigation described below.

A single anneal temperature-time combination was first arrived at via preliminary experiments. SiO_2 and Si_3N_4 films (~ 1000Å) deposited both at 900° and 1000°C were annealed in N_2 for time-temperature combinations identical with those used for the barrier to oxidation study. The test samples were withdrawn at 15 min intervals and their refractive indexes and etch rates determined. It was found that these two properties showed no additional change (*i.e.*, "saturated") after a given amount of time at any temperature within the experimental range. The anneal temperature did not influence the saturation values; however, longer times were required to reach the saturation value for lower temperatures. Thus, based on the above experiments, 2 hr at 1000°C appeared to be a reasonable compromise for a temperature-time combination for the annealing experiment. Several samples of SiO_2, Si_3N_4, and $Si_lO_mN_p$ films deposited at both 900° and 1000°C were annealed for 2 hr at 1000°C. Along with investigating the effect of annealing on refractive index and etch rate, we have investigated the effect of annealing on film stress and for a limited number of samples on infrared spectra.

Annealing reduced the films thickness by ≤4% and, correspondingly, the refractive index increased by 0.002-0.015 depending on the composition of the film. The least change in thickness and refractive index occurred at equivalent SiO_2 mole fraction of 0.82 (RI ~ 1.57), *i.e.*, ~1% and 0.002, respectively, for 1000°C deposited films. Other $Si_lO_mN_p$ films deposited at 1000°C showed a decrease in thickness of 1.5-2.0% and refractive index increase of ~0.005. For 900°C deposited films, similar results were obtained except that the magnitude of the changes was somewhat larger; *i.e.*, for most $Si_lO_mN_p$ films, the thickness decreased by 1.5-2.3% and the refractive index increased by ~0.007. The Si_3N_4 films deposited at either temperature showed ~3% decrease in thickness and increase in refractive index of 0.008 ±0.002. The largest increase in refractive index occurred for SiO_2, *i.e.*, 0.012 ± 0.003 for either deposition temperature coupled with decrease in thickness of 3.7 ± 0.3%.

Silicon oxynitride film of thickness ≥4000Å and with a composition of ~25% equivalent Si_3N_4 showed microcracks similar to the ones reported in the literature for pure Si_3N_4 (14), after annealing at 1000°C for 2 hr. These cracks were not present in as-deposited films and they appeared in films after annealing irrespective of the deposition temperature. The stress values after annealing are for those films which did not crack.

For uncracked films, annealing increased the tensile stress in $Si_lO_mN_p$ and Si_3N_4 films and made the stress more compressive for SiO_2 films as shown in Fig. 9 and 10. Again, the least change is seen at equivalent Si_3N_4 mole fraction of ~0.18. However, after annealing, stress remains more tensile in 900°C deposited films than in 1000°C deposited films as shown in Fig. 11. The CVD SiO_2 films are an exception to this rule

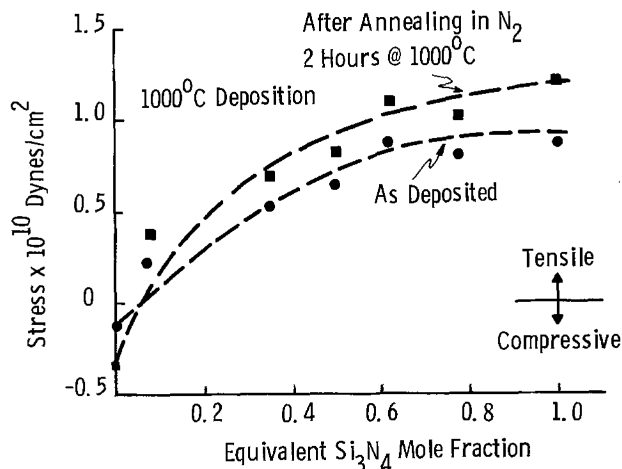

Fig. 9. Film stress as a function of composition and annealing, 1000°C deposited film.

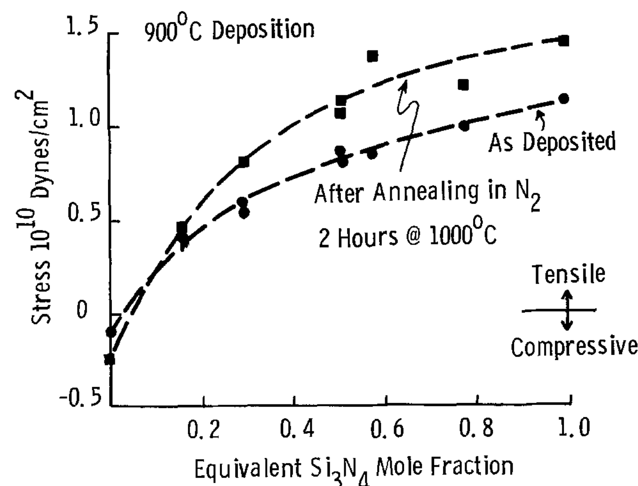

Fig. 10. Film stress as a function of composition and annealing, 900°C deposited film.

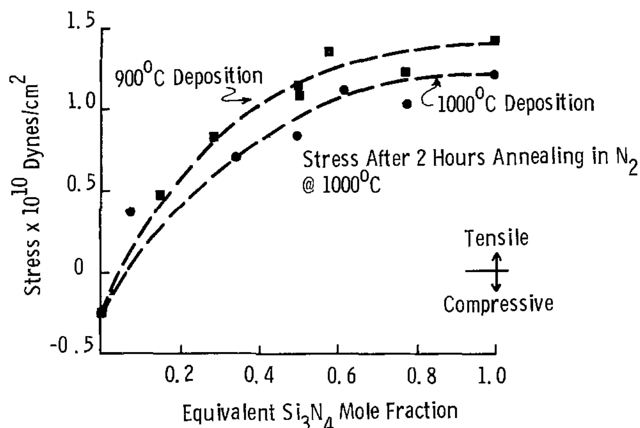

Fig. 11. Film stress as a function of composition after annealing for 900° and 1000°C deposited film.

as can be seen from Fig. 11. The stress in CVD SiO_2 appears to saturate at $\sim 2.5 \times 10^9$ dynes/cm^2 irrespective of the deposition temperature. This strongly suggests that the measured stress in CVD SiO_2 is almost entirely due to the thermal mismatch of the expansion coefficient of SiO_2 and Si. The same conclusion was reached by Jaccodine and Schlegel (19) about the nature of stresses in thermal SiO_2. The stress value for annealed CVD SiO_2 agrees very closely with the one reported for thermal SiO_2 (19).

The etch rates decreased as a result of annealing as shown in Fig. 7 and 8. The Si_3N_4 etch rates for 900° and 1000°C deposited films were nearly identical, within the error of measurement, after annealing in 7:1 buffered HF at 6.3 Å/min, whereas the etch rates of SiO_2 saturated at $\sim$1320 Å/min. However, the silicon oxynitride etch rates were not identical. The 900°C deposited films etched faster in 7:1 buffered HF (Fig. 7). In refluxing H_3PO_4, the Si_3N_4 etch rate of 900° and 1000°C deposited films were not identical either, as shown in Fig. 8. Again, 900°C deposited films etched faster. The infrared spectra of films which had been annealed showed small changes in the location of the major absorption maxima (*i.e.*, between 1100 and 800 cm^{-1}), usually within 5 cm^{-1} of the preannealed absorption maxima. The most striking feature of the postannealed infrared spectra for Si_3N_4 and $Si_lO_mN_p$ films was a near absence of the absorption band at $\sim$3380 cm^{-1}, indicating a marked decrease in the N-H species responsible for this absorption band. This is consistent with the observations of Rand and Roberts (2).

In a final experiment, several wafers of $Si_lO_mN_p$ (RI 1.7-1.9) and Si_3N_4 were broken in half. One half of these wafers was subjected to the annealing treatment (*i.e.*, 2 hr at 1000°C in N_2), and the other half to steam oxidation at 1000°C for 2 hr. The wafers subjected to oxidation were subsequently etched in 7:1 BHF in a sequence shown graphically in Fig. 4. The refractive indexes and etch rates of the unoxidized films were then compared with those of annealed samples. Both refractive indexes and etch rates were found to be identical (within the error of measurement) in the two cases. This last experiment showed to our satisfaction that densification and changes in other properties also occur during the process of steam oxidation.

Discussion

Using Rand and Roberts' (2) composition data, we have demonstrated the validity of two calculation procedures for determination of $Si_lO_mN_p$ composition. The novelty of these procedures lies in the fact that they are both written with the underlying assumption that $Si_lO_mN_p$ films are homogenous mixtures of Si_3N_4 and SiO_2. Silicon oxynitride films are clearly not mixtures for two reasons: (*i*) the infrared spectra do not show the separation of SiO_2 and Si_3N_4 absorption peaks, and (*ii*) the kinetic investigation by Gaind *et al.* (9) clearly shows that the deposition rate constants of $Si_lO_mN_p$ cannot be determined by assuming codeposition of SiO_2 and Si_3N_4. Thus neither the Lorentz-Lorenz theory nor the procedure of molar averaging based solely on the properties of SiO_2 and Si_3N_4 (*i.e.*, refractive index and density) should have yielded any meaningful results. However, the fact remains that by the use of these procedures, the composition of $Si_lO_mN_p$ is determined quite accurately. In view of this, we suggest that these procedures may also be applicable, despite their simplistic approach and assumptions, to other complex films such as aluminum oxynitrides.

The work in this paper was undertaken with an important application in mind, *i.e.*, the use of $Si_lO_mN_p$ films during the formation of recessed oxide isolation (ROX). The details of the ROX process have been published recently by Bassous *et al.* (23). The $Si_lO_mN_p$ can easily replace Si_3N_4 in the combination of thermal SiO_2 and Si_3N_4 during the formation of ROX isolation. For this application, one needs to know the barrier to oxidation for selected $Si_lO_mN_p$ composition. The knowledge of film stress is of significance since it probably determines the dislocation density in the silicon mesa covered by the selected film during the ROX formation (23). The etch rates of $Si_lO_mN_p$ in both BHF and hot phosphoric acid are needed for device application. The changes in these properties after annealing or ROX process are also important since subsequent device processing may require either selective or blanket etching of these films. All the above experimental data are available in this paper.

Besides the pragmatic aspects of this paper, some issues of fundamental importance need to be reviewed. For example, why is the etch rate of thin dielectric films a function of deposition temperature, especially when the infrared absorption spectra (structure) and the refractive indexes are identical? The concept of density difference alone, as an explanation of this etch rate difference as proposed by Chu *et al.* (22), and furthered by Brown *et al.* (1), is not consistent with the experimental data presented here, especially in the case of as-deposited Si_3N_4 films. Also, upon annealing, the change in density is $\sim$3% in most cases. Such a small change in density cannot explain the $\sim$50% change in etch rate. Therefore, there is no satisfactory explanation of changes in the etch rate of dielectric films like Si_3N_4 and $Si_lO_mN_p$ as a function of deposition temperature. It is suggested here that the change in film stress or the amount of H incorporated during film growth, when the deposition temperature is altered, may be some of the causes of observed differences in etch rate as a function of deposition temperature.

Some preliminary experiments (not reported in detail here) also suggest that in the case of Si_3N_4 the etch rate is a function of the NH_3 concentration used in the reactor during deposition, *i.e.*, etch rates increasing with increasing NH_3 concentration. Similar observations have been reported by others (24). The difference in Si_3N_4 etch rates observed in our studies and by Brown *et al.* (see Table II) may be due to the fact that Brown *et al.* used only SiH_4 and NH_3 (*i.e.*, no carrier gas) to deposit Si_3N_4. Therefore the NH_3 concentration in their case would be considerably higher than in our study, and hence the difference in observed etch rates. We have shown that the stresses in $Si_lO_mN_p$ and Si_3N_4 are tensile and that the stress measured at room temperature increases (becomes more tensile) with decreasing deposition temperature. Since the stress measured at room temperature is a sum of intrinsic and thermal stress, an increase in measured stress at room temperature implies that the thermal stress for Si_3N_4 and $Si_lO_mN_p$ is compressive

and that the intrinsic stress is tensile. Same conclusions were drawn by Tamura *et al.* (17) concerning the nature of stresses in Si_3N_4. The nonlinearity of $Si_lO_mN_p$ stress as a function of composition is not surprising since a linear stress *vs.* composition curve would have implied that $Si_lO_mN_p$ are codeposited SiO_2 and Si_3N_4. As already pointed out, $Si_lO_mN_p$ films are not codeposited SiO_2 and Si_3N_4 but are "polymers" of silicon, oxygen, and nitrogen (2, 9).

Summary and Conclusions

We have studied several important properties of silicon oxynitride ($Si_lO_mN_p$) films. The knowledge of these properties is especially useful if the $Si_lO_mN_p$ films are to be used in LSI processing for the formation of recessed oxide isolation (ROX). We have also investigated similar properties of Si_3N_4 and SiO_2 mainly to provide the end points of $Si_lO_mN_p$ series. In general, the physicochemical properties of $Si_lO_mN_p$ do not vary linearly as the composition is altered from SiO_2 to Si_3N_4. For example, the film stress is approximately a parabolic function of composition. The barriers to oxidation in steam, etch rate in 7:1 BHF, and hot refluxing H_3PO_4 all are nonlinear functions of composition. We have also investigated the effect of annealing on the above properties and find that the film stress increases and etch rate decreases for all $Si_lO_mN_p$ films. We have simultaneously studied the properties of $Si_lO_mN_p$ deposited at two deposition temperatures (*i.e.*, 900° and 1000°C) and find that both the stress and etch rates increase as the deposition temperature is reduced from 1000° to 900°C. The effect of deposition temperatures on $Si_lO_mN_p$ properties has not been previously reported. We have also shown that the composition of silicon oxynitride can be calculated most satisfactorily by either weight fraction averaging (Lorentz-Lorenz theory) or by mole fraction averaging knowing only the density and refractive index of Si_3N_4 and SiO_2. The novelty of the above calculation procedures is in the fact that both assume that $Si_lO_mN_p$ films are homogeneous mixtures of SiO_2 and Si_3N_4. It is clear that $Si_lO_mN_p$ are not mixtures but compounds (or polymers) of silicon, nitrogen, and oxygen. Thus the above procedures should not have yielded meaningful results. However, the fact remains that the results of these procedures are most satisfactory in arriving at the composition of $Si_lO_mN_p$ Finally, we have shown that the oxynitride films deposited from SiH_4-CO_2-NH_3-H_2 are in general identical in composition and properties with oxynitride films deposited from other chemical systems.

Acknowledgments

We are grateful to Dr. W. A. Pliskin for his help with infrared absorption data. Our thanks are due to Drs. L. A. Kasprzak and W. A. Pliskin for very stimulating discussions during the course of this work. We are deeply indebted to V. E. Elliott for sample preparations, T. Dicastro for measurements of film properties other than stress, and to C. Hoogendoorn for stress measurements.

Manuscript submitted Oct. 21, 1976; revised manuscript received Sept. 12, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by IBM Corporation.

Kinetics of Lateral Autodoping in Silicon Epitaxy

G. R. Srinivasan

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The kinetics of lateral autodoping in silicon epitaxy over silicon substrates containing localized arsenic diffusions was studied as a function of deposition temperature, growth rate, and preepitaxial heat cycling. The lateral autodoping increases either with the decrease of deposition temperature or with the increase in growth rate. The autodoping *vs.* temperature plot yields an enthalpy of ~ -64 kcal/mole for the process in the temperature range 950°-1100°C and at 0.08 μm/min growth rate. Thermodynamic calculations showed that the arsenic redistribution during lateral autodoping cannot be completely described by equilibria considerations and that an incorporation model based on dopant trapping during epitaxy is capable of explaining quantitatively the growth rate and temperature effects observed here. The effect of preepitaxial baking is such that the lateral autodoping decreases with the increase in either the bake temperature for constant bake time or the bake time for constant bake temperature. These results were analyzed in terms of the evaporation of arsenic during prebake and consequent surface depletion in the diffused regions. Arsenic evaporation velocity was calculated for several temperatures, which yields an activation energy of 5.16 eV for arsenic evaporation from (100) silicon surface in an H_2 flow ambient. This high activation barrier pertains to the evaporation of arsenic from the silicon surface through a nearly stagnant boundary layer in a typical CVD epitaxial system.

Autodoping refers to that part of the epitaxial doping which originates from the substrates during the deposition process. Lateral autodoping involves lateral transport of gaseous dopants which are released to the gas stream from the substrates during the preepitaxial and initial stages of the deposition. There have been several studies of autodoping [see Ref. (1) for a brief review] and yet very few of them (2-4) relate to the kinetics of lateral autodoping. We present here the details of such a study using silicon substrates which have localized arsenic diffusions of high surface concentration. Since the dopant diffusions are only at the top surface, contributions to autodoping from the bottom surface of the substrate are negligible. The use of substrates with localized diffusions allows a convenient way of separating the outdiffusion and lateral transport kinetics. Also, these cases are more typical of the processes involved in the fabrication of high performance bipolar integrated circuits.

Thermodynamics of Autodoping

Let us consider an intrinsic epitaxial process (*i.e.*, no external dopants added) during which a redistribution of the arsenic present in the substrate occurs. Just prior to the deposition, a certain concentration of arsenic exists in the vapor phase, and if a thermodynamic equilibrium were to exist between this vapor and the arsenic incorporated into the first few layers of the epitaxy, we can write

$$\text{As (vapor)} \rightleftarrows \text{As (epitaxy)} \qquad [1]$$

Assuming monatomic species and ideal gas behavior for the arsenic vapor, we obtain an expression for the equilibrium constant for this reaction as given by

$$k_{eq} = \frac{a_{As}}{p_{As}} \qquad [2]$$

where a_{As} is the activity of arsenic in the silicon epitaxial solid solution and p_{As} is the partial pressure of the arsenic vapor. If we now invoke Henry's law for the low arsenic concentrations incorporated into the epitaxy we can write for the dissolution process, assuming no kinetic limitation

$$a_{As} = k' N_{As} \qquad [3]$$

where N_{As} is the concentration of arsenic in the epitaxial solid solution and k' is the proportionality constant. The assumption of Henry's law is valid up to arsenic concentrations of 10^{18} cm^{-3} at typical epitaxial temperatures as pointed out by Rai-Choudhury and Salkovitz (5). The equilibrium constant is, thus

$$k_{eq} = \frac{k' N_{As}}{p_{As}} \qquad [4]$$

The enthalpy change for the above process is given by

$$\frac{-\Delta H}{R} = \frac{d \ln k_{eq}}{d(1/T)} \qquad [5]$$

where R is the gas constant and T is the growth temperature. If we define the standard state of arsenic in the epitaxial solid solution as an infinitely dilute solution of arsenic in silicon (*i.e.*, $k' = 1$), we have from Eq. [4] and [5]

$$\frac{-\Delta H}{R} = \frac{d \ln N_{As}}{d(1/T)} - \frac{d \ln p_{As}}{d(1/T)} \qquad [6]$$

One can also write the enthalpy change for the equilibrium reaction of Eq. [1] as

$$\begin{aligned}\Delta H &= \overline{H}_{As(epi)} - \overline{H}_{As(vap)} \\ &= \{\overline{H}_{As(epi)} - \overline{H}_{As(pure\ solid)}\} + \{\overline{H}_{As(pure\ solid)} - \overline{H}_{As(vap)}\} \\ &= \Delta H_s + \Delta H_c\end{aligned}$$

where ΔH_c is the heat of condensation and ΔH_s is the heat of solution.

Rearranging Eq. [6], we obtain the following expression for the enthalpy change associated with the formation of the epitaxial solid solution of arsenic in silicon

$$\Delta H_s = \frac{R d \ln p_{As}}{d(1/T)} - \frac{R d \ln N_{As}}{d(1/T)} - \Delta H_c \qquad [7]$$

Equation [7] can be used to evaluate ΔH_s from autodoping experiments in which N_{As} is determined for various epitaxial growth temperatures and from a knowledge of the temperature variation of the arsenic vapor pressure in equilibrium with the solid solution and from the heat of condensation of arsenic.

In the above derivation, we have assumed monatomic arsenic in the vapor, and an equivalent expression may

be obtained for any other polyatomic species. The validity of Eq. [7] assumes, of course, an equilibration between the vaporized arsenic and the arsenic incorporated into the initial layers of the epitaxy.

Arsenic Evaporation Kinetics

In a typical CVD epitaxial deposition process, the substrates are subjected to a preepitaxial bake cycle in order to establish stabilized thermal and gas flow conditions prior to the deposition. During this prebake, some of the dopant impurities evaporate from the substrates; and since autodoping mainly arises from these substrate sources, changes in the prebake cycle are expected to cause changes in autodoping. In order to interpret these prebake effects, we developed a theory based on the rate limitation for the evaporation of arsenic from the silicon substrate surface. An expression is derived here which relates the lateral autodoping concentration to the arsenic evaporation velocity, arsenic diffusivity in silicon, and prebake time.

Theory of surface-limited evaporation.—One-dimensional Fick's law solution for the case of dopant evaporation from homogeneously doped crystal into vacuum yields, in the absence of any surface rate limitation, an error function distribution of the dopant in the crystal with zero surface concentration at all times. If a kinetic barrier at the surface were to exist for the evaporation process, however, the solution to the diffusion equation becomes analogous to that for the heat flow with the radiation boundary condition and yields a finite buildup of the dopant at the surface. Miller and Smits (6) have demonstrated this to be the case for the evaporation of dopants from Ge. More recent studies (7, 8) show similar results for the case of dopant evaporation from silicon. The solution for these cases takes the form

$$\frac{C(x,t)}{C_o} = \text{erf}\left(\frac{x}{2\sqrt{Dt}}\right) + \left\{ \exp\left(\frac{K^2t}{D} + K\frac{x}{D}\right) \bullet \text{erfc}\left(\frac{x}{2\sqrt{Dt}} + K\sqrt{\frac{t}{D}}\right)\right\} \quad [8]$$

where $C(x, t)$ is the dopant concentration at time t from the start of evaporation and depth x from the surface of the crystal, C_o is the uniform initial concentration, D is the dopant diffusivity in the crystal, and K is a mass transfer coefficient which has the dimension of velocity and is referred to as evaporation velocity. As $K \to \infty$ the rate-limitation case reduces to one of erf distribution.

For the case of inhomogeneously doped crystal, such as in the case of substrates with dopant diffusions, the one-dimensional solution is given by (9)

$$C(x,t) = \frac{1}{2\sqrt{\pi DT}} \int_0^\infty f(x')\,[\exp\{-(x-x')^2/4Dt\} + \exp\{-(x+x')^2/4Dt\}]dx' - (K/D)\int_0^\infty f(x') \exp\{(K^2t/D) + K(x+x')/D\} \bullet \text{erfc}\{(x+x')/2\sqrt{Dt} + K\sqrt{t/D}\}dx' \quad [9]$$

where $f(x')$ represents the initial dopant distribution prior to evaporation. Equation [8] is a particular case of the above solution for which the initial distribution $f(x')$ is a constant.

For the case of arsenic diffusion used in this study, the initial distribution $f(x')$ of arsenic diffusion in the p-type substrate may be approximated by

$$f(x') = \begin{cases} C_o & \text{for} \quad 0 < x' < x_j \\ 0 & \text{for} \quad x' > x_j \end{cases} \quad [10]$$

where x_j is the junction depth and C_o is the arsenic surface concentration prior to evaporation.

Substituting Eq. [10] in Eq. [9] one obtains for the surface concentration ($x = 0$)

$$\frac{C(0,t)}{C_o} = I_1 - I_2 \quad [10a]$$

where $I_1 = \text{erf}\, x_j/2\sqrt{Dt}$

and

$$I_2 = \frac{K}{D}\int_0^{x_j} \exp\left\{\frac{K^2t}{D} + K\frac{x'}{D}\right\} \left[\text{erfc}\left\{\frac{x'}{2\sqrt{Dt}} + K\sqrt{\frac{t}{D}}\right\}\right]dx'$$

With proper change of variables and integrating by parts, we obtain

$$I_2 = \text{erf}\frac{x_j}{2\sqrt{Dt}} + e^{\frac{K^2t}{D}}\left\{ e^{\frac{Kx_j}{D}} \text{erfc}\left(\frac{x_j}{2\sqrt{Dt}} + K\sqrt{\frac{t}{D}}\right) - \text{erfc}\,K\sqrt{\frac{t}{D}}\right\}$$

Substituting this in Eq. [10a], we get

$$C(0,t)/C_o = \exp\,(K^2t/D)\{\text{erfc}\,K\sqrt{t/D} - \exp(Kx_j/D)\,[\text{erfc}\,(x_j/2\sqrt{Dt} + K\sqrt{t/D})]\} \quad [11]$$

Equation [11] describes the variation of arsenic surface concentration as a function of evaporation time for substrates with initial arsenic diffusion given by Eq. [10]. For the case of evaporation from homogeneously doped substrates for which $x_j \to \infty$, the second term in Eq. [11] approaches zero, so that Eq. [11] reduces to Eq. [8] with $x = 0$. Further, since $\text{erfc}(x_j/2\sqrt{Dt})$ converges to zero for $x_j \gtrsim 4\sqrt{Dt}$, the evaporation from substrates with arsenic diffusions from the top surface becomes equivalent to that from homogeneously doped wafers, provided the evaporation conditions are chosen such that $4\sqrt{Dt} \lesssim x_j$. This condition is satisfied for the experiments reported here, and thus, the variation of arsenic concentration at the substrate surface with evaporation time (bake time) as given by the first term in Eq. [11] is

$$C(0,t) = C_o\{\exp\,(\beta^2 t)\} \bullet \text{erfc}\,(\beta t^{1/2}) \quad [12]$$

where $\beta(T) = K(T)/\sqrt{D}(T)$.

If we assume (6, 7) an Arrhenius behavior for both K and D, such that

$$D(T) = D_o \exp\,(-E_D/kT)$$

and

$$K(T) = K_o \exp\,(-E_K/kT)$$

where E_D and E_K are the activation energy for arsenic diffusion in and evaporation from the silicon substrate, respectively, and k is the Boltzmann constant and T is the evaporation temperature, we can write

$$\beta(T) = \beta_o \exp\,(-\Delta E/kT)$$

where $\Delta E = E_K - E_D/2$. Thus, by measuring the surface concentration as a function of evaporation time for constant temperature or as a function of evaporation temperature for constant time, one can determine β and ΔE. Evaporation velocity K and activation barrier to evaporation E_K can then be evaluated from a knowledge of $D(T)$.

Preepitaxial bake cycle and lateral autodoping.—As mentioned earlier, some of the dopant impurities in the substrate wafers evaporate during the prebake cycle in an epitaxial run. Part of this impurity is carried away in the flow stream, and a part gets redeposited on

the substrate, thereby causing lateral autodoping. Skelly and Adams (10) and Shachnev (11) have shown that the level of autodoping in the epitaxy is directly proportional to the substrate dopant concentration. Thus, changes in the lateral autodoping due to changes in the prebake cycle should reflect the changes in the surface concentration prior to epitaxial deposition. Equation [12] can now be rewritten in terms of lateral autodoping peak concentration, C_{max}, as

$$C_{max}(T, t) = Ae^{\beta^2 t} \bullet \text{erfc}(\beta t^{1/2}) \quad [13]$$

where A is a constant of proportionality which is constant for identical postbake epitaxial deposition conditions. T and t are bake temperature and time, respectively. Since C_{max} is expected to vary with distance from the diffused area, applicability of Eq. [13] requires that lateral autodoping peak concentration be measured at the same distance from the arsenic diffusion and in the same direction relative to the gas flow in all the experiments.

Experimental

The substrates used in this study were p^{-}-silicon wafers (10-20 Ωcm) of (100) orientation. Arsenic diffusions were made on these substrates to cover 20% area in five square regions for the growth temperature studies and 2.5% area in four square regions for the prebake studies. The surface concentration C_o of arsenic over the diffusion was $\sim 1.5 \times 10^{21}$ cm^{-3} and $x_j \sim 1$ μm. (The concentration profile was made using Rutherford backscattering technique.)

All epitaxial depositions were made in an rf heated horizontal reactor with a 3°-inclined, silicon-carbide coated graphite susceptor. The depositions were ~ 2 μm thick and were intrinsic; *i.e.*, no external doping was used. An H_2 carrier gas with a linear flow velocity of ~ 10.5 cm/sec (20.6 liters/min flow rate) was used. $SiCl_4$ flow rates were adjusted to yield different growth rates used in this study; and the growth rates varied linearly with $SiCl_4$ flow rates at all the deposition temperatures used here. A log growth rate *vs.* reciprocal deposition temperature gave a nearly linear region between 950°-1100°C with a slope corresponding to ~ 30 kcal/mole, and a flattening beyond that temperature. Substrate temperatures were read optically with appropriate emissivity corrections including those due to quartz wall absorption.

In the prebake experiments, the deposition conditions were held identical, varying only the preepitaxial bake cycle. In the bake time experiments, the bake temperature and the deposition temperature were chosen to be the same (*i.e.*, 1150°C), and the baketime was varied from 2 min to 2 hr. The growth rate was 0.25 μm/min. In the bake temperature experiments, all depositions were made at 1000°C, which is lower than or equal to the bake temperatures used (1000°-1200°C). Thus, any contribution to evaporation during reequilibration to the deposition temperature was considered to be small. Further, a bake time of 1 hr used in these experiments was believed to be long enough to ignore the transient effects during heat up and cool down cycles. The depositions were made at 0.25 μm/min.

Lateral autodoping was measured by the spreading resistance technique, in which the vertical depth profiles of arsenic in the epitaxy were determined on a beveled surface. The vertical profiles were made at 0.1 mm away from the diffusion square, and the profiles were corrected using a power law interpolation technique (12).

It should be pointed out that the spreading resistance measurements give the donor concentration at room temperature through Irvin's curve. This concentration will be different from the neutral arsenic present at the epitaxial temperatures, and the determination of one from the other involves a model-dependent calculation. In this present study we ignore this difference and intend to present a refinement of the calculation at a later time.

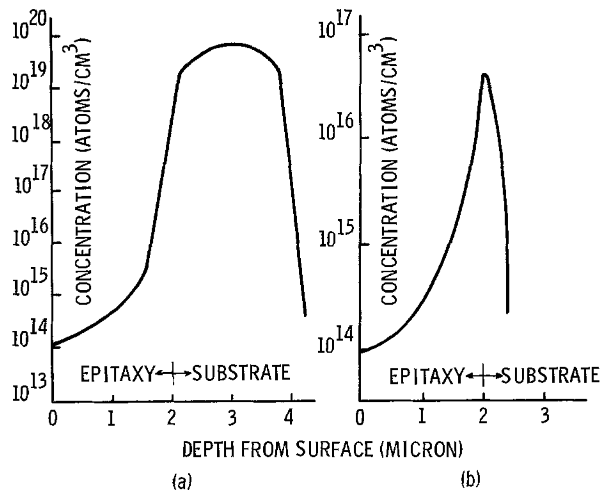

Fig. 1. Vertical depth profiles of arsenic obtained by the spreading resistance technique (a) over diffused region, (b) 0.1 mm away from diffused region. Deposition temperature 1100°C. Growth rate 0.08 μm/min.

Results

Figure 1 shows typical arsenic vertical depth profiles obtained from the corrected spreading resistance data. The vertical profile over the diffused region is shown in Fig. 1(a) and the vertical profile over the nondiffused region (0.1 mm away from the diffused area) is shown in Fig. 1(b). These results are from an 1100°C $SiCl_4$ deposition run for a growth rate of 0.08 μm/min. From Fig. 1(a), it can be seen that the arsenic concentration falls off very rapidly ($\sim 10^8$/cm^4) within the initial layers of the epitaxy and approaches a level of $\sim 10^{14}$/cm^3 toward the end of the epitaxial run, which is typical of the background dopant level in the system. The initial decrease in concentration can be explained by the solid diffusion of arsenic in silicon (13).

Figure 1(b) shows the lateral autodoping effects caused by the transport of vaporized arsenic to regions far removed from the diffused area. A detailed analysis of this lateral distribution as a function of distance from the diffused area will be reported elsewhere (14). Examination of Fig. 1(b) shows that the lateral autodoping reaches a maximum at the initial stages of the epitaxial growth and falls off rapidly in a manner similar to that over the diffused area. In fact, both the on- and off-diffusion profiles superimpose well, once a thickness of a few hundred angstroms of the epitaxy is reached. We summarize these findings in Fig. 2, which shows that out-diffusion

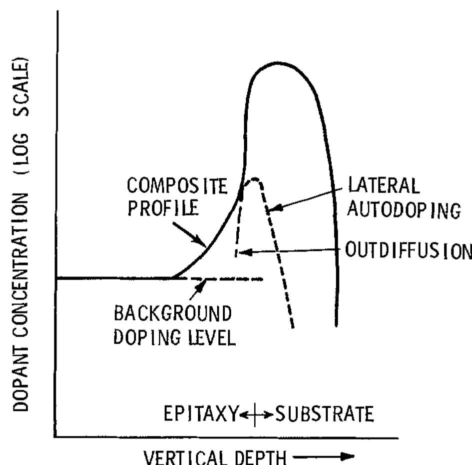

Fig. 2. Vertical profile (schematic) over diffused region

effects predominate in the initial portions of the dopant profiles. Thus, in order to study lateral (*i.e.*, gas phase) autodoping, it is desirable to separate out the out-diffusion effects by obtaining autodoping profiles from nondoped areas such as typified in Fig. 1(b).

Lateral autodoping can be characterized by the maximum concentration, C_{max}, in the vertical profiles over the nondiffused region. We also find that the integrated area under the autodoping profile is an equally valid feature of autodoping, since both this area and the peak concentration vary similarly with the process parameters.

Figure 3 shows the effect of deposition temperature and epitaxial growth rate on the arsenic peak concentration, C_{max}, in the lateral autodoping profiles for the $SiCl_4$ depositions. These results show that (*i*) lateral autodoping increases with decrease in deposition temperature for the same growth rate, (*ii*) lateral autodoping increases with increase in growth rate for the same deposition temperature, and (*iii*) the effect of growth rate is more pronounced at lower deposition temperatures. The 0.25 μm/min growth rate data shows a maximum lateral autodoping at 1000°C deposition temperature. It was also found that, when depositions were made using silane, the autodoping *vs.* temperature curve had nearly identical slope for the 0.08 μm/min growth rate to that of $SiCl_4$ deposition between 950° and 1100°C.

The effect of preepitaxial bake time and bake temperature variations are shown in Fig. 4 and 5. The lateral autodoping decreases by about a factor of 5 when the bake time is increased from 2 min to 2 hr at 1150°C. The solid line is the least squares fit of the data to Eq. [13] which gave the following parameters: $A = 5.03 \times 10^{16}$ cm^{-3} and $\beta = 0.02$ sec$^{-1/2}$.

The effect of bake temperature variation is shown in Fig. 5 as a log C_{max} *vs.* 1/T plot for 1 hr bake time and 0.25 μm/min growth rate depositions. The autodoping increases by about a factor of 4 when the bake temperature is decreased from 1200° to 1000°C. The solid line represents the fit of the data to Eq. [13] using $\beta = 0.02$ at 1150°C as obtained from the bake time experiments. The results of this fit are: $A = 8.834 \times 10^{16}$ cm^{-3} and $\beta = 1.291 \times 10^9 \exp(-3.06/kT)$ sec$^{-1/2}$.

Discussion

Temperature dependence of lateral autodoping.—In an earlier section we developed an expression (see Eq. [7]) for the enthalpy associated with the formation of the arsenic solid solution in epitaxial silicon, assuming an equilibrium reaction for arsenic incorporation. To evaluate this enthalpy, ΔH_s, we plot the 0.08 μm/min growth rate data in an enthalpy plot as shown in Fig. 6. We chose this growth rate data for the evaluation of ΔH_s for the following reasons: (*i*) The growth rate was considered to be low enough to approach thermodynamic conditions, should they exist in autodoping, (*ii*) silane depositions also exhibited the same linearity and slope as in Fig. 6 under identical growth conditions, so that any complicating halide etching effects in $SiCl_4$ deposition can be neglected, and (*iii*) linearity in the enthalpy plot suggests a single operating mechanism for the incorporation process. The slope of the enthalpy plot yields

$$R \frac{d \ln N_{As}}{d(1/T)} \sim 64 \text{ kcal/mole}$$

In order to evaluate ΔH_s using Eq. [7], it is necessary to know the temperature dependence of the arsenic partial pressure in equilibrium with arsenic solid solution in silicon. Sandhu and Lyons (15) have obtained such data, and their results show that the enthalpy of the process, $-R \frac{d \ln p_{As}}{d(1/T)}$, is 53.52 kcal/mole in the temperature range 800°-1050°C. Using this value and $\Delta H_c = -72.3$ kcal/mole obtained from Honig and

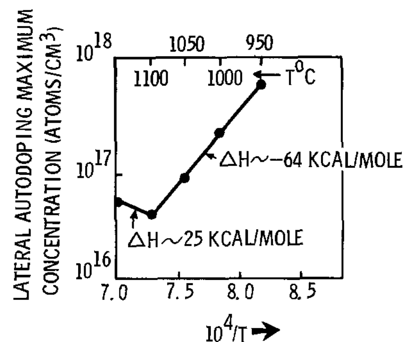

Fig. 6. Temperature dependence of arsenic autodoping. Growth rate 0.08 μm/min.

Kramer's compilation (16) for the heat of condensation of monatomic arsenic, we obtain $\Delta H_s = -45.2$ kcal/mole from Eq. [7].

Rai-Choudhury and Salkovitz (5) have obtained from their doping experiments $\Delta H_s \sim 22.6$ kcal/mole. Their analysis was, however, based on diatomic arsenic in the vapor. If we use a similar argument and assume that arsenic dissolves atomically in epitaxial silicon, we can write

$$As_2 \text{ (vapor)} \rightleftarrows 2As \text{ (epitaxy)} \quad [14]$$

for the incorporation reaction.

The heat of solution for the above reaction is now given by

$$\Delta H_s = \frac{R}{2}\frac{d \ln p_{As2}}{d(1/T)} - R\frac{d \ln N_{As}}{d(1/T)} - \Delta H_c' \quad [15]$$

where $\Delta H_c'$ is the heat of condensation for diatomic arsenic. Taking $\Delta H_c' = -53.1$ kcal/mole again from literature (16), we obtain $\Delta H_s' = -37.7$ kcal/mole from Eq. [15]. (Note that we use 53.52 kcal/mole for the enthalpy of the arsenic equilibration for the diatomic species as well, since the measurement of total arsenic vapor pressure made in these experiments (15) refers to whichever predominant species that is present.) Thus, the heat of solution obtained from autodoping experiments for either the monatomic or the diatomic arsenic species turns out to be a negative value, in contrast with Rai-Choudhury and Salkovitz's value of $+22.6$ kcal/mole. Further, a calculation (5) based on Weiser's model (17) also yields a positive value for ΔH_s of $\sim$7 kcal/mole. The small positive value of ΔH_s is also consistent with the calculations of arsenic activity coefficients in silicon as a function of temperature (18).

In view of the above disagreements with the heat of solution evaluations, we conclude that the arsenic autodoping cannot be described adequately by equilibria considerations alone. It seems likely that other kinetic limitations, such as impurity trapping during the epitaxial growth, play a significant role in the autodoping phenomena.

Growth rate dependence of lateral autodoping.—Since our experiments are in a kinetic region of interface controlled epitaxial growth, we expect the mass transfer limitations to play no important role in the autodoping kinetics. Yet, we see from Fig. 3 that the growth rate has a significant effect on autodoping, especially at lower deposition temperatures.

The theory of Hall (19), which was later extended by Holmes (20), takes into account the effect of growth rate on the solute distribution kinetics in melt-grown crystals. They show that the excess solute concentration in the bulk when solute trapping has occurred is a function of growth rate as given by

$$C_{xs}^* = C_{xs} \exp(-V_i/V) \quad [16]$$

where $C_{xs} = C_s - C_b$ is the equilibrium excess concentration at the surface, C_s and C_b being the equilibrium solute concentration at the surface and in the bulk, respectively. $C_{xs}^* = C_b^* - C_b$ is the excess solute concentration in the bulk due to trapping, where C_b^* is the nonequilibrium bulk concentration due to trapping. V is the growth rate of the crystal, and V_i is the growth velocity for which the relaxation time for diffusion in the interface and the time for the growth of one monolayer are about the same. Thus, Hall's theory predicts that the bulk concentration due to trapping varies from bulk equilibrium concentration at very low growth rates to surface equilibrium concentration at very high growth rates. It should be pointed out here that the deposition temperature should be high enough to permit a diffusional exchange between the buried layer and the growing surface, otherwise the initially adsorbed layer would remain at the surface concentration level for all growth rates.

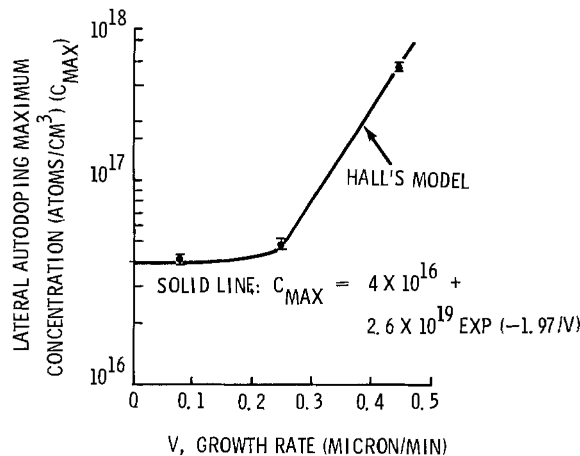

Fig 7. Effect of growth rate on lateral autodoping. Deposition temperature 1100°C.

In view of above considerations. we replot in Fig. 7 the 1100°C autodoping data as log C_{max} *vs.* growth rate. (The 1150°C data has not been used in this analysis since it represents a different slope in the enthalpy plot, which may imply a change in the incorporation mechanism. We take $C_b^* = C_{max}$ to represent the nonequilibrium arsenic concentration.) The data indicate a linear portion for low growth rates up to $\sim$0.25 μ/min with a slope which changes to a higher value at higher growth rates.

Extrapolating our data in Fig. 7 to zero growth rate yields $C_b \approx 4 \times 10^{16}$ cm^{-3}, and if we apply the data to Eq. [16], we obtain $V_i = 1.97$ μm/min and $C_s \approx 2.6 \times 10^{19}$ cm^{-3}. The solid line in Fig. 7 represents the equation: $C_{max} = 4 \times 10^{16} + 2.6 \times 10^{19} \exp(-1.97/V)$. Thus, Hall's theory indicates that the equilibrium surface concentration of arsenic would be $\sim$700 times that in the bulk. This high surface concentration is not untypical of the equilibrium surface segregation observed in many systems (21). Further, taking the relaxation time for diffusion or arsenic at 1100°C to be $\sim$0.07 sec ($t \sim x^2/D$, where $x \sim 4$Å for one monolayer of silicon), we estimate the effective thickness through which the trapped arsenic atoms have to diffuse to exchange with the surface to be $\simeq 0.07V_i$; *i.e.*, $\sim$5 atom layers. The range of this dynamic exchange is about the same as that found by Bloem for phosphorus incorporation in epitaxial silicon (22).

Preepitaxial bake effects on lateral autodoping.—The bake time data yield $\beta = K/\sqrt{D} = 0.02$ sec$^{-1/2}$. Taking $D = 8 \times 10^{-14}$ cm^2/sec for bake temperature of 1150°C from Masters and Fairfield data (23), we obtain the evaporation velocity, K, of arsenic from (100) silicon surface at 1150°C in an H_2 flow ambient to be 5.8×10^{-9} cm/sec. The rate of arsenic evaporation, r, varies with bake time as given by

$$r = KC(o,t) \quad [17]$$

where $C(o,t)$ is the surface concentration of arsenic in the diffused region. From Eq. [12], [13], and [17] we obtain

$$r = \left(\frac{KC_o}{A}\right) C_{max}(T,t) \quad [18]$$

Substituting the values for K and A obtained in the bake experiments, and taking $C_o \simeq 1.5 \times 10^{21}$ cm^{-3}, we obtain the rate of arsenic evaporation from the silicon substrates during prebake to be

$$r_{1150} = 1.73 \times 10^{-4} C_{max}(t) \text{ cm}^{-2}\text{sec}^{-1} \quad [19]$$

where $C_{max}(t)$ is shown in Fig. 4. Since $r \propto C_{max}$, Fig. 4 describes also the variation of arsenic evaporation rate

with bake time at 1150°C. The arsenic evaporation rate varies in present autodoping experiments from 8.75×10^{12} cm^{-2} sec^{-1} at the beginning of the prebake to 1.47×10^{12} cm^{-2} sec^{-1} at the end of 2 hr prebake cycle. This evaporation of arsenic prior to the beginning of the deposition cycle could amount to a substantial depletion of the diffusions in a typical integrated circuit fabrication process.

Arsenic evaporation velocity.—The bake temperature data shown in Fig. 5 gave $\beta = K/\sqrt{D} = 1.291 \times 10^9 \exp(-3.06/kT)$. Using $D = 60 \exp(-4.2/kT)$ for arsenic diffusivity (23), we obtain the following expression for the arsenic evaporation velocity from (100) silicon surface in an H_2 flow ambient

$$K = 1.0 \times 10^{10} \exp(-5.157/kT) \text{ cm sec}^{-1}$$

The evaporation velocity varies from 2.3×10^{-8} cm sec^{-1} at 1200°C to 3.8×10^{-11} cm sec^{-1} at 1000°C. Table I shows this data together with the evaporation velocity values determined by Arai and Terunuma (8) in their vacuum evaporation experiments. Their values are 40-80% lower than our present values, and they obtained an activation energy of 2.92 eV as compared to our value of 5.16 eV. This difference may be related to a possible existence of a stagnant boundary layer (24) in the epitaxial prebake experiments, which would not be the case for the dynamic vacuum evaporation experiments used by Arai and Terunuma. However, in a separate experiment (25), we determined the evaporation velocity of arsenic from (111) surface of a silicon substrate under static vacuum, and this experiment also indicated a higher velocity than that obtained by Arai and Terunuma. It is also possible that at the high C_0 used here nonlinear effects in the diffusivity need to be considered when solving the diffusion equation.

In order to further verify the proportionality assumed in deriving Eq. [13] between the lateral autodoping and the arsenic concentration over the diffusion, we have plotted the sheet (spreading) resistance values, both on and off diffused regions, as a function of bake temperature in Fig. 8. The figure clearly demonstrates a similar variation for these quantities, thus justifying the above assumption.

Conclusions

Kinetics of lateral autodoping is determined, among other factors, by (*i*) preepitaxial bake treatments which determine, in turn, the dopant evaporation kinetics in the epitaxial process, and (*ii*) deposition parameters, such as growth rate and temperature, which imply the existence of nonequilibrium situations in the dopant incorporation process.

Acknowledgments

I would like to express my appreciation to Mr. R. Hoffman for epitaxial depositions, to Mr. W. Patterson for spreading resistance measurements, and to Dr. H. B. Pogge for introducing me to this subject. I would also like to thank Dr. J. Bloem for a critical review of the manuscript.

Manuscript submitted May 11, 1976; revised manuscript received Aug. 10, 1977. This was Paper 191 presented at the Philadelphia, Pennsylvania, Meeting of the Society, May 8-13, 1977.

Table I. Temperature variation of arsenic evaporation velocity

Temp (°C)	Evaporation velocity (cm/sec): Present results of prebake experiments	Arai and Terunuma's results (vacuum evaporation)
1000	4.12×10^{-11}	—
1050	2.42×10^{-10}	—
1100	1.26×10^{-9}	6.0×10^{-10}
1150	5.80×10^{-9}	1.42×10^{-9}
1200	2.41×10^{-8}	3.19×10^{-9}

An Examination of the Chemical Staining of Silicon

D. G. Schimmel and M. J. Elkind

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

Large-scale chemical lapping of diamond-sawed silicon wafers to remove residual mechanical damage results in the formation of wafer stains. Highly doped p-type substrates are particularly susceptible and have been a primary cause of low wafer yields during production. This paper describes an investigation into the cause of silicon staining and a practical solution to the problem. On the premise that the stain is a suboxide of silicon, various nitric-hydrofluoric acid mixtures, as well as mixtures of hydrofluoric acid with oxidizing agents such as Cr^{+6}, Fe^{+3}, Cu^{+2}, and I^0 were used to synthesize silicon stains. Ion-scattering spectroscopy (ISS) and secondary ion mass spectrometry (SIMS) analyses established that all of the stains were suboxides of silicon ($SiO_{<2}$). Their origin is the incomplete oxidation of silicon, which is determined by the nature of the oxidant and its concentration. Although it is not practical to prevent silicon stains from forming, they can readily be removed by a 15 sec immersion in a 2:1 volume ratio of hydrofluoric acid: 0.038M potassium permanganate solution.

Diamond-sawed silicon wafers are chemically thinned, *i.e.*, chemically lapped with solutions of nitric (HNO_3), hydrofluoric (HF), and acetic (HAc) acids to remove residual saw damage. The wafers are then either Syton polished on one side, or, in some instances of discrete devices, subjected directly to production processing without further preparation. A visible stain is generally a reason for rejection of chemically lapped wafers. Staining became more prevalent with the increased usage of boron-doped <100> silicon having resistivities less than 1 Ω-cm (1).

The staining of silicon is not a new phenomenon. Over the years it has been observed to occur under a variety of silicon etching conditions, including anodic dissolution (2, 3), as well as with a variety of etching solutions (4-10). Amorphous silicon (11, 12), silicon hydride (13), mixtures of silicon oxides (14), and silicon monoxide or suboxide (15, 16) have been proposed as compositions to account for the discolorations. Based on these works and further production experience, two characteristics are notable: (*i*) the stain occurs most readily on highly doped p-type silicon; and (*ii*) the stain occurs as a result of treatment with any number of HNO_3-HF-HAc etching compositions.

Chemical lapping consists of immersing the silicon wafers in a temperature-controlled acid etch solution of HNO_3:HF:HAc. A volume ratio of 4:1:2 is a typical example (17). The stains form during removal of the wafers from the acid bath and subsequent immersion in water during the rinse. Because production applications frequently deal with very large etchant volumes, *e.g.*, 35 gallons, it is not feasible to quench the reaction by water dilution.

Silicon staining most readily occurs on highly boron-doped wafers, the degree of staining varying directly with the boron concentration. Staining also occurs on n-type silicon but to a lesser degree. Here again, the staining of n-type silicon varies directly with dopant concentration.

In very general terms the chemical reaction for the dissolution of silicon is as follows

$$Si + \text{oxidizing agent} \rightarrow SiO_2 \quad [1]$$

$$SiO_2 + 4HF \rightarrow SiF_4 + 2H_2O \quad [2]$$

In the presence of water and hydrofluoric acid, SiF_4 is converted to H_2SiF_6.

The stain films formed on silicon by HNO_3:HF:HAc etching solutions are insoluble in HF and in HNO_3. They are partially dissolved, however, in ammonium hydroxide (NH_4OH) solutions with some attendant attack on the silicon substrate. The stains can also be dissolved by reimmersion in the 4-1-2 etch solution, or, indeed, in any of the other usual HNO_3-HF etch solutions, such as the 5-3-3. However, during the interval in which the wafer is withdrawn from the etchant and water rinsed, the stain will reform.

Key words: silicon etching, stain films, chemical lapping.

This suggests that HNO_3-HF etchant compositions may favor the formation of some intermediate reaction product, perhaps a silicon oxide other than SiO_2. As an initial approach, the specificity of HNO_3 as the stain initiator can be rejected. Anodic oxidation of silicon in aqueous HF, for example, forms a stain similar to those chemically induced by HNO_3-HF mixtures. Furthermore, highly boron-doped silicon (~0.01 Ω-cm) has also been observed to stain during defect evaluation (18, 19). Here the defect etchant contains only HF and chromic acid (CrO_3) or potassium dichromate ($K_2Cr_2O_7$) as the oxidizing agent. In fact, highly doped p-type silicon will even stain when immersed in only hydrofluoric acid. The reaction is slow, requiring an hour or two to develop, and incident light is essential. In this instance, the oxidant for silicon is the water present in the concentrated hydrofluoric acid (20). The critical factor involved in stain formation on silicon appears to be the nature of the oxidant and probably its concentration.

If it is assumed that the stain is SiO_x, where $x < 2$, then a fast depletion of the oxidizing agent at the silicon-solution interface could be responsible for its formation. This depletion occurs because of the very high oxidation rate of the highly doped silicon surface. Since the stain film varies in thickness with time, the rate of the silicon suboxide formation is greater than the rate of its dissolution or oxidation to Si^{+4}. Once formed, the stain cannot be attacked by HF.

Experimental

In view of the above considerations, it should be possible to select oxidants having the necessary oxidation potential and concentration for the full conversion of silicon to the solubilized Si^{+4} state. Experiments were first performed to determine the range of HNO_3-HF ratios which cause silicon staining. The use of HAc in all of the formulations employed did not influence the formation of the stain. Since its primary function is that of a diluent, its further use was omitted (6, 21). Except where noted all samples were 0.01 Ω-cm p-type silicon.

Vertically oriented silicon test samples, partially submerged in the etchants maintained at 20°-23°C, showed that staining could occur in any of three ways: (*i*) solution staining of the entire immersed silicon; (*ii*) a thin-line stain at the air-liquid interface; or (*iii*) staining above the etch solution (vapor-phase stain). Formation at each of these locations depended

upon the HNO_3-HF volume ratios used. Nevertheless, staining of one type or the other occurred over a very wide range of ratios.

In general, HNO_3-rich solutions of ~12:1 to ~4:1 (HNO_3:HF by volume) caused air-liquid interface staining. Faster etches of ~3:1 to ~1:3 (HNO_3:HF) caused variable staining. For example, if the etch solution was vigorous enough to generate fumes or mist, a vapor-phase stain occurred on the silicon above the etch solution level. Staining was also found to be dependent upon the interval between withdrawal of the silicon from the etch solution and water rinsing. The more active etchant concentrations appeared to enhance stain formation after withdrawal of the substrate from the solution. For etch solutions of 1:4 to as high as 1:250 (HNO_3:HF ratios), the silicon stain formed only in solution. Obviously, the problem of silicon staining would not be solved merely by simple changes in the HNO_3-HF-HAc etchant composition.

Consequently, to learn more of stain formation and chemical composition of the discoloration, a number of typical oxidizing species were selected as substitutes for HNO_3 in combination with HF. As shown in Table I, these oxidants react by generating changes in oxidation state (valence) involving 1-5 electrons (possibly even 7-8). If partial oxidation of silicon is responsible for the stain, then those oxidants with one-, two-, and even three-electron changes should be candidates likely to produce stains. As mentioned above, CrO_3 and $K_2Cr_2O_7$ which undergo a three-electron change when reduced, do indeed stain silicon.

It was not surprising, then, that solutions of ferricyanide (ranging from 0.5-2 parts of 1M $K_3Fe(CN)_6$ to 1 part HF) with a one-electron change in oxidation state (Fe^{+3} to Fe^{+2}) provided very intense examples of staining on silicon. Prolonged immersion of silicon in such solutions merely intensified the discoloration from a brown to bluish-black color. Another single electron change is associated with the reaction of cupric chloride with silicon (0.5 parts of 1.5M $CuCl_2$ to 1 part HF). Again staining was very intense. Copper is not deposited in this case because insoluble CuCl is formed. With $CuSO_4$, however, the two-electron transfer would cause copper to plate out upon the silicon. Still another example is the reaction of KI-I_2 solutions with silicon (5 parts of KI-I_2 solution, containing 2 moles I_2 and 6 moles KI, to 1 part HF). This single electron type oxidation likewise produced very intense staining. Hydrofluoric acid solutions of hydrogen peroxide and ammonium persulfate, respectively, were inactive; and thus, these two-electron transfer reactions could not be effected. One other oxidant which probably involves a two-electron change is aqua regia. A two-part aqua regia:1 part HF mixture did show some activity by forming a stain.

These observations show that one and probably two-electron type oxidants, regardless of concentration, are incapable of completely oxidizing silicon. Those with a three-electron transfer, chromates and probably HNO_3, likewise tend toward staining. However, increasing their concentration in respect to HF in the etchant solution does enhance their oxidizing capability. For example, by increasing the HNO_3:HF from 1:4 by volume [0.135 mequiv. (22) HNO_3:1 mequiv. HF] to 1:3 by volume (0.180 mequiv. HNO_3:1 mequiv. HF), solution staining can be eliminated.

For chromium, which has an oxidation state change of three, no solution staining of silicon occurs in a 1 part 9.4M CrO_3:2.54 HF by volume solution (0.391 mequiv. Cr^{+6}:1 mequiv. HF). However, when the volume ratio is changed to 1 part 9.4M CrO_3:3 HF (0.325 mequiv. Cr^{+6}:1 mequiv. HF) then staining does occur. On a molar basis, therefore, the minimum concentration of each oxidant required to prevent solution staining is a HF solution 2.64M in Cr^{+6} and a HF solution 3.90M in HNO_3, respectively.

Though solution staining can be completely eliminated for the Cr^{+6} and the HNO_3 acid systems, nonuniform staining will occur upon withdrawal of the wafer, particularly from the HNO_3-HF etchants. This is a time-dependent reaction, since any residual acid (thin films, droplets, or vapor) will continue to react with the silicon. In addition, the instability of the HNO_3 in air accelerates the decrease in its effective concentration. That is to say, there is a rapid change in the HNO_3:HF ratio from a nonstaining region to one which stains by the incomplete oxidation of the silicon. In the case of the Cr^{+6} system, a longer time will elapse before staining occurs, simply because the Cr^{+6} is not degraded in air as is the HNO_3; and, hence, its effective concentration remains higher.

For a powerful oxidizing agent, such as $KMnO_4$ with a five-electron change occurring in acid solutions, no silicon staining of any type was encountered throughout a four-order-of-magnitude range of oxidant concentration. In fact, stains were not even apparent in solutions of 6.67×10^{-5} mequiv. Mn^{+7}:1 mequiv. HF. This remarkable performance is violated only when p-n junctions are present. Then the high boron-doped areas become stained when the Mn^{+7} concentration is only 3.27×10^{-3} mequiv. Mn^{+7}:1 mequiv. HF.

With this as a basis, it follows that this powerful oxidant might well be able to interact with residual stains formed on silicon by other etchants. In fact, a solution of 2 parts hydrofluoric acid to 1 part 0.038M potassium permanganate by volume readily dissolves stains formed by HNO_3-HF etchants on silicon within 10-15 sec at room temperature. The silicon etch rate for this solution is ~0.4 μm/min for <100> silicon ranging from 0.002 Ω-cm n-type to 0.01 Ω-cm p-type. The actual etch rates determined for two resistivities each of n- and p-type <100> silicon are listed in Table II.

In view of the results obtained with $KMnO_4$, iodic acid (HIO_3) and periodic acid (HIO_4) with oxidizing capabilities involving at least five-electron changes, respectively, were also evaluated. Both oxidants exhibited strong etch activity. However, they apparently formed some intermediate metastable iodine compounds during their reduction, which interfered with the completeness of the oxidation process. Silicon wafers treated in HF solutions containing each of these iodic acids turned dark and upon exposure to air continuously liberated iodine vapor.

Since the concentration of the oxidant has been shown to be one of the controlling factors in minimizing or eliminating stain formation on silicon, the use of solid fluoride salts in conjunction with HNO_3 and CrO_3, or $K_2Cr_2O_7$, was explored to avoid the dilution

Table I. Oxidizing agents

effect inherent with the water present in concentrated HF. The results showed clearly that undissociated HF rather than fluoride ions was essential for removing silicon dioxide (23). For example, the Secco etch (2 parts HF:1 part 0.15M $K_2Cr_2O_7$) readily generated a stain on 0.01 Ω-cm p-type <100> silicon. Replacing the HF with the equivalent concentration of potassium fluoride (KF) solution gave no reaction with silicon, even with the KF concentration increased to saturation. However, additions of hydrochloric (HCl) or sulfuric (H_2SO_4) acids to the nonreactive solution resulted in silicon staining. Hydrofluoric acid was evidently formed by the hydrochloric acid addition: $H^+ + Cl^- + K^+ + F^- \rightleftarrows HF + K^+ + Cl^-$.

Potassium fluoride added to HNO_3-HF solutions (1:1 by volume) reduced the normally violent silicon etch reaction to nil. Partial regeneration of the solution reactivity to silicon was achieved with HNO_3 additions. However, additions of water, hydrofluoric acid, or acetic acid were ineffectual. It is presumed that the potassium fluoride in this instance had initially caused massive nitric acid ionization to form undissociated HF and to simultaneously lower the oxidizing capability of the nitric acid.

Ammonium fluoride and potassium fluoride were also used as replacements for HF in HNO_3-HF (1:1 by volume) solutions. Silicon staining resulted in each case, but not the expected violent etch reaction. Nitric acid additions increased the solution etch activity, whereas sulfuric acid additions were not as effective. Violent silicon etching occurred, however, when hydrofluoric acid was added. Thus, it appears that the sulfuric acid did not completely convert all the fluoride ions from the fluoride salts into undissociated hydrofluoric acid.

Silicon stain composition.—Silicon samples with stains generated from hydrofluoric acid solutions containing oxidizing agents of items 6, 7, 8, 9, and 10 of Table I were analyzed for oxygen:silicon ratios and residual metallic contamination (24) with ion-scattering spectroscopy (ISS) and secondary ion mass spectrometry (SIMS). Two oxidized silicon wafers were used to establish the calibration for the oxygen:silicon ratio determination. The oxides of these calibration samples were approximately 50 and 2000Å thick. Figures 1A and 1B show the data obtained from the ISS for each of these oxide thicknesses. As expected, the ratio is essentially 2:1, oxygen:silicon. Figure 1C shows the oxygen:silicon ratio of the HNO_3:HF (1:110) generated stain film. This ratio is constant at about 1.4-1 over a thickness of 100Å. Similar ratios were obtained from the stain samples prepared in the HF solutions of $K_3Fe(CN)_6$, $CuCl_2$, CrO_3, and KI-I_2, respectively.

Figure 1D represents a production-type stain sample. The stain is very thin, probably 20Å or less. Accordingly, there is no extended flat portion above the base line to the oxygen:silicon ratio curve. Nevertheless, the stain is a silicon suboxide with a ratio of <2:1. Figure 1E shows the ISS oxygen:silicon ratio curve for the surface of a clean epi control wafer. As expected, there is only a very small quantity of oxygen present on the surface.

Both ISS and SIMS analyses showed that the elements Fe, Cu, Cr, and I_2 were not significant constituents in any of the stain samples. Though fluoride ions were also present, they were in such low concentrations as to preclude any Si-O-F combinations. It is clear, then, that all of the stain films formed by the 1, 2, and 3 electron change oxidants used in these experiments have a similar composition involving only oxygen and silicon in a ratio of <2:1.

Stain removal.—It is obvious from the results obtained that it is impractical to achieve a stain-free chemically lapped silicon wafer by using the conventional etchants, such as HNO_3-HF, on a large scale. The ease with which the 1 part 0.038M $KMnO_4$:2 parts HF solution completely removes such stains without

Fig. 1. significant attack on the substrate itself (0.1 μm per side in 10-15 sec) makes it very attractive for post-chemical lapping stain removal.

The possibility of residual manganese and potassium contamination exists for stained wafers treated in the $KMnO_4$-HF stain-removal etch solution. Accordingly, after treatment of a production-stained wafer in the $KMnO_4$-HF solution to remove the stain, water rinsing, and drying, it was analyzed for residual surface contamination by SIMS and ISS. Manganese was not detected, and the residual potassium level was consistent with that normally detected on clean silicon surfaces (<0.1 ppm). A large variety of devices were also fabricated from wafers that had been treated for stain removal on a limited production quantity basis. These device yields were consistent with the regular production yields. Added assurance against residual manganese and/or potassium contamination is that the stain removal treatment is performed prior to the preoxidation and prediffusion cleaning which all wafers receive.

Characteristics of the $KMnO_4$-HF etchant.—Although the silicon etch rate for 2 parts hydrofluoric

acid: 1 part 0.038M potassium permanganate is about 0.4 μm/min, it is not surprising that increasing the permanganate concentration also increases the etch rate. Accordingly, $KMnO_4$-HF solutions were surveyed as possible chemical-lapping etches.

The strongest formulation examined was a solution of 7g $KMnO_4$ in 100 ml HF, which upon mixing produced a very vigorous exothermic reaction. This solution exhibited limited stability, however, and produced inconsistent etching results. A preferred combination for etching silicon was formulated with 3.5g $KMnO_4$, 100 ml HF, and 10 ml H_2O. This etchant produced highly polished surfaces and exhibited an etch rate of 4.4 μm/min. Typically, 4:1:2 (HNO_3:HF:HAc) etches about three times faster and leaves the surface with a matte finish. A matte surface is preferred to provide friction for holding wafers in position during the Syton polishing operation.

Even though a $KMnO_4$-HF formulation contains considerably less oxidant than does a HNO_3-HF solution to stoichiometrically solublize silicon, rejuvenation by simple addition would eventually lead to solution buildup of manganese and potassium salts. The HNO_3-HF etchant, on the other hand, can be readily maintained by routine acid additions. Thus, considering the low etch rate, the polished rather than matte surface finish, and solution by-product buildup, $KMnO_4$-HF is not a suitable direct replacement for HNO_3-HF in a production chemical-lapping operation.

The low surface etch rate, $\sim$0.4 μm/min, of the 2 parts HF: 1 part 0.038M $KMnO_4$ stain-removal solution suggests that this type of etch solution might be adaptable to defect etching (25-27). An advantage of permanganate solutions would be that no special disposal is required, as is the case with the chromium-containing defect etches, such as those of Sirtl and Secco. Solutions containing one part of $KMnO_4$ in concentrations ranging from approximately 0.1-0.004M with 2 parts HF were surveyed for potential defect etchants, both with and without ultrasonic agitation.

The $KMnO_4$-HF defect etch solutions were evaluated on $<100>$ wafer samples with p-n junctions. Stacking faults and some dislocations were nicely delineated by etch pits in the junction areas. However, in the n-epi areas dislocation etch pits did not develop where dislocations were known to exist. This is not too surprising, since Landgren (28) found that $KMnO_4$-HF etchants were almost completely preferential to p-type material when p-n junctions are present.

Conclusions

The causes of the chemical staining of silicon, such as that which occurs during production quantity chemical lapping, have been shown to arise from the incomplete oxidation of silicon in the usual HNO_3-HF etchant compositions. Staining may occur in solution or in the vapor phase prior to rinsing as a result of oxidant depletion. Highly boron-doped $<100>$ silicon is particularly susceptible to stain formation. It has been shown that these stains can occur over a very wide range of HNO_3-HF compositions. Consequently, formulation variations to prevent silicon stain formation in a production process are impracticable.

Silicon stains were also generated with Cr^{+6}, Fe^{+3}, Cu^{+2}, and I^0 as oxidants in hydrofluoric acid solutions. These stains as well as those formed in various HNO_3-HF mixtures have been shown to be a suboxide of silicon, SiO_x, where $x < 2$.

$KMnO_4$-HF solutions do not form any kind of silicon stain over a wide range of permanganate concentrations. Though relatively active as a general silicon etch, the attack rate of the $KMnO_4$-HF solutions is only about 1/3 of that of a typical 4-1-2 HNO_3-HF-HAc solution. Furthermore, the resultant polished rather than matte surface finish and solution by-product buildup preclude its direct substitution for the usual HNO_3-HF-HAc etchants used in large scale chemical lapping operations.

Compositions of $KMnO_4$-HF in dilute form, however, are extremely effective for rapid postchemical lapping HNO_3-HF stain removal. A 2 part HF: 1 part 0.038M $KMnO_4$ solution at 20°-25°C completely dissolves stains in 10-15 sec without any significant silicon dissolution.

Investigation of the Ti-Pt Diffusion Barrier for Gold Beam Leads on Aluminum

S. P. Murarka,* H. J. Levinstein, I. Blech,[1] T. T. Sheng, and M. H. Read

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In order to avoid Al-Au interactions and to ensure the electrical and mechanical stability of the Au beam leaded structures using Al metallization, a Ti-Pt diffusion barrier between Al and Au has been investigated. Ti and Pt films of different thicknesses were employed as diffusion barriers. The resulting Al-Ti-Pt-Au thin film sandwich structures were aged at temperatures in the range of 300°-500°C to evaluate the effectiveness of the barrier in preventing Al-Au interaction. The interaction was followed by use of optical and electron microscopy, x-ray diffraction, and sheet resistance measurements. It was found that metallurgical interactions in these structures occurred at preferential sites which were shown to be hillocks in Al. On continued aging, reaction spread around these sites and finally covered the entire surface. The number of such reaction sites increased with decreasing barrier metal thickness and with increasing time and temperature of anneal. The reaction was considerably inhibited (*i*) by annealing Al at 450°C for ½ hr prior to barrier metallization and (*ii*) by using at least 2000Å each of Ti and Pt in the barrier. An understanding of the effectiveness and need of a 2000Å Ti-2000Å Pt diffusion barrier between Al and Au was obtained by additional studies of the metallurgical interactions induced in Al-Pt, Al-Ti, and Al-Ti-Au thin film sandwich structures by aging at temperatures in the range of 200°-500°C. Ti is required to cover Al well so as to prevent Al-Pt interactions and Pt is required to prevent Ti-Au interactions caused by diffusion of Au through Pt to Ti.

Aluminum is most widely used as a practical metallization material in the IC technology. In order to extend the use of aluminum metallization to multichip assemblies it is advantageous to form gold beam leaded sealed structures using such metallization. To avoid gold-aluminum (1) interactions, a suitable diffusion barrier between Al and Au has to be provided. This barrier metallization must prevent Al-Au interactions and must not lead to a loss of electrical conduction between the outside world and the circuit during its operation.

Several barrier metallization schemes—such as Ti-Pd, Ti-Pt, Ti-Rh, Ti-Ni—have been considered in the past (2-9) in one form or the other. Such two metal schemes have been chosen to satisfy both the adherence and barrier criteria and to provide sufficient corrosion resistance. The results of both Melliar-Smith and Polito (7) and DeBonte *et al.* (8) indicate that a Ti-Pt diffusion barrier between Al and Au would be a good choice. Speight and Bill (2), who studied the effects of aging in dry air at 150° and 250°C and in wet and dry air with 10 ppm HCl at 150°C on the contact resistance of Ti-Pt-Au conductor film metallization on Ta_2N, reported such metallization to exhibit by far the greatest stability.

We have investigated the feasibility of using a Ti-Pt diffusion barrier between Al metallization and the Au beams. In order to understand the barrier characterestics and its effectiveness, one must learn about the metallurgical interactions in two (*e.g.*, Al-Pt, Al-Ti, etc.), three (*e.g.*, Al-Ti-Au, Al-Pt-Au, etc.), and four metal (the Al-Ti-Pt-Au) systems. In the temperature range of 200°-600°C there is considerable interdiffusion in Ti-Au (8-9) and Pt-Au (10-11) films although no intermetallics are reported for the latter. Al-Au films are known (1) to react catastrophically. Al-Ti films have been reported (12) to react at higher temperatures, leading to the formation of Al_3Ti which retarded further interaction between Al and Ti. On the other hand, there is very little interdiffusion reported in Ti-Pt (8) films. In a recent paper (13) we have reported the results of our investigations of the metallurgical interactions in thin films of Al and Pt. Al and Pt films were found to interact very rapidly, leading to the formation of several intermetallics. In this paper we report and discuss the results of our studies of the Al-Ti-Pt-Au metallization scheme together with the results of the relevant studies of the metallurgical interactions in Al-Pt, Al-Ti, and Al-Ti-Au thin film structures. It will be shown that Ti-Pt diffusion barrier provides excellent barrier characteristics between Al and Au.

Key words: aluminum metallization, beam leads, diffusion barrier.

Experimental

The metal films were always deposited on oxidized silicon substrates. Throughout this paper the metal deposited first is written first. For example, Al-Ti-Au would mean that Al was deposited on the substrate, followed by Ti deposition on this Al, and Au (the outermost layer) deposition on Ti.

Al-Ti-Pt-Au structures.—Three different test structures were used in this investigation as shown in Fig. 1. The first [Fig. 1(a)] was the simple planar structure formed by depositing various films one after another. 1.5 μm thick Al was evaporated onto hot substrates at 320°C. Ti (or Ti/TiN) and Pt were sputter deposited on chemically cleaned (in 30:1 ammonium fluoride:HF for 30 sec) Al in the desired thicknesses. 5000Å thick Au was then electroplated on top of Pt. (In a typical beam lead about 10-15 μm of Au is electroplated on Pt. Such a thick layer of Au is, however, not suitable for the metallurgical interaction studies.) Most of the initial studies were made by measuring the sheet resistance of the composite film and by following the reaction visually under an optical microscope. A few x-ray diffraction patterns were obtained for the reacted specimens to learn about the possible intermetallics formed.

Based on the results of the studies on the above-mentioned test structures, new test structures of the type shown in Fig. 1b were made using a metallization scheme 2000Å Ti-2000Å Pt-5000Å Au on hot-deposited (320°C) Al. The Al was annealed at 450°C for 0.5 hr in hydrogen to simulate the actual device-fabricating conditions, and to reduce the hillock growth

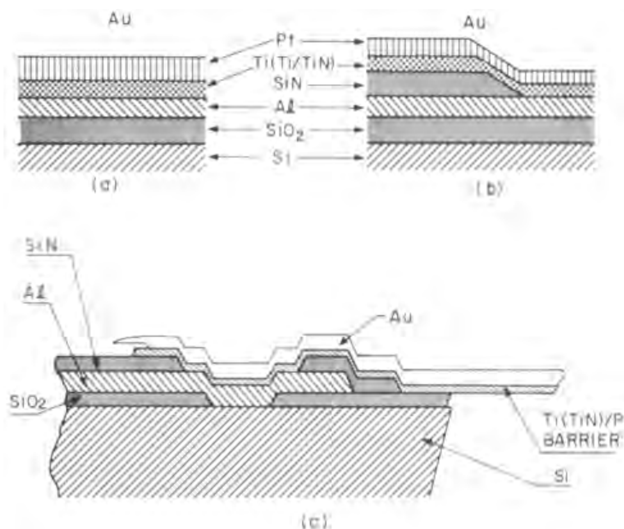

Fig. 1. Schematic drawings of the various Ti/Pt barrier layers between Al and Au.

in subsequent 350°C agings. Also, in some cases half of each wafer was coated with 1 μm of plasma silicon nitride prior to Ti-Pt deposition so that a comparison could be made between the Al-Ti-Pt-Au and Ti-Pt-Au interactions. It may be noted that in the rest of the investigation we have used only hot-deposited (320°C) Al films which were annealed to 450°C for ½ hr in hydrogen prior to any subsequent metallizations.

Al-Pt structures.—In a recent publication (13) we have already reported the results of thin film interactions of Al and Pt. Al and Pt react very rapidly at higher temperatures and Ti is needed to avoid this interaction. In this paper we report the results of our investigation of the hillocks in aluminum as the preferential reaction sites. Since Al-Pt interact very rapidly, a very thin (200Å of Ti) barrier was used between Al and 2000Å of Pt to retard the reaction so it could be followed during heating on a hot stage in the scanning electron microscope in a reasonable length of time. One of these samples was heated on the hot stage of a SEM. A Chromel-Alumel thermocouple connected to the hot stage measured the temperature of the hot stage. The reaction, as it occurred, was recorded as snapshots. The maximum temperature attained during these interactions was 510°C.

Al-Ti-Au structures.—In order to establish the usefulness of Pt in the Al-Ti-Pt-Au metallization scheme, we studied a few Al-Ti-Au thin film sandwich structures. Ti and Au films were deposited on 1.5 μm thick (hot-deposited and preannealed) Al films in two different manners: (*i*) On some wafers Ti and Au films were sequentially sputtered in the same sputtering chamber without breaking vacuum. Samples with 1000, 2000, and 3000Å thick Ti films were prepared. Each had 5000Å Au film on top; (*ii*) In another case, 2000Å of Ti was sputtered on Al and the wafer was taken out in air prior to Au evaporation. In many of these samples Au did not adhere very well to the Ti surface, which could be a serious drawback in using gold directly on Ti if the Ti gets exposed to air before the Au deposition.

Al-Ti-Au samples thus prepared were then annealed at 350°C in forming gas ambient. The interaction between the metallic films was followed by optical examination of the top surface of the structure, four-point probe sheet resistivity measurements, and x-ray diffraction studies.

Results and Discussion

Al-Ti-Pt-Au structures.—Ti film thicknesses of 1000 and 2000Å with or without 100-200Å of TiN and Pt films of 1000, 2000, and 4000Å thicknesses were used. These thicknesses are indicated on the figures. All

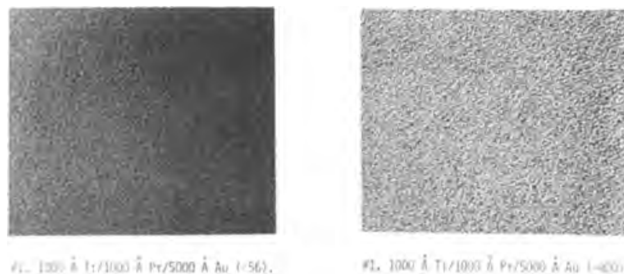

Fig. 2. Top view of the surface of Al/Ti/Pt/Au samples as-prepared

the high temperature agings were carried out in forming gas. Most of the samples were annealed at 350°C, and some were annealed at 300° and 400°C.

All sample surfaces were identical in the as-prepared state. The optical photomicrographs in Fig. 2 show the top view of one as-prepared 1.5 μm Al-Ti-Pt-Au sample. Figure 3 shows the surfaces of various samples annealed at 350°C for 5 hr. As a result of the aging, the metallurgical interaction in these films has become visible. As can be seen in Fig. 3, the reaction appears as black spots (in fact, they were slightly purple hillocks) indicating preferential reaction sites. Very similar spot formation has been reported by Kolesnick *et al.* (14). The number of such sites increased with the increase in aging time. It can be seen that both thicker Ti (≈2000Å) and Pt (≈2000Å) films help to reduce the extent of the interaction. The intermediate layer of TiN would also seem to help in reducing this interaction.

Composite film sheet resistances were monitored as a function of the annealing time and temperature. Figure 4 shows the sheet resistance before and after the annealing for 22 hr at 350°C for various samples. One finds a good qualitative correlation between the results of Fig. 4 and those of Fig. 3. A 2000Å Ti-2000Å Pt barrier between Al and Au films seems to be very effective in controlling the metallurgical interactions which lead to high sheet resistances. Figure 5 shows the sheet resistance of Al-2000Å Ti-2000Å Pt-Au structures as a function of time at several temperatures of anneal.

The number of interaction sites (so-called black spots) increased with increasing time of anneal. Figure 6 shows the number of these sites per square centimeter as a function of time of anneal at 400°, 350°, and 300°C. This result is very similar to one shown in Fig. 5. It may be pointed out that even after 45 hr of aging at 350°C the number of reaction sites on specimen No. 11 (with 2000Å Ti-2000Å Pt)

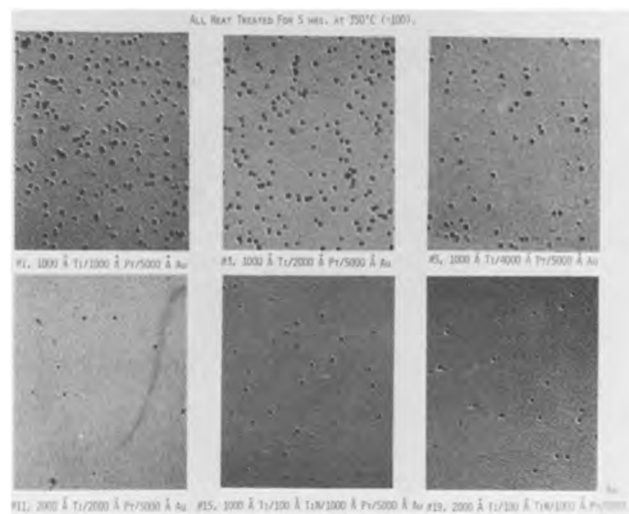

Fig. 3. Top view of the surface of Al/Ti/Pt/Au samples after 5 hr anneal at 350°C.

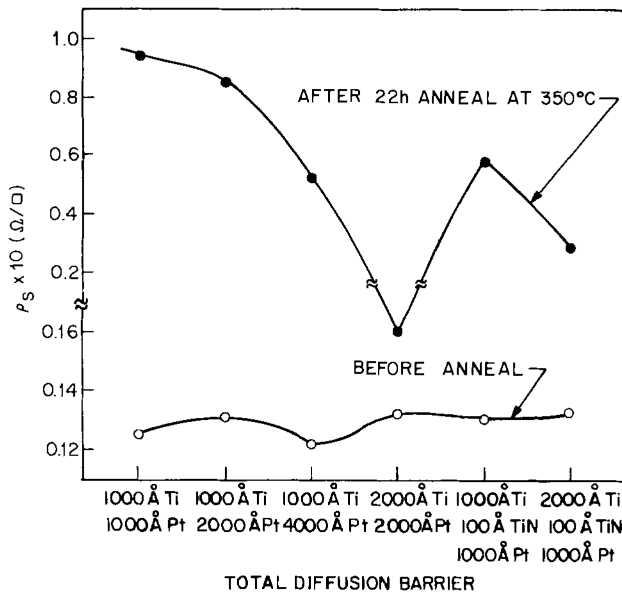

Fig. 4. Effect of a 22 hr anneal at 350°C on the composite film sheet resistance of samples with different barrier thicknesses.

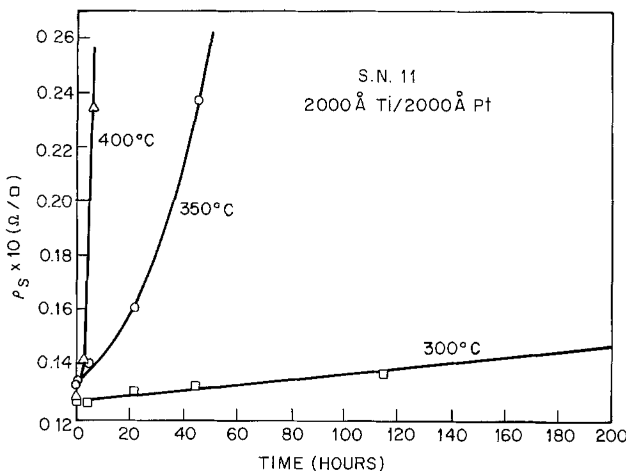

Fig. 5. The sheet resistance of the sample with the 2000Å Ti/2000Å Pt barrier as a function of time and temperature of anneal.

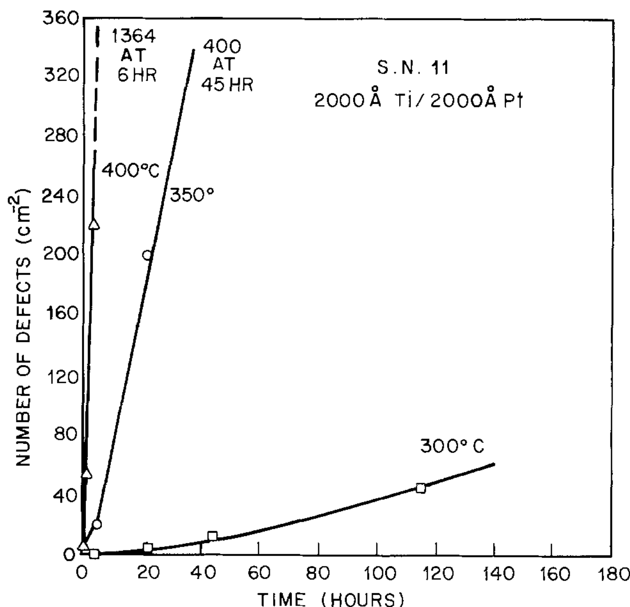

Fig. 6. The number of observed defects in the sample with the 2000Å Ti/2000Å Pt barrier as a function of time and temperature of anneal.

was only 0.08 per 200 μm × 100 μm area, a typical metallization area.

A comparison of the sheet resistances and the number of the black spots appearing after the 400°, 350°, and 300°C anneals (Fig. 5 and 6) shows that the over-all metallurgical interaction in the 1.5 μm Al-2000Å Ti-2000Å Pt-5000Å Au system is a thermally activated process. Although it is not possible to characterize this process, which could be a composite of several thermally activated reactions, one can extract a very useful number in terms of the over-all activation energy as reflected in sheet resistance and number of defect measurements (Fig. 5 and 6). The activation energy in the present case was found to be ~1.5-1.7 eV. Knowledge of this number and of the useful life at the accelerated aging temperature can be utilized to approximate the life of the composite film structure at the operating temperature of the devices.

Results of x-ray diffraction studies of the reacted films are given in Table I. The only reaction product detected was Al_2Au which confirms the observation of purplish color of the reacted spots. Phases other than the purple Al_2Au were optically visible but were undetected by x-rays.

As stated earlier, in all these specimens the Al films were deposited on substrates heated to 320°C, and no postannealing was carried out prior to Ti-Pt-Au depositions. Al is known (15) to form hillocks during annealing. These hillocks may punch through Ti-Pt films during the 350°C anneals, leading to direct contact between Al and Au. Also, the hillocks present at the interface may be high enough that Ti-Pt coverage is poor, leading to thinning of the barrier metal and permitting reaction to occur at these sites in subsequent heat-treatment. To test this hypothesis and to minimize hillock growth during annealing, a few samples were prepared according to the schematic shown in Fig. 1(b). Here, Al was annealed at 450°C for 30 min in hydrogen prior to silicon nitride deposition. Such a heat-treatment of Al prior to further metallization is a common practice during device fabrication.

Figures 7(a) and 7(b) show optical photographs of the surface of two samples (with 200Å Ti-2000Å Pt and 2000Å Ti-100Å TiN-2000Å Pt between Al and Au) annealed for 42 hr at 350°C. The reaction, as represented by black spots, has taken place only in the half where Al was in contact with Ti-Pt-Au. There is very little change in the sheet resistance on this half of these samples. In the other half, where silicon nitride formed a thick barrier between Al and the Ti-Pt-Au metallization, no reaction seemed to have occurred. There is no change in the measured sheet resistivity of Ti-Pt-Au on this half of the wafer. The number of defects on the reacted side (on Al) is considerably less in these samples (even after 42 hr of anneal) compared to those shown in Fig. 3. This difference in reaction rate (compared to that discussed earlier with as-deposited Al, *e.g.*, Fig. 4) could be attributed to the 450°C anneal of

Table I. X-ray diffraction studies of the reacted films

Metallization	Heat treatment (°C)	Intermetallics identified
Al-1000Å Ti-1500Å Pt-5000Å Au	1 hr at 350	None
	3 hr at 350	None
	20 hr at 350	Strong spotty lines due to Al_2Au only
Al-2000Å Ti-2000Å Pt-5000Å Au	5 hr at 350	None
	22 hr at 350	Definite Al_2Au but not as strong as in other sample (above)
	115 hr at 300	A few spots only indicating 2-10% Al_2Au
Al-1000Å Ti-5000Å Au	8 hr at 350	Al_2Au and Au_4Ti
Al-2000Å Ti-5000Å Au	8 hr at 350	Au_4Ti only
Al-3000Å Ti-5000Å Au	8 hr at 350	Au_4Ti only

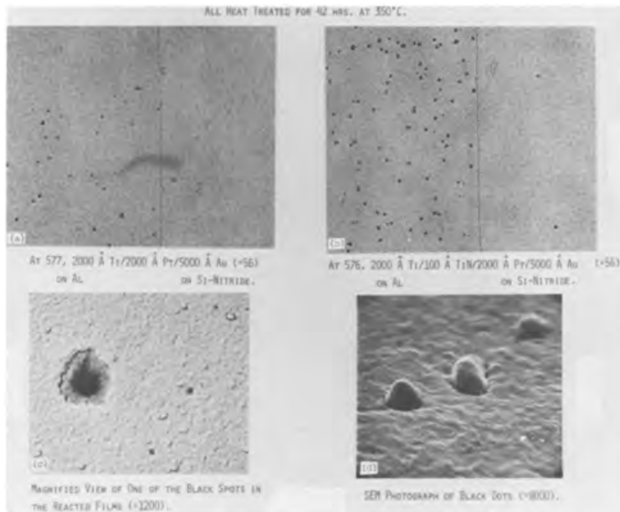

Fig. 7. Top view of heat-treated samples made at 450°C for 1/2 hr prior to barrier metallization. (a) With 2000Å Ti/2000Å Pt/5000Å Au on Al and on Si nitride; (b) with 2000Å Ti/100Å TiN/2000Å Pt/5000Å Au on Al and on Si nitride; (c) one reacted spot as visible in optical microscope and; (d) several reacted spots as visible in SEM.

Al prior to Ti-Pt-Au depositions. Due to this treatment hillock formation in Al is considerably retarded at lower temperatures. Figure 7(c) shows an isolated black spot in high magnification. The periphery of the spot was purple and the central area was protruding out of the surroundings. These spots appear as hillocks in the SEM, as can be seen in Fig. 7(d).

Hillocks as the reaction sites: Al-Pt reaction.—In the absence of Ti, Al and Pt react very rapidly and reaction occurs preferentially at sites which appear as black spots during optical examination. Figure 8 shows a series of SEM snapshots as the Al-Pt interaction (slightly slowed down by a 200Å Ti barrier in between) occurred on the heated stage of the SEM. Figure 8(a) shows a window in the as-prepared sample. The description under each photograph describes the total time since heat-treatment began, as well as temperature and the magnification. Going through the sequence of these photographs it is very clear that there is a one-to-one correspondence between the hillocks present in Al and the reaction site (black dot as it appears in the optical microscope). Some hillocks start to grow early and they are the first to react. Others follow in time. Figure 8(d) shows a cross section of one of these hillocks. In Fig. 8(d) the hillock has the typical conical shape. Such hillocks were subsequently found to have folded on themselves on prolonged heating. From these it is clear that as the hillocks grow in size, a void increasing in volume is created under the top surface of the hillock. The formation of the void is caused by the separation of the intermetallics from the underlying aluminum. It may be noted that the hillock underneath the silicon nitride layer separating Al from Ti-Pt did not grow during this treatment (as shown by the arrows in Fig. 8). These observations clearly establish that the black dot formation in Al-Ti-Pt-Au structures (due to accelerated aging at elevated temperatures) was due to the presence of hillocks in the Al and subsequent growth due to reaction at these hillocks.

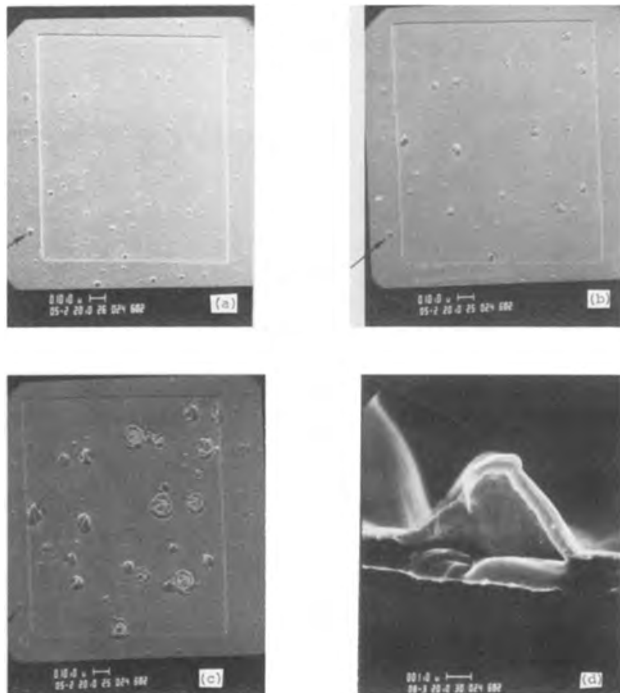

Fig. 8. SEM snapshot photographs of the sample with 200Å Ti/2000Å Pt on 1.5 μm thick annealed Al film (in window). Sample was annealed on the hot stage of the microscope. (a) As-prepared, X500; (b) after 109 min of heating, hot-stage temperature 510°C, X500; (c) after 135 min of heating, hot-stage temperature 510°C, X500; (d) heater shut off after 135 min (510°C), cooled, and cleaved, X8000.

The absence of any Al-Ti, Al-Pt, or Ti-Au intermetallics and the presence of only Al_2Au in the reacted Al-Ti-Pt-Au films can now be explained. Interaction was initiated at the localized Al-hillocks between Al and Ti-Pt. The interaction led to void formation and collapse of the reacted volume leading to metallurgical contact between Al and Au. The rapid delocalization of Al-Au interaction follows leading to the formation of detectable amounts of Al_2Au over the entire surface. Other intermetallics, formed at localized sites, were not present in large enough amounts to be detected by x-ray diffraction in a decisive manner.

Al-Ti-Au structures.—Samples with in situ-deposited Ti and Au.—Figure 9 shows the surface of Al-Ti-Au films after a 4 hr anneal. Intermetallic reaction products are visible in samples with 1000 and 2000Å Ti but not in the sample with 3000Å Ti. In the sample with only a 1000Å Ti barrier between Al and Au, reaction seems to start at preferential sites, which according to Fig. 8 could be the hillocks in Al. The surface away from these black spots has also turned grayish in all samples, indicating some metallurgical interaction. In samples with a 2000Å Ti as barrier, such reaction sites (black spots) are very limited in number and there appears to be interaction occurring everywhere as denuded (or reflecting) regions.

Figure 10 shows the surface of the same samples after 8 hr of anneal. Interaction is now visible even

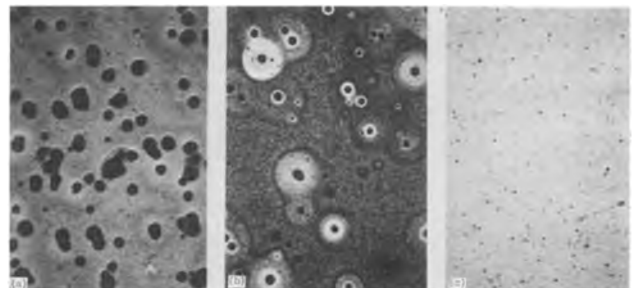

Fig. 9. Photomicrographs showing interaction in samples with *in situ*-deposited Ti/5000Å Au on 1.5 μm thick and annealed Al—after 4 hr/350°C/forming gas anneal. (a) 1000Å Ti; (b) 2000Å Ti; (c) 3000Å Ti.

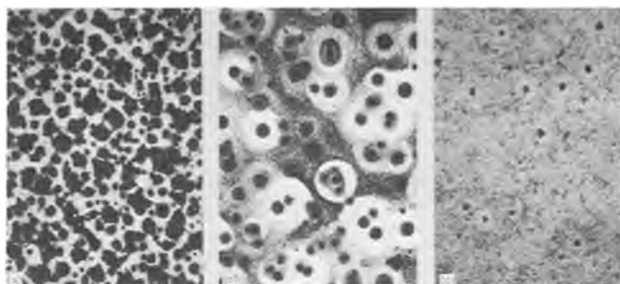

Fig. 10. Photomicrograph showing interaction in samples with *in situ*-deposited Ti/5000Å Au on 1.5 μm thick and annealed Al—after 8 hr/350°C/forming gas anneal. (a) 1000Å Ti; (b) 2000Å Ti; (c) 3000Å Ti.

on the sample with 3000Å Ti. The surface of the sample with 1000Å Ti is now purplish in color, whereas the other two surfaces are increasingly grayish black. Absence of black spots on samples with 2000Å and 3000Å Ti, in as large a number as is visible on sample with 1000Å Ti, would indicate a better coverage of Al hillocks with thicker Ti films.

The sheet resistance of the samples was measured on the top surface (Au layer) at room temperature. Figure 11 shows a plot of the sheet resistance of various Al-Ti-Au samples as a function of time. These results confirm the microscopic observations of Fig. 9 and 10. As seen in the case of Al-Pt samples (13) there is an instantaneous decrease in the sheet resistance of all the samples that could be associated with the annealing of the films. For the sample with 1000Å Ti, there is a gradual increase in the resistivity with time and at the end of 8 hr anneal there has been approximately 100% increase in ρ_s indicating considerable consumption of Al (13). There has been no change in the sheet resistivity of the sample with 3000Å Ti besides the initial decrease. After the initial decrease, there has been only slight (~6%) increase in the resistivity of sample with 2000Å titanium. There has been thus a negligible interaction involving Al since the total sheet resistivity of the Al-Ti-Au samples is largely contributed by Al only.

X-ray diffraction studies of the films after 8 hr of anneal show the intermetallics listed in Table I. In samples with 2000 and 3000Å Ti films the only identified intermetallic is Au_4Ti. On the other hand, in the sample with 1000Å Ti, $AuAl_2$ is predominantly present together with Au_4Ti.

Samples with Au deposited on air-exposed Ti.—Figure 12 shows the optical micrographs of the sample after 350°C anneal in forming gas. Note that in half of this sample Al was covered with plasma silicon nitride. Ti-Au was on top of aluminum in the other half. This enabled us to compare the Ti-Au interaction occurring on one half with Al-Ti-Au interaction on the other. Since nitride as well as Ti and Au replicate

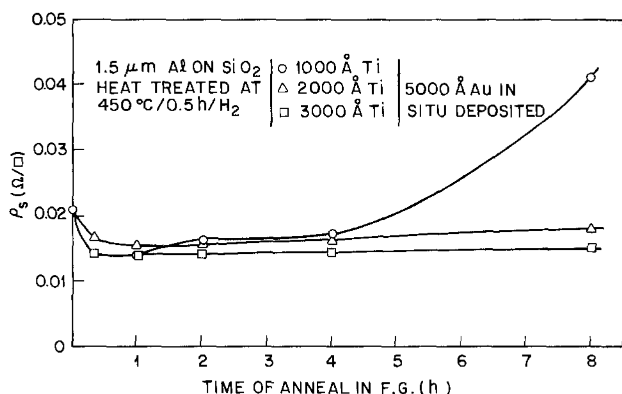

Fig. 11. Sheet resistance of various Al/Ti/Au samples as a function of time of anneal at 350°C in forming gas.

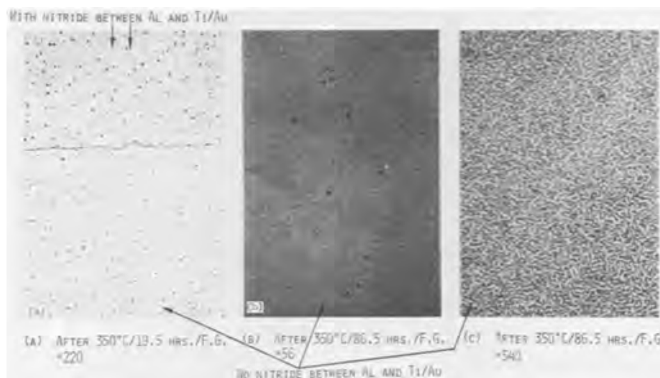

Fig. 12. Photomicrographs showing an absence of interaction on the sample with titanium exposed to air prior to gold evaporation.

the halves, they look identical and any differences in the mode of interaction could be easily detected. As can be seen in Fig. 12, there is no reaction visible even after 19.5 hr of anneal. Surface discoloration only has become visible after 86.5 hr of anneal. A few small black spots are also visible. There was no significant change in the sheet resistance of the sample of Al-Ti-Au or Ti-Au halves. X-ray diffraction study of the two halves does not show anything intermetallic. Only metallic Ti, Au, and Al are detected.

Al-Ti interaction.—We have also investigated samples with 2000Å Ti on Al annealed at 350°C up to 86.5 hr in forming gas. No interaction has been visible at the surface. There has been no significant change in the sheet resistance, indicating absence of any significant reaction. X-ray diffraction study of this sample does not show any intermetallics.

Absence of any Al-Ti intermetallic in all the samples has been unique and surprising. It would appear that under the present circumstances Al and Ti do not interact at any appreciable rate at 350°C. Bower (12) has described an Al-Ti metallization scheme and has reported the formation of $TiAl_3$ at the Ti-Al interface. The amount X of the Ti consumed to produce $TiAl_3$ was given by

$$\frac{X^2}{t} = 0.15 \exp(-1.85 \text{ eV}/kT) \text{ cm}^2/\text{sec}$$

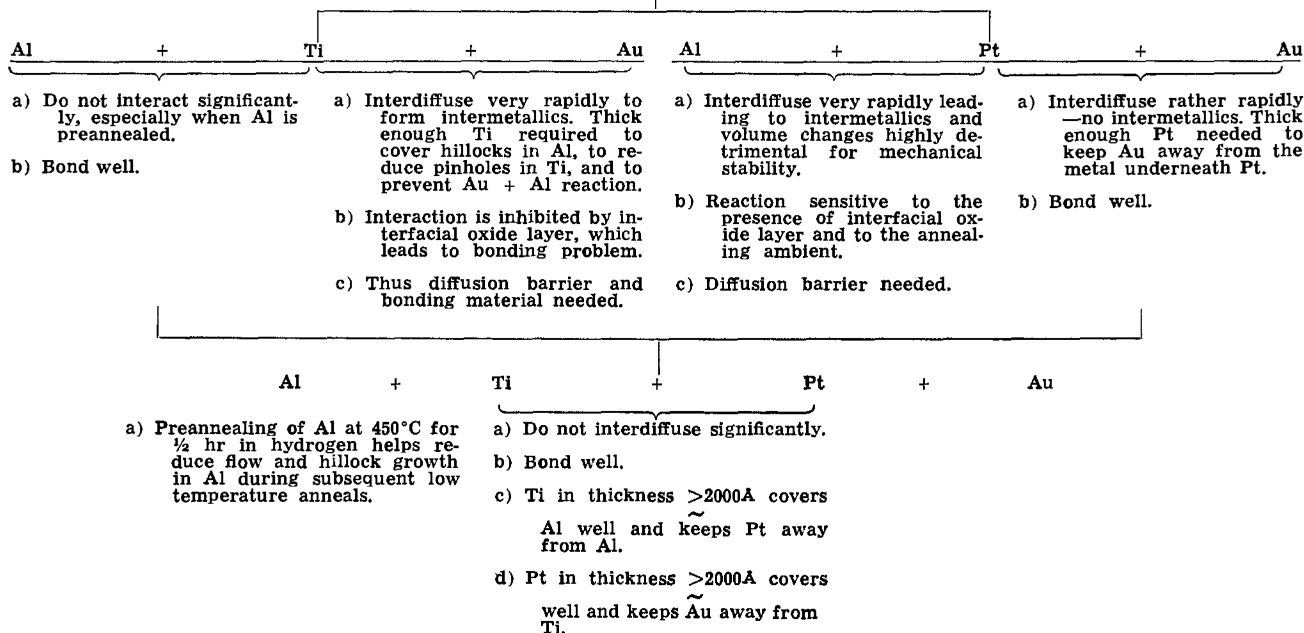
where t is the time of anneal in seconds at the temperature T°K. This expression may be used to calculate the approximate amount of Ti consumed during 86.5 hr anneal at 350°C. Thus if the Al-Ti interaction occurred in our samples, 600Å of Ti should have been consumed to form $TiAl_3$. Such an amount of $TiAl_3$ should have been large enough to be detected by x-ray diffraction studies.

Absence of the formation of any detectable amount of Al-Ti intermetallics could be attributed to either or both of the following. (*i*) In the present case, Al films were preannealed in hydrogen at 450°C prior to Ti deposition, leading to considerable grain growth and hillock formation in Al. Such a heat-treatment of Al will retard the migration of Al in subsequent aging at lower temperatures. (*ii*) The interaction may be considered to be inhibited by the presence of the interfacial oxide layer on Al. The latter, however, would seem unlikely because unlike Pt, Ti is an excellent oxygen getter with the ability to absorb almost half its weight in reaction products interstitially. Ti will thus bond easily with Al and the presence of any oxide layer should not inhibit Al-Ti interaction. It may be noted here that Bower (12) deposited both Ti and Al at 100°C in a single evaporation during one pumpdown of the evaporator. He had thus eliminated the interfacial oxide layer formation and had low temperature Al which could react at a much faster rate than our annealed Al.

Ti-Au and Au-Al interactions.—In samples with *in situ*-deposited Ti-Au on Al, the reaction between Ti and Au seems to occur fairly rapidly in all the samples as indicated by discoloration of Au and presence of $TiAu_4$ in all the samples. Thus given enough time to interact with Ti, Au eventually could get to the Al-Ti interface, and the Al-Au interaction, which is catastrophically fast at these temperatures, would be initiated. That is what happened in the case of the sample with only 1000Å Ti between Al and Au. This amount of Ti may not be enough to cover the hillocks in Al and may have a larger density of pinholes, both of which lead to Al-Au interaction at an early stage of heat-treatment This was the case leading to the formation of $AuAl_2$ in this sample.

In samples where Au was evaporated on Ti exposed which have been annealed prior to Ti-Pt-Au metallization and (*ii*) 2000Å Ti-2000Å Pt (at least) barrier between Al and Au. The first of these two reduces flow in Al and growth of hillocks during subsequent anneals. Thicker Ti-Pt provides a good coverage on the Al hillocks and prevents Al-Pt, Al-Au, interactions any one of which could be catastrophic. The high temperature aging studies of the Al-Ti-Pt-Au composite films have thus clearly established that 2000Å Ti-2000Å Pt barrier between Al (which is annealed at 450°C) and Au beam leads forms metallurgically stable structures.

We now understand the need of a Ti-Pt (with at least ~2000Å of each) diffusion barrier between Al and Au. This understanding can be summarized in the schematic given below.



in air (Fig. 12), there was no new phase detected even after 80.5 hr of anneal, indicating absence of any significant Al-Ti, Ti-Au, or Al-Au interactions. Thus the oxidized Ti surface very effectively inhibited the Ti-Au interaction which was otherwise visible in *in situ*-deposited samples. Similar results were reported by Poate *et al.* (9) who found considerable Ti-Au interdiffusion leading to the formation of $TiAu_4$ and $TiAu_2$ in samples annealed in vacuum. For air-annealed samples, the interaction was retarded and Ti was found in oxidized form on top of the gold layer.

During preparation of the samples by evaporation of Au on air-exposed Ti, it was realized that occasionally Au film would not adhere to Ti. Since Au has very poor affinity for oxygen, such a behavior is expected. This would thus provide an additional reason to use Pt not only as the diffusion barrier between Ti and Au, but also as a bonding layer between them.

Conclusion

Results of this investigation show that the high temperature metallurgical interaction in the Al-Ti-Pt-Au composite film structures leads to the formation of several intermetallics, but only Al_2Au was detected in the x-ray diffraction studies. The reaction preferentially occurred at the hillocks in Al leading to black spot formation. The number of such spots increases with time and temperature of anneal and decreases by increasing the thickness of the Ti-Pt barrier. The reaction spreads around such reacted sites and given enough time it covers the whole surface area and entire thickness of both Al and Au. The interaction in Al-Ti-Pt-Au composite structure is drastically slowed down by use of (*i*) Al films

Interaction of Fluorine and Fluorides with Tantalum, Tungsten, and Rhenium at Low Pressures and High Temperatures

J. L. Philippart, J. Y. Caradec, B. Weber, and A. Cassuto

CNRS, Laboratoire de Recherches sur les Interactions Gaz-Solides, Laboratoire Maurice Letort, B.P. 104-54600 Villers-Nancy, France

ABSTRACT

Reactions of fluorine and tantalum fluoride at low pressures with tantalum, tungsten, and rhenium at high temperatures have been investigated using line-of-sight mass spectrometry. Results are interpreted using a model which assumes: dissociative adsorption of incident molecules; surface reactions of adsorbed species; and desorption of products. Dissociative adsorption occurs upon each collision of the gaseous reactant with the surface. The adsorption is followed by the rapid establishment of a thermodynamic surface equilibrium. The model shows that the valency of the products decreases as the substrate temperature is increased in agreement with experimental results. The model has been used to predict the possibility of chemical vapor deposition at low temperatures by means of disproportionation reactions. The prediction has been verified.

In previous studies of reactions on a high temperature tantalum surface involving chlorine (1) and tantalum pentachloride (2) at low pressures, a reaction mechanism was proposed and shown to be consistent with the experimental results. This mechanism assumed dissociative adsorption followed by surface reactions in which the desorption products are formed. Quantitatively, the model is an extension of one proposed for oxidation reactions of transition metals by molecules other than oxygen (3-5). Using this model we were able to explain some chemical vapor deposition reactions involving chlorine and chlorides (2, 6). This study presents similar results for fluorine and tantalum pentafluoride reactions with tantalum, tungsten, and rhenium. The same model has been applied and has been found to be valid.

Experimental

The main apparatus has been described previously (4). Basically it consists of a ribbon, heated by direct current, enclosed in a cooled reactor which is in turn enclosed in the main vacuum chamber. The reactor has a slit directly in front of the ribbon through which it is pumped. This slit defines a molecular beam for unstable and condensible products which then can pass directly into the ionization chamber of the mass spectrometer (Veeco GA5). A second slit, positioned in front of the ionization chamber, prevents any collisions with the walls of the mass spectrometer. A shutter allows interruption of the beam. After bakeout, the system regularly attains vacua of the order of 5×10^{-10} Torr.

The samples (tantalum, tungsten, and rhenium ribbons of dimensions 20 mm × 2 mm × 30 μm supplied by Heraeus, initial purity 99.95%) are recrystallized at high temperature (2200°K) and carbon is removed by heating in oxygen at 10^{-6} Torr for 24 hr. After flashing off the oxygen in vacuum, AES shows less than 1% impurities on the surface. X-ray back-reflection analysis shows {110} orientation parallel to the surface for tantalum with large grains, several centimeters long; {0001} orientation for rhenium with small grains of the order of 0.1 mm with a possible 10° misorientation; and {111}, {100}, {110} orientations for tungsten.

Gaseous reactants (fluorine and pentafluoride, Comurhex) are distilled in a stainless steel inlet system and transferred into a gas reservoir confined between two valves. One of the valves is a leak valve connected directly to the reactor. Because of reactions at the walls of the vacuum system, HF and O_2 levels cannot be decreased below a few percent. Various fluorides are also observed, resulting from parasitic reactions, as well as fluorine atoms, even when the sample is cold. This phenomenon, which was described in a previous study (7), may be interpreted in terms of reactions with the walls and the filament of the mass spectrometer. It restricts the precision of the measurements and the detection limit of the reaction products, particularly fluorine atoms.

Calibration Procedures

From the pumping speed of the main vacuum system, the mass spectrometer is calibrated by a dynamic flow technique. From the dimensions of the slit connecting the reactor to the main system the pressure around the sample is deduced.

When a simple product can be identified in a restricted temperature range its flux is determined from a material balance, and the over-all yield of the reaction B can be written

$$B = 1 - \frac{P}{P_o} \quad [1]$$

where P is the pressure of reactant during the reaction and P_o the reactant pressure without reaction, with the ribbon cold. For a perfect isotropic reactor B can be expressed as $\nu b/1 + \nu b$ (8) where b is the reactive sticking probability and ν the mean number of collisions of the reactant molecules with the surface before being pumped away from the reactor. The net flux per square centimeter and per second is therefore, if fluorine is the reactant

$$Z_{M_xF_y} = \frac{2}{y} p_{F_2} b/\sqrt{2\pi M_{F_2} k T_g} \quad [2]$$

Key words: fluorine, tantalum fluoride, line-of-sight mass spectrometry.

[Corrections to b due to pressure anisotropy are obtained by comparison with oxidation reactions (9)]. Assuming complete equilibrium between desorbed products and surface temperatures, flux values are derived from measured ionic currents using the relation $Z_x = I_x T^{1/2}$.

For the production of fluorine atoms occurring at high substrate temperatures because of the background at m/e = 19, intensities at m/e = 9.5 have been used with the shutter close to the mass spectrometer open. When only fluorine atoms are produced, the atomic flux is strictly proportional to $|I_{F^{++}} - (1 - B) I^{\circ}_{F^{++}}|$. $I_{F^{++}}$ and $I^{\circ}_{F^{++}}$ represent the ion intensities when the ribbon is hot and cold. B is obtained from the fluorine pressure variations between reacting and nonreacting conditions. When monofluoride is also formed at high temperatures (on tantalum), its flux is obtained from the total yield of the reaction and the fluorine atom flux (neglecting the contribution of TaF to m/e = 9.5). TaF desorption corresponds to only 6% of the over-all fluorine reaction yield. Finally this TaF_5 pressure is estimated by comparison with fluorine, using the two observed reactions

$$F_2 + \text{Surface} \rightarrow 2F.$$

$$TaF_5 + \text{Surface} \rightarrow 5F. + Ta$$

Reactions with Fluorine

Reports that high valency fluorides and chlorides do not yield parent peaks in the mass spectrum (10, 11) have been confirmed in this laboratory using $TaCl_5$ and TaF_5, and so TaF_4^+ and WF_5^+ peaks have been used to measure TaF_5 and WF_6 partial pressures. All analyses have been performed using 150 eV electron beam energies to overcome the problem of sensitivity of the mass spectrometer at lower ionization energies.

Fortunately, by varying the temperature, constant mass spectra are obtained for tantalum and rhenium in restricted temperature ranges. Results, given in Fig. 1 and 2, include fluorine atom production. Tables I and II analyze the mass spectra of the observed fluorides; their nature is identified using the quantitative analysis of the data and are presented in the next section.

With tungsten, the separation of WF_6 and WF_5 formation is almost impossible (11); except at very high temperatures where only fluorine atoms are formed, no constant spectrum is observed. However, progressive transfer from production of the high valency fluoride, WF_6, to the lower valency WF_5 is clear as the temperature increases from 1200° to 1500°K.

Fluorine atoms are produced on all three metal surfaces. Figures 3-5 are representative of the results. At high temperatures and low pressures, atomic fluorine

production is first order with pressure and is characterized by unit sticking coefficient.

Quantitative interpretation.—The same model which was applied to oxygen-transition metal interactions (5, 12) and more recently to tantalum-chlorine (1) and tantalum-chlorides (2) interactions is developed here. The elementary steps are: a nonactivated dissociative adsorption

$$F_2 + 2M \rightarrow 2M - F_{ads}$$

followed by desorption of products

$$y(MF)_{ads} \rightarrow M_xF_y + (y - x)M$$

Table III defines x and y values for the various reactions.

Qualitatively, it is clear that as the substrate temperature increases, the valency of the product fluorides must decrease. Taking θ as the fluorine atom coverage, defined as the ratio of the number of fluorine atoms adsorbed to the maximum possible number of fluorine

atoms adsorbed, the desorption flux can be written

$$Z_{M_xF_y} = \nu_{M_xF_y}(n_s\theta)^y \exp - \left| \frac{y\chi(\theta) + xL_M - \epsilon_{M_xF_y}}{RT} \right| \quad [3]$$

where $\nu_{M_xF_y}$ represents a preexponential factor, n_s the number of adsorption sites, $\chi(\theta)$ the heat of chemisorption of fluorine atoms, L_M the heat of sublimation of the metal M, and $\epsilon_{M_xF_y}$ the heat of formation of the gaseous product M_xF_y, from gaseous metal and fluorine atoms.

Since the $\epsilon_{M_xF_y}$ values are unknown for most of the fluorides ($y < 4$), direct comparison is difficult. However, using two values of the flux, θ and χ can be eliminated and we obtain expressions of the general form

$$\frac{(Z_{M_xF_y})^{y'}}{(Z_{M_{x'}F_{y'}})^y} = \frac{(\nu_{M_xF_y})^{y'}}{(\nu_{M_{x'}F_{y'}})^y} \cdot \exp \left| \frac{y'\epsilon_{M_xF_y} - y\epsilon_{M_{x'}F_{y'}} - (xy' - x'y)L_M}{RT} \right| \quad [4]$$

The main advantage of these expressions for testing the model is that they are dependent only on temperature and not pressure. A set of such ratios is given in Fig. 1 and 2.

Knowing ϵ_{TaF_5} (13) we calculate, $\epsilon_{TaF_4} = 580$ kcal/mole, $\epsilon_{TaF_3} = 430$ kcal/mole, and $\epsilon_{TaF} = 180$ kcal/mole using relation [4] and compare them with the corresponding values estimated by Zmbov and Margrave (10), (assuming that Ta-F bonds are identical in all fluorides), 576, 432, and 144 kcal/mole, respectively.

There is a discrepancy only for TaF. Experimentally, at high temperatures the ratio $Z_{TaF}/Z_{F.}$ is constant. Our model predicts such a constancy if $\epsilon_{TaF} \simeq L_{Ta} =$ 189 kcal/mole. Two independent determinations ($Z_{TaF}/Z_{F.}$ and $[Z_{TaF_3}/(Z_{TaF})^3]$ confirm that ϵ_{TaF} is of the order of 180 kcal/mole. The agreement between our ϵ' values for TaF_4, TaF_3, and Ref. (10) plus the pure TaF_5 mass spectrum confirm the nature of the tantalum fluorides.

In the case of the high temperature fluoride, an alternative could be TaF_2 production instead of TaF. Using TaF^+ ions as a measure of Z_{TaF_2}, a straight line is indeed obtained when $Z_{TaF_2}/(Z_{F.})^2$ *vs.* $1/T$ is plotted. But ϵ_{TaF_2} then appears to be 380 kcal/mole, an unrealistic value when compared to 430 for ϵ_{TaF_3} and 290 calculated with an average 144 kcal/atom derived from $\epsilon_{TaF_5} = 720$ kcal/mole.

In the case of rhenium, ϵ_{ReF_4} is again determined, by comparison with the ReF_6 or F. flux. The two values are respectively 370 and 350 kcal/mole. The difference between these two values gives an idea of the uncertainties in the measurements. The data have also been analyzed assuming ReF_4 production at high temperatures. To choose between ReF_4 and ReF_5 production, a plot of $Z_{ReF_5}/(Z_{F.})^5$ *vs.* $1/T$ has been made, using the ReF_4^+ ion intensity as a measure of Z_{ReF_5}. The ϵ_{ReF_5} value determined in this way leads to an average value of 60 kcal for the Re-F bond. This value is inconsistent with the 95 kcal per bond, determined from heat of formation of ReF_6 (14). A similar argument holds in the low temperature range. ReF_7 formation instead of ReF_6 formation is excluded because no straight line is obtained when $(Z_{ReF_4})^7/(Z_{ReF_7})^4$ *vs.* $1/T$ is plotted.

In a recent investigation of the fluorine-tantalum system, using a modulated molecular beam, Ollander (15) proposed an alternative mechanism for TaF_5 desorption in a lower temperature range. The main step is the diffusion of fluorine atoms through a subhalide surface layer. In our temperature and pressure range, we are in the submonolayer coverage range and that kind of mechanism may not apply. Agreement of the experimental results with our model when volatile products are formed is therefore again satisfactory as in the case of the formation of oxides and chlorides. Even at higher pressures (10^{-2}-10 Torr) similar products are observed, using infrared spectroscopy (6). The only change is a shift towards higher temperatures at the higher pressures.

Reaction Products Using Fluorides—Application to Chemical Vapor Deposition

Tantalum pentafluoride.—The reaction of TaF_5 and tantalum gives the same products as those observed when fluorine reacts with this metal. As the temperature is increased, TaF_4, TaF_5, and finally fluorine atoms are observed. However, because the incident molecule contains a tantalum atom, the over-all reaction can be either one of attack or of deposition, depending on the temperature range. The reaction can be followed by resistivity measurements.

At low temperatures (~ 1200°K), TaF_5 is produced by reaction of F_2 and tantalum, and therefore no decomposition of TaF_5 occurs. At higher temperatures (above 1300°K) TaF_4 and TaF_3 appear resulting from the attack reactions

$$Ta + 4TaF_5 \rightarrow 5TaF_4$$

$$2Ta + 3TaF_5 \rightarrow 5TaF_3$$

Finally, at temperatures above 2000°K fluorine atoms are the major product and tantalum deposition is observed.

This result confirms the low value observed for TaF desorption when using fluorine molecules at high temperatures. The reaction of TaF_5 with tantalum leads to deposition only if the TaF flux represents less than 20% of the over-all reaction flux. The experimental value of 6% is consistent with this argument. It also explains, due to the high fragment peak coming from TaF_5, why no measurement of TaF production has been possible when TaF_5 decomposition occurs.

X-ray back-reflection analysis indicates complete epitaxy of the deposited tantalum on recrystallized {110} tantalum, even up to thicknesses of 90 μm (three times the original ribbon thickness). Microscopic examination shows that tantalum crystals develop simply perpendicularly to the surface, keeping the same grain boundaries and crystallite cross sections.

The model proposed for fluorine reactions is therefore still valid if one assumes that after dissociative adsorption and incorporation of tantalum atoms into the lattice, forgetting their origin, reaction products are determined only by the temperature and coverage of fluorine atoms. Such an interpretation has already been proposed in the case of $TaCl_5$ reactions on tantalum (2).

This interpretation is confirmed by observing TaF_5 reactions on tungsten. At low temperatures (~ 900°K), WF_6 is the only product formed. Its production rate decreases with time, simultaneously with the growth of a tantalum layer. If the tantalum is removed from the surface by dissolution into the bulk at high temperatures, the same experiment may be repeated on the now clean surface. In the high temperature range, where tantalum is dissolved in tungsten (> 2000°K), fluorine atoms become the only product. Using this technique, tantalum-tungsten homogeneous alloys have been prepared with a variable tantalum atom concentration between 10 and 40%.

Despite difficulties in interpreting the data due to the complexity of the phase diagrams, TaF_5 reactions with rhenium lead to the same result: it is possible to prepare tantalum-rhenium alloys or compounds with a variable but controlled composition.

Reactions of low valency fluorides.—The model predicts that disproportionation reactions such as

$$5TaF_4 \rightarrow 4TaF_5 + Ta$$

or

$$5TaF_3 \rightarrow 3TaF_5 + Ta$$

are possible in a temperature gradient and may lead to tantalum deposition at low temperatures, as in the

case of chlorides (6). The principle of the experiment is simple. It consists of the attack by TaF_5, of a tantalum ribbon at a temperature above 1300°K (where TaF_4 or TaF_3 are formed), and consecutive reaction of the low valency fluoride products with a second tantalum sample, maintained at a lower temperature (600°-1000°K), where TaF_5 is the stable product. A double ribbon arrangement has been used to confirm this hypothesis. Resistivity measurements were used as a continuous control of the high temperature ribbon attack and the low temperature ribbon growth. Using such an arrangement tantalum deposits have been formed on substrates in the (600°-1000°K) temperature range. Confirmation of the process was obtained in a higher pressure range (10^{-2}-1 Torr) using gravimetric measurements.

Conclusion

As in the case of reactions with chlorine molecules and chlorides, fluorine and fluoride reactions can be described by a mechanism involving, as a first step, dissociative adsorption and product formation controlled by the halogen atoms surface coverage. This depends on the temperature and the pressure, but is independent of the means to bring halogen atoms to the surface. This mechanism is an extension of the model previously used to describe oxidation reactions of transition metals (3-5, 12).

The model leads to a general method for chemical vapor deposition at low temperatures, without the help of hydrogen for most of the transition metals, which form halides of more than one valency. An arrangement of two samples at different temperatures was used to demonstrate the deposition of tantalum and other metals, using chloride or fluoride reactions on different substrates at low temperatures. The resulting deposits have good adhesion.

Technical Notes

Irregular Growths of $B(OH)_3$ on the Surface of Oxidized Silicon

M. Crooke, S. Wittstock, and E. Köck

National Electrical Engineering Research Institute, Solid State Electronics Division, Council for Scientific and Industrial Research, Pretoria 0001, South Africa

During process experimentation for new bipolar logic circuits, growths emanating from the oxidized silicon surface were observed. These growths are tentatively identified as crystalline orthoboric acid, $B(OH)_3$.

To accommodate the requirements of the design engineer for new experimental logic circuits, it was necessary to perform an extra p^+ (boron) deposition (and simultaneous shallow diffusion) at the termination of the normal high temperature processing sequence of the standard npn bipolar process.

About three days later growths were observed on the oxidized silicon wafer surface. Available literature was consulted and a limited number of tests were performed on the sample in the time available, which gave rise to the belief that these growths are composed of orthoboric acid, $B(OH)_3$. Optical photographs and scanning electron micrographs as well as the results of energy dispersive x-ray (EDX) analysis of the growths are provided in support of this tentative supposition.

Key words: crystalline orthoboric acid, orthoboric acid growths, boron deposition, storage conditions.

Experimental

When the additional p^+-window photomask was applied ~18 hr after the diffusion of the n^+ (phosphorus) emitter, no surface irregularities were visible. After a further 18 hr had elapsed, the additional p^+(boron) deposition was performed but not deglazed. The wafer was stored and submitted for further photoprocessing (contact windows) about 66 hr later. It was at this stage that the growths on the

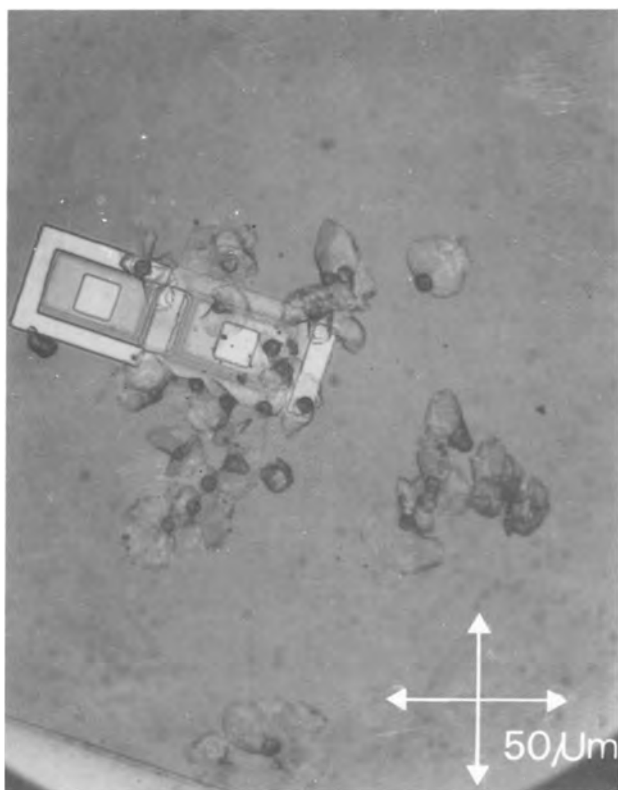

Fig. 1. Optical micrograph showing appearance of the surface irregularities on and around a photoengraved device.

wafer surface were observed through an optical microscope with coaxial illumination in white light.

Figure 1 illustrates the appearance of these growths so observed, which in our laboratories were labeled "butterflies" and "fans". These terms describe in some measure the region of irregularity emanating from a "nucleus" which is not necessarily visible or central to the effect. The fan appears to be relatively thin and largely transparent, particularly where it extends over an opened window in the SiO_2 layer, as the window edge can be seen through it.

With the assistance of a scanning electron microscope (SEM), Fig. 2 and 3 show that the nucleus observed optically now appears to be a surface mound from which the fan emanates. However, only two of these were observed. When observed at high angles of tilt (from the vertical) Fig. 4 indicates fans which have probably collapsed as a result of "rough" handling, or grown so large that they could no longer be supported by the mound. Figure 5 shows a mound without the fan. On this basis, the fans appear to be surface rather than bulk and do not appear to have caused any damage to the surface.

The EDX attachment coupled to the SEM is a rapid qualitative method for determining the presence of elements of atomic number $Z \geq 11$ (Na). (Na represents the lower limit of element detection in this case, due to the low detection efficiency for elements of $Z \leq 11$ caused by detector window absorption of these characteristic x-rays). EDX analysis showed the absence of any element with $Z \geq 11$ in an amount greater than the detection limit [about 0.1-1.0 weight percent (w/o)] which therefore excludes the possibility of phosphorus ($Z = 15$) from the deposition and diffusion for the n^+ (phosphorus) emitter, being a component in either the fan or mound.

Project demands at this stage prevented further sophisticated analyses. It was observed, prior to further photoprocessing, that all the fans had been removed from the surface and only a few mounds of very much reduced size remained after cleaning the wafers in boiling trichloroethylene, cold acetone, and rinsing them in cold water. As a large percentage of the fans were only resting on the surface (see Fig. 4) these could easily be removed, but the continued existence of a few mounds on the surface (see, for example, Fig. 5) after this cleaning process indicates their more permanent character. Attempts to regrow the fan were unsuccessful.

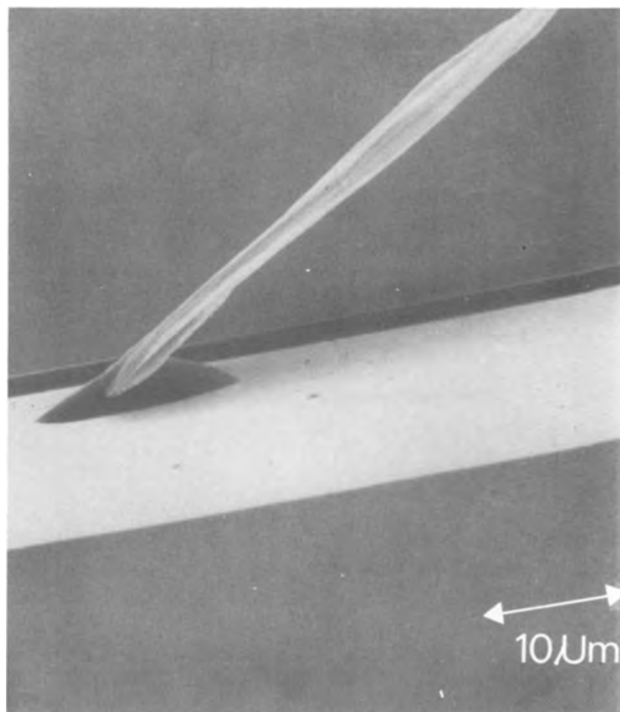

Fig: 2. SEM micrograph of the fan and mound seen edge-on (width of channel is 110 µm).

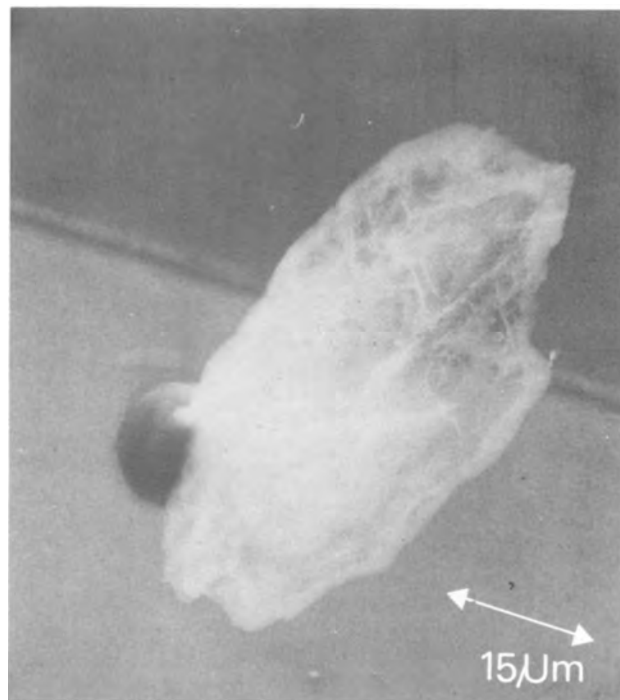

Fig. 3. SEM micrograph of the fan and mound when taken at a low angle of tilt.

Discussion

As EDX has excluded phosphorus and its compounds as a constituent of the fan—certainly in an amount greater than the detection limit—its com-

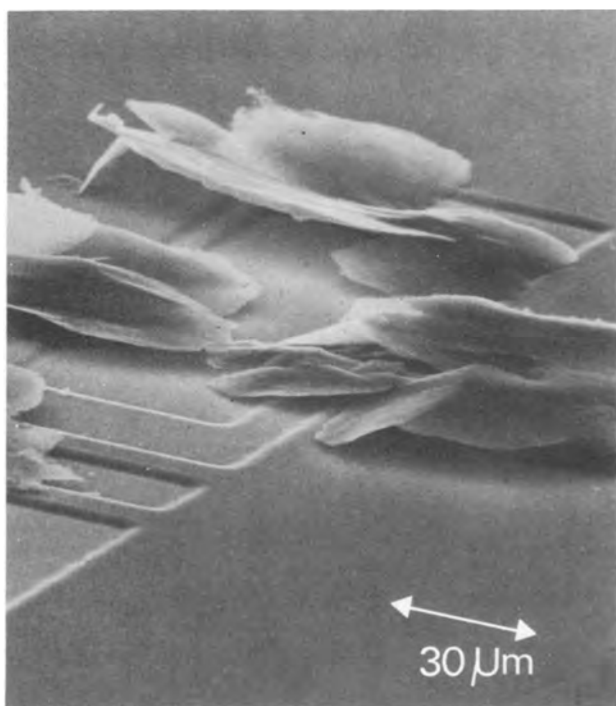

Fig. 4. SEM micrograph showing collapsed fans over a photoengraved device, (76° tilt).

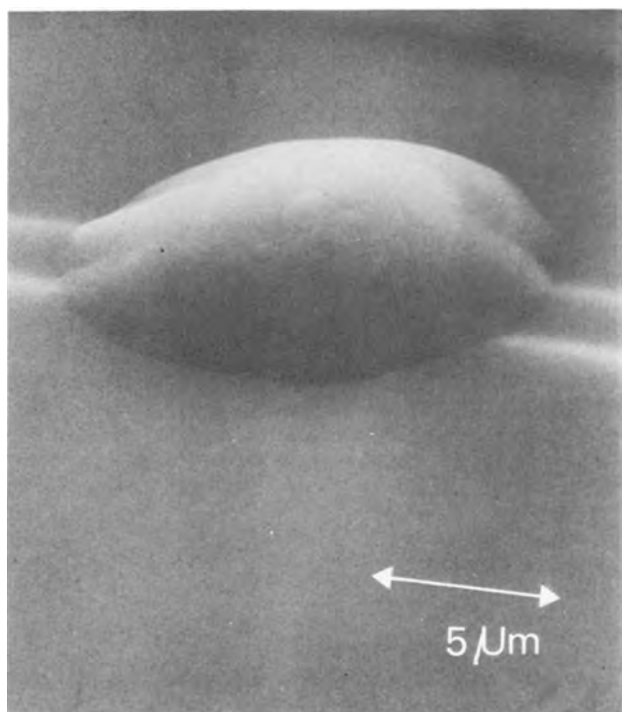

Fig. 5. SEM micrograph of a single mound, (65° tilt)

position is dependent on the major compounds involved at the last high temperature (1323°K) boron deposition stage (involving oxidized boron nitride disks) and the subsequent reaction of these compounds with water vapor of the room air. These include B_2O_3 (1) (boric oxide) and HBO_2 (2, 3) (metaboric acid.[1] Thus the mound and the fan probably contain the element boron ($Z = 5$) in some combination with appropriate elements that were similarly not detected by EDX, *viz.* oxygen and/or hydrogen. Due to the great difficulty in crystallizing (5) glassy B_2O_3 (*i.e.*, transforming a randomly ordered three-dimensional network into an ordered one at room temperature) the possibility that they contain boron and oxygen only, as B_2O_3, was excluded. It was thus inferred that the mound and the fan consist largely of boron and hydroxyl groups from the reaction of the oxide of boron with the water vapor of the room air. Although relatively slow compared to the pure B_2O_3 films, water absorption in the mixed $(yB_2O_3 \cdot zHBO_2)xSiO_2$ (borosilicate) glass film, which forms on the surface of the passivating SiO_2 during the high temperature boron deposition, is rapid in environments of high relative humidity and is largely dependent on the B_2O_3 content of the film (6-8).

[1] Particularly in the presence of water vapor, a small percentage which occurs in the ultrahigh purity argon (99.995% min.) employed, the following reaction takes place preferentially (2, 4)
$B_2O_3(s \text{ or } l) + H_2O(g) \rightarrow 2HBO_2(g) \quad \Delta H^\circ = 47.6$ kcal/mole

Thermodynamic data and hydration reactions of interest concerning the change from the glassy B_2O_3 to the whitish, powdery substance that occurs particularly when the boron nitride deposition system is removed from the furnace and permitted to cool to room temperature in the moist atmosphere of the clean work station before storage, include (9-11)

$$B_2O_3 + H_2O \rightarrow B_2O_3 \cdot H_2O \cdots\cdots 2HBO_2$$

$$HBO_2 + H_2O \rightarrow HBO_2 \cdot H_2O \cdots\cdots B(OH)_3$$

(orthoboric acid)

i.e.

$$B_2O_3(\text{glass}) + 3H_2O(l) \rightarrow 2B(OH)_3(s)$$

$(\Delta H^\circ = -9.1$ kcal/mole$)$

$$B(OH)_3(s) + nH_2O(l) \rightarrow B(OH)_3(aq)$$

$(\Delta H^\circ = -5.2$ kcal/mole$)$

The heat of hydration of amorphous $B_2O_3 \rightarrow$ crystalline $B(OH)_3$ is -18.3 kcal/mole.

During storage in a sealed container that traps a portion of the atmosphere of the same relative humidity as the working area, the hydration reaction proceeds over a period of many hours at a rate that is determined by the diffusion coefficient of water in the borosilicate glass film at room temperature. The reaction continues until the water vapor present in the container is depleted. According to Arai (7) the $B(OH)_3$ migrates out of the boron-rich surface, leaving water behind.

On the basis of this limited information, it is inferred that the fan observed is composed of crystalline orthoboric acid, $B(OH)_3$, and the mound of concentrated aqueous $B(OH)_3$ in which an impurity has provided the seed for crystalline growth of the fan.

Because the logic circuits were experimental in nature, they were exposed to the ambient and stored for periods longer than normal during the p^+ deposition evaluation. Under the proper processing conditions of minimum storage time in a dry ambient, these growths would not normally be observed. The growths of orthoboric acid can be removed by rinsing in pure methanol (8).

The Reduction of Poly-Si Dissolution and Contact Resistance at Al/n-Poly-Si Interfaces in Integrated Circuits

H. M. Naguib* and L. H. Hobbs

Bell-Northern Research, Ottawa, Ontario, Canada K1Y 4H7

In a previous investigation (1), we reported a rapid increase in Al/n-poly-Si contact resistance following 5 min isochronal sintering at temperatures in excess of 450°C. This increase in contact resistance, R_c, was attributed to the precipitation of a p-type (Al-doped) layer on n-poly-Si with the consequent formation of a "quasi-Schottky diode." To minimize this effect, the thickness of this precipitated layer should be kept to a minimum. Practically, this can be achieved by: (*i*) decreasing the amount of Al available for reaction by reducing the thickness of the Al metallization; (*ii*) placing a Ti barrier film between the Al layer and the Si substrate; or (*iii*) using Al-2% Si alloy. The aim of the present investigation is to evaluate the validity of these various metallization techniques for application in the fabrication of Si integrated circuit using standard processing techniques.

Experiments

The phosphorus-doped poly-Si (CVD layer, 0.3 μm thick, sheet resistivity of ~17 $\Omega/\square$) resistors used in the present investigation were prepared using the same resistor structure and the same process sequences as described in the previous paper (1). The metallization systems used were the following: (*i*) Al deposited by electron beam evaporation to thicknesses of 0.25 and 1.0 μm; (*ii*) a 0.25 μm layer of Ti deposited by electron beam evaporation followed by 0.7 μm of Al deposited in the same pumping cycle; and (*iii*) an Al-2 weight percent (w/o) Si layer deposited by magnetron sputtering to a thickness of 1 μm.

The electrical measurements and SEM analysis were carried out after 5 min isochronal sintering at various temperatures in a N_2 ambient. After sintering, all specimens were pulled out of the furnace rapidly (~15 sec) and then left (~5 min) to cool down to room temperature in a N_2 ambient. For SEM analysis, the Al metallization was removed from the contact windows by chemical etching.

Results and Discussion

The effect of Al thickness.—In our previous work (1) we observed that the increase in contact resistance, R_c, is correlated with the increase in barrier heights of Al/Si junctions, ϕ_B, during sintering as reported by Chino (2). The increase arises from the precipitation at the interface of Si dissolved in the Al during sintering. Card (3) reported that the increase in ϕ_B is more pronounced for thicker Al contacts. Accordingly, we anticipated a similar effect of the Al thickness on the contact resistance of Al/n-poly-Si contacts.

The effect of sintering temperature on contact resistance of poly-Si resistors with 1 and 0.25 μm Al metallization is shown in Fig. 1. The average value of the contact resistance before sintering was 5 ± 0.3Ω. The results show that R_c is slightly lower for 0.25 μm Al contacts than for 1 μm Al. The effect is more pronounced at high sintering temperatures in excess of 500°C. However, contacts with 0.25 μm Al layers still exhibit a significant increase in R_c following the high temperature sintering (*e.g.*, a 400% increase in R_c after sintering at 560°C for 5 min).

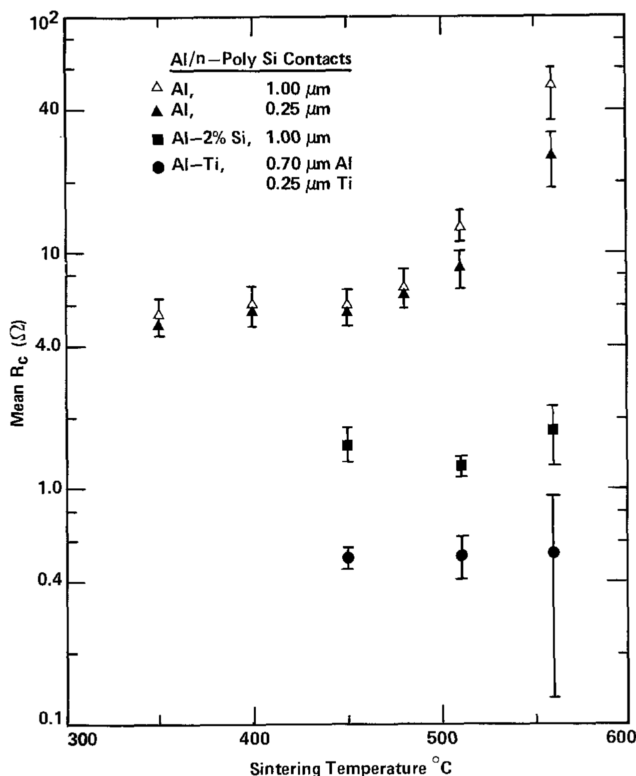

Fig. 1. Al/n-poly-Si contact resistance as a function of sintering temperature for various metallization systems. The sintering was carried out for 5 min in N_2. The electrical measurements were performed on poly-Si resistors having contact windows of 12 × 10 μm^2.

Key words: aluminum metallization, contact characterization, ohmic contacts, silicon technology.

SEM examination showed no significant difference in the amount of poly-Si dissolved for Al thicknesses of 0.25 and 1 μm, as shown in Fig. 2 and 3. In both cases, poly-Si pitting can be observed at contact windows after 5 min sintering at temperatures as low as 350°C. Further reduction in the Al thickness might reduce poly-Si pitting and R_c values, but would also result in poor step coverage over the substrate, creating potential reliability problems (4).

The effect of Al-Ti contacts.—Ti has been used as an intermediate layer between Al and single crystal Si (5) and between Al and poly-Si (6) to prevent the dissolution of Si into Al during sintering. In both cases, this layer effectively acts as a barrier as long as the Ti is not completely consumed in the reaction with Al to form the intermetallic compound $TiAl_3$. If all the Ti is consumed, a Si-rich ternary phase $Ti_7Si_{12}Al_5$ is formed (5) which is virtually transparent to both Al and Si.

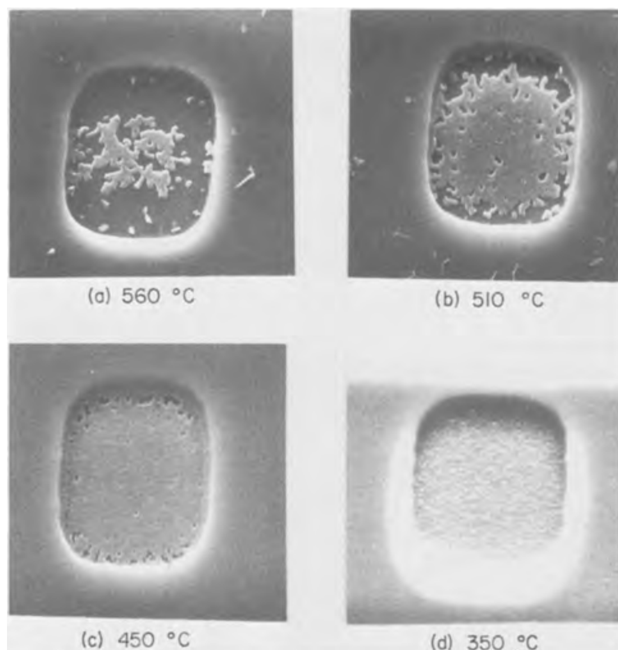

Fig. 2. Poly-Si contacts sintered for 5 min at various temperatures and then etched to remove 1.0 μm Al metallization (X3K).

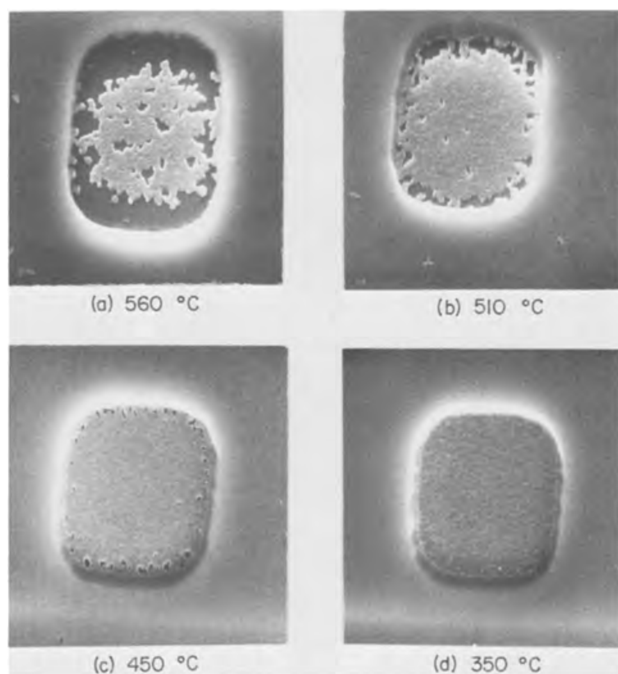

Fig. 3. Poly-Si contacts sintered for 5 min at various temperatures and then etched to remove 0.25 μm Al metallization (X3K).

Before sintering, the contact resistance of Al-Ti contacts on n-poly-Si was $\sim$0.52 $\pm$ 0.05Ω. The average value of R_c remained unchanged after 5 min sintering at temperatures $\geq$450°C. However, the standard deviation increased significantly after the 560°C sintering, as shown in Fig. 1. In addition, poly-Si dissolution was found in contacts sintered at 560°C. Typical SEM results are shown in Fig. 4. To reveal the poly-Si for SEM observations, the samples were first etched in H_3PO_4 to remove the top Al layer, then, in dilute HF solution to etch the Ti layers. Since HF also etches the SiO_2 layer between the contact windows this layer is thinner than the oxide originally covered by the metallization layer as shown in Fig. 4. Energy dispersion x-ray was used in the SEM to confirm the complete removal of Ti from the contact sites.

The time required to consume a 0.25 μm layer of Ti during sintering at 560°C is approximately 11 min (5). Accordingly, the appearance of poly-Si pits at contact windows following sintering at 560°C for a period of 5 min was rather unexpected. However, this may be attributed to local variation of Ti thickness over the wafer resulting in rapid dissolution of Si from contact sites. Also, the Al-Ti reaction may be influenced by the microstructure and the internal stresses of the deposited films, particularly at high sintering temperatures. These parameters were not considered during the course of this investigation.

The use of a Ti barrier layer between Al metallization and poly-Si substrates produces low contact resistance at n-poly Si contacts. However, in agreement with previous work (5, 6), careful consideration must be given to sintering temperature, sintering time, and Ti thickness to avoid the consumption of the barrier layer during sintering. In addition, further studies are needed to evaluate the long term performance and reliability of Si devices with Al-Ti contacts.

The effect of Al-2% Si alloy metallization.—Finally, we have examined the effect of Al-2 w/o Si alloy metallization on Si dissolution and contact resistance of Al/n-poly-Si contacts. This metallization system has been used successfully to reduce the formation of Si pits in single crystal Si substrates (7, 8). In this case, sufficient Si is present in the Al metallization to satisfy the solid solubility limits during high temperature heat-treatment processes.

Figure 1 shows the effect of sintering temperature on contact resistance of poly-Si resistors with 1 μm Al-2% Si alloy metallization. The average values of contact resistance before sintering was 16 $\pm$ 7Ω. After 5 min sintering at temperatures $\geq$450°C, R_c was 1.5 $\pm$ 0.25Ω and was virtually independent of the sintering temperature.

SEM micrographs of poly-Si contacts after removing the Al-Si alloy metallization are shown in Fig. 5. No sign of poly-Si pitting can be observed even after sintering at 560°C. However, a large number of Si precipitates are evident on the surface of the wafer. These

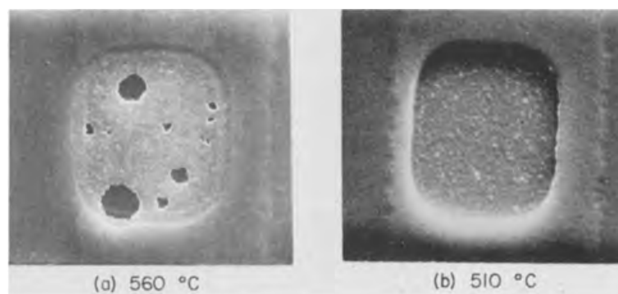

Fig. 4. Poly-Si contacts with a barrier layer of Ti under the Al after sintering and etching of the Al-Ti layers (X3K).

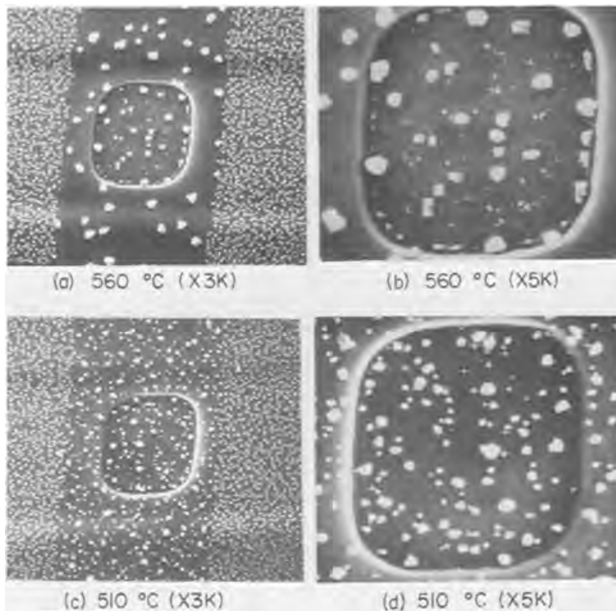

Fig. 5. The effect of Al-2% Si alloy on poly-Si dissolution. The central strip is sintered at 510° and 560°C for 5 min and then etched to remove 1.0 μm Al-2% Si layer. All specimens were subjected to the same standard cooling cycles as described in the text. The metallization film outside the central strip was photoengraved and etched before sintering.

precipitates are formed during the alloy deposition because of the negligible solubility of Si in Al at room temperature (~0.001%). Most of the Si precipitates in as-deposited Al-Si alloy were found predominantly at the surface/film interface and also near the free surface (9). The precipitates at the Al/poly-Si interface may have contributed to the high contact resistance at this interface before sintering.

Si precipitates on Al/SiO_2 interface remained on the oxide surface after the photoengraving and etching of the Al metallization. The Si precipitates present in the metallization are partially redissolved in the Al during sintering. However, since the maximum solubility of Si in Al at 560°C is 1.3 w/o even at this sintering temperature, there is still excess Si present as a second phase in the alloy and these serve as nucleation sites for the reprecipitation of Si during cooling. The size and density of the reprecipitated Si particles are dependent on the sintering temperature, assuming identical cooling cycles after each sinter. After 510°C sintering, the density of Si particles was about $1.8 \times 10^8/cm^2$ with an average diameter of 0.25 μm. A much coarser structure with lower density of $1.0 \times 10^8/cm^2$ and an average diameter of 0.8 μm was observed after 560°C sintering.

These observations of Si precipitates from Al-2% Si alloys are similar to those reported by van Gurp (9) for Si precipitates from Al/Si alloys deposited on single crystal substrates. Although the precipitates at the contact sites are particles of Si doped with Al, the sintering process caused a significant reduction in the area covered by these p-type precipitates, as seen in Fig. 5, which may result in the observed decrease in the contact resistance. It would be interesting to examine the effect of Al-Si alloy metallization on the barrier heights, ϕ_B, at Al-Si junctions to establish their correlation with the contact resistance.

Conclusion

The present results indicate that the use of Al-2% Si metallization is the most practical technique to minimize poly-Si dissolution and reduce the resistance at the Al/n-poly-Si contacts in integrated circuits. A similar conclusion has been reached for the metallization of contacts to single crystal substrates (7, 8). However, Si process technologists have been reluctant to use Al-Si metallization because of the lack of a proper technique for the deposition of alloy films. This problem was greatly minimized recently with the development of the magnetron sputtering technique for the deposition of alloys (10). For Al alloys, this new technique provides high deposition rates, consistent stoichiometry, and minimum radiation damage to dielectric films which can be easily annealed out at temperatures compatible with standard device processing (11).

A Computer Study of pH Effect in Electroless Copper Deposition

Milan Paunovic*,[1]

Kollmorgen Corporation, Photocircuits Division, Glen Cove, New York 11542

It was found by Schoenberg (1) that the rate of electroless deposition of copper first increases, passes through a maximum and then decreases when the concentration of formaldehyde, copper ions and copper complexing agent are held constant and that of sodium hydroxide varied. The maximum rate and the falling off of the rate at high pH values was explained (1) on the basis of dissociation of methylene glycol and the change of the relative concentration of the methylene glycolate and the hydroxide ions with pH. In order to contribute to the interpretation of this pH effect we have derived series of mathematical models of electroless copper deposition and obtained computer solutions for the change of the rate of deposition and the mixed potential with pH. The starting point of our derivations was the current (i) potential relationship for the high overvoltage (η) range

$$i = i^\circ \exp(\alpha\eta\, F/RT) \qquad [1]$$

where i°, α, F and T are the exchange current density, the transfer coefficient, faraday constant and temperature, respectively. On the basis of this equation, using the basic principles of the mixed potential theory (2), we have derived the following equations, for the mixed potential E_{MP}

$$E_{MP} = (b_M b_{Red}/b_M + b_{Red}) \ln(Q/R) \qquad [2]$$

where

$$Q = i^\circ_M \exp(E_{RM}/b_{RM}) \qquad [3]$$

$$R = i^\circ_{Red} \exp(-E_{RRed}/b_{Red}) \qquad [4]$$

$$b_M = RT/\alpha_M n_M F,\quad b_{Red} = RT/\alpha_{Red} n_{Red} F$$

and the rate of deposition i_{dep}

$$i_{dep} = (i^\circ_M)^p\, (i^\circ_{Red})^q \exp(V) \qquad [5]$$

$$\text{where } V = [(E_{RM} - E_{RRed})/(b_M + b_{Red})] \qquad [6]$$

$$p = b_M/(b_M + b_{Red}),\quad q = b_{Red}/(b_M + b_{Red})$$

and the meaning of other symbols are as follows: i°_M, i°_{Red}, E_{RM}, and E_{RRed} are the exchange current densities and the rest (equilibrium) potentials for the cathodic and anodic partial reactions, respectively.

This communication discusses only two mathematical models. In both models the dissociation of methylene glycolate (formaldehyde) is taken into account using for the dissociation constant $K = 1.62\times10^{-13}$ (1). In Model I it is assumed that the electrochemical kinetic parameter α_{Red} (the transfer coefficient) is independent of pH. The variation of the exchange current density i°_{Red}, with pH, was calculated on the basis of the theoretical equation (3)

$$i^\circ = nFk^\circ\, (c^\circ_{Ox})^{1-\alpha} (c^\circ_{Red})^{\alpha} \qquad [7]$$

as applied to this case (introduction of OH^- factor).

Previous interpretation did not consider that α_{Red} and i°_{Red} could vary with pH. However, Paunovic and Pearson (4) have determined experimentally that these parameters are pH dependent. Analytical expressions derived from these data, with the use of Newton's interpolation formula (5) are given as follows

$$\alpha_{Red} = -10.59 + 1.784\text{pH} - 7.40\times10^{-2}(\text{pH})^2 \qquad [8]$$

*Electrochemical Society Active Member

Key words: copper, electroless plating, formaldehyde, mixed potential

$$i^{\circ}_{Red}=\text{const}+9.26\times10^{-3}\text{pH}-3.85\times10^{-4}(\text{pH})^2$$

$$\text{const}=-5.52\times10^{-2} \qquad [9]$$

for the 0.2M CH_2O at 25°C.

In both models it was assumed that i°_M and α_M are independent of pH. Results obtained from equations [2-9] are shown in Fig. 1 and 2. For Model I a value of 0.15 was taken for α_{Red}. It is seen that only Model II gives the same pH effect as the experimentally observed relationship: the initial increase, a maximum and fall off of the rate with increasing pH. Model I gives continuously increasing rate of deposition when plotted vs. pH.

From these results we can conclude that the maximum and the falling off of the rate at high pH values are caused by the pH dependence of the kinetic parameters α_{Red} and i°_{Red} for formaldehyde. Dissociation of methylene glycol is an important factor in electroless deposition of copper but it is not sufficient to explain the pH effect.

Electrochemical Determination of Activities in Cr_2O_3-Al_2O_3 Solid Solution

K. T. Jacob

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada, M5S 1A4

ABSTRACT

The activity of Cr_2O_3 in Cr_2O_3-Al_2O_3 solid solution has been determined in the temperature range 800°-1320°C from electromotive force measurements on the solid oxide galvanic cell

$$Pt,Cr + Cr_2O_3/Y_2O_3\text{-}ThO_2/Cr + Cr_xAl_{2-x}O_3,Pt$$

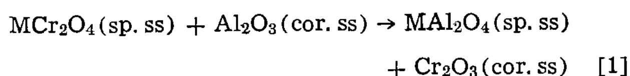
The activities of Cr_2O_3 and Al_2O_3 in the solid solution show both positive and negative deviations from Raoult's law. The heat and entropy of mixing of the solid solution obtained from the temperature dependence of the emf can be expressed as

$$\Delta H = X_{Cr_2O_3}X_{Al_2O_3}[31{,}700X_{Cr_2O_3} + 37{,}470X_{Al_2O_3}] \text{ J mole}^{-1}$$

$$\Delta S = -1.8R[X_{Cr_2O_3} \ln X_{Cr_2O_3} + X_{Al_2O_3} \ln X_{Al_2O_3}]$$

The entropy of mixing is 10% lower than that predicted by the Temkin model. The large positive heat of mixing in the Cr_2O_3-Al_2O_3 solid solution, however, suggests that this apparent entropy discrepancy originates with the clustering of positive ions on the cation sublattice. The asymmetric miscibility gap exhibited in the Cr_2O_3-Al_2O_3 system below 900°C is consistent with the thermodynamic data trends recorded at the more elevated temperatures.

Base metal catalysts such as copper chromite ($CuCr_2O_4$) supported on alumina have recently been considered for the oxidation of carbon monoxide and hydrocarbons to carbon dioxide and water vapor (1). A knowledge of phase relations in ternary systems of the type MO-Al_2O_3-Cr_2O_3, where MO is a divalent oxide like FeO, CoO, NiO, or CuO, would be useful for evaluating the interaction between chromium ion containing catalysts and alumina supports. Such systems often contain two series of solid solutions at high temperatures, one with the spinel structure ($MCr_xAl_{2-x}O_4$) and the other with the corundum structure ($Cr_xAl_{2-x}O_3$). The conjugate lines which connect these two solid solution regions on the ternary diagram have their directions determined by the ion exchange reaction



$$MCr_2O_4(\text{sp. ss}) + Al_2O_3(\text{cor. ss}) \rightarrow MAl_2O_4(\text{sp. ss}) + Cr_2O_3(\text{cor. ss}) \quad [1]$$

The composition of the conjugate phases can be calculated from a knowledge of the relative stability of the two pure spinel phases (MAl_2O_4 and MCr_2O_4) and activities in the two solid solutions. Some progress has recently been made in relating activities in spinel solid solutions to the distribution of cations between the tetrahedral and octahedral sites of the spinel lattice, and to the site preference energies of the cations (2). This paper reports measurements of the thermodynamic properties of Cr_2O_3-Al_2O_3 solid solutions using a solid oxide galvanic cell.

Key words: alumina-chromium sesquioxide solid solution, thermodynamics, solid electrolyte, galvanic cell, entropy of mixing, enthalpy of mixing, activities, miscibility gap.

Information on activities in Cr_2O_3-Al_2O_3 solid and liquid solutions are of interest in the physical chemistry of the aluminothermic reduction of Cr_2O_3. The high temperature phase diagram of the Cr_2O_3-Al_2O_3 system (3) is of the isomorphous type, in which the two oxides are mutually soluble in all proportions in the solid and liquid state. Knapp (4) has shown that the calculated separation between the solidus and the liquidus curves based on the assumption that activities are equal to mole fractions in both solid and liquid solutions, and using estimated heats of fusion of oxides, is smaller than experimentally observed. A miscibility gap has been reported (5, 6) in this system at temperatures below 900°C, and under high pressures or hydrothermal conditions. The lattice parameters a and c show slight positive departure from the linearity predicted by Vegard's rule (6).

Experimental Methods

Materials.—Fine powders of Cr,Cr_2O_3 and α-Al_2O_3, each 99.99% pure, were obtained from Alfa Inorganics. The $Cr_xAl_{2-x}O_3$ solid solutions were prepared by mixing fine powders of component oxides in the required ratio, compacting the mixture into pellets and sintering at 1450°C under a flowing stream of argon gas for 65 hr. One composition of the spinel solid solution ($x = 0.74$) was also synthesized at 1600°C. The formation of homogeneous solid solutions was confirmed by x-ray diffraction analysis and microscopic examination. Thoria pellets doped with 15 mole percent (m/o) $YO_{1.5}$ were supplied by Cerac Incorporated. This composition is close to that of maximum ionic conductivity. The Y_2O_3-ThO_2 material was chosen as the electrolyte because its ionic transport number is greater than

0.995 at the low oxygen potentials encountered in this study.

Apparatus and Procedure

The apparatus was identical to that used for the measurements of the free energy of formation of $MgCr_2O_4$, and has been described earlier (7).

The $Cr + Cr_2O_3$ and $Cr + Cr_xAl_{2-x}O_3$ electrodes were prepared by compacting a mixture of their powders in the molar ratio 1.5:1. Preliminary experiments indicated a slight tendency for the oxidation of chromium in the pellet despite the use of titanium internal getters. Electron microprobe examination of the surface of a pellet in contact with the electrolyte showed a slightly lower metal concentration at the end of the experiment than at the start. To compensate for this effect, excess chromium was used in the pellets. The pellets were sintered at 1300°C in prepurified argon stream for 35 hr. Titanium internal getters were placed 2.5 cm above and below the pellets to remove any residual oxygen in the argon or oxygen bearing species desorbing from the refractory tubes. The reversible electromotive force (emf) of the cell

$$Pt,Cr + Cr_2O_3/Y_2O_3\text{-}ThO_2/Cr + Cr_xAl_{2-x}O_3,Pt \quad [1]$$

was measured in the temperature range 800°-1320°C with a "Solatron" digital voltmeter, which had an input impedance of $10^{12}\Omega$. The reversibility of the cell was checked by passing a small current ($\approx$ 50 μA) through the cell for 1-2 min in either direction, and it was found that the emf returned to its initial value in approximately 30 min, after which it remained constant for up to 5 hr. The emf's were also found to be independent of the flow rate of inert gas through the cell.

Some contamination of platinum wires in contact with the electrodes was observed. The extent of contamination was similar at both electrodes. To check for possible errors caused by the thermal emf of the contaminated platinum leads, the emf of a junction made from two contaminated wires, used as leads in one experiment, was measured as a function of temperature. The highest emf obtained was 0.15 mV.

Results and Discussion

The emf of the cell is shown as a function of temperature in Fig. 1, for different compositions of the solid solution. Reproducible emf's could not be measured below 800°C in experiments in which the compositions of the solid solution were given by $x = 0.2$, 0.48, 1.54, and 1.8. This is probably related to the sluggish reaction between Cr and Cr_2O_3 to establish the equilibrium oxygen potential. In experiments with solid solutions characterized by values of $x = 0.74$, 1.0, and 1.28, steady emf's could not be obtained below 900°C. The slow exsolution of the solid solution below 900°C probably contributed to this drift in the emf. It was also observed that in order to yield reproducible emf's the cell had to be heated initially to 1100°C. After this initial heat-treatment, steady emf's were obtained in 20-60 min after the cell had attained a contant temperature. The reproducibility of the emf's varied from 0.5 to 1.5 mV depending on the composition of the solid solution; the reproducibility was better when the solid solution contained more Cr_2O_3. Almost identical emf's were obtained for $x = 0.74$ using samples synthesized at 1450° and 1600°C. This observation and the reproducibility of emf's after repeated temperature cycling confirm the homogeneity of the solid solutions. The equations representing the variation of the emf with temperature for each composition of the solid solution, obtained by the least mean squares regression analysis, are summarized in Table I.

The activity or the partial free energy of mixing of Cr_2O_3 in the solid solution is simply related to the emf of the cell

$$\Delta G_{Cr_2O_3} = RT \ln a_{Cr_2O_3} = -6\mathbf{FE} \quad [2]$$

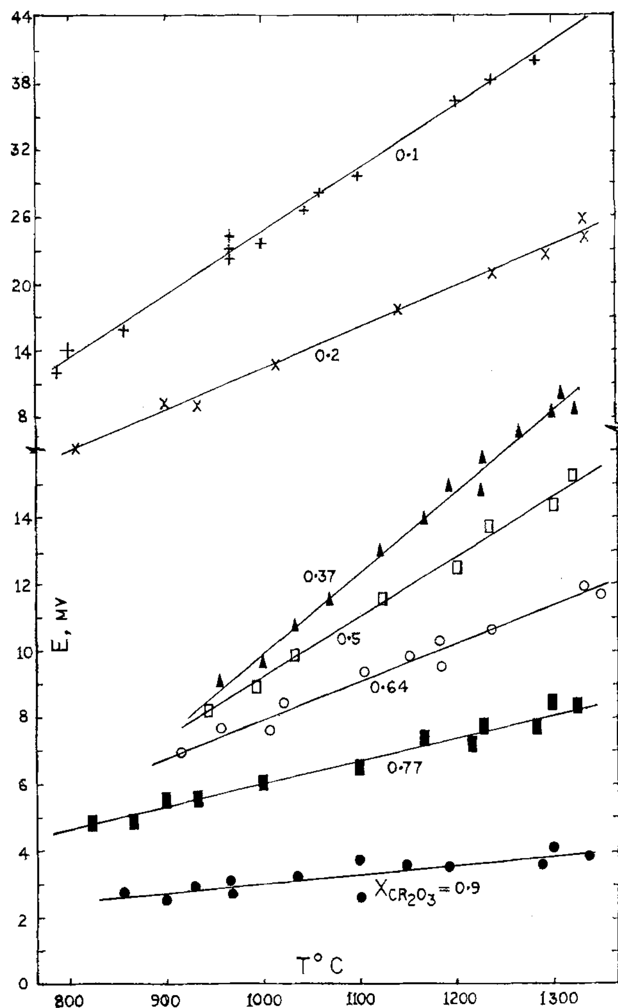


Fig. 1. Variation of the emf of cell [1] with temperature for different compositions of the corundum solid solution. $X_{Cr_2O_3}$ is the mole fraction of Cr_2O_3 in the solid solution.

where **F** is the Faraday constant (96,500 J V^{-1} mol^{-1}) and E is the emf in volts. The activity of Cr_2O_3 at 1000° and 1300°C is plotted against the composition of the solution in Fig. 2. The activity coefficient of Al_2O_3 is calculated using the Gibbs-Duhem relation

$$\ln \gamma_{Al_2O_3} = -\int_{X_{Al_2O_3}=1}^{X_{Al_2O_3}} \frac{X_{Cr_2O_3}}{X_{Al_2O_3}} d \ln \gamma_{Cr_2O_3} \quad [3]$$

where $\gamma(= a/X)$ is the activity coefficient. The activities of both components of the solid solution show positive deviations from Raoult's law at low concentrations and negative deviations at high concentrations. The integral free energy of mixing of the solid solution at 1000°C given by

$$\Delta G = RT\,[X_{Cr_2O_3} \ln a_{Cr_2O_3} + X_{Al_2O_3} \ln a_{Al_2O_3}] \quad [4]$$

is shown in Table I.

The partial heat of mixing of Cr_2O_3 in the solid solution is calculated directly from the temperature de-

Table I. The temperature dependence of the emf of cell [1] and the integral free energy of mixing of the $Cr_xAl_{2-x}O_3$ solid solution

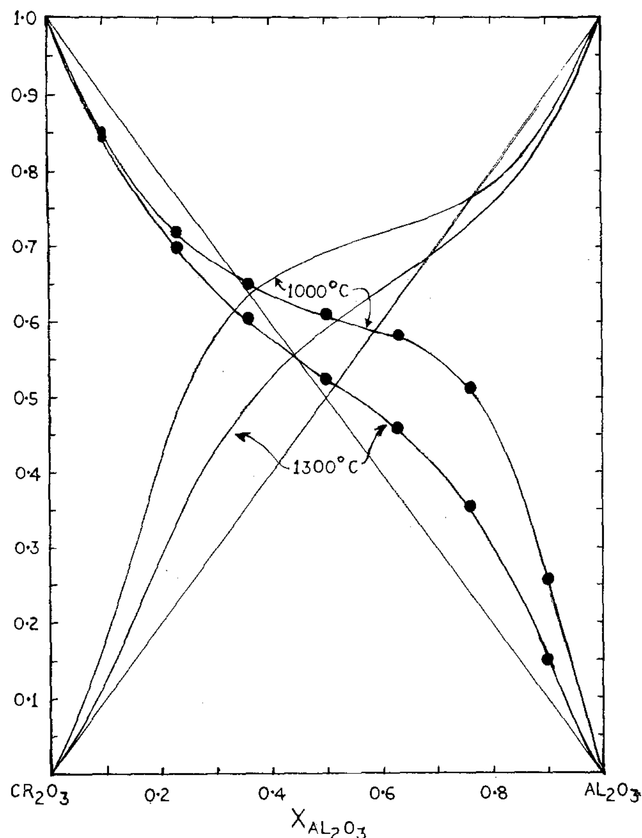

Fig. 2. Activities of Cr_2O_3 and Al_2O_3 in the Cr_2O_3-Al_2O_3 solid solution at 1000° and 1300°C.

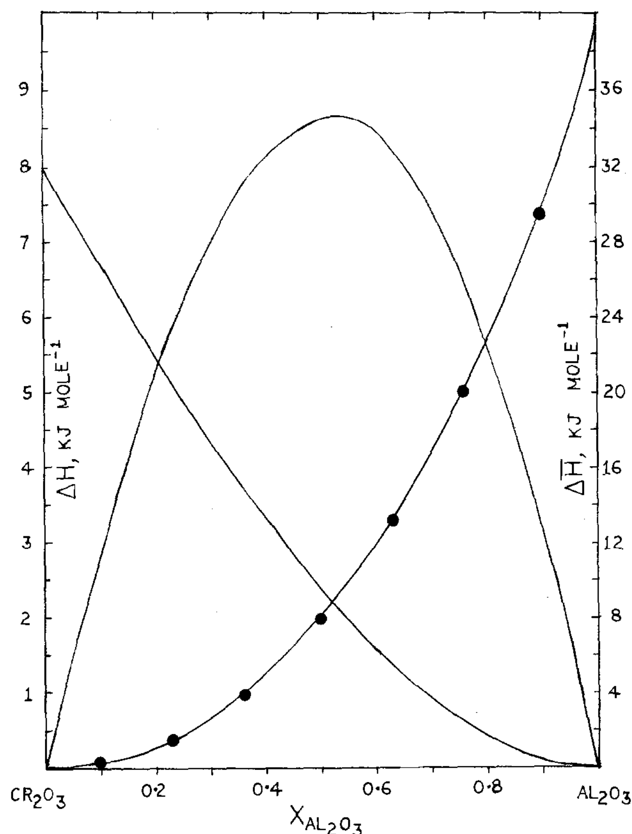

Fig. 3. Partial and integral molar heat of mixing of the Cr_2O_3-Al_2O_3 solid solution.

pendence of the emf

$$\Delta H_{Cr_2O_3} = -6F\,[E - T(\partial E/\partial T)_P] \quad [5]$$

The partial heat of mixing of Al_2O_3 is calculated from the composition dependence of the partial heat of Cr_2O_3 using the Gibbs-Duhem relation. The integral heat of mixing is given by

$$\Delta H = X_{Cr_2O_3}\Delta H_{Cr_2O_3} + X_{Al_2O_3}\Delta H_{Al_2O_3} \quad [6]$$

The variation of the partial and integral heats of mixing with the composition of the solid solution is shown in Fig. 3.

The integral heat of mixing is not a symmetric function of composition. However, the plot of $\Delta H/X_{Cr_2O_3}X_{Al_2O_3}$ *vs.* composition, shown in Fig. 4, yields a straight line. The integral and partial heats of mixing can therefore be expressed analytically

$$\Delta H = X_{Cr_2O_3}X_{Al_2O_3}\,[31{,}700\,X_{Cr_2O_3} + 37{,}470\,X_{Al_2O_3}]\,\text{J mol}^{-1} \quad [7]$$

$$\Delta H_{Cr_2O_3} = 25{,}910\,X^2_{Al_2O_3} + 11{,}560\,X^3_{Al_2O_3}\,\text{J mol}^{-1} \quad [8]$$

$$\Delta H_{Al_2O_3} = 43{,}250\,X^2_{Cr_2O_3} - 11{,}560\,X^3_{Cr_2O_3}\,\text{J mol}^{-1} \quad [9]$$

These equations are similar to the "subregular" model suggested by Hardy (8). The positive heat of mixing probably arises from the difference in ionic radii of Al^{3+} and Cr^{3+} ions. On the Shannon and Prewitt (9) scale the ionic radii of Al^{3+} and Cr^{3+} ions are 0.67 and 0.755Å, respectively, for sixfold coordination. It is conceivable that the introduction of a larger ion in a lattice of smaller ions would cause a larger positive heat effect than the incorporation of a smaller ion in a host lattice of larger ions.

The entropy of mixing of the solid solution is calculated from the values of free energy and heat of mixing discussed above

$$\Delta S = -(\Delta G - \Delta H)/T \quad [10]$$

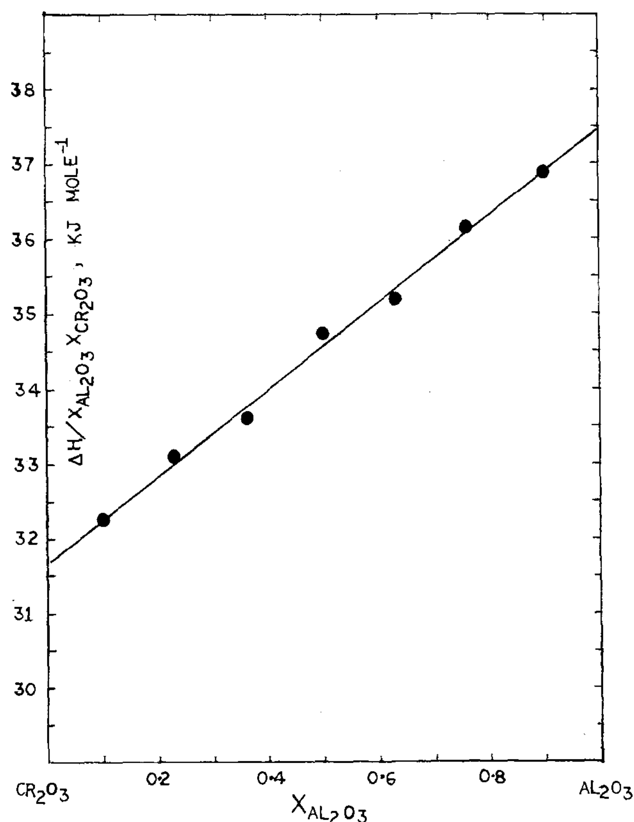

Fig. 4. Variation of the function, $\Delta H/X_{Cr_2O_3}X_{Al_2O_3}$, with composition in the Cr_2O_3-Al_2O_3 system.

The entropy of mixing is compared with that calculated using Temkin's model in Fig. 5. The corundum structure is basically a hexagonal close-packed oxygen lattice with the two trivalent cations occupying two-thirds of the available octahedral sites. Since two cat-

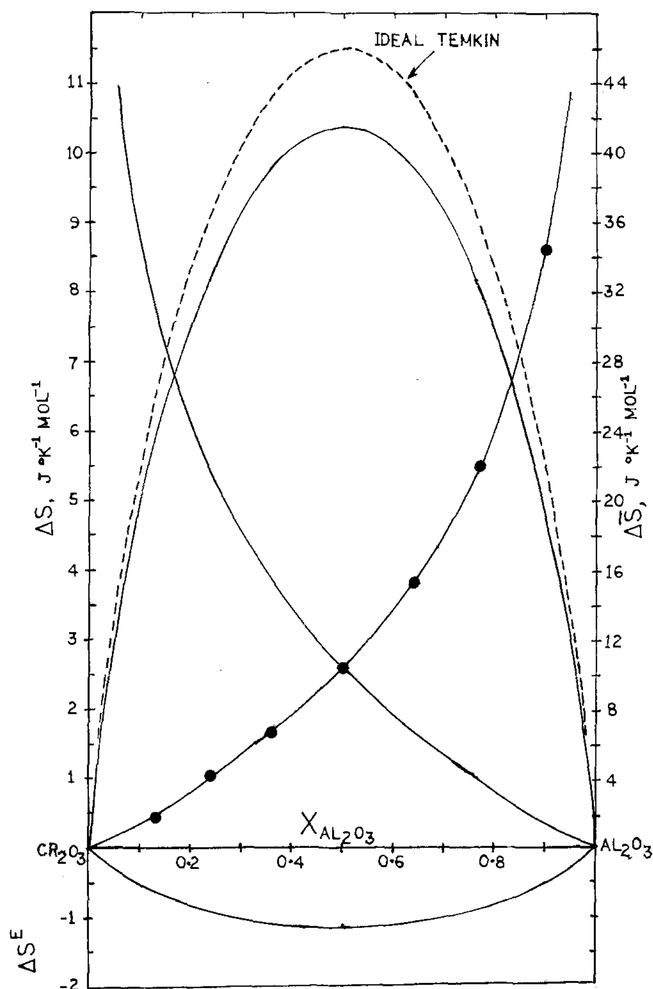

Fig. 5. Comparison of the entropy of mixing of Cr_2O_3-Al_2O_3 solid solution with that predicted by Temkin's model. The composition dependence of partial and excess entropies are also shown. ——— Results obtained in this study; ---- Temkin's model.

ions are involved in the mixing process on the octahedral sublattice per mole of oxide solid solution, the Temkin entropy of mixing is given by

$$\Delta S_{\text{Temkin}} = -2R\,[X_{Cr_2O_3} \ln X_{Cr_2O_3} + X_{Al_2O_3} \ln X_{Al_2O_3}] \quad [11]$$

The experimental entropy of mixing of the solid solution is 10% lower than the Temkin entropy of mixing, although both are symmetric functions of composition. The experimental entropy of mixing can be expressed as

$$\Delta S = -1.8R\,[X_{Cr_2O_3} \ln X_{Cr_2O_3} + X_{Al_2O_3} \ln X_{Al_2O_3}] \quad [12]$$

Similarly the partial molar entropy of Cr_2O_3 and Al_2O_3 can be expressed as

$$\Delta \bar{S}_{Cr_2O_3} = -1.8R \ln X_{Cr_2O_3} \quad [13]$$

$$\Delta \bar{S}_{Al_2O_3} = -1.8R \ln X_{Al_2O_3} \quad [14]$$

The partial molar entropy of Cr_2O_3 obtained directly from the temperature dependence of the emf

$$\Delta \bar{S}_{Cr_2O_3} = 6\mathbf{F}(\partial E/\partial T)_P \quad [15]$$

is in almost exact agreement with Eq. [13].

The excess entropy of mixing on the Temkin model is negative

$$\Delta S^{E}_{\text{Temkin}} = \Delta S - \Delta S_{\text{Temkin}} = 0.2R\,[X_{Cr_2O_3} \ln X_{Cr_2O_3} + X_{Al_2O_3} \ln X_{Al_2O_3}] \quad [16]$$

The large positive heat of mixing suggests that the origin of the negative excess entropy on the Temkin model lies in the clustering of positive ions on the octahedral cation sublattice. It is obvious from Eq. [12] that the Raoultian excess entropy of mixing is positive. However, for ionic solids the concept of Raoult's law has little physical significance.

At the critical point corresponding to the appearance of a miscibility gap

$$\frac{\partial \Delta \bar{G}_{Cr_2O_3}}{\partial X_{Cr_2O_3}} = \frac{\partial \Delta \bar{G}_{Al_2O_3}}{\partial X_{Al_2O_3}} = 0 \quad [17]$$

$$\frac{\partial \Delta \bar{G}_{Cr_2O_3}}{\partial X^2_{Cr_2O_3}} = \frac{\partial \Delta \bar{G}_{Al_2O_3}}{\partial X^2_{Al_2O_3}} = 0 \quad [18]$$

Expressing the partial free energies in terms of partial heats (Eq. [8] and [9]) and partial entropies (Eq. [13] and [14]) and solving Eq. [17] and [18] gives the following relations between the temperature (T_c) and composition ($X_{Cr_2O_3(c)}$ and $X_{Al_2O_3(c)}$) of the critical point

$$T_c = \frac{190{,}140\, X^2_{Cr_2O_3(c)} X^2_{Al_2O_3(c)}}{1.8R\,(-9X^2_{Cr_2O_3(c)} + 10X_{Cr_2O_3(c)} - 2)} \quad [19]$$

$$T_c = \frac{224{,}820\, X^2_{Cr_2O_3(c)} X^2_{Al_2O_3(c)}}{1.8R\,(-9X^2_{Al_2O_3(c)} + 10X_{Al_2O_3(c)} - 2)} \quad [20]$$

Remembering that

$$X_{Cr_2O_3(c)} + X_{Al_2O_3(c)} = 1 \quad [21]$$

numerical values characterizing the critical point, where the miscibility gap is imminent, can be evaluated

$T_c = 1173°K\,(900°C)$, $X_{Cr_2O_3(c)} = 0.44$, $X_{Al_2O_3(c)} = 0.56$

The solubility limits at temperatures below 900°C can be determined by drawing common tangents to

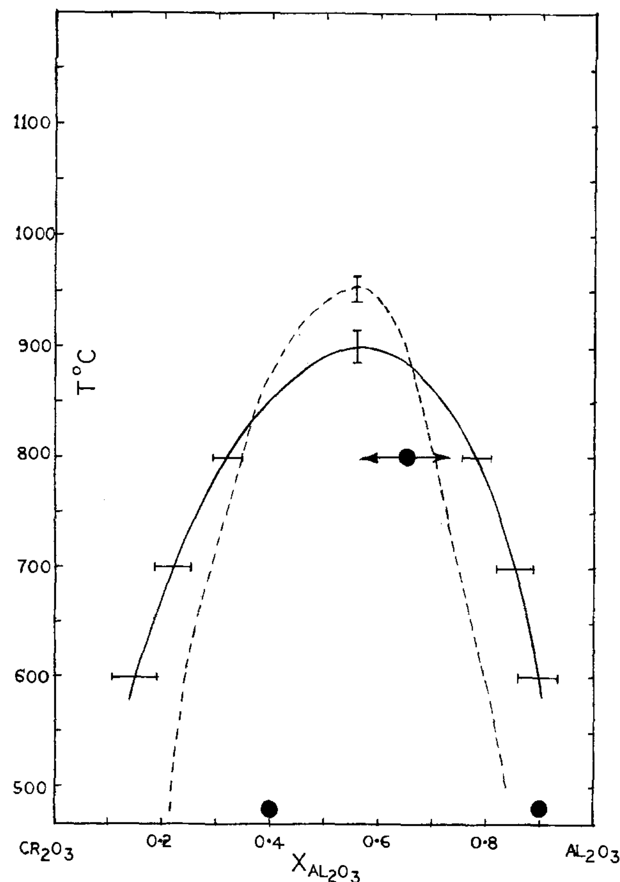

Fig. 6. Comparison of the miscibility gap derived from thermodynamic data obtained in this study with direct measurements at high pressures. ——— This study; ● Neuhaus et al. (5); ---- Roy and Barks (6).

the free energy composition curves. The results so obtained are compared with direct measurements of Neuhaus *et al.* (5) at 2000 atm pressure and Roy and Barks (6) at 988 atm (hydrothermal). The critical temperature calculated from the present results lies between the values 800° (5) and 945°C (6) reported at higher pressures. There is also qualitative agreement between the three sets of data regarding the asymmetry of the miscibility gap. The solubility limits at lower temperatures differ significantly. Since the formation of the solid solution is accompanied by an increase in molar volume, the miscibility gap may be expected to be narrower at high pressures.

Effects of Composition Changes, Substitutions, and Hydrostatic Pressure on the Ionic Conductivity in Lithium Aluminosilicate and Related Beta-Eucryptite Materials

R. M. Biefeld,* R. T. Johnson, Jr., and R. J. Baughman

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

The effects of selected compositional changes, substitutions, and hydrostatic pressure on the lithium ion conductivity in lithium aluminosilicate solid electrolytes which exhibit the β-eucryptite ($LiAlSiO_4$) structure when in crystalline form have been determined. Substitutions of Ga_2O_3 for Al_2O_3 and GeO_2 for SiO_2 in glass and glass-ceramic materials have no significant effect on the ionic conductivity; however, the addition of Li_2O and substitution of B_2O_3 for Al_2O_3 increases the conductivity. The highest conductivities [2×10^{-2} (Ω-cm)$^{-1}$ at 500°C] were obtained for glasses with enhanced Li_2O concentrations (*e.g.*, $3.1Li_2O \cdot Al_2O_3 \cdot 3.8SiO_2$), and for glass-ceramics with both enhanced Li_2O concentrations and B_2O_3 substitutions (*e.g.*, $3.1Li_2O \cdot B_2O_3 \cdot 3.8SiO_2$). Generally, the glass-ceramics have a lower conductivity than the glass except for certain B_2O_3 substituted glass-ceramics where this trend is reversed. Hydrostatic pressure experiments (to 2.0 GPa) on various glasses and glass-ceramics showed only slight variations in the ionic conductivity characteristics. All of the results can be consistently interpreted in terms of the existence of glass-crystalline interfacial layers in the glass-ceramics. Ionic conductivity data are also presented on $LiAlSiO_4$ single crystals.

Lithium aluminosilicate glasses and glass-ceramics with the stoichiometric β-eucryptite (1, 2) composition $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ ($LiAlSiO_4$) have been shown to have high Li ion conductivities [$\sigma > 10^{-3}$ (Ω-cm)$^{-1}$] at temperatures above 400°C (3). Thus these materials are of interest as possible high temperature solid electrolytes. We have previously examined the effects of the degree of crystallinity on the ionic conductivity in the stoichiometric β-eucryptite composition (4). The studies reported here examine the effects of compositional changes from stoichiometric $LiAlSiO_4$ and the effects of pressure on the ionic conductivity in glasses and glass-ceramics with emphasis on determining the extent to which the ionic conductivity can be increased. Since glass-ceramics consist of crystallites grown within a glass matrix the conductivity of $LiAlSiO_4$ (β-eucryptite) single crystals is also reported.

In β-eucryptite the Li ions reside in one-dimensional channels parallel to the c-axis and are most easily transported along these channels (2, 5, 6). In this ordered crystalline phase as well as in the disordered glassy phase the size of the conductive pathways (or channels) through which the ions move probably influences the ionic conductivity. The channel size can be varied both by changing the composition of the material by replacing some of the ions in $LiAlSiO_4$ with ions of different sizes and by applying high pressure. In this investigation, a large number of glasses and glass-ceramics with composition changes and substitutions were prepared and their electrical, thermal, and structural characteristics were examined. The ionic conductivity of several of these materials was also determined under hydrostatic pressure to 2.0 GPa. Compositional substitutions into $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ included B_2O_3 and Ga_2O_3 for Al_2O_3, and GeO_2 for SiO_2. The effect of changing the Li_2O concentration (and thus the number of ionic carriers) on the ionic conductivity was also examined.

Materials Preparation and Characterization

The glasses used in this investigation are listed in Table I and were prepared from reagent grade Li_2CO_3 and the required oxides following procedures previ-

† Contains 3 w/o TiO_2 + 1 w/o ZrO_2 as nucleating agents.
‡ Partially crystallized during the initial preparation.

ously described (3). After melting at ~ 1600°C the glasses were quenched and then annealed in the temperature range of 400°-650°C for 5-10 min to remove strain. X-ray powder diffraction photographs of the glasses revealed no crystalline structure. The annealing temperatures, which were the glass transition temperatures (T_g), are listed in Table I and were determined from differential thermal analysis (DTA) performed on unannealed glass samples. The results show that the T_g values decrease as the composition deviates from $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$.

The glass-ceramics were prepared by controlled devitrification of the glasses. The heat-treatments used to devitrify the glasses (Table I) were also determined from DTA. These heat-treatments involved annealing the glasses from slightly below to slightly above the crystallization exotherms over a period of 1-4 hr. TiO_2 and/or ZrO_2 [concentrations to ~ 4 weight percent (w/o)] were added to the glasses as nucleating agents to aid in the formation of the glass-ceramics. Attempts to crystallize the glass without any nucleating agent(s) resulted in preferential surface crystallization and cracking of the samples. X-ray powder diffraction photographs were taken of the glass-ceramics to determine the phase or phases present. In most of the glass-ceramics examined, β-eucryptite was the only crystalline phase present or the most predominant crystalline phase. Other phases such as α-eucryptite, lithium metadisilicate, $Li_2Si_2O_5$, lithium orthosilicate, Li_4SiO_4, and lithium metasilicate, Li_2SiO_3, were also found in some samples. The phase(s) observed for each composition are given in Table I.

Single crystals of β-eucryptite were grown by the flux technique (7). The starting materials were Li_2CO_3, Al_2O_3, and SiO_2 powders mixed in the appropriate proportions. This material (46.4 w/o) was mixed with LiF (29.2 w/o), AlF_3 (10.3 w/o), and V_2O_5 (14.1 w/o) powder as fluxing agents. The mixture was ball milled in ethyl alcohol for 12 hr and dried in a convection oven. The ball-milled material was then charged in a 7.6 cm diam × 7.6 cm high platinum crucible with a tight fitting lid. The loaded crucible was placed in a furnace and the temperature raised to 1200°C. This temperature was held for 4 hr. The temperature was then immediately lowered to 1130°C. From this point, the temperature was driven down to 900°C at a constant rate of 1.25°C/hr. The crucible was then removed from the furnace, opened, and the molten flux decanted from the crucible and the solid $LiAlSiO_4$ (8). The crucible, which contained the $LiAlSiO_4$, was then returned to the furnace and allowed to slowly cool. The resulting single crystals had dimensions of the order of several millimeters.

Electrical Measurement Techniques

The glass and glass-ceramic samples used for the ionic conductivity measurements had dimensions of about 1 × 1 × 0.1 cm^3. Evaporated Cr electrodes were applied to the 1 × 1 cm^2 faces. The methods for sample preparation and contacting have been described (3). The single crystal samples were cut so that electrical measurements could be made normal to the (00·1) plane (*i.e.*, parallel to the c-axis and the Li ion containing channels). The single crystal specimens were ~ 1 mm thick and were (nearly) visually free of imperfections (*e.g.*, flux inclusions). No measurements were made in directions parallel to the (00·1) plane (*i.e.*, perpendicular to the c-axis) because of difficulties encountered in obtaining a large sample with this orientation that was free of imperfections. Evaporated Cr electrodes were also used on these samples.

The high pressure experiments were under hydrostatic pressure conditions and utilized a 3.0 GPa Harwood pressure system with a heater coil (9). The sample was emersed in pentane which was the pressure transmitting medium. The pressure was determined from a calibrated manganin coil. The temperature was determined by using thermocouples.

The ionic conductivity measurements were made by using 2-terminal and 3-terminal a-c techniques over the frequency range from 5 to 5 × 10^5 Hz (3). Previous work showed that the measured conductance and thus the conductivity is that associated with Li ions in the bulk material (3). A least squares method was used for analyzing the temperature dependent data.

Results

Stoichiometric $LiAlSiO_4$.—The ionic conductivity results for stoichiometric $LiAlSiO_4$ glass, glass-ceramic

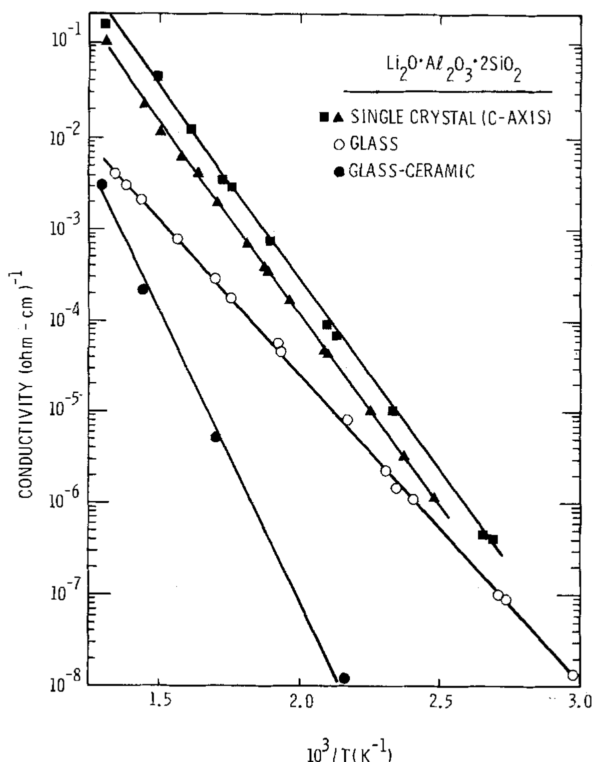

Fig. 1. Ionic conductivity temperature dependence for $LiAlSiO_4$ single crystals (c-axis), glass, and glass-ceramic (88% crystallinity). The single crystals (β-eucryptite) are one-dimensional conductors parallel to the c-axis, whereas the glass is a three-dimensional conductor. The glass-ceramic is polycrystalline material in a glass matrix prepared by devitrification of the glass.

[88 volume percent (v/o) crystalline] and single crystals (parallel to the c-axis) are shown in Fig. 1. The ionic conductivity, σ, for these materials is thermally activated ($\sigma = \sigma_0 e^{-E/kT}$) over the temperature range examined. The activation energies, E, and the preexponential factors, σ_0, are given in Table II.

The results obtained from two different single crystal samples are given in Fig. 1. The activation energy for the Li ion conductivity along the one-dimensional (c-axis) channels is nearly the same for both of these crystals but the σ_0 values are somewhat different. The crystal with the higher σ_0 value appeared by visual examination to be a nearly perfect crystal, whereas the crystal with the lower σ_0 value appeared to contain some flux inclusions which probably blocked ionic transport in some of the channels. This would account for the different σ_0 values observed for these two crystals. Our results are in reasonable agreement with those of van Alpen *et al.* (6) and suggest that the ionic conductivity for Li ion transport along the one-dimensional channels in single crystal β-eucryptite is described by $E \approx 0.83$ eV and $\sigma_0 \gtrsim 8 \times 10^4$ (Ω-cm)$^{-1}$.

Table II. Ionic conductivity activation energies, E, and preexponential factors, σ_0, for stoichiometric $LiAlSiO_4$ determined from $\sigma = \sigma_0 e^{-E/kT}$

† 88 v/o crystallinity.

The ionic conductivity for $LiAlSiO_4$ glass is characterized by $E = 0.68$ eV and $\sigma_0 = 1.8 \times 10^2$ (Ω-cm)$^{-1}$. Previous studies have shown that the nucleating agent(s) do not significantly affect these results, at least for the concentrations used here (*i.e.*, ≤ 4 w/o) (3). The conductivity of the glass is somewhat less than that for the single crystal (c-axis) over the temperature range examined. The interesting feature of these results, however, is that the glass is a good conductor for Li ions in three dimensions (with no long-range structural order) when compared to the single crystal where the Li ions reside in the one-dimensional c-axis channels and are transported along these channels.

The results in Fig. 1 (and Table II) for the $LiAlSiO_4$ glass-ceramic show that the conductivity decreased on conversion of the glass to the glass-ceramic. Furthermore, E for the glass-ceramic ($E = 1.23$ eV for 88% crystallinity) does not approach the value found for single crystal β-eucryptite ($E \sim 0.83$ eV). Several explanations for this discrepancy have been presented including the probable existence of an interfacial layer between the glass and the crystallites in the glass-ceramic which retards ionic transport through the crystalline regions (4). Such an interface would make the crystalline regions appear as insulating regions. This explanation has been advanced in conjunction with a continuum percolation model for describing the dependence of the ionic conductivity on the degree of crystallinity in these materials (4).

Composition variations and substitutions.—The effects of compositional variations and substitutions on the ionic conductivity were examined in the glass and glass-ceramic materials. In the glass-ceramics with compositions which differ from that of stoichiometric $LiAlSiO_4$, the composition of the glass and crystalline phases are generally not the same. In these materials, the volume fraction of crystalline material was not determined. The presence of substituents or other crystalline phases would change the x-ray results from those expected for stoichiometric mixtures of $LiAlSiO_4$ (β-eucryptite) crystallites in a $LiAlSiO_4$ glass matrix (4). Although a detailed dependence of conductivity on degree of crystallinity was not obtained for each composition, the results of the electrical measurements do give the general trend in ionic conductivity changes associated with compositional variations and substitutions.

Ionic conductivity results on a variety of glasses and glass-ceramics which contain GeO_2 and Ga_2O_3 are shown in Fig. 2. A complete listing of the materials examined and the corresponding values for E and σ_0 are presented in Table III. Substitution of GeO_2 for SiO_2 or Ga_2O_3 for Al_2O_3 causes a slight decrease in the conductivity of the glasses. This effect is not very large and the conductivities of these substituted glasses and glass-ceramics are very similar to those of stoichiometric $LiAlSiO_4$ glass and glass-ceramic (Fig. 1). This suggests that if there is a resistive glass-crystalline interfacial layer in these substituted glass-ceramics as in the $LiAlSiO_4$ glass-ceramics, the composition substitutions do not significantly influence the interfacial resistance. The results of the x-ray diffraction experiments indicated that the β-eucryptite lattice constants increased in the Ga_2O_3 or GeO_2 substituted glass-ceramics. For example, the lattice constants for $Li_2O \cdot Al_2O_3 \cdot GeO_2 \cdot SiO_2$ are a = 10.61(3) and c = 11.44(6) Å while for $LiAlSiO_4$, they are a = 10.49(1) and c = 11.18(1) Å (1, 2). This increase of the lattice constants in the crystalline phase did not appear to affect the ionic conductivity for the GeO_2 and Ga_2O_3 substituted glass-ceramics. It should be noted, however, that any conductivity changes within the crys-

Table III. Ionic conductivity activation energies, E, and preexponential factors, σ_o, obtained from $\sigma = \sigma_o \exp(-E/kT)$ for glasses and glass-ceramics with compositions based on $Li_2O \cdot Al_2O \cdot 2SiO_2$. For an indication of the magnitude of the errors, see Tables II and IV.

tallites may have been masked by a resistive interfacial layer.

The ionic conductivity results for the B_2O_3 substituted glasses and glass-ceramics are given in Fig. 3 and 4 and Table III. Comparison of the results for $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass with the results of the B_2O_3 substituted glasses (Fig. 3) indicates that B_2O_3 substitution causes a net decrease in the ionic conductivity of the glass. However, the results in Fig. 4 show that the ionic conductivities of some B_2O_3 substituted glass-ceramics are similar to or in some instances, even greater than, the conductivities for the corresponding

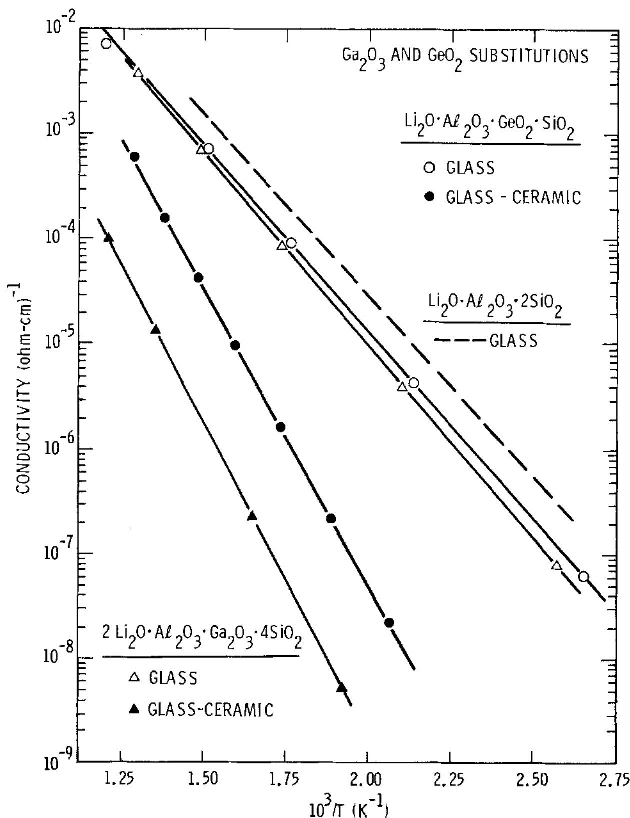

Fig. 2. Ionic conductivity temperature dependence for substitutions of GeO_2 for SiO_2 and Ga_2O_3 for Al_2O_3 in lithium aluminosilicate glasses and glass-ceramics. Results are compared with stoichiometric $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass (dashed line) and show that these substitutions do not significantly affect the conductivity when compared wih $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass and glass-ceramic (see Fig. 1).

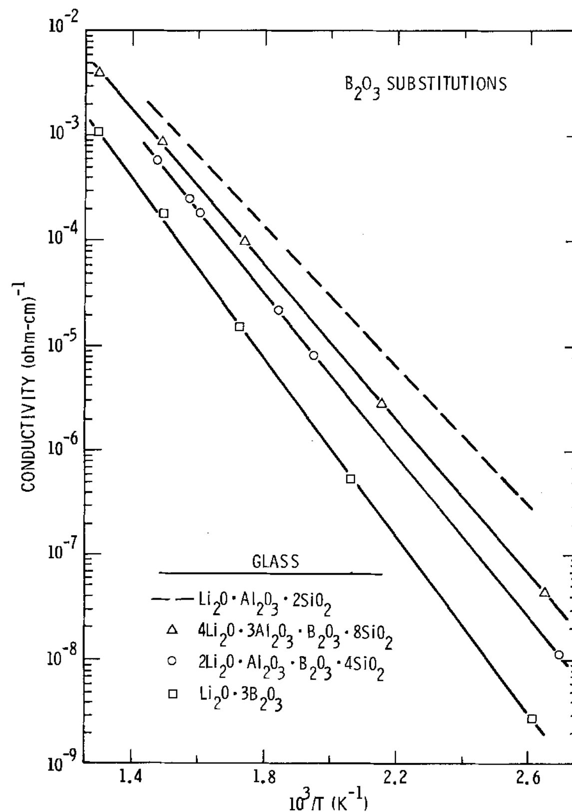

Fig. 3. Ionic conductivity temperature dependence for B_2O_3 substitutions for Al_2O_3 in $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ (*i.e.*, $LiAlSiO_4$) glass. Results show that substitution of B_2O_3 causes a net decrease in the ionic conductivity of the glass.

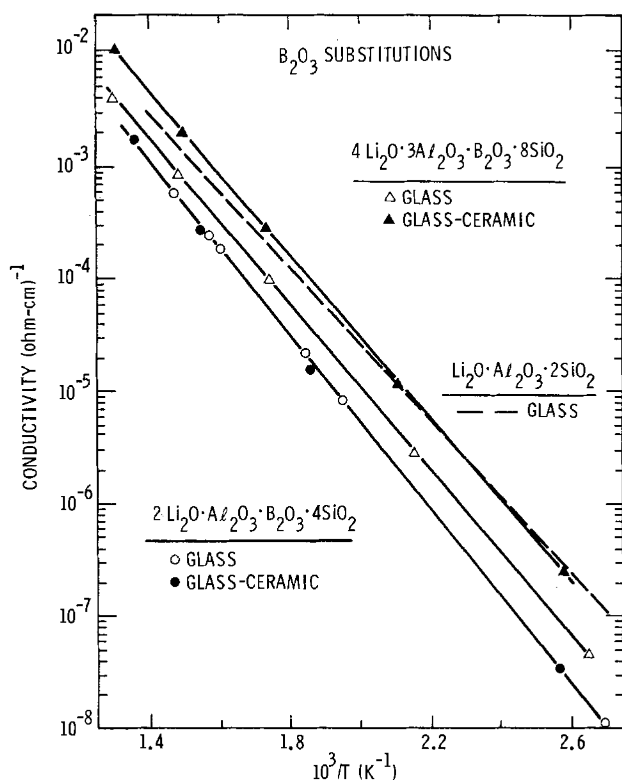

Fig. 4. Ionic conductivity temperature dependence for B_2O_3 substituted lithium aluminosilicate glasses and glass-ceramics. The conductivities of the glass-ceramics are similar to (or greater than) the conductivities for the corresponding glass. This is in contrast to the trends observed for stoichiometric $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ and for the GeO_2 and Ga_2O_3 substituted materials (see Fig. 1 and 2).

glasses. This is exactly opposite to the behavior observed for the stoichiometric $LiAlSiO_4$ glass-ceramics, for the GeO_2 and Ga_2O_3 substituted glass-ceramics, and for several other glass-ceramic systems (10-13). To our knowledge, this is the first reported observation of an increase in ionic conductivity in a Li_2O containing system upon conversion from a glass to a glass-ceramic.

In interpreting these results, the degree of crystallinity must be considered. For the composition $2Li_2O \cdot Al_2O_3 \cdot B_2O_3 \cdot 4SiO_2$ in Fig. 4 the glass and glass-ceramic are observed to have the same conductivity. The x-ray data on this particular glass-ceramic indicated that it is only slightly crystalline as evidenced by both the long exposure time needed to obtain the x-ray diffraction photograph and the presence of a large amount of low angle scattered x-rays associated with the glass phase. From the previous results for the dependence of the ionic conductivity on the percent crystallinity in the ($LiAlSiO_4$) glass-ceramics (4), it is reasonable to expect that a low crystallinity glass-ceramic would have a conductivity similar to that for the corresponding glass. Thus for the $2Li_2O \cdot Al_2O_3 \cdot B_2O_3 \cdot 4SiO_2$ material, it is not possible, with the present data, to determine whether the observed conductivity effects are due to the B_2O_3 substitution or the low degree of crystallinity. The situation is a little clearer, however, for $4Li_2O \cdot 3Al_2O_3 \cdot B_2O_3 \cdot 8SiO_2$ (Fig. 4). The glass-ceramic of this composition had a relatively high degree of crystallinity. The conductivity data indicate an increase in conductivity above that for the corresponding glass. We interpret this behavior as due to a compositional change (*i.e.*, substitution of B_2O_3). The magnitude of the conductivity increase observed in Fig. 4 is of the order of what might be expected if the β-eucryptite crystalline regions began to contribute to the conductivity. It is possible that boron may be lowering the resistance of the glass-crystalline interfacial layer in the glass-ceramic.

X-ray diffraction results on these boron containing glass-ceramics showed that they contained β-eucryptite crystallites (see Table I); however, the lattice constants [a = 10.45(1) and c = 11.13(4)Å] are smaller than those for $LiAlSiO_4$. Since the crystallite lattice constants are smaller, the size of the channels through which the Li ions move should be reduced. Whether this actually causes an increase or decrease in conductivity is not known. There does appear to be an optimum channel-to-ion size ratio for maximizing the conductivity in crystallographic tunnels in solid electrolytes (14, 15).

Studies were also pursued on compositions for which the Li_2O content of the material is greater than that in stoichiometric $LiAlSiO_4$. The results of the ionic conductivity measurements on these lithium enriched glasses and glass-ceramics are presented in Fig. 5, 6, and 7 and in Table III. Increasing the Li_2O content of the Al, Ga, or Ge containing glasses, Fig. 5 and 6, causes an increase in the ionic conductivity of the glasses. [This has also been observed for Li_2O-SiO_2 glasses (11, 13).] However, the corresponding glass-ceramics have ionic conductivities that are similar to or even lower than the ionic conductivities for $LiAlSiO_4$ glass-ceramics. The results for B_2O_3 substituted glasses and glass-ceramics with an enhanced Li_2O content are given in Fig. 7. The ionic conductivities of the glasses are greater than that of $LiAlSiO_4$ glass, which is consistent with the results for the other Li_2O enhanced glasses. The conductivity of these Li_2O enriched glasses does not appear to be significantly affected by B_2O_3

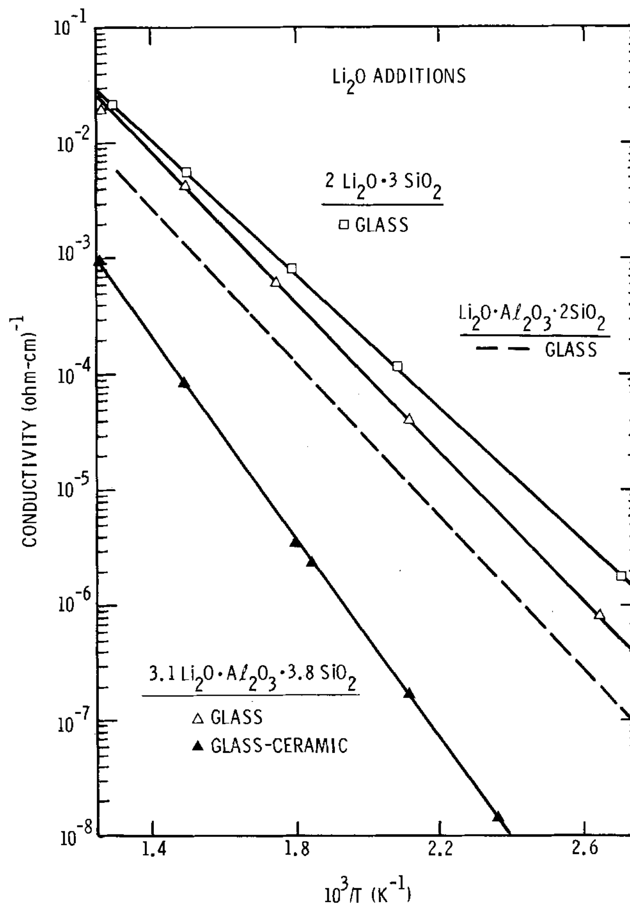

Fig. 5. Ionic conductivity temperature dependence for lithium silicate and lithium aluminosilicate glass and glass-ceramic with enhanced Li_2O concentrations. Results are compared with stoichiometric $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass (dashed line) and show that the addition of Li_2O increases the conductivity of the glass. The decrease in conductivity upon forming a glass-ceramic is similar to that observed in $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass-ceramics (Fig. 1).

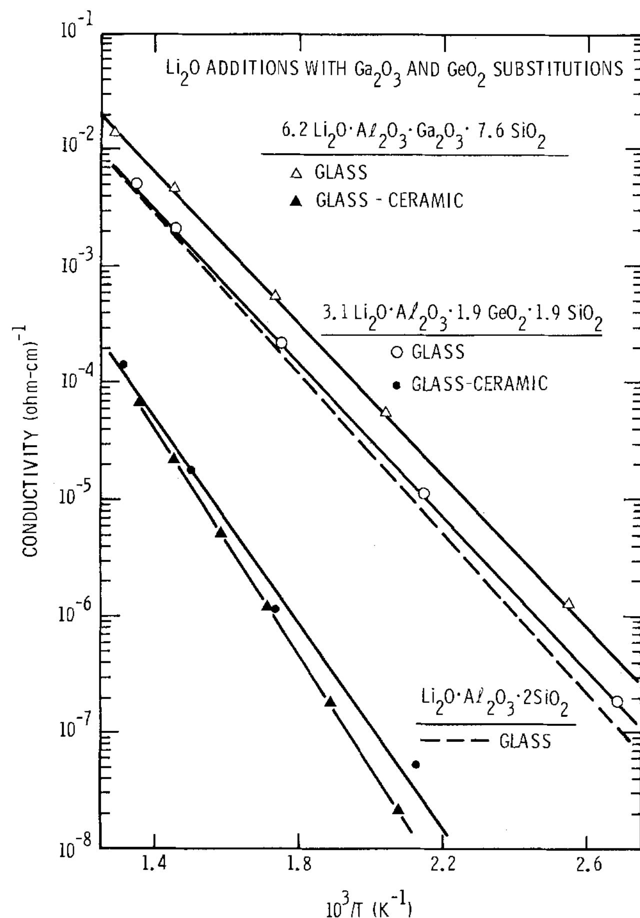

Fig. 6. Ionic conductivity temperature dependence for Li_2O additions to lithium aluminosilicate glasses and glass-ceramics with GeO_2 and Ga_2O_3 substitutions for SiO_2 and Al_2O_3, respectively. Results are compared with stoichiometric $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass (dashed line) and show that the conductivity of the glasses is increased by Li_2O additions. The conductivity decrease upon forming a glass-ceramic is similar to that observed for $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass-ceramics (Fig. 1).

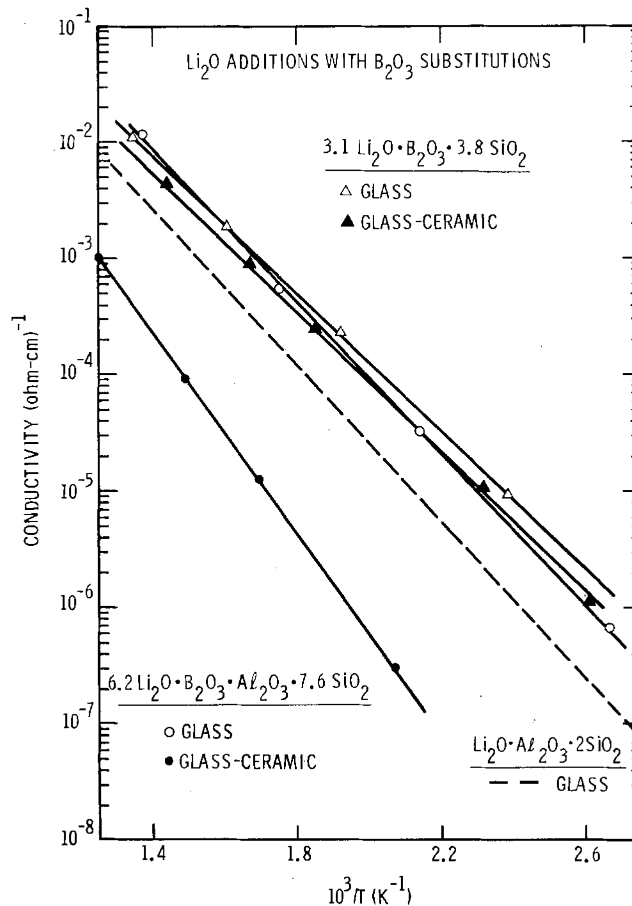

Fig. 7. Ionic conductivity temperature dependence for lithium aluminosilicate glasses and glass-ceramics with Li_2O additions and B_2O_3 substitutions for Al_2O_3. Results are compared with those for $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass (dashed line) and show that Li_2O additions enhance the conductivity and that some B_2O_3 containing glass-ceramics ($3.1Li_2O \cdot B_2O_3 \cdot 3.8SiO_2$) exhibit a conductivity which is greater than that for the corresponding glass.

substitutions, at least for the compositions examined in Fig. 5 and 7. The most striking effects of B_2O_3 substitutions, however, are seen for the glass-ceramic materials. Some of the B containing Li_2O enriched glass-ceramics ($3.1 Li_2O \cdot B_2O_3 \cdot 3.8 SiO_2$) have conductivities very similar to those of the glass. These results further emphasize the anomalous behavior of some boron containing glass-ceramics. Both of the glass-ceramics examined in Fig. 7 have a high degree of crystallinity. As seen in this figure, the $6.2 Li_2O \cdot B_2O_3 \cdot Al_2O_3 \cdot 7.6 SiO_2$ glass-ceramic has a much lower conductivity than the glass. It is not clear why some of the boron containing glass-ceramics do not show the anomalous behavior. A good comparison between the conductivities of glasses and glass-ceramics with and without B_2O_3 substitution is seen by comparing the results for $3.1 Li_2O \cdot Al_2O_3 \cdot 3.8 SiO_2$ in Fig. 5 with those for the corresponding B_2O_3 substituted material, $3.1 Li_2O \cdot B_2O_3 \cdot 3.8 SiO_2$, in Fig. 7. In contrast to the Al_2O_3 containing materials the B_2O_3 substituted glass-ceramic has a conductivity which is nearly the same as that of the glass. This glass-ceramic $3.1 Li_2O \cdot B_2O_3 \cdot 3.8 SiO_2$, (Fig. 7) contains largely lithium metasilicate (Li_2SiO_3) crystallites instead of β-eucryptite crystallites. The sample is mostly crystalline as evidenced by its opaqueness, absence of low angle scattering, and the short exposure time needed to obtain the x-ray diffraction photograph. The anomalously high conductivity can be explained by assuming that glass-ceramics with only lithium metasilicate crystallites have higher conductivities than glass-ceramics which also have β-eucryptite crystallites. However, this appears to be unlikely since results reported by Kinser and Hench (13) indicate that Li_2O-SiO_2 glass-ceramics which contain lithium metasilicate crystallites also have conductivities that are lower than those of the starting glass. Another possible way to explain the high conductivity in some of the boron containing glass-ceramics is to assume that the boron reduces the glass-crystalline interfacial resistance.

It appears from all of these experimental results that the glass-crystalline interfaces play a very important role in influencing the ionic conductivity characteristics of glass-ceramics based on the lithium aluminosilicate (β-eucryptite) system.

Pressure dependence.—The effect of hydrostatic pressure on the ionic conductivity was examined in a glass and glass-ceramic (81% crystallinity) of the basic β-eucryptite composition ($LiAlSiO_4$), in a glass which exhibits one of the highest conductivities resulting from an enhanced Li_2O content ($3.1 Li_2O \cdot Al_2O_3 \cdot 3.8 SiO_2$), and in a B_2O_3 substituted glass-ceramic which has a conductivity greater than that of the corresponding glass ($4 LiO_2 \cdot 3 Al_2O_3 \cdot B_2O_3 \cdot 8 SiO_2$). The ionic conductivity was first measured at 250°C as a function of pressure to 2.0 GPa and the results showed only slight (20-50%) variations with pressure. The temperature dependence of the conductivity was then measured at 2.0 GPa. The E and σ_o values determined from these experiments are given in Table IV and are compared to similar data obtained at atmospheric pressure on "sister" samples. The results show that E and σ_o were not significantly affected by pressure. There does appear to be a slight lowering of σ_o at 2.0 GPa, but these differences are nearly within experimental

† 81 v/o crystallinity.

error. This is consistent with results on sodium aluminosilicate glasses where only a small pressure effect on ionic conductivity was observed (16).

Although there is no significant pressure effect on the glasses examined here, it is reasonable to expect more of an effect in the crystalline material since the β-eucryptite lattice does change with pressure (17). However, the conductivity of the crystalline grains in the glass-ceramics may be masked by a resistive interfacial layer. The lack of a significant pressure effect on the glass-ceramics examined here could be explained by assuming that an increase in pressure has no effect on the conductivity of the glass-crystalline interface.

Summary

The ionic conductivities of stoichiometric $LiAlSiO_4$ glass, glass-ceramic, and single crystal show that the glass is a good three-dimensional conductor when compared to the single crystal (along the one-dimensional conducting channels) and is a considerably better conductor than the glass-ceramics (for high degrees of crystallinity and at low temperatures). Substitution of Ga_2O_3 or GeO_2 for Al_2O_3 or SiO_2, respectively, in $Li_2O \cdot Al_2O_3 \cdot 2SiO_2$ glass and glass-ceramic has little effect on the ionic conductivity. However, substitution of B_2O_3 for Al_2O_3 increases the ionic conductivity in some of the glass-ceramics when compared to that of the starting glass. This effect is opposite to the trend observed for the Al, Ga, or Ge containing glass-ceramics. When the Li_2O content of a glass is increased over that for $LiAlSiO_4$, an increase in the ionic conductivity results. When B_2O_3 is substituted into the enhanced lithium materials an anomalous effect on the conductivity is again observed for some of the glass-ceramics. The anomalous enhancement of the ionic conductivity in some boron containing glass-ceramics is explained by its effect on the glass-crystalline interface. The existence of glass-crystalline interfacial layers which significantly affect the conductivity of the glass-ceramics provides a consistent interpretation for all of the results.

The effect of hydrostatic pressure (to 2.0 GPa) on the ionic conductivity in glass and glass-ceramic materials was determined for a number of samples with different compositions and conductivities. No significant pressure effect was observed. This is consistent with the results for other glasses (16) and with the important role thought to be played by the interfacial layers in the glass-ceramics.

At the present time the highest ionic conductivities [$\sim 2 \times 10^{-2}$ $(\Omega\text{-cm})^{-1}$ at 500°C] have been obtained in the glasses with enhanced lithium concentrations and in the glass-ceramics with both enhanced lithium concentrations and B_2O_3 substitutions for Al_2O_3. It is possible that the ionic conductivity of a glass-ceramic may be increased further by orienting the crystallites within the glass-ceramic. Atkinson and McMillan (18) have reported an increase of up to a factor of 38 in the conductivity of aligned Li_2O-SiO_2 glass-ceramics when compared to the conductivity of the unaligned glass-ceramics. By aligning the crystallites in the boron containing lithium aluminosilicate glass-ceramics, higher ionic conductivities than those reported here may be obtainable at high temperatures.

Efficiencies of Cycling Lithium on a Lithium Substrate in Propylene Carbonate

R. D. Rauh,* T. F. Reise, and S. B. Brummer*

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

To assess the cycling efficiency of the Li electrode in a positive-limited secondary battery, Li has been plated and stripped from a Li substrate. This has been carried out in a specially designed cell containing a Li electrode of known volume: Li is plated and stripped from this electrode until the substrate is depleted. Individual efficiencies can also be determined from inflections in the stripping curves. Average efficiencies were best for PC, 1M $LiAsF_6$ which had been preelectrolyzed and treated with activated neutral alumina. Here, for 10 C/cm² cycles about 85% cycling efficiency was obtained, essentially without change until the substrate was depleted. In general, $LiClO_4$ showed inferior behavior to $LiAsF_6$.

Secondary Li batteries have generated renewed interest over the last several years (1-6). One type of system under investigation is the ambient temperature cell with an aprotic solvent-based electrolyte. A principal difficulty in the development of such a battery is the inefficiency of the Li electrode (7-10). Studies to date of the Li electrode have concentrated on a negative-limited system in which the Li is plated from solution onto an inert or alloying substrate (11-13) and then either removed immediately or following a waiting period. By such experiments, the cycling efficiency and rate of activity loss could be measured.

The over-all efficiency of the cycling process in such experiments appears to be a multidetermined variable. Variations in efficiency have been noted for plating and stripping current density, charge density, supporting electrolyte, electrolyte additive, substrate (12), and cycle number (7-9, 14). In the propylene carbonate (PC), $LiClO_4$ system, and probably in many other systems, the efficiency of the plating step is nearly 100% (10). All of the inefficiencies are realized in the stripping process. Following such inefficient stripping, most of the unaccounted Li remains on the electrode, and is electrically insulated from it. On stand, the rate of capacity loss has been observed to exceed by roughly a factor of 10 the rate of Li oxidation (10). For both types of activity loss, insulation of Li granules through encapsulation by resistive Li-electrolyte reaction products has been suggested (7, 8). Finally the efficiency of the plating-stripping process decreases markedly with cycle, apparently due to blockage of portions of the substrate with reaction products, and accumulations of insulated Li (7, 8, 14).

In practice, then, the efficiency of the Li electrode is diminished by encapsulation of active material and by associated deterioration of the substrate. Approaches to the encapsulation problem are to eliminate all reactivity of the electrolyte with Li, to alter the morphology of the Li so it is less susceptible to attack, and to add a material to the electrolyte which will form a protective Li^+-permeable film on the electrodeposit. The latter idea is in analogy to the $Li/SOCl_2$ (15-17) and Li/SO_2 (18, 19) primary batteries, in which the Li is obviously protected from the highly oxidizing liquid cathode by a passivating film, yet can be discharged.

Most of the secondary Li battery systems which have been studied have been positive electrode-limited devices. However, the relative merits of positive and negative limitation have not been discussed in the open literature. A positive-limited system would be the better arrangement to achieve highest energy density, and this is why all primary systems are positive-limited. Indeed, if a battery contains an insoluble positive with 100% cycling efficiency and there is zero self-discharge rate, a negative-limited system with a less efficient Li electrode would not be feasible. With a soluble-positive system, in which much or all of the Li capacity loss can be attributed to self-discharge, such as the Li/Br_2 battery described by Weininger (20), a negative-limited system is feasible and perhaps even desirable.

It is the purpose of this study to investigate the cycling behavior in PC of Li on a dense Li substrate. This is the situation which would be present in a positive-limited Li secondary battery. Better deposit morphology might be expected in plating a metal onto itself than onto a foreign substrate. Correspondingly, the effect of cycle number on the efficiency should be improved, although this is not easily predictable.

Experimental

Propylene carbonate (PC) obtained from Burdick and Jackson Laboratories was used as-received. The latter material was characterized by lot analysis to contain 0.005% H_2O, and to be of otherwise high purity ("distilled in glass").

Lithium perchlorate ($LiClO_4$, Foote Mineral Company, anhydrous) was dried for 24 hours *in vacuo* (< 0.1 mm) at its fusion point (230°C). Lithium hexafluoroarsenate ($LiAsF_6$, electrochemical grade) was obtained from United States Steel, Agri-Chemicals Division, Decatur, Georgia, and was used as-received. It was indicated by the manufacturer to contain from 50 to 100 ppm H_2O (Karl Fischer method). Details concerning the preparation and analysis of high purity anhydrous $LiAsF_6$ have been discussed by Lawless *et al.* (21).

Neutral alumina (Fisher) was activated at 350°C in an argon stream overnight. The desiccant was immediately transferred to the dry box antechamber and allowed to cool under vacuum. Linde 5A molecular sieves were used as-received. All desiccants were used only in the dry box. In the appropriate experiments, 50 ml of electrolyte were slowly percolated through a chromatograph column containing 10g of desiccant. The first 10% through the column was discarded; the remainder was collected and stored in a tightly capped flask in the glove box.

All cycling studies were conducted at room temperature in a Vacuum/Atmospheres Company dry box. The argon atmosphere was continuously recirculated through a column containing molecular sieves and an activated Cu gettering material (BASF catalyst R3-11), for removing moisture and O_2.

Plating and stripping of Li were carried out galvanostatically using either a specially constructed constant current power supply or a Wenking Model LT 73 po-

tentiostat operating in the constant current mode. Cycles were performed continuously, without waiting periods between half cycles.

Results

Using a Li substrate for Li cycling studies is not as straightforward as using an inert substrate, chiefly due to the difficulty of determining the electrochemical stripping end point. An experiment for determining the average Li cycling efficiency over 10 or more cycles was therefore designed. The substrate consisted of a well-defined area of commercially available 0.13 mm (5 mil) thick Li foil. Exactly 10 C/cm^2 of Li were first deposited, then stripped from this substrate. If the process were not 100% efficient, some of the substrate would be oxidized during the stripping process. From the number of cycles required to deplete the substrate, the average efficiency per cycle could be calculated.

The cell used for these studies is illustrated in Fig. 1. The working and counterelectrodes were 0.13 mm and 0.39 mm (15 mil) thick Li disks, respectively. The reference electrode consisted of Li in 1M Li^+/PC in a Luggin capillary with fiberglass filter paper plugging the tip. Counter and working electrodes were pressed against Ni backings. The cell body was made of Teflon and was held together using a C clamp.

The reproducibility of the capacity of the 0.13 mm Li was determined by totally stripping several electrodes taken from various parts of the Li ribbon. The electrolyte was PC/1M $LiClO_4$; stripping was carried out at 5 mA/cm^2. Theoretically, 0.13 mm Li contains 91.6 C/cm^2. The experimentally determined value was 82.9 $\pm$ 7.0 C/cm^2 for 10 samples taken at random from this particular roll of foil. This experimental value was used in calculating average cycling efficiencies.

Li cycling experiments were carried out using a plating and stripping current density of 2.5 mA/cm^2. The average efficiency per cycle, $\overline{E}$, was calculated from the equation

$$\overline{E} = 1 - \frac{N}{nQ} \quad [1]$$

Here, N is the number of coulombs/square centimeter of Li present initially on the substrate, Q is the number of coulombs/square centimeter plated and stripped in each cycle (10 in these experiments), and n is the number of cycles until Li substrate depletion.

Before the initial plating cycle, 1 C/cm^2 was stripped from the substrate to remove any surface films. The chronopotentiogram for this initial stripping step showed an anodic overshoot, then a leveling off of potential at a less anodic value. This latter potential was taken to be the stripping potential of substrate Li, uncorrected for IR, but constant within a given cell. Li surface films could also be removed by abrading the Li substrate with a paper towel before introduction into the cell. The initial stripping chronopotentiograms for nonabraded and abraded Li are reproduced in Fig. 2. The curves are uncorrected for IR, explaining the differences in the limiting Li stripping potentials in the two cells.

The cycling efficiency of Li on a Li substrate was studied as a function of electrolyte purification and of electrolyte salt ($LiClO_4$ or $LiAsF_6$).

PC/$LiClO_4$.—The results of cycling Li on Li in PC/1M $LiClO_4$ solutions are summarized in Table I. In

Table I. Effect of electrolyte preparation and purification procedures on the efficiency of cycling Li on a Li substrate. Electrolyte is 1M in Li salt. $Q_p = Q_s$ = 10 C/cm^2; $i_p = i_s$ = 2.5 mA/cm^2.

Solution	Purification procedure	Average cycling efficiency
PC, 1M $LiClO_4$	/	44.2, 34.0
	A/	44.2
	A/A	44.2
	S/	40.0

PC, 1M $LiAsF_6$	/	79.0
	A/	82.0
	A/A	83.0
	S/S	68.0
	S/	81.0
	/P	77.3
	/PA	84.2

A/ — Pass through column of activated neutral Al_2O_3.
S/ — Pass through column of activated molecular sieves.
/ — Add fuse-dried $LiClO_4$ or anhydrous $LiAsF_6$.
P/ — Preelectrolyze between Li electrodes.

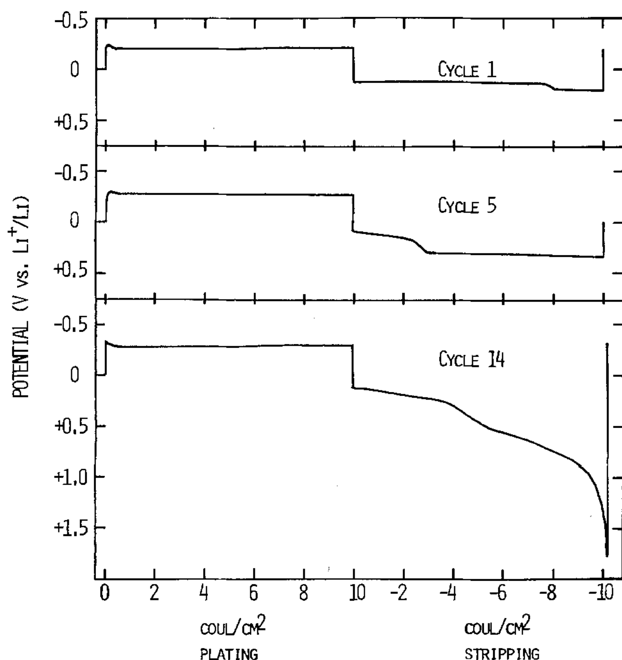

Fig. 3. Chronopotentiograms for plating and stripping Li on a Li substrate: $i_p = i_s = 2.5$ mA/cm²; $Q_p = Q_s = 10$ C/cm². Electrolyte is 1M $LiClO_4$ in PC.

general, inspection of the individual stripping chronopotentiograms allowed an estimate of the single cycle efficiencies. As shown in Fig. 3, the stripping curve following electrodeposition has two components, separated by about 100 mV. The more cathodic component, which is recorded initially, is ascribed to removal of the electrochemically accessible portion of the deposit, with its high surface area. The low surface area substrate is removed at the more positive potential, because of the higher effective current density. This latter potential corresponds to the stripping potential of the substrate, as determined at the beginning of each run.

The average efficiencies over 10-20 cycles showed some sensitivity to electrolyte purification. Electrolyte prepared by adding the $LiClO_4$ to as-received solvent gave an average efficiency of only 40%. Treatment of the electrolyte or solvent with molecular sieve led to no improvement. Addition of 500 ppm H_2O to sieve-treated electrolyte even yielded slightly higher efficiencies, in accordance with earlier results utilizing a Ni substrate (7). Alumina treatment of the electrolyte or solvent yielded a slightly improved 44%. The only significant enhancement of cycling efficiency was observed for electrolyte which had been preelectrolyzed between Li electrodes, then passed through alumina. This procedure resulted in a 65% average cycling efficiency. Similar effects of purification have been observed on a Ni substrate (14).

Figure 4 shows the single cycle efficiency profile for the PC/$LiClO_4$ system. The cell containing the untreated electrolyte showed an initial efficiency of 74%. This dropped rapidly over the next five cycles, yielding around 30% until electrode failure. The sieve-treated material gave only 44% on the first cycle, and cycled between 24 and 38% thereafter. Similarly, the preelectrolyzed electrolyte maintained a single cycle efficiency of ~40% over the 13 cycles needed to exhaust the substrate. When this same solution was passed over activated neutral alumina, the first cycle was 78%, dropping gradually to about 40% over 10 cycles, and staying at this level until the final cycle.

PC/$LiAsF_6$.—It has been reported that Li in contact with solutions of esters and $LiAsF_6$ is quite stable even at elevated temperatures (22). Higgins has also demonstrated a higher stability of Li to several aprotic solvent electrolytes if $LiAsF_6$ is used as the supporting electrolyte compared to $LiAlCl_4$ (23). In addition, studies of the Li electrode in MA, utilizing an inert substrate, indicate higher efficiencies for $LiAsF_6$ solutions than for those containing $LiClO_4$ (24). Galvanostatic cycling experiments were therefore undertaken using PC, 1M $LiAsF_6$.

Results of the cycling studies, reported in Table I, show generally higher efficiencies than obtained for PC, 1M $LiClO_4$. Thus, the untreated solution gave an average efficiency of 79%, going 34 cycles before the substrate was exhausted. As with PC, $LiClO_4$, alumina treatment enhanced this efficiency. Treatment of just the solvent with molecular sieves also improved the average cycling efficiency, while treatment with sieves after the addition of the salt gave poorer results. Again, the best cycling efficiency, 84.2%, was obtained using electrolyte which had been preelectrolyzed, then passed through a column of alumina.

The single cycle efficiencies, plotted *vs.* cycle in Fig. 5, confirm the high average efficiencies. Compared to the $LiClO_4$ solutions, the stripping plateaus were usually separated by a smaller potential, indicating a more compact, lower surface area deposit. With the preelectrolyzed solvent, plateaus were not even discernable until the 9th cycle. The average of the single cycle efficiencies was generally a few percent lower than the average efficiency computed from Eq. [1]. Probably, some stripping of electrodeposited Li continued into the second plateau. It is particularly noteworthy that the deterioration in efficiency with cycle, so evident when a Ni substrate is used with similar preparations (14), is much reduced on Li.

Discussion

Compared to $LiClO_4$, $LiAsF_6$ enhances the cycling efficiency of Li on a Li substrate in PC. This has also been observed on a Ni substrate in PC (14) and in MA

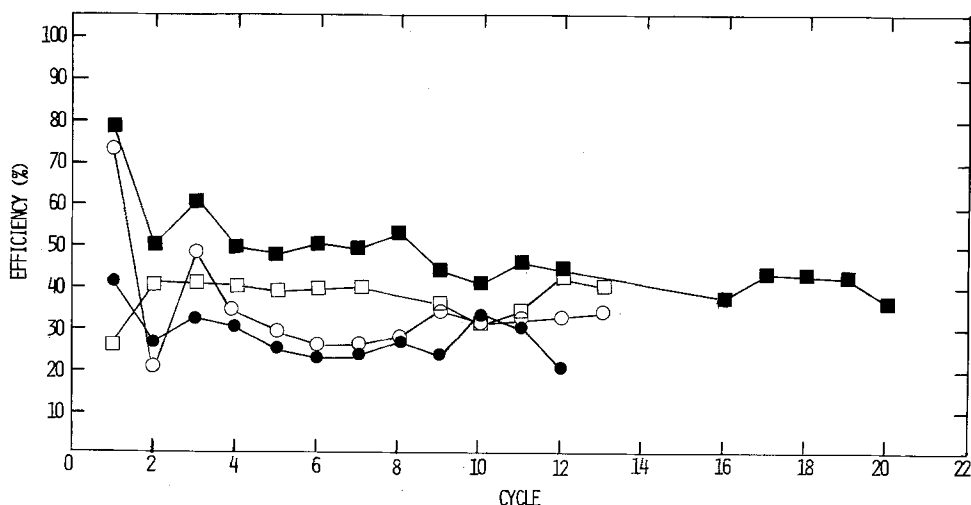

Fig. 4. Efficiencies of cycling Li on a Li substrate, as a function of cycle and electrolyte purification, in PC, 1M $LiClO_4$. $i_p = i_s = 2.5$ mA/cm²; $Q_p = Q_s = 10$ C/cm². ○ No purification. ●, Solvent and electrolyte solution passed through a column of Linde 5A molecular sieves. □, Electrolyte solution electrolyzed between Li electrodes. ■, Electrolyte solution electrolyzed between Li electrodes, then filtered through Al_2O_3.

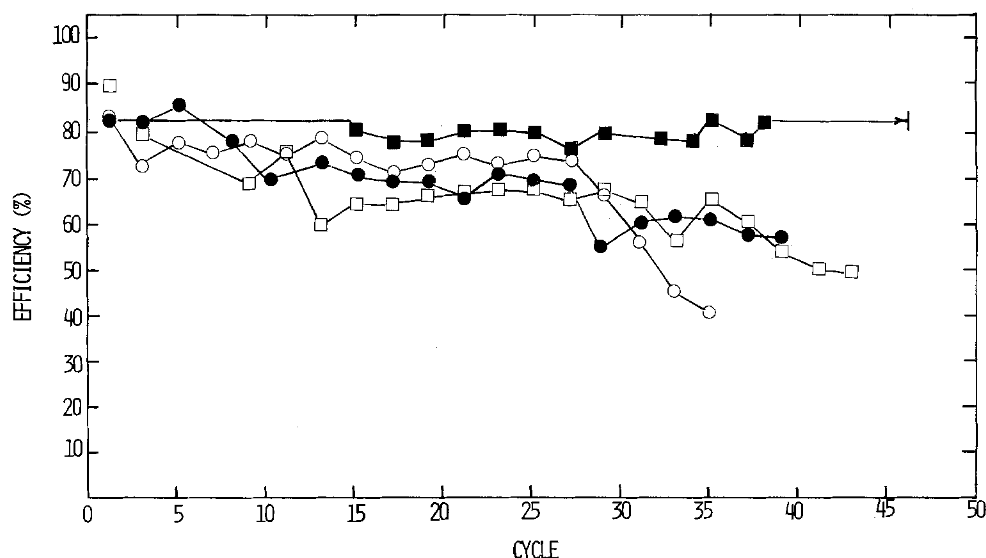

Fig. 5. Efficiencies of cycling Li on a Li substrate, as a function of cycle and electrolyte purification in PC, 1M $LiAsF_6$. $i_p = i_s = 2.5$ mA/cm²; $Q_p = Q_s = 10$ C/cm². ○, No purification. ●, Solvent only passed through a column of Linde 5A molecular sieves. □, Solvent and electrolyte solution passed through a column of activated neutral Al_2O_3. ■, Electrolyte solution electrolyzed between Li electrodes, then filtered through Al_2O_3.

(24). The main cause of inefficiency appears to be encapsulation of electrodeposited Li, leading to its insulation from the substrate.

Studies of 1 C/cm² plates on Ni show in general a more catastrophic drop of efficiency with cycle (14) than the 10 C/cm² plates in the present paper. This may reflect the more efficient reduction of solvent or impurities on Ni (at the Li potential) than on Li. As already mentioned, such reaction products and/or insulated Li remaining from previous cycles could lead to a lower effective substrate surface area and a poorer morphology. Perhaps as important, stripping away part of the Li substrate on each cycle probably provides new nucleation centers for each succeeding cycle, which is not possible on an inert substrate.

Examination of Li plated on a Li substrate reveals a dendritic habit similar to that found on Ni. However, electrodeposits are considerably more adherent with $LiAsF_6$ than with $LiClO_4$. In cycled half-cells, more Li was found floating in the electrolyte in the presence of the latter salt, and the individual granules appeared smaller. A mechanism presented by us for dendrite growth involved the filming of as-deposited Li with insulating reaction products, preventing the growth of large granules and, rather, enhancing the formation of trees and dendrites (7, 8). However, as described in the introduction, films selectively permeable to small ions, namely Li^+, may actually help grain growth, by allowing Li plating while preventing the intrusion of insulating-film-forming reactants. It is possible that $LiAsF_6$ contains, as an impurity, a substance which reacts with the Li to form such a semipermeable film, or that adsorption of AsF_6^- has the same function. It is also possible that we have been unable to rid $LiClO_4$ of certain oxidizing impurities not found in $LiAsF_6$.

The implications of these results for the construction of a practical battery based on this electrolyte are readily apparent. We estimate that a typical charge for a Li D cell (25) would be approximately 50 C/cm². Even if 85% cycling efficiency could be achieved, our best results for only 10 C/cm², a Li loss of 7.5 C/cm² per cycle would result. An extravagant tenfold excess of Li would allow only 67 complete cycles before anode failure. Correspondingly, 100 full capacity cycles would require a 90% cycling efficiency and 1000 cycles a 99% cycling efficiency. Losses can also be incurred due to isolation of electrodeposited Li on open-circuit stand. Since the phenomena of efficiency loss and Li isolation appear to result from the intrinsic reactivity of Li with the solution, improvements would surely be noted if a more inert electrolyte were found. However, since a certain amount of Li encapsulation may be inevitable, methods should be sought of recontacting the isolated dendrites or resolubilizing them via a controlled self-discharge reaction to avoid using large excesses of Li in cell construction. Such approaches are currently under investigation in our laboratory.

Behavior of Maleic Acid during the Anodization of Aluminum

Michiko Shimura

Faculty of Engineering, Tokyo Metropolitan University, Tokyo, Japan

ABSTRACT

Anodization of aluminum in aqueous maleic acid at constant current densities showed that the formation of the anodic film took place competitively with the oxidation of maleic acid. In dilute electrolyte, except for the initial short period where the colorless thin film was formed, the over-all current served to oxidize the double bond of maleic acid into glyoxal or carbon monoxide. In concentrated electrolyte, the brownish anodic film was readily formed and became black as it thickened. The colored film was shown to favor the passage of ionic current and was made up of aluminum oxide complexed with maleate. The coloration of the film was considered to be induced from carboxylate anion radicals, which were coordinated to the aluminum ion as a ligand, as in the case of oxalic acid film reported previously.

The properties of aluminum anodic films differ according to the electrolytes employed. For instance, the change of the activity of hydronium ions near the anodic film is considered to affect the properties of the film because the hydronium ions react with the aluminum oxide to give an unstable soluble substance resulting in the formation of a porous film (1). However, the effect of the anion species of the acids has been scarcely explained in spite of the important fact that anodic film cannot be formed in electrolytes containing acetate or other specific anions.

Recently, the author studied the behavior of oxalic acid during the anodization of aluminum and found that oxalate ions coordinate to aluminum ions competitively with water to form aluminum complexes such as $[Al(C_2O_4)_n(H_2O)_{6-2n}]^{m-}$ which changes to $[Al \cdot O_x \cdot (C_2O_4)_y]_z$ polymer by deprotonation and olation, and that the aluminum anodization process scarcely involves Kolbe's reaction for the oxalic acid (2, 3). The coloration of the oxalic acid anodic film was suggested to have come from $C_2O_4^{2\cdot-}$ radical which should be produced by transferring charges from central low-valency aluminum ion to the oxalato ligand.

As the continuation of these studies, this paper deals with the behavior of maleic acid in the aluminum anodization process.

Experimental

Anodization.—Aqueous maleic acid electrolyte of 0.1-1.0 moles/liter was prepared from analytical grade reagent and distilled water. Cleaned 99.99% aluminum sheets and wires were anodized at 15°-45°C in vessels filled with stirred electrolytes with current supplied from a galvanostat or selenium rectifier.

Measurement of ESR spectra.—For the anodized aluminum wire, ESR spectra were measured in air using a JEOL, JES-PE 3X instrument.

Analysis of gases generated at the anode.—In order to prevent mixing of gases generated at the anode and cathode, a closed vessel with two compartments, each of which was fitted with a silicone rubber stopper, was used as the anodizing cell (4). Prior to anodization, the electrolyte was flushed with argon for several minutes. During galvanostatic anodization at 20 mA/cm², gaseous products at the anode (1 × 1 cm) were collected in a 0.1 ml syringe through the silicone rubber stopper and successively were injected to a gas chromatograph (Shimazau GC-4 AIT) equipped with molecular sieve 5A columns (Nishio Industry). Reference and sample columns were maintained at 65°C, and the helium flow was adjusted to ∼8.14 ml/min.

Detection of aldehyde.—A small ceramic beaker was inserted in a glass beaker. Into the space between the two beakers was poured 200 ml of the anolyte. The catholyte of 100 ml was poured into the ceramic beaker. A cleaned aluminum sheet of 3.5 × 8 cm was dipped in the anolyte, and 5 mA/cm² current was supplied from a selenium rectifier. The total amount of charge was measured with a copper-coulometer which was connected in series to the anodizing circuit. Every 2 hr the anodization was interrupted for a minute, the sample was replaced with another new one, and water was added to the anolyte and catholyte so as to attain initial levels. The anodization was stopped when the total amount of charge reached 10,000C. Small parts of the used anolyte and catholyte were tested with Schiff's reagent. Aldehyde was found in the anolyte but not in the catholyte. The whole anolyte was reacted with dinitrophenylhydrazine to separate the aldehyde as insoluble dinitrophenylhydrazone-derivative, which was identified by infrared absorption spectra, melting point, and so on. The yield of the aldehyde

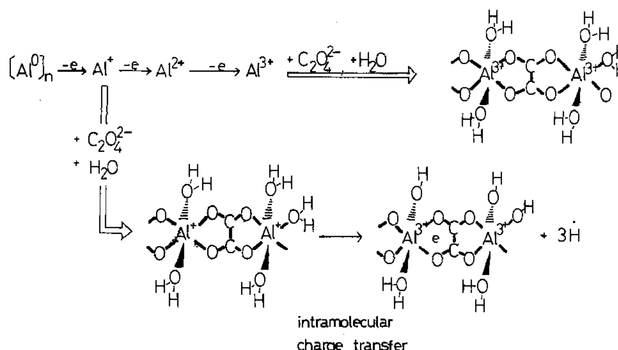

Fig. 1. Formation of aluminum complexes during anodization

Key words: anodic oxidation, aluminum, carbon monoxide.

was calculated on the basis of charge passed as electron transfer at the interface of the anode/electrolyte.

Gravimetric measurement of oxidized aluminum.—The amount of aluminum oxidized during the anodization at a given number of Faradays was measured in the following way: Al samples were weighed, to an accuracy of 10^{-4}g, before anodization and after dissolving anodized layers with H_3PO_4-CrO_3 solution. The difference of the two values, *i.e.*, the amount of aluminum anodized by a certain number of Faradays, is taken as the measure of the anodic oxidation.

Detection of succinic acid.—To investigate the behavior of maleic acid at the cathode, the catholyte after prolonged anodization was separated with paper-chromatograph using butanol-formic acid solution as developer. The separated substance was confirmed to be succinic acid from its R_f value and infrared absorption spectrum.

Results and Discussion

Profiles of the anodization.—Anodization in maleic acid electrolyte shows some unique phenomena such as vigorous evolution of gases, sharp increase of voltage accompanying the browning of the anodic film, and unusual *V-t* behaviors.

Figure 2 shows the *V-t* curves for 0.2, 0.5, and 1.0 mole/liter of maleic acid at 20 mA/cm², 20° ± 1°C. In the beginning of the anodization, all *V-t* curves increased rapidly up to about 80V, likely due to barrier layer formation. Then, they either maintained constant values, decreased, or increased depending on the concentration of maleic acid. In 0.2 mole/liter maleic acid, the voltage decreased to a steady value where bubbles were constantly produced throughout the course of anodization. Colored film was not formed even at 60 min anodization. In 1.0 mole/liter maleic acid, the voltage increased progressively in accordance with the growth of brownish anodic film. It saturated at about 160V due to the occurrence of breakdown of the film. At this voltage the anodic film started to become black and finally became completely black. In 0.5 mole/liter maleic acid, the voltage decreased to reach amost steady state as in the case of 0.2 mole/liter maleic acid but, after 10 min, it again increased suddenly up to 170V with the appearance of brownish anodic film. At the end of the anodization (60 min), the color of the film was as black as in the case of 1.0 mole/liter maleic acid.

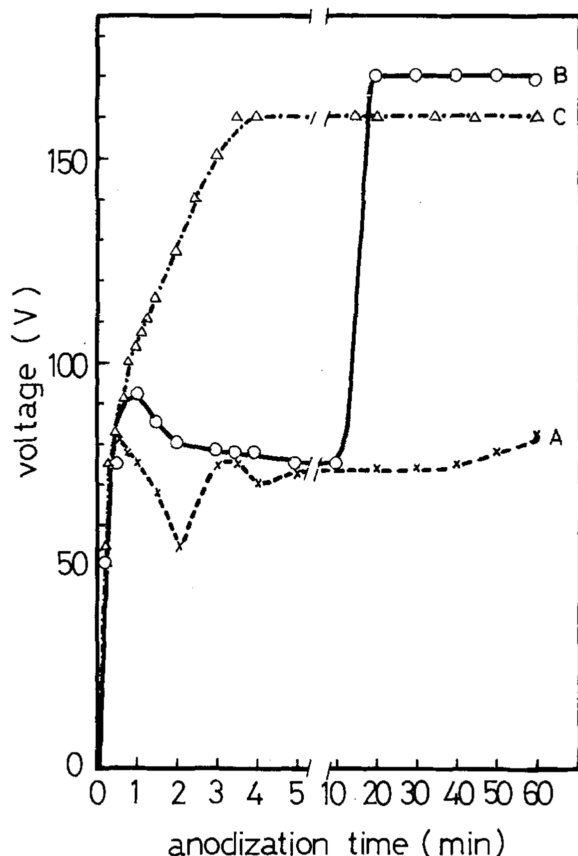

Fig. 2. Voltage-time curves in anodization. 20 mA/cm², aqueous maleic acid electrolyte. Curve A, 0.2; curve B, 0.5; curve C, 1.0 mole/liter.

The black anodic film was lusterless, rough, and loosely adhered on the aluminum substrate[1] unlike the brown anodic films formed in oxalic and malonic acids. Occasionally, it adsorbed slightly yellowish deposits at the surface of the maleic electrolyte.

The aluminum substrate after stripping off the black anodic film with H_3PO_4-CrO_3 solution was remarkably rugged, indicating that the aluminum substrate did not dissociate uniformly during the anodization. It is assumed that the uneven dissociation is caused by the heterogeneous incorporation of maleate in the anodic film and the different ionic conductances with sites.

Anodic dissociation of aluminum.—The aluminum consumption during the anodic oxidation (or anodic dissociation) was remarkably smaller than the estimated value from Faraday's law. This means that the efficiency of the ionic current was extremely small and dependent upon the concentration of the electrolyte (Table I). In 0.2 mole/liter maleic acid, the efficiency was no more than 0.01 and violent gas evolution occurred as mentioned above. In case of 0.5 mole/liter, the efficiency was 0.30; however, it can be corrected to 0.39, the same value as in 1.0 mole/liter, if the charge passed at the initial gas evolution period was substracted. Thus, the same efficiencies for the colored films suggest that the efficiency was determined mainly by the ionic conductivity of the anodic film, into which maleate was incorporated, and not by the electrolyte concentration.

Infrared spectra of the anodic films.—Figure 3 shows infrared absorption spectra by KBr disk method for the slightly yellowed deposits adsorbed at the black anodic film during prolonged anodization (curve A) and for a sample of maleic acid (curve B). It is found that the deposit is identical with maleic acid except for additional absorption peaks at 3650, 1570, 1450, 1010, 830, 680, 580, and 500 cm^{-1}. Since the aluminum ion has been detected from HCl solution of the deposit by the aluminon colorimetry method, and the foreign absorptions at 3650, 1010, 830, 680, 580, and 500 cm^{-1} can be assigned to the vibrations of M-OH or M-H_2O (5), it is considered that the deposit partly contains hydroxides of aluminum. The other foreign absorptions (at 1570 and 1450 cm^{-1}) can be assigned to COO^- stretching vibration of maleate because the same absorption has been found for H_2SO_4 anodic film after prolonged immersion in aqueous maleic acid, and assigned to COO^- of maleate chemisorbed at acidic sites of the H_2SO_4 anodic film (curve C). From these results, the deposit is considered as a mixture of maleic acid in a free state and aluminum hydroxide complexed with maleate. The deposition of maleic acid on the anode is explained in the following way: most of the maleate ions, which are migrated to the anode

[1] The black anodic film was discolored gray when it was scraped off from the aluminum substrate. The blackness was not completely inherent to chemical composition but changed with physical states.

Table I. Ionic current efficiency of the anodization
20 mA/cm², 20°C, 60 min, 4 cm²

Mole/liter	Anodically dissociated aluminum (mg)	Ionic current efficiency	Color of the anodic film
0.2	0.3	0.01	Colorless
0.5	8.2	0.30	Black
1.0	10.5	0.39	Black

in the electric field, combine with the protons which are released from the aluminum hydroxides on the anode, and become neutral acid molecules. When the concentration of the neutral molecules becomes high, they deposit on the anode. A small part of the maleate ions would be brought into the aluminum oxide and coordinate to Al^{n+} ions as can be seen in the following description.

At curve D of Fig. 3 another infrared spectrum for the black anodic film by KBr disk method is shown. The spectrum is characterized by intense and broad absorption in the region 1570-1450 cm^{-1} and below 900 cm^{-1} but has no absorption in the region 3500-3000 cm^{-1} which is commonly observed as water for usual aluminum anodic film (5). The broad absorption in 1570-1450 cm^{-1} probably indicates various states of carboxylate incorporated in the anodic film, *i.e.*, the carboxylate adsorbed on the surface of the film, coordinated to Al^{3+} ion as ligand, or combined with Al^{3+} ion electrostatically during the anodization. It is deduced that the black anodic film is composed of well-dehydrated aluminum oxide with maleate incorporated in complicated ways. It can be considered that there is a relationship between the development of the dehydration and the incorporation of maleate in the anodic film. When the anodic film grows, the electrochemical circuit has to be closed so as to allow the flow of anodizing current. At the interface of the barrier layer/electrolyte, ionic species should migrate instead of the Al^{3+} ion, as the Al^{3+} ion stays on the anode as the anodic film. The ionic migration is known to be induced by protons which are released from the anodic film (aluminum hydroxide) in the electric field. In the aluminum complexes intricately incorporated with maleate, ligand water should be deprotonated completely with the progress of the anodization.

ESR spectra of the anodic film.—The black anodic film showed a singlet ESR signal at $g = 2.004$ with $\Delta H_{msl} = 8G$. The signal intensity was saturated at small microwave output (0.8 mW), indicating that the relaxation time T_1 was long and therefore the signal was from organic radicals.[2] It was found that the signal intensity decreased uniformly with the increase of temperature up to 298°C (Fig. 4), but at room temperature it remained unchanged for several months. These facts agree precisely with the observations for the anodic film prepared in oxalic acid (2, 3), for which the ESR signal was considered attributable to $C_2O_4^{2-}$ radical coordinated to aluminum ions. The results obtained for the black anodic film seem indicative of carboxylate radicals coordinated to Al^{3+} ion. Generation of hydrogen at the anode supports this consideration and is explained in the following section.

Gaseous products at the anode.—Generation of gases at the anode during anodization was much more brisk in aqueous maleic acid than in common electrolytes (*i.e.*, sulfuric, oxalic, or malonic acid). This was a side reaction (6) because electronic current was about 60-99% of the charge passed across the anodic film (Table I).

Analysis of the gases in three experimental runs gave average volume ratios as shown in Table II.[3] An important observation was that the major part of the anode gases was carbon monoxide, whereas the gases were hydrogen (98%) and oxygen (2%) and scarcely contained carbon monoxide or carbon dioxide in the case of aqueous oxalic and malonic acids. The percentage of carbon monoxide became larger with the decrease of the concentration of maleic acid in the electrolyte. The increase of the side reaction is responsible for it, since the electronic current became predominant over the ionic current with the decrease of the concentration (see Table I) coincident with a trifling growth of the anodic film.

Another important observation was the generation of hydrogen truly collected in the anodic compartment and not leaked from the cathodic compartment. The volume ratio of the hydrogen increased remarkably with the concentration of maleic acid in the electrolyte, coincidently with the increase of ionic current. The generation of hydrogen is induced to accompany the

[2] T_1 is spin-lattice relaxation time. It is indicated by Bloch's equation as follows

$$\frac{dM_z}{dt} - \gamma(M_xH_y - M_yH_x) + \frac{M_z - M_o}{T_1} = 0$$

where M_x, M_y, and M_z are components of magnetic moment, γ is gyromagnetic factor, and H_x, H_y, and H_z are components of magnetic field

[3] Nitrogen is considered from the air leaked in when sampling. The value for oxygen also contain the one for leaked air.

Table II. Composition of anode gases

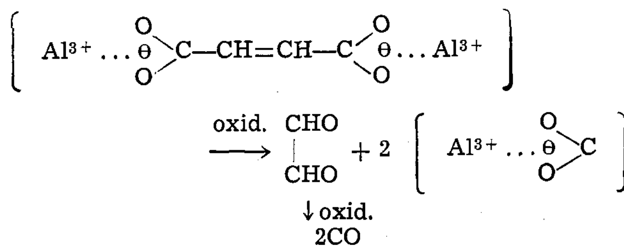
Mole/liter	C.D. (mA/cm^2)	H_2 (%)	CO (%)	O_2 (%)	N_2 (%)
0.2	20	1.5	74.7	11.1	12.7
0.5	20	37.0	41.2	10.0	13.0
1.0	20	45.0	35.0	8.7	11.3

formation of the anodic film. In previous papers (2, 3), the generation of hydrogen has been inferred as due to "anodic reduction" in the following way: providing that aluminum oxidation proceeds by three steps as $Al^{0} \xrightarrow{-e} Al^{+} \xrightarrow{-e} Al^{2+} \xrightarrow{-e} Al^{3+}$ and water can coordinate to the low valency aluminum ions to make aluminum aquo-complexes, intramolecular charge transfer will take place from the aluminum ions to the ligand water, resulting in the production of hydrogen atoms (see Fig. 1).

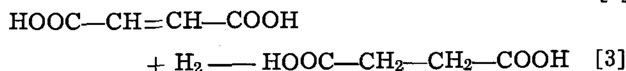
The anodic gases, carbon monoxide, hydrogen, and oxygen,[3] are thought to have arisen from different processes. Carbon monoxide and oxygen[3] are produced by the electrochemical oxidation of maleic acid and water, respectively. Hydrogen is probably produced from "anodic reduction" of ligand water with the low valency aluminum ions.

Formation of aldehyde at the anode.—A water insoluble substance was isolated from the reaction product of used anolyte and 2,4-dinitrophenylhydrazine. The substance was identified as 2,4-dinitrophenylhydrazone of glyoxal from its infrared absorption spectrum and melting point. From the whole precipitate of 78.9 mg, the amount of glyoxal was estimated 10.9 mg for the anodization of the passed charge of 10,000C. While aldehyde formation at an aluminum anode in the case of saturated carboxylic acid has been explained by the "anodic reduction" of the carboxylic acid (2, 3) (Eq. [1]), the glyoxal production is considered due to the oxidation of easily oxidizable —C=C— double bond of maleate (Eq. [2]). Reduction of carboxyl groups to aldehyde does not seem likely in maleic acid electrolyte since the reaction of maleic acid with hydrogen was found favorable to the formation of succinic acid through the analysis of the infrared absorption spectrum of the substance isolated from the used maleic acid catholyte by paper-chromatography (Eq. [3])

$$R\text{—}COOH \xrightarrow{+H} R\text{—}CHO \qquad [1]$$



[2]



$$HOOC\text{—}CH{=}CH\text{—}COOH + H_2 \text{——} HOOC\text{—}CH_2\text{—}CH_2\text{—}COOH \qquad [3]$$

Assuming that the electronic current is one-half of the total current, yield of the glyoxal is only 1.4% for the passed charge of 10,000C. Most of the oxidation product of maleate should be carbon monoxide. The formation of carbon monoxide can not be explained by the reaction of carbon dioxide with hydrogen (Eq. [4]) because the formation of carbon dioxide or Kolbe's reaction (Eq. [5]) did not take place at the aluminum oxide anode

$$CO_2 + H_2 \rightarrow CO + H_2O \qquad [4]$$

$$2R\text{—}COO^- \rightarrow R\text{—}R + 2CO_2 \qquad [5]$$

Vijh has suggested that the greater the bandgap of oxides, the smaller the electronic conductivity and the larger the relative ionic conductivity due to the lack of electronic carrier (7). Aluminum oxides are indeed high bandgap oxides and show relatively higher ionic conductivity than electronic conductivity. In order to transfer electrons from COO^- of maleate to the interior (or conduction band) of the aluminum oxide film across the barrier of the conduction band of the oxide/H.O.M.O. levels of the COO^-, the anodic field should be intensely supplied with external voltage. In such high field, however, Al^{n+} ions can easily migrate from the aluminum substrate towards the surface of the oxide film, resulting in the formation of the anodic film. The —C=C— double bond of maleic acid, of which energy levels are located at the higher state, is considered easily oxidizable at low anodic field.

Conclusions

At the anodization of aluminum in aqueous maleic acid, various *V-t* curves were observed in accordance with the concentration of maleic acid. In case of 1.0 mole/liter, the *V-t* curve increased rapidly up to about 170V resulting in a breakdown of the anodic film. In case of 0.2 mole/liter, the *V-t* curve stayed at about 80V with a violent gas evolution.

Ratios of ionic current against the total current were 0.39 and 0.01 for 1.0 mole/liter and 0.2 mole/liter, respectively.

When the ionic current ratio was 0.39, black anodic film with rough and rugged surface was formed. The anodic film was dissimilar to the ones formed in aqueous oxalic and malonic acids. It was found with infrared absorption spectra that the black anodic film was incorporated with maleate ion in complicated ways, coordinated to Al^{3+}, combined electrostatically with Al^{3+}, and adsorbed on the surface of the anodic film. The blackness of the film was assumed to have come from carboxylate radicals. It should be noticed that hydrogen evolution at the anode accompanied the anodic film formation. The "anodic reduction" is presumably related to the formation of the carboxylate radical.

The oxidation product of maleic acid on the aluminum anodic film was mainly carbon monoxide.

Ionic conductivity of the anodic film is assumed to vary with the amount of maleate incorporated.

A New Voltammetric Stripping Method Applied to the Determination of the Brightener Concentration in Copper Pyrophosphate Plating Baths

Dennis Tench* and Cameron Ogden

Rockwell International, Science Center, Thousand Oaks, California 91360

ABSTRACT

A new voltammetric stripping method for determining the concentration of brightening or leveling additives in plating baths is described. The method is based on the effect that such additives exert on the rate of metal electrodeposition. To determine the latter, the potential of an inert rotating electrode is cycled in the bath, so that a small amount of metal is alternately deposited on the surface and then stripped off, *i.e.*, anodically dissolved. The charge required to strip the copper is related to the deposition rate and, thus, to the concentration of additive in the plating bath. Errors caused by changes in the electrode surface or bath composition are mitigated by using the internal standard provided by the static electrode. Results are reported for the determination of both 2,5-dimercapto-1,3,4-thiadiazole and proprietary brightener PY61-H in copper pyrophosphate baths, for which a precision of about 0.1 ppm (0.1 ml/liter of PY61-H) was attained in the concentration range from 0.0 to 2.5 ppm (0.0-2.0 ml/liter). The effect of bath contamination is also considered and a model is proposed to explain the effectiveness of dimercapto-thiadiazoles as leveling agents.

A key process in the manufacture of multilayer printed circuit boards is the plating of through-hole interconnections, which involves both electroless and electrodeposition methods. When high reliability is required, as in military and space applications, through-holes are usually electroplated from copper pyrophosphate baths (1). An organic additive generally used is proprietary brightener PY61-H (2, 3), whose active ingredient is a dimercaptothiadiazole.

A major difficulty with the plated through-hole process is maintaining constancy of the brightener concentration in the low ppm range necessary to obtain acceptable deposits. Its concentration fluctuates because of oxidation at the anode, reduction and inclusion at the cathode, and chemical reactions. When the brightener level is insufficient, deposits are burnt and powdery, whereas, excess brightener induces brittleness and nonuniform deposition (4). Hull cell and ductility tests, combined with periodic additions of fresh additive, have been the only methods available to maintain a controlled brightener concentration. Since these methods are unreliable, circuit board quality has suffered and rejection rates have been objectionably high. The voltammetric stripping method described here is a new means of monitoring the brightener concentration in copper pyrophosphate baths and the technique should be applicable to other plating systems.

Voltammetric Stripping Method

In performing their functions, brightening and leveling additives affect the rate of metal electrodeposition at a given electrode potential (5) and this effect can be used to determine the concentrations of such additives in plating baths. In the simplest case, the deposition current would simply be followed at a particular cathodic potential, with sufficient solution agitation to maintain an adequate concentration of additive at the electrode. Obtaining and maintaining a reproducible electrode surface, however, are formidable problems, and the latter is complicated at longer deposition times by changes in the surface area of the electrode. In addition, the current measured may include contributions from competing processes like hydrogen evolution and reduction of oxygen and impurities.

Key words: electroplating, copper pyrophosphate, brightener determination, voltammetric stripping analysis.

In the voltammetric stripping method, the potential of an inert electrode (*e.g.*, Pt) is cycled as a function of time, so that a small amount of metal is alternately deposited on the electrode and stripped off by anodic dissolution. This is illustrated in Fig. 1 by the steady-state voltammetry curve for a Pt disk electrode rotated at 2500 rpm and swept continuously at 50 mV/sec between −0.700 and 1.000V *vs.* SCE (saturated calomel electrode) in copper pyrophosphate baths with 1.0 and 2.0 ml/liter of brightener PY61-H added. The electrode rotation maintains an adequate, reproducible concentration of brightener at the electrode surface (6). Deposition of copper occurs between −0.3 and −0.7V for both sweep directions and the copper deposit is removed by oxidation, *i.e.*, stripped, on the anodic sweep between −0.3 and −0.05V *vs.* SCE. The area under the stripping peak corresponds to the charge required to oxidize the copper deposit and is proportional to the average deposition rate for that cycle. Comparison of the peak areas for baths containing 1.0 and 2.0 ml/liter of PY61-H shows that the brightener in this concentration range exerts a strong decelerating effect on the rate of copper deposition. The area of the stripping peak can therefore be related to the concentration of PY61-H in the bath.

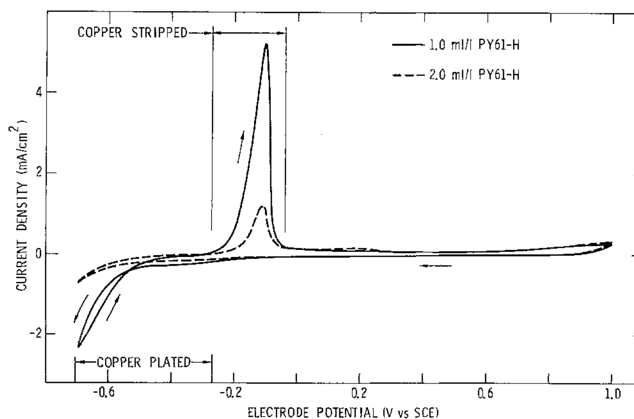

Fig. 1. Steady-state linear sweep cyclic voltammograms at 50 mV/sec for a Pt disk electrode rotating at 2500 rpm in argon-saturated copper pyrophosphate plating baths (22°C) containing 1.0 and 2.0 ml/liter of PY61-H.

Although copper stripping is essentially completed by −0.050V (see Fig. 1), the sweep is extended to 1.000V since this procedure was found to give more reproducible results. This probably relates to the state of oxidation of the Pt electrode surface. The small oxidation peak at 0.2V and the corresponding reduction peak at −0.3V (hardly discernible on the current scale of Fig. 1) presumably indicate a somewhat irreversible oxidation of the Pt surface since they are dependent on the sweep rate, but not the electrode rotation (in the absence of brightener). If the anodic sweep is not extended past the oxidation peak at 0.2V, the surface is slowly reduced on each subsequent sweep and a steady state for the stripping peak is not attained even after 20-30 cycles. The extended anodic sweep probably maintains the state of oxidation of the Pt surface at a steady-state level. In addition, the small current plateau beginning at 0.8V presumably results from brightener oxidation since it is only observed in solutions containing PY61-H. Thus, another beneficial effect of the more anodic sweeps may be removal of accumulated brightener on the electrode surface. Since this plateau depends only slightly on electrode rotation rate or brightener concentration in the range of interest, the oxidation of brightener is kinetically controlled and cannot itself be used as an indication of PY61-H level.

When brightener breakdown products are present in the bath, they oxidize in the same potential region as the brightener, producing a well-defined current plateau. A plot of the current on this plateau *vs.* the square root of the rotation rate is linear but does not pass through the origin. This indicates some kinetic limitation. Thus, the current in this potential region can be used as an indication of the bath purity, but the proportionality to the concentration of breakdown products will not be unity. As will be shown later, bath impurities and breakdown products of the brightener also seem to interfere somewhat with its functioning, but the voltammetric method yields an effective concentration, which can be used directly to adjust the additive level of the bath.

Experimental Details

Unless otherwise noted, measurements were made at room temperature in electrolytes prepared from plating bath concentrates C10XB, C11XB, and PY61-H obtained from M&T Chemicals Inc. Baths typically had a pH of 8.3 and contained 22.5 g/liter Cu^{++}, 173 g/liter $(P_2O_7)^{-4}$, and 2.25 g/liter NH_3. Argon gas was always bubbled through the solution via a glass frit for at least 15 min before making measurements. The controlled-atmosphere cell was Pyrex glass with a Teflon top and had a volume of 100 ml. The Pt-40% Rh counterelectrode and commercial SCE were dipped directly in the cell. Although no Luggin capillary was used, ohmic losses should be negligible considering the concentrated electrolyte and current levels involved.

The indicator electrode was a 99.95% Pt disk (The Wilkinson Company) of 0.13 cm^2, which was mounted concentric and flush with the end of a 12 mm diam Kel-F cylinder by compression molding at elevated temperature. After mounting, the electrode was polished on successively finer aqueous alumina powder slurries to 0.05 μm particle size and then was cycled at 50 mV/sec from −0.700 to 1.000V *vs.* SCE in the argon-saturated plating bath without brightener until a steady-state voltammogram was obtained. Subsequently, the electrode was always stored in the copper pyrophosphate solution without brightener.

The indicator electrode potential was controlled, relative to the SCE reference, with a PAR (Princeton Applied Research Corporation) Model 173 potentiostat/galvanostat in conjunction with a PAR Model 175 Universal programmer. Anodic current peaks were integrated electronically to −0.05V *vs.* SCE using a PAR Model 179 digital coulometer. For the data reported, the sweep rate was always 50 mV/sec and the sweep limits were −0.700 and 1.000V *vs.* SCE. At faster sweep rates the stripping peaks were broader and less reproducible, whereas slower sweeps were unnecessarily time consuming. Sweeps to a more cathodic limit than −0.7V resulted in broader stripping peaks and a loss in brightener sensitivity, possibly because of mass transport limitations at the higher current densities.

To achieve maximum sensitivity, the electrode rotation must be sufficiently fast to maintain an adequate supply of brightener at the electrode surface. The effect of rotation rate (ω) on the integrated peak area (A_r) is shown in Fig. 2 for a previously heat-treated bath (16 hr at 50°C) containing 2.0 ml/liter of PY61-H concentrate. At lower rotation rates, the brightener becomes depleted at the surface and exerts an accelerating effect on the deposition rate. With faster electrode rotation, the brightener surface concentration approaches the bulk solution value and decelerates the deposition rate, producing the observed peak. At the PY61-H concentration used here (2.0 ml/liter), further deceleration above 2500 rpm is small. For convenience, this value for the electrode rotation rate was used for all data reported here, but a faster rotation rate might prove advantageous, especially at lower brightener concentrations.

Care must be exercised in preparing brightener standard solutions from PY61-H concentrate. For freshly prepared baths, the brightener activity at room temperature is very low, but increases over a period of several hours upon heating at 50°C. This is illustrated in Fig. 3, which shows the stripping peak area at 2500 rpm and room temperature as a function of heating time at 50° ± 2°C before quenching of a copper pyrophosphate bath containing 2.0 ml/liter of PY61-H concentrate. The heating may be necessary to depolymerize the brightener to an active form or promote formation of a complex species. In any case, other bath constituents are involved in the activation process since heating PY61-H alone, or solutions of 2,5-dimercapto-1,3,4-thiadiazole, does not produce active brightener. At room temperature, activated solutions slowly lose activity, possibly because of repolymerization or chemical degradation. To minimize errors, standards were

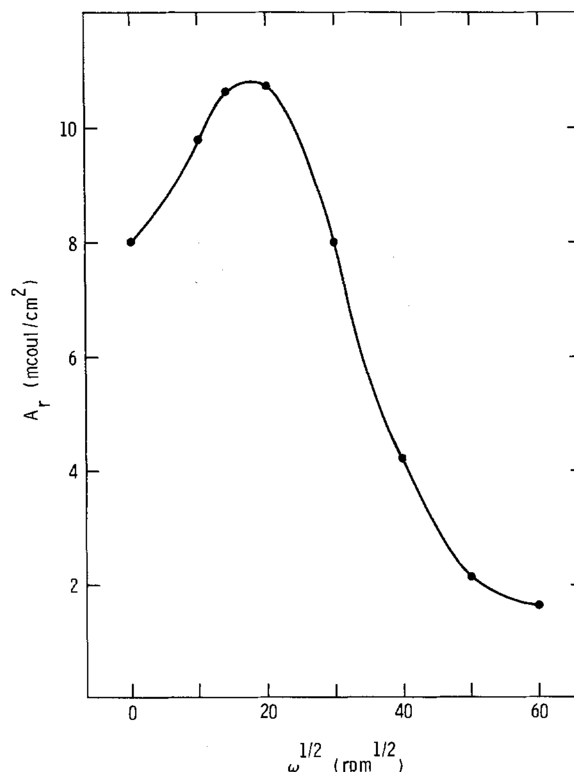

Fig. 2. Effect of rotation rate (ω) on the steady-state Cu stripping peak area (A_r) for a Pt disk electrode cycled at 5 mV/sec between −0.700 and 1.000V *vs.* SCE in an argon-saturated copper pyrophosphate bath (22°C) containing 2.0 ml/liter of PY61-H.

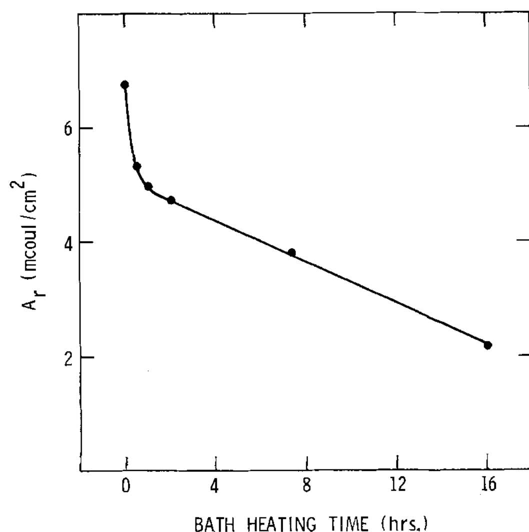

Fig. 3. Effect of bath heating time at 50° ± 2°C on the steady-state Cu stripping peak area (A_r) for a rotating Pt disk electrode (2500 rpm) cycled at 50 mV/sec between −0.700 and 1.000V vs. SCE in argon-saturated copper pyrophosphate baths (22°C) containing 2.0 ml/liter PY61-H.

always heat-treated at 50° ± 2°C for 16 hr and run at room temperature (22°C) within a few hours of preparation.

To generate standard curves, steady-state stripping peak areas were determined with electrode rotation at both 2500 rpm (A_r) and 0 rpm (A_s) for a series of baths containing (*i*) no brightener, (*ii*) a standard amount, and (*iii*) 1.0 ml/liter of PY61-H. After immersing the rotating electrode in the bath or after stopping rotation, steady-state voltammograms were usually obtained after 3-5 cycles.

Results and Discussion

A plot of the Cu stripping peak area at 2500 rpm (A_r) *vs.* the brightener concentration is shown in Fig. 4. There is considerable scatter in the data which seems to result from changes in the electrode surface from experiment to experiment. Such variations can be mitigated by measuring a fixed standard immediately before or after each data point and plotting the ratio. This is shown in Fig. 5 for a rotation rate of 2500 rpm and a fixed standard of 1.0 ml/liter. From 0.6 to 2.0 ml/liter of PY61-H, which covers the actual operating range, the curve is practically linear. Reproducibility is illustrated by the dual data points which show that a precision of about 0.1 ml/liter can be attained at PY61-H concentrations between about 1.0 and 2.0 ml/liter. Some error in the PY61-H determination results from the dependence of $A_r(x)$ on the bath composition. Variations in the NH_3 concentration over the range 1.12-2.81 g/liter were found to introduce a maximum error in the measured brightener concentration of 20% for a bath containing 1.0 ml/liter of PY61-H. The corresponding maximum error for $(P_2O_7)^{-4}$ variations over the concentration range 164-190 g/liter was also 20%. Since these bath fluctuations would represent extremes, these errors are not too serious.

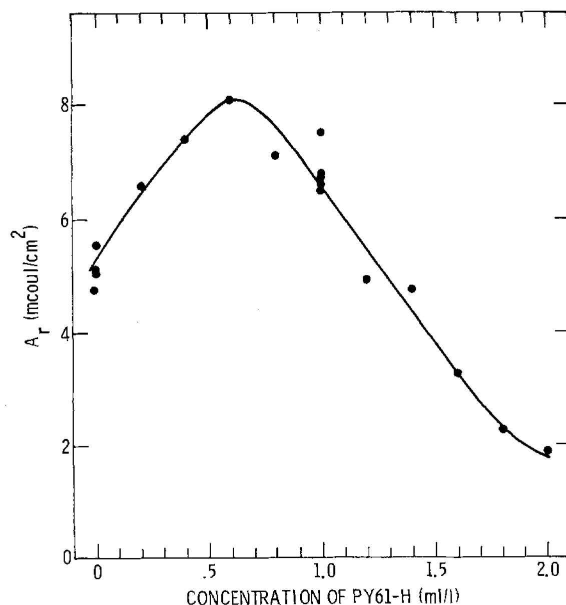

Fig. 4. Dependence of the Cu stripping peak area (A_r) on PY61-H concentration (other conditions always the same as for Fig. 1).

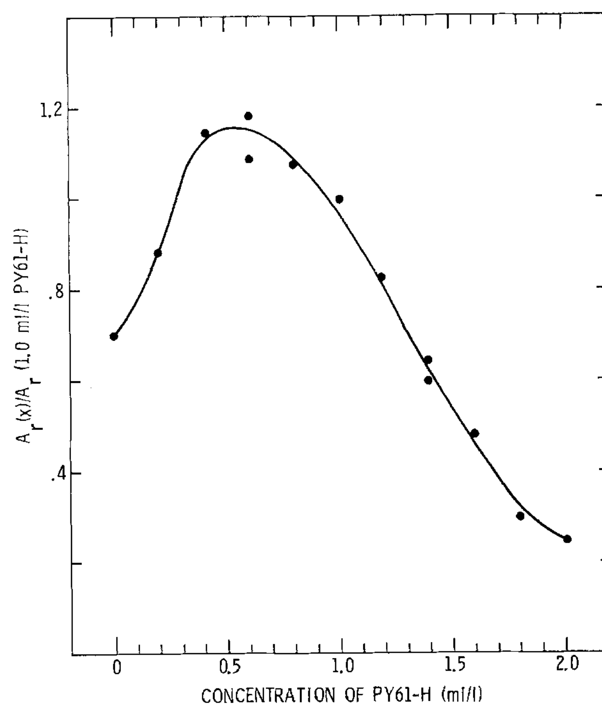

Fig. 5. Brightener concentration dependence of the ratio of the Cu stripping peak area for a given PY61-H concentration [$A_r(x)$] to that for a 1.0 ml/liter standard [A_r(1.0 ml/liter PY61-H)] determined immediately after each $A_r(x)$ measurement (other conditions always the same as for Fig. 1).

Variations in A_r caused by changes in the electrode surface can more conveniently be mitigated by using the internal standard provided by the static electrode in the same bath. When the electrode rotation is stopped, the concentration of brightener at the surface decreases with continued potential cycling until a small steady-state level, determined by diffusion, is established. Steady-state curves with and without electrode rotation are shown in Fig. 6. The larger static peak area (A_s), corresponding to nearly zero brightener concentration at the electrode, can be used as an internal standard. A plot of A_r/A_s *vs.* brightener concentration is shown in Fig. 7. The reproducibility is somewhat better than that obtained using the 1.0 ml/liter fixed external standard, so that a precision of 0.1 ml/liter is attained even at the lower PY61-H concentrations.

As would be expected, the use of the static electrode as an internal standard also tends to lessen the effects of changes in bath composition. Percent variations in the measured A_r/A_s values and the corresponding percent error in the brightener determination are shown in Table I for the maximum variations in both parameters expected for copper pyrophosphate baths. The percent errors are seen to be usually small (<10%). It should also be mentioned that errors introduced by *p*H fluctuations from 8.0 to 8.5 are small (<10%), but become appreciable at significantly higher *p*H values. This is not a serious problem since *p*H can be easily adjusted. These effects produced by variations in the bath com-

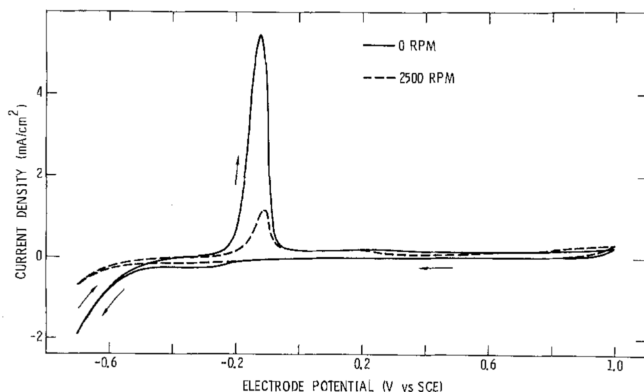

Fig. 6. Steady-state linear sweep cyclic voltammograms at 50 mV/sec for a Pt disk electrode rotating at 0 and 2500 rpm in an argon-saturated copper pyrophosphate plating bath (22°C) containing 2.0 ml/liter of PY61-H.

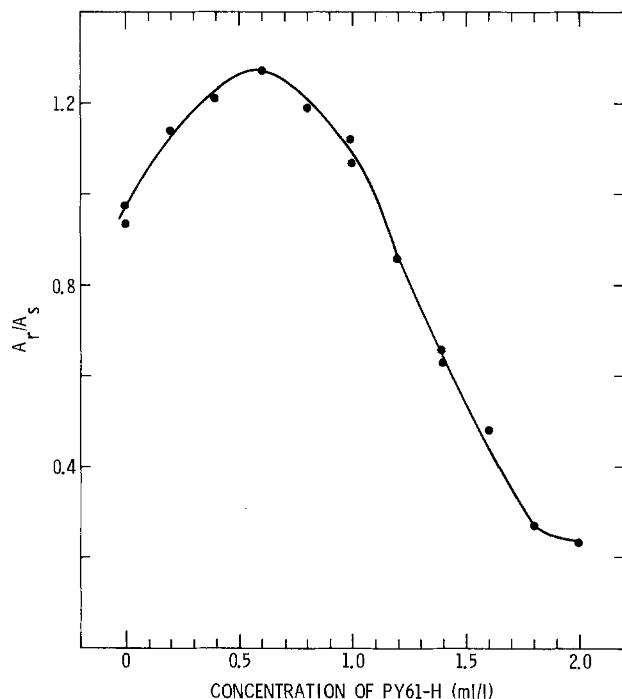

Fig. 7. Dependence of the ratio of the Cu stripping peak area with (A_r) and without (A_s) electrode rotation on the concentration of PY61-H (other conditions always the same as for Fig. 6).

position may to some extent reflect changes in the effective brightener concentration.

As was indicated by the variation in A_r with rotation rate, the brightener is seen to accelerate deposition at lower concentrations while decelerating it at higher levels. This results in a peak in the standard curves, so that two concentrations correspond to the same A_r or ratio value. The correct concentration can be determined, however, since the voltammetry peak is shifted cathodically by as much as 50 mV for brightener concentrations less than about 0.5 ml/liter.

Table I. Changes in A_r/A_s and the corresponding error in PY61-H concentration at 1.0 ml/liter resulting from variations in the copper pyrophosphate bath composition

Bath variation		Change in A_r/A_s (%)	Corresponding error in PY61-H concentration (%)
Low NH_3	(1.13 g/liter)	−19.5	20.0
Low NH_3	(1.69 g/liter)	9.2	−10.0
High NH_3	(2.81 g/liter)	0.4	0.0
Low $(P_2O_7)^{-4}$	(164 g/liter)	−3.1	3.0
High $(P_2O_7)^{-4}$	(181 g/liter)	−1.7	2.0
High $(P_2O_7)^{-4}$	(190 g/liter)	−4.5	5.0

All of the results reported here were obtained using standards prepared from the same batch of PY61-H, but for four other batches tested the effective concentrations of brightener measured by the voltammetric stripping method were 30-70% smaller. These variations could reflect aging effects or actual differences in the concentrations or properties of the brightener concentrates obtained from the supplier.

To provide a better defined reference, standard brightener solutions were prepared using 2,5-dimercapto-1,3,4-thiadiazole (Aldrich Chemical Company, Incorporated). The solid was first dissolved in 6*N* KOH which was then diluted 3:1 with water before addition to freshly prepared copper pyrophosphate plating solution. Before use, samples were heat-treated as described earlier (50° ± 2°C for 16 hr). Standard curves of A_r/A_s *vs.* concentration of solid brightener are shown in Fig. 8 for both freshly prepared and contaminated baths. For the freshly prepared bath, the pure 2,5-dimercapto-1,3,4-thiadiazole is seen to accelerate the Cu electrodeposition rate at the lower concentrations to a greater extent than PY61-H, but above 1.3 ppm a constant relationship obtains such that the incremental effect on the electrodeposition rate of 0.12-0.14 ppm of the pure compound is equivalent to 0.1 ml/liter of the proprietary additive. Based on a few data points, the pure brightener seems also to reach its maximum effective concentration more quickly, after only about 4 hr at 50°C.

To investigate the effect of bath contaminants on the voltammetric stripping analysis, standards were prepared by addition of 2,5-dimercapto-1,3,4-thiadiazole to samples of a production bath which had been used to plate circuit board through-holes for several years and had then stood at room temperature for several weeks to allow residual brightener to decompose. The procedure used was the same as that described in the preceding paragraph. A relatively large level of bath contamination was apparent from the voltammetric curves which, for electrode rotation of 2500 rpm, ex-

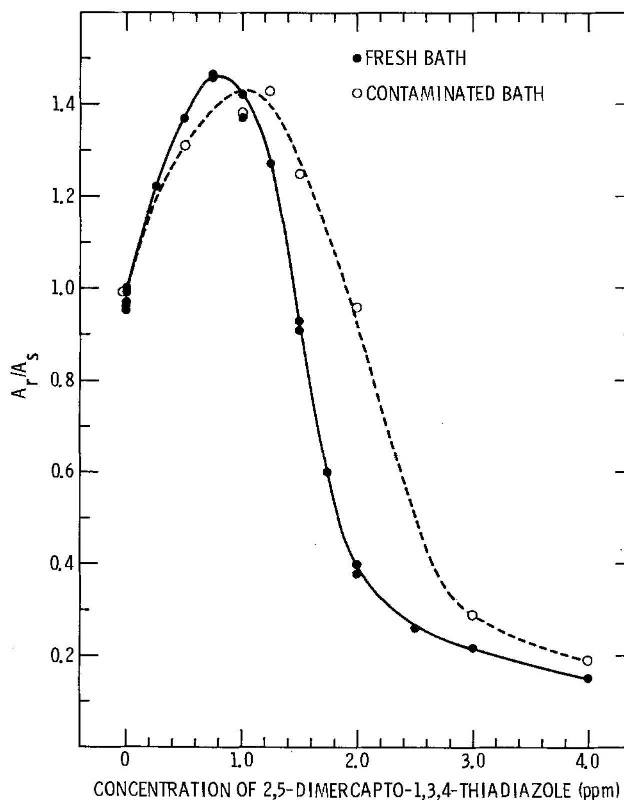

Fig. 8. Dependence of the ratio of the Cu stripping peak area with (A_r) and without (A_s) electrode rotation on the concentration of 2,5-dimercapto-1, 3, 4-thiadiazole in freshly prepared and contaminated copper pyrophosphate baths (other conditions always the same as for Fig. 6).

hibited anodic current plateaus of 26 mA/cm^2 in the potential range from 0.8 to 1.0V *vs.* SCE. Contaminants are expected to include brightener breakdown products, residues from photoresist and solvents used in circuit development, oils from pumps and drilling equipment, epoxy laminant residues, substances leached from plating tanks and other cell components, and airborne impurities.

A plot of the A_r/A_s ratio *vs.* concentration of pure solid brightener added to the contaminated bath is also shown in Fig. 8. By comparison with the curve for the freshly prepared bath, it is evident that the contaminants interfere somewhat with the functioning of the brightener, diminishing the decelerating effect which the latter exerts on the electrodeposition rate. For additive levels of more than 1.5 ppm, the effective concentration of the brightener is reduced by a constant amount of 0.6 ppm for this degree of contamination, which represents an extreme. It should be mentioned that proper conditioning of the Pt electrode is even more important when bath impurities are present. To obtain reproducible voltammetric stripping results, the electrode must be conditioned after polishing by potential cycling in a clean bath with no brightener before being introduced into contaminated baths.

The voltammetric stripping data reported here are for argon-saturated baths at 22°C, but similar results are obtained at 55°C in air-saturated solutions, which represent normal production conditions. Thus, the technique should be applicable to on-line monitoring. At 55°C, the cross-over point between the accelerating and decelerating effect of PY61-H occurs at lower concentrations compared to that at 22°C. Thus, at some concentrations the brightener will exert an accelerating effect on the electrodeposition rate at room temperature, but a decelerating effect under operating conditions. The opposite of the last two statements is observed for 2,5-dimercapto-1,3,4-thiadiazole.

As a side issue, the present results, establishing the dual accelerating-decelerating effects of the brightener, provide the basis for understanding why the dimercaptothiadiazoles are so effective in inducing uniform deposition of copper (leveling). In actual circuit board plating, freshly prepared baths generally contain 2.0 ml/liter of PY61-H, so that the bulk brightener concentration presumably exerts a decelerating effect on the electrodeposition rate. Thus, as brightener is depleted at the electrode by inclusion in the deposit, its concentration at micro and macro peaks on the electrode remains sufficient to inhibit deposition, as long as solution agitation and bulk brightener level are adequate. At the same time, because of reduced solution agitation in recesses, the brightener concentration becomes sufficiently depleted that acceleration of deposition occurs. Hence, peaks are plated more slowly than without brightener and recesses are plated more rapidly, so that very efficient leveling results. Of course, either acceleration or deceleration alone would also level the deposit, but the two operating together should be most effective.

Conclusions

The voltammetric stripping method described in this paper is a sensitive means for determining the concentration of brightener additive in copper pyrophosphate plating baths. For the greatest precision, measurements of the steady-state Cu stripping peak areas for a Pt disk electrode should be made with and without electrode rotation. This permits the effects of changes in the electrode surface and bath composition to be minimized by using the ratio of the two measurements to determine the brightener concentration. With this ratio technique, a precision of about 0.1 ppm can be attained in the concentration range from 0.0 to 2.5 ppm of 2,5-dimercapto-1,3,4-thiadiazole. The voltammetric stripping method should also be applicable to the determination of brightening and leveling additives in other plating systems.

This voltammetric technique has the advantage over conventional analytical methods of yielding a parameter (A_r or A_r/A_s) which reflects the effectiveness of the additive in performing its function, rather than simply an absolute concentration. Thus, the effects of breakdown products or impurities which interfere with the functioning of the addition agent can automatically be taken into account. Also, inactive forms of the additive which are chemically similar, such as polymers and breakdown products, are not measured with the voltammetric stripping method.

A Mechanism for the Effect of Heat-Treatment on the Accelerated Corrosion of Zircaloy-4 in High Temperature, High Pressure Steam

A. W. Urquhart,* D. A. Vermilyea,* and W. A. Rocco

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Potential differences which develop across growing oxide films and effects of applied electric fields on oxide growth have been measured on specimens of Zircaloy-4 corroding in high temperature, high pressure steam. From these results it is concluded that the accelerated corrosion process observed in this environment is associated with the development of metal-negative potential differences across the oxide (analogous to potential differences associated with cathodic polarization in aqueous corrosion). Initiation of this form of attack is inhibited on suitably heat-treated material because the relatively high effective electronic conductivity of the oxide film growing on this material shifts these potential differences toward the metal-positive direction. The effect of alloy heat-treatment on the oxide conduction characteristics is explained in terms of the microstructure of the metal, and it is suggested that hydrogen absorption into the oxide under metal-negative potential differences leads to initiation of the accelerated attack.

In a previous publication (1) it was noted that the accelerated corrosion of Zircaloy[1] in high temperature, high pressure steam may correlate with an accelerated corrosion process found during exposure in a neutron flux in oxygenated water. While this correlation is not established on the strength of existing in-reactor data, it was suggested (1) that studies of the mechanism of accelerated corrosion in 500°C, 1500 psi steam may be useful. This paper reports some of the results of such a study.

The accelerated corrosion process that occurs in high temperature, high pressure steam (*e.g.*, 500°C, 1500 psi) has been described previously (1-4). The phenomenon involves the nucleation of a relatively nonprotective oxide which grows at a much faster rate than would be expected for the normal linear (post-transition) oxidation kinetics of Zircaloy at 500°C, as measured in other environments such as low pressure steam or oxygen. It has also been observed that the resistance of Zircaloy to this accelerated corrosion phenomenon is very dependent on the heat-treatment of the alloy. Specifically, heat-treatments in the β-phase field followed by reasonably rapid cooling to room temperature provide greatly improved resistance to accelerated steam corrosion. In fact, data from Ref. (3), when plotted to reveal the corrosion kinetics, indicate that β heat-treated Zircaloy in 500°C, 1500 psi steam follows approximately the normal oxidation processes expected from other 500°C tests. The purpose of this research is to gain some insight into the mechanisms which result in the nucleation of a fast-growing, nonprotective oxide film in high temperature, high pressure steam tests and to clarify the reasons for the beneficial effects of β heat-treatments on corrosion resistance.

This paper presents evidence that initiation of the accelerated corrosion process is associated with the development of potential differences across the initially protective oxide barrier film in the metal (zirconium) negative direction, as measured with an electronically conducting electrode on the oxide surface. These potential differences are assumed to be associated with anion diffusion potentials which arise naturally when the effective ionic conductivity of the oxide is comparable to or greater than the electronic conductivity. The possible effect of proton currents on these diffusion potentials is ignored as a first approximation.

Metal negative potential differences across the oxide do not lead to accelerated corrosion by direct enhancement of anion transport in a barrier-type oxide, since the resulting electric fields actually oppose this process. Rather, the accelerated corrosion phenomenon is associated with some sort of disruption of the barrier film giving a loss of protectiveness due to porosity or other damage to the oxide. It will be argued that this results from proton migration into the oxide when the electric fields are favorable to this process.

Thus, the present experimental work is primarily concerned with measurements of the open-circuit potential differences across growing oxide films, correlation of the results with susceptibility of the material to accelerated corrosion, and observation of the effects of applied potential differences on corrosion rates.

Experimental Procedure

The test environment of 500°C, 1500 psi steam was produced in a one liter stainless steel autoclave connected to a flowing water loop. The replenishment rate was 5-10 cm^3/min of degassed, deionized water. Corrosion test samples for weight gain measurements were supported on stainless steel hooks; separate experiments have shown that insulating the specimens from the autoclave structure does not affect the results, as might be expected from the low conductivity of the steam environment and the tendency of the samples to become isolated from the support hooks by the growing oxide films. During start-up the samples were initially covered with water which was boiled away at atmospheric pressure to degas the autoclave. The desired test pressure was established at ~350°-400°C during the heat-up process. For comparison purposes, some testing was also done in the same apparatus using pure oxygen gas at 500°C and 1500 psi.

Because the steam phase is a poor conductor under the specified test conditions, it is necessary to make contact directly with the surface of the oxide film for electrical measurements. Sputtered platinum electrode spots were used for this purpose. One contact was made by spot-welding a Pt lead directly to the specimen while mechanical contact was made to the electrode

[1] Two Zircaloy compositions are of practical interest. The experimental work in this paper was performed with Zircaloy-4 which contains nominally 1.5% tin, 0.2% iron, and 0.1% chromium (by weight) in addition to zirconium. Zircaloy-2 is a similar zirconium alloy, containing 1.5% tin, 0.15% iron, 0.1% chromium, and 0.05% nickel. The latter alloy is somewhat more resistant to accelerated corrosion in steam, but it responds to heat-treatment similarly to Zircaloy-4.

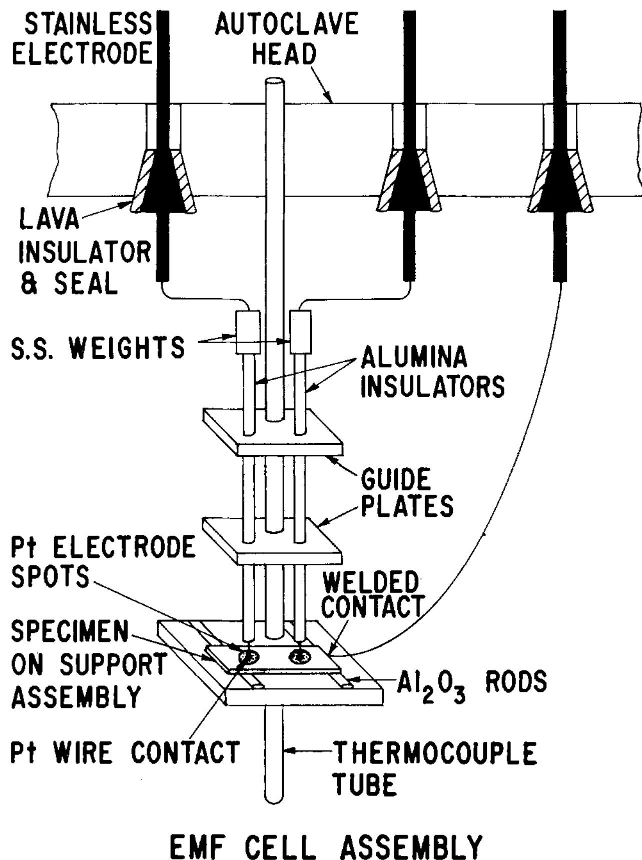

Fig. 1. Electrode arrangement for open-circuit potential measurements and experiments on the effects of applied potential differences.

spots with contact forces maintained by weights of 5-9g. This arrangement is illustrated in Fig. 1. Each specimen contained two independent Pt spots which were ~6 mm in diameter and ~150Å thick. At this thickness the platinum is both electrically continuous and permeable, such that oxidation of the underlying metal is not prevented by lack of access of the oxidant.

It should be noted that electronically conducting potential probes measure only the difference in the electrochemical potential for electrons across the oxide. The actual electric fields in the oxide are related to these observed potential differences through contact potentials which are in general unknown but are assumed to be constant. Thus, the experimental observations are limited to relative changes in the potential differences in one direction or the other for different cases, without attempting to specify the actual field in the oxide. A review of these techniques with references to the original literature has been given by Kröger (5).

An important concern is the possibility that the Pt electrodes may not be reversible with respect to the charge transfer reactions occurring on the surface of the oxide. If reversibility is not achieved, then reaction overpotentials will tend to reduce both the observed open-circuit potential differences and the extent to which applied potential differences actually appear across the oxide. Literature data (5) suggest that the test temperature of 500°C may be marginal for platinum electrode reversibility, although in the present experiments it was found that observed open-circuit potential differences were rapidly regained following a deliberate perturbation. In the absence of definitive information on this point, it will be assumed only that comparisons between observations from different specimens provide indications of differences in the relative balance between effective ionic and electronic conductivities; no quantitative interpretation will be attempted. Some other possible effects of the electrodes which might influence the interpretation of the test results are discussed in later sections.

All specimens were pickled in the usual H_2O-HNO_3-HF pickling solution prior to application of electrodes or autoclave testing. In one case the specimen was preoxidized prior to electrode sputtering.

The potentials developed across the growing oxide were monitored using Keithley 602 electrometers with a high input impedance. The specimen resistance was measured in an approximate way by periodically adding in shunt resistors across the electrometer input and observing the resistance at which the specimen potential was reduced appreciably. It was sometimes found that the parallel resistance of the electrode feedthrough insulation in the autoclave head (~50,000Ω) was limiting, and it will be noted below when the data may have been affected. In some experiments a d-c power supply was used to impose potentials from the electrode spots to the zirconium metal to determine the influence of applied electric fields.

All of the experiments were carried out with specimens cut from the same piece of Zircaloy-4 strip. The metallurgical condition of the starting material is the result of a conventional process involving β-quenching at the large forging stage with subsequent hot working in the α-phase field and final coldworking with intermediate and final anneals at 732°C (1350°F), also in the α-field. This metallurgical condition is referred to below as the starting material or initial material. Pieces of this material were also given further heat-treatments at several temperatures as listed in Table I. These treatments involved 15 min exposures at temperature under vacuum with cooling in helium to produce an estimated cooling rate of ~10°C/sec.

The heat-treated material used in evaluating the effects of applied electric fields was given a β-phase treatment at 1020°C followed by relatively slow cooling. This was accomplished by heating the specimens in evacuated capsules which were immersed intact in cold water after the heat-treatment. The resulting relatively coarse structure provided reasonably good protection (weight gain of 69 mg/dm²) in a 24 hr test in 500°C, 1500 psi steam. However, some small nodules of thicker oxide were found on the wider lamellae of the Widmanstätten structure. This material condition of intermediate corrosion resistance was selected in order to allow observation of either favorable or unfavorable response to applied electric fields.

Results

Corrosion weight gains.—Table I illustrates the influence of various heat-treatment temperatures on the weight gains of Zircaloy-4 specimens after 24 hr in 500°C, 1500 psi steam. These results are entirely consistent with earlier work in which it was noted that heat-treatments in the β-phase field followed by reasonably rapid cooling produce a substantial improvement in the resistance of the material to accelerated corrosion in steam (2-4). In fact, these heat-treatments reduced the weight gains from ~3000 to <50 mg/dm². As discussed above, the large weight gains found on the starting material (or after α-phase annealing) correspond to a much more rapid corrosion process than would be expected for the normal oxidation of Zircaloy at 500°C, based on measurements in other environments such as low pressure steam or oxygen. Other tests have shown that all of the material conditions listed in Table I show good corrosion resistance at lower temperatures, such as 400°C, 1500 psi steam.

Table I. Effect of heat-treatment on corrosion weight gains

(24 hr in 500°C, 1500 psi steam)

Heat-treatment temperature (°C)	Weight gain (mg/dm²)
Starting material	2930
600	2830
700	2550
1000	47
1050	49

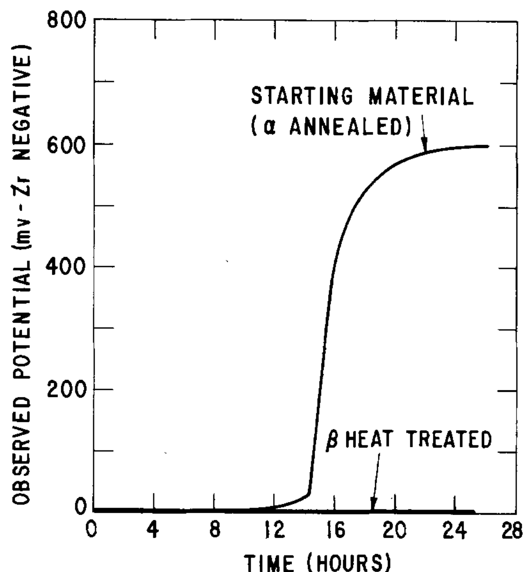

Fig. 2. Potential differences observed across oxide films growing in steam at 500°C, 1500 psi. Potentials for which the Zircaloy becomes negative relative to the oxide surface are plotted as positive along the potential difference axis.

Potential difference measurements.—Figure 2 shows typical results obtained by monitoring the potential differences which develop across the growing oxide films. On the starting material one initially finds low potential differences which, after several hours, increase quite rapidly to about 600-700 mV (Zr negative). During this time the resistance of the oxide is also increasing, and at the final potential the results may be limited by the insulation resistance of the electrode feed throughs. Thus, it can be concluded that significant potentials develop across the oxide on the starting material, but that the final measured potential values may be lower than the actual values by some unknown amount.

For the heat-treated materials the observed potentials never exceed a few millivolts, and in this case the oxide resistance was always very much less than the feed-through resistance. These potential values are therefore considered to be reasonably accurate.

The experiments reported in Fig. 2 have been repeated several times with very reproducible results. Varying the probe contact force from 5 to 9g did not affect the results, and exposure of a specimen of the starting material with electrode spots for 6 hr prior to establishing the mechanical contact produced the same values of potential difference *vs.* total oxidation time as given in Fig. 2. In addition, potential measurements on a heat-treated specimen which had been preoxidized in the test environment for 24 hr prior to application of the sputtered electrodes resulted in low measured potential differences comparable to those found on similar specimens oxidized with the Pt electrode spots present from the outset. These observations tend to suggest that the results given in Fig. 2 do not depend on mechanical damage to the oxide by the contact probe or on the continuous presence of the Pt layer possibly inhibiting some step in the initial oxidation process.

However, it is clear that the presence of the electrodes does influence the oxidation process under open-circuit conditions. Thus, by metallography it has been found that the thick oxide (~250 μm) which normally forms on the starting material during a one-day test has been suppressed under the open-circuit electrodes; here one finds only a relatively uniform oxide ~3 μm thick. For the β heat-treated material there is little difference between the oxide thicknesses (also ~3 μm) found with and without electrodes on the surface, although even in this case the oxidation process may be more uniform under the electrode material as previously suggested by Cox (6). These observations are interpreted in a later section. For the present it is noted that all of the potential difference measurements were obtained across thin, barrier-type oxide films, and it is suggested below that these values are indicative of differences in the relative ionic and electronic conduction characteristics of the thin oxides which form initially and which control the initiation of the accelerated corrosion process.

Effect of applied potential differences.—Since the accelerated corrosion process is being correlated with the occurrence of metal-negative potential differences across the oxide film, it should be possible to apply an external potential source to induce the accelerated attack process where it otherwise would not occur. This has in fact been accomplished in the experiments summarized in Fig. 3, where it is found that applied potential differences in the Zr-negative direction are harmful, while smaller Zr-negative or Zr-positive potentials are beneficial. The oxide thickness data given in Fig. 3 were obtained by metallographic examination of the oxide formed directly under the electrode spot.

Similar experiments were also done in pure oxygen gas at 500°C and 1500 psi. In this case no accelerated corrosion was observed even under large applied potential differences; the resulting oxide films were estimated at about 3 μm in thickness. Trowse *et al.* (7) have also reported that accelerated corrosion does not occur in high temperature, high pressure oxygen.

The currents associated with the applied voltages were monitored during each of these tests. The initial currents were found to be quite high (as much as 350 mA/cm^2), and it was initially thought that high local currents might be causing disruption of the oxide and initiating an enhanced corrosion process. However, this seems rather unlikely, since comparable currents were passed during the application of potential differences in both directions and in oxygen as well as steam, while accelerated corrosion was found only in steam under Zr-negative potentials. In addition, in one experiment the potential difference was not applied for several hours after test initiation. In this case accelerated corrosion was still observed, despite the passage of very much smaller currents (maximum of ~15 mA/cm^2) due to the growth of a more resistive oxide prior to applying the voltage.

Discussion

The open-circuit potential difference measurements (Fig. 2) indicate that the starting material tends to develop a large metal-negative potential drop across the oxide; this material is highly susceptible to accelerated corrosion. The heat-treated material shows very small potential differences and is resistant to accelerated at-

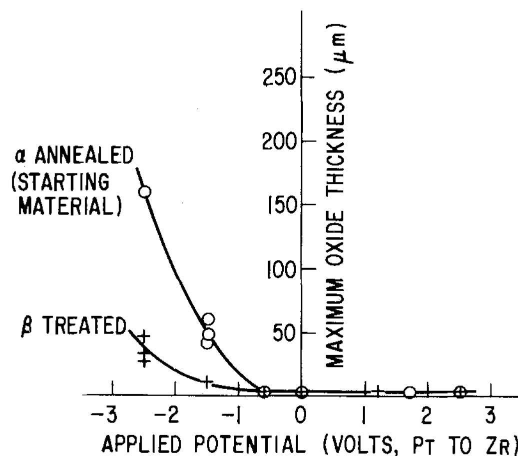

Fig. 3. Effect of applied potential differences on the maximum oxide thickness measured under the electrodes. For comparison, it is noted that away from the electrodes, the maximum oxide thicknesses observed were 220 μm on the starting material and ~10 μm on heat-treated specimens. Further details on the metallurgical condition of these specimens are given in the text.

tack. Furthermore, the accelerated corrosion process can be induced or inhibited by artificially imposing external potentials, with large Zr-negative potentials leading to accelerated attack and smaller negative or positive potential differences inhibiting it. Taken together, these results provide good support for a model in which accelerated corrosion is prevented on suitably heat-treated Zircaloy by a shift in the potential difference across the oxide toward the metal-positive direction. This results from the relatively good electronic conductivity of oxides growing on the heat-treated material.

The oxide conductivity characteristics observed with different heat-treatments can be rationalized in terms of the effect of heat-treatment on the microstructure of the alloy. Since there is evidence (8) that intermetallic precipitates in the Zircaloy provide sites for electron transport through the zirconium oxide, it is suggested that the distribution of these particles is the critical parameter. As shown in Fig. 4a, the starting material contains a random array of intermetallic particles distributed throughout the α-zirconium matrix. In the heat-treated condition, Fig. 4b, the particles tend to form two-dimensional networks along grain boundaries or subgrain boundaries, again in an α-zirconium matrix.

A possible model for the effect of these particle distributions on electron conduction through the oxide is shown schematically in Fig. 5. On the starting material, intermetallic particles initially provide adequate sites for electron transport through the oxide (Fig. 5a). One would therefore expect to observe during initial film growth the relatively low film resistance and small potential drops that are displayed in Fig. 2. At a later stage (Fig. 5b), after growing an oxide which is thicker by some amount than the larger intermetallic precipitates, the particles tend to become isolated by the growing oxide and insulated from the underlying metal. Under these conditions the oxide resistance should increase and the potential drop across the oxide should drift in the metal negative direction, as is indeed observed after about 15 hr. At this time the average oxide thickness is about 2 μm, which compares reasonably well with the size of the intermetallic particles (as much as about 1 μm in diameter).

On heat-treated material the intermetallic particles tend to be quite closely spaced along grain boundaries, and Fig. 5c is intended to suggest that in this case the particles never become insulated from either the metal or the oxide surface. In this case, both the oxide resistance and the observed potential differences should remain low indefinitely as was found experimentally (Fig. 2). This argument assumes that the precipitates, identified as $Zr(Fe, Cr)_2$ in Zircaloy-4 (9, 10), remain reasonably conductive even when oxidized (8), a point requiring further confirmation. In addition, observations at higher resolution by transmission electron microscopy (11) show that the precipitates are not actually in contact, and it must therefore be argued that the few hundred angstroms of ZrO_2 which may form between the particles is also a relatively good electron conductor due to doping effects from the nearby particles. Nevertheless, it is suggested that the microstructural changes produced by the heat-treatment process may provide a quite natural explanation for the effect of heat-treatment on the observed potentials and on the improved resistance of heat-treated Zircaloy to accelerated corrosion in steam.

It was noted above that the Pt electrode spots are permeable, and this point is confirmed by the occurrence of accelerated corrosion under the electrodes when suitable potential differences are applied. Nevertheless, in the absence of applied voltages the electrodes do tend to inhibit the accelerated corrosion process. This is believed to result from the imposition of an equipotential on the oxide surface due to the high conductivity of the sputtered platinum. In the absence of an electrode, it is suggested that surface iR potential drops can result in increased metal-negative potential differences as one moves along the surface away from localized sites for electron conduction through the oxide. With no electrode these high local potentials probably control initiation of the accelerated corrosion process. Under the electrodes the maximum potential differences are reduced because the electrodes average the oxide transport characteristics over macroscopic areas of the surface. It is suggested that these average potentials are not negative enough to initiate the accelerated oxidation. For the same reason, one cannot expect a direct correlation between the measured potential differences on the starting material (which is susceptible to accelerated attack away from the elec-

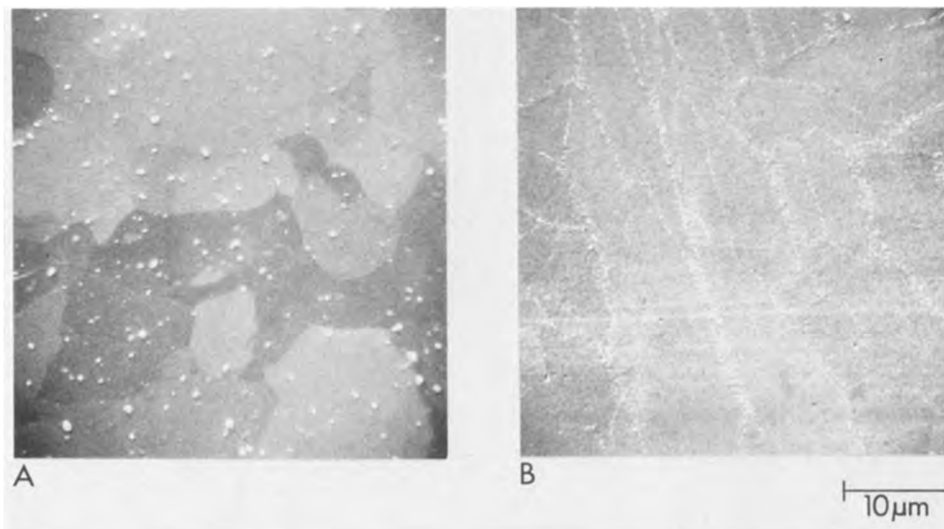

Fig. 4. Effect of heat-treatment on the distribution of intermetallic precipitates in Zircaloy-4: (a) material typical of the starting condition described in the text, and (b) material heated at 1025°C (β-phase field) and cooled at ~10°C/sec.

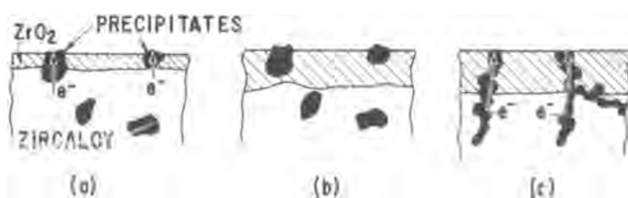

Fig. 5. Schematic of model for effect of intermetallic precipitate distribution on electronic conductivity of oxide film: (a) starting material after short exposure, good electronic conductivity because precipitates span the oxide; (b) starting material after longer exposure, poor electronic conductivity because precipitates are isolated by the oxide; and (c) heat-treated material, good electronic conductivity because precipitates arrayed along grain boundaries do not become isolated.

trodes) and the applied potentials necessary to initiate the process under the electrodes for either of the material conditions tested.

This argument leads naturally to an explanation for the necessity (2) of relatively rapid cooling rates after β heat-treatments to maintain good corrosion resistance. As shown in Fig. 4b, the intermetallic particles after β heat-treatment reside at the boundaries between lamellae in a Widmanstätten or platelike structure. These lamellae become progressively coarser as the cooling rate is reduced, so that the sites for electron transport become more widely separated across the surface. It is suggested that this results in local potentials near the center of the lamellae (at a maximum distance from the intermetallic particles) which, when the structure is sufficiently coarse, can become large enough to initiate the accelerated attack. In fact, examination of the β heat-treated specimens in these tests indicates that accelerated corrosion often initiates on the larger lamellae and tends to be confined initially to individual lamellae until spreading occurs in the more extreme cases.

The nodular oxide morphology commonly observed on the starting material during accelerated corrosion in steam is also consistent with the occurrence of localized conditions favorable to the initiation of the process. It is suggested that these may be sites of lower intermetallic particle concentration, such that the necessary local control of the potential difference across the oxide is not maintained.

An alternative explanation (6) for the effect of the electrodes involves the production of a more uniform oxide (due to the imposition of equipotential surfaces on both sides of the film) which is more resistant to breakdown simply because of its uniformity. However, the above explanation in terms of the reduction of local potential differences seems to fit more naturally with the observed effects of applied voltages.

There is at present no firm evidence to indicate why the development of metal-negative potential differences across the film results in initiation of accelerated corrosion. The electric fields associated with these potential differences are in fact opposite to the direction which tends to promote anion transport through a barrier-type oxide as in normal oxide growth processes. Thus, the phenomena being observed in these experiments are not the same as the much smaller effects reported (12) from experiments on pure zirconium in oxygen gas, where short-circuiting the growing oxide produced an increase in the oxidation rate. Small effects in the opposite direction were reported (13) on short-circuiting Zircaloy-2 specimens oxidizing in molten salt baths. While similar, relatively minor effects may be occurring in the present experiments within the uncertainty of the oxide thickness measurements, these processes seem unrelated to the much more dramatically accelerated corrosion phenomenon of present interest.

What is required is a process leading to the breakdown of the normally protective oxide scale and the nucleation of a rapidly growing, nonprotective oxide. Since the phenomenon of interest is observed in steam but not in oxygen, it is suggested that hydrogen liberated by the corrosion reaction may play a role. In fact, the migration of protons into the oxide under the favorable electric fields associated with metal-negative potential differences fits naturally with all of the reported observations. This could lead to disruption of the oxide film and loss of protectiveness perhaps through an effect of hydrogen on the phase transformation or recrystallization processes that occur in the oxide. Measurements made with a capillary condensation technique described previously (14) have shown that the oxide grown under accelerated conditions in steam contains more fine porosity (per unit weight) than a normal post-transition film, and this may be related to its less protective character. In any case, it is clear that further work is necessary to establish the mechanism by which hydrogen in the oxide might reduce its protectiveness and accelerate the oxidation process.

In arguing that hydrogen migration into the oxide leads to accelerated corrosion, the present model resembles some aspects of previously suggested (15, 16) mechanisms for various accelerated corrosion processes in zirconium and other alloys. However, these earlier studies were not focused on heat-treatment effects or on the particular accelerated corrosion phenomenon which occurs with Zircaloy in high temperature, high pressure steam. A more recently proposed (17) model for nodular corrosion based on cathodic depolarization at intermetallic particles is in some respects opposite to the mechanism suggested here.

Conclusions

1. Large potential differences in the Zr-negative direction are observed across oxide films growing on Zircaloy which is susceptible to accelerated attack in 500°C, 1500 psi steam. When the material has been heat-treated for resistance to such attack, the observed potential differences are much smaller.

2. On Zircaloy with different metallurgical treatments, accelerated attack may be initiated by applied external potential differences (Zr-negative) and inhibited by imposing smaller or oppositely directed electric fields.

3. The data support a model in which accelerated corrosion is prevented on suitably heat-treated Zircaloy by the reduction of unfavorable (metal-negative) potential differences due to the relatively good electronic conductivity of oxides growing on heat-treated materials.

4. The electronic conduction characteristics of the oxide can be explained by differences in the distribution of intermetallic precipitates for different heat-treatments. These differences determine how long during the oxidation process the precipitates can serve as paths for electron conduction through the oxide.

5. Because of the lack of similar effects in pure oxygen gas, it is suggested that proton migration into the oxide film under favorable electric fields causes a loss of protectiveness, although the details of this process cannot be specified at this time.

Acknowledgments

The authors would like to acknowledge J. L. Walker for helpful discussions concerning phase transformations in Zircaloy and metallographic procedures, D. E. Broecker for assistance with the experimental work, B. M. Beach, S. R. Hayashi, and M. D. McConnell for scanning electron microscopy, and C. R. Rodd for metallography. H. S. Spacil contributed a critical review of the manuscript with helpful comments, and several useful suggestions were provided by anonymous reviewers.

Manuscript submitted Feb. 25, 1977; revised manuscript received Sept. 12, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by General Electric Company.

Electrolytic Purification of Nickel Plating Solutions

Luther E. Vaaler

Battelle Columbus Laboratories, Columbus, Ohio 43201

ABSTRACT

Data from published and unpublished sources on electrolytic removal of small quantities of copper, zinc, and iron from nickel-plating baths have been compared. As expected the more noble copper plates out preferentially at a rate limited only by diffusion to the cathode. Zinc ions increase the cathodic potential for nickel deposition to the point that zinc plates out with nickel at a diffusion-limited rate. Removal of iron may also be diffusion limited but results are less clear than for copper and zinc.

Nickel plating solutions become contaminated with metal ions, such as copper, zinc, and iron which are brought into a bath by solution clinging to the work or by dissolution of the surface of the work. A convenient and efficient way of removing these impurities is by low current density electrolysis (dummying), either directly in the plating bath during nonproduction periods or in a separate electrolysis unit to which the plating solution is pumped and from which it is returned to the cell.

The objective of the present study was to reduce the data available (obtained under widely varying conditions) to a common basis for comparison. Some previously unreported experimental data were considered along with published information. Then the effect of such independent variables as the current density and degree of agitation on the rate of impurity removal could be more accurately ascertained.

Sources of Data

Max and Whitehurst (1) studied the removal of copper and iron from nickel plating solutions using a channel cell with vertical anodes and cathodes 5.08 cm high and 38 cm long spaced 2.54 cm apart. Flow rate was varied from 3.15 to 25.4 cm/sec and the current density from 5.38×10^{-4} to 1.72×10^{-2} A/cm^2. The concentration of impurity was followed as a function of time. Plots of log copper concentration *vs.* time were linear indicating that removal of the copper follows first-order kinetics. The authors measured the time for removal of half of the 100 mg/liter of copper originally present and used this value as an index of performance for a given set of conditions.

Schaer and Layer (2) used a rotating-rod cathode 10 cm in diameter to remove copper, iron, and zinc from a nickel plating solution at constant current density. They plotted the impurity concentration in milligrams per liter *vs.* the ampere-minutes/liter and obtained a curve whose negative slope became smaller as electrolysis proceeded.

Other investigators were less precise in defining the conditions of agitation used during electrolysis. Case (3) and Ewing *et al.* (4) used impellers to stir small volumes of nickel plating solution past flat-panel cathodes, and made rough estimates of the linear flow rate. They removed copper, iron, zinc, and nickel at constant current density. Curves of concentrations *vs.* ampere-minutes or ampere-hours/gallon also showed smaller negative slopes as electrolysis proceeded. Raub (5) electrolyzed nickel plating solutions containing small but approximately constant concentrations of zinc. The solution was stirred but no details were reported. A range of current densities was used with each bath. The composition of the deposits was determined. Plots of zinc content of the deposit *vs.* current density for each bath showed negative slopes that became smaller with continued electrolysis.

Treatment of Data

Following Max and Whitehurst's plots of log concentration *vs.* time, other data (3-5) were replotted in terms of log concentration *vs.* ampere-seconds/cubic centimeter. Since amperes and volume for any experiment are fixed the abscissa is proportional to time. Least squares plots are shown in Fig. 1-9. Most of the data are approximated by the straight lines with some exceptions, *e.g.*, Fig. 2. Data were available only as plots rather than as tabulations. Therefore, an error in estimating these points was added to any error in the original experiments.

Raub's (5) data were replotted in a different manner since the bulk concentration of the zinc was maintained constant during the experiment and the deposit rather than the bath was analyzed. The curves of zinc content *vs.* current density had a hyperbolic shape suggesting that a plot of the reciprocal of the zinc content *vs.* current density would be linear. Such plots are shown Fig. 10. The larger reciprocal values were particularly hard to estimate from the original plot so that these points are more scattered.

Discussion

Basis for comparing results.—Comparing the curves from the various sources obtained under a variety of conditions is difficult. To make comparison easier a simple model was assumed that would give a directly comparable rate constant for each curve independent of the impurity concentration, C_b, in the bulk solution. The model assumes that the impurity ions diffuse through a uniform layer to the cathode and that migration is negligible by comparison. It also assumes that the current for depositing the impurity is proportional to its concentration at the electrode. Current in excess of that for impurity deposition plates out nickel.

$$i_d = n\mathbf{F}k_c(C_b - C_i) = n\mathbf{F}k_iC_i \quad [1]$$

Where i_d = current density for impurity deposition,

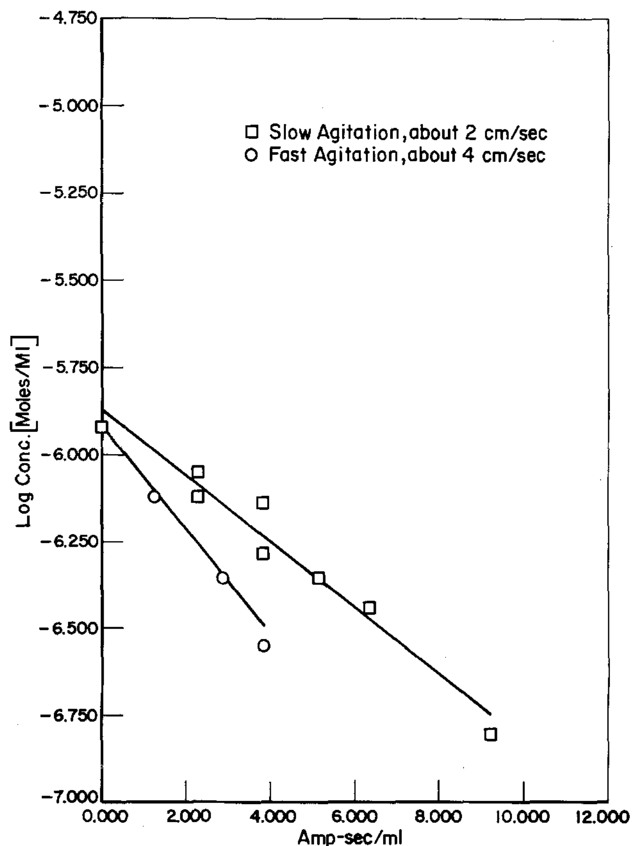

Fig. 1. Copper; Case (3), 0.00538 A/cm²

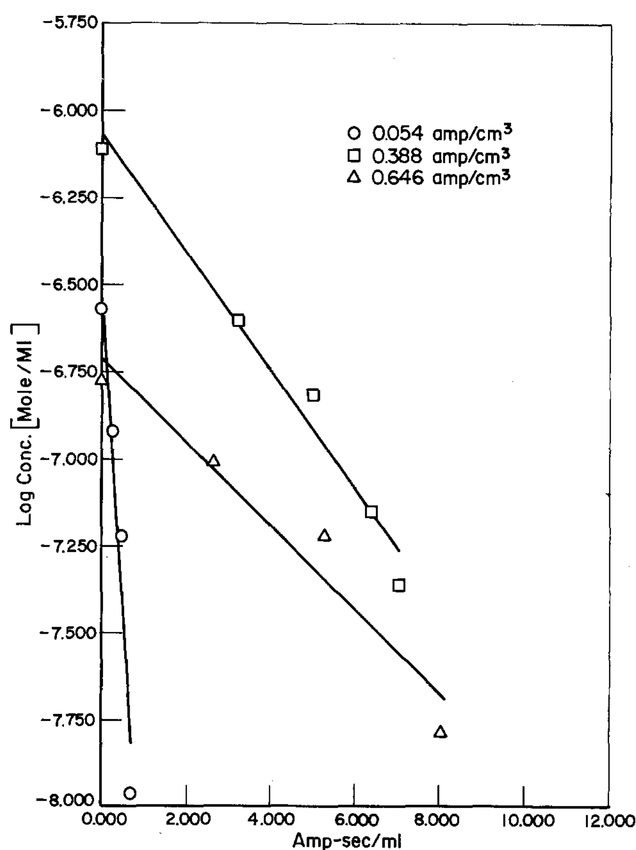

Fig. 3. Copper; Schaer and Layer (2), 10 cm diam. cylinder rotated at 7.6 rps.

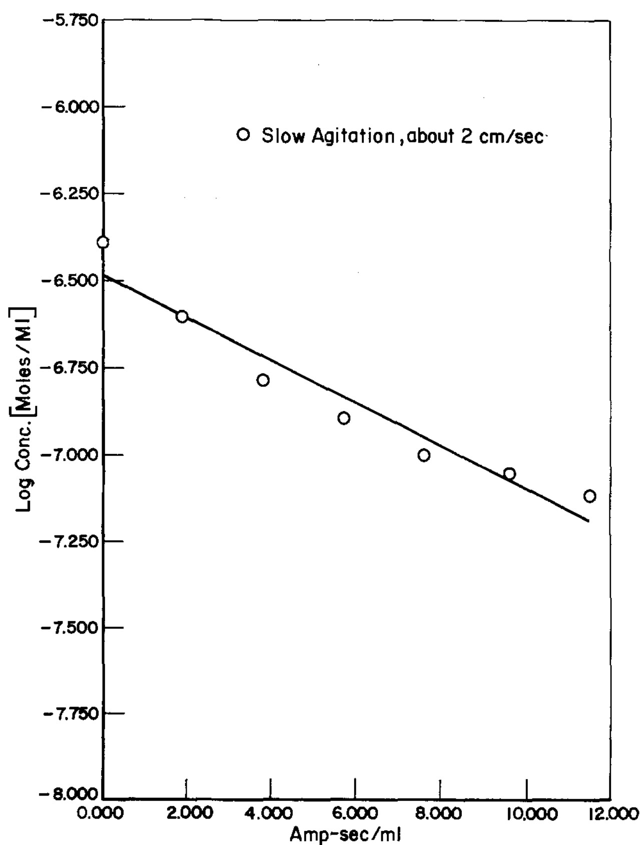

Fig. 2. Copper; Ewing *et al.*, (4), 0.00215 A/cm²

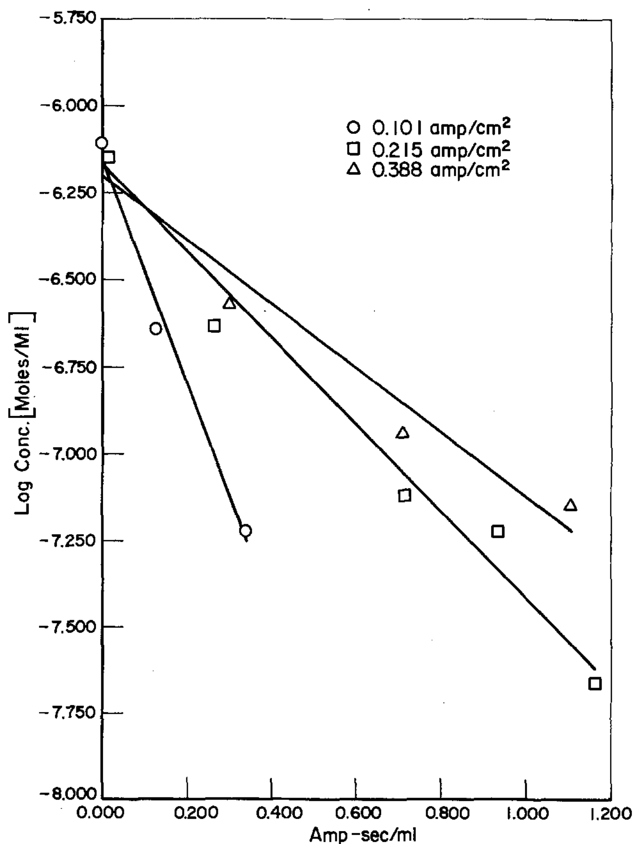

Fig. 4. Copper; Schaer and Layer (2), 10 cm diam cylinder rotated at 11.5 rps.

A/cm²; k_c = mass transfer coefficient through the diffusion layer, cm/sec; C_b = bulk concentration of impurity, moles/ml; C_i = concentration of impurity at the electrode, moles/ml; and k_i = constant relating i_d and C_i, cm/sec.

Using k_i as a constant strongly implies that the cathode potential is constant as C_i changes. If the current density for nickel deposition is much larger than that

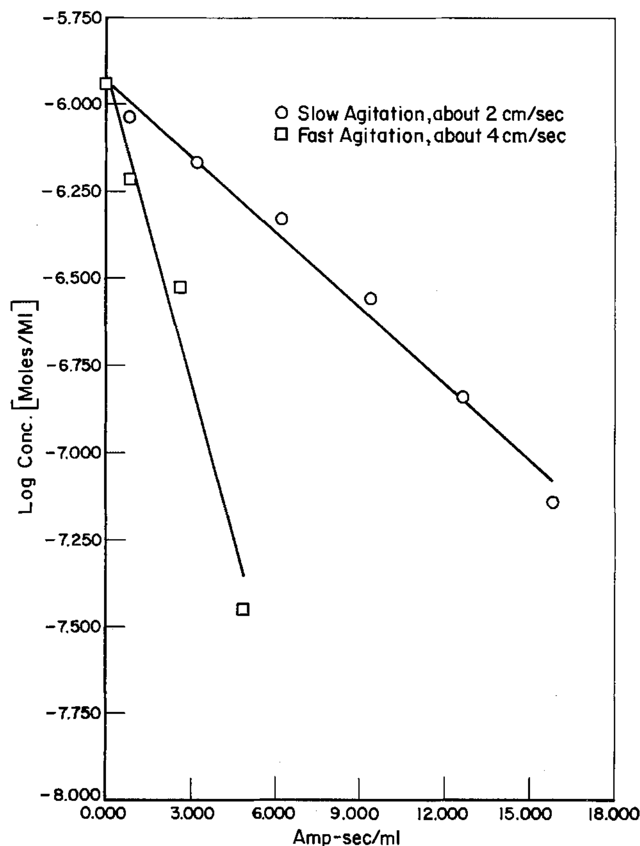

Fig. 5. Zinc; Case (3), 0.00538 A/cm²

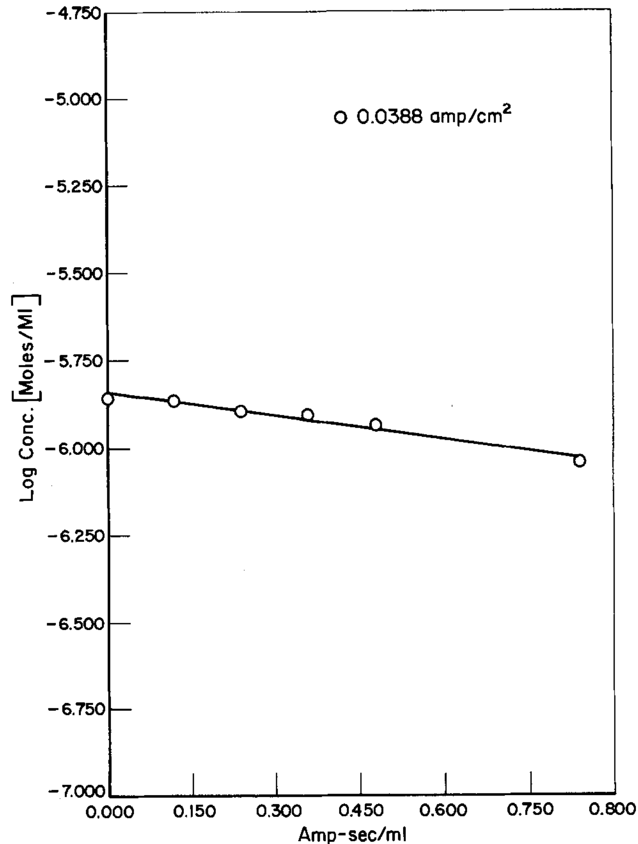

Fig. 7. Zinc; Schaer and Layer (2), 0.63 cm diam cylinder rotated at 183 rps.

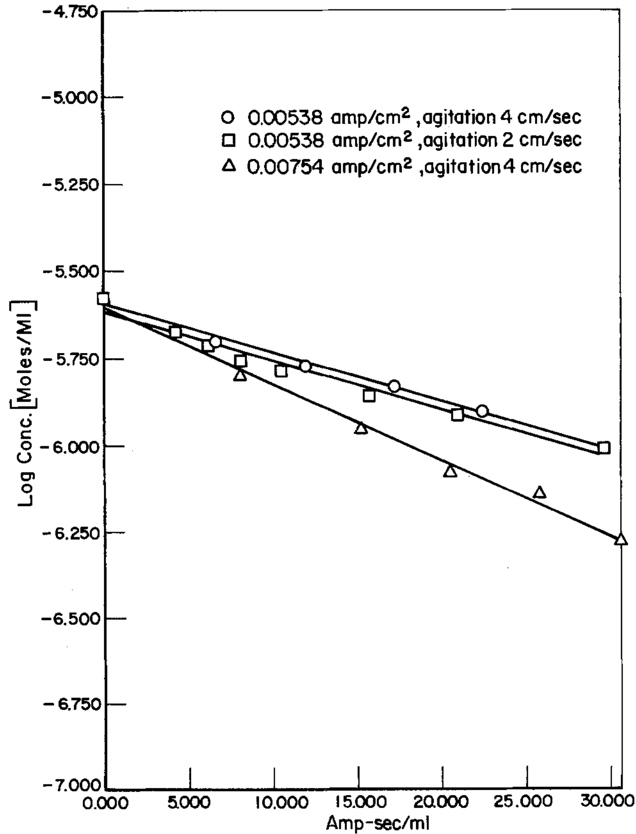

Fig. 8. Iron; Case (3)

for impurity deposition and therefore approximately constant at a constant total current density, the cathode potential will remain approximately constant. In many of the experiments reported the amount of nickel deposited greatly exceeded that of the impurity. Equation [1] can be rearranged to give

$$i_d = n\mathbf{F}(k_i k_c / k_1 + k_c) C_b = n\mathbf{F}KC_b \qquad [2]$$

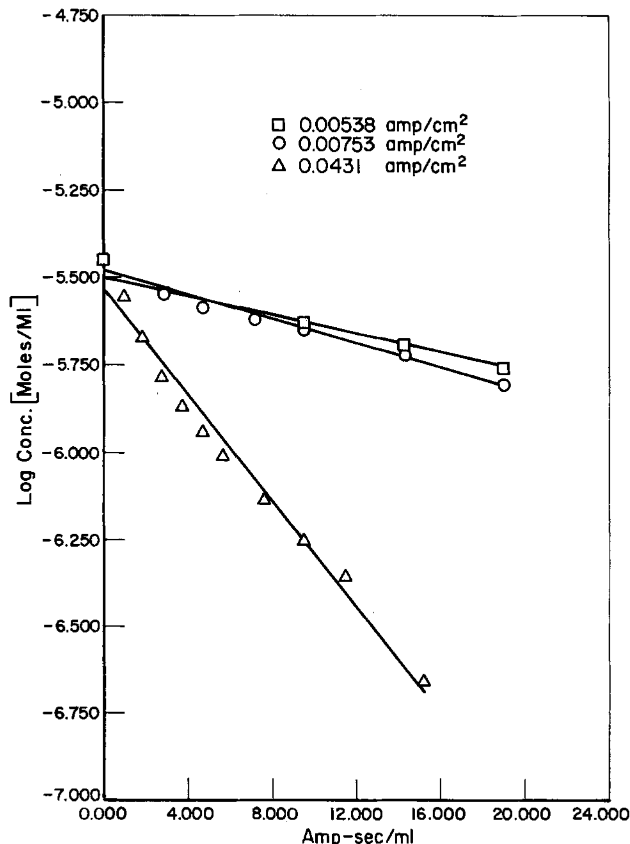

Fig. 9. Iron; Ewing *et al.* (4), agitation 2 cm/sec

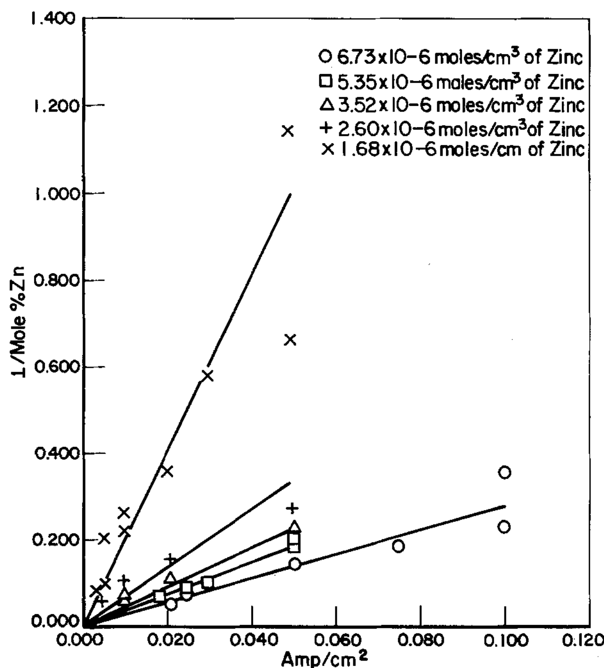

Fig. 10. Zinc; Raub (5), agitated bath at 50°C

If the current density for deposition of an impurity is diffusion limited ($C_i \approx 0$)

$$i_d = n\mathbf{F}k_cC_b \quad [3]$$

However, a linear relation between i_d and C_b does not imply a diffusion limitation and further evidence is needed to establish such a limitation.

Experiments were run at a constant total current density i_T so that i_d was not actually measured. Therefore, the value of K cannot be determined from Eq. [2] or [3]. The following derivation makes feasible the evaluation of K from the available data.

A balance between the rate at which the impurity is deposited and removed from solution can be written as follows

$$i_dA = -n\mathbf{F}v\frac{dC_b}{dt} \quad [4]$$

A is the cathode area, cm^2 and v is the solution volume, cm^3. Combining Eq. [2] and [4]

$$\frac{dC_b}{dt} = -KAC_{b/v} \quad [5]$$

and integrating

$$-\ln(C_{bt}/C_{bo}) = KAt/v \quad [6]$$

C_{bt} is the bulk concentration at t, moles/ml and C_{bo} is the bulk concentration at $t = 0$, moles/ml.

The ampere-time/volume units C_T, *i.e.*, coulombs/cubic centimeter, in which the experimental data of Fig. 1-8 are reported are equivalent to

$$C_T = i_TAt/v \quad [7]$$

combining Eq. [6] and [7]

$$-\ln(C_{bt}/C_{bo}) = KC_T/i_T$$

Therefore K can be determined from the slope $-K/i_T$ of the plots in Fig. 1-8 since i_T is known.

The same rate constant can be derived from Max and Whitehurst's values for the time required to remove one-half of the copper originally present. Substituting in Eq. [7]

$$C_T = i_TAt_{1/2}/v \quad [9]$$

and Eq. [8]

$$-\ln 0.5 = KAt_{1/2}/v \quad [10]$$

$$K = 0.693v/At_{1/2} \quad [11]$$

Where $t_{1/2}$ is the half-time in seconds.

A rate constant can also be obtained from the plot of Fig. 9, of reciprocal zinc content of the deposit *vs.* current density.

The mole fraction of zinc in the deposit M_b is

$$\frac{1}{M_b} = \frac{i_T}{i_d} = \frac{i_T}{n\mathbf{F}KC_{bl}}$$

The linearity of the $1/M_b$ *vs.* i_T plots indicates a constant value for i_d, or that zinc is being deposited at a limiting current density.

From Eq. [2] a value of i_d can be determined knowing K and C_b and the composition of the deposit calculated from the ratio i_d/i_T. The maximum mole fraction, M_b, of the impurity deposited during an experiment was calculated and included in the results. M_b is highest at the beginning of electrolysis and decreases as C_b is lowered during the electrolysis.

Results

The composition of the nickel bath for which the rate constants for removal of copper, zinc, and iron have been determined are shown in Table I. Case and Ewing *et al.* and Raub used essentially the same bath. Max and Whitehurst used a more concentrated bath. Experiments of Schaer and Layer were with the most concentrated bath but without chloride.

Copper.—Values of K were calculated from the $t_{1/2}$ values of Max and Whitehurst as a function of flow rate and current density. An analysis of variance showed that flow rate was significant but current density was not. Results obtained from the plots of the other investigators and from $t_{1/2}$ values for copper are summarized in Table II. Accuracies of K's in term of standard error were determined from the variance of line slopes or, in the case of Max and Whitehurst's data, from the values of K for the six current densities at each flow rate. The independence of K and current density in data of Max and Whitehurst and in that of Schaer and Layer with the rotating cathode strongly suggest that copper is being plated out at its limiting current density.

This result is expected for the more noble copper present in low concentrations. However, in the experiment with the rotating cathode the mass transport rate was high enough to allow essentially 100% deposition of copper (the calculated value of 111% is probably due to the inherent error of the slope from which K was calculated). Ettel, Tilak, and Gendron (6) added small amounts of silver ion to a copper electrowinning bath and measured the limiting current density of silver deposition by analysis of the silver content of the copper deposit: From the measurement they were able to define the mass transfer rate for copper deposition. Limiting deposition rates for copper in a nickel plating bath provide a similar measurement of mass transfer conditions and are a function of the degree of agitation as found experimentally by Max and Whitehurst (1) and Schaer and Layer (2).

Agitation conditions for experiments of Case (3) and Ewing *et al.* (4) are poorly defined. Case's results, by comparison with Max and Whitehurst's, indicate a fairly high degree of mass transfer, while Ewing's results indicate very poor mass transfer conditions. The results as a whole show the importance of agitation in obtaining rapid removal of impurities at a high current efficiency.

Zinc.—The calculated K values for zinc removal are shown in Table III. Values for Case (3), Ewing (4), and Raub (5) are within the same order of magnitude. The reciprocal relation between zinc content of the deposit and the total current density strongly suggests that zinc is plated out at its limiting current density. The K values with the rotating cylinder used by Schaer and Layer (2) are significantly higher, showing the improvement possible by increasing the mass transfer rate. The zinc content of the nickel deposits is relatively high for such an active metal, and Knodler (7) has suggested that this is due to the pronounced effect that zinc exerts upon the potential for nickel deposition. Nickel is plated out at a cathode potential of −500 to −600 *vs.* SHE in the absence of zinc. In the absence of nickel zinc deposits at −800 to −900 mV *vs.* SHE. Small additions of zinc to a nickel bath shift the deposition potential for nickel to that for zinc. Knodler suggests that the shift is due to adsorption of a zinc hydroxide layer on the cathode surface.

Iron.—Results for iron are shown in Table IV. The removal of iron from nickel baths would appear to involve a more complex mechanism than for copper and even than for zinc. K values are generally lower than for copper and zinc and are not increased to the same extent as for copper by enhancing mass transfer by using a rotating cathode. Max (1) found that no iron was removed at less than 4.3×10^{-3} A/cm^2 and that results at 8.6×10^{-3} A/cm^2 were uncertain. Only at

	Fe	3.58×10^{-6}	4.31×10^{-2}	2	−0.175	7.56×10^{-3}	4.2	12.1

1.72×10^{-2} A/cm^2 was consistent removal obtained. Ewing *et al.* (4) show a drastic increase in K when current density is raised to 4.3×10^{-2} A/cm^2. Iron offers the possible complication of forming Fe(III) at the anode and Fe(II) at the cathode rather than elemental iron, so that the current efficiency of iron removal can be very low.

Removal of Impurities in Electroplating and Electrowinning

Electrolytic purification has been successfully used but considerably more nickel than impurity is removed. It is evident that more agitation and lower current densities, at least for copper and zinc removal, would be beneficial and possibly a separate divided cell to prevent anodic oxidation of the iron would aid its removal. A certain amount of nickel deposition is probably beneficial in maintaining a deposit that is coherent so that it will not fall back into the bath. While removal of the three impurity elements have been considered separately, in actual practice they are removed together and how zinc hydroxide adsorption, for example, affects deposition of copper and iron in this system has not been well defined. Codeposition of small concentrations of copper, zinc, and iron in the presence of much higher concentrations of nickel requires some additional careful experimental work to elucidate mechanisms, and would be of considerable interest not only for impurity removal but also for the plating of alloys.

Much development work is now going on to increase current density and mass transfer in the electrowinning of metals. Increasing agitation and mass transfer increases the deposition of impurities that are mass transfer limited. Thus, the total current density must be increased proportionately to keep impurity levels low. On the other hand, if it is desirable to recover one of two metals in solutions without contamination from the other, increased mass transfer can increase the limiting current density to a point that a single metal can be selectively removed to a low concentration at practical current densities provided one metal does not affect the deposition kinetics of the other. Thus, it is possible to separate copper from nickel to a concentration of 10 mg/l of copper without significant deposition of nickel. While considerable effort has been devoted to electrowinning dilute solutions of copper under high mass transfer-high surface area conditions, *i.e.*, forced flow, rotating-cylinder cathodes, packed and fluidized beds, less attention has been devoted to these techniques for selective recovery of metals from solutions containing more than one metal ion.

Current Distribution Leveling Resulting from Auxiliary Bipolar Electrodes[1]

Werner Engelmaier* and Thomas Kessler[2]

Bell Laboratories, Whippany, New Jersey 07981

and Richard Alkire*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The effect of auxiliary electrodes on cathodic current distribution is determined both in terms of visual characteristics of plated copper and direct measurements. Experiments are carried out using a Hull cell with high conductivity $CuSO_4/H_2SO_4$ electrolyte. The results indicate that leveling of the distribution takes place when certain types of conductive auxiliary electrodes are placed within an electrolysis cell even though the auxiliary electrodes are not connected to an external source of current. Experiments are described which compare the leveling power of several geometric arrangements of auxiliary electrodes within a cell, as well as the effect of chemical composition of the auxiliary electrodes. The study clarifies the fundamental nature of the process by which leveling is obtained.

The desirability of uniform cathodic current distributions during copper electroplating of multilayer printed wiring boards (MLB's) has been discussed (1-3). MLB's contain plated through-holes (PTH's) which provide electrical connections between the various circuit layers of the MLB. During the electroplating step, copper is deposited in the drilled PTH's as well as on the outer MLB surfaces. Uniform deposit thickness in the PTH's over the whole MLB is critical for connector pin inser-

Key words: electroplating, electrodeposition, current density, copper plating, printed wiring boards.

tion on the one hand, and functional integrity on the other (1-4). Methods for achieving uniform distributions include: (*i*) modification of electrode and cell configuration, (*ii*) variation of electrolyte composition, and (*iii*) use of auxiliary aids such as dielectric shields and conductive thieves to redistribute the current within the cell. Configuration changes to improve current distribution uniformity have recently been discussed (5). Only a slight increase in the electrolyte conductivity can be achieved by increasing the H_2SO_4 concentration in the 0.27 molar $CuSO_4$/1.76 molar H_2SO_4 baths. This beneficial increase would not lead to a major improvement in plating uniformity on the MLB's. Since methods (*i*) and (*ii*) offer only limited possibilities, method (*iii*) is the most likely method for achieving more uniform copper. References (6) and (7) contain examples of the extensive use of auxiliary aids to improve the uniformity of cathodic current distributions.

The following studies describe a new type of auxiliary aid, a bipolar screen auxiliary double electrode, which consists of two metal pieces immersed in the cell and connected to each other but not to any external source of current. With proper choice of material and position within the cell, such double auxiliary electrodes can provide highly uniform current distributions under highly adverse operating conditions.

The purpose of this investigation is to conduct experiments to demonstrate the effect of auxiliary metal aids and to assess which materials and geometries are most effective in leveling the current distribution. The cell geometry chosen for study is the Hull cell; it is designed to give a highly nonuniform current distribution at the cathode and is the traditional test cell configuration used to illustrate current distribution effects.

Apparatus

The geometry and dimensions of the Hull cell used in this study are shown in Fig. 1(a). A copper anode was positioned perpendicular to the insulating side walls of the cell; the cathode was placed at a 40° angle with respect to the anode. The following tests were conducted: (*i*) conventional Hull cell tests with visual inspection of the plating on a 6.9 × 10.0 cm brass cathode and (*ii*) measurements of cathodic current distributions with segmented cathodes.

The segmented cathode was divided into ten sections as shown schematically in Fig. 2. Note that the width of segment 10 is 0.5 cm whereas the other segments are 0.9 cm wide. The segmented cathode was fabricated from 2-oz copper-plated epoxy board which was pattern-etched to remove strips between segments.

Within the Hull cell were placed metal pieces of several types acting as auxiliary electrodes: copper screen (Cu), copper-plated platinized titanium expanded mesh (Cu/Pt-Ti), platinized titanium expanded mesh (Pt-Ti), and titanium screen (Ti). These auxiliary electrodes were placed, two by two, in three geometrical arrangements within the Hull cell as indicated in Fig. 1(b), (c), and (d). For geometry III the dimension L was 1.25 cm with the solid cathodes and 0.6 cm with the segmented cathodes. Parametric calculations for the dimensional requirements are given in the Appendix.

The electrolytic solution used in the study was copper sulfate in sulfuric acid and distilled water without plating additives. As discussed below, measurements by Baker (8) show that the cathode current distribution is independent of additives presently in use. The approximate concentration of the solution was 0.3M $CuSO_4$, 1.5M H_2SO_4; the nature of the experiments was such that determination of the precise composition was unnecessary.

The electrical circuit used for supplying power and making measurements is given in Fig. 3. The power supply (Hewlett-Packard, 6281A) was deployed in constant current mode. Measurement of the applied current and the current passing between auxiliary electrodes was made with a multimeter (Keithley, 160).

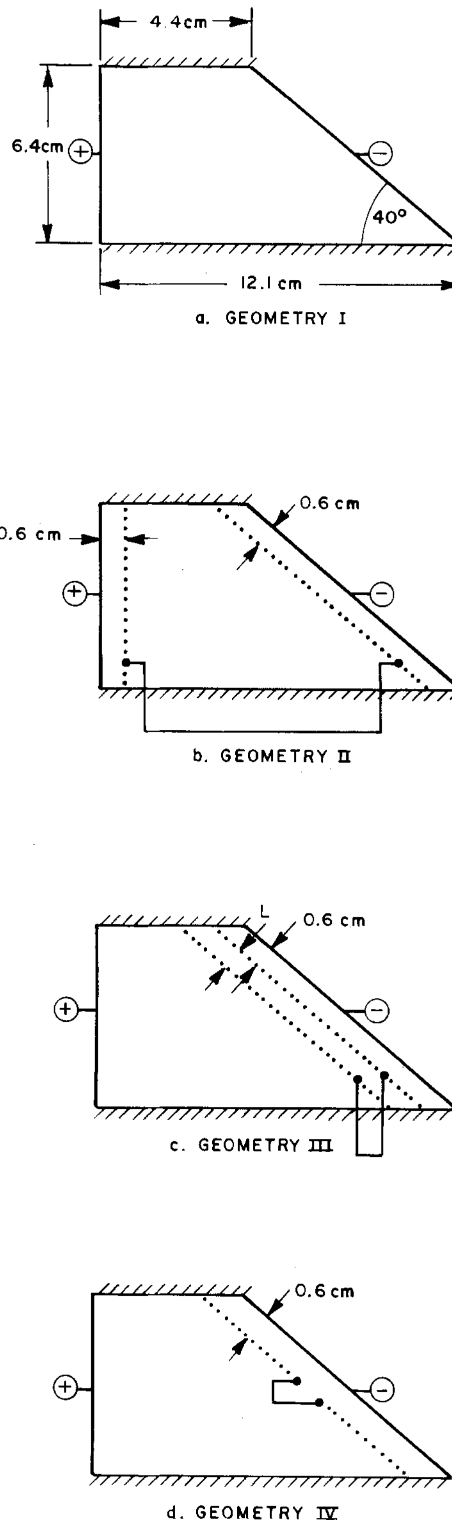

Fig. 1. Hull cell and auxiliary electrode geometries and dimensions

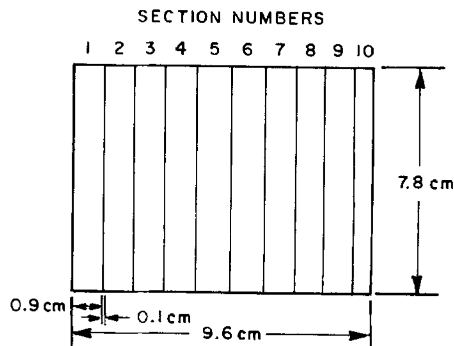

Fig. 2. Segmented cathode for current distribution measurements

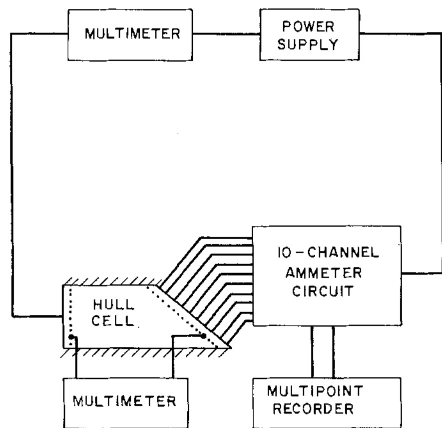

Fig. 3. Circuitry for plating current supply and current distribution measurements.

For the tests with segmented cathodes the section currents were measured with a 10-channel operational amplifier zero-resistance ammeter circuit which supplied a voltage signal to a potentiostatic multipoint recorder (Esterline Angus). The zero-resistance ammeter circuit maintained the potentials of the ten electrode sections to within $\pm 20\ \mu V$.

Procedure

The Hull cell was filled with solution to an approximate depth of 5 cm for the conventional cathodes and to a depth of 2.5 cm for the segmented cathode studies. For the solid cathode experiments the plating times ranged from 1-30 min, with the length of plating time inversely dependent on the applied current. Experiments were carried out at the applied currents given in Table I.

The procedure for making measurements consisted of turning on the current, measuring the section currents, the current flowing between auxiliary electrodes, and the total applied current. Because the solid cathode experiments indicated that mass transfer effects were important at the higher applied currents, measurements of the current distribution was initiated within 1 sec of switching on the current. The section currents were measured in order of section number (see Fig. 2), beginning with No. 1; that is, the current to the most reactive section was measured within about 2 sec of circuit activation. Measurements were conducted for a period of about 40 sec after which the current was switched off. Between experiments, at least 30 sec was allowed before reinitiating current in order to allow for the relaxation of concentration gradients within the cell, should they exist. Measurements were made at the applied currents indicated in Table I.

Results and Discussion

A compilation of experiments performed is given in Table I, in which the geometries, materials, and currents are indicated. From the geometry of the cell, the applied current is related to the average cathodic current density by

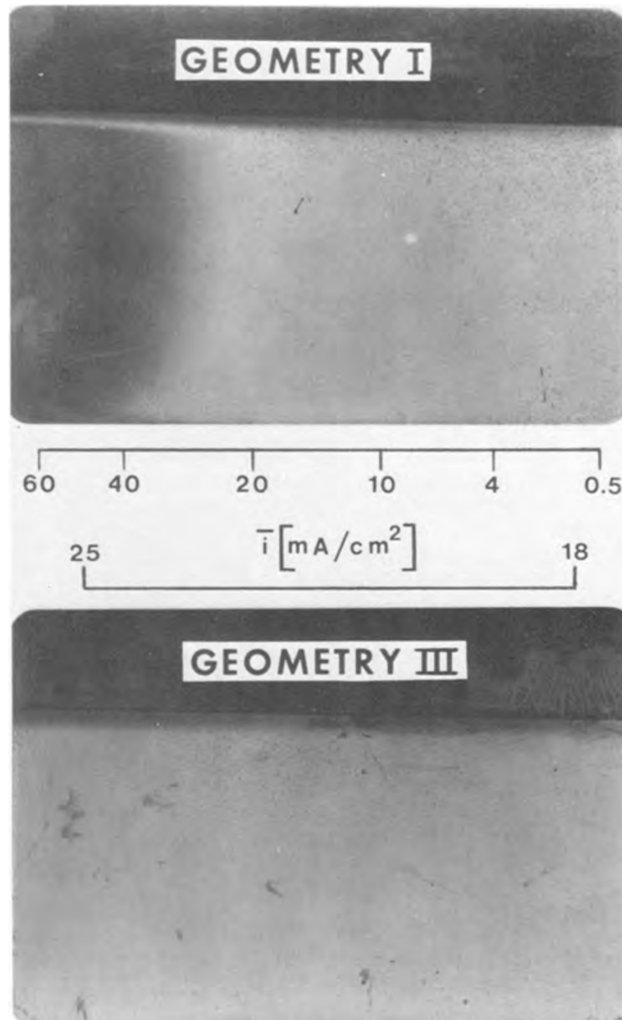

Fig. 4. Visual appearance of Hull cell copper deposit at I = 1000 mA without (geometry I) and with (geometry III) bipolar auxiliary electrodes.

for the solid cathodes and for the segmented cathodes by

$$\bar{i}_{cath}(mA/cm^2) = 0.0465 I (mA)$$

Conventional Hull cell cathodes.—The effect of the auxiliary electrodes was investigated by observing the visual characteristics of the plated copper for several of the geometries of Fig. 1 by plating on conventional brass Hull cell cathodes. From the experiments listed in Table I it was found that current densities greater than 25 mA/cm² result in a brownish powdery deposit for geometry I; such deposits are characteristic of plating at or near the limiting current density.

Figure 4 shows the difference in visual appearance of the deposit for plating at 1000 mA with two different

Table I. Summary of experimental cathodes

geometries. A sample plated using geometry I is shown in Fig. 4(a) with the standard Hull cell current density scale to indicate the current density gradient present. Figure 4(b) shows a sample plated using geometry III with copper screens; the current density scale shown for geometry III is estimated from the segmented cathode data (see Fig. 11). As can be seen, for geometry III, the plating is quite uniform; the auxiliary electrodes average out the current densities and all plating takes place at the average current density which for the applied current of 1000 mA is below the limiting current density.

Table II lists the test results for the various electrode material/geometry combinations. From the materials tested it is clear that only auxiliary electrodes that have copper surfaces, and thus facilitate bipolar anodic and cathodic electrochemical processes to take place at the auxiliary electrodes, will be useful in leveling the current distribution. The placement of auxiliary electrodes made of platinized titanium or titanium had no discernible effect on producing more uniform plating.

Segmented cathodes.—Segmented cathode experiments were carried out to place the qualitative results found with the conventional Hull cell cathodes on a quantitative basis. The current flowing between the auxiliary electrodes was measured and is shown in Table III. It is seen that the current flowing between the auxiliary electrodes depends on the applied current, the material of the electrodes, and the geometric positions of the electrodes within the cell. The significance of these variations is discussed below.

The following paragraphs discuss results of experiments on four different geometric configurations shown in Fig. 1.

Geometry I: no auxiliary aids.—Figure 5 provides current distribution data measured at five different applied currents in the absence of aids. Recall that the width of segment 10 is 5/9 of the width of the other segments; none of the data have been adjusted to compensate for this difference in area. The dashed line corresponds to the theoretical primary current distribution (for a total applied current, $I = 350$ mA) which would be observed if electrolyte conduction processes alone controlled the current distribution. It is seen that the measured current distributions are more uniform than the primary distribution, indicating a small resistive contribution from perhaps charge transfer or mass transfer processes. However, the most important resistance is the ohmic resistance of the electrolytic solution. All measured distributions are highly nonuniform, indicating that deposition under these geometric conditions represents a stringent configuration for testing the effectiveness of auxiliary aids for leveling the distribution.

Previously unpublished measurements in an identical Hull cell by Baker (8), presented in Fig. 6, show simi-

lar distributions. Baker's experiments were conducted with a 2100 mA total cell current, a solution depth of approximately 5 cm, and a cathode divided into seven equal segments. Note the negligible effect of additives on the current distribution.

Geometry II: two screens, each parallel to the adjacent electrodes.—Figure 7 shows experimental current distribution data for two auxiliary copper screens. The magnitude of current flowing between auxiliary screens is given in Table III. It is seen from these data that the function of the two screens is to remove the current from the anolyte region and redistribute it in the catholyte region. If 100% of the applied current were to pass between the auxiliary electrodes, then the electrical path would be equivalent to the two-compartment cell depicted in Fig. 8; if the distance denoted d is small, then the primary current distribution at the cathode would be highly uniform.

Figure 9 gives current distribution data for the Cu/Pt-Ti mesh near the cathode and the Cu screen near the anode. It is seen that the electrochemical properties of the copper-plated titanium mesh are such that virtually the same current distribution is obtained as with the copper screen.

Figure 10 gives current distribution data for a Ti screen near the cathode and a Cu screen near the anode. No leveling is obtained and the current distributions are essentially identical to those measured in the absence of auxiliary aids (Fig. 5). Further, it is seen from Table III that no electrical current is induced to flow between the Ti and Cu screens. The reason that the screens do not support reaction is that there is no anodic electrochemical reaction possible, under these conditions, at the Ti screen so that current is thereby blocked from flowing through it. All of the current is

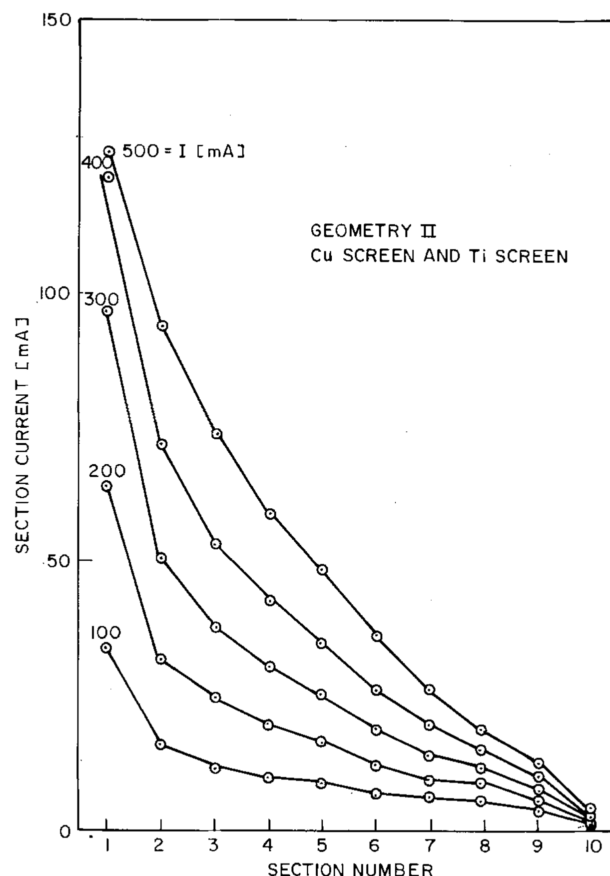

Fig. 10. Current distributions in Hull cell with titanium screen and copper screen auxiliary electrodes arranged in geometry II.

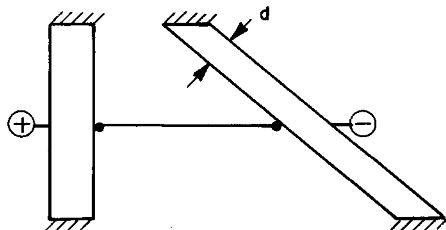

Fig. 8. Double cell geometry nominally equivalent to auxiliary electrode geometry II.

forced to remain in the electrolyte phase, as is the case in geometry I.

Geometry III: two screens, each parallel to the cathode.—Figure 11 gives current distribution data for two auxiliary copper screens. Generally speaking, the cathodic distributions are nearly identical to those provided in Fig. 7, where one screen was parallel to the anode. These observations indicate that the screen near the cathode is important in controlling the cathodic

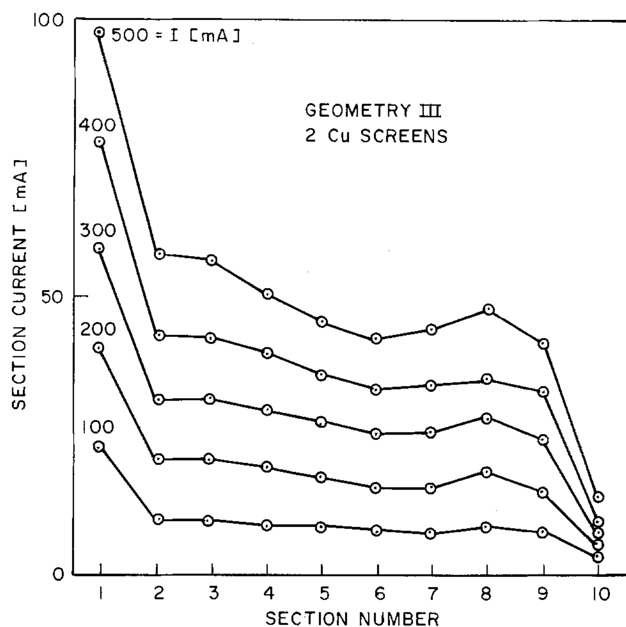

Fig. 11. Current distributions in Hull cell with copper auxiliary electrodes arranged in geometry III.

current distribution. The screen near the anode must merely be positioned sufficiently far from the other screen that an appreciable fraction of the applied current flows between the two screens (see Appendix). Otherwise, redistribution of current will not occur.

Geometry IV: two screens parallel to and equidistant from the cathode.—Current distribution data for the geometry of Fig. 1(d) are given in Fig. 12. It should be recognized that geometry IV corresponds to the conducting shield device reported by Rousselot (6). Figure 12 shows that the conducting shield geometry improves the current distribution with respect to the nonaided case (Fig. 5), but that the improvement is not as good as with either geometry II or III. The screen used in geometry IV was segmented into two adjacent sections, and the current flowing between sections is indicated in Table III.

Comparison of segmented cathode results.—The results of the current distribution measurements for geometries I through IV can best be compared by a cross plot of the data. Such a plot is shown in Fig. 13 for two currents: $I = 100$ mA and $I = 500$ mA. For this plot, the measured I for section 10 has been multiplied by 1.8 so that all I's are for the same surface area.

The results quantitatively substantiate the findings from the conventional Hull cell experiments. A single auxiliary electrode (geometry IV) offers some improvement in the distribution from geometry I. However, the improvement in uniformity with two auxiliary electrodes (geometries II and III) is seen to be substantial.

The foregoing data clarify events which occur when auxiliary metal electrodes are placed in electrolysis cells. When electrical current passes through the electrolyte, a potential field arises owing to the ohmic resistance of the electrolyte. If auxiliary electrodes are placed such that they cut across equipotential surfaces in the electrolyte, the possibility of induced cocurrent electronic conduction arises. In order that cocurrent conduction can occur in the auxiliary electrodes, both anodic and cathodic electrochemical reactions must occur on the auxiliary electrodes in a bipolar mode to provide a source and sink for electrons.

Conclusions

1. The current distribution at the cathode of a Hull cell can be made substantially more uniform by placing suitably reactive metal electrodes between the anode and the cathode.

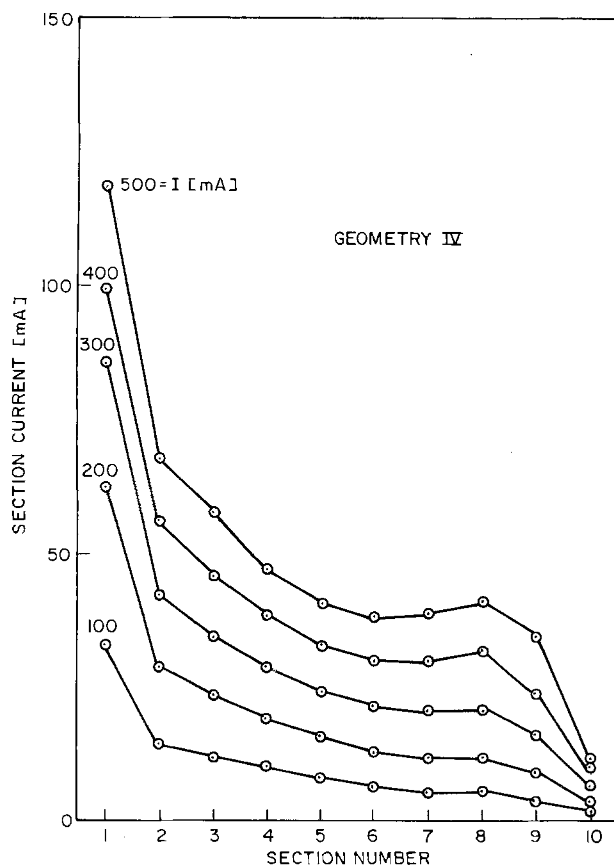

Fig. 12. Current distributions in Hull cell with auxiliary electrodes arranged in geometry IV.

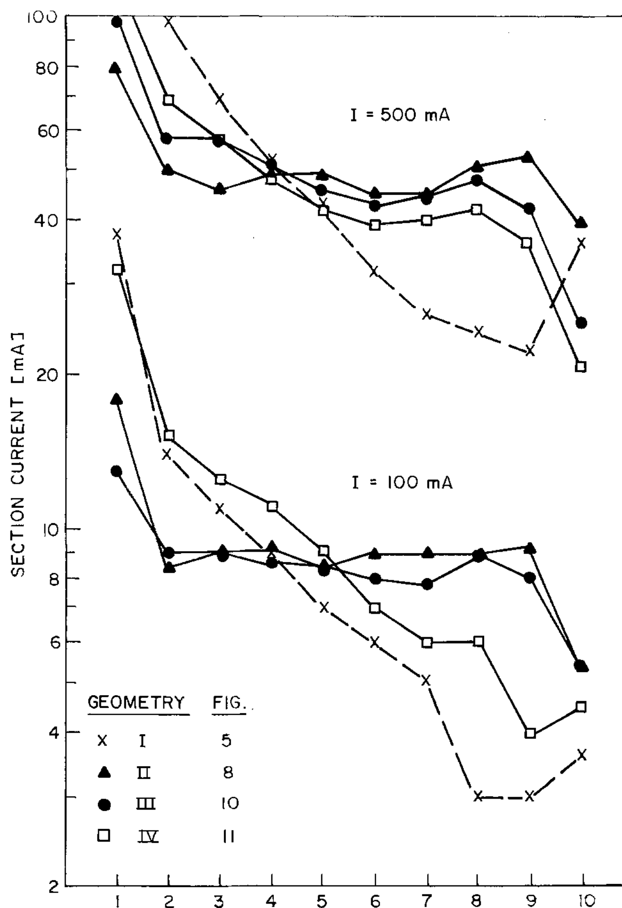

Fig. 13. Comparison of current distributions resulting from geometry I through IV ploting arrangements.

2. With appropriate choice of geometries, two electrically connected auxiliary electrodes can be made more effective in leveling the cathodic current distribution than a single screen placed near the cathode.
3. Material other than screen could be used such as mesh, wires, rods, metal brushes, porous metal sheets, etc.
4. Auxiliary electrodes must be of such material, *i.e.*, for copper plating the electrode surface has to be copper, and of sufficient surface area that both anodic and cathodic electrochemical processes occur in a bipolar mode within the potential difference resulting at the screens.
5. The potential difference induced between the screens is determined by the distance along the path of current flow (in the electrolytic phase) which separates the auxiliary electrodes.
6. For leveling to occur, the current flowing between the two auxiliary electrodes must be an appreciable fraction of the total applied current.
7. A Hull cell is a convenient test configuration to assess the effectiveness of current leveling aids and with a sectioned cathode for direct measurement of the current distribution.

APPENDIX

To produce the desired leveling effect for the cathodic current distribution, it is necessary for an appreciable fraction of the applied current to flow between the two auxiliary electrodes. To obtain this bipolar operation, it is necessary for the following criteria to be met

$$R_\Omega << R_{CT} << R_{\Omega S} \quad [A-1]$$

These criteria establish dimensional requirements for the auxiliary electrode system.

The charge transfer resistance (3)

$$R_{CT} = \frac{R_g T}{\alpha_c \mathbf{F} \bar{i} A} \quad [A-2]$$

the ohmic solution resistance

$$R_{\Omega S} = \frac{L}{\kappa A_s} \quad [A-3]$$

using the most conservative model, and the ohmic electrode resistance

$$R_\Omega = \frac{\bar{t}}{\sigma A_\phi} \quad [A-4]$$

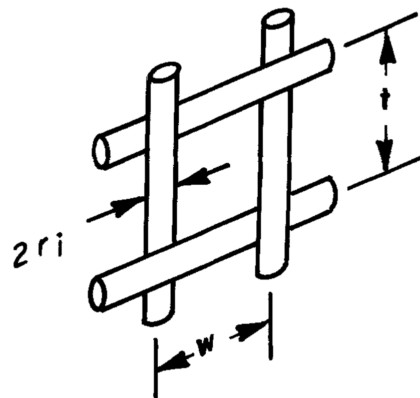

Fig. 14. Geometry of screen used for auxiliary electrodes

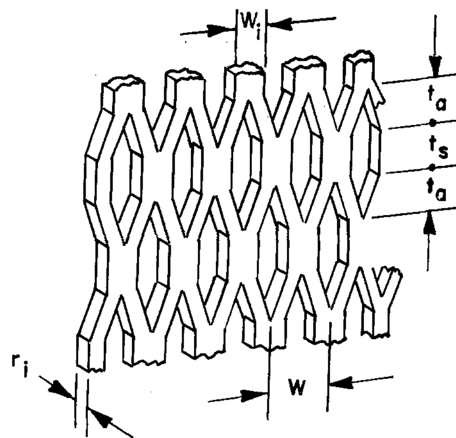

Fig. 15. Geometry of mesh used for auxiliary electrodes

Using the screen geometry indicated in Fig. 14, the criteria of Eq. [A-1] become the following dimensional criteria

$$r_i >> \frac{2\bar{t}^2}{\sigma}\left(1 + \frac{w}{t}\right)\frac{\alpha_c \mathbf{F}}{R_g T}\bar{i} \quad [A-5]$$

and

$$L >> \frac{1}{2\pi r_i\left(\frac{1}{w} + \frac{1}{t}\right)}\frac{R_g T}{\alpha_c \mathbf{F}}\frac{\kappa}{\bar{i}} \quad [A-6]$$

Similarly, from the geometry of the expanded mesh shown in Fig. 15 follows

$$r_i >> \frac{2\bar{t}^2}{\sigma}\left[1 + \frac{r_i}{w_i}\frac{2t_a + t_s}{t_a + t_s}\right]\frac{\alpha_c \mathbf{F}}{R_g T}\bar{i} \quad [A-7]$$

and

$$L >> \frac{w}{2w_i\left[1 + \frac{r_i}{w_i}\frac{2t_a + t_s}{t_a + t_s}\right]}\frac{R_g T}{\alpha_c \mathbf{F}}\frac{\kappa}{\bar{i}} \quad [A-8]$$

Using Eq. [A-5]-[A-8], Table IV gives the dimensional criteria for the three auxiliary dual electrode geometries used in the experiments.

Table IV. Dimensional criteria status for Hull cell experiments

Auxiliary electrode	Criteria: $r_i >>$ (μm)	Criteria: $L >>$ (cm)	Actual: r_i (μm)	Actual: L (cm)	Criteria status
Copper screen	0.8	0.42	108		o.k.
				L (II) = 3.0	o.k.
				L (III) = 1.3	o.k.
				L (III) = 0.6	?
Titanium screen	1.6	1.08	140		o.k.
				L (II) = 3.0	o.k.
				L (III) = 1.3	?
Titanium expanded mesh	3.3	0.24	7870		o.k.
				L (II) = 3.0	o.k.
				L (III) = 1.3	o.k.

Electrochemical Studies of β-Carotene, all-*trans*-Retinal and all-*trans*-Retinol in Tetrahydrofuran

Su-Moon Park*

Department of Chemistry, The University of New Mexico, Albuquerque, New Mexico 87131

ABSTRACT

Detailed electrode mechanisms involved in oxidations and reductions of all-*trans*-β-carotene, all-*trans*-retinal, and all-*trans*-retinol have been investigated employing cyclic voltammetry, chronoamperometry, chronopotentiometry, and controlled potential coulometry at the platinum electrode in rigorously dried tetrahydrofuran (THF) solutions with *tetra*-n-butylammonium perchlorate (TBAP) as a supporting electrolyte, and the results are described. Pseudo first-order decay rate constants of intermediate species of β-carotene and retinal reductions are obtained and reported. β-Carotene was oxidized to β-apo-12-carotenal in the presence of water and was reduced mainly to 15,15′-dihydro-β-carotene in dry THF. Retinal was reduced at various double bonds, resulting in many products including retinol, both in dry and wet THF.

Carotenoid compounds, especially β-carotene, play a very important role in plants for the transfer of the energy absorbed from solar radiation to chlorophyls for the photosynthetic processes. β-Carotene is also important as a source of vitamin A, since it is absorbed in the animal systems and undergoes an oxidative cleavage at the 15,15′-double bond in the liver to all-*trans*-retinal, which eventually is reduced to vitamin A alcohol (1). There has been a large amount of effort (2-6) to elucidate the reaction mechanisms involved in this sequence of reactions and to reproduce this reaction *in vitro*. Chemical oxidation of β-carotene, however, did not generally show the same specificity as in the *in vivo* reaction. Since this sequence of the reaction is a redox one, we thought it would be very interesting to carry out an electrochemical investigation on this system and compare the result with those occurring *in vivo* systems and those obtained by the oxidation of β-carotene with chemical oxidants.

Electrochemistry of β-carotene and retinal was first reported by Takahashi *et al.* (7, 8), in which reduction potentials, the number of electrons transferred, and diffusion coefficients were measured with polarographic methods in the benzene-acetonitrile mixed solvent. Some of these results were shown to be erroneous later by Mairanovsky *et al.* (9) from their more refined studies. There have also been reports on controlled electrolysis of carotenoid compounds (10, 11).

In our present report, we have carried out a detailed study on electrode mechanisms of β-carotene, retinal, and retinol employing chronoamperometry, chronopotentiometry, cyclic voltammetry, and controlled potential coulometry in rigorously dried tetrahydrofuran solutions, and the results obtained are presented.

Experimental

Mallinckrodt A. R. tetrahydrofuran (THF) was dried over sodium metal under the vacuum for at least half a week and was distilled directly into the electrochemical cell *in vacuo* by the vapor transfer method without being exposed to the air to make up the solution. Eastman Organic's (E.O.) polarographic grade *tetra*-n-butylammonium perchlorate (TBAP) was dried at approximately 100°C under vacuum for at least

* Electrochemical Society Active Member.

Key words: β-carotene, all-*trans*-retinal, all-*trans*-retinol (vitamin A).

Table I. Electrode potentials*,†

° Cyclic voltammetric peak potentials *vs.* the aqueous saturated calomel electrode (SCE) in THF at the platinum disk electrode ($A \simeq 0.017$ cm²) with TBAP as a supporting electrolyte. The scan rate was 100 mV/sec in all measurements.
† Numbers in parentheses are n_{app} determined voltammetrically using 9,10-diphenylanthracene as a reference compound under the same experimental conditions.

24 hr and was used as a supporting electrolyte throughout the study. β-Carotene (E.O.) was recrystallized from diethyl ether three times and stored in the freezer. All-*trans*-retinal (E.O.) and all-*trans*-retinol (E.O.) were used without further purification but were stored in the freezer.

Solutions were prepared by distilling the solvent (THF) into the cell directly under vacuum, which contained the preweighed sample and the supporting electrolyte (TBAP) corresponding to 0.1*M* solution. This solution was degassed by 3∼5 freeze-pump-thaw cycles by pumping down to a vacuum of 10^{-6} Torr.

A three-electrode cell, where the platinum disk (area ≅ 0.017 cm²) and a platinum wire were used as working and auxiliary electrodes, respectively, was used for the voltammetric and potentiostatic measurements. For most of the electrochemical measurements, a shielded silver wire pseudo-reference electrode was used, while an SCE electrode was used as a reference for the measurements of the electrode potentials reported in Table I. In coulometry experiments, a three compartment cell described by Childs *et al.* (12) with a large platinum gauze electrode was used. All experiments were carried out at room temperatures. In all cyclic voltammetric measurements, the *iR* drop was compensated by the positive feedback built in the potentiostat used.

A Princeton Applied Research (PAR) 173 (potentiostat-galvanostat) with a PAR 175 (Universal programmer) was used for chronoamperometric, chronopotentiometric, and cyclic voltammetric measurements. For coulometric experiments, a PAR 179 (digital coulometer) attached to the PAR 173 was used. A Cary-14 UV-VIS spectrophotometer was used for recording electronic absorption spectra of the electrolysis products.

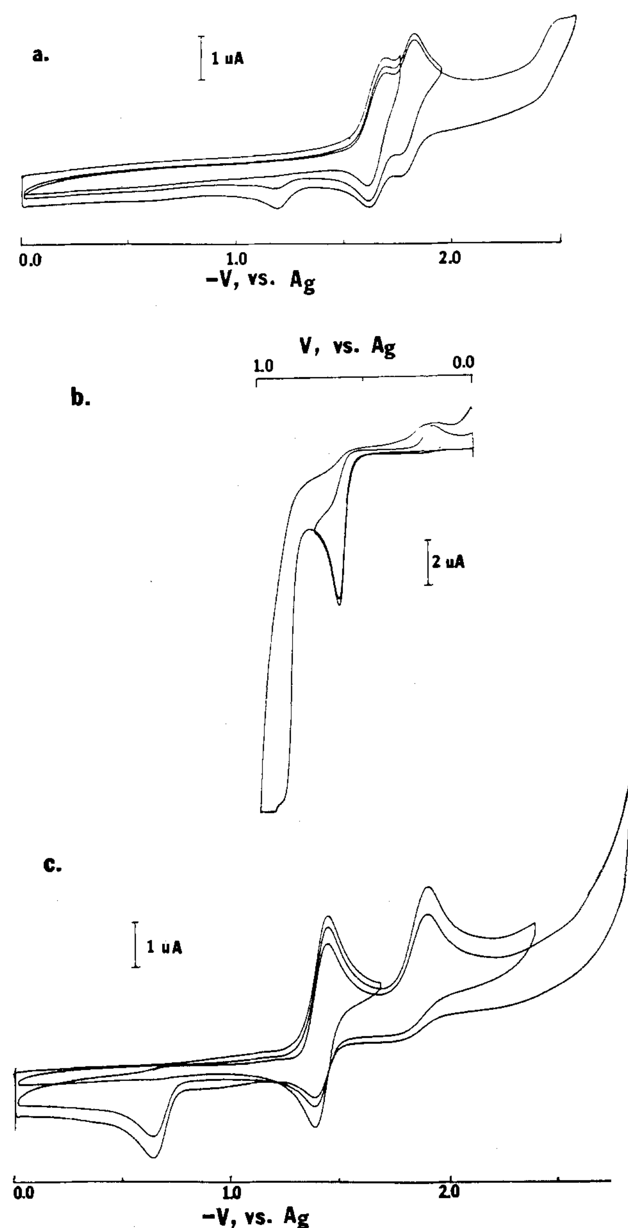

Fig. 1. (a) Cyclic voltammogram of β-carotene reduction at Pt disk electrode in THF solution with TBAP (0.1*M*) as a supporting electrolyte. The solution was 0.94 mV in β-carotene. (b) Cyclic voltammogram of β-carotene oxidation (1.0 m*M* in β-carotene). (c) Cyclic voltammogram of retinal reduction (1.1 m*M* is retinal). Scan rates were 100 mM/sec in all cases.

Results and Discussion

Electrode potentials of these compounds, cyclic voltammetric data of β-carotene and retinal reductions, and coulometric data are summarized in Tables I-IV. Part of the cyclic voltammetric results are reproduced in Fig. 1(a)-(c). Electrode potentials listed in Table I are in good agreement with the literature values (8, 9) within experimental error. More detailed observations and discussion follow.

Cyclic voltammetric results.—Cyclic voltammograms (CV) of selected redox systems are shown in Fig. 1. As is evident from Fig. 1(a) and (c), reductions of β-carotene and retinal are reversible, one-electron transfer processes, while oxidations of β-carotene and retinal (not shown) are irreversible. Oxidation and reduction of retinol, however, were totally irreversible, and the redox potentials were further beyond those of β-carotene and retinal (Table I). In the cases of β-carotene and retinal reductions, the electrogenerated species (radical anions) decay to some other product slowly, as can be seen from Tables II and III (i_{pa}/i_{pc}) and from CV's in Fig. 1. The number of electrons transferred, listed in Table I, was obtained by comparison of the current functions of these compounds with that of a known one, *i.e.*, 9,10-diphenylanthracene under the same experimental conditions, assuming that diffusion coefficients are not very different.

† In acetonitrile, the oxidation wave heights were almost the same as those of reduction waves, indicating 1e-transfer process.

Cyclic voltammetric data listed in Tables II and III indicate that reductions of β-carotene and retinal are characteristic of EC or ECE. It is not clear from these tables, however, whether the electrode reaction has the EC or ECE character.

Peak separations between the cathodic and anodic waves of β-carotene and retinal reductions are approximately 60 mV, consistent with the one-electron transfer process. Employing the diffusion coefficients reported by Takahashi *et al.* (8), the heterogeneous electron transfer rate constant (k_s) at the platinum electrode is estimated to be $(3.3 \pm 2.7) \times 10^{-3}$ and $(2.4 \pm 1.3) \times 10^{-2}$ cm/sec for β-carotene and retinal, respectively, from the formula given by Nicholson (13). The aldehyde group on retinal seems to affect the k_s value by approximately one order of magnitude, even though the length of the carbon chain is only a half of β-carotene.

It is apparent from the cyclic voltammogram shown in Fig. 1(b) and the CV data that the oxidation of β-carotene is a two-electron transfer process, followed by rapid chemical reaction. Retinal, however, undergoes four-electron, irreversible oxidation.

Retinol, as already pointed out, undergoes one-electron reduction and oxidation at the platinum electrode in THF. The electrode reaction product, however, rapidly blocks the electrode surface, making further measurements difficult. We therefore did not pursue a detailed study on this system.

Chronoamperometric results.—Chronoamperometric data on β-carotene and retinal reduction are shown in Fig. 2, where $i \cdot t^{1/2}$ is plotted for the different time durations. In both cases, the potential was controlled such that the current at the first reduction waves was monitored. For the reduction of β-carotene, the plot is characteristic of a reversible, diffusion-controlled reaction, with a possible slow following reaction. The plot shown for the retinal reduction is more characteristic of an ECE reaction, since $i \cdot t^{1/2}$ increases with time. This result, along with CV data, may establish an EC nature for the β-carotene reduction and an ECE nature for the retinal reduction, although it is not so clear-cut.

Chronopotentiometric results.—Since it is certain from CV and chronoamperometric data that the reduction of both β-carotene and retinal has either EC or ECE character, it would be interesting to see how fast the electrogenerated species, *i.e.*, the radical anion, decays to the products or other intermediate species. To determine this pseudo-first-order decay rate constant, reversal (or cyclic) chronopotentiometric experiments were performed and the results are presented in Fig. 3(a) and (b). Here kt_1, obtained from the table prepared according to Testa and Reinmuth (14) was plotted against t_1, where k is the pseudo first-order decay rate constant and t_1 is the current reversal time. For a reversible electron transfer reaction, in which

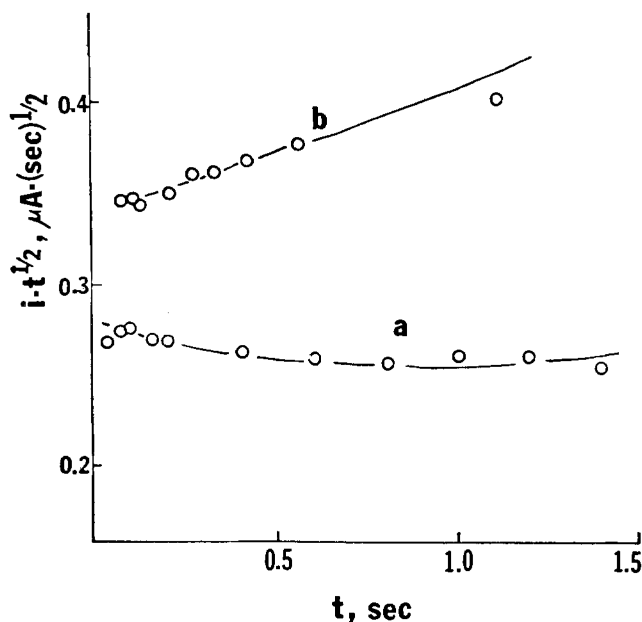

Fig. 2. Chronoamperometric data. Plot of $i \cdot t^{1/2}$ vs. t for the potential step at the first reduction potential for (a) β-carotene and (b) retinal.

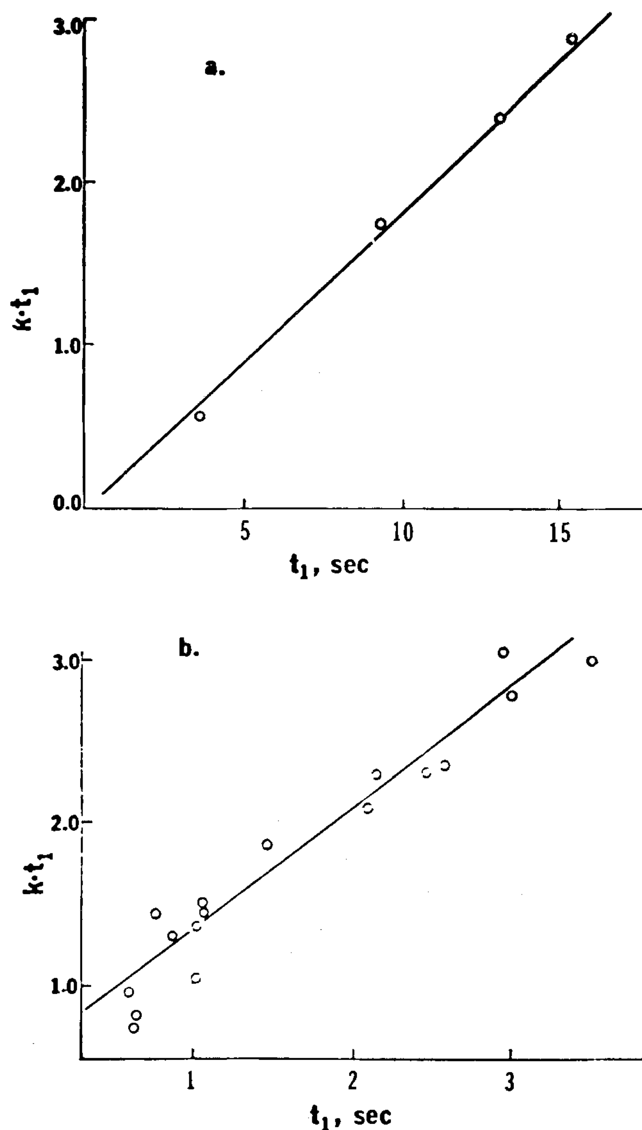

Fig. 3. Chronopotentiometric determination of pseudo-first-order decay rate constant. Plot of kt_1 vs. t_1 for (a) β-carotene and (b) retinal reduction.

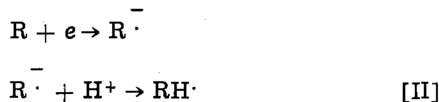
the electrogenerated species is very stable (or k is practically 0), the ratio of τ_2/t_1, where τ_2 is the chronopotentiometric transition time after the current reversal, should be 1/3 irrespective of the reversal time (14, 15). When there is a kinetic complication, this ratio is a function of the reversal time, and from the ratio of τ_2/t_1, one can read kt_1 from the tabulated values or the working curve. If one plots kt_1 thus obtained against t_1, a straight line should result with the slope equal to the pseudo first-order decay rate constant. The slopes thus obtained from Fig. 3(a) and (b) are 0.21 and 0.74 sec^{-1} for radical anions of β-carotene and retinal, respectively. Mairanovsky *et al.* (9) reported that the rate constant of the anion radical of β-carotene was 0.21 and 0.76 sec^{-1} in a THF solution with 0.3% H_2O present.

A suggested route of the decay process could be the abstraction of and combination with the hydrogen ion, H^+, either from the solvent or a trace amount of water present in the solvent, *i.e.*

$$R^{\bar{\cdot}} + H^+ \rightarrow RH\cdot \qquad [I]$$

This reaction path is further rationalized by coulometric experiments. The fate of RH· thus produced is discussed in the next section.

Coulometric results.—The number of electrons transferred for reductions or oxidations of these compounds was determined from the CV data and shown in Table I. To further study the electrode mechanisms, coulometric measurements were made and the results are listed in Table IV. Apparently the coulometric results shown in Table IV are not in agreement with n_{app} obtained voltammetrically. This indicates that the reductions and oxidations of these compounds at the electrode are very complicated. The coulometric result obtained here can be explained by the reduction mechanism proposed by Mairanovsky *et al.* (9) as follows



$$R + e \rightarrow R^{\bar{\cdot}}$$

$$R^{\bar{\cdot}} + H^+ \rightarrow RH\cdot \qquad [II]$$

$$RH\cdot + e \rightarrow RH^-$$

$$\text{Over-all} \quad R + H^+ + 2e \rightarrow RH^-$$

or

$$R + e \rightarrow R^{\bar{\cdot}}$$

$$R^{\bar{\cdot}} + H^+ \rightarrow RH\cdot \qquad [III]$$

$$RH\cdot + R^{\bar{\cdot}} \rightarrow RH^- + R$$

$$\text{Over-all} \quad R + H^+ + 2e \rightarrow RH^-$$

The coulometric result does not distinguish whether the reaction sequence [II] or [III] is really occurring in the reduction. The chronoamperometric results presented above seem to indicate that β-carotene reduction may have an EC character and retinal ECE. One may therefore conclude that β-carotene may follow route [III], while retinal follows route [II]. This is not clear, for even route [III], it is a catalytic process.

Table IV. Coulometric data, n_{app}*

	Reduction		Oxidation	
Substances	First wave	Second wave	w/o H_2O	w/H_2O‡
β-Carotene	2.2	2.7†	4.7†	10.1
Retinal	2.0†	2.7†	—	—

* See potentials listed in Table I.
† Average values of more than two measurements.
‡ Water was about 20% of the solution.

These two reactions are too close to be distinguished, although the above argument is reasonable.

These results indicate that an intermediate RH^- is produced regardless of whether one has $R^=$ or $R^{\bar{\cdot}}$ as a product of the reduction. Inspection of CV's in Fig. 1(a) and (c) suggests that the anodic wave observed at about $-1.2V$ ($\sim -0.65V$ for retinal) on potential reversal results only from the scan to the second reduction wave. Since the dianion ($R^=$) is formed on scanning to the second wave, we attribute this wave to the reaction

$$R^= + H^+ \rightarrow RH^- \qquad [IV]$$

$$R^- - e \rightarrow RH\cdot$$

after the second electron transfer

$$R^{\bar{\cdot}} + e \rightarrow R^=$$

at the second reduction wave. According to reaction path [II] or [III] above, one should have the same result, even if one generates $R^{\bar{\cdot}}$ at the first reduction potential. Indeed, this was found to be true for reductions of β-carotene and retinal, as is demonstrated in Fig. 4. When the potential is reversed after the first reduction wave, there is no discernable RH^- oxidation wave observed [(a) in Fig. 4]. If, however, one holds for a while at the first reduction potential before the reversal, the RH^- oxidation peak is observed. This peak height is also found to be a function of the electrolysis time [see (b) and (c) in Fig. 4]. This was true even when the scan was reversed at the peak potential of the first reduction wave. The same behavior was observed for the reduction of retinal, where the first and second waves are separated by about 400 mV. This result confirms that either reaction [II] or [III] is occurring at the electrode. This also indicates that the rate of combination with H^+ is faster for $R^=$ than for $R^{\bar{\cdot}}$. One can therefore readily see that, in the long-term electrolysis as in the coulometric experiment, the product is RH^-. This is clearly shown in Fig. 5, where CV's are recorded during the exhaustive electrolysis. As the electrolysis proceeds, the third and fourth reduction waves as well as the one attributable to RH^- oxidation at about $-1.2V$ increase at the expense of the first and the second reduction waves, even the potential is controlled so that only the first electron is transferred. The CV recorded after the electrolysis has been completed is shown in Fig. 5(b), where the anodic wave at $-1.2V$ as well as the third and fourth cathodic waves remained with improved shapes. We also found that the anodic wave appearing at $-1.2V$ decayed slowly as a function of time. The decay curve

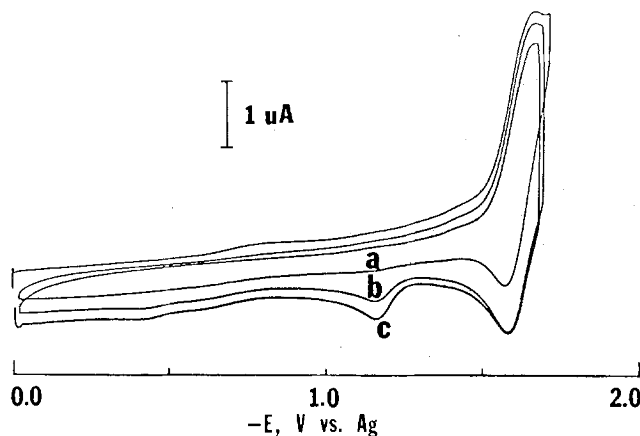


Fig. 4. Time dependence of RH^- generation. (a) Scan reversed without delay. (b) Scan reversed after 15 sec delay at the reversal potential. (c) Scan reversed after 30 sec delay. This was the reduction of β-carotene. Scan rates were 100 mV/sec.

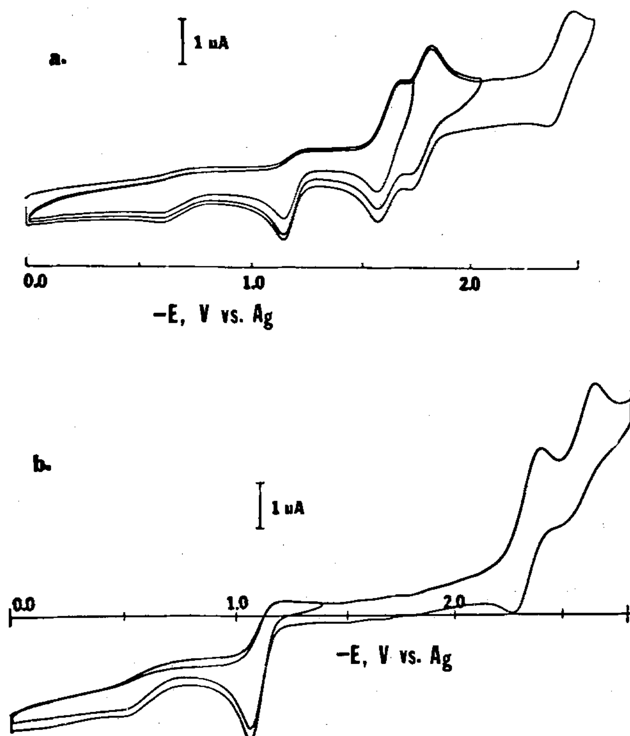

Fig. 5. (a) Voltammogram of β-carotene after about 40% exhaustive electrolysis at the first reduction potential with a scan rate of 100 mV/sec. (b) Cyclic voltammogram of β-carotene after complete electrolysis. Scan rate was 100 mV/sec.

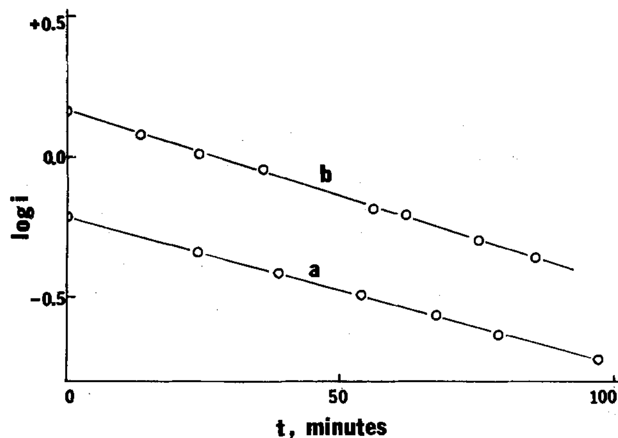

Fig. 6. Log i vs. t plot for the oxidation of RH^- (i in μA). Species RH^- derived from (a) β-carotene and (b) from retinal.

(log i vs. t plot) is shown in Fig. 6. The excellent linearity of this plot clearly demonstrates that the decay is a first-order process. The slope of these lines gives the pseudo first-order decay rate constants of 0.0052 min^{-1} for RH^- species derived from β-carotene and 0.0060 min^{-1} for retinal. Even after these RH^- peaks disappeared, the third and fourth waves remained. This leads us to conclude that these reduction waves, which resemble the first and the second waves of the parent compound, respectively, can be attributed to the reduction of the other carotenoid compound produced by the reduction of β-carotene, *i.e.*

$$RH^- + H^+ \rightarrow RH_2$$

$$RH_2 + e \rightarrow \overset{-}{RH_2}\cdot \qquad [V]$$

$$\overset{-}{RH_2}\cdot + e \rightarrow RH_2^{=}, \text{ etc.}$$

We also notice that the CV current corresponding to RH_2 reduction recorded after electrolysis at the first reduction potential is approximately 1.5 times higher than the reduction current observed for the parent molecule before electrolysis. The higher current of the product reduction wave can be explained by assuming that two identical molecules are produced by exhaustive electrolysis and reduced. This observation along with those to be described below may answer the question as to the identity of the reduced product. The most reasonable conclusion could be that the reduction occurred at 15,15′-positions, resulting in two isolated identical olefinic hydrocarbons, *i.e.*, two axerophtenes linked with an ethylene bridge among others. Theoretically, one should have exactly two times the current by having this 15,15′-dihydro-β-carotene, since one generates two identical molecules by reduction. The fact that we have only 1.5 times the current indicates that there should be another product(s). In order to confirm this, an absorption spectrum was recorded for the product in the THF solution. The λ_{max}'s were 336 and 399 nm with fine vibration structures at 321 nm (shoulder) and 356 nm, and 369 and 424 nm, respectively. According to an empirical formula devised by Hirayama (17) for the calculation of λ_{max} of this type of compounds

$$\lambda_{max}^2 = (37.56 - 39.68 \times 0.920^N) \times 10^4 \text{ nm}^2 (\text{in THF})$$

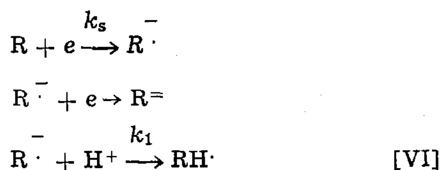
where N is a constant determined by the number of effective double bonds and the nature and number of substituents the prospective product, *i.e.*, two axerophtenes, should have the λ_{max} of 332 nm in THF. If, instead, some portion of β-carotene is reduced at either the 11,12- or the 11′,12′-position, the product has one more double bond than axerophtene, and is expected to have the λ_{max} of 393 nm. Both λ_{max}'s observed are in good agreement with those calculated and one may therefore conclude that the major reduction product is 15,15′-dihydro-β-carotene and the by-product may be 11,12-dihydro-β-carotene. Further, the reduction potential of this product is −2.46V *vs.* SCE (Table I) and the reduction potential of axerophtene (9) is reported to be −2.32V *vs.* SCE. There was always some current observed between the second and the third reduction peaks, although the wave was not well defined. This may be due to the reduction of 11,12-dihydro-product, since this compound is expected to reduce at lower potential than 15,15′-dihydro-product.

When the exhaustive electrolysis was carried out at the second reduction potential, where only $R^=$ is produced instead of $\overset{-}{R}\cdot$, the result was exactly the same. The number of faradays per mole of the parent molecule at the first reduction potential is also the same as the one obtained by the electrolysis at the second reduction potential within experimental error (Table IV). These results are justified by the electrode mechanisms already described.

In the case of retinal reduction, the result was the same except that the reduction current corresponding to the product was much lower. The reduction wave corresponding to that of the product appeared at approximately the same potential as those of retinol, but the yield was quite low, judging from the current observed after reduction. When the absorption spectrum was obtained from the electrolyzed product, there apparently was a component corresponding to the absorption of an alcohol (~ 325 nm retinol), but this was not the major band. The major absorption bands were at 245 and 292 nm. This indicates that the reduction occurred mostly at the double bond of the hydrocarbon rather than at the carbonyl group. From the same calculations as above, one can deduce that the most reduction occurred at 11,12- and 13,14-positions, whose calculated λ_{max} are 243 and 290 nm, respectively. The alcohol, apparently a by-prodcut of the reduction of retinal, could be simply retinol or a glycol, as already reported (10, 11). Addition of H_2O to the solution (~20%) did not change the reduction product dras-

tically. The same result was obtained by electrolysis at the second reduction potential.

In summary, the following electrode mechanisms are consistent with results presented



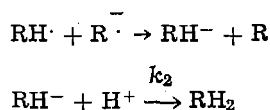
$$R + e \xrightarrow{k_s} \bar{R}\cdot$$

$$\bar{R}\cdot + e \rightarrow R^{=}$$

$$\bar{R}\cdot + H^+ \xrightarrow{k_1} RH\cdot \quad [VI]$$

$$RH\cdot + e \rightarrow RH^-$$

or



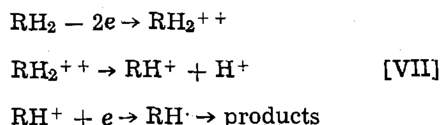
$$RH\cdot + \bar{R}\cdot \rightarrow RH^- + R$$

$$RH^- + H^+ \xrightarrow{k_2} RH_2$$

where k_1 is 0.21 and 0.74 sec^{-1} and k_2 is 5.2×10^{-3} and 6.0×10^{-3} min^{-1} for β-carotene and retinal, respectively.

Oxidation of β-carotene.—Since the oxidation of β-carotene is of a major interest in terms of the *in vivo* reaction, our study is limited to that of β-carotene only. No attempts were made to study oxidation processes of retinal and retinol in detail.

Two electrons were found to be involved in oxidation of β-carotene at the electrode by both our result and the one reported by Mairanovsky *et al.* These authors proposed an oxidation mechanism, where RH_2 is a parent molecule



$$RH_2 - 2e \rightarrow RH_2^{++}$$

$$RH_2^{++} \rightarrow RH^+ + H^+ \quad [VII]$$

$$RH^+ + e \rightarrow RH\cdot \rightarrow \text{products}$$

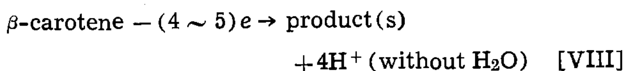
i.e., β-carotene. The most probable product could be a dimer, and/or polymers, if the above mechanism describes the electro-oxidation, since the free radical would initiate dimerization. This reaction, however, was found to be more complex than the one postulated above. The controlled potential coulometry result shows that 4 or 5 electrons may actually be involved in the over-all oxidation reaction. With water present, approximately 10 electrons are involved as shown in Table IV.

Inspection of CV shown in Fig. 1(b) indicates that there are two reductions of either a product or an intermediate species at ~ 0.20 and ~ −0.10V on reversal scan. The reduction wave at about −0.10V is not apparent from the figure shown, but this was true in all of our observations. This voltammetric behavior is different from the one reported by Mairanovsky *et al.*, where they had only one reduction wave on reversal, which they attributed to H^+ reduction. We have carried out the exhaustive electrolysis and the CV's were recorded, while the electro-oxidation was being carried out (not shown). On electrolysis at the large platinum electrode, the two reduction waves behaved differently: The cathodic current at 0.20V was decreased as the concentration of β-carotene was depleted, while the one at −0.10V increased as the electrolysis proceeds. The increase in the cathodic current at −0.10V was much faster than the decrease in β-carotene concentration. This result indicates that the former must be a reduction of an intermediate, while the latter should be a product, *e.g.*, H^+. After the electrolysis was completed, the current at −0.10V was approximately twice the oxidation current or four times the reduction current of β-carotene before electrolysis. Assuming that this is the H^+ reduction, the amount of H^+ was determined coulometrically and the number of H^+ released was about 4.1 moles for each mole of β-carotene. After this was completely reduced coulometrically, no major reduction peaks appear within the background potential of THF. There were, however, low currents observed at potentials which might correspond to reduction of alcohols. Products, therefore, seem to be the cleaved hydrocarbons having fewer double bonds, and/or the alcohol derived from the carbonium ion with the trace of water.

Absorption spectrum of the electrolyzed solution without water shows that there are many products absorbing at wavelengths ranging 240 ~ 400 nm. Dimerization, therefore, is not a likely process and oxidative cleavages seem to be the main ones occurring instead. No attempts were made to analyze the products.

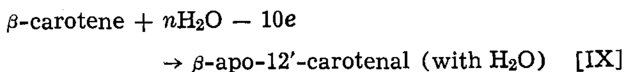
When water was added (~ 20%) and electrolyzed, there seemed to be a single product formed, or at least a large amount of a single compound with small or trace amounts of by-products. The CV recorded after exhaustive electrolysis at the first oxidation potential in the presence of water is shown in Fig. 7, and we notice that this resembles the reductions of both retinal and β-carotene. The fact that the reduction potential is lower suggests that this compound should be an aldehyde with longer chains than retinal. The absorption spectrum of this solution was obtained and λ_{max} was at 406 nm with two vibrational structures at 383 and 428 nm (408 nm in petroleum ether and 409 nm in ethyl alcohol). This product is identified to be β-apo-12′-carotenal by comparison with absorption spectra in the literature (2, 18, 19).

We do not have data to conclude the electrode mechanism of this process, but the over-all reaction is found to be



$$\beta\text{-carotene} - (4 \sim 5)e \rightarrow \text{product(s)} + 4H^+ \text{ (without } H_2O\text{)} \quad [VIII]$$

and



$$\beta\text{-carotene} + nH_2O - 10e \rightarrow \beta\text{-apo-12'-carotenal (with } H_2O\text{)} \quad [IX]$$

Since the one-step oxidative cleavage at 11,12-position to form the above product from reaction [IX] would require a four-electron process, we can conclude that reaction [IX] is a multistep process.

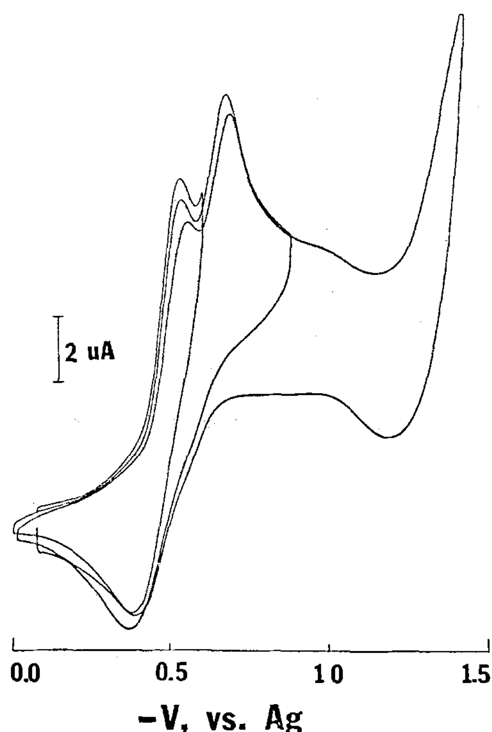


Fig. 7. Cyclic voltammogram after exhaustive oxidation of β-carotene in the presence of H_2O (~20%) with a scan rate of 100 mV/sec.

Conclusion

The results of both oxidation and reduction of selected carotenoids in THF solutions indicate that electrode reactions do not have the same specificities shown by *in vivo* reactions. The reaction specificities cannot be explained by the theoretical indexes, either. Quantum mechanical indexes calculated by Pullman (20, 21) with the LCAO method are reproduced in Fig. 8. All of these indexes indicate that the double bond at the 5,6- or terminal position has a higher reactivity than those inside; yet the result we obtained is not in agreement with theoretical predictions. As the Pullmans discuss (21), the terminal attack is more likely than the attack at the central double bonds. This might have been what has happened in the β-carotene oxidation as suggested by the number of electrons transferred for reaction [IX], as already pointed out. There have been some evidences that β-apo-12′-carotenal is an intermediate in rat metabolism (6) of β-carotene. We still cannot offer any explanation as to why the electrochemical reaction stops at the 12-position, while *in vivo* reaction stops at the 15-position to produce the retinal. There is also no reasonable explanation for the reduction of β-carotene at either the 15,15′- or 11,12-position. Since the LCAO method of Pullman (20, 21) failed to explain the reactivities, a more elaborate theoretical treatment may be desired.

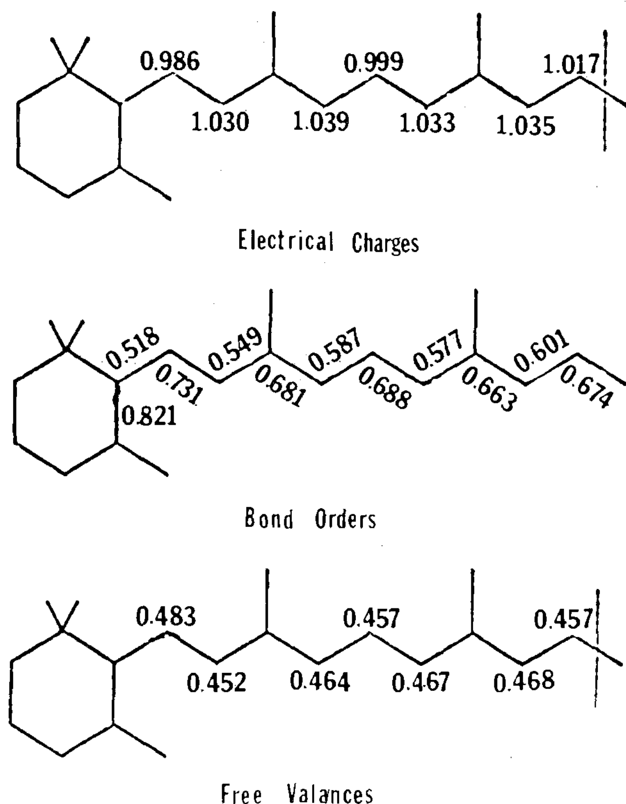

Fig. 8. Quantum mechanical index of β-carotene. Taken from Ref. (21).

Although we did not reproduce the *in vivo* reaction at the electrode surface, the electro-oxidation of β-carotene in the presence of water may find some synthetic applications, since β-apo-12-carotenal is known to be a good vitamin A precursor (22).

The Theory of the Light-Induced Evolution of Hydrogen at Semiconductor Electrodes

J. O'M. Bockris* and K. Uosaki[1]

School of Physical Sciences, Flinders University of South Australia, Adelaide, Australia

ABSTRACT

The photoelectrode kinetics of the hydrogen evolution reaction is considered, using the WKB approximation for the penetration of the barrier at the semiconductor-solution interface. The absorption characteristics of photons in the electrode are introduced and the number of electrons produced at the surface is obtained as a function of the semiconductor statistics, and also diffusion and field effects. The model makes use of the conclusion that the photo-produced electrons have been deactivated to the bottom of the conduction band by the time they have diffused from the point of photon absorption to the surface. Image energy and the potential difference in the double layer at the semiconductor-solution interface are taken into account. The expression obtained for the photo hydrogen current density is tested in its ability to predict the photo-current-potential curves at the gallium phosphide cathode. Agreement with experiment is fair. Discrepancies are discussed.

Although photoeffects on electrochemical reactions at semiconductor-solution interfaces have been studied intensively (1-3), few theoretical analyses have been given (4-6). These all have the substantial defect that they consider the activation of electrons arising from interactions within the semiconductor and neglect an analysis of transfer through the electric double layer at the semiconductor-solution interface.

Photoeffects on electron transfer reactions at the metal/solution interfaces have been studied by Brodsky *et al.* (7). Bockris *et al.* (8) have treated photoeffects in hydrogen evolution reaction at metals, using the WKB approximation for electron tunneling through the double layer (9, 10).

In the present paper, we apply this approach to photoeffects in the hydrogen evolution reaction at p-type semiconductors, taking into account the activation and transport of photogenerated electrons to the electrode surface. The approach made is quasi-phenomenological and does not attempt a general solution, independent of any assumption as to a rate-determining step.

Assumptions

In the absence of evidence to the contrary (11, 12), it is assumed that charge-transfer is the rate-determining step for the semiconductors used

$$\text{p-SC}(e) + H_3O^+ \rightarrow \text{p-SC—H—}H_2O \qquad [1]$$

The cathodic current, i_c, is given by (8, 13)

$$i_c = e_o \frac{C_A}{C_T} \int_o^\infty N(E) W(E) G(E) dE \qquad [2]$$

where e_o is the unit charge; $N(E)$ is the number of electrons arriving at the surface per unit area per unit time with energy, E; $W(E)$ is the WKB tunneling probability of electrons through the potential barrier at energy, E; $G(E)$ is the distribution function of the vibrational-rotational states of an acceptor, H_3O^+, at energy, E; C_A is the number of acceptors per unit area in the Outer Helmholtz Plane (OHP); C_T is the total number of sites per unit area in the OHP. Energy levels are counted as zero in value at the bottom of the conduction band.

In p-type electrodes, the absorption of photons activates electrons in the conduction band where they are available for cathodic reactions. (Contrast thermal electrochemical reactions at the semiconductor-solution interface, where p-type electrodes usually function as anodes).

The validity of the use of the WKB approximation was examined by Sen and Bockris (9), who compared the approach with that of the time-dependent perturbation theory, the results showing that the WKB approximation does not differ in order of magnitude from a time-dependent perturbation calculation for electron transfer (though there are significant discrepancies for proton transfer calculations).

Photon Absorption and Electron Excitation

The number of photons, the energy of which is $h\nu$, absorbed by the semiconductor between x and $x + dx$ from the surface, $N_{ph}(x)dx$, is given by

$$N_{ph}(x)dx = I_o(1 - R_\lambda)\alpha_\lambda e^{-\alpha_\lambda x}dx \qquad [3]$$

where I_o is the total number of photons of incident light of energy $h\nu$ per unit area per unit time ($cm^{-2} \cdot sec^{-1}$); R_λ and α_λ are, respectively, the reflectivity and the absorption coefficient of the semiconductor for the wavelength λ.

Each absorbed photon, the energy of which is greater than the energy gap of the semiconductor, makes an excited electron in the conduction band and a hole in the valence band. Therefore, the number of electrons excited between x and $x + dx$, $N_e(x)dx$, is equal to the number of photons absorbed between x and $x + dx$, $N_{ph}(x)dx$, and also to the number of holes produced in the valency band. From Eq. [3], $N_e(x)dx$ is given by

$$N_e(x)dx = N_h(x)dx = N_{ph}(x)dx \qquad [4]$$

Number of Electrons Arriving at the Electrode Surface

The electric field at the surface of a semiconductor is well known from the work of Kingston and Neustädter (14). It is possible to extend their result in finding an expression for the field at any point within the semiconductor.

* Electrochemical Society Active Member.
[1] Present address: Mitsubishi Petrochemical Company Limited, Ami, Ibaraki, Japan.
Key words: hydrogen, semiconductor, photoeffect, energy level.

One finds

$$\left(\frac{dV}{dx}\right)_x = \pm\sqrt{\frac{8\pi kT}{\epsilon}\left[-(N_D - N_A)y + p_0(e^{-y} - 1) + n_0(e^{y} - 1)\right]} \quad [5]$$

where

$$y = \frac{e_0(V_x - V_b)}{kT} \quad [6]$$

and the + sign is for $y < 0$.

The number of photoexcited electrons, originally expressed for $x = x$ in Eq. [3] and [4], decreases to $N_{e,x=x-dx}(x)dx$, after traveling dx. Then

$$N_{e,x=x-dx}(x)dx = N_e(x)e^{-\frac{1}{L(x)}dx}dx \quad [7]$$

where $L(x)$, the mean free path of electrons at x, is given by (15)

$$L(x) = \frac{2l_D^2}{\sqrt{l_E^2 + 4l_D^2} - l_E} \quad [8]$$

where l_D is the diffusion length and l_E is the drift length. The terms l_D and l_E are given by[2]

$$l_D = \sqrt{D\tau_e} = \sqrt{300\mu_e\tau_e kT/e_0} \quad [9]$$

$$l_E = \tau_e\mu_e V'(x) \quad [10]$$

respectively, where μ_e is the mobility of the electron $cm^2\ V^{-1}\ sec^{-1}$, τ_e is the lifetime of the electron, and $V'(x)$ is the potential gradient at $x(-(dV/dx)_x$ in $V\ cm^{-1})$.

Similarly

$$N_{e,x=x-2dx}(x)dx = N_{e,x=x-dx}(x)e^{-\frac{1}{L(x-dx)}dx}dx$$

$$= N_e(x)e^{-\left(\frac{1}{L(x)} + \frac{1}{L(x-dx)}\right)dx}dx \quad [11]$$

After N steps ($N = x/dx$), at the surface

$$N_{e,x=0}(x)dx = N_{e,x=dx}e^{-\frac{1}{L(dx)}dx}dx$$

$$= N_e(x)e^{-\left(\frac{1}{L(x)} + \frac{1}{L(x-dx)} + \cdots + \frac{1}{L(dx)}\right)dx}dx \quad [12]$$

$N_{e,x=0}(x)dx$ is the number of electrons excited between x and $x + dx$ arriving at the surface per unit area per unit time. Therefore, the total number of electrons arriving at the surface per unit area per unit time $N_e(h\nu,V)$, is given by

$$N_e(h\nu,V) = \int_0^\infty N_{e,x=0}(x)dx \quad [13]$$

which represents all the electrons excited by photons at any distance inside the semiconductor and which reach the surface, where V is the p.d. inside the semiconductor.

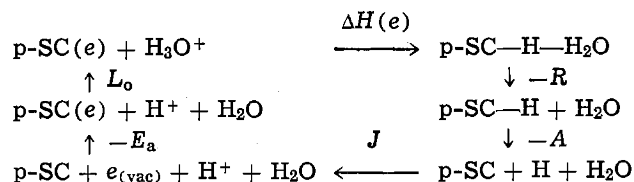
The Energy of an Electron Arriving at the Surface

The experimentally observed independence of the so-called critical potential (*i.e.*, the potential at which, for light of a given wavelength, the current begins) with the energy of the exciting photons, Fig. 1 (16), suggests that the energies of all the photoexcited electrons are the same by the time they reach the surface. It seems reasonable to postulate that this energy is the bottom of the conduction band. Thus, the average path length of an electron is $1/\alpha \simeq 10^{-4}$ cm. A typical mean free path for an electron-phonon collision is (17) 60Å. Hence, a typical energy loss for electrons in reaching the surface is $(10^4/60)$. 0.025 eV ($\simeq$ 4 eV). Thus, the photoexcited electron is effectively deactivated to the energy at the bottom of the conduction band before it reaches the surface (though it does not cross the energy gap, which would need a deactivating cause equivalent in energy to several electron volts).

[2] k and e_0 must be in gaussian units.

Electron Transfer Process

Energy level of an acceptor in solution.—The enthalpy change for electron transfer from a semiconductor to H_3O^+.—The standard enthalpy change, $\Delta H(e)$, for an electron transfer reaction corresponding to Eq. [1] from the bottom of the conduction band of the semiconductor at the surface to the proton in solution when the proton-solvent system is in its ground state and no potential drop it in the electric double layer can be obtained by using the following thermodynamic cycle



where R, A, J, E_a and L_0 represent the H-H_2O repulsive force, the heat of adsorption of a hydrogen atom on the semiconductor, the ionization potential of the hydrogen atom, the electron affinity of the semiconductor, and the hydration energy of proton, respectively. In respect to R and A, these quantities are distance dependent and the distance assumed was that appropriate to their state at neutralization. Therefore

$$\Delta H(e) = -L_0 + E_a - J + A + R \quad [14]$$

The energy level of an electron in the ground state of the H_3O^+ ion.—By taking into account the potential drop in the electric double layer at the flatband potential (Fig. 2), the energy level of an electron in the ground state of H_3O^+ with respect to the bottom of the conduction band at the flatband potential, $\Delta H'(e)$, is given by

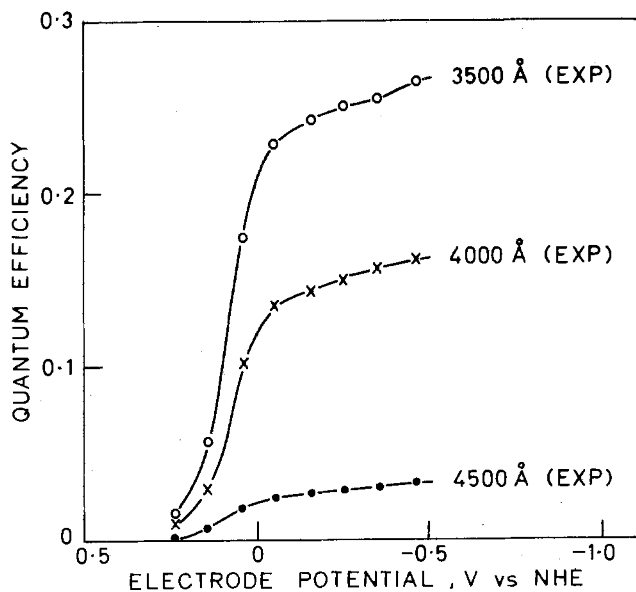


Fig. 1. The experimental quantum efficiency-potential relations of p-GaP in 1N H_2SO_4.

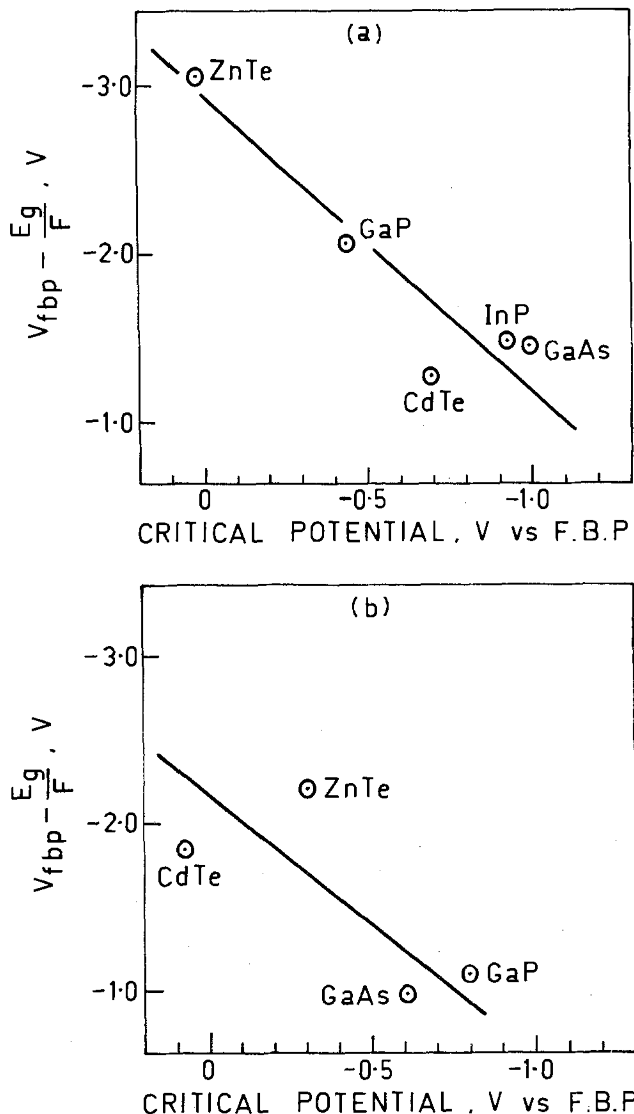

Fig. 2. The relations between (V_{fbp} $-E_g/F$) and the critical potential with respect to the flatband potential in 1N NaOH (a) and 1N H_2SO_4 (b).

$$\Delta H'(e) = \Delta H(e) + F(^{SC}\Delta^{S}\phi)_{fbp}$$

$$= -L_o + E_a - J + A + R + F(^{SC}\Delta^{S}\phi)_{fbp} \quad [15]$$

where $^{SC}\Delta^{S}\phi$ is an absolute potential (18, 19).

The barrier for electron transfer.—Image interaction and the dielectric constant of water.—We have neglected the interaction energy between an emitted electron and its image in a metal in the barrier construction for the photoeffect at metal electrodes (8). In these calculations, the optical dielectric constant was used for the dielectric constant of water. The reason for the neglect of the image interaction was that the emitted electrons travel across the barrier too quickly to make an image in the semiconductor. The optical dielectric constant was used for the same reason.

However, there was some misunderstanding in these considerations. When one wants to construct a potential barrier, one should consider an ideal test charge, *i.e.*, a ("classical") electron moving slowly enough to make its image in the semiconductor. Thus, the interaction energy between the emitted electron and its image should be taken into account in determining the energy barrier and the static dielectric constant of water [=6 for the oriented water molecules adsorbed on the electric double layer (20, 21)].

The image interaction, $U_{im}(x)$, is given by

$$U_{im}(x) = \frac{e_o^2}{4x\epsilon_{st}} \frac{\epsilon_{st} - \epsilon}{\epsilon_{st} + \epsilon} \quad [16]$$

Interaction with ions in the OHP and their images.—When a photoexcited electron leaves the semiconductor surface, it interacts with all ions in the OHP and their electrical images in the semiconductor. The Coulombic force between this electron (x from electrode) and all ions in OHP and their images, $F(x)$, is given by (8)

$$F(x) = -\frac{e_o^2}{(\delta_r - d_{O\text{-}H} - x)^2\epsilon_{st}} + \frac{e_o^2}{(\delta_r - d_{OH} + x)^2\epsilon_{st}} \frac{\epsilon - \epsilon_{st}}{\epsilon + \epsilon_{st}} - \frac{2\pi e_o^2}{\epsilon_{st}} \sum_{n=1}^{\infty} \left\{ \frac{d - x}{\{(d-x)^2 + n^2R_i^2\}^{3/2}} - \frac{d + x}{\{(d+x)^2 + n^2R_i^2\}^{3/2}} \frac{\epsilon - \epsilon_{st}}{\epsilon + \epsilon_{st}} \right\} \quad [17]$$

where δ_r is the distance between the electrode surface and the nearest proton of the H_3O^+ ion, $d_{O\text{-}H}$ is the distance between hydrogen and oxygen atom in water, d is the distance between the semiconductor surface and OHP, ϵ_{st} is the static dielectric constant of water, n = 1, 2, 3 and represents the succession of rings of ions around a given central ion, and R_i is the distance between two ions in the OHP, depending on its coverage with ions and determined by $R_i = 4r_i/(\pi\theta)^{1/2}$, where θ is the coverage and r_i is the radius of the ions. *Potential barrier.*—From the above considerations, the potential energy barrier for electron transfer, $U(x)$, from the surface of the semiconductor surface to the H_3O^+ is given by

$$U(x) = U_{im}(x) + \int_0^x F(x)dx + e_oX_xx \quad [18]$$

where X_x is the field in the double layer.

Potential Drop in the Semiconductor and in the Double Layer

The potential drop in the electric double layer at the SC-solution interface is often considered to be negligible (22). However, when the carrier density of the semiconductor is high, or the density of the surface states is high, the potential drop in the electric double layer cannot be ignored. We can obtain this quantity from an analysis of the Mott-Schottky plot (23, 24).

The Mott-Schottky relation is given by

$$\frac{1}{C_{SC}^2} = \frac{8\pi}{\epsilon e_o N_A}\left(\psi_{SC} - \frac{kT}{e_o}\right) \quad [19]$$

where C_{SC} is the space charge capacity, N_A is the concentration of ionized acceptors, and ψ_{SC} is the potential drop in the space charge layer.

The appropriate relation in the case of measurements in solution is[3]

$$\frac{1}{C^2} = \frac{8\pi}{\epsilon e_o N_A}\left(V - V_{fbp} - \frac{kT}{e_o}\right) \quad [20]$$

where C is the total capacity of the electrode (neglecting the roughness factor) and V and V_{fbp} are the electrode potential and the flatband potential with respect to a reference electrode, respectively.

Since (see Fig. 2)

$$V - V_{fbp} = \psi_{SC} + \Delta\Delta\phi_H \quad [21]$$

[3] C_{SC} has been assumed equal to $C_{measured}$ because other capacitances (*e.g.*, that of the counterelectrode and Helmholtz layer) are much larger than C_{SC} and hence negligible in series array.

where

$$\Delta\Delta\phi_H = ({}^{SC}\Delta^S\phi)_V - ({}^{SC}\Delta^S\phi)_{fbp} \quad [22]$$

and $\Delta\phi$ is the Galvani p.d. in the double layer at V and the fbp, respectively, then, Eq. [21] becomes

$$\frac{1}{C^2} = \frac{8\pi}{\epsilon e_o N_A}\left(\psi_{SC} + \Delta\Delta\phi_H - \frac{kT}{e_o}\right) \quad [23]$$

Only when $\Delta\Delta\phi_H = 0$ or $\Delta\Delta\phi_H = c\psi_{sc}$, where c is a proportional constant, does the plot between $(1/C^2)$ and V become linear (23, 24).

If $\Delta\Delta\phi_H = 0$, Eq. [21] becomes Eq. [20] and the slope of the experimental plot (Eq. [21]) must be the same as that of the theoretical plot.

In the case of $\Delta\Delta\phi_H = c\psi_{SC}$, Eq. [24] becomes

$$\frac{1}{C^2} = \frac{8\pi}{\epsilon e_o N_A}\left\{\psi_{SC}(1 + c) - \frac{kT}{e_o}\right\} \quad [24]$$

and thus, c can be calculated by comparing the experimental slope with the theoretical one. This is the case found in recent experimental work (16). $(V - V_{fbp})/(1 + c)$ gives the potential drop in the space charge layer in the semiconductor.

De Gryse *et al* (25) criticized reasoning of this type by showing that the slope of the plot has the same value whether the potential drop occurred in the electric double layer or not. However, in their treatment they assumed an absence of surface charge and this assumption limits the applicability of the interpretation.[4] The experimental *p*H dependence of the flatband potential can only be interpreted by assuming the existence of surface states, and the discussion of de Gryse *et al.* on this matter is no longer directly applicable to situations of this kind.

Photocurrent Expression

By taking into account the above considerations and Eq. [2], the photocurrent, i_p, is given by

$$i_p = e_o \frac{C_A}{C_T}\int_0^\infty N(E)W(E)G(E)dE$$

$$= e_o \frac{C_A}{C_T} N_e(h\nu,\psi_{SC})$$

$$\exp\left\{-\frac{\pi^2 l}{h}\sqrt{2m_e(U_m + e_o\Delta\Delta\phi_H)}\right\}$$

$$\exp\{-\beta(\Delta H(e) + e_o\Delta\Delta\phi_H)/kT\} \quad [25]$$

where $N_e(h\nu,\psi_{SC})$ is the number of electrons arriving at the surface when the potential drop in the semiconductor is ψ_{SC} and can be obtained from Eq. [13] replacing V by ψ_{SC}; U_{max} is the barrier maximum with respect to the bottom of the conduction band at the flatband potential; $\Delta\Delta\phi_H$ is defined in Eq. [22]; and V is defined in Eq. [21]. The use of $e_o\Delta\Delta\phi_H$ for the electron energy in the tunneling expression is consistent with a model in which the electrons arrive with a uniform energy at the bottom of the conduction band, *i.e.*, $E_e = 0$; and the barrier is then influenced by the p.d. in the double layer in the sense that the barrier is reduced when $\Delta\Delta\phi_H$ is negative.[5,6]

Computation of the Photocurrent-Potential Relation and Comparison with Experimental Results

Photocurrents were calculated for the example of GaP for different wavelengths of light as a function of potential. A schematic energy diagram, which shows the shape of the barrier, is shown in Fig. 3. It was constructed by the use of Eq. [16] and [17] in Eq. [18].

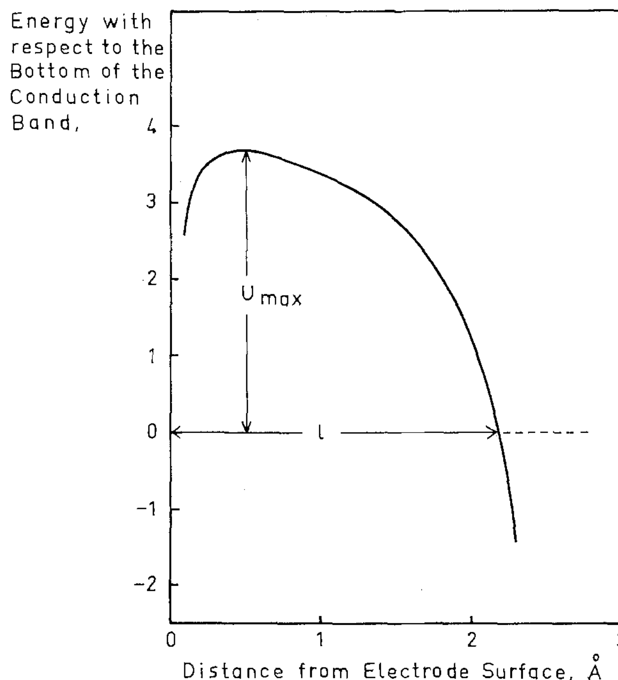

Fig. 3. Schematic diagram of the potential energy barrier for electron transfer from GaP electrode at flatband potential to an acceptor. (E_g is the energy gap; critical potential = potential at which photocurrent commences.)

The values used for the calculation of i_p through such a barrier by the use of [25] are: $\tau_e = 10^{-10}$ sec (26), $\mu_e = 300$ cm^2/V · sec (27), $L_o = -11.3$ eV (28), $E_a = 4.3$ eV (27), $J = 13.6$ eV (28), $A = -0.3$ eV (29), $R = -0.1$ eV (30), $\epsilon = 11$ (31), $E_g = 2.25$ eV (27), $V_{fbp} = 1.13$V (NHE) (16), and $c = 1.32$ (16). $({}^{SC}\Delta^S\phi)_{fbp}$ is taken from values given in the paper of Bockris and Uosaki (32). The theoretical results are shown in Fig. 4(a), (b), and (c) and are compared with experimental results. The calculated and experimental results agree fairly in respect to the position and shape of the quantum efficiency-potential relation. The potential at which the photocurrent commences (the so-called critical potential) is predicted to be 0.2-0.4 too positive.

Discussion of Discrepancies Between Theory and Experiment

Discrepancies between theory and experiment exist as follows:

1. Theoretically estimated quantum efficiencies are only 20-30% of the experimental quantum efficiencies.
2. The position of the theoretical quantum efficiency-potential relations appear at about 0.2-0.4V more positive than those of experiment.

These discrepancies may be due to cumulative uncertainties in the quantities of Eq. [17] which give the energy levels of electrons in the neutralized H_3O^+; $\Delta H(e)$ at the flatband potential and uncertainties in the value of the barrier width, which has been taken at 2.2Å, following the reasoning of Matthews and Bockris (28).

In respect to the determination of $\Delta H(e)$, the difference betwen the Fermi level and the top of the valency band was assumed to be zero. However, this quantity depends on the carrier density and has the order of 0.01 ~ 0.2 eV. Were this taken into account, the theoretical quantum efficiency-potential relations would shift toward more negative potentials (*i.e.*, an improvement) by 0.01-0.2V, depending on the carrier density.

[4] In general, the p.d. at a semiconductor-solution interface will be partly in the solution if the doping is very high or there is a significant concentration of surface states.

[5] Equation [25] is no longer an integral because transfer is seen as occurring only from electrons at the bottom of the conduction band (*i.e.*, photogenerated electrons have been deactivated until they arrive at the interface at a potential V_c).

[6] A rough computation for GaP-NaOH at 0 on the NH scale suggests that about 50% of the electrons activated by light reach the surface. Those which do not tunnel to the solution deactivate at the surface to the valence band.

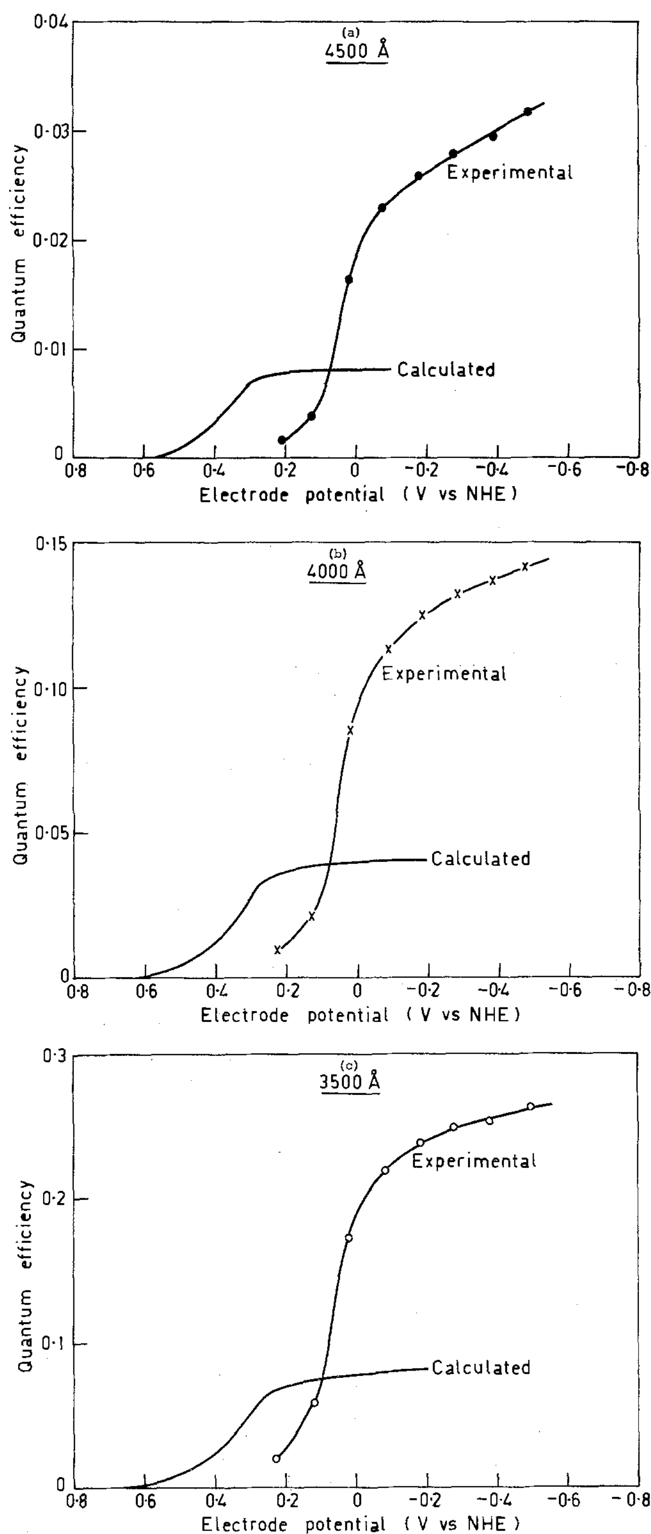

Fig. 4. Calculated and experimental quantum efficiency vs. electrode potential curves for GaP in 1*N* NaOH at the three monochromatic wavelengths (a) 4500; (b) 4000; and (c) 3500.

In respect to the determination of the barrier dimension, the electron was assumed to transfer to a proton in the second layer of water, to which a proton transfers from H_3O^+ in the OHP prior to electron transfer (28).[7] However, it may be possible that a proton transfers to water attached to the electrode surface, and electrons transfer to that. In this case, the barrier thickness becomes much smaller than that assumed and, therefore, higher quantum efficiency than those calculated in the present model would be expected.

[7] The origin of this model lies in the interpretation of the values observed for the dependence of the separation factor on the potential (11). Much lower barrier widths give separation factors which are too large.

Acknowledgment

Prediction of Flatband Potentials at Semiconductor-Electrolyte Interfaces from Atomic Electronegativities

M. A. Butler* and D. S. Ginley*

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

The electron affinities of several metal oxide semiconductors that have been used as anodes in photoelectrochemical cells are calculated using the atomic electronegativities of the constituent atoms. These electron affinities are quantitatively related to the measured flatband potentials by considering the effects of specific adsorption of potential-determining ions (for metal oxides used in photoelectrolysis, these are usually OH^- and H^+). Methods are discussed for determining the *p*H at which net adsorbed surface charge and thus potential across the Helmholtz layer is zero (point of zero zeta potential, pzzp). This *p*H value is shown to correlate with the electronegativity of the metal oxides. The application of these ideas to other semiconductor-electrolyte systems is discussed.

The use of semiconducting metal oxides to decompose water photoelectrolytically is a process which has recently attracted considerable interest (1). The ability of the photoelectrolysis cell to operate with little or no external bias in the system is a function of the degree to which the flatband potential is more negative than the hydrogen evolution potential. Thus it is very useful to be able to predict the flatband potentials of possible semiconducting metal oxide electrodes. In a recent publication (2) we showed that a correlation existed between the atomic electronegativities of the constituent atoms in titanates of the form $MTiO_3$ and the flatband potentials. In this paper, we extend this idea to all metal oxides and show it is capable of quantitatively predicting the flatband potentials.

In actuality, the quantity predicted from the atomic electronegativities is the electron affinity, *EA*, of the semiconductor. However, since the semiconductor's flatband potential, V_{fb}, and its electron affinity, *EA*, are essentially measures of the position of the intrinsic conduction band with respect to different references (standard calomel reference electrode and vacuum, respectively), they can be directly related by

$$EA = E_o + V_{fb} + \Delta_{fc} + \Delta_{pH} \quad [1]$$

where E_o is a constant relating the reference electrode to the vacuum level ($E_o = 4.75$ eV for SCE) (3), Δ_{fc} corrects for the difference between the doped Fermi level and the bottom of the conduction band ($\Delta_{fc} \sim 0.1$ eV for heavily doped metal oxides) (2), and Δ_{pH} is the potential drop across the Helmholtz layer due to specific adsorption of OH^- and H^+ ions. There exists some unique point for each semiconductor where the number of positively and negatively charged potential-determining ions at the interface are equivalent. At this point, the potential drop across the Helmholtz layer due to adsorbed ions is zero and Δ_{pH} or its equivalent for other adsorbed ions is zero. This point, called the point of zero zeta potential (pzzp) (4), is the only point at which truly meaningful flatbands can be measured and it is this flatband to which the calculated electron affinities should be compared. We will discuss the determination of the pzzp for several metal oxides and show that it correlates to the Fermi energy of the undoped metal oxide semiconductor. With these two correction factors (Δ_{fc} and Δ_{pH}) taken into account, the predicted and measured flatband potentials are in excellent agreement. Additionally, we will discuss some of the implications of these ideas to nonoxide electrodes and other than aqueous redox couples.

Calculation of Semiconductor Electron Affinity

Considerable success has been achieved in calculating Fermi energies and photoelectric thresholds for several classes of compounds (5) using the atomic electronegativities of the constituent atoms. Mulliken's definition of the electronegativity of a neutral atom is the arithmetic mean of the atomic electron affinity and the first ionization energy

$$\chi(M) = \tfrac{1}{2}\,(A_f + I_1) \quad [2]$$

where, for clarity's sake, we use A_f for the atomic electron affinity and I_1 is the first ionization potential. Since the ionization potentials (6) and electron affinities (7) for most atoms are tabulated, the Mulliken electronegativities $\chi(M)$ form a readily evaluated absolute electronegativity scale based only on measurable physical parameters. In a sense, $\chi(M)$ is the electrochemical potential of the electron in the neutral atom. When atoms are brought together to form compounds, charge will flow until the electrochemical potentials (electronegativities) are equalized. Sanderson (8) and more recently Nethercot (5), have postulated, based on bond length arguments, that the resulting bulk electronegativity of the compound is the geometric mean of the electronegativities of the constituent atoms. This assumption appears to be valid for a large number of compounds (5, 9). For a semiconductor the bulk electronegativity corresponds to the undoped Fermi level or halfway between the bottom of the conduction band and the top of the valence band. Thus the electron affinity of the compound will be given by

$$EA = \chi - \tfrac{1}{2}\,E_g \quad [3]$$

where E_g is the bandgap energy. Applying this equation and the postulate of the geometric mean, we find, for example, that for TiO_2, the electron affinity is

$$EA(TiO_2) = \chi(TiO_2) - \tfrac{1}{2}\,E_g = [\chi(Ti)\,\chi^2(O)]^{1/3} - \tfrac{1}{2}\,E_g = 4.33\ \text{eV} \quad [4]$$

relative to the vacuum level. We have calculated the electron affinities for a number of metal oxides and they are listed in Table I. Even without considering the correction terms in Eq. [1], there is obviously a strong correlation between the measured flatband potentials and calculated electron affinities as is illus-

Key words: photoelectrolysis, zeta potential, electron affinity.

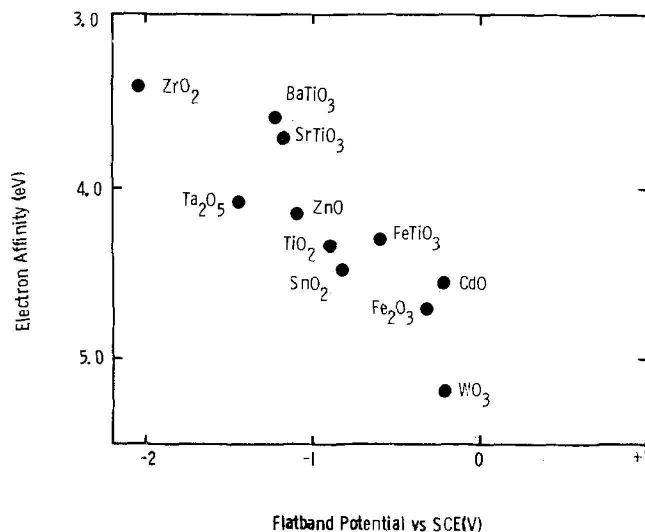

Fig. 1. The electron affinity calculated using atomic electronegativities vs. the flatband potentials measured at pH = 13.3 (1M NaOH).

strated in Fig. 1. As expected (10), the more negative flatband potentials come from semiconductors with smaller electron affinities. The correction for the difference between the doped Fermi level and the bottom of the conduction band depends, naturally, on doping level. However, for heavily doped metal oxides, commonly employed for photoelectrolysis, this term is only about 0.1 eV. Such a small correction cannot account for the scatter observed in Fig. 1. This must come from the specific adsorption of ions.

Point of Zero Zeta Potential (PZZP)

A brief discussion of the nature of the pzzp and the techniques employed for its measurement are in order due to the importance and magnitude of Δ_{pH}. There is a sizeable literature on the pzzp of metal oxides (4, 11-17), which colloidal chemists have traditionally referred to as the point of zero charge (pzc). This terminology is clearly inappropriate in the context of semiconductor electrochemistry where pzc refers to the flatband potential. Thus we adopt the notation of the point of zero zeta potential (pzzp) (18). Historically, the determination of the pzzp for materials has had important ramifications in the area of flotation processes (4). While several ionic species may be specifically adsorbed, for metal oxides, the point of zero zeta potential usually refers to specific adsorption of OH and H^+ ions. The pzzp is then the pH at which the net surface charge is zero or the concentration of adsorbed OH^- and H^+ ions is equal. Under these conditions, there is no net potential across the Helmholtz layer other than the small dipole contribution of the solvent. The energetics of this condition can be examined by considering the electrochemical potential ($\bar{\mu}$) of the ions in the adsorbed layer and in the solution.

Any adsorbed ion in equilibrium with the same ion in solution will have

$$\bar{\mu}_{ad} = \bar{\mu}_{sol} \quad [5]$$

and under equilibrium situations this should apply to all adsorbed ions. Thus at the pzzp we can write

$$\bar{\mu}_{ad}^{OH^-} - \bar{\mu}_{ad}^{H^+} = \bar{\mu}_{sol}^{OH^-} - \bar{\mu}_{sol}^{H^+} \quad [6]$$

The chemical potential of any component, A, in solution can be written as

$$\bar{\mu}_{sol}^{A} = {}_{0}\bar{\mu}_{sol}^{A} + RT \ln (a_A) \quad [7]$$

where ${}_{0}\bar{\mu}_{sol}^{A}$ is the electrochemical potential in the standard state, a_A is the activity of A in the solution phase, R is the ideal gas constant, and T is the absolute temperature. Normally the assumption is made that the solution is close to ideal and a_A can be replaced by C_A, the concentration of A. In the adsorbed phase at pzzp the concentration of OH^- and H^+ are equal; thus we may write

$${}_{0}\bar{\mu}_{ad}^{OH^-} - {}_{0}\bar{\mu}_{ad}^{H^+} = {}_{0}\bar{\mu}_{sol}^{OH^-} - {}_{0}\bar{\mu}_{sol}^{H^+} + RT \ln C_{OH^-sol} - RT \ln C_{H^+sol} \quad [8]$$

Since (2.303) pH = $-\ln C_{H^+sol}$ and the difference in standard state electrochemical potentials in solution for OH^- and H^+ is 1.23 eV, this may finally be written

$${}_{0}\bar{\mu}_{ad}^{OH^-} - {}_{0}\bar{\mu}_{ad}^{H^+} = 1.23 \text{ eV} + 4.606\, RT\, (pH_{pzzp} - 7) \quad [9]$$

It is possible to determine the standard-state electrochemical potentials for the adsorbed species if the appropriate hydroxylated and protonated species and their standard free energies of formation are known. In this case, the pzzp may be calculated directly using Eq. [9]. In general, this information is not known and the pzzp must be measured experimentally or estimated from knowing the semiconductor electronegativities. We show in Fig. 2 the pzzp for several metal oxides *vs.* the electronegativity of those oxides. The data suggest that there is a strong correlation. The observed slope has the same pH_{pzzp} dependence as in Eq. [9]. However, the quantitative relationship between Eq. [9] and Fig. 2 is not clear. The scatter in the data undoubtedly arises from the difficulty in measuring pzzp's. Measured pzzp's seem to depend somewhat on the method of preparation of the oxide (4).

Several techniques have been used to determine pzzp's (4). The simplest is just addition of the metal oxide powder to an aqueous solution of a known pH with no other adsorbable species present. The pH of the solution will shift on addition of the powder toward the pzzp. At the pzzp the pH of the solution is independent of the amount of metal oxide added. A more quantitative measure of specific ion adsorption is obtained from the potentiometric titration of a metal oxide suspension with either acid or base for solutions of specific ionic strength. Since the ions added must either go to changing the pH of the solution or be adsorbed on the metal oxide surface, it is possible to determine the surface charge density as a function of pH for several concentrations of supporting electro-

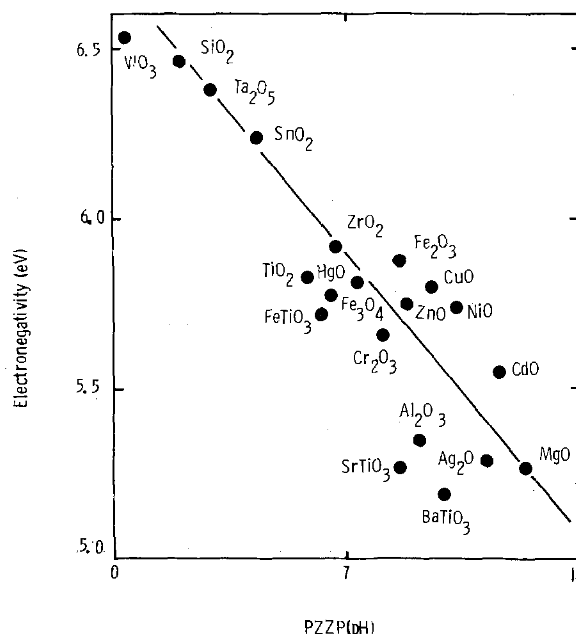

Fig. 2. Plot of the pH where the zeta potential is zero (pzzp) vs. calculated electronegativity for the bulk semiconductor in electron volts. The line is drawn through the data and has a slope of 0.12 eV/pH.

lyte. The point at which these curves intersect is the pzzp.

We have found that a simple differential potentiometric titration of an aqueous suspension of the semiconductor of interest in a solution of known ionic strength gives good peaks for the pzzp on plots of $\Delta pH/\Delta ml$ *vs.* pH.

In general this technique is similar to that employed for obtaining the fast adsorption isotherms but is somewhat less complex as only one titration is required. A procedural outline is included so as to clarify the experimental parameters. All glassware was cleaned by boiling in distilled water, from an all-glass Autostill, after an Alconox wash and distilled water rinse, then subsequently rinsed five times with distilled water. Reagents used were of the highest available purity and all of the oxide powders were four nines or better purity. The pH was measured with a Markson Electromark pH analyzer equipped with an Orion combination pH electrode and a digital readout. All titrations were performed in argon purged, stirred solutions. Typically, 1-10g of the oxide of interest were added to 600 ml of deionized, distilled water typically 0.001M in KNO_3, which is a nonadsorbing species. The KNO_3 was found to be unnecessary, but some ionic strength in the solution helped stabilize pH readings near the equivalence point. The pH of the solution was then adjusted to near 10-11 with 1M KOH. The solution was back titrated with HNO_3 first with 1M and then with 0.1M as was indicated by the rate of change of pH with additional increments of titrant. All additions were carried out with microburettes and typical accuracies were ±0.002 ml and ±0.005 pH units. The reproducibility of the peaks corresponding to the pzzp was excellent.

On the addition of titrant, conservation of charge requires that

$$A(\Gamma_{H^+} - \Gamma_{OH^-}) = xC_1 - V[(C_{H^+} - C_{OH^-}) - (C_{H^+} - C_{OH^-})_{\text{initial}}] \quad [10]$$

where A is the surface area of the suspended metal oxide, Γ is the surface density of the appropriate ion, x is the volume of titrant added, C_1 is the concentration of titrant, V is the volume of the suspension, and C is the appropriate concentration of ions in solution. This equation assumes that total added volume due to titration is negligible compared to the total suspension volume. If we differentiate this equation with respect to x, we find

$$\frac{A}{V}\frac{\partial(\Gamma_{H^+} - \Gamma_{OH^-})}{\partial x} = \frac{C_1}{V} - \frac{\partial C_{H^+}}{\partial x}[1 + k_w/C_{H^+}{}^2] \quad [11]$$

where k_w is the ionization constant for water. By expanding the partial of the surface charge density, we obtain

$$\frac{\partial C_{H^+}}{\partial x} = (C_1/V)\left[1 + \frac{A}{V}\frac{\partial \Gamma}{\partial C_{H^+}} + \frac{k_w}{C_{H^+}{}^2}\right]^{-1} \quad [12]$$

where $\Gamma \equiv (\Gamma_{H^+} - \Gamma_{OH^-})$. Now $C_{H^+} = \exp(-2.303\ pH)$. This equation and its derivative with respect to x allows us to convert Eq. [12] to a pH dependence. Finally we find

$$\frac{\partial pH}{\partial x} = \frac{-(C_1/V)\exp(2.303\,pH)}{2.303\left[1 + k_w \exp(4.606\,pH) - (A/2.303V)\dfrac{\partial\Gamma}{\partial pH}\exp(2.303\,pH)\right]} \quad [13]$$

The behavior of this equation is displayed in Fig. 3 for pure water and for 10^{-3}M KNO_3 solution with two different amounts of TiO_2 powder added. The solid curve for pure water is just Eq. [13] with A the surface area of suspended metal oxide set equal to zero. In general, the data agree excellently with the theory

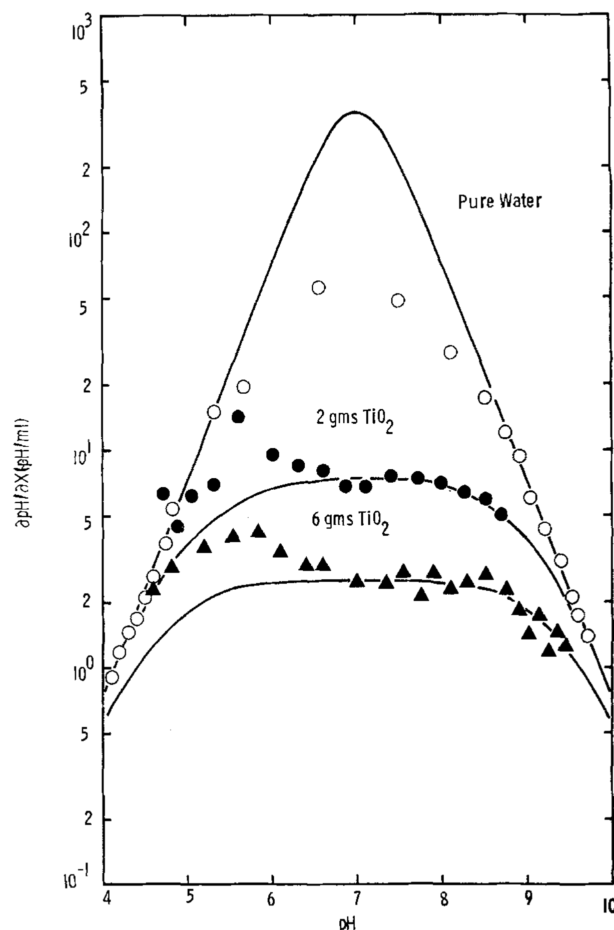

Fig. 3. Differential potentiometric titrations plotted as $\partial pH/\partial X$ (Δ_{pH}/Δ_{ml}) vs. pH for 3 solutions: ○○○ 600 ml distilled-deionized water, initial pH adjusted with 0.1M KOH, ●●● 600 ml distilled-deionized water 0.001M in KNO_3 with 2g of suspended TiO_2 (99.995%) initial pH adjusted with 0.1M KOH, ▲▲▲ 600 ml distilled-deionized water 0.001M in KNO_3 with 6g of suspended TiO_2 (99.995%). The solid lines represent theoretical fits of the data from Eq. [13] in the text. All solutions were stirred under a constant purge of argon and all titrations were performed with 0.1M HNO_3.

(no adjustable parameters) except where the rate of change of pH becomes quite large (near the equivalence point). Here, adsorption onto the glass surface and small amounts of impurities can buffer the solution to significantly lower the rate of change in pH. The "theoretical" curves for the TiO_2 suspensions were calculated from Eq. [13] with an assumed constant value for $\partial\Gamma/\partial pH$ of 4×10^{-11} moles/cm² (13). The surface area was then adjusted to fit the data at pH = 7. Note that the rate of change in pH at pH = 7 scales inversely with the amount of TiO_2 added. This indicates that the particle size was the same for two powders. We find from the fit a surface area for the powder of ~ 17.3 m²/g. This may be compared to the results of Berube and DeBruyn (13) who used TiO_2 powder of 43 m²/g. If we assume spherical particles, our surface area corresponds to diameters of ~ 900Å. These numbers are quite reasonable. At the pzzp it is evident (4) that $\partial\Gamma/\partial pH$ becomes small. From Eq. [13] we would thus expect a peak in the derivative curve at the pzzp. As you can see in Fig. 3, this is indeed the

† There is a great deal of scatter in the measured pzzp's. These are believed to be the most reliable values.

case for TiO_2 whose pzzp is ~ 5.8. A word of caution is perhaps relevant at this point. Contamination of the suspension by a buffer or other metal oxides will result in spurious peaks in the curve. The reality of the peak can be checked by using the simple method of direction of pH change with addition of additional metal oxide. The pzzp's for several metal oxides are shown in Table I. In general, we have found that this simple technique yields results in good agreement with previously published results.

Discussion

Since both of the correction terms can now be evaluated, we can compare the measured flatband potentials directly to the calculated electron affinities as is shown in Fig. 4. The solid line is the behavior expected from Eq. [1] with no adjustable parameters. One expects a unitary slope and an intercept at zero flatband potential of E_0. The agreement with theory is excellent and

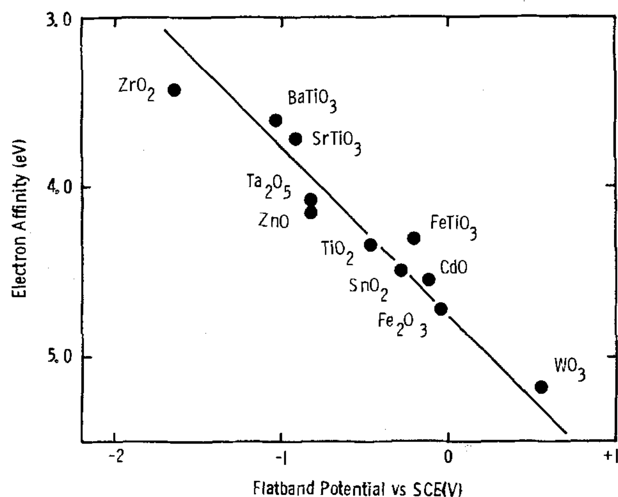

Fig. 4. The electron affinity calculated using atomic electronegativities vs. the measured flatband potentials for the labeled semiconductors corrected to their respective pzzp's. The solid line is that expected from Eq. [1] if the correction term, Δ_{fc}, is ignored. The flatband potentials and pzzp's not measured by us are those listed in Table I.

shows that the flatband potentials for metal oxides can be calculated with an accuracy of ~ 0.2V from the atomic electronegativities of the constituent atoms if specific adsorption of potential-determining ions is properly taken into account. Even without an accurate accounting for the pzzp the predicted flatbands are close enough so as to act as a guideline for electrode selection.

While most of the considerations in this paper have been concerned specifically with OH^- and H^+ as the potential-determining ions, the results certainly are more generally applicable. It is possible, for instance, that the flatband could be shifted by the addition of other ions which are specifically absorbed while not changing the pH and consequently the H_2 and O_2 evolution reaction potentials. The effect of specific ion adsorption on the cathode should also be evaluated since this may result in an additional potential drop in the circuit.

These ideas are of considerable importance with respect to wet photovoltaic cells and other systems employing nonoxide electrodes with nonaqueous redox couples (29-31). Many of these systems show no pH dependence of the flatband potential but do show a Nernstian type dependence on the concentration of potential determining ion. For example, in the cadmium sulfide, sulfur, sulfide ion cell ($CdS/S-S^{-2}-OH^-/Pt$), the flatband potential of the CdS depends on the S^{-2} concentration. Thus, there will be a Δ_{pS} correction term in Eq. [1] and a pzzp for sulfide ion, since the potential across the Helmholtz layer will depend on (S^{-2}). Therefore, in general, one must correct the measured flatband potentials to the respective pzzp of the potential-determining ions to obtain a measure of the intrinsic flatband potential. We are currently in the process of evaluating some of these numbers for nonoxide systems.

ABSTRACT

Polymeric sulfur nitride, $(SN)_x$, has been characterized as an electrode material in aqueous solution by cyclic voltammetry and cyclic chronoamperometry. Background currents, resulting from oxidation and reduction of electrode surface functional groups, were studied in different supporting electrolytes and pH values. A large influence of the nature of the alkali metal cations and Ca^{2+} of supporting electrolytes on the magnitude of background currents and cathodic breakdown potentials was found. This was interpreted in terms of differences in the interaction strength between these cations and electrode surface functional groups. The ferro-ferricyanide couple was used to determine relevant electrochemical parameters as well as electrode surface areas. Other redox couples which are active at $(SN)_x$ electrodes are discussed, *e.g.*, Pb^{2+}/Pb^{0}, $Ru(NH_3)_6^{3+}/Ru(NH_3)_6^{2+}$, quinone/hydroquinone. It was not possible to reduce Cr^{3+} at $(SN)_x$ electrodes. Furthermore, a dramatic decrease in background currents was observed for Cr^{3+} electrolyte solutions. The $(SN)_x$ was found to be remarkably stable in aqueous solutions under a wide variety of conditions and a suitable electrode material for chemical modification.

Polymeric sulfur nitride, $(SN)_x$, has been reported recently (1) as a new electrode material. This substance has been classified as a metal even though there are no metal atoms present in its structure (2). The $(SN)_x$ exhibits electrical and chemical anisotropy and its surfaces make available numerous types of functional groups and surface types for possible chemical modification (3). In order to use $(SN)_x$ in this capacity, it is of primary importance to characterize its general electrochemical behavior before any modification experiments are performed. Therefore, we report here systematic fundamental studies using $(SN)_x$ as a working electrode in order to evaluate it with respect to the criteria suggested by Mueller and Adams (4).

Experimental

Reagents.—All chemicals were of reagent grade and were used without further purification. Chromium(III) perchlorate was obtained from Ventron Corporation. Solutions were prepared with distilled water which was passed through ion exchanger and, finally, activated carbon columns. Solutions were deoxygenated with argon or high purity nitrogen.

Instrumentation.—Cyclic voltammetric and chronoamperometric experiments were carried out with the use of PAR™ Model 173 potentiostat/galvanostat equipped with a PAR™ Model 176 current to voltage converter, a PAR™ Model 175 universal programmer, and a Hewlett Packard Model 2D-2M X-Y recorder or alternatively, a PAR™ Model 170 electrochemistry system. Micrographs were obtained with a Coates and Welter Cwikscan 100-4 or International Scientific Instruments Model 7 scanning electron microscope.

Electrode preparation.—High purity crystals of $(SN)_x$ (*ca.* 10^{-6}-10^{-3} cm^3) were prepared from S_4N_4 by a published method (2). Elemental analysis (Galbraith Laboratories, Incorporated) yielded the following results: Calc for $(SN)_x$: S, 30.41; N, 69.59. Found: S, 30.32; N, 69.73. Crystals were cemented to the end of a silver wire (0.040 cm radius, sealed in glass) with conducting silver paint (GC Electronics) and all but the crystal face of interest was masked off with Torr Seal® (Varian Associates). In this way electrodes could be constructed which had the $(SN)_x$ fiber bundles parallel or perpendicular to the electrode/solution interface. Thus, electrodes are designated as being "parallel" or "perpendicular" henceforth.[2] Projected surface areas for electrodes prepared in this way as measured by a calibrated microscope were in the range: 1-50 $\times$ 10^{-3} cm^2. New mounted electrodes with over-all resistances of less than 20Ω were used for each type of electrochemical experiment. It was not possible to renew the surface of a used electrode by polishing without severely damaging the crystal. All electrodes were stored in a vacuum desiccator as $(SN)_x$ crystals begin to tarnish after exposure to air for many weeks, although there appears to be little decomposition of $(SN)_x$ when it is immersed in water for six days (5).

Working electrodes made from platinum, palladium, and silver wires, having areas comparable to $(SN)_x$ electrodes, as well as a Kemula type hanging mercury drop electrode (radius = 0.043 cm) were used to compare the electrochemical behavior of selected redox couples on $(SN)_x$ or modified $(SN)_x$ with that on the metallic electrodes.

Platinum wire and KCl or NaCl saturated calomel electrodes served as counter and reference electrodes, respectively. All experiments were carried out at room temperature (*ca.* 25°C) unless otherwise mentioned.

Results and Discussion

Studies in supporting electrolyte.—The first step in evaluating $(SN)_x$ electrodes involved cyclic voltammetric studies in aqueous media in the absence of electrochemically active substances. In this way background and breakdown currents could be studied, and the feasibility of using $(SN)_x$ electrodes to study solutions containing electroactive materials could be determined. The electrochemical behavior of $(SN)_x$ electrodes was found to be dependent on *p*H, ionic strength, scan rate, scan number, and the nature of the supporting electrolyte. All experiments were performed with both parallel and perpendicular electrodes. A distinction between experimental results obtained with parallel or perpendicular electrodes is made here only if their electrochemical behavior was significantly different under identical experimental conditions.

Many different supporting electrolytes were used to characterize the nature of background currents. Cyclic voltammograms recorded in supporting electrolytes such as MCl (M = Li^+, Na^+, K^+, Cs^+), NaX (X = ClO_4^-, $SO_4^=$, NO_3^-, F^-, Cl^-, Br^-, N_3^-, SCN^-) or $Ca(NO_3)_2$ varied as a function of scan number. NaI was not used as it is electrochemically active at $(SN)_x$ electrodes (6). Usually, residual currents were very high on the first scan and gradually decreased on subsequent scans (Fig. 1). When negative and positive reversal potentials were kept constant, background currents fell to constant, reproducible values after five to ten scans. However, whenever the potential was held at positive values for a few seconds, high cathodic currents, typical of the first scan (Fig. 1), were observed. The magnitude of these cathodic currents was also directly proportional to the value of the positive reversal potential. Hysteresis of the cathodic current

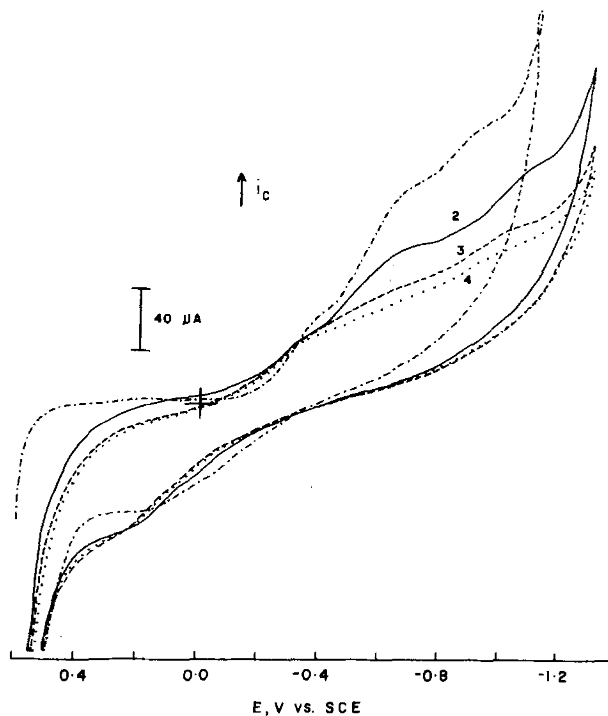

Fig. 1. Cyclic voltammogram in 0.5M $NaClO_4$. Scan number is indicated on each curve. Scan rate 0.05 V sec^{-1}.

was observed in the negative breakdown region for all electrolytes (unless otherwise noted) provided the current was allowed to reach negative enough values. (In Fig. 1 [scans 2-4], the potential reversal occurred prior to values necessary to cause this hysteresis.)

In order to investigate the nature of the cathodic breakdown process, the *p*H was varied. With perpendicular electrodes in the presence of acetate (*p*H = 4.75) or phosphate (*p*H = 7.3) buffers (sodium or potassium salts) the cathodic peaks attributed to surface redox processes of $(SN)_x$ itself (*vide infra*) were diminished or not present but the cathodic hysteresis still remained.

Using perpendicular electrodes, the *p*H was varied from 7 to 0 with H_2SO_4 solutions. The cathodic hysteresis disappeared only for acid concentrations of 0.5M (Fig. 2). Bubbles of hydrogen gas were observed on the electrode surface in the latter solution after negative polarization into the breakdown region. The high cathodic overvoltage of 0.5M H_2SO_4 solutions

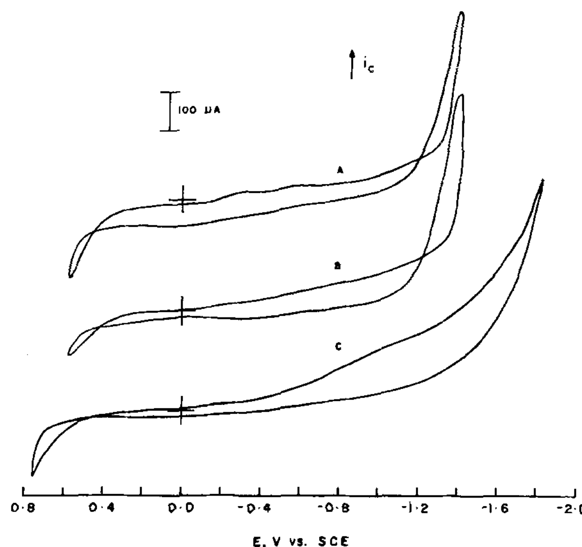

Fig. 2. Cathodic current breakdown dependence on solution acidity (A) 0.5M Na_2SO_4, (B) 0.45M Na_2SO_4 + 0.05M H_2SO_4, (C) 0.5M H_2SO_4. Scan rate 0.05 V sec^{-1}.

[2] Torr Seal resin appears to dissolve or decompose the $(SN)_x$ when fibers were mixed with it forming a paste. The latter material was found to be insulating. The larger $(SN)_x$ crystals used in this study were not significantly affected by Torr Seal.

might result from the increase in the electrode resistance due to gaseous hydrogen adsorption.

In similar experiments both parallel and perpendicular electrodes were used in solutions of 3M KCl with 10^{-3}, 10^{-2}, 10^{-1}, and 1M HCl added. There were no significant differences in (*i*) the cathodic breakdown potential (which was the same for 3M KCl without added HCl), (*ii*) the magnitude and form of the background currents, and (*iii*) the cathodic hysteresis (which was observed on all scans). If only HCl was present (0.1 or 1M) there was no cathodic hysteresis and an increase in background currents with increased concentration was observed. These results, plus the observation of visible dissolution and corrosion of the surface, indicate that the cathodic current breakdown is predominately a result of the decomposition of the electrode material rather than water electrolysis in solutions of $pH > 1$.

At least three cathodic peaks at *ca.* −0.35, −0.65, and −0.85V and three anodic peaks at *ca.* 0.10, 0.30, and 0.40V could be distinguished when the potential was scanned negatively and positively, respectively, in neutral unbuffered solution (Fig. 3). A mutual dependence of anodic and cathodic peaks was noted from scan reversal experiments (Fig. 3). If the negative scan was reversed at −0.65V prior to the cathodic process at the most negative potential before breakdown, the subsequent anodic peaks were shifted negatively with a simultaneous decrease in current magnitudes (Fig. 3C). Similar results were obtained as the reverse potential was made more positive on subsequent scans (Fig. 3D) until no anodic peaks were observed when the scan reversal was at +0.05V (Fig. 3E). These results demonstrate the faradaic and irreversible character of background currents which are probably due to the electrochemical oxidation and reduction of surface functional groups of the $(SN)_x$ itself. The observed peaks were better developed at lower scan rates (10-20 mV sec^{-1}) presumably due to the decrease in capacitance currents and/or the increase in the extent of oxidation or reduction of surface functional groups resulting from longer electrolysis times (cf. Fig. 3A, B).

Generally, background currents were higher for higher ionic strength electrolytes for all salts used. The values of potentials of anodic and cathodic current breakdown (*ca.* 0.5 and −1.2V, respectively) as well as the magnitude of the faradaic currents appeared to be independent of the cation or anion of the supporting electrolyte for perpendicular electrodes. However, background currents showed a marked dependence on the type of cation with only minor effects observed with different anions when parallel electrodes were used. Changing the cation of the supporting electrolyte from lithium through cesium resulted in a large shift in the cathodic breakdown potential to less negative values (*i.e.*, $Li^+ = -1.54$, $Na^+ = -1.25$, $K^+ = -1.15$, and $Cs^+ = -1.20V$), an increase in the hysteresis of the current on the reverse (positive) scan and an increase in background currents. In the experiment shown in Fig. 4 the same electrode was used for all of the cyclic voltammograms and results were identical if the experiments were performed by changing the cation in the reverse order, *i.e.*, cesium

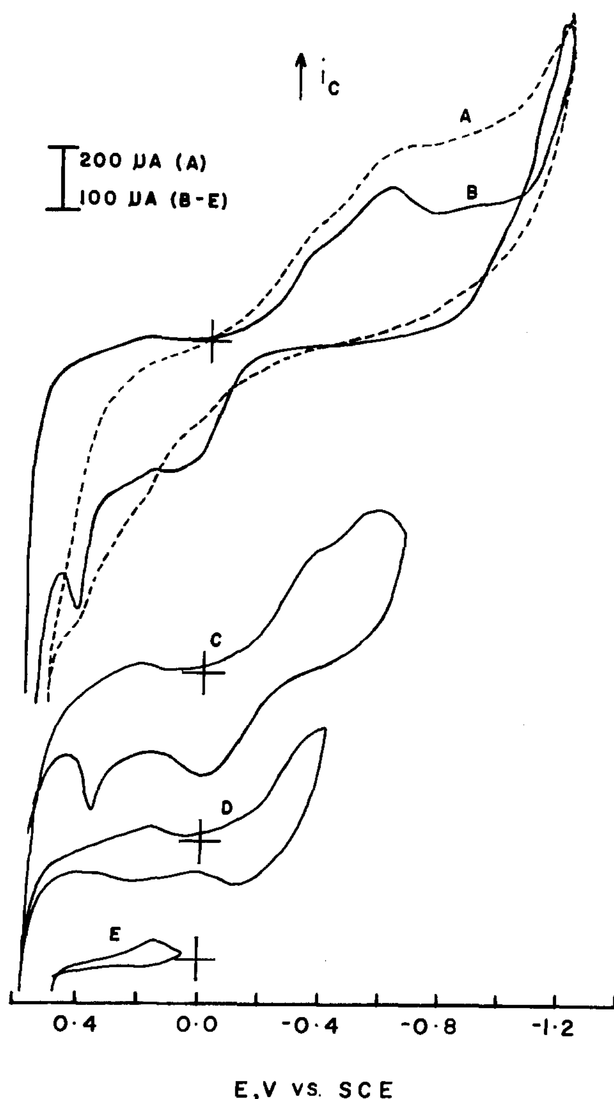

Fig. 3. Dependence of anodic peaks on cathodic reverse potential in 3M CsCl. (A, B) −1.200V, (C) −0.650V, (D) −0.400V, (E) +0.050V. Scan rate: (A) 0.2 V sec^{-1}; (B-E) 0.01 V sec^{-1}.

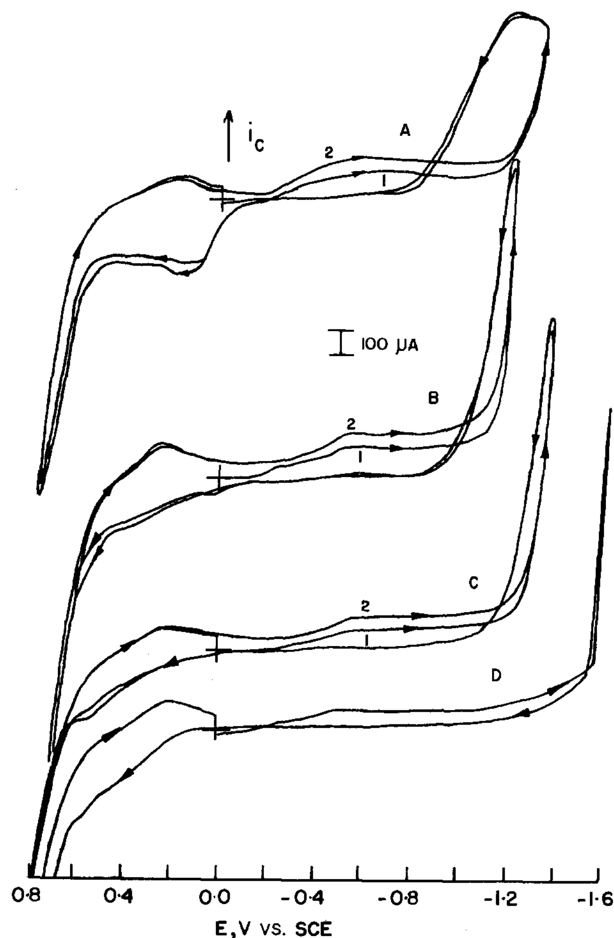

Fig. 4. Dependence of background currents on the cation of supporting electrolyte for parallel electrode in 3M solution of (A) CsCl, (B) KCl, (C) NaCl. (D) LiCl. Scan rate 0.02 V sec^{-1}.

through lithium. Furthermore, the cathodic breakdown potential for CsCl solutions was dependent on the scan rate (varied between 5 and 200 mV sec^{-1}) whereas with LiCl, the scan rate did not substantially affect this potential. At lower scan rates (5 mV sec^{-1}) the cathodic breakdown potential in CsCl solutions was approximately −1.20V but approached −1.50V at higher scan rates (100 mV sec^{-1}). Nonetheless, the slope of the *i-E* curves at cathodic breakdown was much less for CsCl than LiCl at all scan rates. From the above, one might conclude that Li^+ interacts most strongly with the parallel $(SN)_x$ surface, inhibiting redox transformation of surface functional groups. The order of magnitude of these interactions, increasing in the series $Cs^+ < K^+ < Na^+ < Li^+$, is exactly opposite to the order of adsorptivity of these cations on mercury (7).

The current hysteresis observed in the cathodic breakdown region was completely eliminated in $Ca(NO_3)_2$ supporting electrolyte on both parallel and perpendicular $(SN)_x$ electrodes (Fig. 5). On perpendicular electrodes, an increase in the concentration of $Ca(NO_3)_2$ resulted in the disappearance of the background current peaks (normally observed in alkali metal ion solutions) with a concomitant appearance of new reduction peaks at −1.0 and −1.25V (Fig. 5). In 5M $Ca(NO_3)_2$, where the activity of water is only 0.58, two reduction peaks at +0.1 and −0.7V, and one oxidation peak at +0.5V appeared. Furthermore, the potential of cathodic breakdown remained the same as for solutions of the alkali metal cations.

Cathodic breakdown in $Ca(NO_3)_2$ solutions using parallel electrodes was not detected as far negatively as −2.0V. A single cathodic peak at *ca.* −1.7V appeared during the first scan only, and there was no evidence of hysteresis upon scan reversal. There was no effect observed upon changing the concentration of $Ca(NO_3)_2$. These results are consistent with the previous studies with the alkali metal cations in that cathodic breakdown is extended more negatively using parallel electrodes with supporting electrolytes containing cations with increasingly higher charge densities. Perpendicular electrodes showed no extension of the cathodic limit. The additional cathodic peaks observed with perpendicular electrodes might be related to nitrate ion reduction.

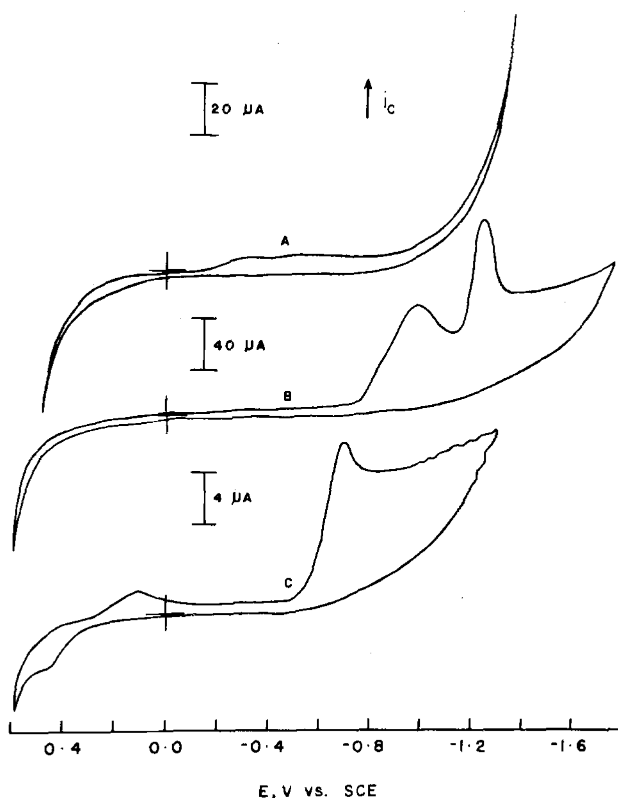

Fig. 5. Cyclic voltammogram for perpendicular electrode in $Ca(NO_3)_2$: (A) 0.1. (B) 1, (C) 5M. Scan rate 0.05 V sec^{-1}.

Finally, the faradaic background currents decreased and the cathodic breakdown potential became more negative when chromium(III) perchlorate or chromium(III) chloride was added to a solution of supporting electrolyte (Fig. 6). It is of interest to note that no chromium(III) reduction peaks were observed on either surface. Chromium(III) may interact strongly with the $(SN)_x$ surface at these potentials which increased the overvoltage necessary to reduce it. The nature of this interaction and why chromium(III) reduction may be inhibited by it is not understood at this time. It is interesting to note, however, that the electrode is not poisoned. The presence of chromium(III) in the interface did not influence charge transfer in the ferri-ferrocyanide system. Normal cyclic voltammograms are observed.

The differences in interactions with respect to alkali metal cation solutions between mercury and parallel $(SN)_x$ electrodes might be related to the type of process occurring. Clearly, adsorption is the predominant electrochemical process occurring on mercury electrodes but this may not be true at $(SN)_x$ electrodes. In this case some specific chemical interaction might be present. In general, the higher the charge density of the cation (when crystallographic radii are used), the lower the background currents and the more negative is the potential of the cathodic decomposition of $(SN)_x$. These effects are noticed only at parallel electrodes in the alkali metal cation series. A much higher charge density ion, *e.g.*, chromium(III), is needed to produce similar effects on the perpendicular surface. These results indicate that the parallel surface could be considered to be chemically softer (8) than the perpendicular surface. This is not surprising as the parallel surface consists predominantly of a conjugated π-electron system but the perpendicular surface presumably has harder functional groups.

Ferri/ferrocyanide.—The ferri-ferrocyanide couple has been previously recommended (9) and widely used (4, 9-11) for the study of solid electrodes because of its polarographic reversibility and the availability of the diffusion coefficients for both the oxidized and reduced forms under a variety of solution conditions (12). We also found this couple to be very useful in cyclic voltammetric and cyclic chronoamperometric studies with $(SN)_x$ electrodes even though the electron transfer mechanism has been shown recently (13) to be more complex than once thought. Formal poten-

tials, $E_f{}^\circ$, were calculated as the mean of the cathodic and anodic peak potentials obtained from cyclic voltammetric experiments in KCl supporting electrolyte solutions. Typical results for two parallel and two perpendicular $(SN)_x$ electrodes are shown in Table I. At moderate potential scan rates (0.01-0.2 V sec^{-1}) the separation of the oxidation and reduction peak potentials for both electrode orientations was close to the theoretical value for a reversible system (57 mV at 25 °C).

The diffusion-controlled nature of the currents for the ferri-ferrocyanide couple at $(SN)_x$ electrodes was demonstrated by the following results (Table I): (*i*) the ratio of the cathodic to anodic peak currents was close to 1.09 which is the predicted value for a diffusion controlled process (taking into account the differences in diffusion coefficients of the ferri- and ferrocyanide), (*ii*) the dependence of peak currents on scan rate yielded the expected result of $\partial \log i_p / \partial \log V = 0.5$, and (*iii*) the temperature dependence of the cathodic peak currents in the temperature range 15°-75°C, *i.e.*, $(2.303/\Delta T)\Delta \log i_{pc} \cdot 100\% = 0.4\%$. It should be noted that the platinum disk electrode yielded similar values of the formal potential, i_{pc}/i_{pa} and $\partial \log i_p/\partial \log V$ under the same experimental conditions.

The dependence of the peak current and formal potential on *p*H was also found to be the same for both platinum and perpendicular $(SN)_x$ electrodes (Table II). The results obtained with parallel electrodes (not shown) were identical.

As $(SN)_x$ electrodes varied markedly in projected area and macroscopic surface roughness it was difficult to compare the electrochemical behavior of individual $(SN)_x$ electrodes. In order to obtain current densities so that results could be normalized, cyclic chronoamperometry was used to determine the electrochemically active surface area of $(SN)_x$ electrodes. For this reason a 10 sec current decay period was chosen so that the diffusion layer thickness in chronoamperometry experiments was comparable to that in cyclic voltammetry experiments under the scan rates employed. Ferricyanide was chosen as it was shown above to be well behaved at $(SN)_x$ electrodes. The potentials chosen were 0.1V more negative and positive than the reduction and oxidation peak potentials, respectively. Using the Cottrell equation (14, 15), the electrochemical area was calculated from the slopes

Table II. *p*H dependence of peak current and $E_f{}^\circ$ for $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$

	Pt (disk)		$(SN)_x \perp$	
pH	i_{p_c} (μA)	$\frac{E_{p_a} + E_{p_c}}{2}$ (V)	i_{p_c} (μA)	$\frac{E_{p_a} + E_{p_c}}{2}$ (V)
1.5	38.4	0.250	20.0	0.260
2.5	40.0	0.225	21.2	0.230
4.6	38.2	0.215	18.5	0.215

of linear i *vs.* $t^{-1/2}$ (14) and i *vs.* $\{(t - 10)^{-1/2} - t^{-1/2}\}$ (15) plots for the cathodic and subsequent anodic decay curves, respectively. The results indicate that the electrochemical area is significantly larger than the area obtained by using a calibrated microscope (Table I). This is not surprising as the surface roughness of $(SN)_x$ electrodes can often be seen with a magnifying glass. Similar chronoamperometric studies with a platinum disk electrode, having a surface area comparable to those of the $(SN)_x$ electrodes, yielded areas which were nearly identical to those obtained with the calibrated microscope (Table I). Thus, it is recommended that the $(SN)_x$ electrode areas be determined using the chronoamperometric technique with ferricyanide solutions, as it is not possible to polish $(SN)_x$ crystals in order to produce a smooth surface because of the delicate nature of this material.

After the potential scan experiments in ferricyanide solution, the $(SN)_x$ electrodes were rinsed with water and scanned in supporting electrolyte solution. There was no evidence of reduction or oxidation peaks of ferri- or ferrocyanide, respectively. This indicates that there is no permanent alteration of the surface due to exposure to ferricyanide solution, *i.e.*, these electrodes were considered to be unmodified in subsequent studies.

Cyclic voltammetry in ferricyanide solutions was also found to be useful in assessing the condition of $(SN)_x$ electrodes. After extended exposure to air or solutions containing adsorbing species, voltammograms of ferricyanide solutions occasionally appeared ill defined (Fig. 7A) with larger peak potential separations than for the reversible case. These electrodes were not used for further study. Thus, the cyclic voltammetric behavior in ferricyanide solution served as a selection criterion for electrodes which were to be used.

Although the $(SN)_x$ crystals used were somewhat porous (Fig. 8) it is doubtful that electrolysis occurs deep within the fibers because: (*i*) there is no "memory effect" for ferricyanide solutions, (*ii*) the solution resistance in the "pores" is much greater than at the surface, and (*iii*) the data fit equations which assumed linear diffusion conditions.

Lead(II) deposition.—Parallel and perpendicular $(SN)_x$ electrodes were used in lead deposition studies (1-40 mM $Pb(NO_3)_2$) in the *p*H range 3.5-4.5 using 0.1M KNO_3 as the supporting electrolyte. Typical results are shown in Fig. 9. Cyclic voltammograms obtained with perpendicular (Fig. 9A) and parallel (Fig. 9B) $(SN)_x$ electrodes differ markedly in the separation between cathodic and anodic peak potentials. There is a pronounced current hysteresis (following potential reversal at −0.72V) for parallel electrodes only (Fig. 9B) which is not uncommon in cyclic voltammetric studies of metal depositions on carbon (16, 17) and mercury (18, 19) electrodes. No well-defined underpotential deposition or stripping peaks were observed with either perpendicular or parallel $(SN)_x$ electrodes. Instead, a gradual increase in the current was observed prior to the bulk lead deposition peak. The voltammetric behavior of parallel $(SN)_x$ elec-

trodes in lead ion solutions became nearly identical to that of perpendicular electrodes when the former are pretreated by immersion into a 0.1M $Hg(NO_3)_2$ solution ($pH = 2.5$) for 1 min followed by thorough rinsing with distilled water before the voltammetric experiment (Fig. 9C). That is, the potentials for the deposition and stripping peaks are the same as for perpendicular electrodes, and there is no hysteresis of

the current on the positive scan. These effects do not depend on whether or not lead has been previously deposited on the parallel surface. Parallel electrodes were also treated by exposure to air or to solutions of the same composition and pH as the mercuric ion solution, but without mercury(II) present. Such pretreatment had no effect on lead cyclic voltammograms obtained with parallel electrodes. Further studies dealing with the chemical modification of $(SN)_x$ surfaces with metal cations will be reported in the future.

No significant differences in the appearance of the lead waves were observed between mercuric ion pretreated and untreated perpendicular $(SN)_x$ electrodes. There was, however, an additional cathodic wave observed of similar magnitude on the first scan only at more positive potentials (between −0.1 and −0.2V). This additional wave was not observed with similarly treated parallel electrodes.

When $(SN)_x$ crystals were placed in 0.1M $Hg(NO_3)_2$ solution, small droplets of metallic mercury formed almost exclusively on the perpendicular surface after 5-10 min. Thus, mercury(II) chemically oxidizes functional groups on the ends of the fiber bundles with a concomitant production of mercury metal which coalesces on the perpendicular surface. The additional cathodic peak observed in voltammograms after mercury(II) pretreatment of perpendicular electrodes is probably due to the reduction of chemically oxidized functional groups or of unreacted absorbed mercury(II).

The presence of mercury on the parallel $(SN)_x$ surface affects the cyclic voltammograms of lead dramatically and reproducibly upon indefinite cycling. Stripping experiments were carried out in order to determine if mercury was present in the metallic state on mercuric ion pretreated parallel electrodes. Attempts to electrochemically oxidize metallic mercury which may have been present on these surfaces were not successful. No oxidation peak of mercury was observed and there were no differences in voltammograms obtained in 0.1M KCl for untreated and mercury(II) pretreated parallel $(SN)_x$ electrodes when the potential was scanned from 0V to the anodic current breakdown potential (*ca.* +0.7V). If mercury(II) is present in solution and is electrochemically reduced, the metallic mercury produced is oxidized at *ca.* +0.7V (20). Thus, the amount of metallic mercury on on the parallel surface, if present, is small. Scanning electron micrographs have revealed the presence of mercury droplets on perpendicular but not parallel mercuric ion pretreated electrodes. Mercury is thought to be present on parallel surfaces as a thin metallic film rather than in a strongly adsorbed or complexed ionic form.

The cathodic and anodic currents for cyclic voltammograms obtained in lead ion solutions were integrated in order to determine the ratio of charge exchanged in each of these processes. For a platinum disk electrode, $Q_c/Q_a = 1.07$. For $(SN)_x$ electrodes this ratio was always greater than unity typically being between 1.25 and 4.0. This might be due to (*i*) cathodic background currents in this potential region, but this source of excess cathodic current seemed too small; (*ii*) the irreversible formation of sulfur and/or nitrogen containing Pb^{2+} compounds, *e.g.*, thionitrosyls (21), caused by the catalytic reduction of the $(SN)_x$ surface; or (*iii*) the initial deposition of metallic lead which is not subsequently stripped off. Scanning electron micrographs were obtained after the deposition and subsequent stripping of lead at parallel and perpendicular electrodes (Fig. 10, 11). Some material remained on the surface despite attempts to oxidize it electrochemically. On perpendicular electrodes, the deposit is restricted to the ends of the fibers (Fig. 10). Most of the remaining material on the parallel electrodes was found to be at breaks in the fiber bundles (Fig. 11) which are, of course, perpendicular ends.

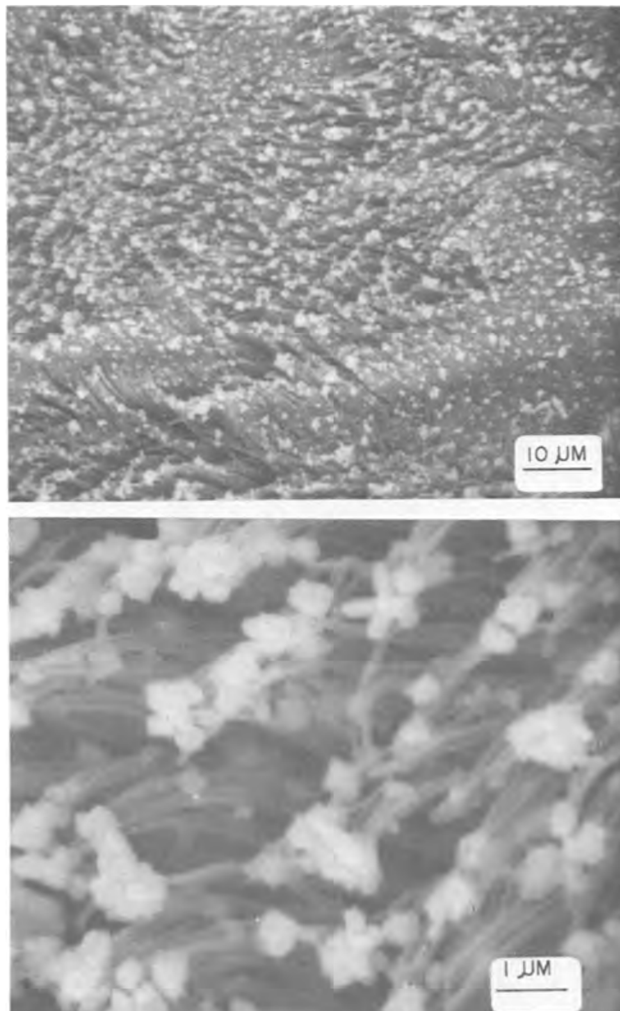

Fig. 10. Scanning electron micrograph of lead deposit on perpendicular electrode or fiber bundle ends.

In order to investigate the mechanism of the lead deposition reaction at $(SN)_x$ electrodes, the procedure developed by Mamantov (22) was employed. It has been suggested that plots of log $(i_p - i)$ *vs.* E (in the potential region 0.5 i_p to 0.9 i_p) and values of $\Delta E = E_p - E_{p/2}$ be used to assess the reversibility of metal deposition reactions at solid electrodes (22). Although plots of log $(i_p - i)$ *vs.* E were linear in the appropriate region for $(SN)_x$ electrodes, the slopes (*ca.* 8-40) and the values of ΔE (*ca.* 0.032-0.118V) indicated that lead deposition at $(SN)_x$ electrodes was not a reversible, diffusion-controlled process. Under the same experimental conditions slopes of these plots for lead deposition on a platinum disk electrode were $\partial \log (i_p - i)/\partial E = 91$ (theoretical $\partial \log (i_p - i)/\partial E = 75$) and the value of ΔE was 0.020V (theoretical $\Delta E = 0.010$V).

As the effect of alkali metal cations of the supporting electrolyte on background currents and breakdown potentials was so pronounced on parallel electrodes, the lead deposition reaction was also studied in the presence of 1M $LiNO_3$ or 1M $CsNO_3$ supporting electrolyte solutions (Fig. 12). A platinum disk electrode was used for comparison. The $E_{pc/2}$ for the deposition of lead was found to be more negative in $LiNO_3$ than $CsNO_3$ for the two parallel electrodes studied. This is consistent with earlier results which indicated a stronger interaction of parallel $(SN)_x$ with Li^+ than Cs^+. The effect of cation on the deposition at the platinum electrode, if any, was just the opposite.

Other systems.—The electrochemical behavior of hydroquinone on $(SN)_x$ electrodes appeared to be

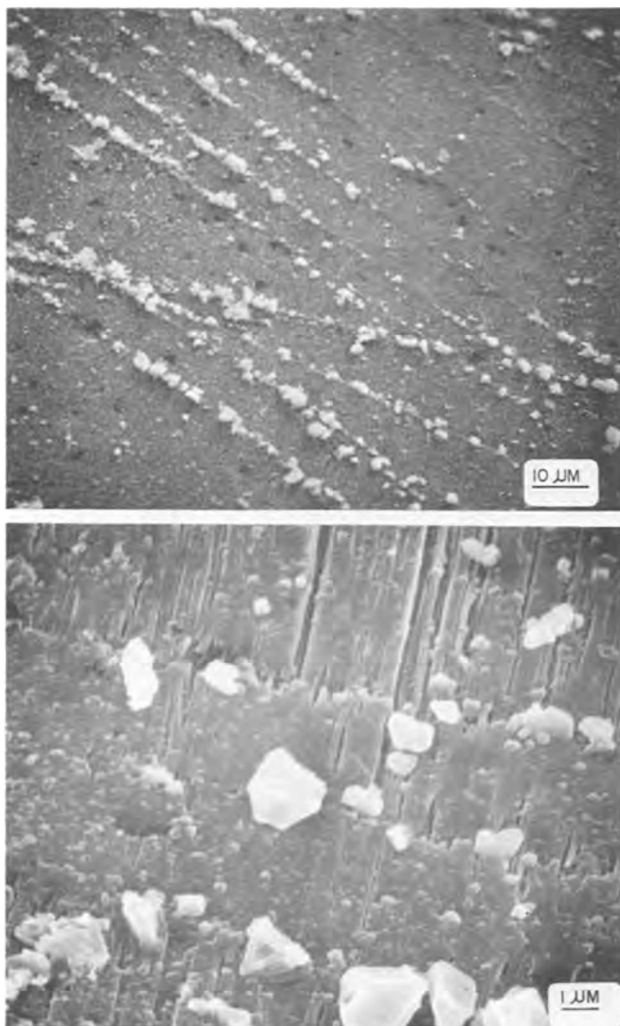

Fig. 11. Scanning electron micrograph of lead deposit on parallel electrode.

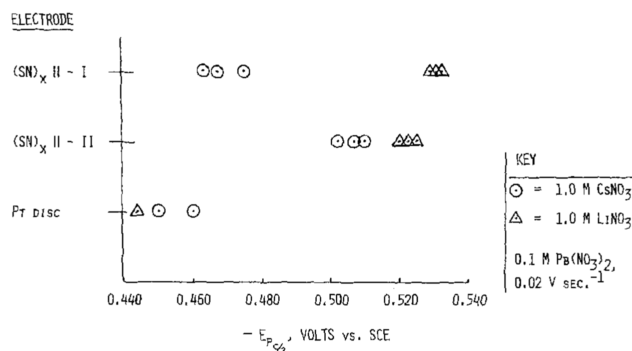

Fig. 12. Effect of nature of cation of supporting electrolyte on $E_{pc/2}$ for lead(II) deposition on two different parallel electrodes.

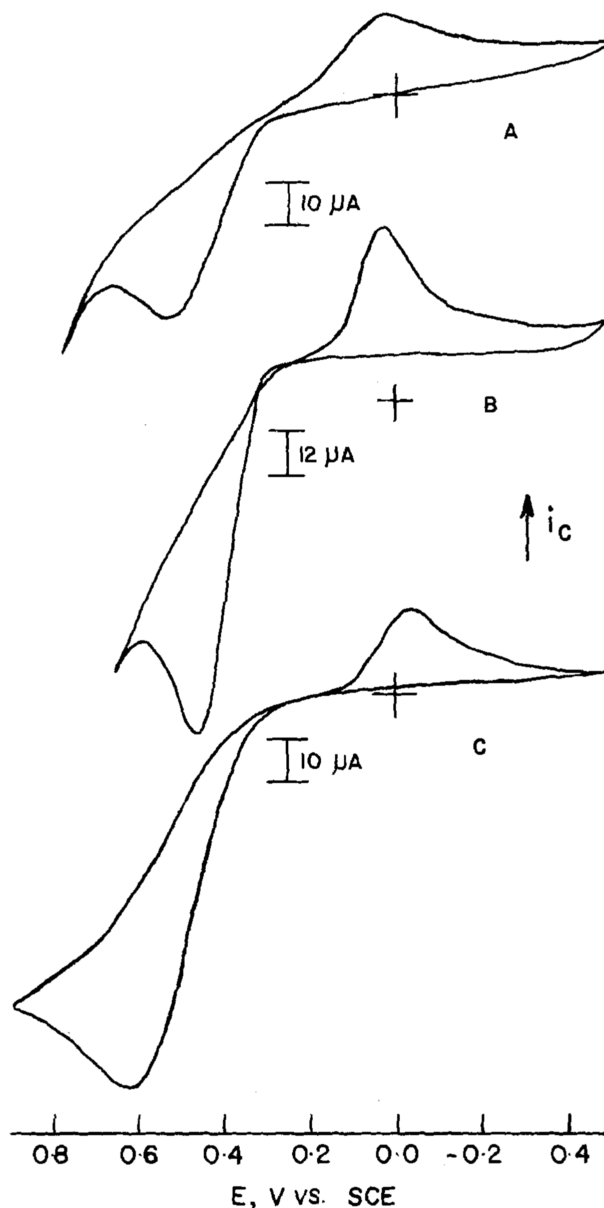

Fig. 13. Cyclic voltammogram in 0.1M hydroquinone solution in 0.5M acetic buffer (pH = 4.75): (A) parallel, (B) perpendicular, (C) Pt disk electrode. Scan rate 0.02 V sec^{-1}.

nearly the same as on Pt-disk electrodes. In 0.5M acetate buffer (pH = 4.75) one irreversible oxidation and reduction peak at $E_{pa} = 0.45V$ and $E_{pc} = 0.03V$, respectively, at scan rate 0.02 V sec^{-1} was obtained (Fig. 13). Anodic, βn_β, and cathodic, αn_α, transfer coefficients calculated from equations $\beta n_\beta = 0.048/(E_{pa} - E_{pa/2})$ and $\alpha n_\alpha = 0.048/(E_{pc/2} - E_{pc})$ were equal to 0.4 and 0.5, respectively, for both $(SN)_x$ and Pt electrodes.

Also, no differences in behavior on $(SN)_x$ and Pt electrodes were found for ruthenium(III)hexammine trichloride reduction being reversible with $E_f° = -0.210V$ in 0.5M KCl (Fig. 14).

Finally, it has to be noted that several redox systems appear to be electrochemically inactive on $(SN)_x$ electrodes. Among them were: $Co(CN)_6^{3}$, $Cr(SCN)_6^{3-}$, $S_4O_6^{2-}$, $S_2O_8^{2-}$, Fe^{3+}, Eu^{3+}, BrO_4^-. The reasons for this inactivity are not known at this time, and are the subject of further investigation.

Summary and Conclusions

In conclusion, $(SN)_x$ appears to be a suitable electrode material for chemical modification studies in aqueous solutions. Thus, regarding the behavior of $(SN)_x$ electrodes in aqueous media: (*i*) Both parallel and perpendicular $(SN)_x$ surfaces exhibit a useful overvoltage region in aqueous media and fulfill the criteria presented for the use of working electrodes in voltammetric studies (4). (*ii*) Surface rather than bulk physiocochemical features of the material govern its electrochemical properties. (*iii*) Electrochemically active surface functional groups undergo irreversible charge transfer reactions. Electrochemical transformations in the bulk of the material are not likely. (*iv*) In addition to typical metallic electrode behavior, $(SN)_x$ exhibits some very unusual surface properties. Metal cations interact more strongly with the $(SN)_x$ surface than other metal electrodes. This is particularly true for the interaction of the alkali metal cations with the parallel surface and of Cr^{3+} with both surfaces. (*v*) Lead cyclic voltammograms

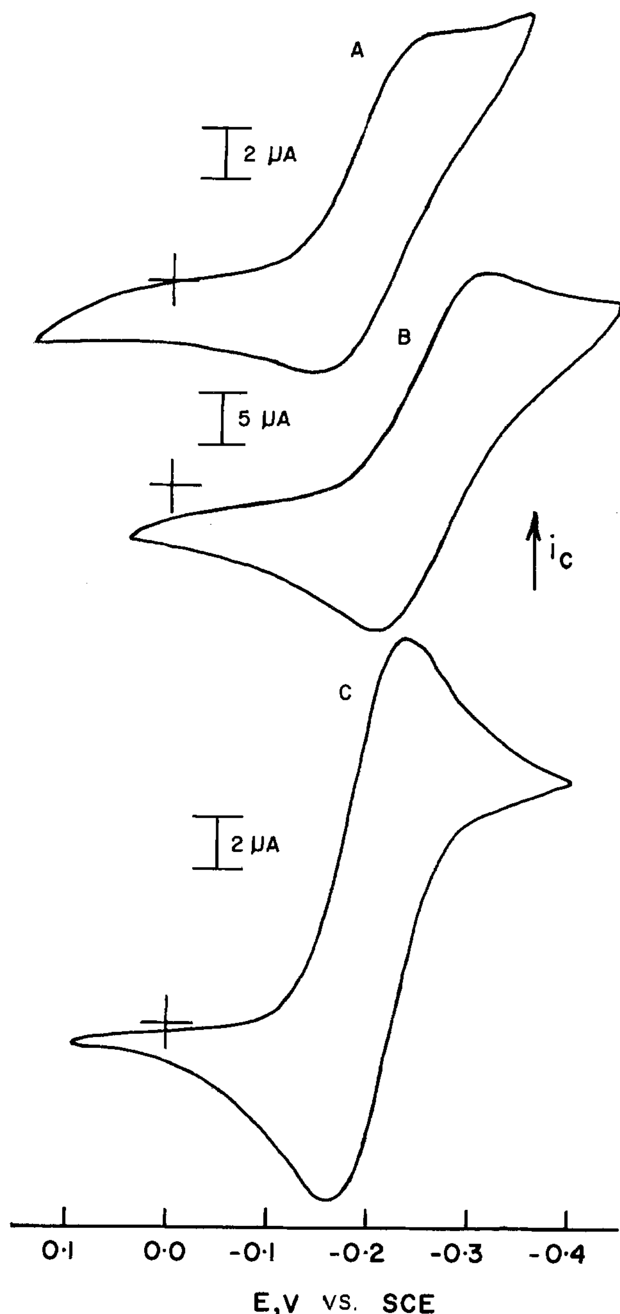

Fig. 14. Cyclic voltammogram in 0.02M $Ru(NH_3)_6Cl_3$ in 0.5M KCl. (A) parallel, (B) perpendicular, (C) platinum disk electrode. Scan rate: (A), (C) 0.02 V sec^{-1}; (B) 0.05 V sec^{-1}.

are dependent on electrode orientation. It is not possible to remove all of the electrodeposited lead by anodic polarization. (*vi*) Mercury(II) chemically oxidized $(SN)_x$ with the simultaneous reduction of mercury(II) to metallic mercury. Mercury droplets form on the perpendicular surface, but mercury metal is probably present on the parallel surface in the form of a thin film.

Electrochemistry of 2,2'-Bipyridine Complexes of Cobalt in the Presence of Acrylonitrile

Shlomo Margel, Wayne Smith, and Fred C. Anson*

Arthur Amos Noyes Laboratory, California Institute of Technology, Pasadena, California 91125

ABSTRACT

The previously claimed (1) catalysis of the electroreduction of acrylonitrile by means of a complex of Co(I) and 2,2'-bipyridine is shown to be erroneous. The "catalytic currents" result instead from the two-electron reduction of a mixed complex of Co(I) acrylonitrile and 2,2'-bipyridine. The equilibrium and forward rate constants for the formation of the mixed complex have been estimated and its spectrum is given. The behavior of a number of other vinyl monomers, which mimic acrylonitrile, is described.

Some time ago Tanaka and Sato described experiments (1) in which they claimed to have shown that a low valent complex of cobalt with 2,2'-bipyridine, generated electrochemically in acetonitrile as solvent, was an effective catalyst for the electrochemical reduction of acrylonitrile. We were intrigued by this report for three reasons: (*i*) The claimed catalysis was very notable ($E_{1/2}$ for the wave attributed to acrylonitrile reduction is shifted from −2.3 to −1.3V *vs.* SCE); (*ii*) the reduction of acrylonitrile is a reaction of considerable industrial importance; and (*iii*) the catalytic mechanism was speculated to involve the adsorption of a low valent complex on the surface of the mercury electrode. We have therefore examined this system in more detail at both mercury and platinum electrodes by means of controlled potential electrolysis, cyclic voltammetry, and polarography. Contrary to the previous report (1) we find that the cobalt-2,2'bipyridine complexes do not function as catalysts for the reduction of acrylonitrile. The increase in current that results when both reactants are present arises instead from the reduction of a complex containing bipyridine, acrylonitrile, and cobalt(I) to a new complex containing cobalt in the (−I) oxidation state. Several other vinyl monomers which form complexes with cobalt(1), *e.g.*, 2,2'-bipyridine, also facilitate the reduction to cobalt(−I). This report summarizes the experimental evidence which has led us to these conclusions.

Experimental

Apparatus.—Polarograms were obtained with a Princeton Applied Research (PAR) Model 174 polarographic analyzer and recorded with a Hewlett-Packard Model 7004 X-Y recorder. Cyclic voltammograms were obtained by means of a PAR Model 173 potentiostat driven by a conventional signal generator. The voltammograms were recorded with the X-Y recorder or by photographing the screen of a Tektronix 564 oscilloscope. Controlled potential coulometry was conducted with the PAR Model 173 potentiostat equipped with a Model 179 digital coulometer. Gas chromatographic analyses for acrylonitrile in acetonitrile were obtained with a Hewlett-Packard Model 5830 A gas chromatograph with an 18 ft column containing Carbowax 20 M on Chromosorb W. Spectra were recorded with a Cary 11 spectrophotometer using cuvettes capped with rubber septums which were deoxygenated by purging with argon.

Measurements were conducted in a three-compartment cell. The reference electrode was a silver wire immersed in 0.1M $AgNO_3$ in acetonitrile which was double isolated by fritted glass disks from the main cell compartment. The potential of this reference electrode was 392 mV more positive than an aqueous SCE when both were immersed in 0.01M aqueous KNO_3. All potentials are given with respect to the Ag/0.1M $AgNO_3$ reference electrode.

The platinum indicator electrode was a platinum wire (diameter = 0.076 cm) sealed in soft glass and cut and polished to expose a 0.045 cm^2 disk flush with the glass surface. The working electrode for the controlled potential electrolyses was a cylindrical platinum gauze electrode supported with stout platinum wire.

Solutions were deoxygenated with prepurified argon which was passed successively through an aqueous chromous chloride solution, purified acetonitrile, and a calcium chloride drying tower before entering the test solution.

Materials.—Polarographic grade tetraethylammonium perchlorate (TEAP) (Southwestern Analytical Company) was used as supporting electrolyte without additional purification. Spectroquality acetonitrile was stirred over CaH_2 for 24 hr, distilled under reduced pressure, and stored under argon.

$Co(bipy)_3(ClO_4)_3$ and $Co(bipy)_3(ClO_4)_2$ (bipy ≡ 2,2'-bipyridine) were prepared by standard methods (2), $Co(phen)_3(ClO_4)_2$ (phen ≡ 1,10-phenanthroline) was prepared by mixing a slight excess of 1,10-phenanthroline monohydrate with $CoCl_2 \cdot 6H_2O$ in ethanol in the absence of air. Addition of a concentrated aqueous solution of $NaClO_4$ followed by cooling to 0°C produced the desired solid. Ethyl cinnamate, cinnamonitrile, and 4-vinyl pyridine were distilled before use. Vinyl monomers used as received included ethyl acrylate, methyl methacrylate, styrene, and methacrylonitrile.

Preparation and properties of $[Co(bipy)_2CH_2CHCN]ClO_4$.—Solid $Co(bipy)_3ClO_4$ has been isolated by reduction of $Co(bipy)_3^{3+}$ with Na(Hg) (3) or $NaBH_4$ 4) followed by precipitation with excess perchlorate. To obtain the corresponding acrylonitrile complex 100 mg of $Co(bipy)_3(ClO_4)_2$ was dissolved in 20 ml of a 1:3 mixture of water and ethanol containing 200 mg of acrylonitrile. The mixture was freed of oxygen and all subsequent steps were conducted in an atmosphere of argon. Addition of 2 ml of a 0.7M solution of $NaBH_4$ in water produced a deep purple solution from which a black solid was precipitated by adding a large excess of $NaClO_4$. The solid was filtered, washed with oxygen-free water and ether, and dried at room temperature under vacuum. Elemental analysis of the solid (percentages): C, 49.0; H, 3.5; N, 12.0; Co, 11.9; Cl, 7.2. Calculated for $Co(bipy)_2(CH_2CHCN)ClO_4$: C, 52.8; H, 3.6; N, 13.3; Co, 11.3; Cl, 6.8.

The black solid is oxidized much more slowly by oxygen than is $Co(bipy)_3ClO_4$. The infrared spectrum of the solid (Nujol mull) shows a band at 2210 cm^{-1} (carbon-nitrogen stretch) which is not far removed from the same band in free acrylonitrile, indicating that the nitrile group is not directly involved in the bonding to the cobalt(I). The acrylonitrile-cobalt(I) bond is most likely centered on the double bond.

Results

Polarography: Comparison with the results of Tanaka and Sato (1).—In agreement with Ref. (1), we observed four reduction waves for $Co(bipy)_3^{3+}$ corresponding to the successive formation of complexes containing cobalt in the oxidation states (II), (I), and (−I) followed by the reduction of liberated 2,2′-bipyridine. The half-wave potentials also agreed with those listed in Ref. (1). The addition of acrylonitrile to solutions of $Co(bipy)_3^{3+}$ resulted in the "catalytic wave" described by Tanaka and Sato (1) but the properties of this wave are very sensitive to the concentration of the supporting electrolyte. With the rather low supporting electrolyte concentration employed in Ref. (1) (0.05M tetraethylammonium perchlorate), the "catalytic wave" exhibited the properties described by Tanaka and Sato, *i.e.*, the limiting current of the catalytic wave was approximately proportional to the acrylonitrile concentration up to concentrations as large as 5 times the concentration of the cobalt complex. However, if the concentration of supporting electrolyte is increased, this behavior changes: The magnitude of the catalytic wave is no longer proportional to the concentration of acrylonitrile. Instead it tends toward a limiting value close to that of the wave corresponding to the reduction of Co(I) to Co(−I) in the absence of acrylonitrile (Fig. 1). Even when neat acrylonitrile is used in place of acetonitrile as the solvent the magnitude of the limiting current of the catalytic wave remains about the same (Fig. 1).

In agreement with Tanaka and Sato (1) we observed that the addition of free 2,2′-bipyridine to solutions of $Co(bipy)_3^{3+}$ causes no shift in the half-wave potentials of the waves corresponding to the reduction of Co(III) to Co(II) and of Co(II) to Co(I) while the wave for the reduction of Co(I) to Co(−I) shifts to more negative potentials. In the presence of acrylonitrile the value of $E_{1/2}$ for the reduction of Co(II) to Co(I) does respond to the addition of 2,2′-bipyridine until its concentration is increased sufficiently to cause the value of $E_{1/2}$ to match its value in the absence of acrylonitrile, whereupon further additions of 2,2′-bipyridine are without effect (Table I).

Spectral observations.—The intensely blue complex formed by reducing cobalt(II) in the presence of 2,2′-bipyridine has a visible absorption spectrum with a maximum at 600 nm (5). Since the cobalt(II)-bipy complexes show essentially no absorption in this region of the spectrum, it proved possible to utilize the absorbance at 600 nm to determine the number of molecules of 2,2′-bipyridine coordinated to cobalt in the Co(I) complex by means of the method of continuous variations (6). Figure 2 shows a plot of the absorbance at 600 nm as a function of the ratio of 2,2′-bipyridine to cobalt in solutions prepared by mixing $Co(ClO_4)_2$ and the ligand in oxygen-free methanol and adding a slight excess of $NaBH_4$ dissolved in oxygen-free methanol. The two straight lines drawn through the data points intersect at a ratio of 2,2′-bipyridine to cobalt of 2.95 indicating that the cobalt(I) complex present is predominately $Co(bipy)_3^+$.

Table I. Half-wave potentials for the reduction of Co(II) to Co(I) in acetonitrile solutions containing 2,2′-bipyridine and acrylonitrile. All solutions contained 0.6 mM $Co(bipy)_3(ClO_4)_2$ and 0.1M TEAP

The spectral changes accompanying the conversion of $Co(bipy)_3^+$ to the mixed complex containing acrylonitrile are shown in Fig. 3. It did not prove possible to obtain reliable estimates of the relative concentrations of complexes present from the spectra, but the large spectral changes make it clear that there is substantial complexation of acrylonitrile by cobalt(I). Tanaka and Sato (1) reached the opposite conclusion, but they did not examine the visible spectra of their solutions.

Cyclic voltammetry.—Our observation that the polarographic wave which Tanaka and Sato attributed to the catalyzed reduction of acrylonitrile had a magnitude that was quite sensitive to the ionic strength of the supporting electrolyte suggested that the wave might have been exalted by polarographic streaming maxima in the dilute supporting electrolyte employed in Ref. (1). The system was therefore examined by cyclic voltammetry with a platinum electrode replacing the dropping mercury electrode. The cyclic voltammograms for $Co(bipy)_3^{3+}$ in the absence of acrylonitrile exhibit the same three waves [Co(III) → Co(II), Co(II) → Co(I), Co(I) → Co(−I)] that were observed in the polarographic experiments. The first two waves exhibit reversible behavior at all scan rates with peak

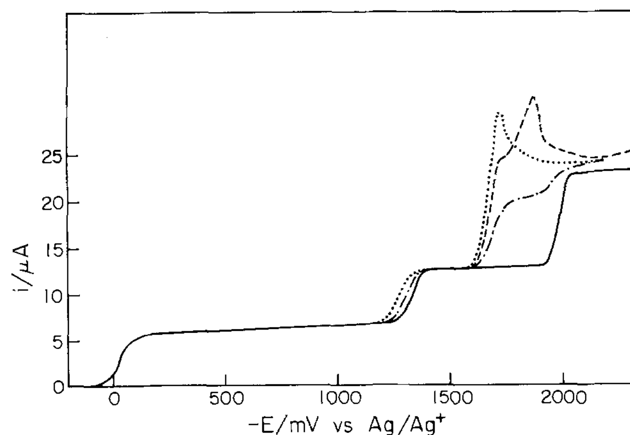

Fig. 1. D-C polarograms for 1 mM $Co(bipy)_3^{3+}$ in acetonitrile: (—) no acrylonitrile; (·—·—·—) 1 mM acrylonitrile; (— — —) 2 mM acrylonitrile; (· · · · ·) pure acrylonitrile as solvent. Supporting electrolyte: 0.1M TEAP. Capillary characteristics: drop time 1 sec, mercury flow rate —1.26 mg sec^{-1}.

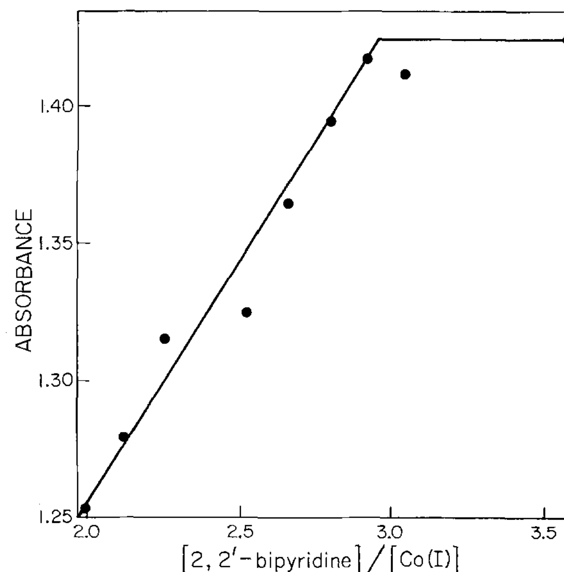

Fig. 2. Absorbance at 600 nm *vs.* the ratio of 2,2′-bipyridine to Co(I) in methanol.

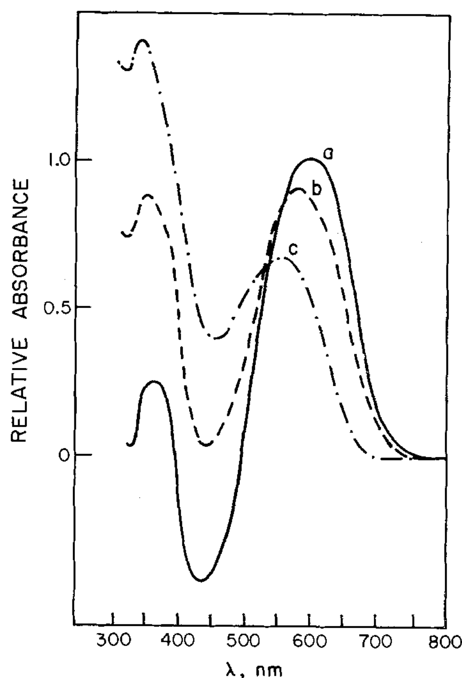

Fig. 3. Effect of acrylonitrile on the absorption spectrum of 0.1 mM Co(I) in a methanol solution containing 0.9 mM 2,2′-bipyridine: (——) no acrylonitrile; (— — —) 0.2 mM acrylonitrile (—·—·—) 1.6 mM acrylonitrile. The Co(I) was obtained by reduction of Co(II) with a slight excess of $NaBH_4$.

potential separations of *ca.* 60 mV and no dependence of peak potentials on scan rate or the addition of 2,2′-bipyridine. The third wave exhibits reversible behavior at moderate scan rates (1 V sec^{-1}) with peak potentials and anodic-cathodic peak potential separations that depend on the concentration of added 2,2′-bipyridine. Figure 4 shows the dependence of the average of the anodic and cathodic peak potentials of all three waves on the concentration of 2,2′-bipyridine. The slope of the line drawn through the points for the Co(I)-to-Co(−I) wave is 25 mV/decade which indicates that one molecule of 2,2′-bipyridine is lost when the Co(I) complex is reduced to Co(−I).

Figure 5 contains a representative set of voltammograms for the second and third reduction steps in

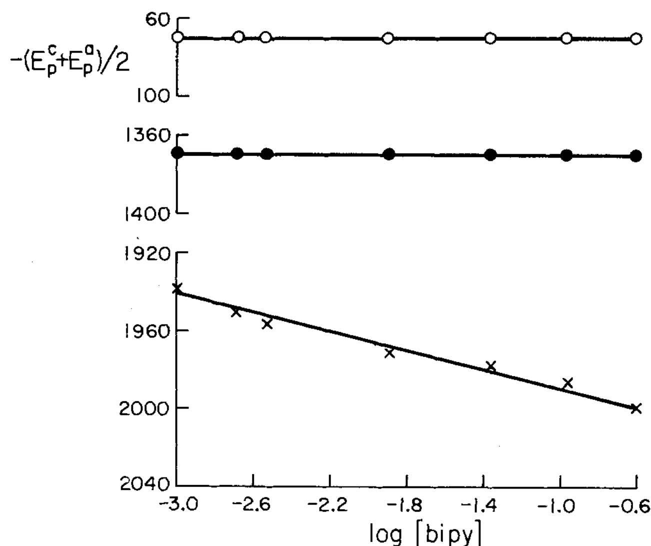

Fig. 4. Average of cathodic and anodic peak potentials for cyclic voltammograms: (○), Co(III) ⇌ Co(II); (●), Co(II) ⇌ Co(I); (×), Co(I) ⇌ Co (−I) in acetonitrile solutions of 2,2′-bipyridine. Concentration of cobalt: 1 mM. Supporting electrolyte: 0.1M TEAP. Scan rate: 1 V sec^{-1}.

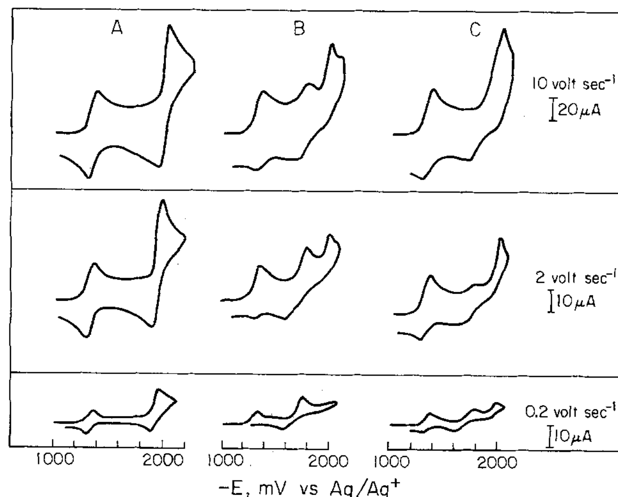

Fig. 5. Cyclic voltammograms for $Co(bipy)_3(ClO_4)_2$ in acetonitrile: A, no acrylonitrile present; B, 2.5 mM acrylonitrile present; C, 2.5 mM acrylonitrile and 2.0 mM 2,2′-bipyridine present. Supporting electrolyte: 0.1M TEAP. Platinum microelectrode: 0.045 cm^2.

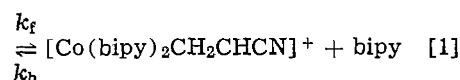
the absence and presence of acrylonitrile. As acrylonitrile is added to the solution of $Co(bipy)_3{}^{3+}$ a new wave appears (Fig. 5B), but its magnitude never exceeds that of the wave corresponding to the reduction of Co(I) to Co(−I) in the absence of acrylonitrile. This wave merely diminishes at the same rate as the new wave grows. Both waves correspond to the two-electron reduction of cobalt(I) without any apparent reduction of acrylonitrile.

The relative magnitude of the two cyclic voltammetric waves depends on the rate of potential scan: The less negative wave is suppressed and the more negative wave is enhanced the higher the scan rate. The less negative wave is reversible at high scan rates but becomes progressively less so as the scan rate is diminished. The wave can also be suppressed or eliminated by addition of 2,2′-bipyridine to solutions containing $Co(bipy)_3{}^{3+}$ and acrylonitrile (Fig. 5C). The behavior is consistent with the presence of a sluggishly established equilibrium as indicated in reaction [1]



$$Co(bipy)_3{}^+ + CH_2CHCN \underset{k_b}{\overset{k_f}{\rightleftharpoons}} [Co(bipy)_2CH_2CHCN]^+ + bipy \quad [1]$$

The new wave resulting from the addition of acrylonitrile can then be understood as the reduction of the mixed Co(I) complex, $[Co(bipy)_2CH_2CHCN]^+$, to the Co(−I) state.

An estimate of the equilibrium constant for reaction [1] was obtained by preparing solutions of $Co(bipy)_3{}^{3+}$ containing various concentrations of acrylonitrile and 2,2′-bipyridine and adjusting the potential of a platinum indicator electrode to −1400 mV [where the cobalt(III) complex was reduced to a mixture of the two cobalt(I) complexes] for 60 sec to allow the equilibrium in reaction [1] to be established. The electrode potential was then scanned toward more negative values and the peak currents for the two waves corresponding to the reduction of Co(I) to Co(−I) were measured. At scan rates of 5 V sec^{-1} or greater the ratio of the two peak currents became essentially independent of scan rate and thus provided a direct measure of the equilibrium concentrations of $Co(bipy)_3{}^+$ and $[Co(bipy)_2CH_2CHCN]^+$. Table II summarizes the results obtained from a series of such measurements and the resulting values of the equilibrium constant for reaction [1]. The reasonable constancy of the equilibrium constants obtained support the stoichiometry indicated in reaction [1], *i.e.*, one molecule of 2,2′-bipyridine is replaced by one molecule of acrylonitrile to form the more easily reduced complex.

Kinetics of reaction [1].—The cyclic voltammetric behavior of the pair of waves corresponding to the reduction of $Co(bipy)_3^{2+}$ and the oxidation of $Co(bipy)_3^+$ can be utilized to inspect the kinetics of reaction [1]. In the absence of acrylonitrile the cathodic and anodic peak currents for these two waves are equal, but the anodic peak current is diminished by the addition of acrylonitrile as reaction [1] proceeds from left to right (Fig. 5B). By working in the presence of excess acrylonitrile the reaction can be made pseudo first order and essentially irreversible. Under these conditions the forward rate constant for reaction [1] can be evaluated from the sweep rate dependence of the peak current ratio (7). Table III summarizes the data obtained from which an average value for k_f of 8×10^3 M^{-1} sec^{-1} was calculated.

Controlled potential electrolysis.—Successive electrolysis of acetonitrile solutions of $Co(bipy)_3^{3+}$ with mercury pool or platinum gauze electrodes at potentials on the plateau of the first and then of the second polarograph waves (*i.e.*, −100 and −1400 mV, respectively) results in the consumption of 1F/mole for each wave as expected for successive reductions to $Co(bipy)_3^{2+}$ and $Co(bipy)_3^+$. During the reduction to $Co(bipy)_3^+$ the solution develops the deep blue color characteristic of this complex (3, 4). If the electrolysis is continued at the same potential an additional faraday per mole of electricity is slowly consumed over a period of a few hours, the blue color fades, and a dark precipitate resembling metallic cobalt appears. This slow, electrolytic decomposition of the complex is diminished by the addition of excess 2,2'-bipyridine.

Acrylonitrile is without effect on the course of the controlled potential reduction of $Co(bipy)_3^{3+}$ and $Co(bipy)_3^{2+}$. However, if sufficient acrylonitrile is present the color developed as Co(I) is produced and is

† The ratio is of the peak current for the oxidation of $Co(bipy)_3^+$ to that for the reduction of $Co(bipy)_3^{2+}$.
‡ Read from a plot of the data in Table XI in Ref. (7). The negligibility of the reverse of reaction [1] under the experimental conditions employed was demonstrated by the lack of significant changes in the peak current ratio when small amounts of 2,2'-bipyridine were added to the solutions.

deep purple rather than the characteristic blue of $Co(bipy)_3^+$. The same color can be produced by adding acrylonitrile to a previously electrogenerated solution of $Co(bipy)_3^+$. It is apparently the color of the mixed complex, $Co(bipy)_2(CH_2CHCN)^+$.

Controlled potential reduction of the purple solution at a potential on the plateau of the new wave now present (Fig. 5B) results in the consumption of almost exactly two additional faradays per mole of Co and yields a brownish yellow solution. This result is independent of the excess of acrylonitrile present: The same behavior is obtained if acrylonitrile is substituted for acetonitrile as the solvent.

That no reduction of the acrylonitrile occurs during the controlled potential reduction was confirmed by gas chromatographic analysis of the solution before and after the electrolysis: Only a negligible loss of acrylonitrile was observed by the time that 2F/mole of cobalt had been consumed and the current had decayed to its background level.

If the controlled potential electrolysis is carried out with a solution containing $Co(bipy)_3^{2+}$ and acrylonitrile the total charge consumed at −1.7V is 3F/mole of cobalt(II), as expected, but the initial current is not as large as would correspond to the simple, direct reduction of cobalt(II) to cobalt(−I). The behavior is consistent with the intervention of a slow chemical step along the electrolytic pathway. A likely candidate for such a slow step is reaction [1]. If the electrolysis is continued beyond the point at which the cobalt has been converted to Co(−I) the current falls to the background level but the concentration of acrylonitrile monitored by gas chromatography decreases slowly over a period of several hours. However, there is no detectable loss of acrylonitrile before this stage of the electrolysis. We found no evidence of acrylonitrile reduction accompanying the reduction of the cobalt.

Reaction of $Co(bipy)_3^+$ with vinyl monomers.—The apparent propensity for acrylonitrile to coordinate to Co(I) and thereby facilitate its further reduction suggested that other vinyl monomers might exhibit similar behavior. This proved to be the case for a number of vinyl monomers which all produce the same wave near −1.7V that results when acrylonitrile is added to solutions of $Co(bipy)_3^{2+}$. The wave height in each case corresponds to the reduction of Co(I) to Co(−I). The equilibrium and forward rate constants for the formation of the assumed cobalt(I)-vinyl monomer complexes according to reaction [2]

$$\text{monomer} + Co(bipy)_3^+ \rightleftharpoons Co(bipy)_2\text{monomer}^+ + \text{bipy} \quad [2]$$

were evaluated by the same cyclic voltammetric procedures employed with acrylonitrile and the results are given in Table IV. Note that the stability of the cobalt(I)-vinyl monomer complexes increases with the ease of reduction of the monomer itself ($E_{1/2}$ values are given in Table IV).

Discussion

The results that have been described can all be accommodated on the basis of the set of reaction se-

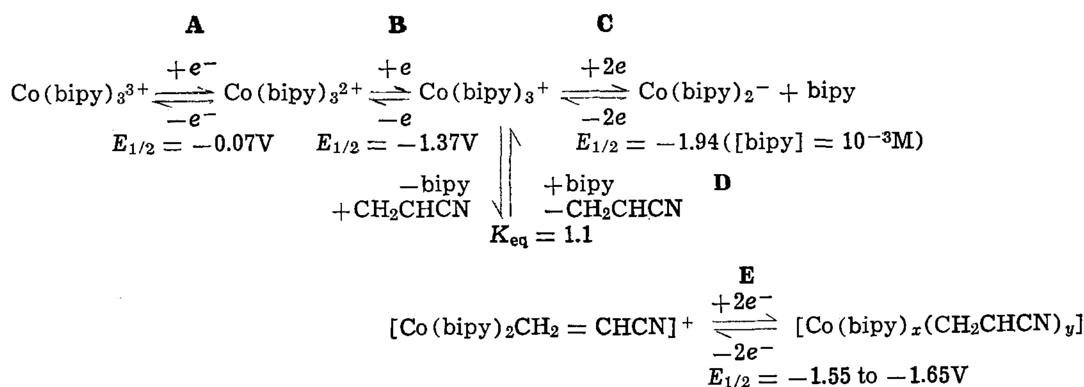
Scheme I



quences given in Scheme I. The evidence to support the conclusion that there is no loss of coordinated 2,2′-bipyridine as Co $(bipy)_3^{3+}$ is reduced to $Co(bipy)_3^{+}$ is the fact that both the polarographic half-wave potentials and the cyclic voltammetric peak potentials corresponding to the reversible steps **A** and **B** in Scheme I show no dependence on the concentration of free 2,2′-bipyridine (Table I; Fig. 4). However, this does not require that the 2,2′-bipyridine retain its bidentate chelation of the cobalt center when the latter is reduced to the Co(I) state. The resulting d^8 complex could well become five-coordinate by the breaking of one of the cobalt-bipy bonds.

Both step **C** and steps **D** + **E** in Scheme I show half-wave and peak potentials which depend on the concentration of 2,2′-bipyridine in the way to be expected if a loss of coordinated 2,2′-bipyridine accompanied the electrode reaction. It is noteworthy that step D could not be observed with the $Co(phen)_3^{+}$ complex even in the presence of large excesses of acrylonitrile. Apparently the steric constraints imposed by the larger and more rigid 1, 10-phenanthroline ligands which cannot become monodentate as readily as can 2,2′-bipyridine, impedes the formation of the π-bonded acrylonitrile complex.

The composition of the product of step **E** was not definitely established. However, it is not the same as the product of step **C** because solutions resulting from the reduction of $Co(bipy)_3^{2+}$ by three electrons in the absence of acrylonitrile are noticeably bluer than those obtained when acrylonitrile is present. Moreover, the latter solutions can be converted to what appears to be the same blue color by the addition of excess 2,2′-bipyridine following the reduction. The Co(−I) complex may contain more than a single acrylonitrile molecule and fewer than two 2,2′-bipyridine molecules but the available data are inadequate to permit a definitive assignment of its composition.

The primary differences between the interpretations offered by Tanaka and Sato and that given in Scheme I are the lack of any reduction of acrylonitrile and the proposed formation in step **D** of a stable, mixed complex of acrylonitrile and 2,2′-bipyridine which undergoes reduction to the Co(−I) state at less negative potentials than does the $Co(bipy)_3^{+}$ complex. That the mixed complex has the composition given in Scheme I is supported by the spectral data, cyclic voltammetric data from which reasonably constant values for the equilibrium constant for step **D** were obtained (Table II), and the fact that a perchlorate salt was isolated which gave an elemental analysis that corresponded reasonably well to that calculated for $[Co(bipy)_2CH_2CHCN]ClO_4$.

Tanaka and Sato concluded that $Co(bipy)_3^{+}$ and CH_2CHCN do not react with each other in the bulk of solution because the height of the polarographic wave they attributed to the reduction of the product of this reaction did not increase linearly with the concentration of $Co(bipy)_3^{+}$. On this basis they argued that the mixed complex was formed only at the mercury electrode surface where it was adsorbed. As mentioned earlier, we believe Tanaka and Sato were misled by the presence of polarographic maxima under the conditions of their experiments. By employing higher supporting electrolyte concentrations or by substituting a platinum electrode for the DME we observed wave heights that remained linearly proportional to the concentration of cobalt(I) throughout the range from 0.1 to 10 mM. We found no evidence of adsorption of $Co(bipy)_3^{2+}$ or $Co(bipy)_3^{3+}$ in the cyclic voltammetric data at mercury electrodes: The cathodic and anodic peak currents for the Co(II)/Co(I) waves remained proportional to the square root of the scan rate and equal to each other up to scan rates of 20 V sec^{-1}. Chronocoulometric measurements indicated some possible adsorption of $Co(bipy)_3^{+}$, but it was not possible to distinguish between adsorption and precipitation of the slightly soluble $Co(bipy)_3ClO_4$ on the electrode surface.

Polarographic maxima were apparently also responsible for the erroneous assertion (1) that acrylonitrile reduction is catalyzed in the presence of $Co(bipy)_3^{+}$. Limiting currents that exceed two electrons per Co(I), the sole basis for the conclusions of Tanaka and Sato, are not observed with larger supporting electrolyte concentrations or at platinum electrodes. Of course, the controlled potential electrolytic reduction of solutions containing both $Co(bipy)_3^{2+}$ and acrylonitrile in which the charge consumed corresponds to precisely three electrons per Co(II) and is independent of the amount of acrylonitrile present provides the clearest proof that acrylonitrile is not reduced. Gas chromatographic monitoring of the concentration of acrylonitrile throughout the electrolysis confirms that none is consumed. Thus, the extremely interesting results of Tanaka and Sato do not constitute an example of a relatively slow electrode reaction being catalyzed by an electrogenerated organometallic intermediate. [The reduction of Co(I) to Co(−I) is "catalyzed" by coordinated acrylonitrile but since the reduction does not lead to the same product in the absence and presence of acrylonitrile, the latter is not functioning as a true catalyst.]

That many vinyl monomers mimic the behavior of acrylonitrile (Table IV) despite having widely different electrochemistry of their own in the absence of $Co(bipy)_3^{+}$ adds support to the notion that one is dealing with a general type of coordination chemistry involving a low valent transition metal center and activated olefins as ligands. Ethylene and acetylene were without effect on the polarography of $Co(bipy)_3^{2+}$. Carbon monoxide appeared to react with $Co(bipy)_3^{+}$ and facilitate its further reduction but the reaction was not examined in detail.

Very recently we observed that electrogenerated $Co(bipy)_3^{+}$ can function as an effective catalyst for the reductive dimerization of allyl halides to produce hexadienes in a reaction having many of the features Tanaka and Sato believed they had observed in the case of acrylonitrile. The details of these experiments will be described in a forthcoming publication.

Semiconductor Electrodes

XIV. Electrochemistry and Electroluminescence at n-Type TiO_2 in Aqueous Solutions

Rommel N. Noufi,* Paul A. Kohl,* Steven N. Frank, and Allen J. Bard****

Department of Chemistry, The University of Texas, Austin, Texas 78712

ABSTRACT

The electrochemical behavior of single crystal n-TiO_2 was investigated in aqueous solutions. Charge transfer at the semiconductor/electrolyte interface was probed with several redox couples with standard redox potentials spanning a wide range. Most reductions occurred at potentials close to V_{fb}, the flatband potential and the current-voltage behavior suggested involvement of surface states in the charge transfer process. Evidence for the adsorption of phosphate ion and its effect on the reduction of $Fe(CN)_6^{3-}$ is also presented. Electroluminescence was observed during reduction of $S_2O_8^{2-}$ at wavelengths longer than 700 nm, suggesting the existence of intermediate levels.

The electrochemical behavior of n-TiO_2 has been the subject of several recent investigations including a previous report in this series (1), which utilized an aprotic solvent, acetonitrile (ACN), and which postulated that electron transfer can occur via intermediate levels or surface states within the bandgap region. Studies in aqueous solutions with TiO_2 (2) and other semiconductors (3, 4) have also investigated the mechanism of charge transfer of added redox couples at the semiconductor/solution interface. Although not as many Nernstian, one-electron redox couples are available in aqueous, as compared to nonaqueous solutions, the relative location of the energy levels of TiO_2 at the semiconductor/solution interface (*i.e.*, the flatband potential) can be changed in aqueous solutions by relatively large amounts by changing the solution pH. This provides another variable for investigating the band structure. This approach has previously been used to study SiC (4) and SnO_2 (5).

In the present study the semiconductor/solution interface was investigated by several techniques. Electron transfer reactions of couples, including some with standard redox potential well positive of those used in a previous study (2), were investigated at different pH's. To probe the existence and role of intermediate levels within the bandgap, electroluminescence of the n-TiO_2 semiconductor caused by electron-hole recombination from minority carrier injection from the electrolyte was studied. Hole injection into n-type semiconductors leading to radiative recombination has previously been demonstrated for GaP (6), SnO_2, ZnO, CdS, and GaAs (7).

In addition a study of the space charge capacitance, C_{sc}, as a function of potential, E, was undertaken in an attempt to determine the donor density (N_D) and flatband potential (V_{fb}), via the Schottky-Mott equation (Eq. [1]) (8)

$$1/C_{sc}^2 = (\Delta\phi_s - kT/e)\ 2/(\epsilon\epsilon_0 e N_D) \qquad [1]$$

where C_{sc} is the space charge capacitance, $\Delta\phi_s$ is the amount of band bending, k is the Boltzmann constant, T is the absolute temperature, e is the electronic charge, ϵ is the dielectric constant of the semiconductor, and ϵ_0 is the permittivity of free space. In several previous studies these plots of C_{sc}^{-2} *vs.* E showed deviations from the behavior predicted by Eq. [1] [see, for example, (2, 9, 10) and references therein]. In this work, two independent methods were used to calculate N_D for several n-TiO_2 crystals: (*i*) capacitance determined by a-c methods and cyclic voltammetry via Eq. [1] and (*ii*) conductance. Ohmic contacts were made by four different methods to determine their effect on the capacitance-potential behavior.

Experimental

The single crystal n-TiO_2 semiconductors used for the electrochemical investigation of redox couples were obtained from National Lead (Niagara Falls, New York). Two of the crystals were cut perpendicular to the C_2 axis and one of these was heated to 650°C in vacuum at 10^{-4} Torr for 3 hr and will be called "the moderately doped sample" with $N_D \simeq 10^{18}/cm^3$, as determined from a Schottky-Mott plot. The other was heated at 650°C in a hydrogen atmosphere for 15 min and will be denoted "the highly doped sample," with $N_D \cong 10^{20}/cm^3$. An ohmic contact was made to one side of each crystal by electrochemically depositing In from a 0.1M $InCl_3$ solution.

The capacitance measurements were made with four crystals cut perpendicular to the C_2 axis from a boule

Key words: semiconductors, luminescence, surface states.

generously donated by Fuji Titanium (Hiratsuka, Japan). The 1.5 mm thick crystals were heated in a hydrogen atmosphere for 15 min at 650°C. Two ohmic contacts were made to each crystal by one of the following methods:

1. Electrochemical deposition of indium from a 0.1M $InCl_3$ solution.
2. Electrochemical deposition of indium from a 0.1M $InCl_3$ solution followed by heating in vacuum (10^{-4} Torr) for 1 hr at 650°C.
3. Soldering a copper wire to the rear of the crystal with indium solder.
4. Smearing with In-Ga alloy (1:1 by volume mixture). In methods 1, 2, and 3, copper wires were attached to the contacts with conducting silver epoxy cement (Allied Corporation, New Haven, Connecticut).

The crystals were insulated, except for the (001) face, with Devcon epoxy cement (Devcon Corporation, Danvers, Massachusetts) and mounted on glass rods for use as electrodes as described previously (1). Each crystal was etched for about 15 sec in an HF/HNO_3 solution (11) prior to use except when special etchants were employed, as noted.

All compounds used in this study were reagent grade obtained from commercial sources. Solution concentrations were usually 1 and 10 m*M* in electroactive species. The solutions were prepared with triply distilled water and deaerated with prepurified nitrogen for 30 min. The electrochemical cell, similar to previous design (1), contained an optically flat Pyrex window for illuminating the semiconductor working electrode. A conventional three electrode design was used with an aqueous saturated calomel reference electrode (SCE) and a coiled platinum wire counterelectrode separated from the main compartment by a medium porosity glass frit. The capacitance measurements were performed in the dark with a platinum counterelectrode with an area at least ten times that of the working electrode. The d-c faradaic current was less than 0.2 $\mu A/cm^2$ in the voltage range used for capacitance measurements.

A PAR Model 173 potentiostat (Princeton Applied Research, Princeton, New Jersey) and PAR Model 175 universal programmer were used for the electrochemical measurements. Positive feedback was used to compensate for the *iR* drop in the solution and semiconductor working electrode. The cyclic voltammetric (*i-E*) curves were recorded on a Houston Instruments (Austin, Texas) Model 2000 X-Y recorder for scan rates less than 1 V/sec. For faster scan rates the *i-E* curves were recorded on a Tektronix Model 564 (Tektronix, Incorporated, Beaverton, Oregon) storage oscilloscope. The semiconductor electrodes were illuminated with a 450W xenon lamp (Oriel Corporation, Stamford, Connecticut) employing a Model 6242 power supply. The cell capacitance was measured by an a-c method which superimposed a 5 mV sine wave (500-10,000 Hz) on a d-c voltage, and corresponding phase shift between the current and voltage was measured with a PAR Model HR-8 lock-in amplifier. The potentiostat in these measurements was a Wenking Model 61 RH (G. Bank Electronik, Germany), and the instrumental setup has been described previously (12). The capacitance was also estimated by measuring the charging current of the cyclic voltammograms in the absence of electroactive species as discussed in the next section.

The electroluminescence emitted in the ultraviolet and visible region was detected with a Barr and Stroud (Glasgow, United Kingdom) circular interference filter and a sensitive photomultiplier tube (Dumont 6467). The near infrared light was detected with an Oriel Model 7240 grating monochromator (grating blazed at 1 μm) in conjunction with an ultraviolet cut off filter and Radiometer/photometer (E. G. & G. Incorporated, Salem, Massachusetts).

Results

Capacitance measurements.—The d-c and a-c current measured between the two contacts made on the crystals was directly proportional to the applied voltage and independent of polarity and frequency over the range 100-10,000 Hz for all of the contacts. Thus these can be taken as purely ohmic contacts.

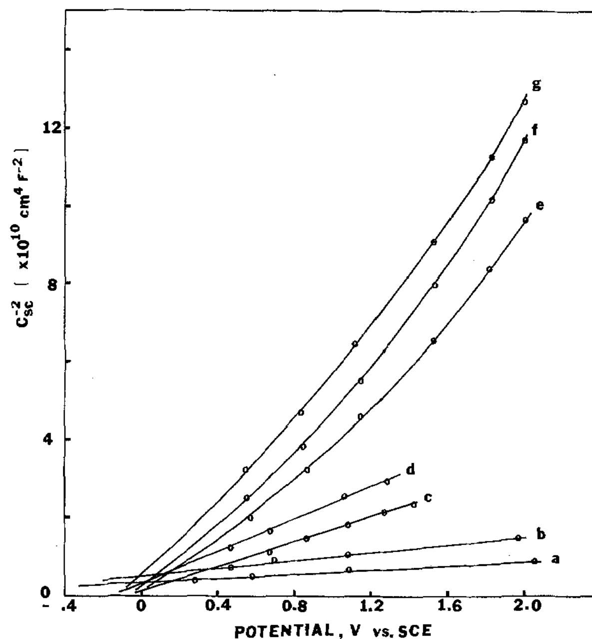

Fig. 1. Plot of C_{sc}^{-2} (cm^4F^{-2}) *vs.* *E* (V, vs. SCE) in 1.0*M* H_2SO_4. Capacitance measured by (a) a-c method at 500 Hz, (b) a-c method at 1000 Hz, (c) cyclic voltammetric method at 5 V/sec (reactivated crystal), (d) cyclic voltammetric method at 500 V/sec (reactivated crystal), (e) a-c method 1000 Hz (reactivated crystal), (f) a-c method 2000 Hz (reactivated crystal), (g) a-c method 5000 Hz (reactivated crystal).

Plots of C_{sc}^{-2} *vs.* *E* (Eq. [1]) of a moderately doped TiO_2 crystal under various conditions are shown in Fig. 1. Curves a and b were obtained by a-c methods at 500 and 1000 Hz, respectively, after the crystal had been used for extended periods as a photoanode in a 1.0M H_2SO_4 solution. The current density of these photoanodes decreased with time during irradiation, as previously reported (10). When the crystal was reactivated in vacuum (10^{-4} Torr) at 650°C for 5 min, the C_{sc}^{-2} *vs.* *E* plots shown in Fig. 1, curves e, f, and g resulted. C_{sc} was also estimated from the charging current measured in the cyclic voltammograms in the dark at various scan rates (0.2-500 V/sec) with no electroactive species in solution. The capacitance was calculated by dividing the current at a given potential by the scan rate. Curves c and d (Fig. 1) show the C_{sc}^{-2} *vs.* *E* plots at 5 and 500 V/sec respectively, for a reactivated crystal.

The Schottky-Mott plots for the four crystals with the different types of contacts (see experimental section) were all very similar with the exception of contact b which yielded a smaller slope, apparently because the doping level increased during the heating in vacuum. The donor densities calculated from the a-c measurements (500-10,000 Hz) for contacts a, c, and d were $1 \times 10^{20}/cm^3$ to $2 \times 10^{20}/cm^3$, while the cyclic voltammetry results (0.2-500 V/sec) gave values of $2 \times 10^{20}/cm^2$ to $3 \times 10^{20}/cm^3$. In all cases, frequency dispersion of the C_{sc}^{-2} *vs.* *E* plots was observed with both the a-c and cyclic voltammetric results.

The intersection of the C_{sc}^{-2} *vs.* *E* plot with the x-axis, yielding V_{fb}, was very similar for the a-c methods and cyclic voltammetric results but there was appreciable scatter and frequency dependence in the V_{fb} values obtained by extrapolation. The origin of the frequency dispersion has been studied extensively and several reasons have been given for the observed results, *e.g.*, dielectric relaxation, crystal imperfections, adsorbed species, and filling and emptying of localized levels in the bandgap (2, 9, 10).

N_D was also estimated by making an ohmic contact of known area to opposite sides of the crystal and measuring the conductivity using Eq. [2]

$$\sigma = N_D e \mu_e \quad [2]$$

where σ is the conductivity, e is the electronic charge, and μ_e is the mobility (13). The value of N_D for crystals with contacts a, c, and d determined by this method was about $7 \times 10^{19}/cm^3$.

Redox processes.—Prior to the addition of an electroactive species, the background oxidation of water in 0.5M H_2SO_4 in the dark did not appear at the moderately doped TiO_2 ($N_D = 10^{18}/cm^3$) until +4.5V and with the highly doped ($N_D = 10^{20}/cm^3$) electrode until +4.0V. During dark water oxidation, bubbles were observed at the electrode surface. Only a small charging current, which was directly proportional to scan rate, was observed for scans from about 0V to potentials for the oxidation of water in 0.5M H_2SO_4. When the scan rate was toward negative potentials, two waves with peak heights directly proportional to scan rate and with peak potentials at −0.45 and −0.85V occurred, followed by a large wave attributed to hydrogen ion reduction. On the reverse scan towards positive potentials, an oxidation wave with a peak potential about 30 mV positive of the first reduction peak appeared; this was attributed to the oxidation of hydrogen. These reduction and oxidation peaks shifted towards negative potentials by about 30 mV/pH unit with increasing pH.

The charge transfer processes at the n-TiO_2/electrolyte interface were studied using several redox systems, listed in Table I. Representative examples of cyclic voltammograms for reductions are shown in Fig. 2. The reduction of $Fe(CN)_6^{3-}$, Ce^{4+}, Fe^{3+}, Ag^{2+}, and $IrCl_6^{2-}$ did not start until the electrode potential was well negative of the corresponding $E_{1/2}$ value ($E_{1/2}$ is taken here as $(E_{pc} + E_{pa})/2$) determined at Pt. In all cases the wave was shifted towards V_{fb} which was not changed by the addition of any of the redox systems, but some current flow occurred at potentials positive of V_{fb}. No reversal anodic waves were found for any reduction. For all waves the reduction peak currents varied with the square root of the scan rate, $v^{1/2}$, and the cathodic peak potentials (E_{pc}) shifted negative by about 54 mV/pH unit. The E_{pc} values for the moderately doped TiO_2 electrode were always 20-70 mV more negative of those for the highly doped one at the same pH. The cathodic current density depended exponentially on the applied potential in a region at the foot of the wave near, but positive of V_{fb}. From Tafel plots, *i.e.*, log i_c *vs.* E, as shown in Fig. 3, which were obtained from the exponential current rise in a stirred solution where there was no contribution from mass transfer, the transfer coefficient, α, was calculated, assuming Eq. [3] applies

$$\log i_c = \log i° - \frac{\alpha n \mathbf{F}(E - E_{1/2})}{2.3\,RT} \quad [3]$$

where n is the number of equivalents per mole, **F** is Faraday's constant, R is the ideal gas constant, and T is the absolute temperature. The exchange current, $i°$, was estimated by extrapolation of log i_c to the $E_{1/2}$ value found with a platinum electrode for the redox couple. A summary of the Tafel plot results is given in Table II. The values of the Tafel slope, (dE/d log i), for the different couples were relatively high for TiO_2 compared to values found with other semiconductors as was also observed by Gomes *et al.* (2). The accepted model (8), which assumes isoenergetic electron transfer of an electron from the semiconductor conduction band to unoccupied solution levels predicts a slope of 60 mV ($\alpha = 1$) for a pure conduction band process at potentials positive of V_{fb}.

Effect of supporting electrolyte.—The cyclic voltammetric reduction of $Fe(CN)_6^{3-}$ in buffers containing phosphate in the *p*H range 5-9.5 showed two peaks at TiO_2 (Fig. 4a), but only one at Pt in this buffer. The relative height of the two peaks was a function of scan rate (Fig. 4b) and also of the etchant employed. The more positive peak (P_1) was higher at lower scan rates and also when the electrode was etched in 5*M* NaOH as compared to a concentrated HNO_3 etchant. The second peak was more pronounced after etching in concentrated HNO_3 and at higher scan rates. Addition of Na_2SO_4 or KI to the phosphate electrolyte suppressed the second wave (P_2) until only the first wave appeared during reduction. Only the first wave was observed with other electrolytes (*e.g.*, 0.5*M* H_2SO_4, 0.1*M* KOH). Addition of Na_2SO_4 to produce a solution concentration of 0.2*M* totally suppressed the second wave in 0.33*M* phosphate buffer with an electrode etched in HNO_3. The addition of KCl to the buffer however did not have any effect on the double wave. Other redox couples such as $CuCl_2$, Ce^{4+}, and $IrCl_6^{2-}$ did not exhibit the double wave phenomenon in the phosphate buffers. However, experiments with these required acidic media, and at these *p*H's even $Fe(CN)_6^{3-}$ did not show the double wave. $Fe(C_2O_4)_3^{3-}$ and Fe^{3+} also exhibited a similar double wave behavior. However, for these the two waves were not as well defined as those found with $Fe(CN)_6^{3-}$; in this case the first wave was shifted towards negative potentials, so that it appeared as a prewave on the second wave and quantitative data on the relative peak heights was not possible. A systematic change of the total phosphate concentration from 0.01 to 0.5*M* at a fixed *p*H did not appear to change V_{fb}, as determined by the onset of photoanodic current.

Oxidation.—When the electrode was scanned to potentials positive of V_{fb}, a blocking region was observed in the dark extending to +4.5 and +4.0V *vs.* SCE for the moderately and highly doped electrodes respectively, where no oxidation currents appeared. In Fig. 5 the effect of addition of the reduced forms of several redox couples on the dark anodic current is shown and the behavior of the highly doped electrode is compared to that of the moderately doped one. At the highly doped electrode the blocking region was smaller than that of the moderately doped one with no reducing agent in solution. Upon addition of a reducing agent, an anodic current started at less positive potentials than background oxidation for all species tried at the highly doped electrode. At the moderately doped electrode only $Fe(CN)_6^{4-}$ produced significant anodic current at potentials less positive than the background oxidation; the oxidations of Ce^{3+} and Fe^{2+}, if they occurred, took place along with the background oxidation.

Illumination of the electrode did not have any effect on the reduction processes. Oxidation of the reduced species occurred upon illumination which was evident by the increase in the anodic current at a given potential on the rising portion of the wave for photooxidation of water, which commences positive of V_{fb}. A decrease in the amount of O_2 evolved was observed, indicating competition of the reduced species with water for the photogenerated holes. These types of

experiments on photoprocesses for different redox couples in aqueous solutions at TiO_2 have been discussed elsewhere (14, 15).

Polycrystalline TiO_2 prepared by chemical vapor deposition (16) showed identical electrochemical behavior in aqueous solution to that of the moderately doped single crystal. Similar results have already been demonstrated in acetonitrile (1). However, the photocurrents on the polycrystalline electrodes were smaller than those for the single crystals.

Light emission.—The electroluminescence observed during reduction of persulfate and H_2O_2 at several semiconductors in aqueous solutions has been used to interpret the mechanism of charge transfer and to obtain information about energy levels in the gap (6, 7). Luminescence produced by recombination of an electron with a hole in the semiconductor was also observed with n-TiO_2 electrodes when persulfate was reduced. The mechanism for luminescence probably follows that proposed for other semiconductors (6, 7) with an initial step being transfer of an electron from the conduction band or a surface state below the conduction band to $S_2O_8^{2-}$ (Eq. [4])

$$S_2O_8^{2-} + e^-(CB) \rightarrow SO_4^{2-} + SO_4^{\overline{\cdot}} \qquad [4]$$

Since $SO_4^{\overline{\cdot}}$ is very easily reduced, the $SO_4^{\overline{\cdot}}/SO_4^{2-}$ energy level lies below the valence bandedge, and thus electron transfer to the radical causes injection of a hole into the valence band or a state just above the valence band (Eq. [5])

$$SO_4^{\overline{\cdot}} \rightarrow SO_4^{2-} + h^+(VB) \qquad [5]$$

Electron-hole recombinations then cause emission of radiation. The i-E curve (Fig. 6a) shows that the reduction of persulfate occurs about 100 mV positive of the background reduction of water. The light emission did not start when the reduction of persulfate first occurred. Luminescence began when the electrode potential was pulsed to -1.5V, a value negative of V_{fb}. The emission intensity increased with pulsing to more negative potentials and attained a maximum value at -3.0V. At this potential the intensity was a function of pulse duration and was largest with a 100 msec pulse. Shorter pulses gave weak emission; longer pulses gave an emission with intensity equal to that of the 100 msec pulse which then decayed to a steady state (Fig. 6b). The TiO_2 electroluminescence spectra (Fig. 7) were different than those observed with ZnO (7), although both materials have similar bandgaps and flatband potentials. Most of the light emission occurred at photon energies smaller than that of the bandgap, *i.e.*, only a very small fraction of the emitted light corresponded to bandgap energy (3.2 eV), while most of the emitted light extended into the near infrared region

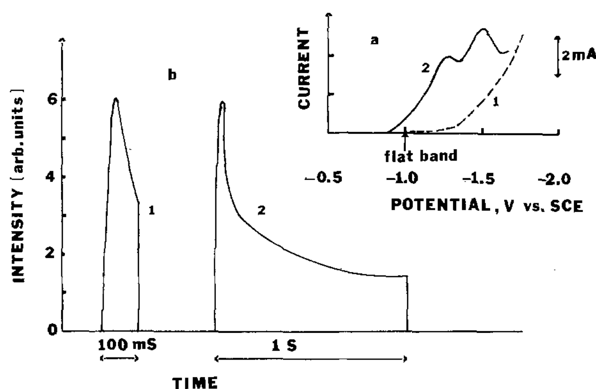

Fig. 6. (a) Linear potential sweep of highly doped n-TiO_2 at 0.1 V/sec in (1) 5M NaOH solution, (2) 0.1M $S_2O_8^{2-}$, 5M NaOH solution, (b) Intensity vs. time curve of the electroluminescence of n-TiO_2 at -3.0V in 0.1M $Na_2S_2O_8$, 5M NaOH (1) 0.1 sec pulse, (2) 1 sec pulse.

with photon energies of 1.5-1.24 eV. This behavior is similar to that exhibited by n-GaAs (7).

The spectral distribution of the luminescence with n-TiO_2 clearly suggests the existence of surface states or intermediate levels located within the bandgap. As in the previous studies (6, 7), the quantum efficiency for the emission is very low suggesting that the extent of nonradiative recombination or reduction of $SO_4^{\overline{\cdot}}$ directly via surface states rather than via the valence band is significant. Previous studies of TiO_2 (1, 14) and other semiconductors (17) in nonaqueous solvents have provided evidence of the importance of levels within the gap in explaining the electrochemical properties of semiconductor materials.

Discussion

Reduction.—The reduction of solution species in the absence of surface states should occur at a wide bandgap semiconductor through either the conduction band or valence band depending upon the standard potential of the redox couple (8). The position of the energy levels and distribution maxima of the solution species investigated and TiO_2 are shown in Fig. 8, where W_{Ox} is the maximum of the distribution for the oxidized form in solution, W_{Red} is the maximum of the distribution for the reduced form, and $E°_{redox}$ is the Fermi level of the redox couple (8). The separation between

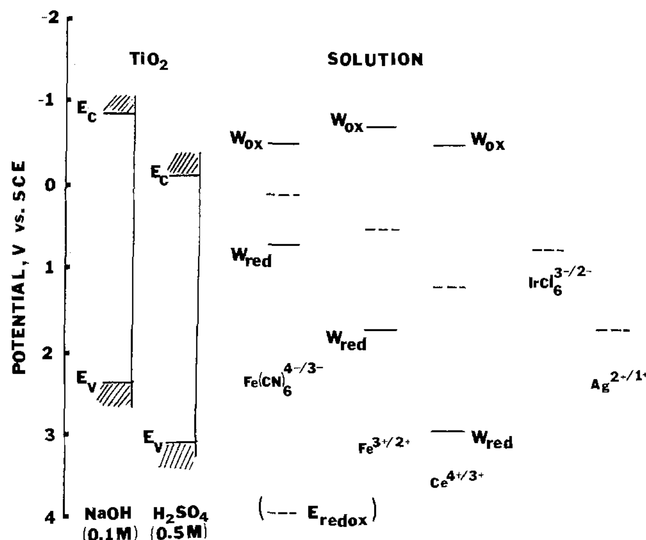

Fig. 8. Relative energy positions of n-TiO_2 and various redox couples where $E°_{redox}$ is the standard redox potential, W_{Red} is the distribution maximum of the reduced species, W_{Ox} is the distribution maximum of the oxidized species, E_c and E_v are the conduction and valence bandedges, respectively.

W_{Ox} and W_{Red} is essential 2λ, where λ is the solvent reorganizational energy during electron transfer. The λ values estimated for several couples by Memming *et al.* (5) have been used in Fig. 8. For all of the couples in this study the distribution of the oxidized form at the valence bandedge, $W_{Ox}(E_v)$, is small so that reduction by hole injection into the valence band should be small. However, for reduction only via the conduction band for a couple where $E°_{redox}$ is below E_c the reduction current should be proportional to the electron density at the surface, n_s, and the overlap of the unoccupied solution levels with the conduction band, $W_{Ox}(E_c)$. The potential dependence of the reduction current should then follow that of n_s and hence the apparent exchange parameter, α (as defined in Eq. [3]) should be equal to unity at potentials positive of V_{fb}. Since α values less than one were observed, a pure conduction band process seems unlikely. We do not think that reduction via tunneling from the conduction band to the oxidized species, as discussed by Pettinger *et al.* (18) is likely in this case. Our results show that the reduction current for $Fe(CN)_6^{3-}$ in both 0.5*M* H_2SO_4 and 0.1*M* KOH starts positive of V_{fb} by about 0.45V. Tunneling from the conduction band to solution, which is a function of the space charge thickness at the energy level distribution of the unoccupied species (18), should give a larger difference between the onset of the reduction current and V_{fb} (because of the negative shift in V_{fb}) in base as compared to acid while the distribution W_{Ox} remains fixed. The onset of reduction on both the highly and moderately doped TiO_2 crystals occurs at potentials where the extent of band bending appears to be too small to satisfy the conditions for such tunneling. Thus the α values measured probably represent involvement of surface states or intermediate levels in the reduction processes. Dutoit *et al.* (2) also found anomalously large Tafel slopes for the reduction of several couples at *n*-TiO_2 and presented strong arguments against variation of the Helmholtz layer potential as the origin of this effect.

The reduction of electroactive species with redox potentials well positive of V_{fb} at both moderately and highly doped TiO_2, in aqueous solutions is different from the behavior found in ACN (1). In ACN couples with redox potentials more than 1.5V positive of V_{fb} were all reduced at potentials about 1V below the conduction bandedge; this was attributed to the location of intermediate levels in the semiconductor near this energy. The redox couples used in this study with $|E_{redox} - V_{fb}|$ greater than 1.2V all showed reduction waves close to V_{fb} (Fig. 2). However, the solvent interaction energy, λ, is larger in water than in ACN. This broadens the W_{Ox} distribution and shifts it closer to the conduction band, making better overlap possible even for couples with very positive values of E_{redox} (Fig. 8). Couples with potentials as positive as those used in ACN could not be employed because they are not stable in water. It is also possible that the different extent of interaction of the water with the TiO_2 surface causes the energy level of surface states to be located closer to the conduction band than in ACN.

The double wave for the reduction of $Fe(CN)_6^{3-}$ in the phosphate-containing media can be attributed to the adsorption of phosphate on the TiO_2 surface and reduction of $Fe(CN)_6^{3-}$ at both phosphate-free and phosphate-covered sites. At the free sites the reduction occurs at similar potentials as found in other supporting electrolytes while at the covered sites the reduction takes place at more negative potentials. The double wave cannot be attributed to solution chemistry, since the behavior at the platinum electrode is the same as in other media, and no type of interaction between $Fe(CN)_6^{3-}$ and a phosphate is apparent. The effect of etchant noted on the double-wave behavior can probably be explained by changes in the extent of adsorption of phosphate with surface treatment with the acidic etchant (concentrated HNO_3) enhancing the adsorption of phosphate as compared to the basic one (5*M* NaOH). The scan rate dependence of the two peaks can be explained qualitatively by considering the two site reduction as analogous to a reversible preceding chemical reaction (CE). P_1 represents the reduction of $Fe(CN)_6^{3-}$ on free sites and P_2 represents the reduction on phosphate-covered ones. At slow scan rates reduction occurs mainly via the free sites, since $Fe(CN)_6^{3-}$ has time to diffuse to these locations; thus $P_1 > P_2$. At fast scan rates reduction occurs via both sites and the ratio of P_2 to P_1 increases (Fig. 4). Note, however, that the total peak height $(P_1 + P_2)$ is constant, proportional to the total electrode area at all scan rates.

Oxidations.—The oxidation of a number of couples in the dark at TiO_2 and other wide bandgap semiconductors (2, 18-20) has been explained by tunneling from filled levels in the electrolyte to empty levels at the same energy in the conduction band. Our results are in agreement with this explanation. The tunneling of electrons from solution species does not occur until the thickness of the space charge region, X, (which is a function of the surface field strength and N_D as shown in Eq. [6]) at the energy level of the reduced species becomes sufficiently thin (18, 21). The steep increase in the anodic current for water oxidation beyond a band bending equivalent to the bandgap of TiO_2 (3.2 eV) is a result of interband tunneling (22)

$$X = (2\epsilon_0\epsilon\Delta\phi/eN_D)^{1/2} \quad [6]$$

The anodic current in the blocking region upon the addition of a reducing agent increases as a result of a tunneling process at an energy where the distribution for reduced form in solution is sufficiently large and the extent of band bending is such that the space charge thickness is sufficiently small. The observed results agree very well with previous studies and with the relative energy positions of the occupied levels (Fig. 8) below the conduction band.

Significance of Effects of High Pressure on Kinetics of Electrode Reactions

I. Applications to Transition States in Hydrogen Evolution Reaction Mechanisms

B. E. Conway and J. C. Currie

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

The effects of high hydraulic pressures on electrode reactions are complex because of (*i*) the variation of reference electrode potentials with pressure so that only an apparent volume of activation can be directly measured experimentally, and (*ii*) dependence of coverage by adsorbed intermediates, such as H, with pressure. Methods of dealing with these problems are treated and the significance of measured apparent volumes of activation for the hydrogen evolution reaction is discussed in terms of the nature of the transition state for proton transfer and neutralization. The negative true volumes of activation found for the cathodic H_2 evolution reaction under some conditions are attributed to increasing electrostriction of the proton in the $H_9O_4^+$ complex as the transition state is formed. The significance of applications to ionic redox reactions is pointed out where pressure effects may be able to distinguish activation associated with long-range Born polarization from that associated more specifically with reorganization of the primary solvation shell or inner coordination sphere of ions.

Studies on the effects of pressure on condensed-phase chemical reactions (1), ionic conductance (2), and ionic equilibria (3) have produced useful new information on the volume changes which occur in these processes and in the activation process in their kinetics. The method is especially useful for studying reactions in which changes of charge, and corresponding changes of electrostriction, occur, *e.g.*, in reactions where polar transition states are developed or in ionic reactions involving a change of charge.

Processes involving elimination or diminution of charge of ions are usually associated with an increase of volume of the system due to decrease or removal of the electrostriction in the over-all reaction. Examples in homogeneous processes are redox reactions, ion-pair association, and the reverse of quaternization of tertiary amines (Menschutkin reaction) (1, 4, 5). In the latter case, it is known that the decrease of electrostriction in the over-all reaction is accompanied by a positive volume of activation, as may be expected. Similar considerations apply to electrochemical reactions where discharge or reduction of cations occurs, giving a decrease in electrostriction in the over-all reaction; *e.g.*, elsewhere (6) we have shown experimentally that the simple electrochemical reaction $H_3O^+ + Pt + e \rightarrow PtH_{ads} + H_2O$ is accompanied by a positive volume change of 7.4 ± 2 cm³ mole⁻¹.

In recent years, some interesting experimental studies have been reported on effects of pressure on the cathodic H_2 evolution reaction where the charge on two protons is lost. The results indicated negative volumes of activation which, in comparison with the behavior in the cases mentioned above, must be regarded as unexpected.

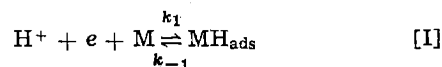
In the case of electrochemical reactions, a number of other factors, besides the true volume of activation, determine the measured values of $(\partial \ln i/\partial p)_{T,\eta}$ and complicate the interpretation of observed pressure effects in kinetics, *e.g.*, of the H_2 evolution reaction. It is, therefore, necessary first to establish their effects before considering the kinetic significance of negative volumes of activation.

It will be shown that, for several reasons, the pressure derivative of the log of exchange currents or currents at finite overpotential η does not give a true volume of activation for the electrode process which can be interpreted like volumes of activation for homogeneous, nonelectrochemical reactions (1). This complication gave rise to an erroneous [see Ref. (7) and the discussion in Ref. (8)] interpretation of the significance of the observed pressure effect in the kinetics of H_2 evolution in Ref. (9).

In this paper, we examine in some detail the significance of effects of high pressure on the kinetics of the hydrogen evolution reaction for several cases and attempt to use the conclusions to clarify conflicting deductions which have hitherto been made regarding the significance of pressure effects on this reaction. The behavior of other types of reaction, *e.g.*, ionic redox processes, is also mentioned (see also Part II which follows).

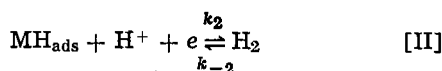
Pressure Effects Arising for Various Reaction Mechanisms of Cathodic H₂ Evolution

The reaction mechanisms considered (10) are



$$H^+ + e + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MH_{ads} \qquad [I]$$

followed by



$$MH_{ads} + H^+ + e \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} H_2 \quad [II]$$

or

$$2MH_{ads} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} H_2 \quad [III]$$

as the desorption pathways. The reaction equations [I], [II], and [III] as written above also serve to define the respective rate constants k_1, k_{-1}, k_2, k_{-2}, k_3, and k_{-3} which are required in the discussion which follows.

Case 1: The problem of pressure-dependence of the reference electrode potential.—The simplest case arises for a rate-controlling discharge step [I] for which

$$i_t = 2\mathbf{F}k_1C_{H^+}(1-\theta_H)\exp - \beta\phi\mathbf{F}/RT \quad [1]$$

where i_t is the total current density passing in the rate-determining step plus that in a subsequent desorption step and θ_H is the steady-state coverage by H. The term ϕ is the metal-solution potential drop. Here, the detailed form of ϕ as determined by double layer ion-distribution and specific adsorption effects will not be considered because the small pressure effects which may arise in the structure of the double layer will divert attention away from the main factors to be discussed here. ϕ can be expressed in the usual way in terms of the experimentally accessible overpotential, η defined by

$$\phi = \eta + \phi_e \quad [2]$$

where ϕ_e in the reversible potential for the over-all reaction

$$H_3O^+ + e \rightleftharpoons \tfrac{1}{2} H_2 + H_2O \quad [IV]$$

The pressure derivative of i_t in Eq. [1] is then

$$\left(\frac{\partial \ln i_t}{\partial p}\right)_{\eta,T} = \left(\frac{\partial \ln k_1}{\partial p}\right)_T - \frac{\beta\mathbf{F}}{RT}\left(\frac{\partial \phi_e}{\partial p}\right)_T \quad [3]$$

noting that $\theta_H \rightarrow 0$ when *I* is rate controlling.

Since $\phi_e = -\Delta G_e/z\mathbf{F}$ for the electrode process [IV] at equilibrium and $\partial(\Delta G_e/\partial p)_T = \Delta V_o$, the volume change per e for the over-all reaction [IV], and because k_1 can be written in terms of the exponential $e^{-\Delta G_1^{\ddagger}/RT}$ it follows that the experimentally measured $\left(\frac{\partial \ln i_t}{\partial p}\right)_{\eta,T}$ does not give the true volume of activation, $\Delta V_t^{\ddagger}$, but rather an apparent quantity, $\Delta V_a^{\ddagger}$, given [cf., (7, 8, 11)] by

$$\Delta V_a^{\ddagger} = \Delta V_{t,1}^{\ddagger} - \beta\Delta V_o \quad [4]$$

Thus, as first pointed out by Conway (7) [cf. Ref. (8, 12)], the true volume of activation, $\Delta V_{t,1}^{\ddagger}$ differs from the apparent value $\Delta V_a^{\ddagger}$ (determined by the pressure-dependence of rate of an electrochemical reaction at constant η) by β times the equilibrium volume change ΔV_o in the over-all reaction ([IV] in this case). Also the molar concentration of reactant ions, C_{H^+}, will increase with pressure, but this is a trivial effect that can easily be allowed for if the compressibility of the solution is known. At 10^4 bars in aqueous solution it gives a 20% effect on rates but appears to have been neglected in previous work.

It is seen that evaluation of $\Delta V_t^{\ddagger}$ for an electrode process involves problems similar to those arising (13, 14) in evaluation of the activation energy of electrode processes from determinations of the temperature dependence of currents at a given η as pointed out in Ref. (7).

The result (9), derived here for case 1, is generally applicable to any electron-transfer reaction (*e.g.*, the redox reaction treated in Part II) in which the kinetics are not influenced by a prior or subsequent step, or in which an intermediate, whose coverage could be pressure dependent, does not arise.

Case 2: The mechanisms [I] and [II] controlled by the rate constant of the desorption step [II].—Here, and for other cases to be treated below, θ_H can be appreciable so that pressure dependence of θ_H, as well as of the rate constant and ϕ_e, determines the value of $\Delta V_a^{\ddagger}$ measured experimentally. For interpretation of pressure effects, the relation between $\Delta V_a^{\ddagger}$ and $\Delta V_t^{\ddagger}$ for various conditions is required.

For mechanisms [I] and [II], the total current i_t is

$$i_t = i_1 - i_{-1} + i_2 = 2i_2 \text{ (in the steady state)} \quad [5]$$

Thus

$$i_t = 2\mathbf{F}k_2C_{H^+}\theta_H \exp(-\beta\phi\mathbf{F}/RT) \quad [6]$$

Then

$$\left(\frac{\partial \ln i_t}{\partial p}\right)_{\eta,T} = \left(\frac{\partial \ln k_2}{\partial p}\right)_T + \left(\frac{\partial \ln \theta_H}{\partial p}\right)_{\eta,T} - \frac{\beta\mathbf{F}}{RT}\left(\frac{\partial \phi_e}{\partial p}\right)_T \quad [7]$$

at constant η, using Eq. [2] to introduce ϕ_e.

Introducing the volume terms that arise from the pressure dependencies of the k_2 and ϕ_e terms, as in Eq. [4], gives the expression for $\Delta V_a^{\ddagger}$

$$\left(\frac{\partial \ln i_t}{\partial p}\right)_{\eta,T} = -\frac{\Delta V_{a,2}^{\ddagger}}{RT} = -\frac{\Delta V_{t,2}^{\ddagger}}{RT} + \left(\frac{\partial \ln \theta_H}{\partial p}\right)_{\eta,T} + \frac{\beta\Delta V_o}{RT} \quad [8]$$

where $\Delta V_{t,2}^{\ddagger}$ is the true activation volume of step [II] and ΔV_o is as in Eq. [4].

The effect of pressure on θ_H at a given η may be derived from the condition that $i_1 \doteq i_{-1}$ when [II] is rate controlling, *i.e.*

$$k_1C_{H^+}(1-\theta_H)\exp(-\beta\phi\mathbf{F}/RT) = k_{-1}\theta_H\exp(1-\beta)\phi\mathbf{F}/RT \quad [9]$$

so that in the usual way (15)

$$\theta_H = \frac{K_1C_{H^+}\exp(-\phi\mathbf{F}/RT)}{1 + K_1C_{H^+}\exp(-\phi\mathbf{F}/RT)} \quad [10]$$

where $K_1 = k_1/k_{-1}$ is the quasi-equilibrium constant for step [I]. Then the pressure derivative of θ_H can be written as

$$\frac{1}{\theta_H}\left(\frac{\partial \theta_H}{\partial p}\right)_{\eta,T} = \left(\frac{\partial \ln \theta_H}{\partial p}\right)_{\eta,T} = \left(\frac{\partial \ln K_1}{\partial p}\right)_T - \frac{\mathbf{F}}{RT}\left(\frac{\partial \phi_e}{\partial p}\right)_T - \frac{1}{1 + K_1C_{H^+}\exp(-\phi\mathbf{F}/RT)} \left[C_{H^+}K_1\left(-\frac{\mathbf{F}}{RT}\right)\exp(-\phi\mathbf{F}/RT)\left(\frac{\partial \phi_e}{\partial p}\right)_T + C_{H^+}\exp(-\phi\mathbf{F}/RT)(\partial K_1/\partial p)_T \right] \quad [11]$$

so that

$$\left(\frac{\partial \ln \theta_H}{\partial p}\right)_{\eta,T} = -\frac{\Delta V_1}{RT} + \frac{\Delta V_o}{RT} - \frac{\theta_H}{RT}(\Delta V_o - \Delta V_1) \quad [12]$$

With further rearrangements of Eq. [12]

$$\left(\frac{\partial \ln \theta_H}{\partial p}\right)_{\eta,T} = (1-\theta_H)(\Delta V_o - \Delta V_1)/RT \quad [13]$$

where ΔV_1 is the volume change in step [I] and $\Delta V_o - \Delta V_1$ is the volume of adsorption of H from ½ H_2 which we have recently determined experimentally at Pt (6) as 7.4 ± 2 cm^3 mole^{-1}.

Then from Eq. [8]

$$\Delta V_{t,2}^{\ddagger} = \Delta V_{a,2}^{\ddagger} + \Delta V_o(1 + \beta - \theta_H)\Delta V_1 \quad [14]$$

Under (experimentally inaccessible) conditions of constant ϕ, the true volume of activation for the over-all processes [I] and [II], with [II] rate controlling, would therefore be[1]

$$\Delta V_{t,2}^{\ddagger} = \Delta V_2^{\ddagger} + (1 - \theta_H)\Delta V_1 \quad [15]$$

or with Eq.]14]

$$\Delta V_{t,2}^{\ddagger} = \Delta V_{a,2}^{\ddagger} + \Delta V_o(1 + \beta - \theta_H) \quad [16]$$

evaluated at a constant η for a corresponding value of θ_H at the given η. It is seen from Eq. [16] that the $\Delta V_t^{\ddagger}$ differs from the measured $\Delta V_a^{\ddagger}$ in this case by one term derived from $(\partial\theta_H/\partial p)_\eta$ and another from $(\partial\phi_e/\partial p)_T$. If $\Delta V_{t,2}^{\ddagger}$ is desired for step [II] itself, information on θ_H and the volume change ΔV_1 in step [I] (6) is evidently required.

Two limiting conditions can usefully be considered: (*i*) If $k_1 >> k_{-1}$, $k_1 >> k_2$, then $\theta_H \rightarrow 1$ so that θ_H is pressure independent. Hence

$$\Delta V_{a,2}^{\ddagger} = \Delta V_{t,2}^{\ddagger} - \beta\Delta V_o \quad [17]$$

(*ii*) $k_{-1} >> k_1$ and $k_{-1} >> k_2$ so that $\theta_H \rightarrow 0$ but is $f(p)$, then

$$\Delta V_{a,2}^{\ddagger} = \Delta V_{t,2}^{\ddagger} + \Delta V_1 - (1 + \beta)\Delta V_o \quad [18]$$

Cases for other mechanisms or conditions follow the same kind of treatment in terms of $(\partial\phi_e/\partial p)_T$ and $(\partial\theta_H/\partial p)_{\eta,T}$ and the results are therefore presented only briefly, as follows:

Case 3: Mechanisms [I] and [II] when [I] is rate controlling and [II] is in quasi-equilibrium as a rapid desorption step.—For some metals, the discharge step [I] can be rate controlling but a coverage by H greater than "zero" can be established through step [II] in quasi-equilibrium. For this case

$$i_t = 2\mathbf{F}k_1C_{H^+}(1 - \theta_H)\exp(-\beta\phi\mathbf{F}/RT) \quad [19]$$

with θ_H determined mainly by step [II]. The steady-state condition gives then

$$1 - \theta_H = \frac{k_2C_{H^+}}{k_1C_{H^+} + k_2C_{H^+} + k_{-2}p_{H_2}\exp(\phi\mathbf{F}/RT)} \quad [20]$$

Taking logarithms and with further rearrangements, the pressure derivative of $1 - \theta_H$ can be obtained, so that from Eq. [19], $(\partial \ln i_t/\partial p)_{\eta,T}$ gives

$$\Delta V_{a,1}^{\ddagger} = \Delta V_1^{\ddagger} - \Delta V_o(1 + \beta) + \Delta V_2(1 - \theta_H)$$
$$\left[\Delta V_o - \Delta V_2 + \frac{k_1k_{-2}p_{H_2}}{k_2^2}(\Delta V_o - \Delta V_1^{\ddagger} + \Delta V_2^{\ddagger})\right] \quad [21]$$

The over-all true volume of activation $\Delta V_{t,1}^{\ddagger}$ for this case is

$$\Delta V_{t,1}^{\ddagger} = \Delta V_1^{\ddagger} + \Delta V_2\theta_H + K'\Delta V_2^{\ddagger}$$
$$- K'\Delta V_1^{\ddagger} - K'\theta_H\Delta V_2^{\ddagger} + K'\theta_H\Delta V_1^{\ddagger} \quad [22]$$

where $K' = (k_1k_{-2}p_{H_2})/(k_2^2)$. Then Eq. [22] can be expressed in terms of the experimental volume of activation, $\Delta V_{a,1}^{\ddagger}$, and ΔV_o by

$$\Delta V_{t,1}^{\ddagger} = \Delta V_{a,1}^{\ddagger} + \Delta V_o(1 + \beta)$$
$$- \Delta V_o(1 - \theta_H) - \Delta V_oK'(1 - \theta_H) \quad [23]$$

Again two limiting conditions may usefully be examined:

(*i*) If $k_1 << k_2 >> k_{-2}p_{H_2}$, then $(k_1k_{-2}p_{H_2})/(k_2^2) \rightarrow 0$ and $\theta_H \rightarrow 0$; then Eq. [21] can be written (cf. Eq. [4]) as

$$\Delta V_{a,1}^{\ddagger} = \Delta V_1^{\ddagger} - \beta\Delta V_o \quad [24]$$

which is, as expected, simply the result for step [I] without any following equilibrium step [II].

(*ii*) If $k_1 << k_{-2} >> k_2$, then $\theta_H \rightarrow 1$ and Eq. [23] reduces to

$$\Delta V_{a,1}^{\ddagger} = \Delta V_1^{\ddagger} - \Delta V_o(1 + \beta) + \Delta V_2 \quad [25]$$

Therefore the over-all true volume of activation can be written as

$$\Delta V_{t,1}^{\ddagger} = \Delta V_1^{\ddagger} + \Delta V_2 = \Delta V_a^{\ddagger} + (1 + \beta)\Delta V_o \quad [26]$$

It is of interest that Eq. [16] becomes identical with Eq. [26] when $\theta_H = 0$ in [16] and 1 in Eq. [23], although of course Eq. [16] applies when step [II] is rate controlling while Eq. [26] applies when step [I] is the limiting process.

Case 4: Recombination step [III] is rate determining.—In this case, step [I] (at quasi-equilibrium) is followed by [III]. This case arises for H_2 evolution at certain noble metals and for Cl_2 evolution on oxidized Pt and Ru surfaces. The total current i_t is given by

$$i_t = 2(i_1 - i_{-1}) = 2\mathbf{F}k_3\theta_H^2 \quad [27]$$

Following the procedures used in the previous cases, the pressure coefficient $(\partial \ln i_t/\partial p)_{\eta T}$, gives

$$\Delta V_{a,3}^{\ddagger} = \Delta V_3^{\ddagger} - 2(1 - \theta_H)(\Delta V_o - \Delta V_1) \quad [28]$$

and the over-all true volume of activation, $\Delta V_t^{\ddagger}$, is

$$\Delta V_{t,3}^{\ddagger} = \Delta V_3^{\ddagger} + 2\Delta V_1[1 - \theta_H]$$
$$= \Delta V_a^{\ddagger} + 2(1 - \theta_H)\Delta V_o \quad [29]$$

The limiting conditions for case 4, are as follows:
(*i*) $K_1C_{H^+}\exp(-\phi\mathbf{F}/RT) >> 1$ in Eq. [10], so that $\theta_H \rightarrow 1$, *i.e.*, when the $i \sim \phi$ relation corresponds to a limiting current, as at high η. Then

$$\Delta V_{t,3}^{\ddagger} = \Delta V_{a,3}^{\ddagger} = \Delta V_3^{\ddagger} \quad [30]$$

(*ii*) $K_1C_{H^+}\exp(-\phi\mathbf{F}/RT) << 1$ in Eq. [10], so that $\theta_H << 1$ and is potential dependent. This corresponds to the $i \sim \phi$ relation having a Tafel slope of $RT/2\mathbf{F}$. Then.

$$\Delta V_{t,3}^{\ddagger} = \Delta V_{a,3}^{\ddagger} + 2\Delta V_o \text{ where } \Delta V_{t,3}^{\ddagger} \equiv \Delta V_3^{\ddagger} \quad [31]$$

Case 5: Coupled mechanism [I] and [II] at high η.—At sufficiently high η, the reverse reaction currents for these steps are negligible, so that the total current is given by

$$i_t = i_1 + i_2 = 2\mathbf{F}k_2C_{H^+}\theta_H\exp(-\beta\phi\mathbf{F}/RT) \quad [32]$$

θ_H is now determined by a steady-state condition $i_1 = i_2$ rather than by Eq. [10], so that $\theta_H = k_1/(k_1 + k_2)$. Then proceeding as in previous cases to obtain $(\partial \ln \theta_H/\partial p)_{\eta,T}$ and deriving $(\partial \ln i_t/\partial p)_{\eta,T}$, we find

$$\Delta V_a^{\ddagger} = \theta_H\Delta V_2^{\ddagger} + (1 - \theta_H)\Delta V_1^{\ddagger} - \beta\Delta V_o \quad [33]$$

The over-all true volume of activation is represented by

$$\Delta V_t^{\ddagger} = \theta_H\Delta V_2^{\ddagger} + (1 - \theta_H)\Delta V_1^{\ddagger} = \Delta V_a^{\ddagger} + \beta\Delta V_o \quad [34]$$

[1] It is convenient to distinguish a quantity, $\Delta V_t^{\ddagger}$, as the over-all true volume of activation from the true $\Delta V_n^{\ddagger}$ for the rate-determining step n, derived from the pressure derivative of the log of the rate constant. ΔV_t differs from $\Delta V_n^{\ddagger}$ when pressure-dependent coverage terms are significant. Both ΔV_t and $\Delta V_n^{\ddagger}$ differ from $\Delta V_a^{\ddagger}$ due to the pressure dependence of ϕ_e. In complex cases, such as that here where θ_H can be $f(p)$, $\Delta V_t^{\ddagger}$ can be expressed either in terms of the true $\Delta V^{\ddagger}$ for the rate-determining step or in terms of $\Delta V_a^{\ddagger}$ with $\Delta V_o^{\ddagger}$ and θ_H.

Table I. Relation between true ($\Delta V_t^{\ddagger}$) and apparent ($\Delta V_a^{\ddagger}$) volumes of activation for various mechanisms or conditions in the hydrogen evolution reaction

Case	Rate-determining step or condition	$\Delta V^{\ddagger}$ relation	Observed or derived values of $\Delta V^{\ddagger}$ (cm³ mole⁻¹) for constant η
1	H_3O^+ discharge step [I]; $\theta_H << 1$	$\Delta V_1^{\ddagger} = +\Delta V_a^{\ddagger} + \beta\Delta V_o$*	$\Delta V_a^{\ddagger} \simeq -3.4$ (Hg) $\Delta V_t^{\ddagger} \simeq +5.6$ (Hg)
2	Desorption of H in step [II]; $\theta_H > 0$ and potential and pressure dependent	$\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} + (1 + \beta - \theta_H)\,\Delta V_o$ $= \Delta V_2^{\ddagger} + (1 - \theta_H)\,\Delta V_t$	
Limiting cases	$\theta_H \to 1$	$\Delta V_a^{\ddagger} = \Delta V_2^{\ddagger} - \beta\Delta V_o$	$\Delta V_a^{\ddagger} \simeq -12.5$ (Cu, Ag, Au)
	$\theta_H << 1$	$\Delta V_a^{\ddagger} = \Delta V_1 - (1 + \beta)\,\Delta V_o + \Delta V_2^{\ddagger}$	$\Delta V_t^{\ddagger} \simeq +2$ (Cu, Ag, Au) for $\phi_H << 1$
3	Step [I], with θ_H determined by quasi-equilibrium in step [II]	$\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} + [1 + \beta - (1 - \theta_H)]\,\Delta V_o - K'(1 - \theta_H)\,\Delta V_o$	
Limiting cases	$\theta_H \to 1$	$\Delta V_a^{\ddagger} = \Delta V_1^{\ddagger} - (1 + \beta)\,\Delta V_o + \Delta V_2$ or $\Delta V_t^{\ddagger} = \Delta V_1^{\ddagger} + \Delta V_2 = \Delta V_a^{\ddagger} + (1 + \beta)\,\Delta V_o$	
	$\theta_H << 1$	$\Delta V_a^{\ddagger} = \Delta V_1^{\ddagger} - \beta\Delta V_o$	$\Delta V_a^{\ddagger} \simeq -12.5$ (Cu, Ag, Au) $\Delta V_t^{\ddagger} \simeq \Delta V_1^{\ddagger} = -7.6$ (Cu, Ag, Au)
4	Recombination step [III]	$\Delta V_t^{\ddagger} = \Delta V_3^{\ddagger} + 2\Delta V_1\,(1 - \theta_H)$ $= \Delta V_a^{\ddagger} + 2\,(1 - \theta_H)\,\Delta V_o$ or $\Delta V_a^{\ddagger} = \Delta V_3^{\ddagger} - 2\,(1 - \theta_H)\,(\Delta V_o - \Delta V_1)$	
Limiting cases	$\theta_H \to 1$	$\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} = \Delta V_3^{\ddagger}$	
	$\theta_H << 1$	$\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} + 2\Delta V_o\ (\equiv \Delta V_3^{\ddagger})$	
5	Coupled [I] and [II]; high η	$\Delta V_t^{\ddagger} = \theta_H\Delta V_2^{\ddagger} + (1 - \theta_H)\,\Delta V_1^{\ddagger}$ $= \Delta V_a^{\ddagger} + \beta\Delta V_o$	$\Delta V_a^{\ddagger} \simeq -12.5$ (Cu, Ag, Au) $\Delta V_t^{\ddagger} \simeq -7.6$ (Cu, Ag, Au)
Limiting cases	$\theta_H \to 1$	$\Delta V_a^{\ddagger} = \Delta V_2^{\ddagger} - \beta\Delta V_o$	
	$\theta_H << 1$	$\Delta V_a^{\ddagger} = \Delta V_1^{\ddagger} - \beta\Delta V_o$	

* This type of relation also applies to any simple discharge step, *e.g.*, as in an ionic redox reaction (see Part II).

The limiting steady-state cases are:

(*i*) If $k_2 >> k_1$, $\theta_H \to 0$; then

$$\Delta V_a^{\ddagger} = \Delta V_1^{\ddagger} - \beta\Delta V_o \quad [35]$$

which is the same result as that derived for the condition that step [I] is rate determining (*i.e.*, case 1); and

(*ii*) If $k_1 >> k_2$, $\theta_H \to 1$; then

$$\Delta V_a^{\ddagger} = \Delta V_2^{\ddagger} - \beta\Delta V_o \quad [36]$$

A summary of the results obtained for the various cases is given in Table I.

Discussion of Previously Published Experimental Results

The proton discharge reaction at Hg.—It is generally agreed that the rate-determining step in H_2 evolution at Hg is step [I] with desorption by [II]. Hills and Kinnibrugh's work (9) on this reaction gave data[2] for $(\partial \ln i/\partial p)_{T,\phi\ \text{calomel}}$ which they assumed corresponded to the true volume of activation; a negative value of -3.4 cm³ mole⁻¹ was found. As shown in case 1, this value is, in fact, the apparent volume of activation [cf. Ref. (7, 8)], *i.e.*, $\Delta V_{t,1}^{\ddagger} = \Delta V_{a,1}^{\ddagger} + \beta\Delta V_o$, where $\Delta V_a^{\ddagger} = -3.4$ cm³ mole⁻¹, $\Delta V_o = 18$ cm³ mole⁻¹, and $\beta = 0.5$. Hence the true activation volume is $-3.40 + 0.5 \times 18$, *i.e.*, a positive value of 5.6 cm³ mole⁻¹. $\Delta V_a^{\ddagger}$ was obtained from $(\partial \ln i/\partial p)_{T,\eta}$ measured at $p > 250$ bars. It appears that a steeper slope would have been measured if $(\partial \ln i/\partial p)_{T,\eta}$ had been derived limitingly at $p = 1$ bar (data at atmospheric pressure were not given). $\Delta V_{t,1}^{\ddagger}$ could then be appreciably smaller than 5.6 cm³ mole⁻¹.

[2] Hills and Kinnibrugh's results were obtained from measurements at "constant electrode potential" *vs.* a calomel reference. They corrected their results to constant overpotential but did not take into account the further correction to constant "metal-solution p.d." which is also required (see Eq. [3] and [4]).

The H_2-evolution reaction at Cu, Ag, and Au.—Heusler and Gaiser (16) measured the pressure-dependence of H_2 evolution currents at Cu, Ag, and Au. Their derived volumes were based on $(\partial \ln i/\partial p)_{\eta,T}$ evaluated at $p > 500$ bars where the derivative is independent of p. Under these conditions, ΔV_o for the over-all reaction [IV] is 8.7 cm³ mole⁻¹ based on Ref. (13); $\overline{V}_{H_2} = 15.0$ cm³ mole⁻¹ at these pressures and including $V_e = 3$ cm³ Faraday⁻¹; $\overline{V}_{H^{+o}}$ was taken (16) as -5.2 cm³ mole⁻¹. The measured $\Delta V_a^{\ddagger}$ is -12.5 cm³ mole⁻¹. Therefore the over-all $\Delta V_t^{\ddagger} = 12.5 + 1/2\,(9.7) = -7.6$ cm³ mole⁻¹.

In Heusler and Gaiser's treatment (16) of their results, allowance was correctly made for $(\partial\phi_e/\partial p)_T$ and the back-reaction of step [I] was neglected (case 5 above). For these conditions, the true volume of activation is given by Eq. [4]

$$\Delta V_t^{\ddagger} = \theta_H\Delta V_2^{\ddagger} + (1 - \theta_H)\,\Delta V_1^{\ddagger} = \Delta V_a^{\ddagger} + \beta\Delta V_o$$

There is no evidence for any substantial coverage by chemisorbed H at Cu, Ag, or Au at normal overpotentials nor is underpotential deposition observed. Thus, $\theta_H \simeq 0$ so that $\Delta V_t^{\ddagger} \doteq \Delta V_1^{\ddagger} = -7.6$ cm³ mole⁻¹. This negative value is surprising since it might be expected that in the electrochemical reaction, when the proton charge is neutralized, a positive volume of activation would arise as for the corrected results at Hg (8).

However, if case 2 (*i.e.*, with quasi-equilibrium in step I) is examined, then from Eq. [16] with $\theta_H \simeq 0$, the over-all $\Delta V_t^{\ddagger}$ is given by

$$\Delta V_t^{\ddagger} = -12.5 + 3/2\,(9.7) = +2 \text{ cm}^3 \text{ mole}^{-1}$$

Then the volume of activation for step [II], $\Delta V_2^{\ddagger} = 2 - \Delta V_1$ from Eq. [15], where ΔV_1 is the quasi-equilibrium volume change in step [I]. If ΔV_1 is positive and greater than 2 for this case, then $\Delta V_2^{\ddagger}$, the true volume of activation for step [II] will have again a negative value. Experimentally (6), at Pt, $\Delta V_1 = 7.4 \pm 2$ cm^3 mole^{-1}.

If case 3 applied, a complicated expression is generated if $\theta_H > 0$. Thus, combining Eq. [21] and [22]

$$\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} + (1 + \beta)\,\Delta V_o - (1 - \theta_H)\Delta V_o - K'(1 - \theta_H)V_o \quad [37]$$

However, if $\theta_H \rightarrow 0$, case 1 would be recovered giving $\Delta V_t^{\ddagger} = \Delta V_1^{\ddagger} = -7.6$ cm^3 mole^{-1}.

It is useful to establish the sign of $\Delta V_t^{\ddagger}$ for an appreciable value of θ_H, say 0.5. Then, from Eq. [37], taking $K' = 0$, $\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} + \Delta V_o = 12.6 + 9.7 = -3$ cm^3 mole^{-1}. Also with $\beta = 0.5$ and $\theta_H = 0.5$, $\Delta V_t^{\ddagger} = \Delta V_1^{\ddagger} + \Delta V_2/2$. Hence, $\Delta V_1^{\ddagger} = -3 - \Delta V_2/2$. But the quantity ΔV_2, which is the equilibrium volume change in the process $MH_{ads} + H^+ + e\ (M) \rightleftharpoons H_2$ (step [II]), is expected [cf. (6)] to be positive. Hence, $\Delta V_1^{\ddagger}$ will still be negative for intermediate coverages of the metal.

The above discussion shows, surprisingly, that negative values of the true volume of activation of the HER arise at certain metals, after allowance for the complicating factors is made.

Significance of negative or small positive values of $\Delta V_t^{\ddagger}$.—On the basis of their original uncorrected results, it was concluded by Hills and Kinnibrugh (9) and by Hills (12) that the observed negative volume of activation (really $\Delta V_{a,1}^{\ddagger}$) indicated electrochemical formation of the hydrated electron as the primary step in the HER at Hg. Various objections to this mechanism, apart from those connected with the difference between $\Delta V_{t,1}^{\ddagger}$ and $\Delta V_{a,1}^{\ddagger}$, were, however, pointed out by Conway (7) (15) and by Bewick and Conway (17).

It is very difficult to see how a negative value of the true volume of activation can arise in the discharge of a cation, here H_3O^+. We show in Part II that the true volume of activation for an ionic redox reaction $Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-} + e$ does have the expected sign (positive for the direction written above). Hence, it may be suggested that the anomalous behavior of H_3O^+ arises from the special nature of the hydrated proton in solution. Thus, good evidence exists (18, 19) that H^+_{aq} exists as the $H_9O_4^+$ ion in which proton charge is decentralized by joint proton tunneling between $4H_2O$ molecules + H^+ and delocalized at any momentarily existing H_3O^+ center. The transition state for classical proton transfer must presumably arise by a reorganization (23) of the $H_9O_4^+$ aqueous complex. If the activation process involves localization of the proton on one of the H_2O molecules in $H_9O_4^+$ in the double layer to produce an excited state to which electron transfer occurs by the usual radiationless transfer (Fig. 1), then it can be seen that a negative volume of activation could arise since more electrostriction could be developed temporarily in the double layer at the localized proton state than in the initial $H_9O_4^+$ ion in which proton charge-density is diffused. The relaxation time of the water structure H-bonding in relation to the lifetime of the proton being discharged will determine the electrostriction in the transition state. That the proton in water has relatively an unusually large partial molal volume is indicated when the volume of ionization of water is compared with that for NH_3 aqueous in the processes

$$H_2O + H_2O \rightarrow \text{“}H_3O^+\text{”} + OH^-$$

$$\Delta V^o = -21.8;\ -22.1\ \text{cm}^3\ \text{mole}^{-1}$$

and

$$H_2O + NH_3 \rightarrow NH_4^+ + OH^-$$

$$\Delta V^o = -28.9;\ -28.5\ \text{cm}^3\ \text{mole}^{-1}$$

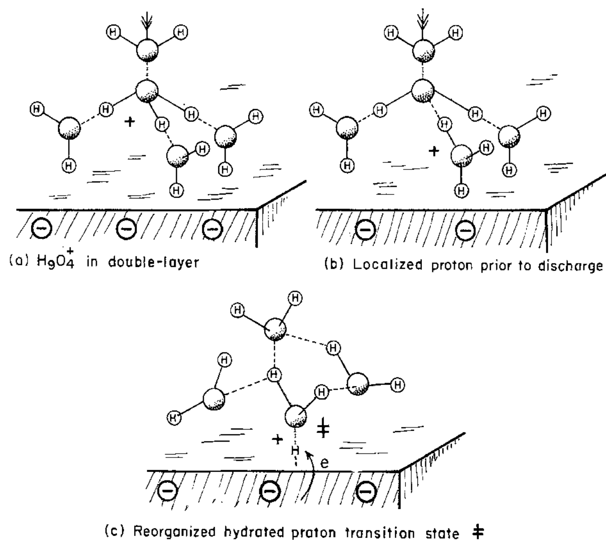


Fig. 1. Configurations of the hydrated proton, as $H_9O_4^+$ + $1H_2O$ in the double layer in the course of the activation process in electrochemical proton discharge (schematic).

in which NH_3 is isoelectronic with H_2O and NH_4^+ with “H_3O^+.” (The first values of ΔV^o are derived from pressure effects on the ionization constant and the second from volumetric measurements; data are from Ref. (20). Assuming that the difference of intrinsic volume of NH_4^+ and “H_3O^+” would be close to the corresponding difference between NH_3 and H_2O, due to the extra H atom, it seems reasonable to conclude that the electrostriction at “H_3O^+” is *ca.* 6.5 – 7 cm^3 mole^{-1} smaller than at the isoelectronic NH_4^+ ion. This is consistent with diffusion of the proton charge in $H_9O_4^+$ which cannot occur in the hydrated NH_4^+ ion. The difference of 6.5-7 cm^3 mole^{-1} is of the correct magnitude to account for the negative $\Delta V_t^{\ddagger}$ values.

While the volume of activation for H_2 evolution from H_{aq}^+ evidently exhibits unusual behavior, that for ionic redox reactions should help to elucidate the nature of the activation process involving solvent reorganization in such cases. In particular, the question arises whether short-range reorganization of the hydration shell is involved or whether less specific fluctuations of the long-range dielectric polarization are mainly operative. These questions will be dealt with in Part II on the $Fe(CN)_6^{3-}$ redox reaction.

Acknowledgments

Grateful acknowledgment is made to the National Research Council of Canada for support of this work and to the Defence Research Board for support in its earlier stages.

Significance of Effects of High Pressure on Kinetics of Electrode Reactions

II. The Nature of Solvent Reorganization in the Activation Process of an Electrochemical Redox Reaction

B. E. Conway and J. C. Currie

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

New information on the nature of the solvent reorganization process involved in formation of the transition state in an electrochemical redox reaction [the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple] is given by studies of the kinetics of this process at high pressures in aqueous solutions at Au. The apparent activation volume is evaluated together with the true volumes of activation for the forward and reverse directions of the redox reaction. By means of calculations of the electrostriction associated with the long-range dielectric polarization in comparison with that associated with ion-solvent interaction in the primary hydration shell, it is shown that the activation process must be mainly (75%) due to short-range solvent reorganization in the primary shell. This is contrary to what has often been assumed in the interpretation of the energy of activation of ionic redox reactions. The experiments also allow some deduction to be made about the "symmetry" of the transition states in the electrochemical reaction in comparison with that in the corresponding homogeneous reaction, in so far as solvent reorganization is concerned.

In Part I (1), some of the general problems of interpretation of effects of pressure on the kinetics of electrode reactions were discussed and exemplified with respect to the hydrogen evolution reaction. It was shown that investigations of pressure effects on the latter reaction are complicated by (*i*) the mechanism having more than one step; (*ii*) the consequent adsorption of an intermediate H; and (*iii*) the unusual properties of the hydrated proton, referred to in Part I, as well as the general point that reference electrode potentials required in all measurements are themselves pressure dependent (2).

It is therefore desirable to examine pressure effects on a simpler reaction where only an electron-transfer step is involved, *e.g.*, as in a redox reaction. Hitherto, studies of electrochemical redox reactions have been concerned with (*i*) evaluation of absolute values of standard electrochemical rate constants (3, 4); (*ii*) their comparison with values for corresponding homogeneous solution reactions (5); and (*iii*) the role of the substrate metal (6) (its work function and the state of its surface) in determining the rate constant.

In the present paper, pressure effects on the $Fe(CN)_6^{3-} + e \rightleftharpoons Fe(CN)_6^{4-}$ reaction at a gold electrode are reported. This type of reaction is of special interest with regard to current theories of electron transfer (7-14) where the reorganization (10) of the initial state is involved in the activation process for electron transfer. One of the questions involved is the extent to which the activation process involves long-range solvent polarization fluctuations (10, 11) around the initial state ion, or more specific short-range changes of hydration shell configuration or inner coordination shell reorganization (7, 8, 12). It may be expected that study of pressure effects on the kinetics of a simple electrochemical redox reaction may provide a means of distinguishing these effects, *e.g.*, in terms of the anticipated changes of electrostriction involved in the reorganization process. Examination of the effect of pressure on the kinetics of a redox reaction thus provides a further dimension from which new data of a useful kind can be derived. Previous high pressure work on a redox reaction has been restricted to a report of values of $\Delta V_t^{\ddagger}$ for the ferro-ferricyanide reaction in a review (15) but no experimental details or commentary on the data have been published. The results quoted are inconsistent with the known electrostrictions at the two ions in this reaction.

A second point, of general interest, is whether a chemically symmetrical reaction such as the ferro-ferricyanide one behaves in a kinetically symmetrical

way (symmetry factor $\beta = 0.5$) when established at an electrode surface.

Experimental

General.—The kinetics of the $Fe(CN)_6^{3-} + e \rightleftharpoons Fe(CN)_6^{4-}$ reaction were studied at a gold electrode. The latter was chosen as the substrate metal because it is known to have a wide range of potentials over which neither H nor O species is chemisorbed (under-potentially deposited). The exchange rate constants for the ferri-ferrocyanide reaction are relatively large (4), so that a nonsteady-state method is required for their proper evaluation. In the present work, the kinetics of the reaction were studied by a-c impedance measurements based on well-known principles (16) which lead to evaluation of the reaction resistance and hence the exchange current density i_o. From this the standard rate constant can be obtained knowing the concentrations of the reactant species.

Method.—The faradaic impedance was measured by means of phase-sensitive a-c voltammetry at phase angles $\phi = 0$ and $\phi = 90°$ which directly give the real and imaginary components of the impedance, that is, the ohmic and capacitative contributions. This method has been referred to in previous literature (17) and provides a convenient way of performing a-c impedance experiments. It is quite precise providing that one component of the impedance is not very much smaller than the other.

Electrical measurements.—The present system employed a Wenking potentiostat and a Servomex function generator which provided a controlled repetitive linear sweep of potential. A small alternating voltage signal, modulating the sweep, was provided from an auxiliary oscillator at various frequencies and mixed with a linear sweep in an operational amplifier. A PAR phase-sensitive amplifier was employed to effect resolution of the ohmic and capacitative components of the impedance. The satisfactory operation of this system was first established by test measurements on dummy series and parallel *C-R* circuits (the phase-sensitive amplifier measures *C* and *R* components in terms of admitted a-c currents in a "parallel" combination). The range of frequencies employed in the measurements was from 25 to 250 Hz. The a-c "polarograms" and the d-c current-potential profiles generated by the linear sweeps were recorded simultaneously.

Cell for high-pressure measurements.—A cell suitable for use in a high pressure environment (Fig. 1) under oil was constructed from glass and shrinkable Teflon tubing. The latter provides a flexible section of the cell that can adjust to the electrolyte volume changes that arise at elevated pressures. This system is preferable to the use of a mercury piston which gives rise to contamination in electrochemical experiments on metals other than mercury itself. The cell is provided with a large gauze counterelectrode for the a-c measurements and the gold test electrode is sealed into the glass head. After filling the cell with deoxygenated solution in a N_2 glove bag, it is closed with a screw cap and set up in the high pressure bomb under the hydraulic fluid.

Complete absence of contamination and of leaks was indicated by demonstrating that the cyclic-voltammetry current-potential profile for a Pt electrode in the high pressure cell could be maintained for many hours with as perfect a form as that previously reported (18) for ultraclean solutions at ambient pressures in a regular glass cell. "Clean electrochemistry" could therefore be satisfactorily performed in the system described over many hours and at elevated pressures.

High pressure system.—The small electrochemical cell, fabricated from glass and shrinkable Teflon, was set up in a 10 in. diam (OD) thermostated high pressure bomb containing hydraulic oil. Electrical connections to exterior instruments are provided through a special head. A manual pumping system enabled pressures up to 3000 bars to be attained. They were recorded on a Heise gauge calibrated at the National Research Council Laboratories. Measurements were made at several increasing and decreasing series of pressures. At each pressure, at least 1 hr was allowed for thermal equilibium to be attained since compression or decompression of the hydraulic fluid causes substantial changes of temperature.

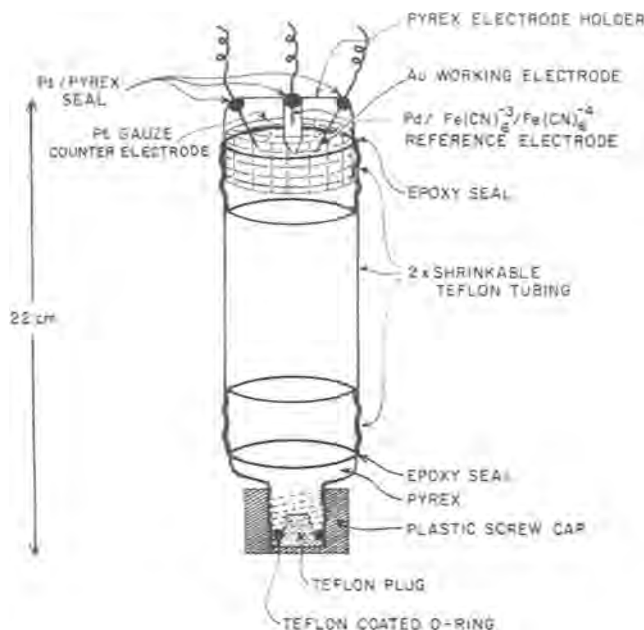

Fig. 1. Electrochemical cell with flexible shrinkable Teflon section for high pressure work.

Solutions.—All measurements were made in a supporting electrolyte of 0.5M K_2SO_4 at 25°C. The ambient-pressure concentrations of $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ were 5×10^{-3}M. Some experiments were carried out with one only of these components at this concentration and other experiments with both components at this concentration. As noted elsewhere in this paper, corrections to these concentrations, which are required as the pressure is increased, were made in all experiments although in other high pressure work this point has often been ignored.

Results

The impedance behavior.—Analysis of the a-c impedance was made in the usual way (19) by means of Randles plots (16) in which the "series" faradaic resistance $R_{F,s}$ and the diffusional capacitance $(1/\omega C_{F,s})$ contributions are plotted as a function of $\omega^{-1/2}$ after separation of the double layer capacity and solution resistance impedance components determined in experiments in the absence of the redox couple. The double layer capacity was also determined from the results at $\phi = 90°$ at potentials well away from the half-wave potentials, *i.e.*, where the Warburg diffusional capacitance is negligible. The faradaic reaction resistance, R_r, was then evaluated by extrapolation of the Randles plots to infinite frequency, as shown in Fig. 2, giving

$$R_r = RT/z\mathbf{F}i_o \quad [1]$$

where the exchange current i_o is related to the standard electrochemical rate constant $\overline{k}_o$ by

$$i_o = z\mathbf{F}\overline{k}_oCA \quad [2]$$

where A is the electrode area, z is the number of

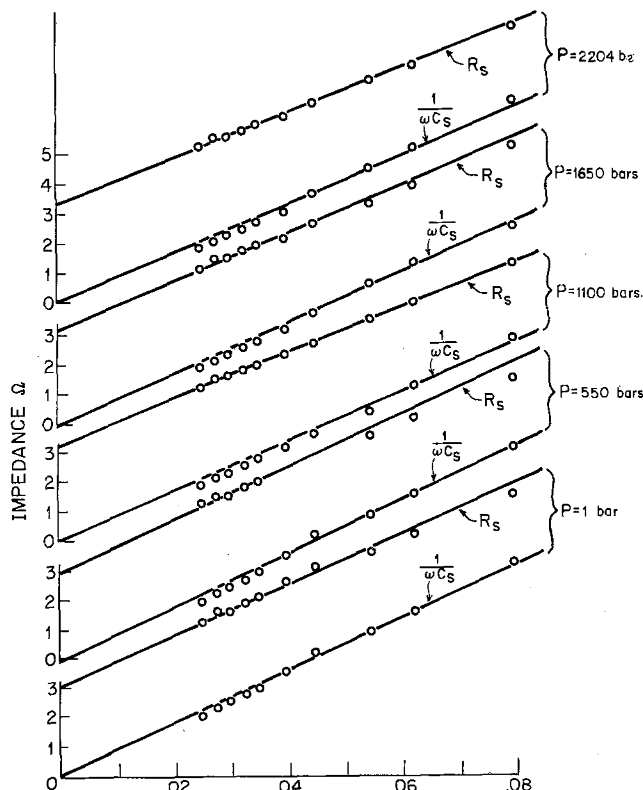

Fig. 2. Randles plots for the impedance behavior of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ reaction at Au at 25°C.

electrons ($z = 1$ here) in the exchange reaction, and C the concentration in mole cm^{-3} of the reactant species. The measured "a-c" currents were evaluated for unit area of the substrate metal and, for high pressures, corrections were made to the ambient pressure concentration using the known compressibility of the solutions.

A test of the satisfactory operation of the electronic measurement system is that the $R_{F,s}$ and $1/\omega C_{F,s}$ quantities should give parallel lines in a plot against $\omega^{-1/2}$ and the $1/\omega C_{F,s}$ relation should pass through the origin.

Figure 2 shows the results at pressures 1, 550, 1100, 1650, and 2204 bars. The plots of $R_{F,s}$ and $1/\omega C_{F,s}$ *vs.* $\omega^{-1/2}$ at each pressure are satisfactorily parallel, with the out-of-phase component passing through the origin as required from the treatment of Randles

$$\frac{1}{\omega C_{F,s}} = \frac{RT}{z^2\mathbf{F}^2AC}\sqrt{\frac{2}{\omega D}} \quad [3]$$

where A is the area of the electrode, C the bulk concentration of the "depolarizer," *i.e.*, $Fe(CN)_6^{-4}/Fe(CN)_6^{-3}$, and D the mean diffusion coefficient of the redox couple ions.

The intercept of the in-phase component line is related to the heterogeneous rate constant $\overline{k}_o$ by the following relation

$$R_{F,s} = \frac{RT}{z^2\mathbf{F}^2AC}\left(\sqrt{\frac{2}{\omega D}} + \frac{1}{k_o}\right) \quad [4]$$

At $\omega^{-1/2} = 0$, the faradaic resistance becomes the reaction resistance, R_r, as represented by the equation (cf. Eq. [1])

$$R_r = \frac{RT}{z^2\mathbf{F}^2AC}\left(\frac{1}{k_o}\right) = \frac{RT}{z\mathbf{F}i_o} \quad [5]$$

The numerical results are recorded in Table I. The results are fitted to a second-order polynomial of the form

$$\ln i_o = a + bp + cp^2$$

then plotted as $\ln i_o$ *vs.* p as in Fig. 3. Also included

Initial slope $(\partial \ln i_o/\partial p)_{p\to 0\ bar} = -7.47 \times 10^{-5}\ bar^{-1}$

* Derived from i_o values after allowance for pressure-dependent concentration of reactant ions.

are the error limits of the best-fit data. The limiting slope $(\partial \ln i_o/\partial p)_{\eta=0}$ at $p \to 0$ bars is evaluated from the coefficient b as $-7.47 \pm 0.4 \times 10^{-5}\ bar^{-1}$. The significance of this finite, rather than zero, value for $(\partial \ln i_o/\partial p)_{\eta=0}$ for the symmetry of the activation process is discussed later.

Relation to volumes of activation.—The pressure coefficient derived above is related to the apparent [see Ref. (1, 2)] volume of activation $\Delta V_a^{\ddagger}$ given by

$$\left(\frac{\partial \ln i_o}{\partial p}\right)_{\eta=0} = -\frac{\Delta V_a^{\ddagger}}{RT} = -7.47 \times 10^{-5}\ bar^{-1} \quad [6]$$

Hence

$$\Delta V_a^{\ddagger} = 1.9 \pm 0.1\ cm^3\ mole^{-1} \quad [7]$$

for the ferri/ferrocyanide couple at its equilibrium potential.

Discussion

Significance of the kinetic data derived from the a-c impedance measurements.—The reaction resistance determined gives the exchange current density, i_o, as indicated by Eq. [1]. It is thus the i_o values which are obtained in a low amplitude a-c electrochemical experiment as a function of pressure. The exchange current density is given by

$$i_o = \overrightarrow{i} = z\mathbf{F}\overrightarrow{k}C_{O,e} \exp -\beta\mathbf{F}\phi_e/RT \quad [8]$$

$$= \overleftarrow{i} = z\mathbf{F}\overleftarrow{k}C_{R,e} \exp (1-\beta)\mathbf{F}\phi_e/RT \quad [9]$$

written for an ionic redox reaction

$$O + ze \underset{\overleftarrow{k}}{\overset{\overrightarrow{k}}{\rightleftharpoons}} R \quad [10]$$

where $C_{O,e}$ and $C_{R,e}$ are the concentrations of O and R at the electrode interface, and $\overrightarrow{k}$ and $\overleftarrow{k}$ are the rate

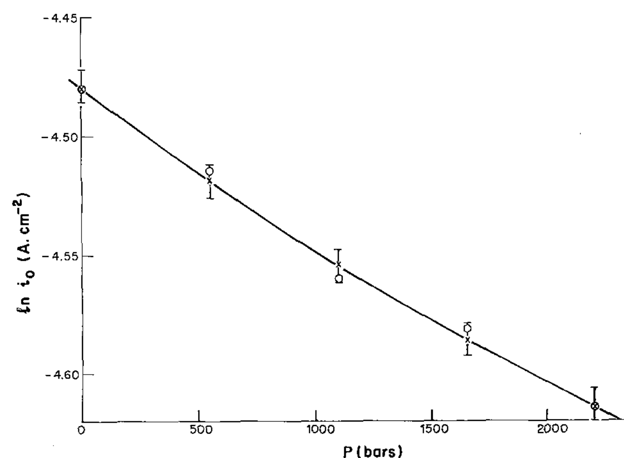

Fig. 3. Plot of ln i_o against pressure for the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ reaction at Au at 25°C at a concentration of 5×10^{-3}M.

constants for the forward and backward directions of the reaction. Experimental studies of pressure effects on i_o lead to evaluation of the pressure-dependence of the electrochemical rate constants $\vec{k}$ $(= \vec{k} \exp -\beta \mathbf{F}\phi_e/RT)$ or $\overleftarrow{k}$ $(= \overleftarrow{k} \exp (1-\beta) \mathbf{F}\phi_e/RT)$, *i.e.*, from the experimental derivative $(\partial \ln i_o/\partial p)_{T,\eta=0}$. Then, neglecting pressure-dependence of molar concentration and of double layer effects as in Part I (1)

$$\left(\frac{\partial \ln \vec{k}}{\partial p}\right)_T + \left[\frac{\partial}{\partial p}\left(\frac{-\beta\phi_e\mathbf{F}}{RT}\right)\right]_T = \left(\frac{\partial \ln i_o}{\partial p}\right)_T \quad [11]$$

or

$$\left(\frac{\partial \ln \overleftarrow{k}}{\partial p}\right)_T + \left[\frac{\partial}{\partial p}\left(\frac{(1-\beta)\phi_e\mathbf{F}}{RT}\right)\right]_T = \left(\frac{\partial \ln i_o}{\partial p}\right)_T \quad [12]$$

Hence the apparent volume of activation, $\Delta V_a^{\ddagger}$, which is found experimentally from $(\partial \ln i_o/\partial p)_T$, is given either by

$$\Delta V_a^{\ddagger} = \Delta \vec{V}_t^{\ddagger} - \beta \Delta V_o \quad [13]$$

or by

$$\Delta V_a^{\ddagger} = \Delta \overleftarrow{V}_t^{\ddagger} + (1-\beta)\Delta V_o \quad [14]$$

where $\Delta V_a^{\ddagger}$ applies to either direction of the reaction at $\eta = 0$, since at the reversible potential, the electrochemical free energies of the reactant and product species are at identical levels. In Eq. [13], ΔV_o is the equilibrium volume change in the over-all reaction [10] corresponding to $(\partial\phi_e/\partial p)_T$. The situation corresponding to Eq. [13] is illustrated schematically in Fig. 4b for volume changes at the reversible potential $(\phi = \phi_e)$ in relation to that in Fig. 4a representing the true volumes of activation $\Delta \vec{V}_t^{\ddagger}$ and $\Delta \overleftarrow{V}_t^{\ddagger}$ for hypothetical $\phi = 0$.

Since (see Part I) a relatively accurate nonthermodynamic estimate can usually be made of the volume change, ΔV_o, for the over-all reaction, both $\vec{V}_t^{\ddagger}$ and $\overleftarrow{V}_t^{\ddagger}$ can be separately evaluated from $\Delta V_a^{\ddagger}$ derived from $(\partial \ln i_o/\partial p)_{T,\eta=0}$.

It is to be noted that by the nature of the equations representing $\vec{k}$ and $\overleftarrow{k}$, the experimental pressure derivative will always give a small or zero (depending on β) apparent volume of activation from which the $\Delta V_t^{\ddagger}$ values for the forward or backward reaction must be obtained by addition or subtraction of about half of the over-all reaction volume (Eq. [13], [14]). This situation is thermodynamically unavoidable.

A relation obtainable from Eq. [13] and [14] is

$$2\Delta V_a^{\ddagger} = \Delta \vec{V}_t^{\ddagger} + \Delta \overleftarrow{V}_t^{\ddagger} + (1-2\beta)\Delta V_o \quad [15]$$

giving

$$(1-2\beta) = [2\Delta V_a^{\ddagger} - (\Delta \vec{V}_t^{\ddagger} + \Delta \overleftarrow{V}_t^{\ddagger})]/\Delta V_o \quad [16]$$

which would enable β to be evaluated if $\Delta \vec{V}_t^{\ddagger}$ and $\Delta \overleftarrow{V}_t^{\ddagger}$, or their sum, were independently available. A symmetrical transition state, $\beta = \frac{1}{2}$, corresponds, of course, to $\Delta V_a^{\ddagger} = \frac{1}{2}(\Delta \vec{V}_t^{\ddagger} + \Delta \overleftarrow{V}_t^{\ddagger}) = 0$. It is evident that with $\beta = \frac{1}{2}$, the true volumes of activation for the forward and backward reactions differ symmetrically from the common apparent volume of activation $\Delta V_a^{\ddagger}$ by $\pm \frac{1}{2}\Delta V_o$; also, as thermodynamically required, $\Delta \overleftarrow{V}_t^{\ddagger} - \Delta \vec{V}_t^{\ddagger} = \Delta V_o$. Hence, $\Delta V_a^{\ddagger} = 0$ for a symmetrical reaction. In the general case, $V^{\ddagger}$, the actual volume of the transition state is, however, not necessarily the mean of the initial and final state volumes in a reaction at an electrode since different adsorption effects can arise. An example is the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ redox reaction treated in the present paper. Unfortunately, it is clear from the foregoing that $\Delta \vec{V}_t^{\ddagger}$ and $\Delta \overleftarrow{V}_t^{\ddagger}$ can be evaluated through Eq. [14] from the measured $\Delta V_a^{\ddagger}$ and a nonthermodynamic value of ΔV_o only by choosing a reasonable value for β which would be presumed to be ½ for a "symmetrical" redox reaction (but see later section on transition state symmetry).

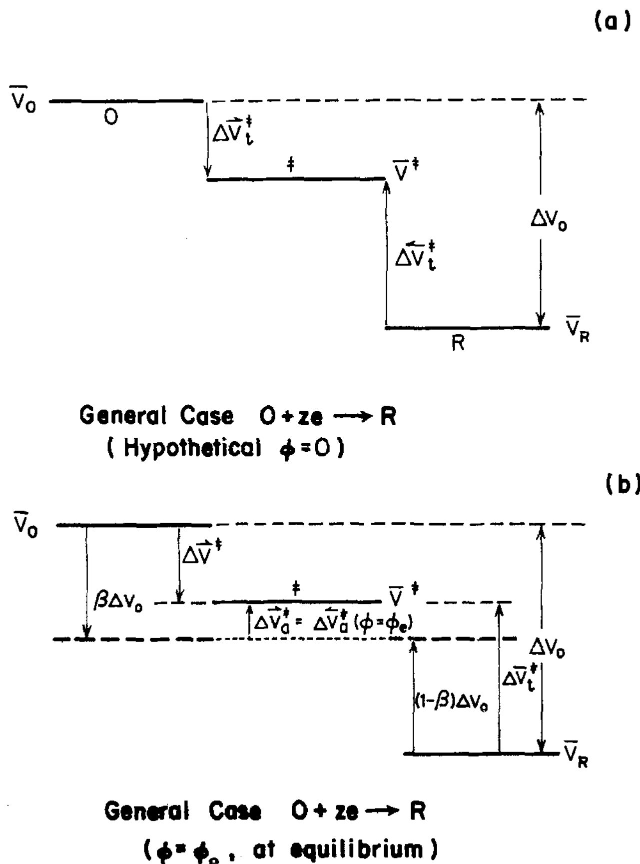

Fig. 4. Schematic relations between the true and apparent volumes of activation for the backward and forward directions of a general electron transfer reaction at $\phi = 0$ (hypothetical) and $\phi = \phi_r$, *i.e.*, at equilibrium, and the over-all partial molar volume difference $\Delta V°$, between products and reactants. $\bar{V}^{\ddagger}$ is the partial molar volume of the transition state.

Applications to the results for the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple.—In order to interpret the solvent reorganization behavior in this reaction, we require the change of electrostriction volume between the initial state and the transition state. The apparent volume of activation $\Delta V_a^{\ddagger}$ is available from the measurement of $(\partial \ln i_o/\partial p)$. Hence we first require ΔV_o (Eq. [13], [14]) for the reaction $Fe(CN)_6^{3-} + e \rightarrow Fe(CN)_6^{4-}$.

For the systems studied here, the individual partial molar volumes for the ions of the couple are (20)

$$\bar{V}°_{Fe(CN)_6^{4-}} = 95.6 \text{ and } \bar{V}°_{Fe(CN)_6^{3-}} = 137.0 \text{ cm}^3 \text{ mole}^{-1}$$

These values are based on the well-established individual ionic volume of the proton $(\bar{V}°_{H^+} = -5.4$ $\text{cm}^3 \text{ mole}^{-1})$ derived in at least two ways which give concordant results, as discussed in previously published literature (21, 22). The volume of the electron V_{e^-} in the half-cell redox reaction should be taken into account. It is difficult to find a reliable value for this term but Heusler and Gaiser (23) have suggested a value of 3 cm³ Faraday⁻¹ in a metal in their work on the H_2-evolution reaction. Using this value

$$\Delta V_o = \bar{V}°_{Fe(CN)_6^{4-}} - \bar{V}°_{Fe(CN)_6^{3-}} - V_{e^-} = -44.4 \text{ cm}^3 \text{ mole}^{-1}$$

Then, following Eq. [14], the true volumes of activation for the forward and backward directions of the reaction can be calculated from the common apparent volume of activation, $\Delta V_a^{\ddagger} = 1.9$ cm³ mole⁻¹

(Eq. [7]). Thus, for the reaction written in the direction $Fe(CN)_6^{3-} + e \rightarrow Fe(CN)_6^{4-}$

$$\overrightarrow{\Delta V}_t^{\ddagger} = 1.9 + \tfrac{1}{2}(-44.4) = -20.3 \text{ cm}^3 \text{ mole}^{-1} \quad [17a]$$

and

$$\overleftarrow{\Delta V}_t^{\ddagger} = 1.9 - \tfrac{1}{2}(-44.4) = 24.1 \text{ cm}^3 \text{ mole}^{-1} \quad [17b]$$

assuming β for this reaction can be taken [see below and Ref. (11)] as ½. The partial molar volume of the transition state, $\overline{V}^{\ddagger}$, is estimated from the relationship

$$\overline{V}^{\ddagger} - \overline{V}^{\circ}_{Fe(CN)_6^{3-}} = \overline{V}_e + \overrightarrow{\Delta V}_t^{\ddagger} + 119.7 \text{ cm}^3 \text{ mole}^{-1} \quad [18]$$

As in Fig. 4a, the changes of volume in the system as it passes from its initial state, through the transition state, to the final state can be represented schematically as shown in Fig. 5.

While the main changes in volume of conjugate ions in a redox couple are associated with the difference of electrostriction between the pair of ions, significant effects which must be considered can also arise from the change of ionic radius or ligand-to-metal bond length (24, 25). Thus, in an isoelectronic series, *e.g.*, Na^+, Ne, and F^-, changes of charge produce appreciable changes, Δr, of radii, from 0.95, through 1.1-1.36Å, respectively, for these three elements. Similarly, for Pb^{4+} to Pb^{2+}, the difference of radii is 0.36Å for 2*e*. It is more difficult to judge the effects of change of charge in $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ because it is a complex ion with some charge delocalization (26). Based on the above figures for simple ions, a reasonable estimate of Δr would be 0.1Å per electron. However, recent crystallographic data (27, 28) on $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ (as their acids or salts) indicate, in fact, that there is very little difference in radius of these two ions and M.O. calculations show that the effective charges on Fe are almost identical. Thus the total Fe-to-N length is 3.07Å in $LaFe(CN)_6 \cdot 5H_2O$ (27) and 3.04Å in $H_4[Fe(CN)_6]$ (28), the value for the 4- ion being surprisingly the smaller of the two. This is consistent with a difference of 0.1Å taken by Mathieson (29) in that direction. The similar sizes of the two ions of the couple are also borne out by the similarity of their ionic mobilities (30-32) at infinite dilution, which indicates they have almost the same Stokes hydration radii.

Bearing in mind that it has been assumed that $\beta = 0.5$ for the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ system, then the transition state for an adiabatic electron transfer [cf. (11)] should bear a charge of $-3.5e$. Taking the radius of $Fe(CN)_6^{3-}$ as 3.31Å (29) an intrinsic volume of 91 cm³ mole⁻¹ is calculated. With $\Delta r = -0.03$Å per *e* (27, 28), the intrinsic volume of the transition state ion (charge $-3.5e$) would be 90 cm³ mole⁻¹, *i.e.*, 1 cm³ mole⁻¹ smaller than the initial state ion. Therefore the volume change due to solvent reorganization ($\overrightarrow{\Delta V}_{t,r}^{\ddagger}$) will be somewhat less than $\overrightarrow{\Delta V}_t^{\ddagger}$ and takes the value $-20.3 + 1$ in cm³ mole⁻¹, *i.e.*, -19.3 cm³ mole⁻¹, since $\overrightarrow{\Delta V}_t^{\ddagger}$ measures the total of all volume contributions associated with the formation of the transition state. Correspondingly $\overleftarrow{\Delta V}_{t,r}^{\ddagger}$ will be 23.1 cm³ mole⁻¹.

The main point to be emphasized is that these figures of -19.3 and 23.1 cm³ mole⁻¹ are relatively large volume changes and are associated mainly with the change of electrostriction about the ion since the small change of intrinsic volume has been allowed for. It is to be noted that the $\overrightarrow{\Delta V}_t^{\ddagger}$ differ significantly, but by a small amount, from half the volume change, ΔV_o, in the over-all reaction. This behavior originates from the fact that $\Delta V_a^{\ddagger}$ differs significantly from zero. The significance of the volume changes in Fig. 5 for the "symmetry" of the reaction will be examined later.

From the above data and Fig. 5, it is seen that the total volume of activation, less the contribution associated with ½*e* that remains in the metal, is -18.8 cm³ mole⁻¹. This is the volume change associated with solvent reorganization about the ion (including any contribution locally in the double layer) plus the change of intrinsic volume of the ion in the activation process in which ½*e* is transferred. Therefore the solvent electrostriction volume change in the activation process is $-18.8 - (-1)$ cm³ mole⁻¹ $= -17.8$ cm³ mole⁻¹ for the forward direction of the reaction and 21.6 cm³ mole⁻¹ for the backward direction. This is to be compared with the solvent electrostriction change in the over-all reaction which is $-41.4 - (-2) = -39.4$ cm³ mole⁻¹. Although the numerical value of the volume of activation depends on the effective volume of the electron, it is to be noted that the evaluation of the solvent electrostriction volume from $\Delta V_a^{\ddagger}$ is independent of the value assigned to V_{e^-}. Values of the electrostriction volumes[1] derived for the present case are illustrated in Fig. 6.

Electrostriction change and the nature of the activation process.—The electrostriction contributions, ΔV_{el}, to the volumes of activation derived above are quite large. In previous theoretical considerations (7, 8), it

[1] The ions of the ferro-ferricyanide couple exhibit unusual partial molal volume behavior (29) as there is evidently an appreciable structure-forming volume in $Fe(CN)_6^{3-}$ aq. like that for R_4N^+ ions (21). There is, however, the expected large electrostriction increase (−39.4 cm³ mole⁻¹) in going from the 3- to the 4-ion (Fig. 6).

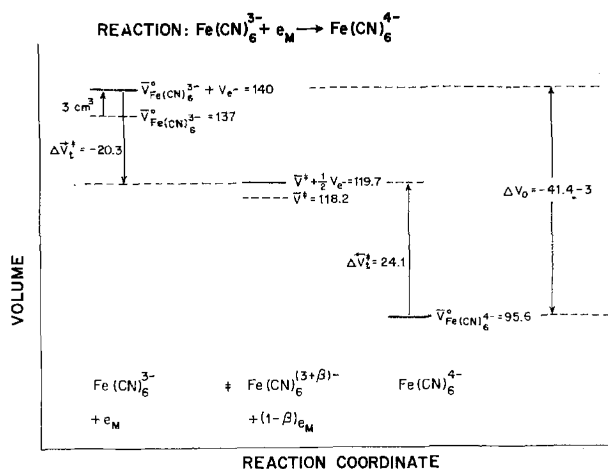

Fig. 5. Schematic relation for the volume changes in the $Fe(CN)_6^{3-} + e \rightarrow Fe(CN)_6^{4-}$ reaction showing the true volumes of activation in relation to the partial molar volumes of the initial, final, and transition state (‡). All volume data are in cm³ mole⁻¹. Volume data including a finite volume of the electron are shown.

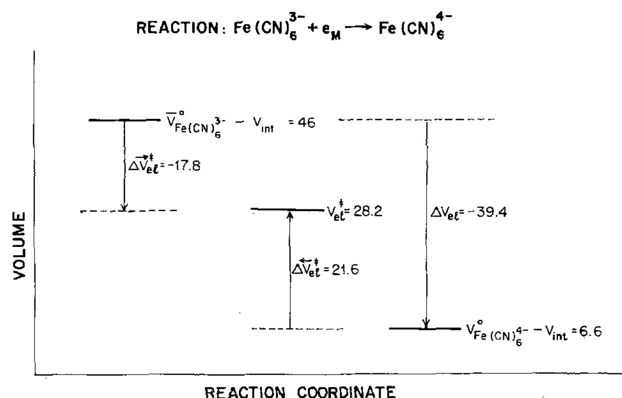

Fig. 6. Schematic relation for the electrostriction volume changes in the $Fe(CN)_6^{3-} + e \rightarrow Fe(CN)_6^{4-}$ reaction. *i.e.*, after the intrinsic volumes of the ions and the e-volume have been subtracted out.

has been pointed out that there are difficulties in accepting the view (10-12) that the solvent reorganization process is associated only with organized fluctuations of long-range (Born) dielectric polarization. The quantum-mechanical objections to primary hydration sphere reorganization being involved in the activation process on the basis that the $h\nu$ values for the modes involved are much larger than kT are weakened by the known (33) important contributions which such solvation-sphere modes make to the heat capacities of solvated ions in aqueous media at ordinary temperatures. Sufficient low frequency vibration and intermolecular modes are available. More recently, the role of inner-shell activation processes has been recognized (34) and treated by Schmickler (35).

It is therefore important to attempt to estimate the relative contributions to the electrostriction, ΔV_{el}, at an ion in water from successive spherical annular elements of the solvent out from the periphery of the ion; especially the contribution to ΔV_{el} from the solvent volume within 3-4Å from the ion in comparison with that further out, viz., 5-50Å, will be of interest.

While it would be desirable to calculate the volume changes associated with charge-transfer from recent quantum statistical calculations (12-14, 34-36) on this process, the required pressure derivatives of the quantities involved in such treatments of $\Delta G^{\ddagger}$ are mostly quite unknown; indeed reliable *ab-initio* numerical evaluations of $\Delta G^{\ddagger}$ quantities themselves have yet to be given. Even for solvation of simple ions (36), quantum statistical calculations of electrostriction have not yet been developed. On the other hand, relatively sophisticated electrostatic calculations have been published (37-40) which give electrostriction volumes at ions within 10-15% of values derived from experimental data. Hence the electrostatic model treatment is pursued here.

The simplest approach for calculation of electrostriction would be through the specific compressibility γ given by

$$-\gamma = \frac{1}{V}\left(\frac{dV}{dp}\right) \quad [19]$$

and the electrostrictive pressure p

$$p = \epsilon_r E^2/8\pi = (ze)^2/8\pi\epsilon_r r^4 \quad [20]$$

where E is the field $ze/\epsilon_r r^2$ due to the ion in the dielectric taking into account the fact that the relative permittivity, ϵ_r, is a function of r, the distance from the ion.

Then, from Eq. [20]

$$\frac{dp}{dr} = -[(ze)^2/2\pi\epsilon_r r^5] - [(ze)^2/8\pi\epsilon_r^2 r^4] \Big/ \left(\frac{d\epsilon_r^{-1}}{dr}\right) \quad [21]$$

The relative volume change dV in a spherical volume element $4\pi r^2 \cdot dr$ about the ion will be given by Eq. [19] as

$$dV = -\gamma 4\pi r^2 \cdot dr \cdot dp \quad [22]$$

Then, introducing dp as $f(r \cdot dr)$ from Eq. [21]

$$dV = [2\gamma(ze)^2/\epsilon_r r^3]dr \cdot dr + [\gamma(ze)^2/2r^2\epsilon_r^2]dr \cdot d\epsilon_r \quad [23]$$

from which changes of volume due to electrostrictive tension in successive annular elements of volume could be calculated by integration. In Eq. [23], it is to be expected (37) that γ as well as ϵ will be a function of r. Hence, integration of Eq. [23] with both γ and ϵ as a function of r is obviously difficult. However, a better approach may be made using the calculations previously published from this laboratory, based on empirical equations for pressure and field effects on ϵ and the thermodynamic theory of electrostriction given by Frank (38).

It is convenient to consider the permittivity near an ion in terms of a step-function (39) related to the semiempirical expression (41) for the differential dielectric constant ϵ_d as $f(E)$

$$\epsilon_d = [(\epsilon_o - n_o^2)/(1 + bE^2)] + n_o^2 \quad [24]$$

where n_o^2 is the square of the refractive index, ϵ_o is the static, zero-field dielectric constant, and b is a coefficient related to field-dependence of ϵ_d derived in Booth's theory (42). Two cases of interest arise in electrostriction theory (37): when $bE^2 << 1$ and $bE^2 >> 1$, *i.e.*, for low and high fields.

The high field approximation gives (37) for the relative volumes of normal (v_o) and electrostricted (v) water

$$\log v_o/v = G \log (KE^2 + 1) \quad [25]$$

where

$$G = D/(1 - C) = 0.1469$$

and

$$K = C(1 - C)n_o^2/8\pi\beta D = 1.102 \times 10^{-11}$$

and β, C, and D are known empirical constants (37) determining the pressure dependence of n_o^2 and ϵ.

The following model of the hydration of the $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions will be considered: Eight hydration shell water molecules can be accommodated in the faces of the octahedral 6CN/Fe arrangement and will be firmly bound electrostatically; another shell, one H_2O molecule in thickness, is also firmly associated ($\epsilon \rightarrow n_o^2$) with the complex further out. Both types of ions presumably will have a similar inner layer of the 8 water molecules. This model seems reasonable since the two kinds of ions have 3 and 4 times the charge of a simple ion like Na^+ but have a hydration radius about twice as great so that, although the field is 2½ times smaller per charge, the net electrostrictive field near the periphery of both ions will be larger than that near a small univalent ion.

Under low field conditions, beyond the primary hydration shell, the equation for dV can be analytically integrated since ϵ can then be assumed (39) to be almost independent of E as can γ. Then Eq. [23] can be integrated to give the electrostriction volume

$$\Delta V_{el} = \int_{r_h}^{\infty} dV = -\int_{r_h}^{\infty}\int_{r_h}^{\infty} \frac{2(ze)^2\gamma}{\epsilon r^3} dr \cdot dr = \frac{-(ze)^2\gamma}{\epsilon}\left[\frac{1}{r}\right]_{r_h}^{\infty} \quad [26]$$

where r_h is the radius of the outer periphery of the primary hydration shell. Taking $\gamma = 4.57 \times 10^{-11}$ cm² dyne⁻¹ for water and $r_h = 6.09$Å (where $r_i = 3.31$Å) for $Fe(CN)_6^{3-}$ and 6.06Å for $Fe(CN)_6^{4-}$ ($r_i = 3.28$Å), enables the Born electrostriction volume, ΔV_{el}, arising beyond the primary hydration shells of these ions to be evaluated as

$$\Delta V_{el,Fe(CN)_6^{3-}} = -12.0; \quad \Delta V_{el,Fe(CN)_6^{4-}} = -21.0 \text{ cm}^3 \text{ mole}^{-1} \quad [27]$$

The relative contributions to the ΔV_{el} in annular volume elements of increasing thicknesses over the first 50Å from the periphery of the primary hydration shells of the ions can be evaluated from Eq. [26] using successively different integration limits and are shown in Fig. 7. The total difference of the long-range electrostriction, which corresponds to the figures in Eq. [27] with ∞ taken as the upper limit in the integrals of Eq. [26], is -9 cm³ mole⁻¹, *i.e.*, -4.5 cm³ mole⁻¹ for the electrostriction change upon activation ($\beta = ½$). It is important to note that this is only *ca.* 25% of the total real volume of activation.

The primary hydration shell volume differences $\delta\Delta V_{el,1}$ in $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ are evaluated using Eq. [25] assuming the field E is given by $E = (ze)^2/\epsilon(r_h')^2$ where r_h' is the mean radius of the hydration shell (*i.e.*, $r_h' \doteq r_i + ½\, d_{H_2O}$, where r_i is the

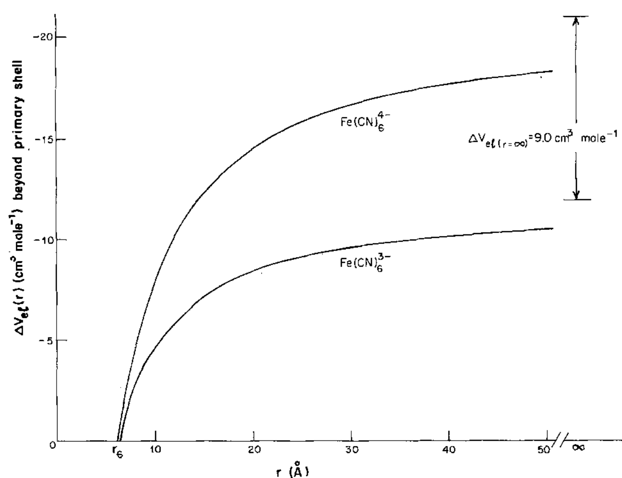

Fig. 7. Calculated Born polarization electrostriction volume changes ΔV_{el} (from Eq. [26]) beyond the primary hydration shells as a function of distance r from the periphery of those shells at $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ ions.

ionic radius and d the diameter (=1.39Å) of a water molecule; also r_h' is related to r_h in Eq. [26] by $r_h' = r_h - \frac{1}{2} d_{H_2O}$. ϵ for the primary hydration shell is taken as 2 [cf. Ref. (39, 41, 42)]. The volume differences will depend (*i*) on the ionic radii taken for the ions themselves, and (*ii*) on the field E in the primary shell.

In order to try to make an objective evaluation of the electrostriction, we have made several estimates of the primary shell contribution to ΔV_{el} based on one assumed and various available values of the differences of ionic radii. The volumes of the primary hydration shells are calculated, the field is estimated as above and then application of Eq. [25] gives the compression ratio (38) v/v_0 to be applied to these volumes for the two ions; hence ΔV_{el} is evaluated. The results of these calculations are given in Table II. Calculations of this kind have been given in Ref. (37) where the uncertainties were examined. However, here, differences in volumes are involved so the reliability of their evaluation may be better than that in calculations for individual ions.

Relation to theories of electron transfer.—Evidence for reorganization in the primary hydration shell.—The experimental value for the over-all volume change in reaction [28] (−44.4 cm^3 mole^{-1}) when corrected for the change of intrinsic volume of the ion and for the finite volume of the electron gives an electrostriction volume change of −39.4 cm^3 mole^{-1}. This agrees best with the total electrostriction change (−40 cm^3 mole^{-1}) calculated for the case where there is a small contraction of ionic radius from $Fe(CN)_6^{3-}$ to $Fe(CN)_6^{4-}$ as indicated by the x-ray diffraction results (Table II). Other assignments of ionic radii differences, except that where $r_{Fe(CN)_6^{4-}} > r_{Fe(CN)_6^{3-}}$, give the right order of magnitude but not such good agreement with experiment. It can be concluded from these calculations that the main contribution (*ca.* 75%) to ΔV_{el} arises from changes in primary hydration shell volume and only *ca.* 25% from volume changes due to long-range polarization (Fig. 7). The latter calculations are relatively reliable since they depend on near normal values of ϵ and γ.

It has been shown above that the activation volume $\Delta V_t^{\ddagger}$ for the forward direction of the reaction is about 40% of the total volume change. Hence the activation volume involves a contribution of about 40% of 9.0 cm^3 mole^{-1} in the long-range polarization effect plus about 40% of 32.4 cm^3 for the primary hydration shell volume change, assuming (11) in an adiabatic reaction there is a progressive change of electron charge density as the transition state configuration is developed from the initial state.

These results lead to the important conclusion that the activation process is associated mostly with a change of state of the primary hydration shell of the reactant ion rather than with fluctuations in the long-range polarization co-sphere of the ion. The latter effect has formed the basis of most theories of the activation process in redox reactions. Were it the main factor, as implied with respect to energies of activation, only a small volume of activation calculated from β times the result given by Eq. [26] would be observed; it is much smaller than that found experimentally.

It is to be noted that whatever is the actual value of β, *e.g.*, 0.5 ± 0.1, it will not materially change the conclusion that the real volume of activation will be *ca.* half the equilibrium volume change in the over-all reaction and thus substantially larger than the Born polarization electrostriction and, of course, much larger than the $\Delta V_a^{\ddagger}$. This conclusion is of a rather general kind, as is seen from Eq. [14].

Symmetry of the transition states.—For a homogeneous reaction between ferri- and ferrocyanide, the transition state must be a symmetrical complex between the ions with each having an intermediate charge −3.5*e*. While the over-all equilibrium in a redox couple established at an electrode, referred to some other reference electrode, will be identical with that in the corresponding homogeneous reaction, a symmetrical transfer of charge will not necessarily occur in the transition states involved in the electrochemical reactions

Table II. Electrostriction volume difference in primary hydration shells of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions in water for various assumed radii

Ion	Ionic radii (A)	Hydration shell volumes (cm^3 mole^{-1})	Field in shell (esu)	Electrostriction factor v_0/v from Eq. [25]	Electrostriction volume difference ΔV_{el} (cm^3 mole^{-1})	Total electrostriction volume difference: primary shell + Born electrostriction beyond

$$Fe(CN)_6^{3-} + e_M \rightarrow Fe(CN)_6^{4-} \quad [28]$$

or

$$Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-} + e_M \quad [29]$$

which occur at an electrode as distinct events at a common potential. The reason is that the ferri- and ferrocyanide ions will probably not interact with the electrode in the same way [cf. Ref. (6)] nor is this interaction likely to be negligible; for example, at Pt and Au, even simple ions such as SO_4^{2-} and ClO_4^- are quite strongly adsorbed. This situation means, of course, that β need not necessarily be exactly 0.5. This does not involve any conflict with the principle of microscopic reversibility, of course, since the equilibrium condition will always involve electrode potential terms in both exp $(-\beta\phi_e\mathbf{F}/RT)$ and exp $(1 - \beta)\phi_e\mathbf{F}/RT$ in the usual way where ϕ_e is the metal/solution p.d. at equilibrium.

The present experimental results, treated in the first approximation with the assumption that $\beta = 0.5$ [cf. Ref. (11)], show that the activation process, from the point of view of the volume changes involved, is not "symmetrical" since the $\Delta \overrightarrow{V}_t^{\ddagger}$ is appreciably less than the $\Delta \overleftarrow{V}_t^{\ddagger}$. This result arises principally from the experimental fact that $\Delta V_t^{\ddagger}$ is not zero (see Eq. [7] and [14]). From the point of view of solvent reorganization in the activation process (10, 11), this means that the hydration shell configurations of the transition states in Eq. [28] and [29] are not symmetrical with respect to those of reactant and product ions as would be the case in the corresponding homogeneous reaction. Presumably this could be due to different adsorption of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ anions at Au, *i.e.*, different interactions of the two ions with the Au surface and with adsorbed water in the inner Helmholtz layer (44). It is of interest to note that the asymmetry is less at higher pressures since $\Delta V_a^{\ddagger}$ decreases with pressure (Fig. 3).

If, in Eq. [14], a value of β were sought that gave equal numerical values for $\Delta \overrightarrow{V}_t^{\ddagger}$ and $\Delta \overleftarrow{V}_t^{\ddagger}$, it would not be 0.5, again indicating asymmetry in the activation processes for the forward and backward directions of the redox reaction at the electrode surface. It is to be noted that values of β for this reaction, differing significantly from 0.5, have been reported in the literature (4, 45).

That the deviation of $\Delta V_a^{\ddagger}$ from zero is connected, in part, with the effect of pressure on the ion-pairing in this system cannot be excluded, *e.g.*, see Bindra *et al.* (46).

Nickel-Based Alloys as Electrocatalysts for Oxygen Evolution from Alkaline Solutions

P. W. T. Lu* and S. Srinivasan*

Department of Applied Science, Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The oxygen evolution reaction on the alloys of Ni with Ir, Ru, or W and on Ni-Ti intermetallic compounds was studied in 30 weight percent (w/o) KOH at 80°C using steady-state potentiostatic and slow potentiodynamic (at 0.1 mV/sec) methods. Since this reaction always takes place on film-covered surfaces, the nature of oxide films formed on these alloys was investigated using cyclic voltammetry. The peaks for the formation and reduction of oxygen-containing layers appearing on the pure metals are not always found on these alloys. Oxygen overpotentials at an apparent current density of 20 mA/cm^2, on the alloys of 50Ni-50Ir and 75Ni-25Ru (in atomic percent, a/o) and the intermetallic compound Ni_3Ti were less than on Ni by about 40, 30, and 20 mV, respectively. On long-term polarization at potentials in the oxygen evolution region, the oxygen-containing films on Ni-Ir and Ni-Ru alloys are predominantly composed of nickel oxide and independent of the bulk composition of the alloys themselves. This accounts for the absence of any direct dependence of electrocatalytic activities for oxygen evolution on their electronic properties. The effects of relative activities of the individual components in the alloys are however detectable on the oxide formation reactions on the surfaces of freshly prepared electrodes.

One of the more difficult problems which limit the operation efficiency of the water electrolyzers and secondary metal-air batteries is the slowness of the oxygen electrode reaction (OER) (1-3). Of the metals, nickel is the best known electrocatalyst for oxygen evolution from alkaline solutions. The metal nickel has 0.54 unpaired electrons in the 3d band (4). Alloying nickel with other transition elements having more unfilled d shells (*e.g.*, Ir) can result in more d-band vacancies (5). Thus, it is possible to deduce significant alteration in other electronic properties such as density of surface states, work function, and Fermi level. In a recent review regarding hydrogen evolution on alloys (6), it was emphasized that the electrocatalytic properties of an alloy parallel changes in its electronic properties.

Data on the kinetics of the OER on alloys and intermetallic compounds are sparse (3). Historically, the only studies of the oxygen overpotential on nickel alloys in alkaline solution have been with Ni-Fe (7, 8), Ni-Co (8), and Ni-Cr systems (9). These investigations on Ni-based alloys provided no evidence of correlation between the electrochemical activities for the OER and the alloy composition. The possible effect of the electronic properties of the alloys on their electrocatalytic properties was not considered.

In the present work, alloys of Ni with Ir, Ru, or W and Ni-Ti intermetallic compounds were investigated as anodes for oxygen evolution from 30 w/o KOH at 80°C. Anodic oxide films formed on the electrode surfaces of these alloys or intermetallic compounds were also characterized. The major purposes of this study are (*i*) to elucidate any possible effect of the electronic properties of the alloys or intermetallic compounds on their electrocatalytic properties, (*ii*) to understand the dependence of the kinetics of electrode reactions on the nature of oxide films, and (*iii*) to find better electrode materials to replace the conventional nickel anodes for oxygen evolution from alkaline solutions.

Experimental

Specimen preparation.—Three Ni-Ti intermetallic compounds, *i.e.*, Ni_3Ti, NiTi, and $NiTi_2$, were prepared in an electric arc furnace under an Ar atmosphere. The alloys of Ni with Ir, Ru, or W were prepared by Paul D. Merica Research Laboratory, International Nickel Company—three alloys of nominal compositions 25, 50, and 75 a/o Ni in the Ni-Ir or Ni-Ru system and two alloys (50 and 75 a/o Ni) in the Ni-W system. These alloys were annealed at 1400°C in a H_2 atmosphere for about 24 hr. The examination of chemical composition and homogeneity of these alloys and intermetallic compounds was carried out using electron microprobe analysis and metallurgical microscopy. The specimens were cut in the shape of cylinders using the electric discharge machine. The electrodes were prepared by sealing the cylindrical specimens and their lead wires into shrinkable Teflon tubes using heat-treatment. Finally, each electrode having a geometric area of 0.20 cm^2 was mechanically polished as described elsewhere (10).

Solution.—The 30 w/o KOH solution was prepared from Baker analyzed reagent grade potassium hydroxide and triply distilled water. The solution was purified by anodic preelectrolysis for 24 hr or more at a C.D. of 2 mA/cm^2. After each experiment, the measuring solution was analyzed using atomic absorption spectroscopy.

Apparatus.—A three-compartment Teflon cell, placed in an air thermostat, was used to carry out the electrochemical study of electrode materials. A saturated calomel electrode (SCE) was employed as a reference. The potentials are referred to the reversible hydrogen electrode (RHE), which is approximately −1.16V *vs.* SCE as obtained by measurement in this investigation. The electrochemical measurements were conducted using a PAR Model 173 potentiostat coupled with a PAR Model 175 programmer and a PAR Model 376 "log converter." When carrying out potentiodynamic measurements, Tafel plots and cyclic voltammograms were recorded by use of an HP Model 7047A X-Y recorder. A Tektronix Model 7623A oscilloscope was used to measure ohmic overpotentials (*i.e.*, *iR* drops) between the edge of Luggin capillary and the working electrode.

Electrochemical measurements.—Tafel plots for the OER on test electrodes were determined using steady-state potentiostatic and slow potentiodynamic (at 0.1 mV/sec) methods. Each electrode was preanodized at a constant C.D. of 200 mA/cm^2 for 2 hr or more to form stable oxide films on its surface. In the potentiodynamic measurements, "log *I* output" signals from the log converter were connected to an X-Y recorder so that Tafel plots appeared directly on the semilogarith-

mic paper. During each run, the electrolyte was deaerated with purified O_2 and magnetically stirred. Experiments were conducted at 80°C in the direction of high currents to low currents. On each electrode, at least two individual steady-state potentiostatic and one slow potentiodynamic measurements were carried out. Ohmic overpotentials were measured by use of an interruptor technique (11).

The formation and reduction of oxide films on the freshly polished electrodes of Ni, Ir, and Ni-Ir alloys were studied using cyclic voltammetric techniques. Each electrode was initially maintained at -0.05V in N_2-saturated 30 w/o KOH at 80°C for 20 min to remove oxide films possibly formed on its surface during polishing. A linear potential sweep at 20 mV/sec was applied between -0.05 and $+1.50$V. The cyclic voltammograms for the first two sweeps on each electrode were recorded.

After long term polarization (up to 80 hr) for oxygen evolution at an apparent C.D. of 20 mA/cm^2 on Ni, Ni_3Ti, and on the alloys of 50Ni-50Ir and 75Ni-25Ru, the potential of each electrode was stepped instantaneously to 1.60V. Then, cyclic voltammograms on the preanodized electrodes were recorded between -0.05 and 1.60V at a sweep rate of 20 mV/sec. The first ten traces of the continuous cyclic voltammograms on each electrode were recorded on an X-Y recorder.

Results and Discussion

Composition and homogeneity of specimens.—The chemical compositions of these Ni-based alloys or intermetallic compounds, determined by the electron microprobe, are slightly different from the nominal compositions with deviations of less than 7 a/o. Figure 1 shows the microstructures of these specimens in the Ni-Ti system. The nominal intermetallic compounds NiTi and $NiTi_2$ exhibit two phases, while Ni_3Ti appears to be a single phase system. As illustrated in Fig. 2, two phases appear on each of Ni-W alloys, being β (*i.e.*, NiW) and one W-rich phase. In the Ni-Ru system, the alloy of 50Ni-50Ru appears to be composed of two phases as expected from the phase diagram, while the other two alloys exhibit only a single phase. Unfortunately, no phase diagram for the Ni-Ir system could be attained. The metallographic examination revealed that two phases appear in the alloys of 50Ni-50Ir and 25Ni-75Ir whereas only one in the alloy of 75Ni-25Ir.

Automation of measurement of Tafel plots.—A typical Tafel plot for oxygen evolution determined with potentiodynamic techniques at a slow potential sweep of 0.1 mV/sec, is shown in Fig. 3. Data from two independent, steady-state potentiostatic measurements for the OER on the same electrode and under the same experimental conditions are also presented for comparison. As illustrated in Fig. 3, the maximum potential deviation (at the same C.D.) between any two individual measurements is about 5 mV in the linear region. The Tafel plot obtained by use of the slow potentiodynamic method exhibits a slightly higher exchange C.D. than that from the steady-state potentiostatic measurements (9.2×10^{-7} and 6.0×10^{-7} A/cm^2, respectively). The potentiodynamic measurements also provide a slightly higher Tafel slope (70 mV, compared to 66 mV obtained from the steady-state potentiostatic measurements). In general, however, Tafel plots determined using both the steady-state potentiostatic and

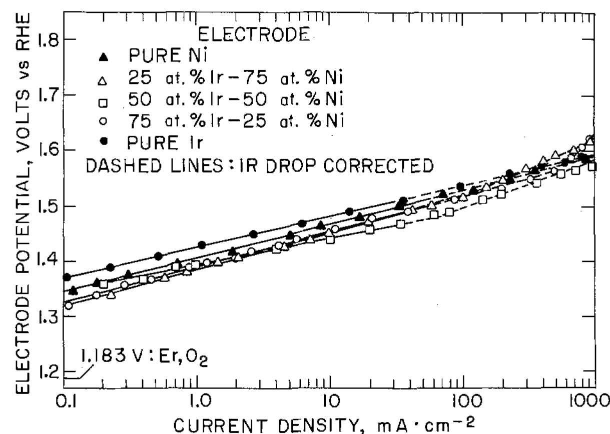

Fig. 4. Tafel plots for oxygen evolution on Ni, Ir, and three Ni-Ir alloys in 30 w/o KOH at 80°C.

the slow potentiodynamic methods are in fair agreement with each other.

Conventional steady-state potentiostatic or galvanostatic techniques used to determine electrode kinetic parameters are time consuming. It has been noted (12) that, using the potentiodynamic method at slow sweep rate (<10 mV/sec), a steady-state condition can be approached. Furthermore, the present work indicates that the slow potentiodynamic technique is efficient, timesaving and, most importantly, accurate in determining electrode kinetic parameters.

Kinetics of oxygen evolution reaction.—The reversible potential of the oxygen electrode in 30 w/o KOH at 80°C was determined empirically to be 1.183V *vs.* RHE. Electrode kinetic parameters for the OER on the various electrodes investigated are summarized in Table I. It is noted that each parameter represents the average value of two independent steady-state potentiostatic and one slow potentiodynamic measurements.

Ni-Ir system.—Figure 4 shows the Tafel plots for the OER on Ni, Ir, and Ni-Ir alloys. The Ni and Ni-Ir alloys are better electrocatalysts than Ir for oxygen evolution from alkaline solution. At an apparent C.D. of 20 mA/cm^2, the oxygen overpotential on any of these Ni-Ir alloys is slightly lower than that on Ni (see Table I). The lowest oxygen overpotential, which is about 40 mV lower than that on Ni at this current, is observed on the alloy of 50Ni-50Ir. As shown in Table I, Tafel slopes and exchange C.D. for the OER on these alloys are very similar to those on Ni. According to thermodynamic data (13), iridium oxide formed on electrode surfaces of Ni-Ir alloys probably tends to dissolve at such high potentials for the anodic evolution of oxygen.[1] Consequently, oxide films on these alloys, on which the OER takes place, are predominantly composed of nickel oxides despite the bulk composition of the alloys themselves. Therefore, the Ni-Ir alloys are expected to exhibit approximately the same electrochemical activities for oxygen evolution as those on pure Ni.

[1] The alternative explanation is that nickel is preferentially anodized in the alloys. However, recent ellipsometric investigations of the iridium electrodes, polarized at potentials over 1.65V, strongly supported the viewpoint of anodic dissolution of iridium oxide in the OER region (14).

Regarding the OER on nickel from alkaline solutions, it has been reported (15-17) that dual Tafel regions of $2RT/\mathbf{F}$ and $RT/2\mathbf{F}$ are observed at high and low current densities, respectively. Further, the discharge of adsorbed OH^- ions and the spontaneous decomposition of NiO_2 are generally accepted as the rate-determining steps at high and low overpotential, respectively. As indicated in Table I, Tafel slopes of $\sim RT/\mathbf{F}$ are observed on Ni and Ni-Ir alloys. Referring to the reaction scheme proposed by Krasil'shchikov (17), a Tafel slope of $RT/\mathbf{F}$ is possible, if the step for the formation of O^- intermediates, on the substrate S, that is

$$S\text{-}OH + OH^- \rightarrow S\text{-}O^- + H_2O \qquad [1]$$

is rate determining. However, since proton transfer between hydroxylic species is generally rapid (18, 19), this step is unlikely to be rate controlling. Recent work of Tilak and Conway (20) indicates that an "electrochemical desorption" type of mechanism leads to a Tafel slope of $\sim RT/\mathbf{F}$, when the lateral interaction parameter (g) for the adsorbed O^- intermediates is large ($g > 20\ RT$).

Ni-Ru system.—On preanodization, Ni-Ru alloys containing 50 a/o Ru or higher tended to dissolve anodically in KOH solution. Consequently, the colorless electrolyte became straw yellow and fine black particles were found to leach out of the solid electrode. Similar results have been observed by Stoyanovskaya, Khomchenko, and Vovchenko (21), who investigated Ru as anode at the potentials of oxygen evolution. The corrosion of Ru electrode essentially arises from the

[c] The observed current densities in the Tafel region for oxygen evolution on the alloy of 50Ni-50W are above 40 mA/cm^2.
[d] Limiting current density for oxygen evolution on $NiTi_2$ is less than 10 mA/cm^2 (see Fig. 5).

formation soluble ruthenate (RuO_4^{--}) or perruthenate (RuO_4^-) ions during anodic polarization (22, 23). The atomic absorption spectroscopic analysis of the solutions, in which the Ni-Ru alloys are preanodized, reveals that the concentration of Ru-containing ions in each solution is about 1.2 mg/ml after 2 hr of preanodization.

Surprisingly, the electrode of 75Ni-25Ru alloy is quite stable on anodization even in long-term studies. As demonstrated in Table I, the alloy of 75Ni-25Ru exhibits slightly lower Tafel slope ($\sim 2RT/3F$) and exchange C.D. in comparison with these on pure Ni. At an apparent C.D. of 20 mA/cm^2, the oxygen overpotential on this alloy is about 30 mV lower than that on Ni.

Ni-W system.—As indicated in Table I, Tafel slopes observed on the alloys of 75Ni-25W and 50Ni-50W are much higher than that on Ni. On polarization in the oxygen evolution region, tungsten oxide is formed on the surfaces of Ni-W alloys. This oxide film, with a low electronic conductivity leads to the barrier-layer effects (24), and thus results in low transfer coefficients (*i.e.*, high Tafel slopes). Further, the transfer coefficient observed for the OER on Ni-W alloys decreases with increasing tungsten content.

Ni-Ti system.—Tafel plots for the OER on the intermetallic compounds Ni_3Ti, NiTi, and $NiTi_2$ are given in Fig. 5. Except for a lower oxygen overpotential of about 20 mV at an apparent C.D. of 20 mA/cm^2, the intermetallic compound Ni_3Ti behaves very similarly to Ni. Two distinct, linear regions corresponding to Tafel slopes of RT/F and $2RT/F$ are observed on the electrode of NiTi. The OER on this electrode exhibits a higher overpotential than that on Ni. The Tafel plot for oxygen evolution on the intermetallic compound $NiTi_2$ shows an unusually high Tafel slope (close to $5RT/F$) and a limiting current density of about 3 mA/cm^2. According to thermodynamic data (13), TiO_2 is formed in the potential range for oxygen evolution. The species TiO_2 has high corrosion resistance but is a poor conductor for electron transfer (25). Thus, the unusually high slope arises from the barrier-layer effect (24).

Cyclic voltammetric studies on freshly polished electrode surfaces.—The first and second traces of cyclic *i-V* curves on the freshly prepared electrodes of Ni, Ir, and Ni-Ir alloys in N_2-saturated 30 w/o KOH at 80°C are shown in Fig. 6. Prior to the determination of cyclic voltammograms, each electrode was maintained at -50 mV for 20 min. The cathodic evolution of H_2 at this potential may result in the chemisorption of hydrogen atoms on the electrode surface. In the first potential sweep on Ni, Ir, or Ni-Ir alloys, the anodic peak between 0.15 and 0.25V is observed to increase with the length of time of the cathodic pretreatment. Thus, this peak is obviously attributed to the oxidation of the chemisorbed hydrogen atoms on the substrate S, namely

$$S\text{-}H + OH^- \rightleftarrows S + H_2O + e^- \qquad [2]$$

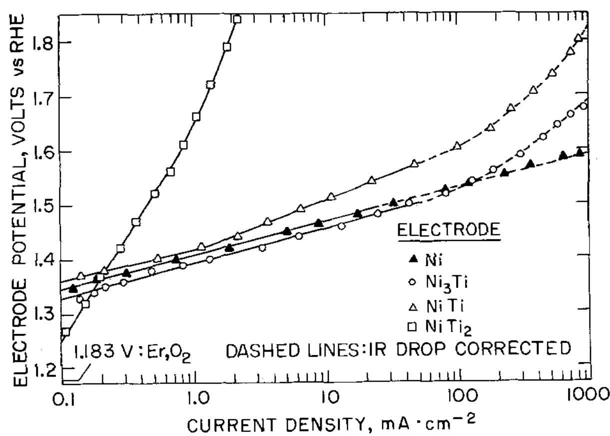

Fig. 5. Tafel plots for oxygen evolution on Ni and three Ni-Ti intermetallic compounds in 30 w/o KOH at 80°C.

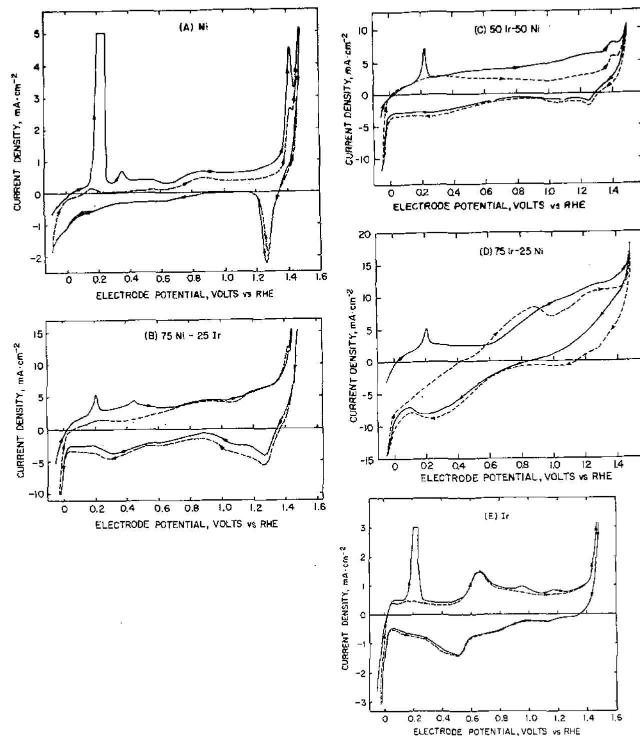

Fig. 6. Cyclic *i-V* curves for freshly prepared electrodes of Ni, Ir, and Ni-Ir alloys in N_2-saturated 30 w/o KOH at 80°C. The solid and dashed lines represent the first and second sweeps (at a rate of 20 mV/sec), respectively.

As seen in Figure 6(A), the second anodic peak on Ni at a potential of $\sim$0.36V disappears on the second trace of the cyclic potential sweep. Furthermore, the position of this peak is found to be independent of the magnitude of potential and the length of time of the cathodic pretreatment. It has been noted (26) that the species $Ni(OH)_2$ is not reduced by the cathodic potential sweep, and thus no peak corresponding to the formation of $Ni(OH)_2$ can be detectable on the second sweep. Therefore, the second anodic peak observed on Ni is no doubt due to the formation of $Ni(OH)_2$ On the electrode surfaces of Ni-Ir alloys, this peak is superimposed by the anodic reaction occurring on Ir sites, and consequently appears not distinguishable.

As has been pointed out (18, 19), the species $Ni(OH)_2$ is further oxidized to β-NiOOH by a proton transfer process at potentials above 0.4V. Following the work of Weininger and Breiter (27), the broad peak observed on Ni (see Fig. 6) in the intermediate potential region of 0.6-1.0V arises from the composite electrode reaction of the growth of $Ni(OH)_2$ and the transformation of $Ni(OH)_2$ to β-NiOOH occurring simultaneously or consecutively. On the Ni-Ir alloys, anodic peaks in the potential region of 0.4-1.2V appear considerably different from those on Ni or Ir. Obviously, these peaks result from the superposition of the anodic peaks on Ni sites with those on Ir sites.

At sufficiently high potential, the species β-NiOOH is formed directly from the substrate Ni (27). As seen in Fig. 6, the formation and reduction of β-NiOOH on Ni take place at potentials of about 1.42 and 1.26V, respectively. The small difference (about 0.16V) between the potentials for the formation and reduction peaks of β-NiOOH implies that the reaction for the formation of β-NiOOH is approximately reversible. These couples for the formation and reduction of β-NiOOH are also detectable on the alloys of 75Ni-25Ir and 50Ni-50Ir, but not on the alloy of 25Ni-75Ir. Consequently, the relative activities of the individual components in the alloys do play a significant role in the reaction of oxide formation on these alloys. Similar results have been reported on smooth noble metal alloys in the work of Rand and Woods (28), who noted that the electrocatalytic activities of the alloys vary with their surface

composition. The latter is in turn strongly dependent on the electrochemical pretreatment of the alloys.

Cyclic voltammetric studies on preanodized electrode surfaces.—Investigations of the cathodic *i-V* curves on preanodized electrodes may lead to important complementary information to identify the major species in oxygen-containing films formed on its surface during the OER. After anodization at an apparent C.D. of 20 mA/cm^2 for 80 hr, the first, second, and tenth cathodic *i-V* curves, obtained from the continued cyclic voltammograms on Ni, Ni_3Ti, and the alloys of 50Ni-50Ir and 75Ni-25Ru, are shown in Fig. 7. Only one reduction peak corresponding to β-NiOOH is observed on Ni electrode. This result is consistent with the work by McIntyre and Kolb (26).

As illustrated in Fig. 7, the first cathodic sweeps on 50Ni-50Ir, 75Ni-25Ru, and Ni_3Ti exhibit electrochemical behavior similar to that on Ni. No distinguishable reduction peak is detected on the first cathodic sweep except for the one corresponding to the reduction of β-NiOOH at about 1.26V. On the preanodized alloy of 50Ni-50Ir, two additional peaks, which are due to the reduction of oxide layer on Ir sites as reported by Böld are Breiter (28), are detectable starting in the third sweep. The second cathodic *i-V* curve on the alloy of 75Ni-25Ru also exhibits two additional peaks which are probably attributed to the reduction of oxide layers on Ru sites. Further, the heights of these reduction peaks on the alloy of 50Ni-50Ir or 75Ni-25Ru increase with increasing the number of potential sweeps. These observations indicate that the oxide film on the preanodized electrodes of Ni-Ir or Ni-Ru alloys is predominantly composed of nickel oxides rather than a mixed oxide of the same composition as the alloy itself. According to the Pourbaix diagrams (13), the oxides of iridium or ruthenium on anodized electrode surfaces of these alloys are expected to dissolve at the potentials in the range for oxygen evolution from alkaline media. Conversely, nickel oxide is extremely stable in alkaline solutions. Thus, when Ni-Ir or Ni-Ru alloys are utilized as anodes, the OER takes place substantially on a layer of nickel oxide. This is the reason for Ni-Ir and Ni-Ru

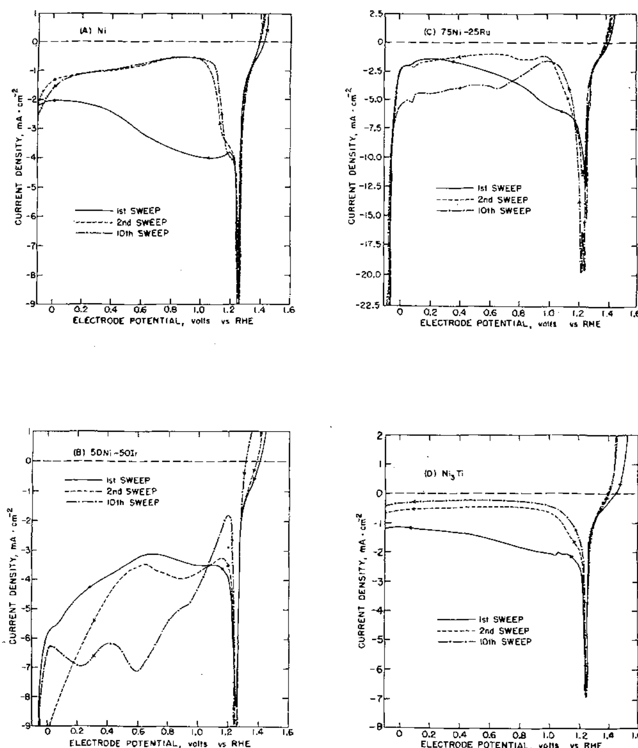

Fig. 7. Cathodic *i-V* curves obtained from the continuous cyclic voltammograms on Ni, Ni_3Ti, and the alloys of 50Ni-50Ir and 75Ni-25Ru in 30 w/o KOH at 80°C with a potential sweep rate of 20 mV/sec. Each electrode was preanodized at a constant C.D. of 20 mA/cm^2 for 80 hr.

alloys to exhibit the same electrocatalytic activities for oxygen evolution as on Ni. The stability of oxide films, formed on metals or alloys under the operating conditions is a significant criterion in the selection and evaluation of oxygen evolving electrodes.

Conclusions

In the potential range for oxygen evolution from alkaline solutions, Ni-Ru alloys containing 50 a/o or more Ru are unstable, while oxide films with extremely low conductivity are formed on the electrode surfaces of Ni-W alloys and $NiTi_2$. Most of stable Ni-based alloys or intermetallic compounds investigated exhibit practically the same electrocatalytic activities as pure Ni. Decreases in oxygen overpotential at an apparent C.D. of 20 mA/cm^2 on the alloys of 50Ni-50Ir, 75Ni-25Ru, and Ni_3Ti are about 40, 30, and 20 mV, respectively, in comparison with that on Ni. With the Ni-W alloys and the $NiTi_2$ intermetallic compound on which poorly conducting oxide films are formed, the relatively higher Tafel slopes observed arise due to barrier layer effect.

Iridium oxide or ruthenium oxide formed on the electrode surfaces of Ni-Ir or Ni-Ru alloys tend to dissolve in the potential region for oxygen evolution. Cyclic voltammetric studies reveal that the electrode surfaces of these alloys after prolonged anodization are predominantly composed of nickel oxide, which consequently determines the kinetic parameters of the oxygen evolution reaction. Therefore, in addition to the electronic conductivity and catalytic properties of oxide films, the stability of these films under the operating conditions is an extremely significant criterion in the selection and evaluation of electrocatalysts for the oxygen evolution reaction.

The present work confirms that, for the anodic evolution of oxygen, there is no simple dependence of the electrocatalytic activities of the alloys on their electronic properties, because of coverage of the alloy electrode surface by films predominantly composed of nickel oxide. However, the effects of relative activities of the individual components in the alloys on the oxide formation reaction on the bare surface of the alloys, are indeed detectable. It was also shown in this study that the potentiodynamic technique at slow sweep rates (say, 0.1 mV/sec) is an efficient, time-saving, and accurate method in determining kinetic parameters of an electrode reaction.

Acknowledgments

The authors wish to thank Mr. F. J. Salzano and Dr. R. H. Wiswall for their constant interest and encouragement throughout this study. Special thanks are due to Professor B. E. Conway and Dr. S. Gottesfeld for their helpful discussions. The authors are also grateful to Mr. G. Kissel for his useful suggestions and invaluable assistance in the design and construction of experimental equipment.

Hot Corrosion Resistance of Nickel-Chromium-Aluminum Alloys

Gilbert J. Santoro and Charles A. Barrett

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

The hot corrosion resistance of nickel-chromium-aluminum alloys was examined by cyclically oxidizing sodium sulfate-coated specimens in still air at 900°, 1000°, and 1100°C. The compositions tested were within the ternary region: Ni; Ni-50 atom percent (a/o) Cr; and Ni-50 a/o Al. At each temperature the corrosion data were statistically fitted to a third-order regression equation as a function of chromium and aluminum contents. From these equations corrosion isopleths were prepared. Compositional regions with the best hot corrosion resistance were identified.

In recent years many promising compositions have been identified in the nickel-chromium-aluminum (Ni-Cr-Al) system for use in application requiring a high degree of high temperature corrosion resistance. Such applications have included coatings for many types of alloys (1) and as the matrices for oxide dispersion-strengthened alloys (2). Recently a program was initiated at NASA-Lewis to determine the optimum compositions with the best balance of cyclic oxidation and hot corrosion resistance, tensile properties, ductility, and strategic element content. In pursuit of this objective an investigation was completed (3) wherein nickel-rich alloys in the Ni-Cr-Al system were evaluated for their cyclic oxidation resistance in still air at 1100° and 1200°C. A first approximation oxidation attack parameter was derived which was related to the Cr and Al content by a multiple linear regression analysis. The resultant equations were translated into contour diagrams showing regions with minimum oxidation attack. This paper is the second step in the over-all program. The same alloys as were used in Ref. (3) were examined in this study for their hot corrosion resistance by cyclically oxidizing sodium sulfate (Na_2SO_4) coated specimens in still air at 900°, 1000°, and 1100°C. The compositions tested were within the ternary region: Ni; Ni-50Cr; and Ni-50Al [all compositions are given in atomic percent (a/o) in this paper]. A limited number of alloys were coated with Na_2SO_4 containing 10 weight percent (w/o) sodium chloride (NaCl) in order to determine the effect of NaCl on the corrosion process. The extent of the corrosion was determined by the specimen's net weight change, the maximum depth of attack, and by the weight of its spalls. The maximum depth of attack data, being the least ambiguous measure of the corrosion, were related to Cr and Al content at each temperature by a multiple linear regression analysis. The resultant third-order regression equations were translated into corrosion isopleths which indicated compositional regions of minimum attack. The corrosion contours from this study were compared to those from Ref. (3) for oxidation resistance, and regions of simultaneously good oxidation and hot corrosion resistance were identified.

Materials

All of the alloys specifically prepared for this program were vacuum melted in zirconia (ZrO_2) crucibles and cast in zirconia shell molds. The zirconium (Zr) pickup of up to 0.6 w/o was detected. Each mold consisted of a tree of ten 2.5 × 5.1 × 0.25 cm coupons, each with its own riser. For each coupon used the risers were removed and analyzed by atomic absorption for chromium and aluminum. The composition of these alloys are given in Table I, castings 1-11.

Most of the supplement alloys used in this study were obtained from a previous program (4) and had been melted in alumina (Al_2O_3) crucibles and cast into 1.9 cm diam cyclindrical ZrO_2 molds. These castings had been annealed 24 hr at 1200°C in quartz tubes which had been evacuated and backfilled with argon and sealed. Their compositions are given in Table I, castings 15-27. Another supplemental alloy was arc melted in a copper mold (casting 13 of Table I). Finally the commerical alloy, IN-671, was also tested as its composition is essentially Ni-50.9Cr, see Table I.

All the specimens used in this investigation were glass-bead blasted, ultrasonically cleaned in alcohol, and weighed prior to testing.

Metallographic examination of the as-cast materials revealed four general types of structures. Figure

Table I. Chemistry and phases of the alloys

Alloys	Composition (a/o) Cr	Al	As-cast phases

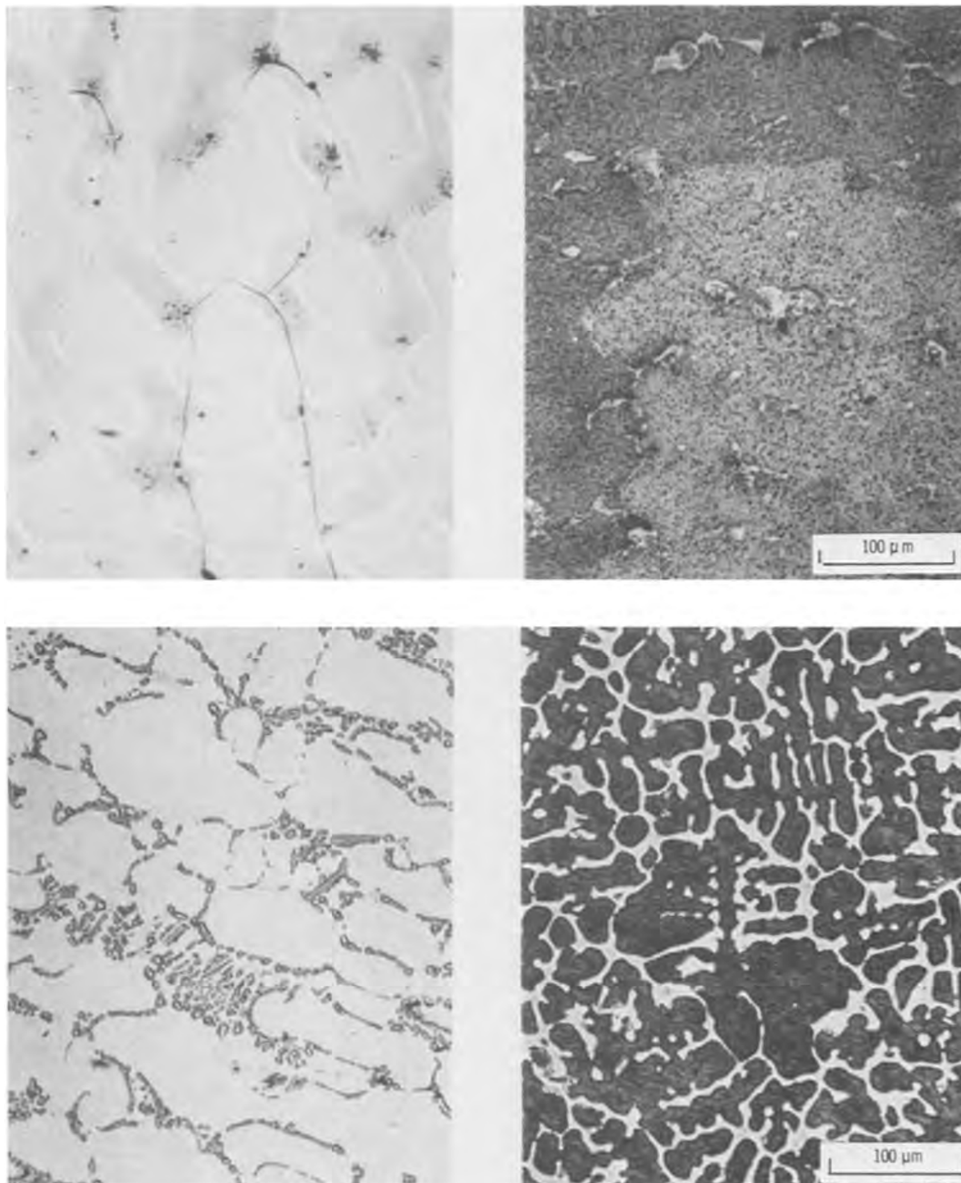

Fig. 1. Representative microstructures in the Ni-Cr-Al system. (a, upper left) Ni-15.81Cr-5.77Al; γ phase. (b, upper right) Ni-9.73Cr-17.18Al; $\gamma + \gamma'$ phase. (c, lower left) Ni-15.98Cr-17.54Al; $\gamma' + \beta$ phase. (d, lower right) Ni-11.5Cr-25.58Al; $\gamma' + \beta + \alpha$ phase.

1(a) is a single-phase structure typical of γ-nickel solid solution, of γ'-(Ni_3Al), and of β-(NiAl). Figure 1(b) shows the $\gamma + \gamma'$ structure found in most nickel base superalloys. Figure 1(c) represents the $\gamma' + \beta$ structure and finally Fig. 1(d) consists of a blocky structure of γ' and β with small particles of chromium solid solution (α-Cr) in the β. Tables I lists the as-cast phases of the alloys tested in this study and Fig. 2 is a phase diagram of the region of interest (5).

Procedures

Test procedures.—Prior to testing sample dimensions were measured and in particular the thickness was measured to a precision of ± 1 μm. Prior to exposure in the furnace, samples were coated with 1 mg/cm^2 of Na_2SO_4, or in some cases 1 mg/cm^2 of the mixture Na_2SO_4 + 10 w/o NaCl. Application of the salt coating was accomplished by heating a weighed sample on a hot plate set at about 200°C and spraying one side with a saturated solution of salt using an airbrush. The sample was then cooled and weighed to check for the correct amount of salt deposition. The same procedure was used to coat the other side of the specimen. The samples were then ready for the cyclic specimen furnace which has been described in detail (6). Samples were thermally cycled to allow 1 hr at temperature and a minimum of 40 min cooling in static air. A typical temperature profile is shown in Fig. 3. Samples reached

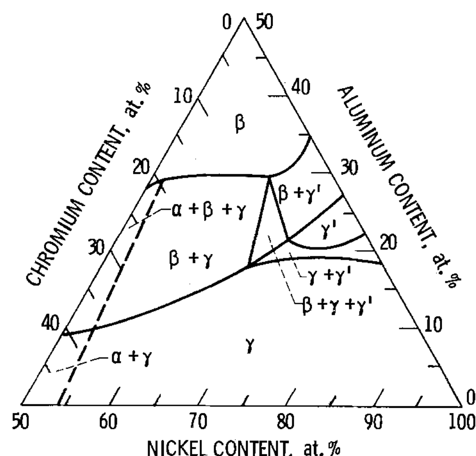

Fig. 2. Phase diagram in the Ni-Cr-Al system at 1100°C after Taylor and Floyd (5).

the highest test temperature in less than 2 min after insertion into the furnace and cooled to ambient temperature in less than 20 min after removal from the furnace. Samples of each alloy were exposed for 100 cycles at 900°, 1000°, and 1100°C. Weight change was determined at regular intervals throughout the test. At

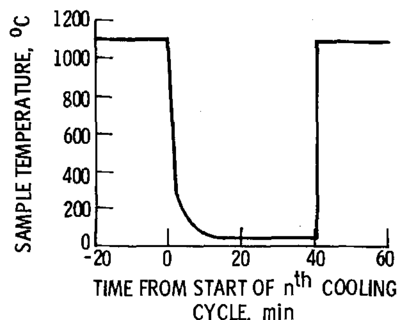

Fig. 3. Temperature profile of typical thermal cycle

the conclusion of the furnace testing the accumulated spall for each sample was weighed and examined by x-ray diffraction. Each corroded sample was also examined by x-ray diffraction and by metallography. The thickness of the alloy visibly unaffected by the corrosion attack was measured on metallographically prepared cross sections with a microscope cathetometer at a magnification of 100X. The original thickness minus the above measurement all divided by two then is defined here as the maximum depth of penetration of the corrosion attack.

Statistical procedures.—A digital computer program, NEWRAP, was used to perform the regression analyses (7). A two independent variable polynomial model was *a priori* judged as suitable for this data. The dependent variable was the maximum depth of corrosion, D, and the two independent variables were C and A, the atomic percent concentrations of chromium and aluminum, respectively, in the alloy. The approach was to begin with a first-order polynomial and to go to higher order equations if necessary. The decision as to which order polynomial provided the best fit was judged from the fraction of total variation (total sum of squares) accounted for by a particular regression equation and how reasonable were the predictions of this equation at locations away from the data points. This fraction of the total variation explained by the regression equation is called the coefficient of determination, R^2

Nonsignificant terms were deleted from the model by the back-rejection technique where the critical significance level is supplied as input. The strategy used here for a given order equation was to minimize the standard error of estimate and still predict reasonable values over the composition range.

It is possible to significantly increase the R^2 of a regression equation by including other factors that might account for a significant added fraction of variability. This is accomplished by the addition of a dummy variable, Z, and setting it either to 0 or 1. Thus in Ref. (3) the alloys were divided into two groups: those melted in zirconia crucibles and not annealed, $Z = 1$, and those that were melted in alumina crucibles and annealed, $Z = 0$. The addition of the dummy variable significantly raised the R^2 and lowered the standard error of estimate. From this result it was inferred that zirconia impurity affected the oxidation resistance. The dummy variable approach was included in this study for each of the three temperature regression runs.

In corrosion studies of this type the dependent variable (in this case the maximum depth of attack, D) usually has the same relative error over a wide range of values. This situation requires the dependent variable to be transformed to the logarithm of the variable. The process is termed homogenizing the error variance.

Results

Measure of corrosion.—The extent of corrosion was measured by the net specific weight change, the accumulated weight of spall, and the maximum depth of attack. In general all three measures gave consistent results. Samples which changed little in weight usually spalled only slightly and had relatively little depth of attack. The reverse statement is also generally true. Figure 4(a) to (c), contains the weight change data

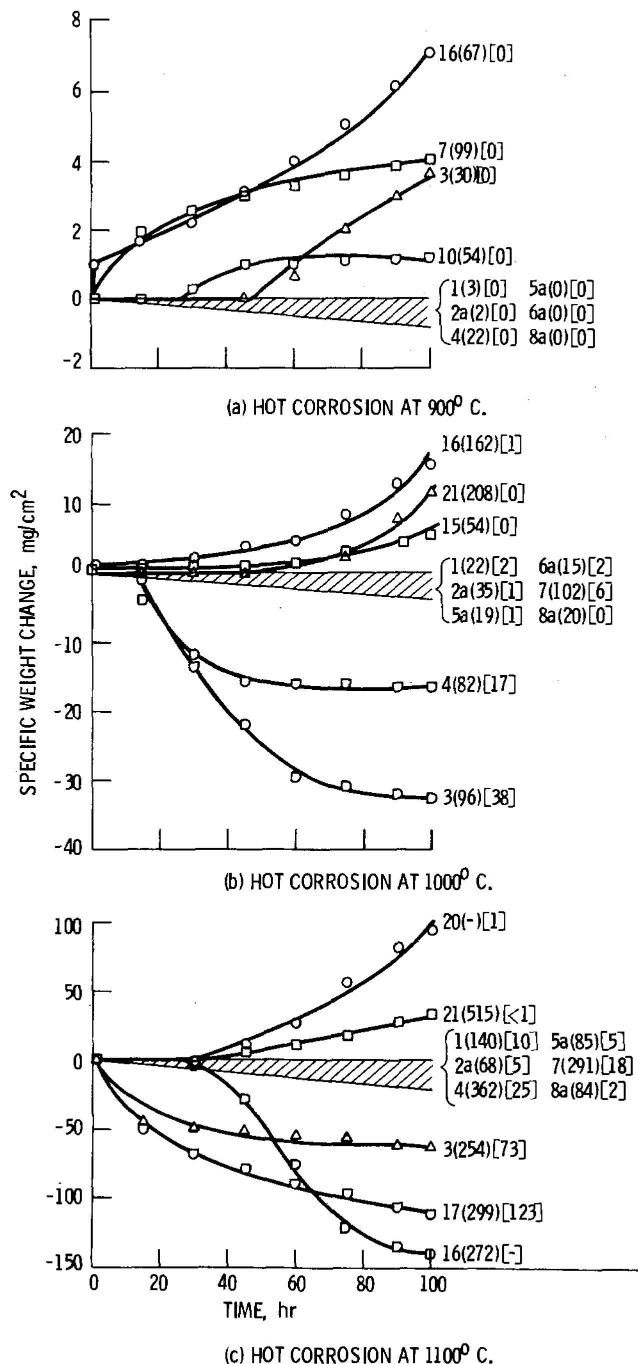

Fig. 4. The first number designates the alloy; the number in parentheses is the maximum depth of attack μm; the number in brackets is the specific accumulated spall weight, mg/cm^2.

from 900° to 1100°C of a random selection of the alloys tested. The values in parentheses following the alloy designations are the maximum depth of attack in micrometers and the values in brackets are the specific accumulated spall weight in milligrams per centimeter squared. The data can be classified into three categories: (*i*) alloys with relatively little weight change, (*ii*) alloys with substantial weight gains, and (*iii*) alloys with substantial weight losses.

A complete set of the corrosion data is presented in tabular form in Table II where the temperature dependence for each alloy is readily discernable. Thus at 900°C only alloy 17 spalled (and then but slightly) while many samples spalled at 1100°C. Comparing the last two columns of Table II, specific net weight change and specific weight of accumulated spall, a negative weight change in the former column ought to be accompanied by a nearly equal weight of spall in the latter column. A fair comparison is observed in this re-

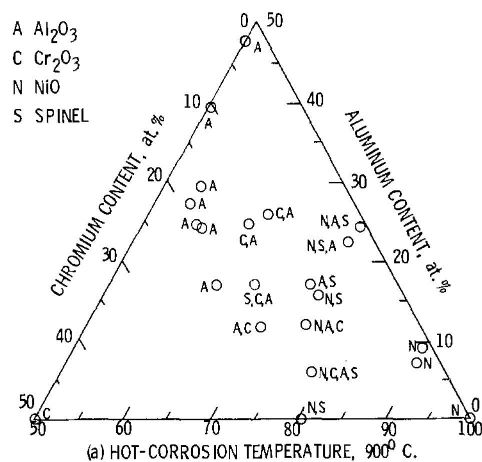
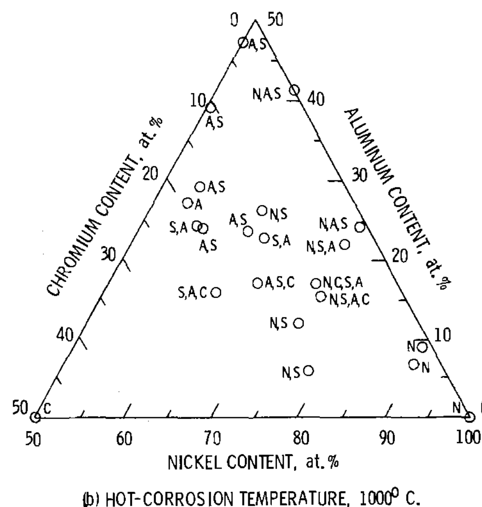
spect for most of the alloys with the notable exception of alloys 22 and 23. For these two alloys there is a large net weight loss but no detectable spall. Since a spall shield surrounded the specimens when they were cooling, a large fraction of the spall should have been collected even if the specimens spalled explosively. Thus it must be assumed these two specimens had spalled either at temperature or while being raised out of the furnace.

X-ray diffraction and metallography.—After the furnace exposure both the retained and the spalled oxides were identified by x-ray diffraction. These oxide phases are listed in Table III. With but few exceptions all specimens formed multioxide phases. Figure 5(a) to (c) is a graphical presentation of the x-ray diffraction data. For the purpose of this figure the spalled and retained oxide data were combined. The figure illustrates two major points. The presence of chromium in the alloy decreases the aluminum content needed for Al_2O_3 formation in the scale. An explanation of this result is given Ref. (8). The other point is that with increased temperature more aluminum is required in the alloy for Al_2O_3 formation. The opposite behavior occurs in straight oxidation because of the increased diffusivity of the aluminum ion with temperature. But under the hot corrosion conditions of this study the spalling increased with temperature and overshadowed





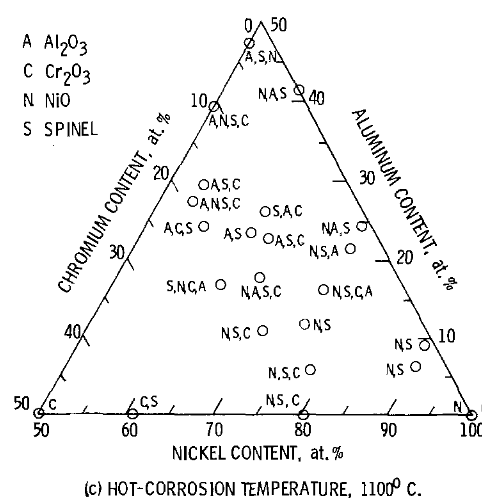


Fig. 5. Oxide phases in the scale of hot-corroded specimens. (Phases are listed in order of decreasing line intensities.)

* Listed in order of decreasing line intensities. (?) Insufficient lines for positive identification.

this effect. Thus at higher temperatures a greater aluminum content in an alloy is necessary to maintain a sufficient level to compensate for that lost due to the increased spalling.

The modes of attack during hot corrosion are described in Table III by listing three major morphological aspects frequently observed in corroded alloys and by identifying which ones are applicable to each of the alloys tested. The three modes are: (*i*) oxide penetration, often along grain boundaries; (*ii*) formation of a depleted zone immediately beneath the scale; and (*iii*) internal corrosion products and/or void formation. Examples of these corrosion modes are presented in Fig. 6(a) and (b).

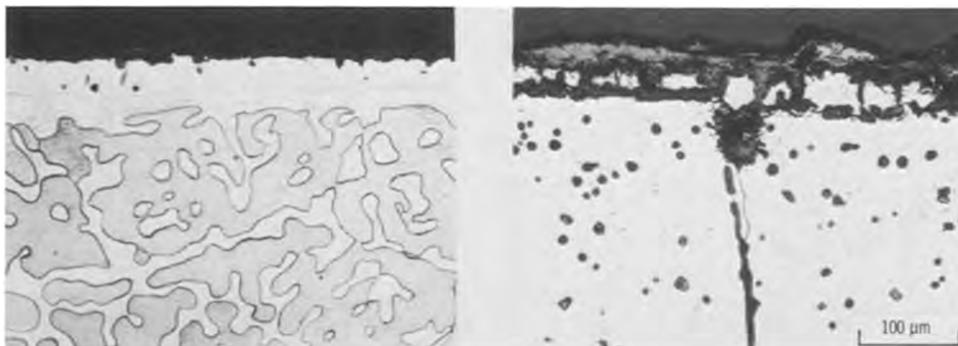

Fig. 6. Hot corroded Ni-Cr-Al alloys at 1100°C showing typical corrosion morphologies. (a, left) $\gamma' + \beta + \alpha$ alloy, Ni-11.50Cr-25.58Al shows a thin retained scale, a depleted zone, and the unaffected alloy. (b, right) γ alloy, Ni-15.81Cr-5.77 Al shows a thick retained scale, oxide penetration, and internal corrosion extending deep into the alloy.

Sodium chloride effect.—Table IV summarizes the data concerning the effect of adding NaCl to the Na_2SO_4 on the hot corrosion of a limited number of alloys. At 900°C the effect is quite apparent. The NaCl caused the scale to spall and thereby accelerated the attack. Also NiO was a prominent phase in the spall of all specimens indicating a depletion in their surface concentration of aluminum and chromium. This result agrees with literature reports indicating sodium chloride vapors can disrupt the protective scale of alloys (9, 10).

At 1100°C the effect of the NaCl is not so evident. NiO was consistently a predominant phase of the spall of specimens with NaCl in their coating but was not always detected in the spalls of specimens corroded in the absence of NaCl. However at 1100°C the presence of NaCl did not seem to be consistently detrimental to the corrosion resistance of the alloys.

Discussion

How a material corrodes depends not only on its composition but also on the testing parameters used. Since there are many hot corrosion testing procedures in use today (11) it would be very difficult to directly compare the corrosion results obtained here with those of other laboratories. Of course the ultimate test procedure would be to test the material in actual application, *e.g.*, in a gas turbine engine. This procedure is not practical for use with all candidate materials and a number of screening-type tests are required so that only a few

"best" candidates are chosen for the actual application test. The procedure used in this investigation must be considered as a screening-type test. Its value lies in the identification of those "best" compositions for further testing.

Based on the data collected in this study, a multiple linear regression analysis was used to identify the "best" compositions in the Ni-rich end of the Ni-Cr-Al system. The procedure used was discussed earlier. The maximum depth of attack data, being the least ambiguous measure of the corrosion, were chosen to relate corrosion to the Cr and Al content of the alloys at each temperature. A summary of the statistical data appears in Table V(a) to (c), and is called the analysis of variance table (ANOVA). Included are the final regression equations. The third order, two independent variables regression equations were translated by a computer program into corrosion isopleths. Figure 7(a) to (c) are the resultant contours at 900°, 1000°, and 1100°C, respectively. Although the contours are related to the logarithm of the maximum depth of attack in micrometers, log D, the values listed in Fig. 7 within the contours are D directly. At 900°C a large minimum attack area exists at the higher chromium, higher aluminum compositions. At 1000°C this area decreases in size. At 1100°C two small areas of minimum attack exist at the edges of the diagram, one centered at about Ni-30Cr-20Al and the other centered at Ni-33Al. These two areas overlap areas of minimum oxidation attack observed in Ref. (3) and are shown here in Fig. 8.

Fig. 7. Hot corrosion isopleths

One effect of increasing temperature is to increase the rate of corrosion which in turn provides a better separation of the corrosion resistance of the alloys. But a surprising feature of Fig. 7 is that alloys with very low aluminum content corroded more at 1000°C than they did at 1100°C. Since the vapor pressure of Na_2SO_4 at 1100°C is moderate, 10^{-1} Nm^{-2} (10^{-6} atm) (12), the decrease in corrosion at 1100°C for these low aluminum-containing alloys cannot be attributed entirely to the loss of Na_2SO_4 via vaporization.[1] The entire Na_2SO_4 coating can be lost, however, by the spalling of the outer portion of the scale. Having lost their Na_2SO_4 coatings the alloys could then heal themselves and further corrosion would be by pure oxidation and at a much lower rate. Figure 7(c) then could represent the recovery ability of those hot corroded alloys that spalled. And most of the alloys at 1100°C did spall. Since the best hot corrosion resistant compositions in Fig. 7(c) overlap the best oxidation resistant compositions in Fig. 8, it can be generalized that for these alloys the ones with the best oxidation resistance have the best hot corrosion recovery ability. In gas turbines the exposure to hot corrosion conditions is thought to be intermittent (10). Thus the ability of material to recover from an hot corrosion attack could be an important factor in the life of that material when used in gas turbine engines.

As was done in Ref. (3) a dummy variable was used to determine if a significant variation could be ascribed to differences in the preparation of the alloys. One set of alloys came from a previous program (4) and were

[1] Fred J. Kohl (NASA-Lewis) extrapolated his 900°C rate data from slowly flowing oxygen and calculated a rate of vaporization of 3.5×10^{-2} mg/cm^2 hr^{-1} for 1100°C. This value would represent an upper limit as the tests in this paper were conducted in still air. Thus sodium sulfate (or perhaps more correctly its reacted products) ought to be present throughout most of the 100 hr duration of these tests.

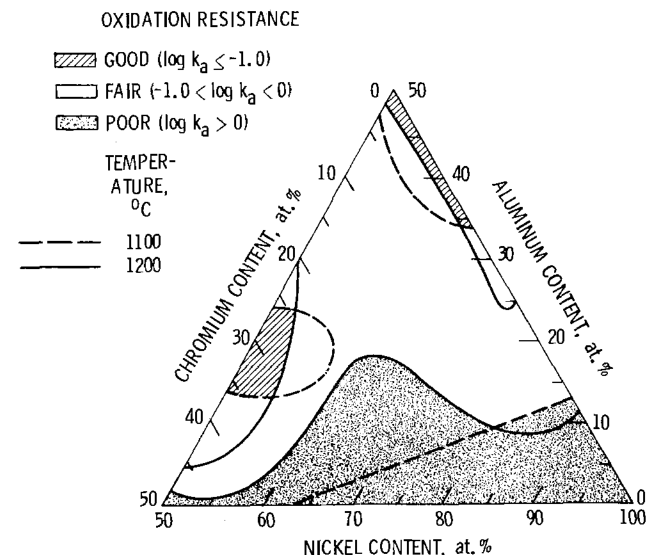

Fig. 8. Over-all cyclic oxidation resistance for Ni-Cr-Al alloys at 1100° and 1200°C in still air; Ref. (3).

melted in Al_2O_3 crucibles and annealed. The alloys prepared specifically for this program were melted in zirconia crucibles and were not annealed. No significant preparation effect could be detected for the 900°C data, *i.e.*, there was not a significant rise in R^2 or lowering of the standard error of estimate. Only a small effect could be detected for the 1000°C data. But at 1100°C a marked difference was detected. The statistical data and the regression equations are listed in Table V (d). Figure 9(a) and (b) are the resultant corrosion isopleths. Figure 9(a), where the dummy variable was set to zero, applies to alloys melted in Al_2O_3 crucibles and annealed. Figure 9(b), where the dummy variable was set to one, applies to alloys melted in ZrO_2 crucibles and not annealed. Analogous to the oxidation of these alloys (3) the latter preparation of the alloys provided superior corrosion resistance. Thus either trace amounts of ZrO_2 and/or the absence of annealing has a significant beneficial effect on the hot corrosion resistance of Ni-Cr-Al alloys.

Summary of Results

Alloys in the nickel-chromium-aluminum system were cyclically hot corroded at 900°, 1000°, and 1100°C for 100 hr. The data were statistically treated to obtain corrosion isopleths at each temperature as a function composition. The hot corrosion results were compared with previous work on the oxidation of these same alloys. The results of this work are summarized as follows:

1. Compositions with simultaneously good oxidation and hot corrosion resistance were found to be centered at about Ni-33Al and Ni-30Cr-20Al.

2. Alloys melted in zirconia crucibles and not annealed had significantly greater hot corrosion resistance at 1100°C than alloys melted in alumina crucibles and annealed. At lower temperatures differences in the preparation of the alloys did not significantly affect their hot corrosion resistance.

3. At low temperatures, the presence of NaCl in the Na_2SO_4 caused the scales of the samples to spall and thereby to increase their rate of corrosion.

Oxidation of an Fe-9 w/o Ni Alloy in CO_2 at 700°-1000°C

W. J. Tomlinson[1] and I. A. Menzies[2]

Corrosion and Protection Centre,
University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

The oxidation of an Fe-9.21% Ni alloy in dry CO_2 has been studied at 700°-1000°C using thermogravimetry, metallography, and electron-probe microanalysis. At all temperatures the kinetics for oxygen consumption (weight gain) followed a linear-parabolic-linear sequence. During the initial linear stage the scale consisted mainly of magnetite with pockets of wustite at the scale/alloy interface, and the observed activation energy of 193 ± 74 kJ $mole^{-1}$ is considered to be due to the dissociation of CO_2 into CO and adsorbed oxygen on the outer magnetite surface. During the parabolic oxidation stage a continuous alloy layer containing ≈60% Ni at the scale/alloy interface forms a barrier to Fe diffusion, and the associated activation energy of 207 ± 33 kJ $mole^{-1}$ is for the diffusion of Fe through the layer. The final linear kinetic stage corresponds to the breakdown of the barrier layer and a return to linear oxidation kinetics with an activation energy of 155 ± 13 kJ $mole^{-1}$ for the dissociation of CO_2 on the outer surface. During the final linear stage extensive subscale formation with pronounced intergranular penetration occurs and alloy particles containing ≈55-60% Ni are isolated in the wustite matrix. The wustite of the scale and subscale are continuous and contain ≈1.0 w/o Ni. Detailed information is presented of the Ni redistribution during oxidation and its correlation with the morphological structures and the oxidation kinetics. The associated oxidation processes are discussed.

Reviews on the oxidation of Fe-Ni alloys (1, 2) showed a considerable amount of information on their high temperature behavior in oxygen and air, but relatively little was known about their oxidation behavior in other gases. Morris and Smeltzer (3) have determined the kinetics and general morphological structures on Fe-Ni alloys containing up to 40% Ni oxidized in CO_2 at 1000°C. However, except for alloys containing 2, 36, and 48% Ni (4, 5, 6) there have been no investigations involving detailed and systematic information on the changing Fe and Ni distribution during oxidation of Fe-Ni alloys in CO_2 over a range of temperatures. The objects of the present investigation were to study the kinetics of oxidation of an Fe-9.21% Ni alloy at 700°-1000°C in CO_2, to examine the scale and subscale morphology as a function of temperature and time, and to determine qualitatively and quantitatively the Fe and Ni composition changes during the oxidation process.

Experimental

The chemical analysis (w/o) of the alloy was: Ni, 9.21; C, 0.0014; N, 0.0017; Si, 0.01; S, 0.005; P, 0.002; Cr, 0.02; Cu, 0.011; Al, 0.01; and Mn, Mo, W, V, Ti, and Co all < 0.01, and the CO_2 was special analytic grade which after drying had impurities less than (ppm): O_2, 6; N_2, 20; H_2O, 10. Full experimental details of the specimen preparation, kinetic, metallographic, and EPMA techniques have been given elsewhere (4). The essential features of the quartz spring thermobalance were that the weight gains were measured to <0.2 mg cm^{-2} and the temperature variation was <4° at 1000°C. The P_{O_2} due to dissociation of CO_2 at 1000°C is only 1.2×10^{-5} atm (20) with the values being less at the lower temperatures.

Results

Kinetics of oxidation.—At all temperatures in the range 700°-1000°C the kinetic behavior was broadly similar and followed the sequence linear, parabolic, linear (Fig. 1-3). Note that in Fig. 2 some points near the origin have been omitted for clarity. The initial linear stage is seen at 800°-950°C, while below 800°C the initial linear stage was absent or not well defined, and at 1000°C the rate of oxidation in the early stages was too fast to allow the kinetic pattern to be clearly

established. The parabolic region occurred over the whole temperature range (Fig. 3) although the kinetics were not strictly parabolic at 750° and 800°C. The final stage of oxidation was always linear. The clearest over-all pattern of kinetics is seen at 850°-950°C. The weight gains and times of transitions were difficult to define accurately and the best values are shown in Table I. It is seen that the duration of the

Table I. Specimen weight gain and time of exposure at the start of the parabolic and final linear oxidation stages

	Parabolic stage		Final linear stage	
Temperature (°C)	Wt. gain (mg cm^{-2})	Time (hr)	Wt. gain (mg cm^{-2})	Time (hr)
1000	9	0.25	19	1
950	4	0.5	15	4.5
900	2	0.25	26	6
850	5	3	12	15
825	—	—	18	18

800	6	5	10	18
700	1	0.5	2	5
700	1	1	4	20

initial linear stage tended to decrease, and the transition to the final linear stage occurred at higher weight gains and shorter exposure times as the temperature of oxidation increased. Typically the oxidation rate in the second linear stage was about half that in the first linear stage. Arrhenius functions for the three stages are shown in Fig. 4 and the calculated (95% confidence limit) activation energies were 193 ± 74, 207 ± 33, and 155 + 13 kJ mole^{-1} for the initial linear, parabolic, and final linear oxidation stages, respectively.

Morphology.—Specimens exposed for 5, 10, 20, 30, and 45 min and 1, 2, 4, 6, and 8 hr at 1000°C for 0.5, 1, 3, 6, and 10 hr at 900°C, and for 5, 10, and 25 hr at 800°C were examined, and at all temperatures the same sequence of structures was observed (Fig. 5-8). In the early stages of oxidation the scale consisted essentially of magnetite, and Ni accumulated in the alloy as a layer at the metal/scale interface and showed marked intergranular penetration which eventually enveloped grains. Subsequent formation of pockets of wustite in the magnetite at the scale/alloy interface and precipitation of subscale oxide were both associated with the greater accumulation of Ni at grain boundaries (Fig. 5a). Growth of the wustite pockets to form a continuous thick inner layer (here shown with magnetite precipitated during cooling) was associated with the breakdown of the Ni-enriched layer to form isolated metal particles in the subscale wustite which became smaller as the distance from the subscale/alloy interface into the subscale increased (Fig. 5b). A mature subscale is shown in Fig. 6b where it is seen that the subscale and scale wustite is continuous and that the metal particles are uniformly dispersed. The unevenness of the interfaces made it difficult to determine the thickness of the layers. However, after the early stages, particularly at 1000°C, it was possible to obtain a reasonable estimate of the magnetite layer thickness and this is shown in Fig. 7a and 8. With the ancillary information incorporated in the figures concerning the continuity of the Ni-rich layer and the

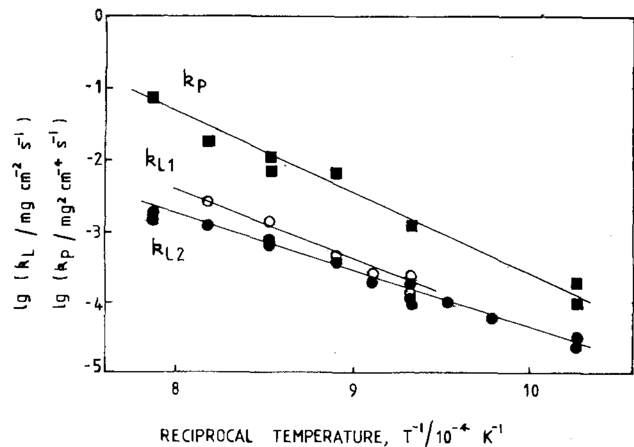

Fig. 4. Arrhenius functions of the linear and parabolic oxidation kinetics.

(a) 5 hr exposure, pockets of darker wustite in magnetite scale opposite largest part of oxide subscale regions; (b) 10 hr exposure, magnetite now a layer on the outside, wustite (with precipitated magnetite) between magnetite and subscale.

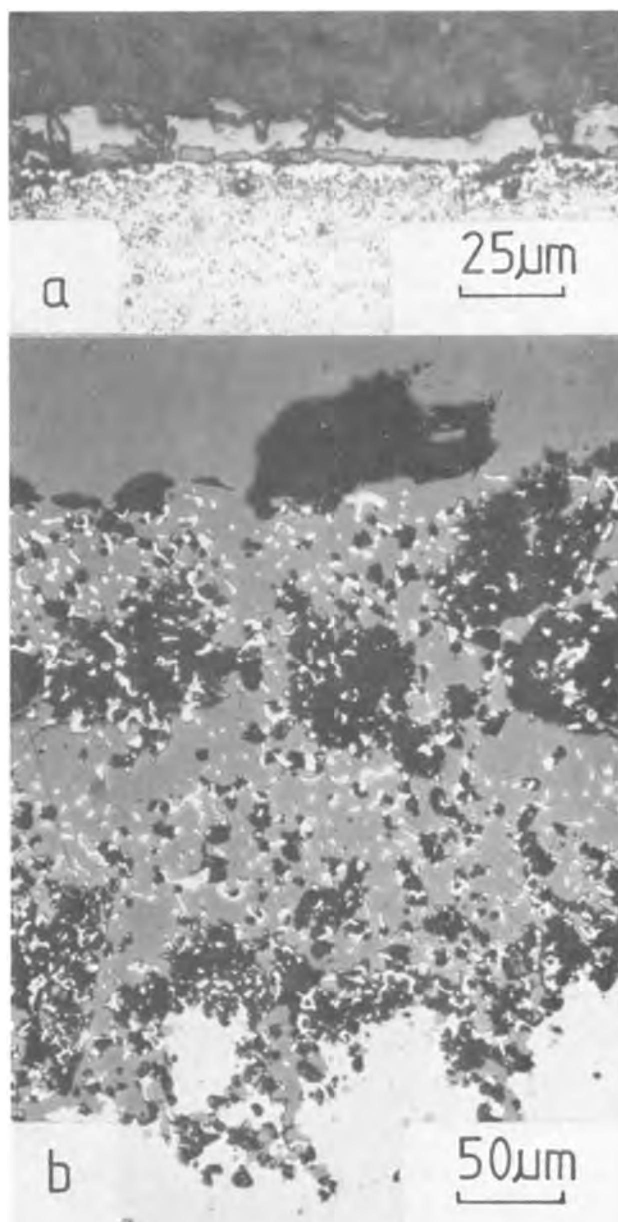

Fig. 6. Scale (at top) and subscale on the alloy oxidized at 1000°C. (a) 10 min exposure; etched nital; nearly continuous pockets of darker wustite in the magnetite at the alloy surface opposite the unetched Ni-enriched layer (light region at alloy surface) in the alloy: (b) 10 hr exposure; unetched; metal particles in the wustite subscale.

kinetics of oxidation (*cf* Table I) it is seen that the magnetite thickness increased during the initial linear stage, decreased during the parabolic stage, and remained constant during the final linear stage when the Ni-rich layer had been dispersed. Owing to the very uneven interfaces, the maximum thicknesses of the wustite layer and the subscale are of limited value. However, they do show that the breakdown of the Ni-rich layer is associated with the start of subscale oxide precipitation, and also give an indication of the relative thicknesses of the layers (Fig. 7a).

Electron probe microanalysis.—The distribution and concentration of Fe and Ni were determined in the scale and subscales of specimens oxidized for 10 and 30 min, and for 1, 2, 4, 6, 8, and 10 hr at 1000°C (Fig. 9, 10, 7b, 7c). Figure 9 shows some of the data for the changing general distribution. Iron phases are difficult to distinguish owing to limited contrast, but the Ni shows clearly the limited amount uniformly dispersed in the scale and the substantial amount segregated within the subscale. It is seen (Fig. 9) that the Ni-rich layer started to breakdown after 1 hr and subsequently metal particles were isolated in the subscale. Pronounced intergranular penetration of Ni occurred. On each specimen many linear scans were examined and Fig. 10 showing the considerable variation along line X of Fig. 9c is typical. The Ni concentration about the grain boundary oxide at B is high (at F and G). It was always observed that Ni accumulation preceded oxide precipitation. Variation parallel to the surface was also considerable, *e.g.*, after 2 hr exposure, within 100 µm along the surface the Ni concentration was 40 and 80%. The maximum Ni concentration in each subscale is shown in Fig. 7b where the rapid accumulation of Ni in the early part of oxidation and its peak nonequilibrium concentration in isolated metal particles is clear. The Ni concentration in the scale was small and decreased during oxidation (Fig. 7c); also the Ni concentration in the subscale wustite tended to be higher than in the scale.

Discussion

The most significant feature of the present work is the correlation between the linear-parabolic-linear stages of the kinetics and the reaction morphologies established by metallographic and EPMA techniques. Most of the processes and sequence of events observed by the different techniques are displayed for comparison in Fig. 7 and 8.

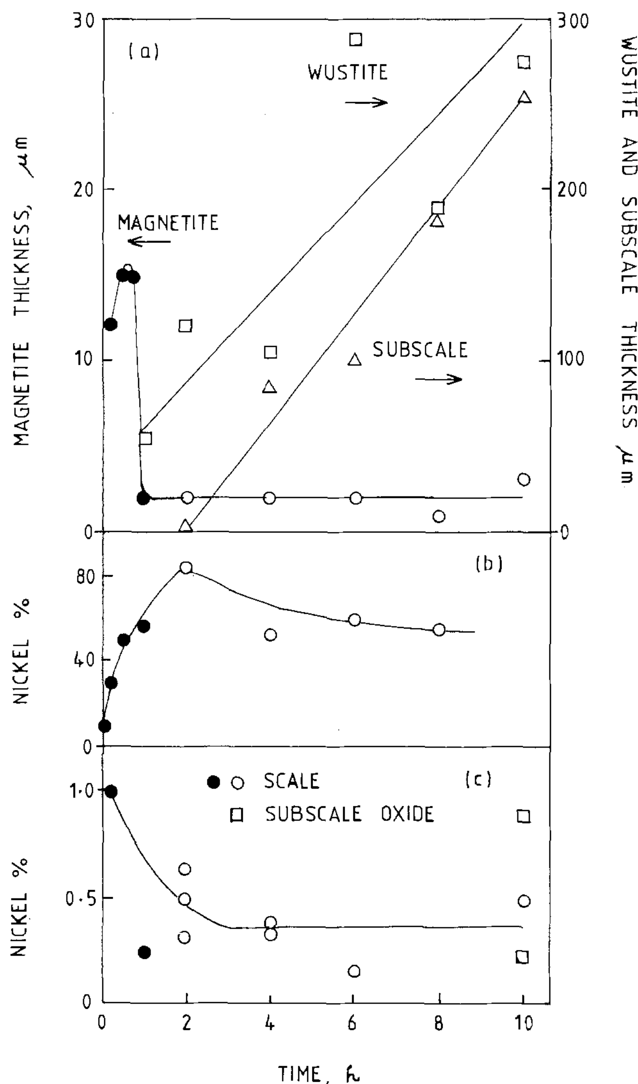

Fig. 7. Oxidation at 1000°C. (a) The scale magnetite and wustite, and subscale thicknesses: (b) the maximum Ni concentration in the subscale: (c) the Ni concentration in the scale and subscale oxide; closed and open symbols show the period when the Ni rich layer was continuous or discontinuous, respectively. Note: the kinetics were linear for 10 min, then parabolic up to 1 hr, then again linear.

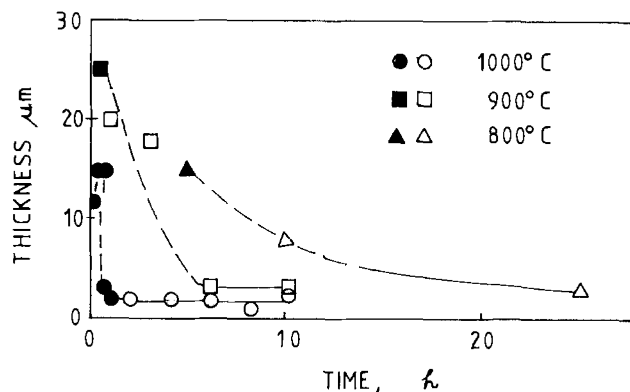

Fig. 8. Magnetite scale thickness formed at 800°-1000°C. Closed and open symbols show the period when the Ni-rich layer was continuous and discontinuous, respectively. Full and dashed lines show the period when the kinetics were in the final linear and parabolic stages, respectively.

During the initial linear stage the scale consists predominantly of magnetite with pockets of wustite at the scale/alloy interface and contains only about 1.0% Ni. The occurrence of magnetite as the predominant

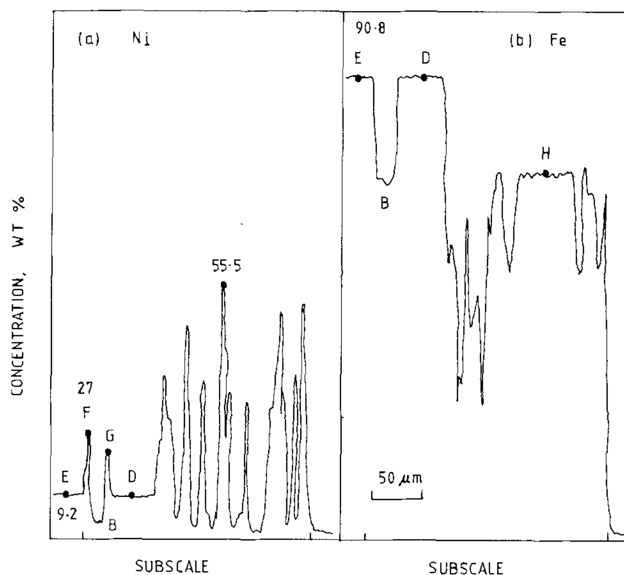

Fig. 10. Fe and Ni concentration profiles along the line X of Fig. 9c.

phase in the scale is unexpected and is discussed later. The selective oxidation of Fe accumulates Ni as a layer in the alloy at its surfaces, and the faster grain boundary diffusion leaves the alloy with an intergranular accumulation of Ni which is sufficiently marked to envelop grains. The linear kinetic law observed here is thought to reflect a phase boundary reaction. A similar linear law has been observed for the oxidation of Fe in CO_2 (7) and it was established (7) that the rate-controlling step was the reaction

$$CO_2(g) = CO(g) + O(ads) \quad [1]$$

on the outer surface of wustite to form adsorbed oxygen. It is probable that a similar mechanism occurs in the present case. The activation energy for the dissociation of CO_2 during Fe oxidation is 211 kJ mole^{-1} (7) compared with the present value of 193 ±

74 kJ $mole^{-1}$. Thus the linear oxidation stage is controlled by the supply of oxygen and the supply of Fe from the alloy is relatively fast.

Continued depletion of Fe from the surface of the alloys means that eventually Fe must be transported from the interior by diffusion through the Ni-rich layer. This process corresponds to the parabolic oxidation stage where the activation energy of 207 ± 33 kJ $mole^{-1}$ is taken to represent the rate-controlling process of diffusion of Fe through the Ni-rich rim. However, this value compares poorly with the activation energy of about 300 kJ $mole^{-1}$ observed for the diffusion of Fe in Fe-Ni alloys (8), and it is thought that the much lower value observed in the present case is due to the changing microstructure and Fe and oxygen concentrations in the Ni-rich layer during oxidation.

Whatever the mechanism of magnetite formation in the early stages of oxidation, it is unstable and decomposes to form wustite

$$Fe_3O_4(s) = 3FeO(s) + O \text{ (in Fe-Ni alloy)} \quad [2]$$

This occurs during the later stages of the linear oxidation period and during the parabolic period (Fig. 7, 8), and is associated with the regions of highest Ni accumulation at the grain boundaries (Fig. 5a). At 1000°C the solubility of oxygen in Fe and Ni is 3 ppm (9) and 150 ppm (10), respectively, and since solid Fe-Ni alloys are nearly ideal (11), as a first approximation we may assume that the solubility of oxygen in the alloy is directly proportional to the Ni concentration. It appears that the increased solubility for oxygen, by the higher amounts of Ni enriched alloy at grain boundaries, is the cause for magnetite decomposition (Eq. [2]) and the disposition of the wustite pockets. The dissolved oxygen diffuses inwards and at the furthest extent of Fe depletion (and Ni accumulation) reacts with the higher Fe activity of the alloy and precipitates wustite. Subscale formation starts after the formation of the Ni-rich layer and its advance is approximately linear and extrapolates to zero time (Fig. 7). The preprecipitation period is the time needed to saturate the Ni-rich layer with oxygen, and the growth of the subscale is linear over-all because it occurs by a repeated process of wustite precipitation enriching the alloy with Ni, and oxygen dissolving and diffusing in the enriched Ni layer till it precipitates more wustite. The decomposition of magnetite (Eq. [2]) causes its thickness to decrease rapidly during the parabolic stage (Fig. 7 and 8). Oxygen solution, diffusion, and precipitation as subscale wustite is the cause of the breakdown of the Ni-rich layer and the end of the parabolic oxidation stage. Once the subscale wustite is continuous, the supply of Fe via the highly nonstoichiometric FeO (12) is faster than the supply of oxygen by CO_2 dissociation and linear kinetics are again observed. The different activation energies of 193 ± 74 and 155 ± 13 kJ $mole^{-1}$ for the initial and final linear stages are considered to be due to the different catalytic activities of the two magnetite surfaces. For example, Kobayashi and C. Wagner (13) showed that the catalytic activity of a surface was a sensitive function of its concentration of electronic defects, and the initial unstable magnetite is unlikely to have the same defect structure, and hence electronic structure, as the later stable magnetite. In addition, Fueki and J. Wagner (14) observed a pronounced effect of the scale composition on the activation energy: with pure Ni oxidized in CO_2 at 1000°-1300°C it was 113 kJ $mole^{-1}$, but with 0.37% Cr in the alloy the value had changed to 54 kJ $mole^{-1}$ (900°-1200°C) and 159 kJ $mole^{-1}$ (1200°-1300°C). When the magnetite is decomposing, the supply of oxygen to the metal is by reaction [2], but during the final linear oxidation stage the magnetite thickness is constant (Fig. 8) and another mechanism must operate. The subscale wustite must supply the oxygen by the process

$$FeO \text{ (high O)} = FeO \text{ (lower O)} + O \text{ (dissolved in alloy)} \quad [3]$$

since oxygen does not diffuse in FeO (12). The wide nonstoichiometry range of FeO (12) may make this a relatively easy process.

The greater reactivity of Fe and its selective oxidation and the subsequent readjustment towards the stable phases of the Fe-Ni-O system are responsible for the sequence of reaction morphologies and kinetics observed. The changes in the early stages are so fast that highly nonequilibrium states are formed. At the start of oxidation at 1000°C the Ni concentration in the scale is ≈1.0% and this adjusts to a constant value of ≈0.3% as oxidation continues (Fig. 7c). A similar pattern occurred during the oxidation of a 2% Ni alloy in CO_2 but in that case (4) the final value was ≈0.2%. The concentration of Ni in FeO in equilibrium with a 60% Ni alloy at 1000°C is 0.13% (15) and this is in reasonable agreement with the present value of ≈0.20%. However, in the present case the Ni concentration of ≈1.0% in the early stages of oxidation when the Ni concentration of the alloy is lower is opposite to what is expected and must represent a condition way out of equilibrium. The most rapid rise in Ni concentration in the alloy is during the initial linear and parabolic stages (Fig. 7b) but the greatest increase occurs once the metal particles are isolated. After 2 hr at 1000°C the Ni concentration adjusted to ≈55-60%, which is similar to the value observed in a 2% Ni alloy oxidized in CO_2 at 1000°C (4), and compares with 54% on a 2.9% Ni alloy oxidized at 1200°C (16) and 45% Ni obtained on 10% Ni alloy at 700°C (17). At 1000°C the concentration of Ni in an Fe-Ni alloy in equilibrium with FeO containing maximum oxygen is 80% (15). The present value of ≈60% Ni is not inconsistent with this value since in a growing scale the oxygen potential of the FeO decreases from the outer surface inwards, and the subscale metal particles are positioned some distance in from the outer surface where the oxygen content of the FeO will be lower and hence the corresponding equilibrium concentration of Ni in the alloy will be less.

Finally we return to consider why the scale is predominantly magnetite in the early stages of oxidation. The magnetite is unstable and appears to form for kinetic reasons (Fig. 7 and 8). Arkharov (18) observed the formation of magnetite during the later stages of oxidation of Fe in CO_2 and attributed this to the lower supply of Fe. However, the situation is opposite in the present case: the magnetite forms when the supply of Fe is fastest. It appears that the magnetite nucleates preferentially. Brauns *et al.* (19) showed that the temperature below which wustite formed in the scale increased as the Ni concentration increased: 21% Ni raised the temperature from 570° to 680°C and this may indicate a tendency to form magnetite under conditions of rapid Ni enrichment. However, it appears likely that magnetite forms because it can dissolve up to 25% Ni whereas wustite can only dissolve a maximum of 0.84% (15). In the initial very fast reaction, diffusion of Ni away from the reaction zone may not be fast enough to avoid a concentration higher than the equilibrium amount for wustite being incorporated in the growing scale, and this would make the formation of magnetite with Ni in solid solution energetically preferred. Evidence that such a process has occurred is supported by the high Ni concentration in the scale in the early stages of oxidation and its subsequent adjustment toward lower values appropriate to a wustite equilibrium as oxidation continues (Fig. 7c). However, these considerations are mere possibilities; the reason for the occurrence of magnetite in the scale is unknown.

Electrochromism in Li_xWO_3

S. K. Mohapatra*,[1]

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

The electrochromic behavior of Li_xWO_3 has been studied by potentiostatic and galvanostatic measurements for both symmetric and asymmetric cells. The kinetics of coloration and bleaching are ascribed to barrier-limited and space charge-limited current flow, respectively, similar to the case of H_xWO_3. Galvanostatic measurements indicate linearity of optical density with injected charge at low injection levels. At high injection levels a nonlinear response is observed which is attributed to the approach of a phase boundary with increasing x in Li_xWO_3. A general comparison of Li_xWO_3 and H_xWO_3 in H_2SO_4: H_2O indicates greater stability for open-circuit memory of the Li_xWO_3 cells. Response times for various symmetric cells are tabulated.

Electrochromism in WO_3 is due to the formation of W-bronze, M_xWO_3, where M^{z+} is a cation in the octahedral interstitial site and z is different from six. Charge neutrality is maintained by the formation of W^{5+} or by a free electron in the conduction band. The coloration in M_xWO_3 is attributed to the shift of the plasma edge in single crystals and to the intervalence transfer transition ($W^{5+} \rightleftharpoons W^{6+}$) (1) in amorphous material where the electron is more localized.

In principle electrochromism in WO_3 is reversible and therefore has promise for passive display applications. Speed of response and contrast are the primary considerations for display applications. The ensuing criteria for cation selection are: (*i*) high solubility, (*ii*) high diffusion coefficient, (*iii*) low injection potential, and (*iv*) high deposition potential. Protons satisfy most of the criteria. However, the thermodynamic stability of H_xWO_3 at room temperature is poor (2). In addition, the electrode (WO_3) tends to dissolve in the electrolyte ($H_2SO_4 + H_2O$), and the electrolyte has a comparatively low decomposition potential of 1.5V. As is shown later, these difficulties can be circumvented by the use of alkali metal ions despite the smaller diffusion coefficients (Table I) of alkali ions compared to protons.

Although there has been considerable work on the electrochromism in WO_3 using protons (5, 8-12) little is known about the electrochromic behavior of Li_xWO_3. Hersh, McGee, and Kramer (13) initiated work on electrochromic aspects of alkali metal tungsten-bronzes. From the coloration and bleaching experiments Green *et al.* (14) postulated a diffusion-controlled process for $WO_3|MClO_4$ in PC|M (where M is Li or Na) cells. In the present paper, the characteristics of electrochromic coloration and bleaching of Li_xWO_3 are reported and compared with that of H_xWO_3. Criteria for stability and reversibility of these electrochromic cells are also discussed.

Sample Preparation and Experimental Procedure

Thin films of WO_3 were prepared by electron beam evaporation of reagent grade WO_3 powder (Ventron

Table I. Impurity diffusion in WO_3 at 25°C

Corporation, 99.7% purity) on transparent In_2O_3 coated glass substrates (PPG Nesatron). The thickness of the films was determined with a Taylor-Hobson Talysurf. Li was injected into WO_3 from a 1M $LiClO_4$-propylene carbonate (PC) electrolyte. $LiClO_4$ was dried for 7-8 hr at 100°C and then dissolved in PC.

Two-electrode potentiostatic measurements were carried out in a cylindrical glass cell with optical windows on opposite sides. Galvanostatic or constant current measurements were carried out with the same cell placed inside a Cary-14 spectrophotometer. A Keithley 225 current source was used for applying a constant current. Two types of cell geometries were studied: (*i*) the asymmetric cell $In_2O_3|WO_3|$electrolyte|metal electrode, and (*ii*) the symmetric configuration $In_2O_3|WO_3|$electrolyte$|M_xWO_3|In_2O_3$. Indium was used as the counterelectrode in the asymmetric configuration. For a practical electrochromic display the symmetric cell type is more favorable. Even though such a symmetric arrangement has been proposed (15), the cell characteristics have not been reported.

Since H^+ rather than Li^+ might possibly be injected into WO_3 in the presence of small quantity of H_2O in the electrolyte, a symmetric cell of H_xWO_3 and WO_3 separated by the electrolyte 1M $LiClO_4$-PC was set up. A bias of 1.5V applied to this cell did not transfer any color (*i.e.*, H^+) from H_xWO_3 to WO_3. In addition, it follows from the galvanostatic measurements (discussed below) that the variation of the optical density with injected charge at high injection levels differs for H^+ and Li^+. Therefore, proton injection in these experiments is unlikely.

Results and Discussion

Characteristics of coloration.—Coloration characteristics of an asymmetrical cell of WO_3 in $LiClO_4$-PC are similar to that of H_xWO_3. As in H_xWO_3, at a constant applied bias the current drops with time, because of the increase in chemical potential of the injected cation with time. Crandall and Faughnan (9) performed an analysis of the kinetics of H^+ incorporation in WO_3 according to which the kinetics is essentially controlled by the proton transport across the WO_3-electrolyte interface. It obeys the well-known Butler-Volmer relation (16)

$$j = j_0 \left[\exp\left(\frac{(1-\beta)e\eta}{kT}\right) - \exp\left(-\frac{\beta e\eta}{kT}\right) \right] \quad [1]$$

where j_0 is the exchange current density, β the barrier symmetry factor, and η the overpotential, *i.e.*, the applied potential minus the reversible potential.

One of three processes may control the kinetics of coloration: (*i*) charge transport across the electrode-electrolyte interface, (*ii*) diffusion in the electrolyte, and (*iii*) diffusion in the WO_3. The barrier-controlled process leads to the current-voltage behavior presented by Eq. [1]. If diffusion in the electrolyte is the dominant process, the current density is represented by (17)

$$j = \pi^{-1/2} n \mathbf{F} D_0^{1/2} C^0 t^{-1/2} \quad [2]$$

where $n = 1$ is the number of electrons participating in the reduction, $\mathbf{F}$ the Faraday constant, D_0 the diffusion coefficient, and C^0, the concentration of the redox species, Li^+. From the equivalent conductance data of Keller *et al.* (18) D_0 of Li^+ in $LiClO_4$:PC can be obtained, which when substituted in Eq. [2] with a C^0 of 10^{-3} mole/cm³ would give a j value two orders of magnitude higher than observed in electrochromic experiments. Therefore, diffusion in the electrolyte cannot control the rate of coloration.

The rate of diffusion in the neutral WO_3 bulk does not depend on voltage. But at elevated levels of charge injection it is possible to go from a barrier-controlled process to a diffusion-controlled process. If a diffusion-controlled process is assumed, concentration of the injected cation at a distance y ($y = 0$ at In_2O_3-WO_3 interface; l is the thickness of the film) and at time t can be expressed as (14, 19)

$$C(y,t) = \frac{J_0 t}{l} + \frac{J_0 l}{D} \mathbf{F}(y,t) \quad [3]$$

where J_0 is the flux at the film-electrolyte interface and D the diffusion coefficient of the cation. The function $\mathbf{F}(y,t)$ depends upon Dt/l^2 and y/l. $\mathbf{F}(y,t)$ values can be obtained from plots (14) of $\mathbf{F}(y,t)$ *vs.* y/l for various Dt/l^2 values. Using $J_0 = 2$ mA cm² (close to the maximum value in our experiments), $D_{Li} \simeq 10^{-9}$ cm²/sec (Table I), $l = 3 \times 10^{-5}$ cm and considering a time $t = 1$ sec, $C(y = 0)/C(y = l) \simeq 0.80$. Therefore a diffusion-dependent coloration process can be ruled out.

Having eliminated diffusion in the electrolyte and in WO_3, it is reasonable to attribute the coloration process to a barrier-controlled process. In such a case j in Eq. [1] can be translated into the time domain if the reversible potential V_0 as a function of the composition parameter x (in M_xWO_3) is known. For $x \leq 0.2$ the emf E of the cell $Li_xWO_3|$1M $LiClO_4$ in PC|Li (20) can be fitted to an analytical expression given by Crandall *et al.* (9).

After substitution of this expression for the equilibrium emf in η, the current density j in the Butler-Volmer relation can be translated to the time domain as $j = kt^{-1/2}$ with a barrier symmetry factor $\beta \sim 0.5$. A typical plot of j *vs.* t for Li incorporation in WO_3 is shown in Fig. 1. The solid line represents $j = kt^{-1/2}$ for $k = 1.6$ mA (sec)$^{1/2}$ cm^{-2}. A reasonable fit with the experimental values is obtained in the initial stage of coloration. It should be mentioned at this point that $j = kt^{-1/2}$ is valid only for short times t and for small x values. For high x values Eq. [1] must be solved numerically. In addition, Arnoldussen (21) has pointed out that j_0 contains the reversible potential which would change as a function of x. Therefore, j_0 would change as a function of x and t. Thus a deviation of the simple relationship of $j \propto t^{-1/2}$ from the experimental points at long coloration times is to be expected.

Characteristics of bleaching.—Faughnan *et al.* (5) have shown that for an asymmetric cell consisting of H_xWO_3:H_2SO_4:In the bleaching of H_xWO_3 is governed by a space-charge limited (SCL) current of H^+ and

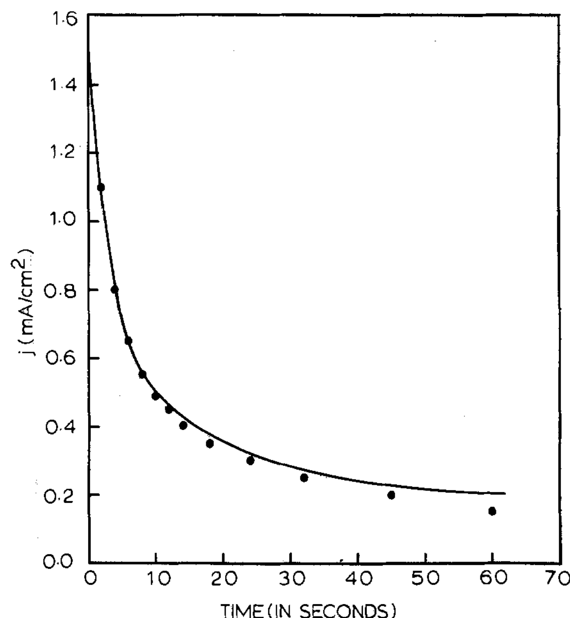

Fig. 1. Current density-time plot for the cell WO_3:1M $LiClO_4$-PC:In during coloration. The solid circles are the experimental points and the solid line is drawn for $j = 1.6t^{-1/2}$.

electrons. The space charge builds up because of the enormous difference between electron and cation mobilities ($D_e \sim 2.5 \times 10^{-1}$ cm²/sec (8) and $D_{M^+} < 10^{-8}$ cm²/sec). The voltage dependence normally observed rules out simple diffusion-limited bleaching.

The SCL current equation of Faughnan *et al.* is expressed as

$$J(t) = (p^3 \epsilon \epsilon_o \mu_p)^{1/4} V^{1/2} / (4t)^{3/4} \quad [4]$$

where p is the volume density of the cations in the intermediate neutral plasma region, ϵ the relative dielectric constant of WO_3, ϵ_o the permittivity of free space, μ_p the mobility of the cation, V the applied voltage, and t the time. The end of the bleaching peroid, or the finish time, t_f is expressed as

$$t_f = ps^4 / (4 \epsilon \epsilon_o \mu_p V^2) \quad [5]$$

s marking the boundary of the cation space charge with respect to the electrolyte-WO_3 interface. Figure 2 represents a $j(t)$ plot for both the symmetric and asymmetric cells of H_xWO_3 and Fig. 3 is that of Li_xWO_3. It is interesting to see that both for symmetric and asymmetric cells of H_xWO_3 and Li_xWO_3 a ¾ slope is obtained according to Eq. [4]. A plot

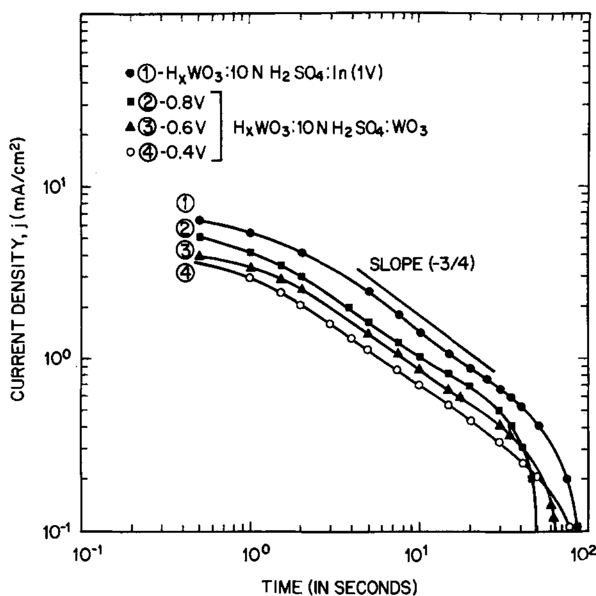

Fig. 2. Bleaching characteristics of symmetric and asymmetric cells for H_xWO_3 in the presence of 10N H_2SO_4.

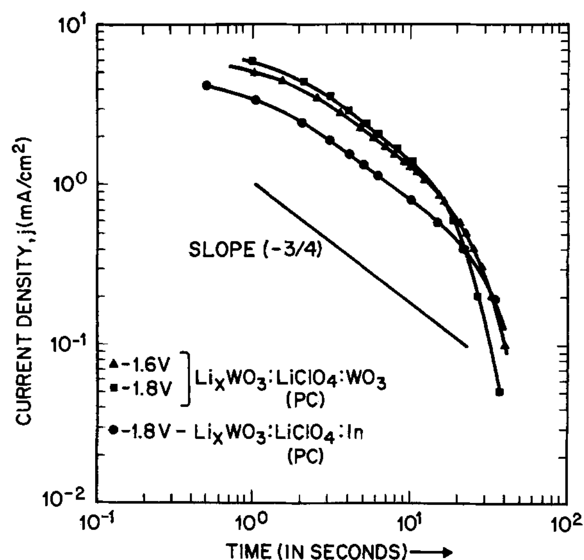

Fig. 3. Bleaching characteristics of symmetric and asymmetric. cells for Li_xWO_3 in the presence of 1M $LiClO_4$-PC.

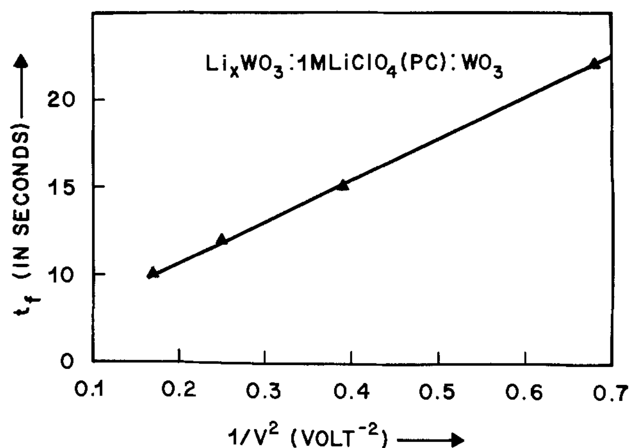

Fig. 4. Plot of response time t_f vs. $1/V^2$ for symmetric cells of Li_xWO_3.

of t_f *vs.* $1/V^2$ for symmetric cells of Li_xWO_3 is shown in Fig. 4, t_f being obtained from the intersection of the −¾ slope with the faster decreasing current slope toward the end of the bleach pulse. Therefore, in analogy with H_xWO_3, it seems appropriate to attribute a SCL current flow model to symmetric cells of Li_xWO_3. The electrochromic characteristic of symmetric cells is then essentially determined by the bleaching kinetics.

From bleaching experiments it is possible to calculate the Li^+ mobility according to Eq. [5]. The arguments given in the previous section make it likely that under the operating current conditions the films will be homogeneous in cation concentration. Using the data of Table II in Eq. [5] with $\epsilon = 50$ and $s = 2.8 \times 10^{-7}$ cm the values of $D = kT\mu/e$ have been calculated and are tabulated in Table I. It is seen that D_{Li^+} in WO_3 is about an order of magnitude smaller than the D_{H^+}. The decomposition potential of the 1M $LiClO_4$:PC electrolyte is 3V (with respect to SCE) compared to that of H_2SO_4:H_2O which is about 1.5V. Since bleaching response $t_f \propto 1/V^2$ it is possible to decrease the response time in the Li_xWO_3 electrochromic cell by increasing the bias voltage.

Constant current measurements.—Constant current measurements were carried out to determine the relationship between the optical density, O.D., and the injected charge. A linear relationship between the two would be expected since

$$\text{O.D.} = k(\lambda) Cl$$

where $k(\lambda)$ is the extinction coefficient, C the concentration of the absorbing species, and l the thickness of the sample. A plot of optical density as a function of injected charge is shown in Fig. 5 for Li_xWO_3 and H_xWO_3 for several current levels. The optical density was measured at a wavelength of 6300Å in the Cary spectrophotometer. Nonlinearity between O.D. and injected charge is observed for Li_xWO_3 beyond an O.D. $\simeq$ 1, whereas linearity up to 1.8 O.D. has been observed in the case of H_xWO_3. Not all the O.D. *vs.* injected charge points lie on the same line because of different film thicknesses.

It is important to note that there is a drop in O.D. with higher injected charge in the case of Li_xWO_3. If we take the apex of the O.D. curve at 35 mC/cm² a

Table II. Response of symmetric cells of H_xWO_3 and Li_xWO_3

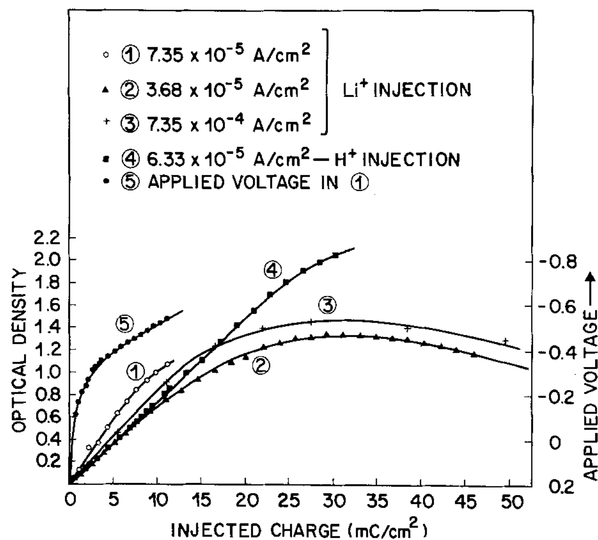

Fig. 5. Injected charge vs. optical density at various current levels for Li^+ and H^+ injection.

Li concentration $x = 0.39$ is calculated for a 3000Å thick film of Li_xWO_3. WO_3 films with $x < 0.4$ are blue in color and turn pink for $x > 0.4$. The optical absorption spectra taken with respect to an uncolored film are shown in Fig. 6. The films with $x > 0.4$ show an increasing absorption toward u.v. It should be mentioned that the extra peak around 1750 nm increased in intensity with increasing coloration (either by H^+ or Li^+). Whether it is a true absorption band or an interference effect is presently under investigation. Dickens and Whittingham (22) have given the stability phase fields of various alkali metal ion tungsten bronzes, according to which $0 < x < 0.4$ seems to be the existence region for Li_xWO_3. Recent emf measurements (20) also indicate a Li-rich phase in equilibrium with $Li_{0.4}WO_3$, supporting the results of galvanostatic measurements. Irreversible coloration at $x > 0.4$ does not pose a serious problem since for a reasonable contrast (O.D. ~0.6 at 600 nm for a film ~3000Å thick) an x value of 0.1 is sufficient.

Stability and response of the electrochromic films.— One of the primary concerns in the performance characteristics of electrochromic display is the long-term stability of the thin films and the persistence of open-circuit memory (long-term persistence of coloration). This is a particularly important consideration for the symmetric cell configuration. The two degradation processes so far as the storage life is concerned are: (*i*) dissolution of the WO_3 film in H_2O and H_2SO_4, and (*ii*) oxidation of M_xWO_3 by dissolved oxygen in the electrolyte.

Dissolution is a process of chemical attack. Thin films of WO_3 are normally attacked by H_2O. Therefore, the present trend in H_xWO_3 electrochromic cells is to use an organic solvent, glycerol or PVA (polyvinyl alcohol) (23, 24) to increase the stability of the film. Likewise, the aprotic Li electrolyte (1M $LiClO_4$ in PC) imparts greater stability to the WO_3 film. The role of dissolved oxygen in limiting the open-circuit memory of H_xWO_3 and Li_xWO_3 is shown in Fig. 7. All the films were colored at a constant current to the same optical density at 630 nm inside the Cary spectrophotometer. Then the optical density was recorded as a function of time. H_xWO_3 in the presence of O_2-saturated H_2SO_4 is unstable compared to H_2SO_4 saturated with argon. Li_xWO_3 was highly stable even in the oxygen-saturated electrolyte. Therefore, the stability of Li_xWO_3 is superior to that of its hydrogen counterpart.

The response times of some of the symmetric cells are tabulated in Table II. An optical density of 0.6 was arbitrarily chosen to give a reasonable contrast. It can be seen that H_xWO_3 with H_2SO_4-glycerol medium and Li_xWO_3 in 1M $LiClO_4$-PC medium have similar response characteristics at a given applied voltage. It should be pointed out that the fast responding cells with H_2SO_4-H_2O are not very stable. The response of the stable electrochromic cells of H_xWO_3 and Li_xWO_3 are essentially the same. An additional advantage in the case of Li_xWO_3 would be the low temperature operation of the cell because of the lower melting point of PC (−20°C) compared to H_2SO_4-glycerol cell (20°C).

Conclusion

Electrochromic coloration in Li_xWO_3 is governed by charge transport across the WO_3-electrolyte interface. Bleaching response of Li_xWO_3 is governed by a space charge limited current flow. The kinetics of symmetric Li_xWO_3 cells appear to be determined by the bleaching cycle, in analogy to H_xWO_3 cells. Galvanostatic measurements indicate a phase boundary of Li_xWO_3 at $x \sim 0.4$. Reversible coloration and bleaching of Li_xWO_3 can be obtained with lower concentrations of Li. Li_xWO_3 electrochromic cells have better memory and resistance to oxidation than its proton counterparts. The response times of stable electrochromic cells of H_xWO_3 and Li_xWO_3 are similar but the lower melting point of the electrolyte 1M $LiClO_4$-PC may facilitate the operation of Li_xWO_3 electrochromics at low temperature.

Cathodoluminescence Measurement Techniques

Michael T. Stevens*

Zenith Radio Corporation, Glenview, Illinois 60025

ABSTRACT

A comparison is made of the three modes of cathodoluminescence excitation: continuous, pulsed, and raster. The proper excitation density needed to correctly analyze data obtained in each mode is discussed. The effects of a shrunken raster are investigated, and a new concept, multiexcitation, is presented. It is shown that the lack of correlation between brightness measurements made on small screens in demountable systems and full-size television picture tubes is due to multiexcitation. Furthermore, multiexcitation tends to linearize sublinear phosphors, such as the sulfides, masking their saturation at high excitation density. It is proposed that, to avoid multiexcitation, phosphor evaluation measurements be made with either pulsed or single line scan rasters.

Although the field of cathodoluminescence is quite old (Braun assembled the display device which bears his name back in 1897), and nonlinearities in the luminescence *vs.* excitation curves have been known for at least forty years, it is only recently that the necessity for more discriminating measurements of cathodoluminescent phosphors has been appreciated.

In the early days of cathodoluminescence, excitation was via a continuous stationary electron beam which was not necessarily even focused. It was soon discovered that a focused beam is capable of damaging the phosphor; the heat generated by the beam can physically destroy the screen. Thus, one had to either keep the beam intensity very low (which ruled out high intensity excitation experiments) or somehow modulate the excitation. Modulation could be achieved by pulsing the beam, thus decreasing the average power input to the phosphor by the duty factor. However, the average current and the average luminescence are also reduced, making them harder to measure. An alternative to time modulation is spatial modulation, *i.e.*, deflect the beam in a regular manner such that each phosphor crystallite is exposed to the electron beam for only a short fraction of the total time. This is achieved via a raster (as used in television) wherein the beam is swept over the screen in a series of scan lines.

We show that raster excitation is not the best scheme in terms of gaining knowledge about the physics of cathodoluminescence. We will also explain why there is, in general, no correlation between measurements made in demountable cathode ray tubes on small area screens and data on full-size picture tubes.

Statement of the Problem

In general, a cathodoluminescence experiment requires (*i*) excitation of a phosphor, (*ii*) measure-

* Electrochemical Society Active Member.

Key words: phosphors, multiexcitation, saturation properties, shrunken rasters.

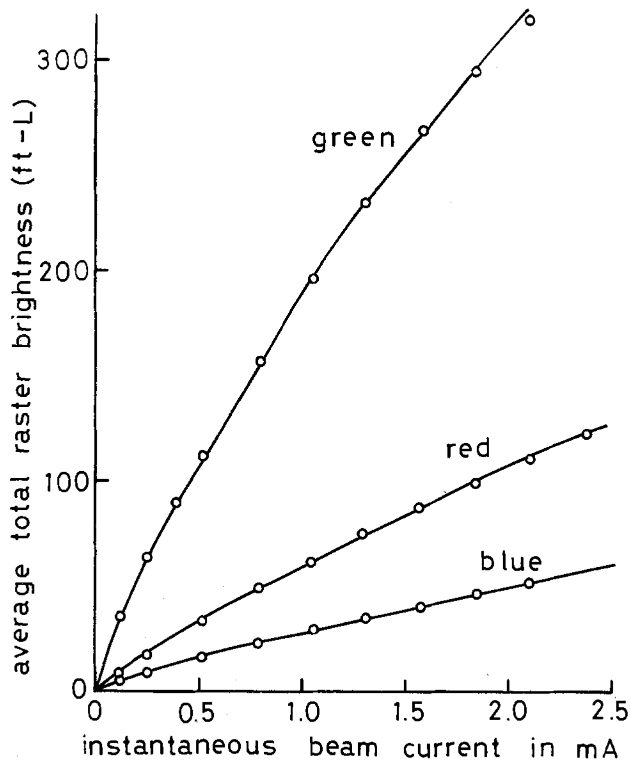

Fig. 1. Dependence of average total raster brightness (ft-L) on beam current (mA), measured on 19 in. cathode ray tubes with a full raster.

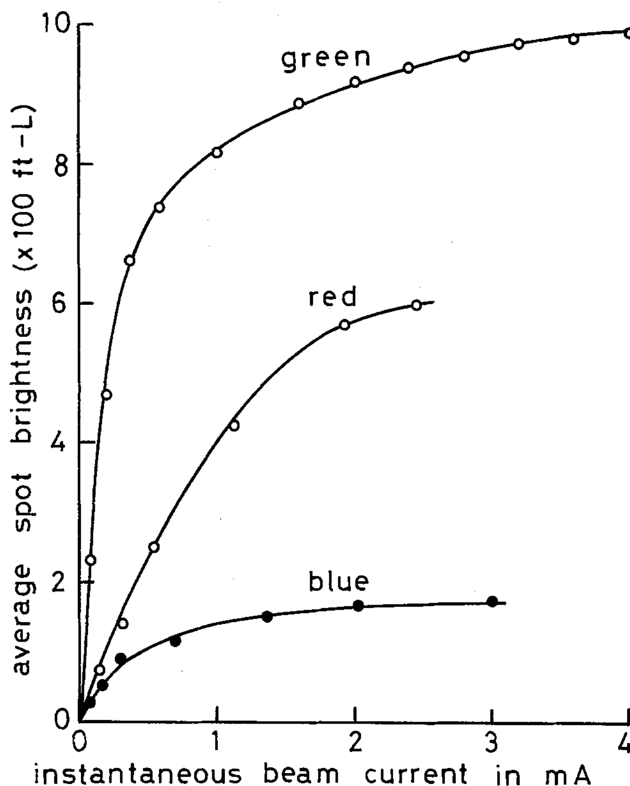

Fig. 2. Dependence of average spot brightness (ft-L) on beam current (mA), measured on 19 in. cathode ray tubes with a single line scan raster.

ment of the resulting luminescence, and (*iii*) interpretation of the results. Both excitation and measurement can be done by one of various techniques, each of which has its advantages and disadvantages, and the particular techniques utilized will influence the results and hence the interpretation.

In Fig. 1 and 2 we present data taken in our laboratory on brightness *vs.* excitation of the red (Y_2O_2S:Eu), blue (ZnS:Ag), and green (ZnCdS:Cu) phosphors used currently in color television picture tubes. (The data were taken on 19 in. tubes with aluminized screens.) The excitation is similar in both cases; only the optical measurement details differ. In Fig. 1 we show the dependence on beam current of the average raster brightness, *i.e.*, the time-averaged brightness of a phosphor screen excited by an electron beam swept across in a regular manner, as in a television display. It is obvious from the data that all three phosphors are reasonably linear; and one would never consider phosphor saturation as a cause of poor picture fidelity, or as being the culprit in gray scale imbalance.

In Fig. 2 we present a spot brightness measurement. This is done with a telephotometer capable of measuring the brightness of an area much smaller than a phosphor dot. Instead of a full raster, here only a single line scan per frame period was used. It is quite obvious that the luminescence is quite sublinear for all three color fields, and one could very easily draw the conclusion that all three phosphors are nonlinear.

The reason Fig. 1 and 2 present misleading results is that they present characteristics of the excitation-deflection-luminescence system, not merely of the phosphor. At high currents, the diameter of the electron beam increases; this causes the brightness data in Fig. 2 to be too low at high excitation levels, and hence, the rare earth red, which is known to be a linear phosphor, appears to be sublinear.

We can correct for the variation in beam diameter by utilizing the excitation density as the independent variable in a brightness *vs.* excitation curve. We shall assume a "pill-box" current distribution, *i.e.*, the current density is uniform over the entire beam. Although the excitation density calculated on the basis of this assumption will not be numerically correct, it will be proportional to the true value, and as such is sufficient for our purposes.

The spot brightness data of Fig. 2 can now be plotted *vs.* excitation density in Fig. 3. We see that the green and blue sulfides saturate at high excitation densities and the red rare earth phosphor remains linear.

Thus, we have shown that there is more than one way to make a cathodoluminescence measurement, and hence, it is quite possible to obtain more than one set

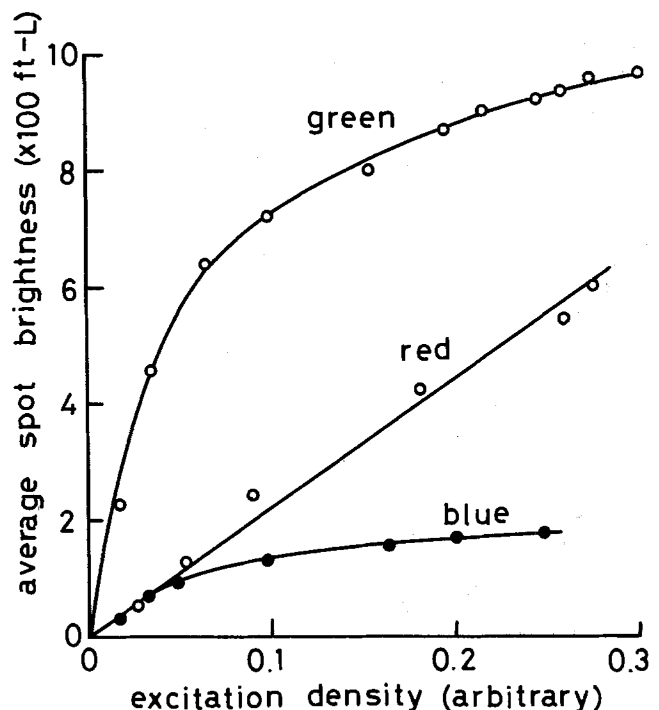

Fig. 3. Dependence of average spot brightness on beam excitation density, measured on 19 in. cathode ray tubes with a single line scan raster.

of data for a particular phosphor. The problem then can be stated in the following way: What is the difference between the various schemes of taking cathodoluminescence data, and which method is the best in terms of understanding phosphor physics?

Excitation Techniques

Three excitation methods currently in use are continuous (or d.c.), pulsed, and raster. The first two are really defined by the characteristic times of the phosphor under study: the rise and decay times of the phosphor must be compared to the excitation pulse length and the period between pulses. These characteristic times can vary from nanoseconds for flying spot scanner phosphors, to microseconds for the materials used in television picture tubes, to milliseconds for oscilloscope phosphors, and to seconds for day-glow phosphors.

To simplify matters, we will consider only those cases where the phosphor rise and decay times are both very short compared to the time between excitation pulses. (One can always arrange an experiment such that this requirement is met.) Then, depending on whether the duration of excitation, *i.e.*, the excitation pulse length, is long or short compared to the phosphor response time, *i.e.*, the phosphor rise time, one has either continuous or pulsed excitation, respectively. We note that a cathode ray tube capable of generating a fixed pulse length electron beam will excite some materials in a pulsed mode and others continuously. It is obvious that the approximations which are possible at these two extreme cases are not valid if the excitation time is the same as the response time of the phosphor. This does not mean that such a situation is not amenable to interpretation, only that interpretation is more difficult. This also holds if the simplifying assumption made above is invalid.

In continuous excitation, a steady-state condition is achieved wherein a constant fraction of the luminescent centers in the phosphor are in an excited state at all times. As excited centers decay (radiatively or nonradiatively), other centers are excited from the ground state by the incident electron beam. Hence, the required input parameter is current density j, which is a measure of the time rate of incident electrons.

In pulsed excitation, the input parameter of interest is charge density, σ. Because the entire excitation takes place in a very short time, the phosphor does not begin to respond to the incident electron beam until the pulse has ended. Thus, the details of the electron beam pulse waveshape are unimportant; the only meaningful measure of excitation is the integral

$$\sigma = \int_{\tau} j \, dt \quad [1]$$

Then, provided the excitation duty factor is low enough, we can conceive of the phosphor as being suddenly excited as the entire charge of the pulsed electron beam is dumped into the crystallites all at once, and then slowly relaxing as the phosphor luminesces and returns to the ground state.

Let us now turn our attention to raster excitation. This is a variant of pulsed excitation which is different enough to warrant special treatment. Rasters are technologically important (as in television) and are easy to generate. A raster is also an easy method of exciting a phosphor screen to uniform brightness. Each phosphor crystallite is excited by the electron beam as it is swept past, so in effect the excitation is a pulse of length τ where

$$\tau = d/v \quad [2]$$

d is the electron beam diameter and v the velocity of the scanned beam. For typical television rasters, this is in the submicrosecond range. Each element of the phosphor screen is excited at a different time, and the light output of the screen appears constant. Hence, a

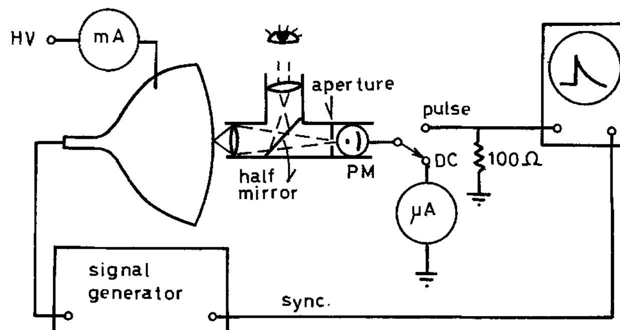

Fig. 4. Experimental arrangement for observing time-averaged and time-resolved luminescence.

measurement of the luminescence of a large area of the screen will show minimal time dependence; if the photodetector can see the entire raster the sensor output will be essentially constant. If, however, the photodetector is illuminated by only a very small region of the screen (smaller than the diameter of the electron beam) then the output signal will be a pulse.

Figure 4 shows the experimental arrangement used to measure the luminance of a phosphor screen. The brightness is measured in relative units by the photomultiplier; the microammeter measures the ordinary time-averaged brightness and the oscilloscope displays the time-resolved brightness. The microscope allows one to measure the brightness of a small region of one phosphor dot; this we call the spot brightness. When the microscope is not present, the photomultiplier measures the brightness over many phosphor dots; we call this the raster brightness. In a television display, the viewer sees the raster brightness. The spot brightness, the brightness of an infinitesimally small area, is needed for analytical purposes if one is to understand the phosphor contribution to the display system.

Excitation Density

We can compute the excitation density for each of the three modes for two different assumed current profiles. We will consider a "pill-box" current distribution and a Gaussian, as shown in Fig. 5.

A word on notation: The first subscript indicates the mode of excitation (continuous, pulsed, or raster), and the second specifies the assumed current profile (pill-box or Gaussian). The radial distance from the center of the beam is r, and the parameter a is the usual measure of width of the Gaussian. The observed electron beam diameter is d.

If the total beam current is i, then for the pill-box

$$j_{cp} = \frac{4}{\pi} \frac{i}{d^2} \quad [3]$$

and for the Gaussian

$$j_{cg} = \frac{i}{\pi a^2} \exp\left[-(r/a)^2\right] \quad [4]$$

These are the excitation densities for continuous excitation.

When $r = 2a$, the exponential term is 0.018, so we will define the effective radius of the Gaussian distribution as $2a$. Hence we have

$$j_{cg} = \frac{16}{\pi} \frac{i}{d^2} \exp\left[-(4r/d)^2\right] \quad [5]$$

which for

$$4r/d < 0.1$$

i.e., at the center of the beam, reduces to

$$j_{cg} = \frac{16}{\pi} \frac{i}{d^2} \quad [6]$$

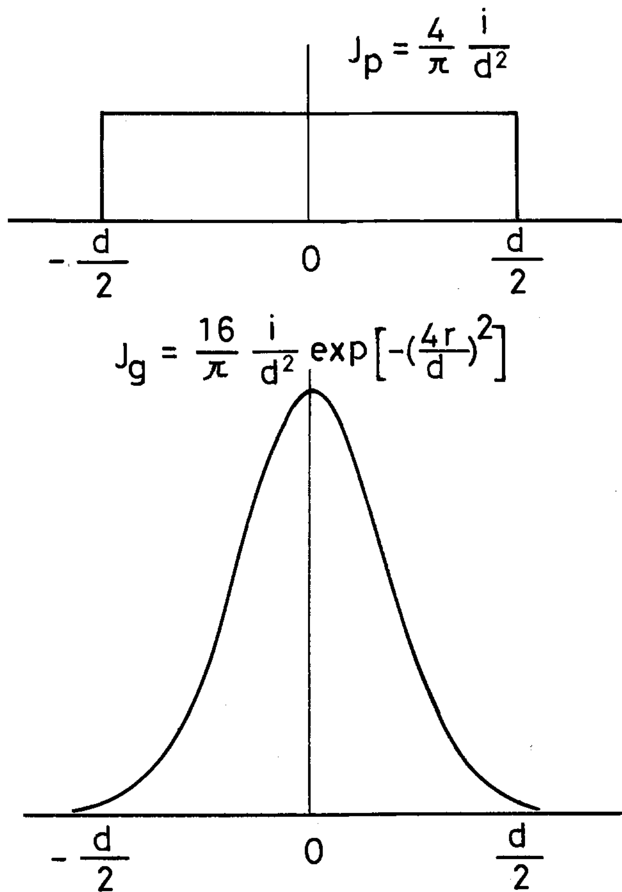

Fig. 5. Current density distributions for a pill box model (top) and a Gaussian (bottom).

For pulsed excitation, the excitation density is the time integral

$$\sigma_p = \int_\tau j\, dt \qquad [7]$$

which, for the pill-box distribution is

$$\sigma_{pp} = \frac{4}{\pi}\frac{i}{d^2}\tau \qquad [8]$$

and is

$$\sigma_{pg} = \frac{16}{\pi}\frac{i}{d^2}\tau \qquad [9]$$

for the Gaussian.

For raster excitation, one performs an integration

$$\sigma_r = \int_{d/v} j\, dt = \int_d \frac{1}{v} j\, dx \qquad [10]$$

which is (for the pill-box)

$$\sigma_{rp} = \frac{4}{\pi}\frac{i}{vd} \qquad [11]$$

where v is the beam-scanning velocity. For the Gaussian

$$\sigma_{rg} = \frac{4}{\sqrt{\pi}}\frac{i}{vd}\exp\left[-(4y/d)^2\right] \qquad [12]$$

which, for

$$4y/d < 0.1$$

reduces to

$$\sigma_{rg} = \frac{4}{\sqrt{\pi}}\frac{i}{vd} \qquad [13]$$

The functional dependence of excitation density on the beam diameter is independent of the assumed distribution. The excitation densities for pulsed and raster excitation differ in their dependence on beam diameter, as in the latter the beam is integrated as it sweeps past the phosphor crystallite being studied.

Inspection of the expressions above shows that for continuous and pulsed excitation, the peak value for the Gaussian is four times that of the pill-box model. For a typical high resolution 19 in. color television picture tube, which has a 1 mm diam spot at a beam current of 1 mA, the current density is 127 mA/cm^2 for an assumed pill-box distribution, and for a Gaussian, the peak current density is over 500 mA/cm^2. For raster excitation, the density for the Gaussian is only $\sqrt{\pi} = 1.77$ times the pill-box value. For the same 19 in. tube, the charge density is therefore 1.91×10^{-8} C/cm^2 for the pill-box model and 3.39×10^{-8} C/cm^2 for the Gaussian.

Multiexcitation Effects in Raster Excitation

There is one complication in raster excitation; this is related to the fact that the distance between scan lines of the raster is not unique. By making appropriate adjustments in the vertical and horizontal deflection fields it is possible to change the size and shape of a raster by an arbitrary amount. The raster brightness will, of course, vary inversely with raster size. Figure 6 shows such behavior. At each value of beam current, as the size of the raster is reduced, the raster brightness goes up. In Fig. 7 we present spot brightness data. The curves are roughly similar to the raster brightness curves, but there is a sharp break in each curve at which the slope changes. This is indicated by the dashed line. This change in slope indicates that two processes may be at work.

To separate these two processes, we show in Fig. 8 the spot brightness as separate functions of raster width and raster height. In the upper set of curves, where only the raster width has been changed, there

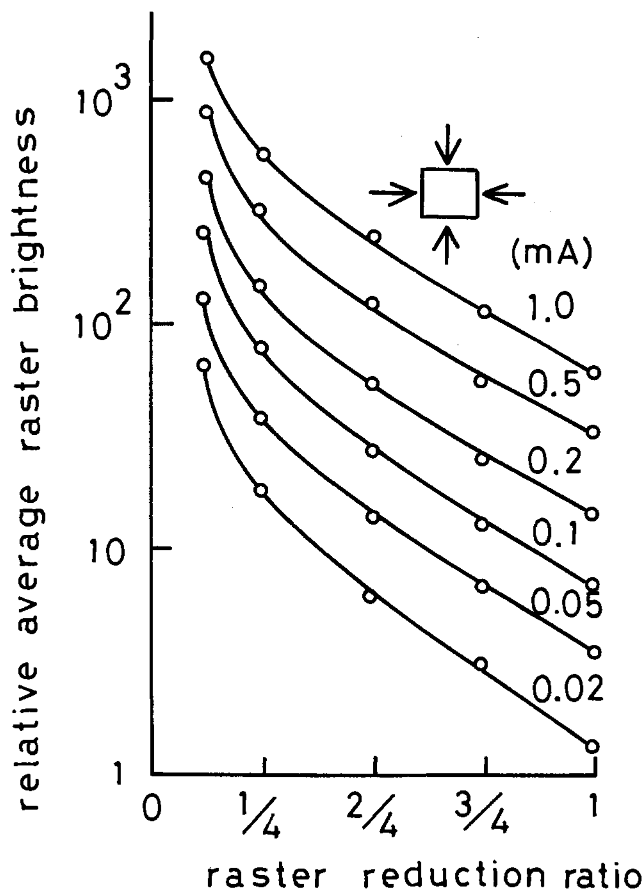

Fig. 6. Dependence of average raster brightness on raster size, simultaneous variation of raster height and width, on 19 in. tube.

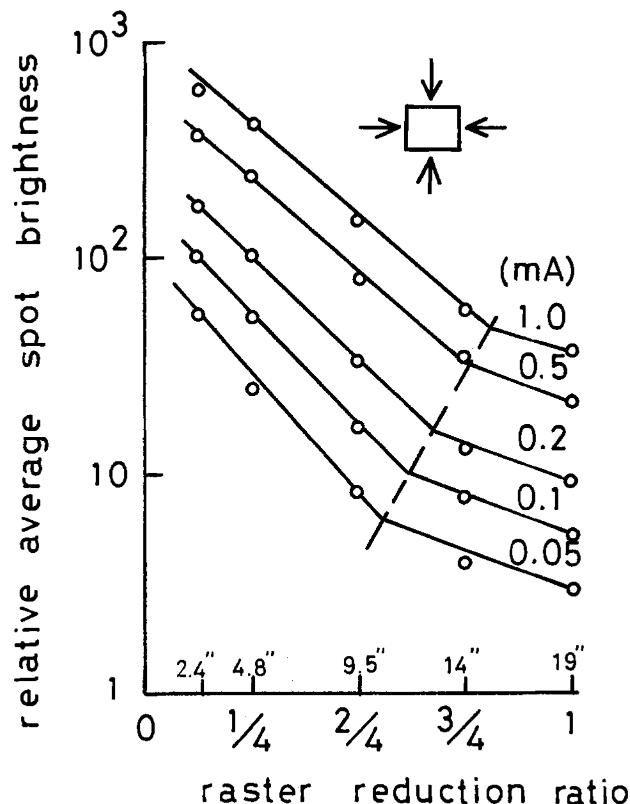

Fig. 7. Dependence of average spot brightness on raster size, simultaneous variation of raster height and width, on 19 in. tube.

is only one slope, indicating only one process. The slope is essentially that of the right-hand lines in Fig. 7. As the raster width is decreased, because the time per scan line is fixed, the beam scanning velocity decreases also, so the effective pulse length of the beam as it excites the small area under study increases. Thus, the increase in brightness as the raster width is reduced is due to the increase in the total time during which the phosphor is excited.

Let us now look at the way the slope changes when the raster height is changed. For small reductions there is no change in spot brightness, but upon further reduction the slope increases, and this increase is sharper than for the same relative decrease in raster width. The explanation is as follows: for a given electron beam current, as the raster height is reduced, the vertical separation between the horizontal scanning lines becomes smaller. If the electron beam diameter is less than this distance there is no effect, and there is no change in the spot brightness. However, when the beam diameter is greater than the raster-line spacing, *i.e.*, when the ratio of the diameter to the spacing is greater than unity, the phosphor dot will be excited more than once per frame period, and the spot brightness will increase. The greater the ratio, the greater the increase in spot brightness. The ratio can be increased either by reducing the raster height or by enlarging the electron beam diameter. Because the beam diameter increases with current, the onset of multiple excitation occurs sooner at higher currents. This multiple excitation phenomenon can be visualized by studying the idealized spot brightness waveshapes of Fig. 9. The upper part shows the photodetector output for a single excitation per frame time, while the lower sketch indicates five excitations per frame. The middle pulse is the result of the center of the electron beam passing the screen element under observation; the two to the left are due to excitation by the bottom of the two previous scans and the two peaks to the right are due to excitation by the top of the next two scans.

A family of oscillograms of the time resolved brightness curves is shown in Fig. 10. The upper left corner

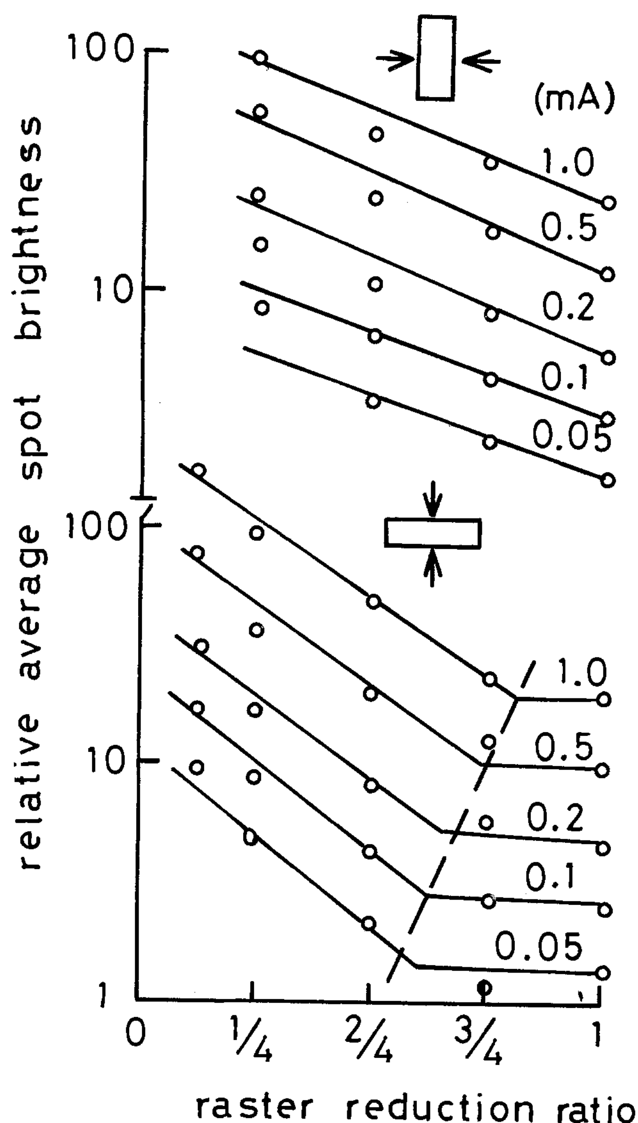

Fig. 8. Dependence of average spot brightness on raster width at full height (top), and on raster height at full width (bottom), on 19 in. tube.

shows one excitation per frame time for the conditions of low current (and hence small beam diameter) and full raster (when the vertical separation between adjacent scan lines is the largest). The photographs clearly show the onset of multiexcitation as the beam current increases and/or the raster size is reduced.

From the viewpoint of the television design engineer, when the degree of multiexcitation is excessive, picture quality will be reduced. From the viewpoint of phosphor physicists who make cathodoluminescence measurements using shrunken rasters, results may be meaningless unless the degree of multiexcitation and current density are specified.

In typical demountable cathode ray tubes, the sample area (which is the same as the raster area) is 10 cm^2 or less, the beam diameter is about 0.1 cm, yielding an effective pulse length of 1.5 μsec, and there may be 100 scan lines per centimeter. This can be compared with a 19 in. color picture tube, which has an area of 1200 cm^2, the same beam diameter of 0.1 cm, an effective pulse length of 150 nsec, and only 8 scan lines per cm.

This then is the reason why there is typically no correlation between demountable tube measurements and data taken on full-size picture tubes. As was shown in Fig. 10, the full size raster will show no multiexcitation effects, whereas the demountable raster, which is about one-tenth full size, will show considerable multiexcita-

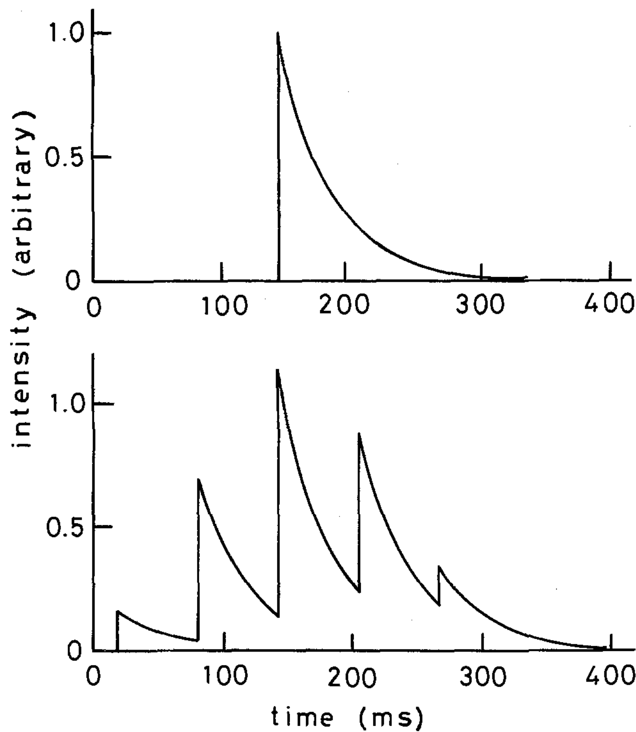

Fig. 9. Idealized time-resolved luminescence without (top) and with (bottom) multiexcitation.

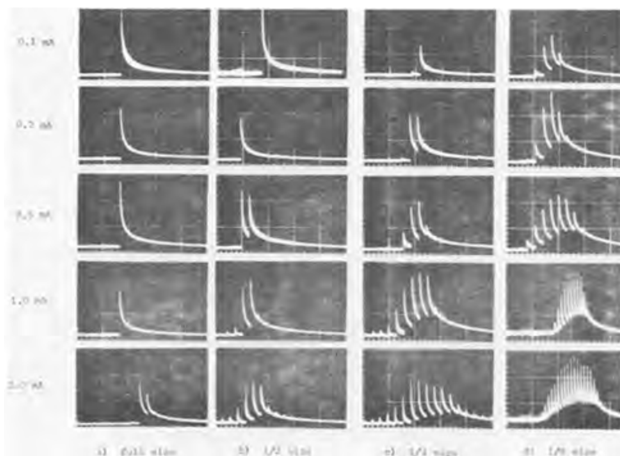

Fig. 10. Actual time-resolved luminescence curves for a 19 in. cathode ray tube at various raster sizes and beam currents.

tion. It is found that multiexcitation tends to linearize raster brightness data, and hides the true degree of saturation (or sublinearity) of the phosphor. In addition, the effective pulse length in the small raster excitation is an order of magnitude longer than in the large area raster, making the impulse approximation invalid for many phosphors.

Determination of Beam Current Density

To calculate the current density requires a knowledge of the current profile, which is determined by the electron gun. The electron beam "diameter" is usually determined by visual observation of the light spot produced by a phosphor. It is possible to use the profile of the oscillograms of a multiply excited phosphor screen to calculate the profile of the electron beam. Figure 11 shows oscillograms of electron beams of different beam profiles, which were created by deliberately defocusing the beam. The envelope of the pulses in the oscillogram is a representation of the electron beam profile, and by an appropriate analytical treatment the beam shape can be extracted. Figure 12 shows a comparison of the beam "diameters" obtained by visual observation (through a telescope) and from multiple excitation oscillograms.

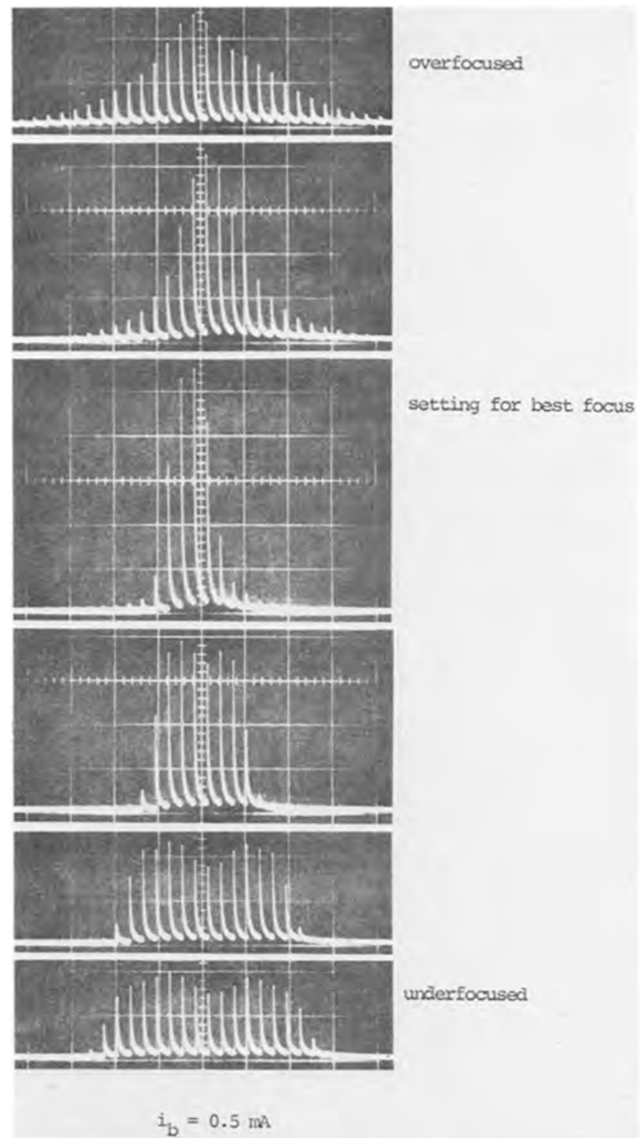

Fig. 11. Multiexcitation effects for a 19 in. cathode ray tube under conditions of focus (center) and defocus (top and bottom).

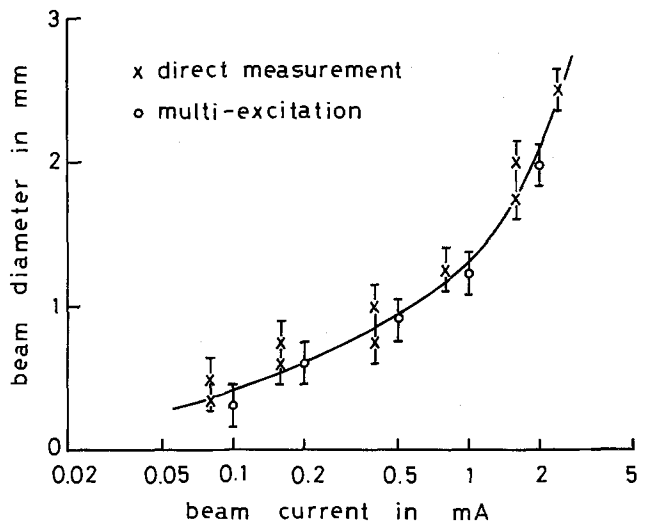

Fig. 12. Dependence of beam diameter upon beam current for a 19 in. cathode ray tube, measured either directly with a microscope or inferred from the number of multiexcitation pulses in a 1/10 height, full-width raster.

One point commonly overlooked is the question of how to define current density. The phosphor crystallites are exposed to an instantaneous current density given by (assuming a "pill-box" current distribution)

$$j = \frac{4}{\pi}\frac{i}{d^2} \quad [14]$$

A common error is to call

$$j' = \frac{i}{A} \quad [15]$$

(where A is the raster area) the current density, while in actuality it is the time-averaged current density. This is not the value to which the phosphor responds. The instantaneous value j, or the integral $\sigma = \int j\,dt$, are the only meaningful quantities if one wishes to study phosphor physics.

Conclusion

Thus we have seen that in a raster excitation experiment, multiexcitation can cause a considerable effect. Any experiment which permits multiexcitation to occur will yield misleading results, as the current density of the excitation pulse will be unknown and the number of excitation pulses per frame will vary as the beam current, and hence beam diameter, varies. It should be pointed out that a raster-scanning experiment wherein only raster brightness measurements are made cannot be properly used even for crude evaluation experiments, for the degree of nonlinearity differs for various phosphors, preventing any comparison, even if the same excitation means (electron gun, deflection yoke, etc.) are used. Hence raster brightness measurements are a poor way to characterize cathodoluminescent phosphors: a much more meaningful technique is a spot brightness measurement as a function of beam excitation density on a single line scan raster, or on a stationary pulsed beam (meeting the criteria discussed above) as a function of current density.

Preparation of Pure and Doped Silicon Carbide by Pyrolysis of Silane Compounds

W. von Muench* and E. Pettenpaul

Institut A für Werkstoffkunde, Technische Universität, D-3000 Hannover, Germany

ABSTRACT

Polycrystalline β-SiC is prepared from three different silane compounds (methyl-trichlorosilane, dimethyl-dichlorosilane, and trimethyl-chlorosilane) by the van Arkel process. The influence of the growth parameters (flow rates, vapor pressures, and deposition temperature) on the growth rate and the stoichiometry of the deposit is investigated. The most satisfactory results in terms of stoichiometry are obtained in the 1400°-1600°C temperature range. Doping is accomplished by adding trimethyl-aluminum and diborane. The 6H silicon carbide crystals are grown by the sublimation technique using doped and undoped polycrystalline material.

The 6H polytype of silicon carbide is considered a potentially useful material for special semiconductor devices, *e.g.*, for light-emitting diodes, high temperature rectifiers, and avalanche diodes. The 6H silicon carbide crystals for electronic applications are produced by sublimation of polycrystalline silicon carbide or elementary silicon and carbon at temperatures around 2500°C (Lely process). In most cases, so far, commercial (green or black) grinding powder has been used as a feed material (1-3); the synthesis from the elements is generally less efficient in terms of crystal size and perfection. With the grinding powder, however, a large amount of various impurities is introduced into the growth system. The resulting (n- or p-type) crystals, therefore, contain compensating (acceptor or donor) impurities and also deep traps. These crystals cannot be directly used for junction formation in most applications. They may serve as a substrate material for VPE or LPE processes; some impurity transfer (autodoping) from the substrate to the epitaxial layer then must be taken into account (4).

The realization of blue light-emitting diodes with a rather high efficiency has prompted the present investigation on the preparation of polycrystalline silicon carbide as a starting material in the Lely process (5). Previous studies on vapor-phase reactions involving silicon carbide were performed with emphasis on single crystal growth of different polytypes (6-13). Knippenberg, Kapteyns, and Hagen were the first to introduce presynthesized (CVD) silicon carbide in the Lely process (14, 15); this material was obtained with a methyl-dichlorosilane source at a low deposition rate (3g/hr). The main purpose of this study is the optimization of the growth rate, the yield, and the stoichiometry of the vapor-grown material. This has been accomplished by proper reactor design, choice of reactants, and deposition conditions. In addition, some observations on the surface morphology are included.

A major problem in the Lely process is the reproducibility of the incorporation of acceptors (mainly aluminum and boron). Previously, these dopants have been added in solid form to the (undoped) feed mate-

* Electrochemical Society Active Member.
Key words: silicon carbide, van Arkel process, methyltrichlorosilane, dimethyl-dichlorosilane, trimethyl-chlorosilane.

rial in the Lely process. It is difficult, however, to obtain uniformly doped crystals in this manner, because of large differences in the vapor pressures of the dopants and the dissociation products of silicon carbide. This problem can be overcome by introduction of dopants during the pyrolysis of the silane compounds. Doping with diborane and trimethyl-aluminum has been investigated in this study.

Experimental

The principle of the van Arkel process is shown in Fig. 1a. Details of the reaction chamber can be seen in Fig. 1b. The (water-cooled) base plate is made from silver-plated copper, the current leads and the gas inlet (nozzles) are of pure silver. It is important that the gas streams ejected from the nozzles are hitting both carbon heater rods uniformly and with high velocity. This can be accomplished by appropriate shaping and adjustment of the nozzles. The carbon rods (6 mm diam, 150-300 mm length) are heated with a.c. under constant voltage conditions. Exact measurements of the temperature (by pyrometry) are possible only in the initial stage of the growth experiment, since reaction by-products are deposited at the inside of the quartz bell jar. It is estimated that the surface temperature of the silicon carbide decreases by about 100°C during the 6 hr growth period. The reaction chamber is carefully evacuated and flushed with pure hydrogen (50 min, at least) before each run. The deposition takes place in hydrogen at atmospheric pressure.

The carrier gas can be saturated with silane compounds kept at (thermostatically controlled) temperatures in the 13°-35°C range. The following compounds have been used: methyl-trichlorosilane, CH_3SiCl_3

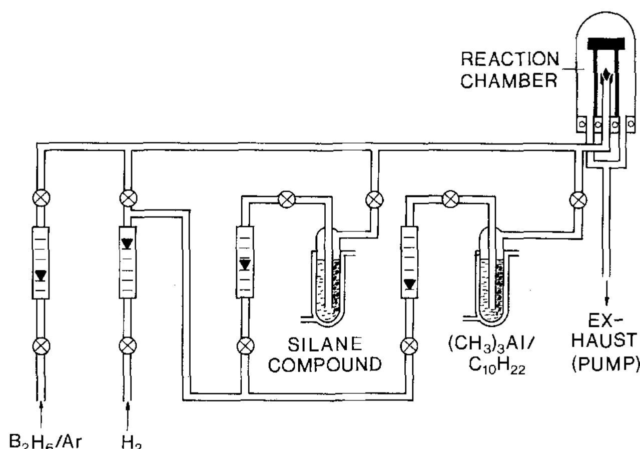

Fig. 1a. Apparatus for the growth of doped and undoped silicon carbide by the van Arkel process.

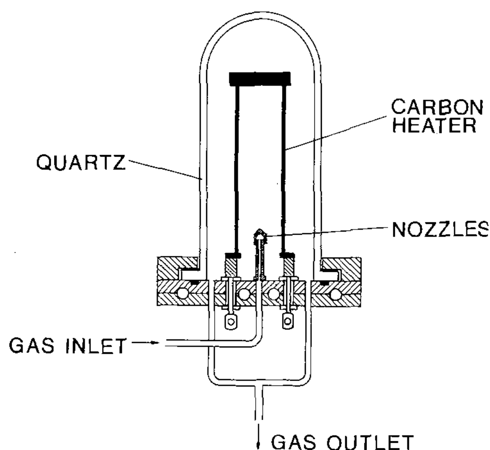

Fig. 1b. Design of reaction chamber

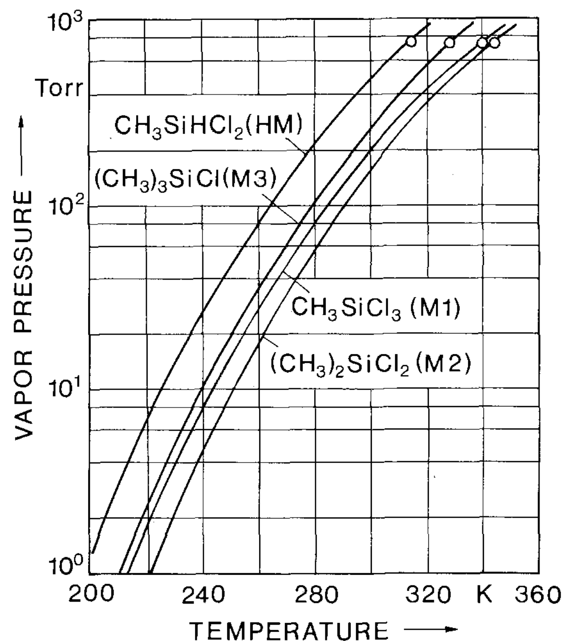

Fig. 2. Vapor pressure of silane compounds. From Landolt-Börnstein (16).

(M1); dimethyl-dichlorosilane, $(CH_3)_2SiCl_2$ (M2); and trimethyl-chlorosilane, $(CH_3)_3SiCl$ (M3). The vapor pressures of these compounds are shown in Fig. 2. The use of methyl-dichlorosilane (HM) appears to be impractical, due to the high vapor pressure at room temperature.

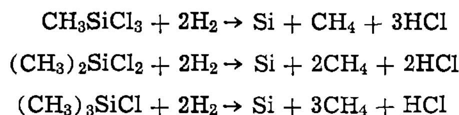
Doping of polycrystalline material with boron is accomplished by adding a metered flow of diborane (diluted in argon) during the deposition cycle. A separate bubbler containing a 10-20% solution of trimethyl-aluminum in n-decane ($C_{10}H_{22}$) serves as the source for aluminum doping; the vapor pressure of n-decane is negligible in the temperature range involved.

The carbon rods and excess carbon (if any) are removed by heat-treatment in oxygen. Any excess of silicon is removed by evaporation in vacuum. Thus, both an excess of carbon and an excess of silicon can be determined quantitatively by simple gravimetric means.

The silicon carbide rods (doped and undoped) are broken into lumps of suitable size and cleaned in hydrofluoric acid. These lumps serve as a feed material for the modified Lely process described previously (5, 14). The 6H silicon carbide crystals are obtained in the form of platelets with flat surface perpendicular to the c-axis. Hall and resistivity measurements are performed by the van der Pauw method.

Growth of Polycrystalline SiC

The growth of polycrystalline silicon carbide from silane compounds can be described in terms of the following reactions (17). At low temperatures (~ 1200°C)

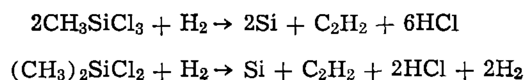


$$CH_3SiCl_3 + 2H_2 \rightarrow Si + CH_4 + 3HCl$$
$$(CH_3)_2SiCl_2 + 2H_2 \rightarrow Si + 2CH_4 + 2HCl$$
$$(CH_3)_3SiCl + 2H_2 \rightarrow Si + 3CH_4 + HCl$$

$$CH_4 \rightarrow C + 2H_2$$

$$Si + C \rightarrow SiC$$

At high temperatures (~ 1800°C)



$$2CH_3SiCl_3 + H_2 \rightarrow 2Si + C_2H_2 + 6HCl$$
$$(CH_3)_2SiCl_2 + H_2 \rightarrow Si + C_2H_2 + 2HCl + 2H_2$$

$$2(CH_3)_3SiCl + H_2 \rightarrow 2Si + 3C_2H_2 + 2HCl + 6H_2$$

$$C_2H_2 \rightarrow 2C + H_2$$

$$Si + C \rightarrow SiC$$

In the intermediate temperature range both methane and acetylene can be formed.

The amount of excess silicon or carbon resulting from the above reactions is dependent on the silane composition and the growth temperature. As shown in Fig. 3, an essentially stoichiometric growth of silicon carbide is possible with all three silane compounds in the 1450°-1550°C temperature range. Methyl-trichlorosilane (M1) yields a relatively large excess of silicon at temperatures below 1400°C. The results obtained with dimethyl-dichlorosilane (M2) and trimethyl-chlorosilane (M3) are quite similar in the 1400°-1500°C temperature range.

The temperature dependence of the over-all growth rate is shown in Fig. 4. With the process parameters fixed as follows: bubbler temperature, 12°C; bubbler flow rate, 60 liters/hr; and total flow rate, 300 liters/hr; one obtains the highest deposition rate with silane M3 (15 g/hr at 1600°C) due to the high vapor pressure of this compound (see Fig. 2). The deposition rates achieved with the silane compounds M1 and M2 are quite similar (6 g/hr. approximately). These figures are valid for a simultaneous deposition on two carbon rods of 150 mm length each. The yield can be increased by 50%, approximately, by using carbon rods of 300 mm length.

A higher growth rate can also be achieved by increasing the bubbler flow rate, at the expense of the bypass flow. An example is shown in Fig. 4 (top curve) for silicon carbide growth using silane M2 (bubbler flow rate 100 liters/hr, no bypass).

Figure 5 demonstrates the influence of the growth temperature on the morphology of silicon carbide (with excess silicon or carbon) produced from dimethyl-dichlorosilane. High density material with small grain size and uniformly distributed excess silicon is obtained at low temperatures. The grain size increases with increasing growth temperature. The excess carbon which is formed at temperatures above 1600°C, is concentrated mainly between particles of silicon carbide. Similar results are obtained with the other silane compounds.

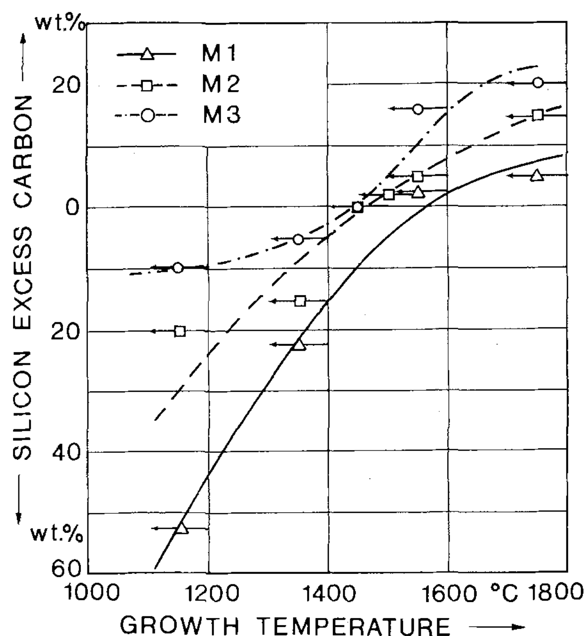


Fig. 3. Deviation from stoichiometry (excess carbon or silicon) vs. growth temperature. Arrows are pointing from the initial growth temperature to the (estimated) temperature at the end of the growth process.

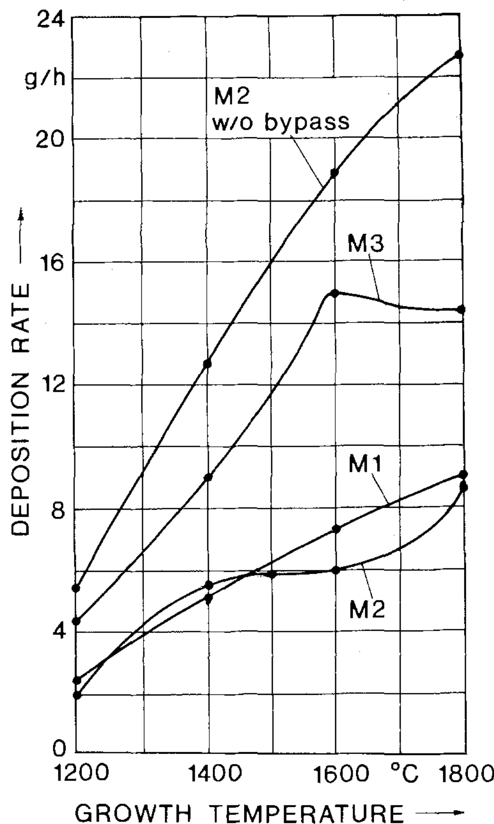

Fig. 4. Temperature dependence of the over-all growth rate. (See text for other growth parameters).

The influence of various process parameters (silane temperature, gas flow) on the growth rate is shown in Fig. 6. As expected, there is a monotonic increase of the growth rate with increasing saturation temperature (silane vapor pressure, Fig. 6a). A higher growth rate can also be achieved by increasing the flow rate through the silane bubbler (Fig. 6b). At flow rates exceeding 60 liters/hr, however, there is only a small further increase of the growth rate. The dependence of the growth rate on the total hydrogen flow (bubbler plus bypass) is shown in Fig. 6c. There is a maximum at 300 liters/hr. Obviously, the deposition reaction will be incomplete if the gas velocity in the vicinity of the carbon rods is too high.

Properties of Silicon Carbide Crystals Grown from the Van Arkel Material

The 6H silicon carbide crystals have been grown by the sublimation technique (Lely process) using commercial "green grit" abrasive and silicon carbide synthesized by the van Arkel process. The electronic properties of these crystals are summarized in Table I. Crystals grown from the abrasive powder are usually p-type and highly compensated; the hole mobility is in the 10-15 cm^2/V sec range. An addition of nitrogen during the Lely process yields n-type crystals with a mobility around 120 cm^2/V sec. Crystals grown from undoped van Arkel material are n-type, with a mobility up to 200 cm^2/V sec. Doping with aluminum and boron has been achieved by adding trimethylaluminum and diborane during the van Arkel process. Using 10 and 20% solutions of $(CH_3)_3Al$ in $C_{10}H_{22}$ (n-decane), hole concentrations between 10^{16} and 10^{18} cm^{-3} have been obtained. The mobility is in the range from 10 to 35 cm^2/V sec.

The dependence of the hole concentration on the partial pressure of the dopant during the van Arkel process is shown in Fig. 7. There is a linear relation-

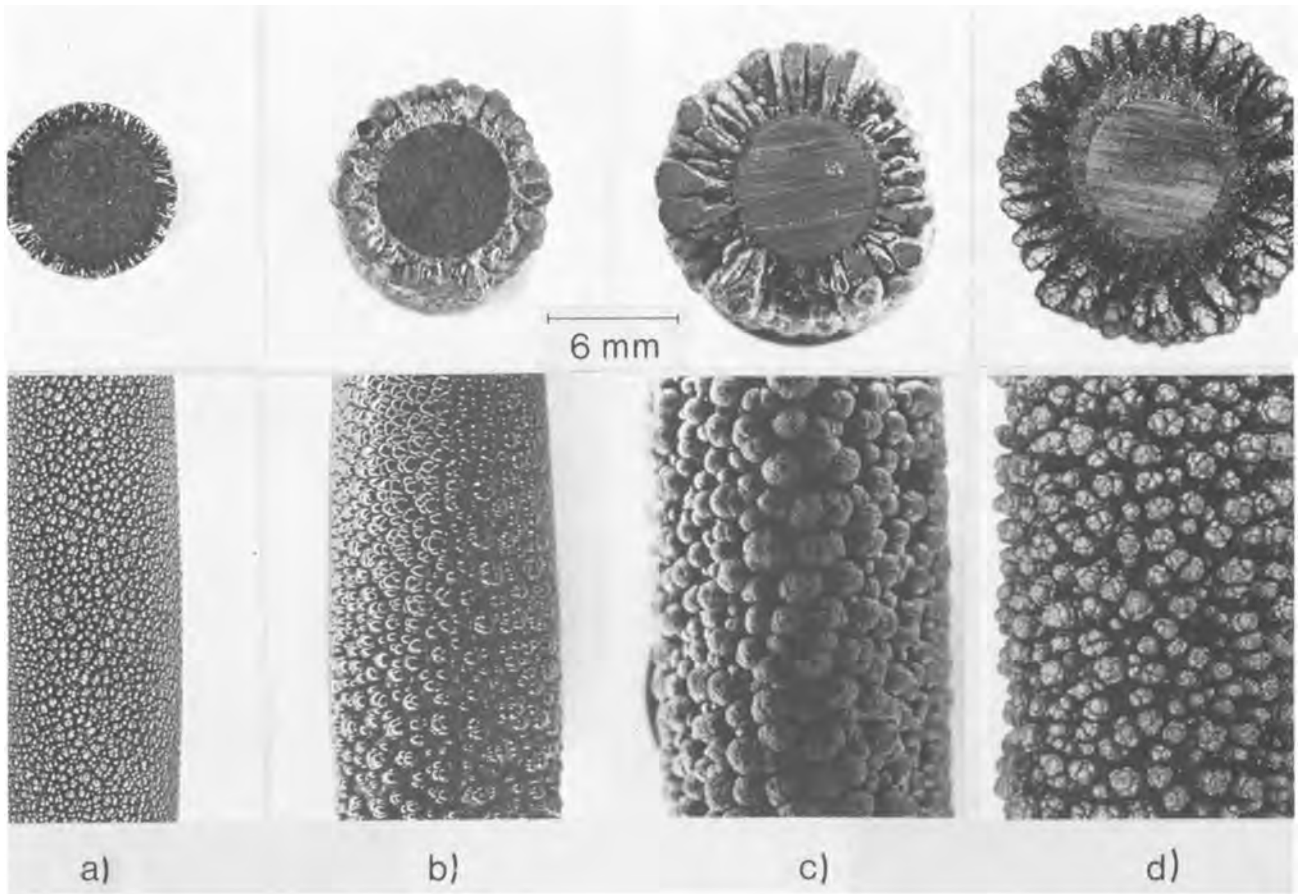

Fig. 5. Morphology of silicon carbide grown by the van Arkel process at different temperatures (silane M2). (a) 1200°C, (b) 1400°C, (c) 1600°C, (d) 1800°C (initial temperatures).

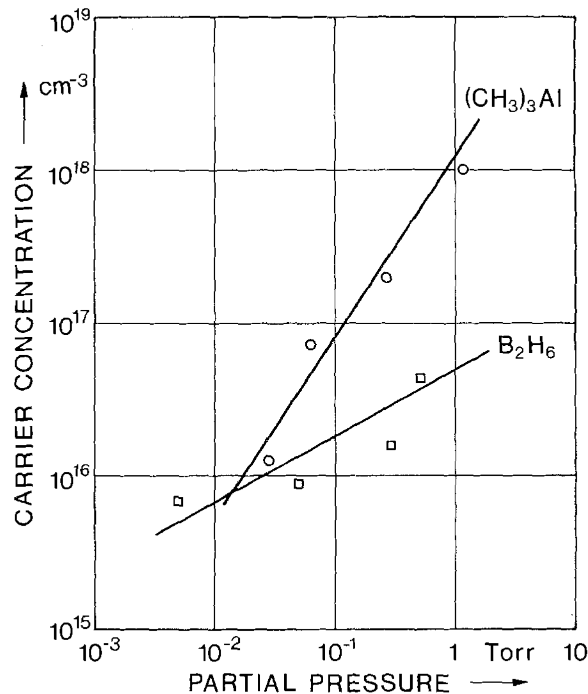

Fig. 7. Hole concentration in Lely-grown silicon carbide crystals vs. partial pressure of doping compound in the van Arkel process.

ship (approximately) for the doping with aluminum. The over-all doping efficiency is much smaller than unity, because of losses of aluminum during the van Arkel process and during the sublimation of silicon carbide (*i.e.*, high vapor pressure of aluminum as compared to silicon carbide). The incorporation of boron exhibits a sublinear behavior. A visual inspection of the polycrystalline material indicates that a large part of the boron is deposited as elementary boron particles. Thus, most of the boron is probably lost during the oxidation and degassing cycles.

The 77°K photoluminescence spectra of silicon carbide crystals grown from different types of polycrystalline material are shown in Fig. 8. Crystals produced from abrasive powder exhibit a broad emission spectrum with a maximum around 640 nm and additional peaks at 505 and 535 nm. The emission spectrum of crystals grown from undoped van Arkel material is dominated by the 640 nm peak. A relatively weak emission peak is found at 475 nm; this peak may be due to a "memory effect" resulting from previous doping experiments with aluminum. Crystals grown from Al-doped van Arkel material exhibit a strong emission peak at 490 nm; the 640 nm peak is also present.

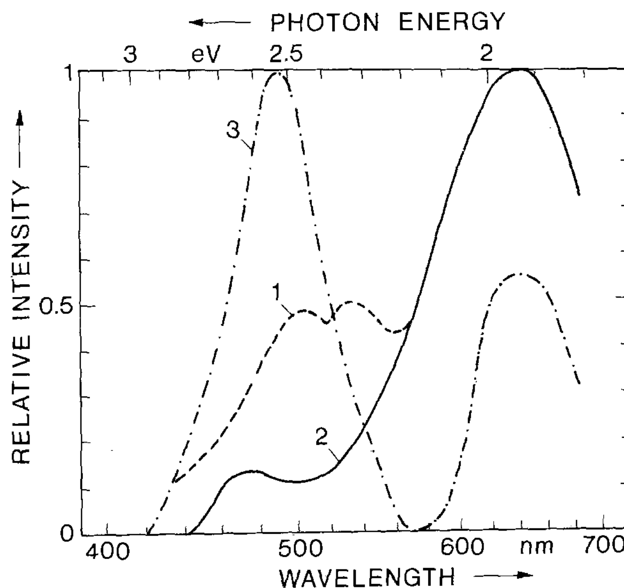

Fig. 8. Photoluminescence spectra (77°K) of silicon carbide crystals grown from different kinds of polycrystalline material: curve 1, "green grit" commercial silicon carbide abrasive; curve 2, undoped silicon carbide produced by the van Arkel process; curve 3, Al-doped silicon carbide produced by the van Arkel process.

The 640 nm peak is also observed for all boron-doped crystals. It is not clear, however, whether boron

		$p = 8 \times 10^{16}$	1×10^{19}	28	270
		$p = 3 \times 10^{17}$	2×10^{19}	22	270
		$p = 1 \times 10^{18}$	2.5×10^{19}	10	270

* Doping during Lely process.
** Doping during van Arkel process.

incorporation is the only reason for the occurrence of this peak; crystal defects may also contribute to the 640 nm emission. The latter process is suggested by the results obtained with crystals of extremely high purity.

Conclusion

Pure and doped polycrystalline silicon carbide can be produced by the van Arkel process using silane compounds. A reasonable growth rate (in the order of 40 g/hr) can be achieved by proper choice of the growth conditions; a stoichiometric deposit is obtained in the 1400°-1600°C temperature range. The polycrystalline SiC material can serve as feed material for the Lely process, *i.e.*, for the growth of 6H silicon carbide crystals. A substantial improvement of the electrical properties (*i.e.*, higher carrier mobility) has been achieved. The process is particularly useful for doping with aluminum; hole concentrations in the 10^{16}-10^{18} cm^{-3} range are obtained reproducibly in this manner.

Optical Reflectance Method for Determining the Surface Quality of Sapphire (Al_2O_3)

P. J. Zanzucchi,* M. T. Duffy,* and R. C. Alig

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Polished sapphire wafers are used as substrates for the growth of crystalline silicon. The quality of the substrate surface is an important factor in determining the crystalline quality of the silicon film and, in turn, relates to silicon device performance and reliability. To improve silicon-on-sapphire device manufacture, a sensitive and nondestructive optical reflectance technique has been developed to determine the quality of polished sapphire surfaces. The correlation between surface damage and single or multiple specular reflectance of sapphire in the lattice mode region, 900-300 cm^{-1}, is reported. As a result of surface damage, the Al_2O_3 vibrational modes of sapphire are distorted and the optical constants associated with these modes change. To interpret the single and multiple reflectance spectra the optical constants of undamaged and damaged ($1\bar{1}02$) sapphire surfaces have been calculated from reflectance data using the Kramers-Kronig method. From this analysis, the reflectance of sapphire at about 600 cm^{-1} is found to be very sensitive to surface quality. In this spectral region multiple reflectance can be used to measure the surface quality of sapphire with a high degree of sensitivity. The technique can, in principle, be used to measure the quality of any semiconductor or dielectric surface in spectral regions of high reflectance, such as regions of lattice band or bandgap absorption.

The crystalline perfection of thin, epitaxial layers is strongly influenced by the crystalline perfection of the substrate surface. From studies of the growth of silicon films (1, 2) on silicon substrates it is well known that defects on the substrate surface lead to crystal growth defects in the epitaxial layer. By the use of Lang topographic techniques, McFarlane and Wang (3) have shown that the crystalline perfection of III-V semiconductor films on sapphire or spinel substrates is significantly altered by defects on the substrate surface. These defects, which often are not visible, are usually scratches introduced in the polishing of the substrate. Defects can cause the epitaxial film to be misoriented in localized regions. As a consequence, this introduces lattice imperfections in the epitaxial film and these imperfections are particularly evident when the epitaxial film is relatively thin, *i.e.*, a micrometer or less in thickness. With the increased use of semiconductors and dielectrics prepared as thin epitaxial films by

* Electrochemical Society Active Member.

Key words: quality control, ($1\bar{1}02$) sapphire, multiple reflectance, Kramers-Kronig method.

chemical vapor deposition, there is a need for a fast and nondestructive technique for determining the quality of polished sapphire surfaces.

An optical multiple-reflectance technique for determining the quality of sapphire surfaces used in silicon-on-sapphire (SOS) device manufacture is described in this paper. It is known from the work of Barker (4) that the procedures used to polish sapphire can introduce lattice damage or strain at the sapphire surface. According to Barker (4), this surface damage deforms the normal modes of Al_2O_3 (sapphire), the associated optical constants change, and forbidden modes appear in the specular reflection spectrum of the lattice modes. Thus optical reflectance can be used to detect polishing-related lattice damage and the magnitude of the optical constants of the sapphire surface can be used to provide a quantitative measure of the damage.

To interpret the reflectance spectrum of sapphire, it is very useful to know the optical constants. These constants are not known for the $(1\bar{1}02)$ orientation, Fig. 1, of sapphire. Since they are important to an over-all understanding of the features of a single and multiple reflectance spectra, we have used the Kramers-Kronig method to determine the optical constants of damaged and undamaged $(1\bar{1}02)$ sapphire surfaces in the lattice mode region. Based on this, lattice mode regions can be selected where the optical properties of sapphire correlate with surface damage. We have used the technique of multiple reflectance to enhance the sensitivity of measuring changes in reflectance associated with surface damage.

Experimental

Materials.—Polished sapphire substrates were obtained from different commercial vendors. Although a best quality "epi" grade polish was specified, the quality of the surface finish varied widely on these substrates. To perform controlled experiments, the observed variation in surface quality was simulated by sapphire substrates which were polished at RCA Laboratories. By using a number of polishing agents with various grit sizes, different degrees of work damage were obtained on the substrate surfaces. Diamond grit, ranging from 1 to 6 μm particle size on a Bakelite base, was used to provide the final surface finish for some. Alumina (Linde A) or colloidal silica (Syton), on a Pellon or Corfam pad, were used to provide better quality surface finish for others. The actual degree of surface damage depended on both the type of agent used and the grit size. For the same grit size, diamond polishes produced more damage at the surface than, for example, alumina polishes. The substrates were 1.5 in.

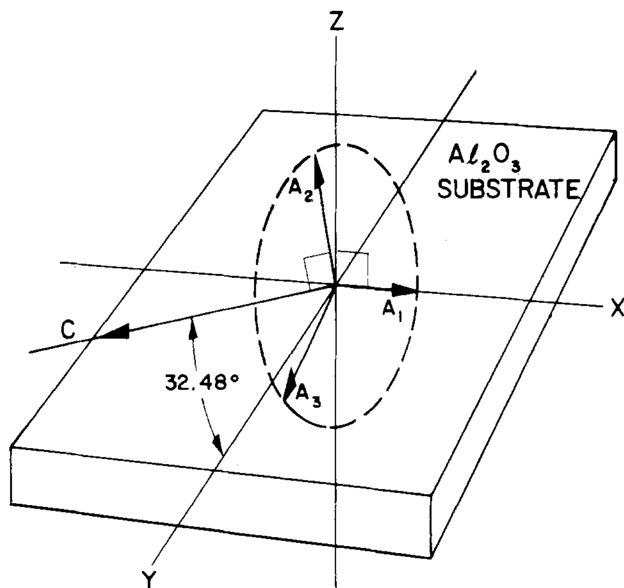

Fig. 1. Vectorial presentation of c and a axes in $(1\bar{1}02)$ sapphire

in diameter with a ground-back surface, and were usually $(1\bar{1}02)$ oriented. In some cases (0001) and $(11\bar{2}0)$ oriented sapphire substrates were examined.

Sapphire is birefringent. The optical constants are measured with the electric vector of light parallel p and perpendicular s to the c-axis. In (0001) oriented sapphire the c-axis is perpendicular to the polished surface. In this case the p and s components are identical. As Barker (4) noted, polishing-related surface damage on the (0001) surface cannot be detected by optical reflectance. With $(11\bar{2}0)$ oriented sapphire the c-axis is in the plane of the polished surface. In the $(1\bar{1}02)$ orientation, the c-axis is about 32° from the polished surface, Fig. 1. For the Kramers-Kronig analysis the polarization of the light with respect to the c-axis must be known. In multiple-reflection measurement the polarization of the light is unnecessary and average effects are measured with unpolarized light.

Evaluation.—As a basis for developing a multiple reflection method to measure surface perfection, it is important to know how the refractive index n and the absorption index k vary in the wavelength region of interest. The values of n and k are related to the measured reflectance, Eq. [1]

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \quad [1]$$

As these constants are altered by the presence of lattice damage, a change in reflectivity occurs and this can be used as a measure of the lattice damage at the reflecting surface. The optical constants for the surface material of the variously polished sapphire substrates were calculated from specular reflectance data using Kramers-Kronig analysis (5-7). The reflectance measurements were made using a Perkin Elmer 457 infrared spectrophotometer and specially designed reflectance jigs. A computer program written by Klucker and Nielsen (6), which is available through the Journal Library at the School of Physics and Applied Mathematics, Queen's University, Belfast BT7, North Ireland, was used to calculate n and k. The program was obtained on tape and used without significant modification.

The calculated optical constants for (0001) Al_2O_3 are similar in magnitude to published data (8). Although optical constants calculated by the Kramers-Kronig method can be inaccurate (9), data from the published work of Arakawa and Williams (10) is used to obtain a reasonable high energy limit of about 25 eV. Our calculated refractive indexes agree well with extrapolated values of the index from the reported data of Malitson *et al.* (11) and Russell and Bell (12).

The absolute reflectance spectra were obtained for the variously polished surfaces using either p or s polarization with respect to the c-axis orientation of the substrate. The direction of the crystallographic axes was determined by Laue x-ray back-reflection. As indicated $(1\bar{1}02)$ is the orientation of sapphire which is of primary interest in silicon-on-sapphire device manufacture and, therefore, this study.

Results and Discussion

Reflectance measurements.—Reflectance spectra obtained on variously polished $(1\bar{1}02)$-oriented sapphire substrates are shown in Fig. 2 which corresponds to p polarization. In this figure, spectrum (a) is used as a reference corresponding to the best surface finish attainable by polishing with silica sol (Sytôn). Spectrum (b) corresponds to a Linde A (Al_2O_3, 0.3 μm grit) polish, and spectra (c), (d), and (e), correspond to surface finishing with 1, 3, and 6 μm diamond grit, respectively. For both polarizations, the spectra show that there is a significant change in the reflectivity near 600 cm^{-1} with increasing grit size, or hardness, of the polishing medium. For other spectral regions, the effect of polishing damage on the reflectance of the sapphire is less evident though clearly present. Similar features occur

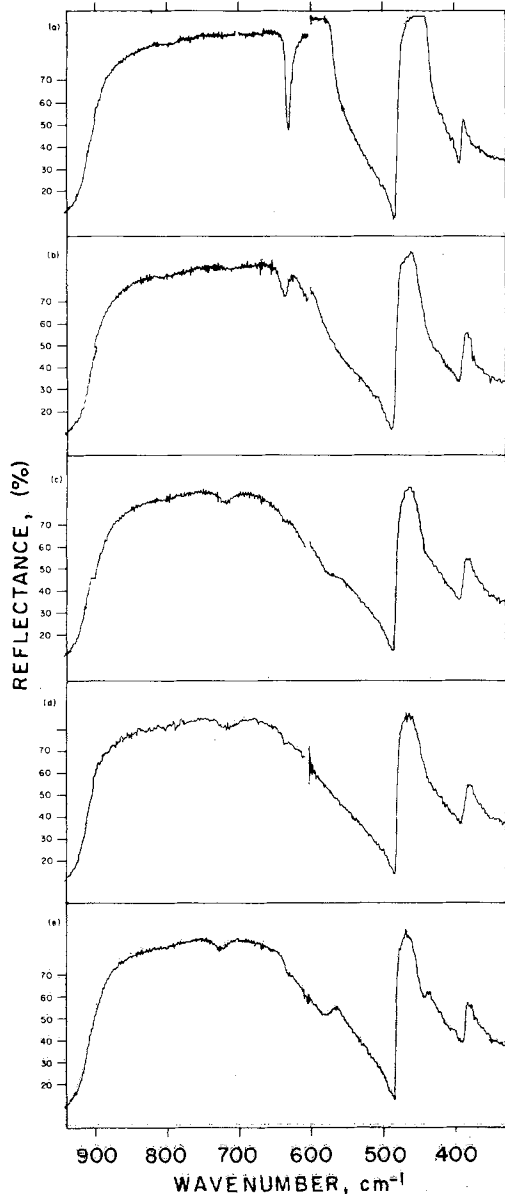

Fig. 2. Comparison of sapphire reflection spectra for variously polished $(1\bar{1}02)$ sapphire, p polarization: (a) Syton polished (best surface), (b) 0.3 μm Al_2O_3, Linde A, (c) 1 μm diamond, (d) 3 μm diamond, and (e) 6 μm diamond.

in the reflectance spectra using s polarization. Using the Kramers-Kronig method, the phase angle θ, refractive index n, and absorption index k, were calculated from the data in Fig. 2. Between 300 and 400 points in the region 250-900 cm^{-1} were used in the calculation.

The computed optical constants corresponding to the different vibrational modes for the variously polished surfaces are summarized in Table I. It is apparent from the data that the surface damage associated with the different sizes of the polishing grit is large. This indicates that any mechanical abrasion, not involving a chemical polishing action as with Syton, is likely to result in a considerable change in the computed values of the optical constants for the sapphire surface. The computed values of the optical constants for a Syton polished (0001)-oriented Al_2O_3 sample are also summarized in Table I.

A basic question concerning these data is their accuracy. Based on the work of Spitzer and Kleinman (7) it is known that the Kramers-Kronig analysis is accurate to better than 10% of "true" value for $k > 0.1$. For lower values of k the accuracy tends to be poor. We observed this. The calculated phase angle for small phase changes was sometimes negative, which is

physically meaningless. In the Kramers-Kronig calculation, the program does not consider the sign of the phase angle. Gross errors are thus expected for small values of the phase angle and correspondingly small values of k. This is not significant at the lattice modes where n and k are very large and, correspondingly, the phase change is large. In comparison to published data (8), the optical constants for the (0001) Al_2O_3 lattice modes reported here are significantly larger in general. However in approximating the limits to the Kramers-Kronig integral, errors can be introduced (7, 9). Simple experimental errors such as determining the angle of incidence, the c-axis orientation, and the polarizer position are not critical. Small errors in these orientations, *e.g.*, a few degrees, do not appear to significantly affect the calculated optical constants, at least not in comparison with the degree the values are affected by the high energy limit selected in the Kramers-Kronig integration. For example, the nominal angle of incidence in these measurements is 10°. If the value is 10° in error, *e.g.*, 20° is used, the error in the optical constants is less than about 5%. The orientation of the c-axis in each crystal was determined by the Laue x-ray technique and the orientations are accurate within a few degrees. Similarly, the polarizer orientation can be accurately adjusted.

Errors in measuring the absolute reflectance are, however, critical in determining the magnitude of the optical constants. When the measured reflectance, R, of our reference sample was deliberately diminished by 0.005, 0.01, and 0.02, respectively, the influence of these small changes on the computed values of the optical constants was considerable as shown in Table II. In this case, the reflectance was measured for s polarization. Thus, small changes in surface reflectance due to residual polishing damage can grossly affect the magnitude of the calculated optical constants. The reflectance data must be accurate to much better than 1% before attempting to determine absolute values of the optical constants. For our purposes, relative changes in the magnitude of these constants gives a reasonable insight into the effects of polishing damage and the absolute values are not critical.

In summary, it is apparent that deliberately introduced polishing damage significantly changes the optical constants of the Al_2O_3 surface. For sapphire with considerably less damage than introduced by our selective polishing, we can expect to measure significant changes in the infrared optical properties of sapphire. However, Kramers-Kronig analysis is not practical for testing the surface quality where frequent testing of many samples is required as in a production facility.

The experimental procedures and the mathematical calculation are time consuming. More significantly, the magnitude of the difference between undamaged and slightly damaged surfaces, while not small, is still not sufficient for detecting lightly damaged surfaces. Based on the data reported here, it is desirable to have a technique with an order of magnitude more sensitivity to surface damage which can be obtained using the technique of multiple reflection as discussed in the following section. It should be emphasized, however, that interpretation of the multiple reflection spectra is not possible without knowing the behavior of the optical constants in the region of interest.

Multiple reflection measurements.—Multiple reflection techniques are well known and are often used to amplify small changes in reflectance. At least two conditions can be specified for the multiple reflection of light: (*i*) multiple external reflection where the light is external to a medium of higher refractive index, and (*ii*) multiple internal reflection where the light is contained by a medium of higher refractive index. For either multiple external or internal reflection, it is well known that surface defects diminish the intensity of the reflected light beam. The loss may be very small for a single reflection but becomes amplified with multiple reflection. For example, the reflectance R_m after m reflections from a pair of parallel metal surfaces (external reflections) is given by

$$R_m = R^m \qquad [2]$$

where R is the absolute reflectance of the surface, *i.e.*, the reflectance measured with a single specular reflection. For 10 reflections between two metal surfaces of 0.96 reflectance, the measured reflectance is 0.66. If damage introduces a 0.01 change in reflectance of the metal surface, *i.e.*, $R = 0.95$, the measured reflectance after 10 reflections is 0.60. A 0.01 change in reflectance is amplified to a 0.06 difference. Obviously, as the surface damage of a good reflector increases, the larger the change in R_m for a given value of R. It is also apparent that the effect of multiple reflection in regions of low reflectivity is to rapidly diminish the measured reflectance. Thus, a multiple reflection spectrum retains only a portion of the spectrum where the reflectance is close to one.

This technique can be applied to dielectrics and semiconductors in spectral regions where the optical constants are very large and the reflectance of the materials is very high. This follows from the relation between R and the optical constants for reflection from single surface at normal incidence, Eq. [1]. For large n and k, R is large. For sapphire this occurs at the lattice modes and R can be as large as 0.96. Thus, as

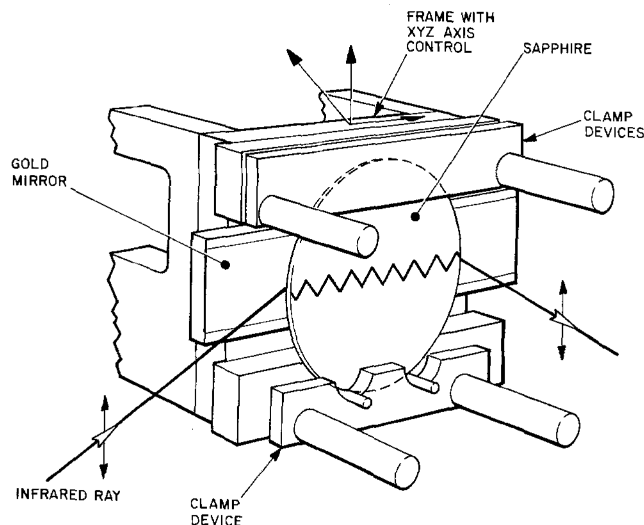

Fig. 3. Schematic representation of multiple reflections between a gold-surfaced mirror and a sapphire substrate.

shown in Fig. 3, multiple external reflections are obtained from a sapphire surface by using a gold mirror. Reproducible mounting of the sapphire wafers is required. As shown by Fig. 3, the sapphire wafer is mounted at a fixed distance from a gold-surface mirror. The distance is selected to produce about 10 reflections. All components are rigid and fixed. The sapphire wafer is demountable. The multiple reflection jig is mounted on a three-axis micrometer stage to precisely position the jig in the infrared beam. The sapphire is strongly reflecting in regions of large n and k and poorly reflecting in regions of small values for the optical constants. The effects of surface damage in relation to the optical constants of the surface material will be amplified by changes in the measured multiple reflectance. The reflectance is measured with unpolarized radiation without regard to the c-axis orientation of the sapphire substrates.

The qualitative features of the resulting single and multiple reflection spectra are shown in Fig. 4. In the multiple reflection spectra, note the loss of weak band structure, the frequency shift, and the decrease in amplitude of the band at 600 cm^{-1} for the damaged

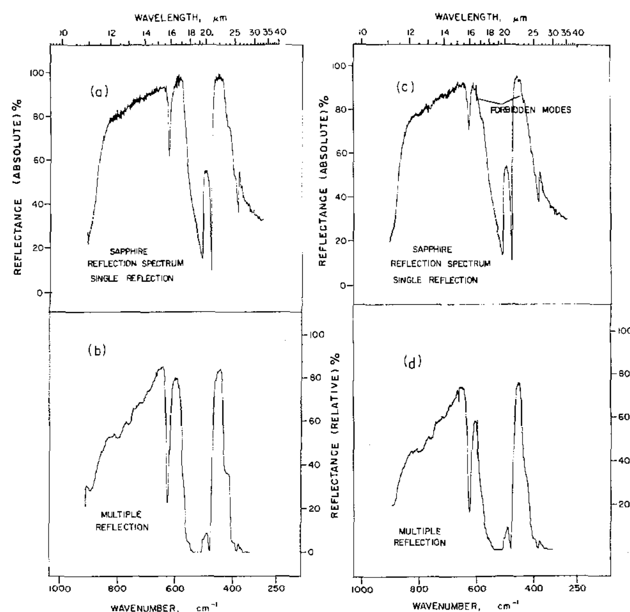

Fig. 4. Reflection spectra of undamaged and damaged sapphire: (a) undamaged, a single reflection spectrum; (b) undamaged, a multiple reflection spectrum; (c) damaged (as received), a single reflection spectrum; and (d) damaged (as received), a multiple reflection spectrum.

sample in comparison with the undamaged sample. The correlation between surface damage and the measured reflectance near 600 cm^{-1} in the multiple reflection spectrum gives a relative, quantitative, and rapid evaluation of surface damage.

Multiple reflection measurements on an absolute scale were performed on the set of variously polished substrates characterized by the Kramers-Kronig analysis. The reflectance scale was calibrated by a gold mirror reflector and a reference trace was obtained by scanning the spectral region 400-900 cm^{-1} using a gold-coated polished sapphire substrate of the same diameter as test samples in the sample beam. The reflectance, after an estimated 10 reflections between the gold mirror and gold-coated sapphire sample, is shown in the upper trace (a), of Fig. 5. The curve shows a sharp discontinuity at 600 cm^{-1} due to instrumental effects. A grating change occurs here which causes a shift in the curves due to grating tilt. All curves show this discontinuity, which is reproducible and does not affect the interpretation of data. After the reference trace was established, the variously polished samples were substituted for the gold-coated sample, and the spectra obtained are sequentially presented in Fig. 5. An analysis of the spectra show that, with diamond polishing, irrespective of grit size, the surface is so badly damaged that the vibrational modes of Al_2O_3 are not detected. In the case of Linde A (0.3 μm alumina grit), a band at 600 cm^{-1} has shifted to approximately 610 cm^{-1} and the amplitude is diminished to less than half the magnitude corresponding to a silica sol surface finish. This is consistent with the previous Kramers-Kronig dispersion analysis of these damaged surfaces. Thus, we expect to be able to detect damage caused by polishes much finer than studied here. After the infrared analysis, the substrates were etched in aqueous KOH at about 300°C to delineate polishing damage. Comparison of etch data with the infrared data in Table I shows the same quantitative trends as observed in the values of the optical constants. Multiple reflectance measurements were also performed on about 30 as-received sapphire wafers obtained from different vendors. Multiple reflection spectra for the best and worst surfaces together with photographs of the corresponding etched surfaces are shown in Fig. 6 and 7, respectively. It is evident from these figures that a wide variation in surface finishing can occur among samples from the different vendors.

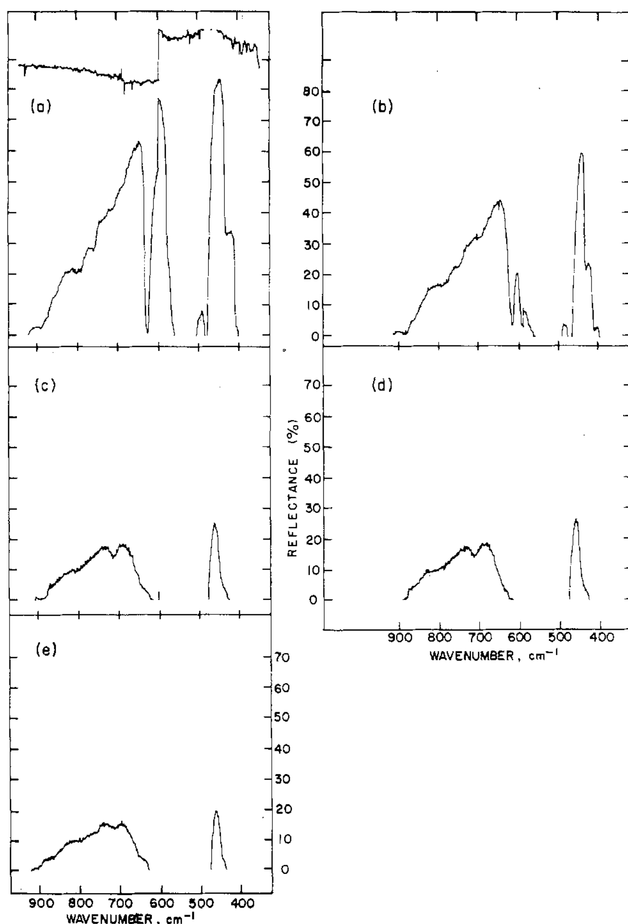

Fig. 5. Absolute multiple reflection measurements for variously polished sapphire surfaces: (a) upper trace gold standard vs. gold mirror normally present, lower trace sapphire wafer with "best" finish, (b) sapphire wafer with a 0.3 μm (Al_2O_3) polish (c) sapphire wafer with a 1 μm diamond polish, (d) sapphire wafer with a 3 μm diamond polish, and (e) sapphire wafer with a 6 μm diamond polish.

Differential methods to evaluate polished surfaces were also examined. However, with this technique it is difficult to obtain a true null signal due to the sharp and widely varying reflectance of the Al_2O_3 vibrational modes.

Factors influencing reflectance measurements.—The symmetry properties of sapphire strongly influence vibrational mode frequency and amplitude. It should be noted that the infrared technique is specifically measuring a molecular distortion which is characteristic of surface damage (4). If this distortion in sapphire is eliminated by an annealing treatment, evidence of such damage is no longer apparent in the infrared reflectance spectra even though etch striations may still appear in chemical etch treatments. It is important, therefore, that the reflectance technique be used prior to sample annealing. Even relatively low temperature annealing, 1000°C, is effective in this respect. Note such anneals may not remove damage but remove the characteristic optical features of the damage. When the surface damage in sapphire is not measurable, due for example, to prior annealing of the material, using the same principles outlined here, the surface quality of the epitaxial semiconductor can be measured in regions well above bandgap. The features of this measurement, and the correlation to electrical properties, will be reported (13).

The external multiple reflectance technique requires reproducible mounting of sapphire samples. For absolute measurements and for comparison purposes, alignment of the various components is important and reflecting surfaces should be very clean. Failure to observe these conditions can result in diminished reflectance throughout the spectral region of interest. Thus, if the reflectance is measured at a given wave number near 600 cm^{-1}, there may be some doubt as to whether the measured value is representative of the degree of surface perfection. For in-line quality control purposes a preferable procedure is to represent the surface condition of a given sample by the ratio of the reflectance at 600 and 450 cm^{-1}, *i.e.*, $R_{600}\ cm^{-1}/R_{450}\ cm^{-1}$. This minimizes errors due to misalignment and surface cleanliness. In addition, for lightly damaged samples the reflectance at 450 cm^{-1} is not noticeably influenced by the presence of damage.

Summary

A quantitative, sensitive, and nondestructive multiple reflectance technique to detect small changes in the surface quality of sapphire has been described. As shown, commercially polished sapphire will have wide variation in surface perfection. The effect of this is to cause wide variation in the crystalline perfection of epitaxial semiconductors grown on these substrates.

The multiple reflectance technique described is based on changes in the optical constants, and thus reflectance, with surface damage in the 600 cm^{-1} spectral region. To interpret the multiple reflectance spectrum, we have obtained the optical constants for $(1\bar{1}02)$ sapphire, with various surface finishes, using the Kramers-Kronig method. The accuracy of this technique has been discussed. From this analysis, the reflectance of sapphire at about 600 cm^{-1} is found to be very sensitive to surface quality. For unannealed sapphire substrates, multiple reflection in this spectral region can be used to

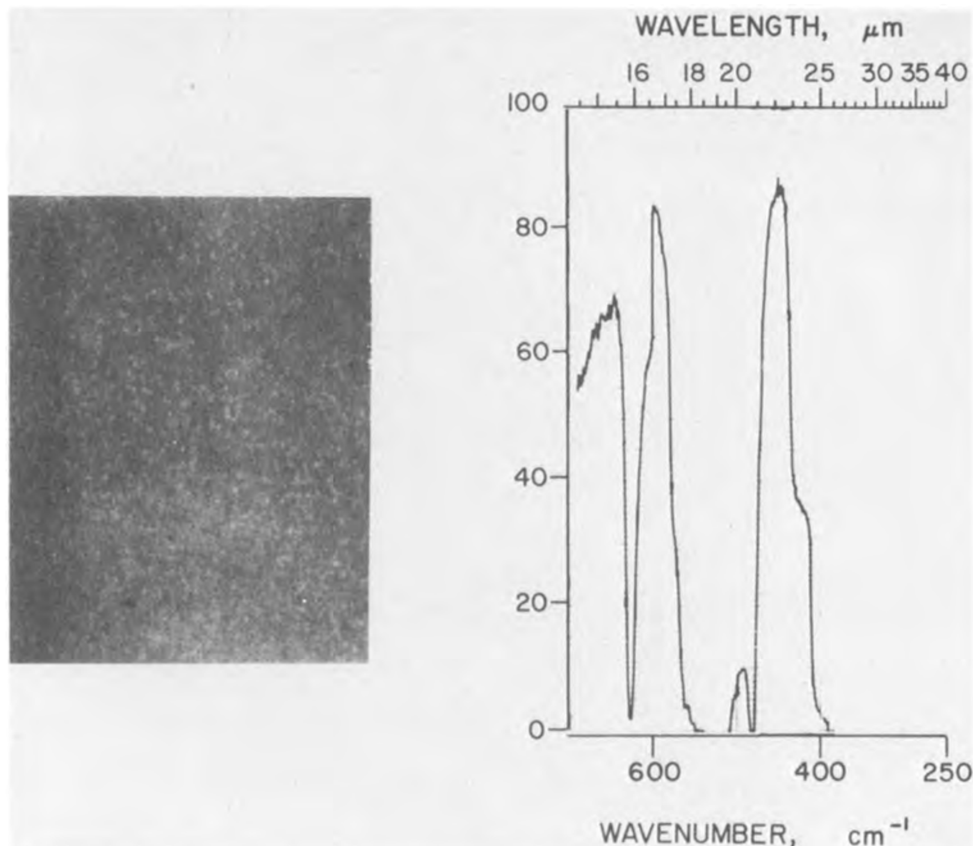

Fig. 6. As-received commercial sample of sapphire, best sample. Comparison of multiple reflection and chemical etch data.

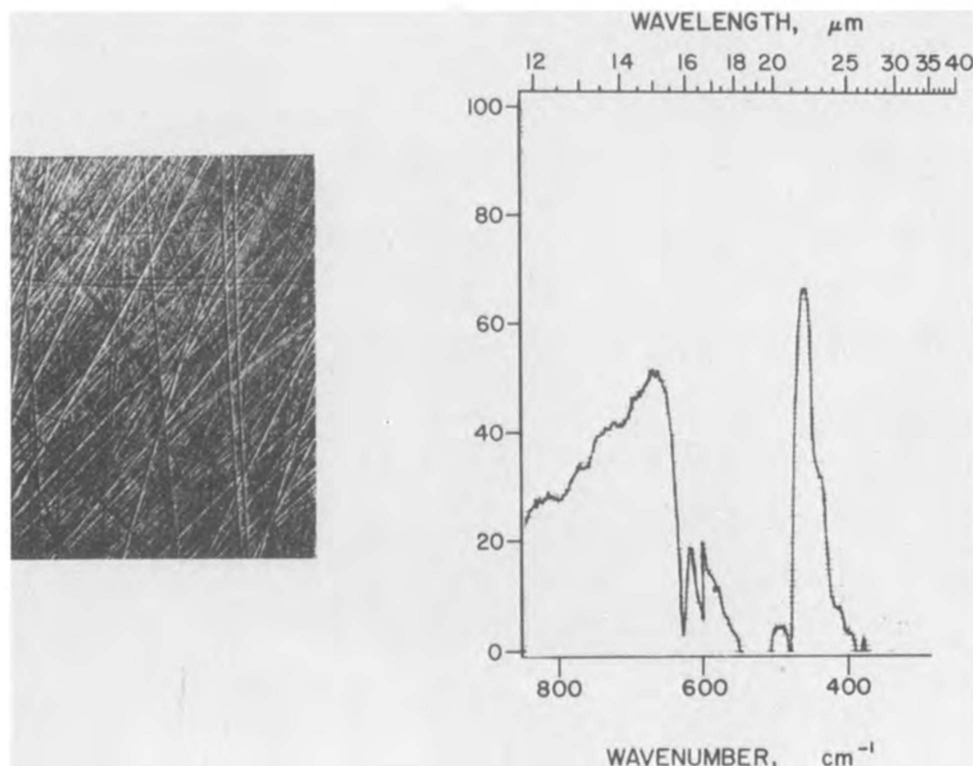

Fig. 7. As-received commercial sample of sapphire, worst sample. Comparison of multiple reflection and chemical etch data.

measure the surface quality of sapphire with a high degree of sensitivity. For clean substrates, the technique is adaptable to quality-control evaluation of substrates used in silicon device manufacture. In principle, the multiple reflectance technique can be used to measure the surface quality of polished semiconductors or dielectrics in spectral regions of high reflectance, *i.e.*, regions of lattice band or bandgap absorption.

Acknowledgments

We greatly appreciate the technical assistance of E. M. Botnick for assisting with the computer calculation and R. A. Soltis and D. A. Kramer for preparing samples and obtaining many of the measured values reported here. Technical discussions with J. I. Gittleman at RCA Laboratories and with K. Galloway and W. M. Bullis at NBS have been helpful and are also appreciated. This research was funded by the Advanced Research Project Agency Order 2397 through the National Bureau of Standard's Semiconductor Technology Program Contract 5-35915. Funding was also provided by RCA Laboratories.

Selective Studies of Chemical Vapor-Deposited Aluminum Nitride-Silicon Nitride Mixture Films

S. Zirinsky and E. A. Irene*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Films of aluminum nitride and mixtures of aluminum nitride and silicon nitride have been chemically vapor deposited upon silicon and sapphire substrates within the temperature range of 600°-1100°C by the ammonolysis of gaseous aluminum trichloride and silane. Characterization of film properties included; film morphology as observed by transmission electron microscopy (TEM), optical properties, dissolution rate, residual stresses, electrical conduction, and charge-storage behavior, as a function of composition and deposition parameters. Some compositions appeared promising for programmable read only memory applications (MIOS-FET) based upon low write-erase voltages, good fatigue, and charge retention properties.

The potential for aluminum nitride (AlN) as a useful dielectric material for device applications has been frequently alluded to, and includes MIS charge storage (1, 2) and surface acoustic wave devices (3). The preparation and properties of polycrystalline films have been thoroughly explored and well documented (4, 5). Their crystalline structure under all reported conditions of vapor deposition minimizes their utility for MIS applications, since amorphous films are considered to show more uniform electrical and physical properties and lower permeability to the diffusion of impurities (6).

Amorphism can be achieved by low temperature sputter deposition (1), but annealing causes reversion to a crystalline structure (1). Oxygen additions [25-45 weight percent (w/o)] will produce amorphous mixtures of AlN and Al_2O_3 (7). Some of these compositions exhibit significant charge-storage hysteresis with bipolar pulse biasing (7, 8). MNOS-type charge-storage devices made with these compositions exhibited instabilities with regard to multiple pulse stressing and read biasing during long-term storage (8).

The thrust of the present study is to obtain candidate materials from which to construct metal-insulator-oxide-silicon, MIOS charge-storage devices which exhibit better charge storage capability than MNOS (metal-Si_3N_4-SiO_2-Si) or MAOS (metal-Al_2O_3-SiO_2-Si) systems. For this purpose candidate insulator films must meet many physical properties' criteria. For example, the electrical conduction characteristics must show charge storage, the films must be etchable in order to be able to fabricate devices, film stress must be low enough so as not to damage other films or silicon, and the morphology is best if amorphous, so as to avoid grain boundary effects. It is also desirable that the dielectric properties be similar to those exhibited by silicon nitride. Therefore these properties are measured in the present study to select the best compositions for charge storage applications. The measurements utilized are those previously applied for the study of materials and processing parameters associated with MNOS structure (11).

Only limited miscibility between AlN and Si_3N_4 has been reported (9) at high temperatures. However, it may be possible to obtain single phase films over a wider composition range by producing metastable amorphous solutions by chemical vapor deposition (CVD). Such solutions have been previously prepared by CVD in the AlN-Al_2O_3 system (7). These compositions exhibited lower electrical conductivity values and enhanced dielectric reliability as compared to the starting materials. Therefore, CVD in the AlN-Si_3N_4 system will be used for film preparation in the present study.

Although the preparation of materials by CVD in the ternary system Al, N, Si in principle involves the control of many parameters (*e.g.*, flow rate, purity, concentrations of reacting species, temperature, etc.), it was reported (5, 6) that AlN and Si_3N_4 can both be prepared similarly by the ammonolysis of $AlCl_3$ and silane, respectively. The deposits even show nearly equivalent deposition rates under the same conditions. These relationships will be utilized to characterize and explore the CVD of mixtures of AlN and Si_3N_4.

Experimental Procedures

Film preparation.—Chem-mechanically polished silicon wafers measuring 3.2 cm in diameter and 0.025

* Electrochemical Society Active Member.

Key words: memory, charge storage, physiochemical properties.

cm thick with <100> orientation were utilized in this study. Typically, 2 Ω-cm p-type Si was used unless otherwise stated. Each Si wafer was thoroughly cleaned by a procedure previously described (10).

Chemical vapor deposition (CVD) was used to prepare the individual and mixed films of AlN and Si_3N_4 by ammonolysis of gaseous $AlCl_3$ and SiH_4, respectively, in an N_2 ambient. The procedures and apparatus for the preparation of the individual AlN and Si_3N_4 films as well as mixed films of AlN and Al_2O_3 were previously described (11, 12). The present study utilized an RF heated furnace (11) with gas handling equipment capable of transpiring $AlCl_3$ with N_2 along with SiH_4 and NH_3 into the reaction zone of the furnace. Final mixing of all the reactants occurred just prior to the entrance into the deposition tube. The deposition chamber consisted of a rectangular (30 mm high by 70 mm wide) fused silica liner. The silicon wafer carrier was heated by radiation from an RF heated graphite susceptor, separated from the wafer carrier by a sealed quartz envelope so as to prevent contamination of the heated wafers from graphite reaction products. The deposition uniformity was also improved by use of a tapered fused silica canopy, positioned so as to compensate for rear position depletion of the gaseous reactants (11). The film compositions were determined by electron microprobe analysis.

Electron microscopy.—The films of interest (AlN, Si_3N_4, and mixtures) were prepared for transmission electron microscopy, TEM, by etching holes through the silicon while leaving free-standing ~500Å films for TEM study. The details of this procedure were previously reported (7). Films prepared in this way were readily transparent to 100 kV electrons.

Optical properties.—The film thicknesses were measured by ellipsometry. The refractive indexes obtained from ellipsometry for both AlN and Si_3N_4 for 5461Å light were ~ 2.0. The AlN and mixtures of AlN and Si_3N_4 were optically absorptive within the visible region, and therefore necessitated the evaluation of their optical absorption coefficients. These were determined, for AlN, Si_3N_4, and the mixtures, with a double beam Cary 14 spectrophotometer. Films on the order of 5000Å were deposited at 900°C on sapphire substrates. Transmission measurements (referenced to a blank sapphire substrate) were carried out to determine the film absorption within the wavelength range of 2800-6000Å. Measurements were carried out with AlN and several AlN/Si_3N_4 mixtures prepared at low NH_3/($AlCl_3$, SiH_4) reactants ratios, all deposited at 900°C. The absorption edges were calculated for all the films examined using the direct transition hypothesis (13).

Stress measurements.—Selective stress studies were carried out as a function of deposition temperature for AlN (using a fixed deposition rate of 250 Å/min), and with varying AlN/Si_3N_4 mixture ratios deposited at 800 °C. All films were prepared with high NH_3/($AlCl_3$, SiH_4) reactants ratio. These were deposited upon <111> oriented silicon substrates with calibration of their radii of curvature prior to film deposition using Taleysurf diametric profile measurements. The change in radius of curvative of the substrate with film deposition permitted the determination of the net stress within the film (14). The weight of the Taleysurf stylus during the surface profiling did not introduce any error from induced surface deflection, since it can be shown analytically (15) that the induced deflection of the substrate (considered as a membrane or cantilever supported at one point) varies linearly with the distance traversed by the stylus. This results in a correctable orientation bias for the stylus displacement and the recorded stylus measurement indicates true radius of curvature.

The stress within the film is then determined to be (14)

$$\Delta_T = \frac{E_{Si}}{(1 - \nu_{Si})} \cdot \frac{t^2_{Si}}{t_f} \cdot \frac{1}{R_{Si}} \quad [1]$$

Δ_T is the total room temperature film stress; E_{Si} and ν_{Si} are the Young's modulus and Poisson's ratio for the silicon substrate, respectively; t_{Si}, the silicon substrate thickness; t_f, the film thickness; R_{Si}, the radius of curvature of the silicon substrate measured along the normal to the coated surface. Measurable radii of curvature are obtainable with 3.2 cm silicon substrates, 0.025 cm thick, and films under 0.5 μm thick. Three radii measurements are required in the order indicated; (*i*) the orginal uncoated substrate, (*ii*) the coated substrate, and (*iii*) the bare substrate after etch removal of the film. The last measurement is required to confirm that no plastic deformation of the substrate has occurred as a result of the high temperature film deposition. For the <111> oriented Si, E_{Si} and ν_{Si} are symmetrical in all directions within the plane of the Si surface. The value, 2.305 × 10^{12} dyne/cm² was used for $E_{Si}/(1 - \nu_{Si})$ (16). The calculated stress values for Si_3N_4 films were found to correlate with stresses evaluated from optically determined radii of curvature (similarly deposited films) (17).

The stress contribution arising from differences in thermal expansion can be calculated by use of the approximate relation

$$\Delta_{Th} = (\alpha_f - \alpha_{Si}) \frac{\overline{E}_f}{(1 - \nu_f)} (T_{dep.} - T_{RT}) \quad [2]$$

Δ_{Th} is the thermal stress contribution to the total film stress at room temperature and is tensile if the thermal expansion of the film is greater than that of the substrate. $(\alpha_f - \alpha_{Si})$ is the algebraic difference in the mean thermal expansion values between room (T_{RT}) and the deposition temperature ($T_{dep.}$). $\overline{E}_f/(1 - \nu_f)$ is the appropriate elastic stiffness term using averaged coefficients over the temperature range evaluated. The appropriate values for the thermal stress calculation are indicated within Table I. The thermal stresses for the mixtures were assumed to be additive in proportion to the volume ratio of the mixed components. The intrinsic stress can then be calculated from knowledge of the measured total room temperature stress and the calculated thermal stress.

Chemical etching behavior.—The chemical etching behavior of the AlN and mixtures was examined in several solvents. For the AlN, rapid solubility was observed in strongly oxidizing acidic and basic solutions (frequently used for Si substrate cleaning), but the films were found to be insoluble in both HF and HF plus HNO_3 mixtures. Quantitative measurement of etch rate in 85% H_3PO_4 was carried out (using ellipsometric measurements for thickness change) for AlN and the AlN-Si_3N_4 mixtures. These measurements

are useful for device processing because of the insolubility of SiO_2 within H_3PO_4 (up to 200° C).

Electrical measurements.—D-c electrical conduction measurements were carried out in the range of 20°-200°C for AlN and Si_3N_4 films as a function of deposition temperature, and with varying composition mixtures at a single deposition temperature. Other deposition parameters were the same as those for the TEM and stress studies. Test devices were simple MIS dot capacitors, using Al gate electrodes and both n and p low resistivity Si substrates. No significant difference in conduction was observed for alternate gate electrode polarity, or change of substrate. Additionally, no thickness dependence was observed for films within the range of 500-3000Å. The log J/E *vs.* $E^{1/2}$ dependence is linear above approximately 1 MV/cm. Linearity of log $J/E|E \rightarrow$ o *vs.* $1/T(o_K)$ was observed between RT and approximately 200°C, above which significant decrease in slope was observed.

The charge storage behavior of AlN and various mixtures were evaluated utilizing MNOS-type configurations as was previously used to study Si_3N_4 (11). The capacitive type test structure used n^+-diffused lines in a grid pattern in 2Ω cm p-type Si substrates that allowed for pulse injection of electrons and holes, yielding high frequency *C-V* traces similar to those observed with low frequency traces, *i.e.*, the V-shaped traces. The *C-V* minima correspond to the "turn on" threshold voltage for FET's.

The charge window is defined by the voltage displacement of the *C-V* trace following application of a sufficiently high voltage to the capacitor gate. The voltage displacement is measured at either capacitive flatband for nongridded substrates or at C_{min} with the gridded substrates (11). The theory of this behavior with "MNOS"-type structures has been well documented (23-25). Two suitable reference charge states are obtained by either positive or negative bias saturation, which is defined as the longest pulse width, at constant voltage, that does not result in additional displacement of the *C-V* trace, and additionally does not result in electrical breakdown, by shorting, of the capacitor. This type of biasing is considered the "erase" mode. "Writing" is carried out by immediate (milliseconds to seconds) application of voltage pulses, shorter than the "saturation" pulse, and of opposite polarity. "Read" measurements are obtained with voltage biasing only within the substrate range of accumulation to inversion, with care observed not to extend the bias into deep depletion, otherwise the state of charge will be changed. This aspect is important for long-term charge leakage (memory life) measurements (26). The dynamic charge window is obtained with the following sequence: erase-read-write-read. The write pulses are applied at varying time lengths at constant voltage. Measurements are made for both positive "write" from negative "erase" (injection of electrons from the substrate into the insulator charge trapping layer) and negative "write" from positive "erase" (injection of holes). Reverse leakage to the substrate (discharge) after "write" biasing (26) results in shrinkage of the dynamic charge window. Therefore, "read" sensing (11) of the charge window was carried out with time delays (following application of the "write" pulse) between 35 and 100 msec. The electrical apparatus for carrying out the procedure has been described previously (11). The same apparatus was used for multiple pulse endurance testing. For these latter studies, the broadening of the V-shaped *C-V* trace, measured at flatband, gave qualitative indication of interface state generation with excessive single, or multiple pulse ("fatigue") stressing. This condition generally presaged device failure (11, 27).

Long-time charge retention behavior was evaluated with the same structures utilized for the dynamic charge window measurements. Chips containing these structures were bonded to TO-5 headers and stored in room ambients for periods up to 15 months. The gate and substrate leads were always shorted except when interrogating the state of the charge. All devices on long term test were pre-exercised over approximately 10^5 cycles and put on standby in either the "write" or "erase" mode.

Experimental Results

Chemical vapor deposition.—Because of the reactivity of $AlCl_3$ and NH_3, prereaction and depletion of these reactants occur in the upstream portion of the heated susceptor. This factor, previously reported for the preparation of $Al_xO_yN_z$ films (13), caused difficulty in obtaining axial uniformity. Higher carrier gas flow rates and the use of tapered canopies over the susceptor were helpful in improving uniformity. However, the most useful solution was obtained by lowering the ratio $NH_3/AlCl_3$ from 170/1 ($HiNH_3$) to 1.7/1 ($LoNH_3$) for the AlN preparation. The improvement is shown in Fig. 1.

A similar effect can be realized for the Si_3N_4 preparation wherein the NH_3/SiH_4 ratio becomes important. However, in both of these cases caution must be exercised, since the films may contain excess Al or Si if the amount of NH_3 is too low. Additionally it is seen in Fig. 1 that for high $NH_3/AlCl_3$ ratio the axial uniformity degrades with increasing temperature. This is due to prereaction as stated above which is enhanced at higher temperature. As expected under these conditions, prereaction upstream depletes the reactants so that a lower deposition rate is observed in the susceptor region containing the test wafers (12).

Ellipsometry measurements on films with mixed compositions [prepared using the high $NH_3/(AlCl_3,$

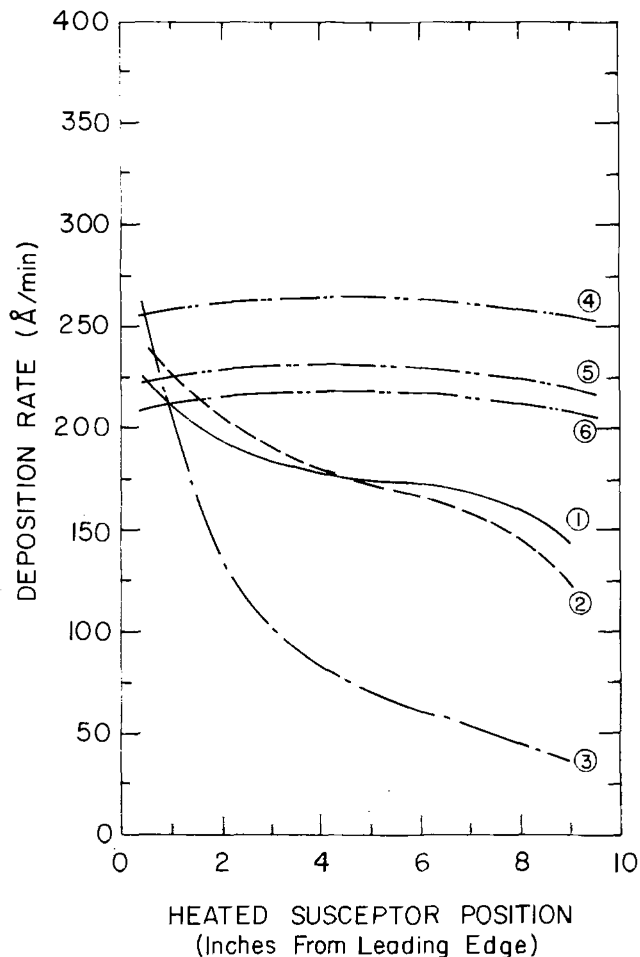

Fig. 1. Deposition rate of AlN along axis of susceptor. 1, 800°C ($HiNH_3$); 2, 900°C ($HiNH_3$); 3. 1000°C ($HiNH_3$); 4, 1000°C ($LoNH_3$); 5, 900°C ($LoNH_3$); 6, 800°C ($LoNH_3$) (See text for definition of high and low NH_3).

SiH_4) reactants ratio] have shown that the film thickness was the sum of the thicknesses which would result from independent deposition of AlN and Si_3N_4, while maintaining the 170/1 NH_3/($AlCl_3$ or SiH_4) reactants ratio. The volume fractions of each component were then additive. Figure 2 shows the calibration of the volume fraction plotted and weight fraction (as determined by electron microprobe analysis) plotted *vs.* the gas phase composition. Such a plot allows control of film thickness and composition for all mixtures and conditions based only on a knowledge of the individual deposition rates of the film components under the prescribed set of film deposition conditions. This finding indicates that the deposition of the AlN and Si_3N_4 components are uncoupled and suggests that the resultant morphology for the mixed composition film will be two phase, *i.e.*, an AlN and a Si_3N_4 phase. The microstructure studies to follow bear out this reasoning.

Film morphologies.—TEM has shown all the AlN films prepared in this study to be polycrystalline. Figure 3 shows that there is a variation of AlN grain size with film deposition temperature. For the films prepared at 650°C, the grains are ~250-350Å and the grain boundaries are not sharp. At 850°C, the grains are somewhat smaller, ~150-250Å, and the grain boundaries are well defined. However, at 1075°C the grains are ~500Å in size and possess well-defined boundaries. A previous study (7) found that the AlN grain size decreased from 770° to 900°C for similarly prepared films. This was explained (7) by invoking the competition between grain growth, which would enable larger grains to grow at higher temperatures due to increased surface mobility of reactants, and the increased nucleation rate with increasing temperature. Apparently, in the 650°-850°C temperature interval, nucleation is dominant. However, for the 1075°C films there is sufficient surface mobility to reverse the competition and render grain growth the dominant mechanism. Furthermore, the lack of sharpness in both diffraction and imaging modes for the low temperature AlN probably indicates that the grains were formed by direct attachment. At high temperatures grains were formed by atoms which would diffuse to more energetically favorable sites.

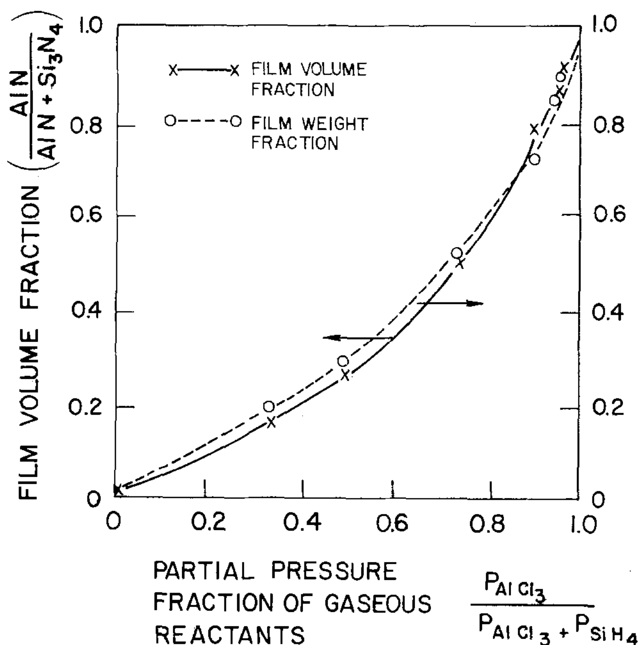

Fig. 2. Prediction of composition of mixed AlN-Si_3N_4 films. Carrier flow velocity = 19 cm/sec, N_2; $NH_3 + H_2 \simeq 0.05$ mole fraction; Al Cl_3 reactor temp. = 120°C with N_2 flush; $SiH_4 + AlCl_3 \simeq 0.01$ mole fraction.

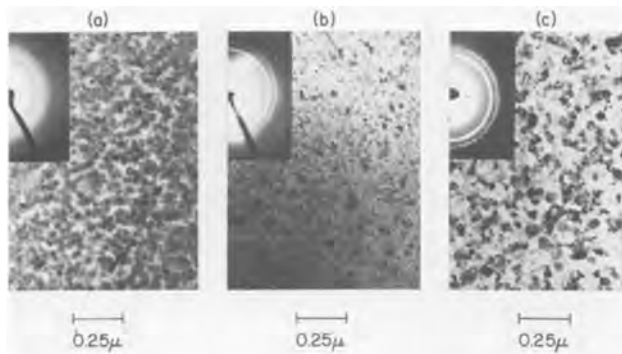

Fig. 3. TEM microstructures of AlN as a function of deposition temperature (a) 650°C; (b) 850°C; (c) 1075°C.

All the Si_3N_4 films prepared in this study were found to be amorphous. Films prepared at lower temperatures were found to contain considerable amounts of particulate matter and this is shown in Fig. 4. The particulates are thought to be Si_3N_4 formed by gas-phase nucleation, carried to the substrate surface by the moving gas stream, and occluded in the growing film. There is more occluded particulate at lower temperatures. We believe that the particulate occurs preferentially for the lower temperature CVD processes because less gas phase depletion of reactants occurs upstream at the lower temperatures. Therefore, within the substrate region, there exists larger concentrations of gas phase reactants, thereby enabling more gas phase nucleation of particulate. A similar phenomena related to film growth rates has been previously reported (12).

The films of mixed composition prepared by codeposition of AlN and Si_3N_4 have been found to contain two phases. The AlN phase is usually polycrystalline and the Si_3N_4 phase is amorphous. When the AlN predominates, grains of AlN are discernible by TEM but the grain boundaries are not sharp. This appears to be due to the Si_3N_4 which surrounds the AlN grains as seen in Fig. 5a. As the amount of AlN in the mixture decreases the AlN grains become smaller as evidenced by the diffuseness of the diffraction patterns for Fig. 5b. In addition, it becomes more difficult to discern grains from particulate or other irregularities. When the Si_3N_4 phase is ~90% or more the mixture appears to be amorphous as seen in Fig. 5c.

Optical properties.—The ellipsometric index of refraction (at 5461Å) for all films deposited at 800°C and above remained constant at 1.99 ± 0.02. Lower dep-

osition temperatures for AlN yielded lower refractive indexes, decreasing to 1.70 for 600°C depositions. The wavelength dependence of the absorption for AlN and Si_3N_4 is shown in Fig. 6 as a function of the gaseous reactants composition. Significant differences are observed when varying the NH_3/SiH_4 ratio for the Si_3N_4, as has been reported elsewhere (28). For the low $NH_3/AlCl_3$ ratio films, the addition of H_2 to the reaction also changes the films' absorptive properties. This effect was not evident with the deposition rates and electron microprobe-determined stoichiometry. Though in principle it may be feasible to extract mixture composition data from the absorption coefficient measurements, the sensitivity of the optical absorption values to film microstructural variations (*i.e.*, grain size, inclusions, etc.), and Si or Al enrichment renders this measurement unreliable for AlN/Si_3N_4 mixture ratio calibration. The calculated absorption edges (13) for the low $NH_3/(AlCl_3,SiH_4)$ ratio films are plotted in Fig. 7 and are compared to the values indicated for high $NH_3/(AlCl_3,SiH_4)$ ratio films of AlN and Si_3N_4.

Apparently the shift in the absorption edge to lower values with less NH_3 correspond with a metal enrichment of the film (either Al or Si). This would cause a reduced bandgap, higher conductivity, and an increased density of states near the conduction band. Such properties have been found to be undesirable for charge-storage layers (8). For devices made using Si-rich Si_3N_4 (8), "read" windows were large for low "write" voltages (15-25V) but charge loss was rapid (seconds) unless thick tunneling oxides were used (50-75Å). However, such thick oxide would require larger "write" voltages and therefore effectively counter the potential advantage of the device. Therefore, it was decided to use compositions prepared with high $NH_3/(AlCl_3, SiH_4)$ ratios for the electrical studies.

Stress measurements.—Figure 8 shows the variation of the components of AlN film stress with film deposition temperature. It can be seen that the AlN net tensile stress is dominated by the differential thermal expansion stress component (arising during cooling from the deposition temperature) which is tensile. The intrinsic stress component (17) deduced from the measured net and calculated thermal components is compressive and apparently increases with film deposition temperature. The increase is slight and may be only an indirect result of an increase in the anisotropic Youngs modulus with the development of some preferred orientation, as shown in Fig. 3b and 3c and reported elsewhere (5, 6).

Similar stress measurements for the mixed AlN, Si_3N_4 films are shown in Fig. 9. The addition of Si_3N_4 to the AlN results in a strong influence upon the total net stress. The morphological studies have shown that the Si_3N_4 deposits around the AlN grains thereby forming the connective phase. Therefore, it is expected that the intrinsic stresses within films of the

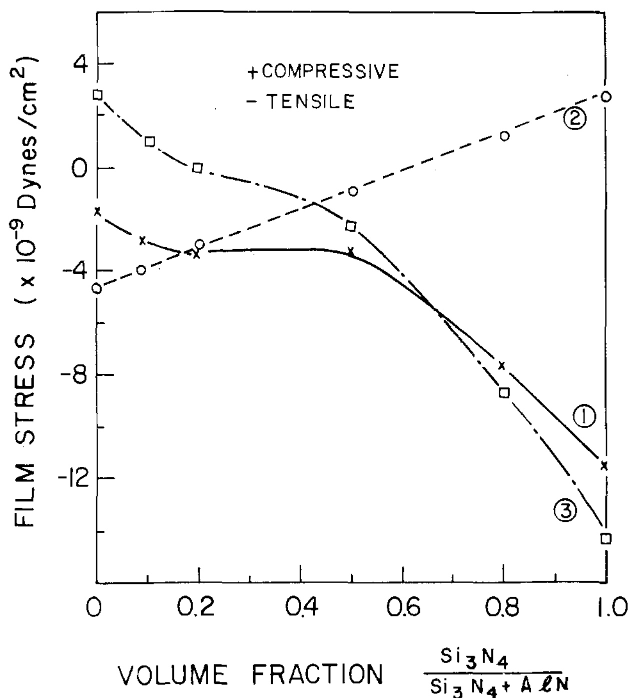

Fig. 9. Stresses in $AlN-Si_3N_4$ mixtures ($T_{dep.} = 850°C$). ×, measured at room temperature; ○. calculated thermal stress; □, net intrinsic stress.

mixed components would be due primarily to the connective Si_3N_4 phase.

Etching behavior.—Both the AlN and $AlN-Si_3N_4$ mixtures show varying solubility within hot 85% H_3PO_4, depending upon film composition and the deposition parameters, as shown in Fig. 10. The mixtures are much more resistant to etching by hot H_3PO_4 than is the pure AlN. This is most likely due to the shielding of the AlN by the matrix of amorphous Si_3N_4 surrounding the AlN grains. The dependence of the deposition temperature for the etch rate of AlN is shown in Fig. 10. Higher deposition temperatures yield lower etch rates as has been reported (5). The influence of the $NH_3/AlCl_3$ reactants ratio is shown for the example of a 4/1 film mixture (AlN/Si_3N_4). The low reactants ratio (1.7/1) causes enrichment of the mixture with silicon. This is known to reduce the etch rate for silicon nitride (29). This factor is more clearly indicated for the apparently anomalous difference in etch rate observed for the film mixture prepared with low $NH_3/(AlCl_3, SiH_4)$ ratio at 800° and 1000°C. The film prepared at lower deposition temperatures contains relatively more excess Si, thereby becoming more etch resistant.

Electrical properties.—The d-c conduction behavior appears to be similar to Poole-Frenkel bulk-limited-type in accordance to the following relationship (30)

$$J/E = \Delta_0 \exp -\{[\psi_d - (B_{P\text{-}F}E)^{1/2}]/rkT\} \quad [3]$$

with J = current density, E = averaged steady-state electric field across the insulator, ψ_d = energy of the coulombic trap below the conduction band, $B_{P\text{-}F}$ = Frenkel-Poole constant, k = Boltzmann constant, T = absolute temperature. Δ_0 is a conduction term at zero field that is interpreted according to assumed distribution, types, and occupany of the traps associated with the P-F type of conduction (31-33). r takes on values of 2 or 1 depending upon whether a donor-trap model (29,32) is applied to the data, or a model invoking both donor traps (which are coulombic) and neutral traps (32) (noncoulombic). For the former case Eq. [3] is as follows

$$J/E = \Delta_0 \exp - [\psi_d - (B_{P\text{-}F}E)^{1/2}]/2kT \quad [4]$$

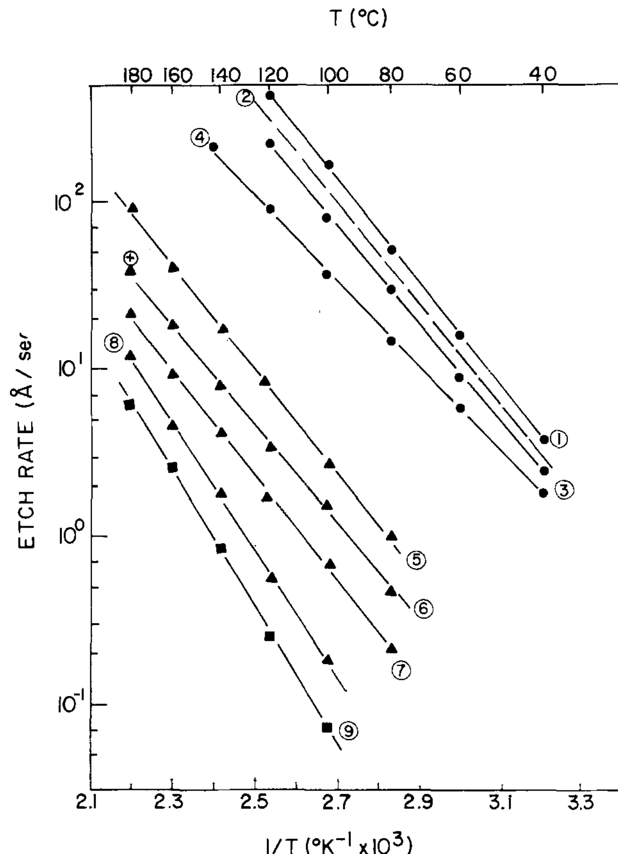

Fig. 10. The etching characteristics of AlN and $AlN-Si_3N_4$ mixtures in hot H_3PO_4. 1, AlN (800°C, $LoNH_3$); 2, AlN [900°C. Ref. (5)]; 3, AlN (900°C, $LoNH_3$); 4, AlN (1000°C, $LoNH_3$); Si_3N_4 (900°C, $HiNH_3$). ⊕ mixtures (volume ratio AlN/Si_3N_4); 5, 4/1 (1000°C, $HiNH_3$); 6, 4/1 (1000°C, $LoNH_3$); 7, 1/1 (1000°C, $LoNH_3$); 8, 1/4 (1000°C, $LoNH_3$); 9, 1/1 (800°C, $LoNH_3$).

with: $\Delta_0 = e_\mu (N_c N_d)^{1/2}$
and for the latter case

$$J/E = \Delta_0 \exp - [\psi_d - (B_{P\text{-}F}E)^{1/2}]/kT \quad [5]$$

with: $\Delta_0 = e_\mu N_c (N_d/N_t)^{1/2}$
μ = carrier mobility (single carrier injection); N_c = density of states within the insulator film's conduction band; N_d = density of film's coulombic traps; and N_t = density of films neutral traps.

The theoretical value for $B_{P\text{-}F}$ is calculated as follows

$$B_{P\text{-}F} = \frac{e^3}{\pi \epsilon_0 \epsilon_f} \quad [6]$$

with e = electronic charge, ϵ_0 = free space permittivity and is approximately equal to the optical index of refraction squared. For room temperature measurements, Eq. [3] can be utilized in the following form

$$\ln (J/E) = \left[\ln \Delta_0 - \frac{\psi_d}{rkT} \right] + \frac{B_{P\text{-}F}^{1/2}}{rkT} (E^{1/2}) \quad [7]$$

which allows for a determination of $[B_{P\text{-}F}^{1/2}/rkT]$ from the slope of the ln (J/E) *vs.* $E^{1/2}$ plot. Isothermal plots at several temperatures were then used to obtain plots of $(1/T°K)$ *vs.* ln $(J/E)_{E=0}$. The slope of this plot then yields values of ψ_d.

The calculated conduction parameters of Eq. [3] are plotted in Table II, from conduction data obtained with (*i*) AlN as a function of deposition temperature, (*ii*) Si_3N_4, as a function of deposition temperature, and (*iii*) several $AlN-Si_3N_4$ mixtures deposited at 850°C. The experimental (J/E) *vs.* $E^{1/2}$ slope ($B_{P\text{-}F}$) for the AlN implies that the coulombic trap model applies and r = 2. The experimetal $B_{P\text{-}F}$ slope for both

** Theoretical for index of refraction = 2.0 and r = 2.

the Si_3N_4 and mixtures imply a mix of coulombic and neutral traps, and therefore $r = 1$. The calculated values for ψ_d from the experimental $(J/E)_{E=0}$ *vs.* $1/T$ slopes take into account the conduction model invoked, and value of "r" used. A more comprehensive $B_{P\text{-}F}$ conduction model [*i.e.*, see, for example Arnett (34)], is beyond the scope of this paper, because of the limited amount of conduction data available. The conduction measurements were in fact initiated mainly for the purpose of providing a useful precursor to selection of the best compositions and deposition conditions for charge storage application. A suitable reference guideline would be the conduction parameters associated with Si_3N_4, deposited at 850°C.

The AlN data show significant variation of the conduction constants with varying deposition temperature. All conduction parameters increase with increased deposition temperature. The major variant is the $B_{P\text{-}F}$ slope for 600°C deposition. When comparing the conduction parameters of the AlN with those for the Si_3N_4 deposited at 850°C, it can be noted that the Δ_0 values are significantly higher and $B_{P\text{-}F}$ slopes lower. Charge storage structures with pure AlN yielded smaller storage windows and rapid charge decay compared to equivalent Si_3N_4 structures. The conduction parameters for the mixtures between (1/1) AlN/Si_3N_4 and (1/9) AlN/Si_3N_4 appeared more similar to those for the Si_3N_4. Both of these compositions were therefore selected for more comprehensive evaluation of charge storage properties.

Charge storage measurements were carried out using standard configurations of the tunneling oxide (thickness range 25-50Å SiO_2) plus the charge storage layer contained within single dielectric films (~500Å). Storage layer compositions evaluated included AlN and $AlN\text{-}Si_3N_4$ mixtures within the volume range of 1/1-1/9. For all oxide thicknesses, charge windows comparable to those observed with Si_3N_4 (11) were obtained, when using "write" pulses (15-25V) in the msec range. These storage windows exhibited very short lifetimes due to rapid charge decay. The storage layer configuration was subsequently modified to include a CVD Al_2O_3 layer. The layer thicknesses were adjusted to yield a total thickness of 500Å (~250Å apiece). The AlN films (deposited at 850°C) exhibited no change in charging behavior and only moderate improvement in charge window lifetime. Si_3N_4 films (deposited at 850°C) exhibited both charging and discharge behavior similar to that exhibited by monolithic Si_3N_4 films (11).

The mixed film compositions, 1/1 and 1/9 volume ratio of AlN/Si_3N_4 were evaluated with the dual dielectric storage structure. Both exhibited similar charging and discharge behavior, therefore the subsequent data for the 1/1 volume ratio are representative of both compositions.

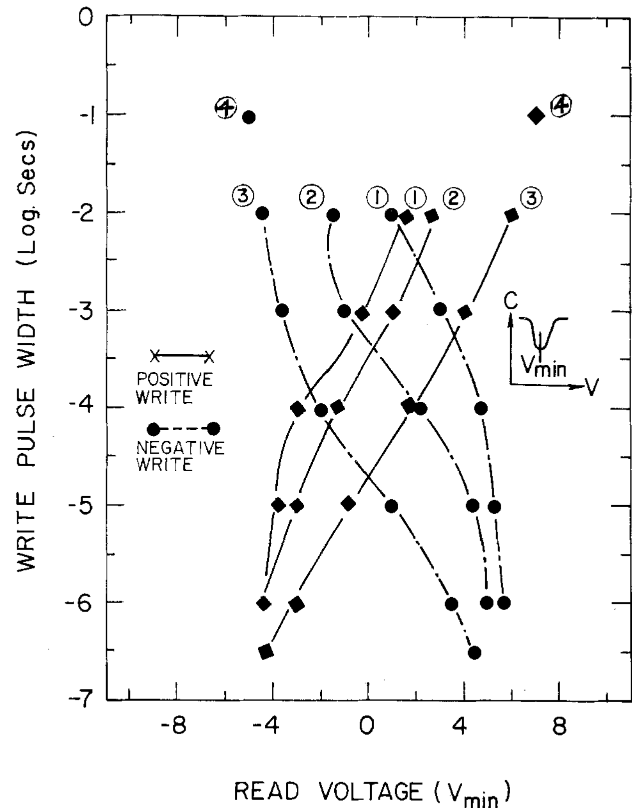

Fig. 11. Charge window using 1/1 volume ratio AlN/Si_3N_4 for charge storage layer (n^+-gridded Si substrate. 24Å SiO_2, 250Å $AlN\text{-}Si_3N_4$, 250Å Al_2O_3, Al gate) (1, 7.5V; 2, 10V; 3, 15V; 4, 25V; saturation erase; 35 μsec read delay).

The dynamic-charge injection behavior as a function of tunnel oxide thickness is indicated in Fig. 11-13. The shift in V_{min} from opposite polarity saturation is shown for varying pulse widths and several voltage levels. Figure 11 indicates that symmetric charge windows can be obtained over a wide range of "low" voltages (7½-25V) for "thin" oxide devices (<30Å SiO_2). These can be used for either n- or p-channel depletion-mode devices (35). For oxide thicknesses between 30 and 40Å, there is a shift to the median of charge polarity to the positive mode (Fig. 12). All positive mode operation is achieved for oxide thicknesses greater than 40Å, as is indicated in Fig. 13. This type of operation is useful for enhancement mode n-channel operation, such as, for example, has been explored with MAOS structures (36). The charge window for 48Å SiO_2 is similar to that for Al_2O_3 with a 30Å tunnel oxide thickness (Fig. 14), excepting that higher write-erase voltages are required for the Al_2O_3 device. Limited multiple cycling studies have indicated good window stability (no window shift, interface state buildup, or device failure) with up to 10^7 for 25V, and at least 10^8 (test cutoff) write-erase cycles for 15-20V. The absolute magnitude of the charge window, as written from "erase" saturation is plotted in Fig. 15, as a function of tunnel oxide thickness for "write" voltages of 15 and 25V. Comparison is also presented with similar Si_3N_4 devices (11). Significantly larger charge windows are observed with the use of the $AlN\text{-}Si_3N_4$ mixtures. Additionally, the observation of large charge windows over a wide range of tunneling oxide thickness (up to 48Å SiO_2) is advantageous from a device fabrication point of view. The relaxation of close oxide thickness tolerances contributes to increased device yield and lowered manufacturing costs.

The long-term charge retention behavior has been monitored with test devices of both 1/1 and 1/9 volume ratio AlN/Si_3N_4, in both the "write" and "erase" mode. Typical results are indicated in Fig. 16 for three

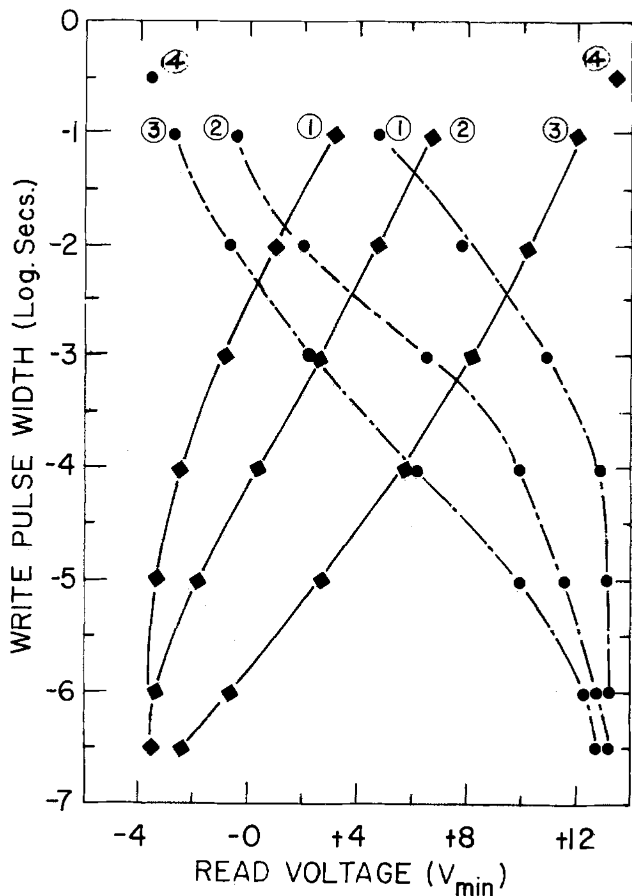

Fig. 12. Charge window, 35Å SiO_2. (1, 15V; 2, 20V; 3, 25V; 4, 25V. Saturation erase; 0.1 min read delay).

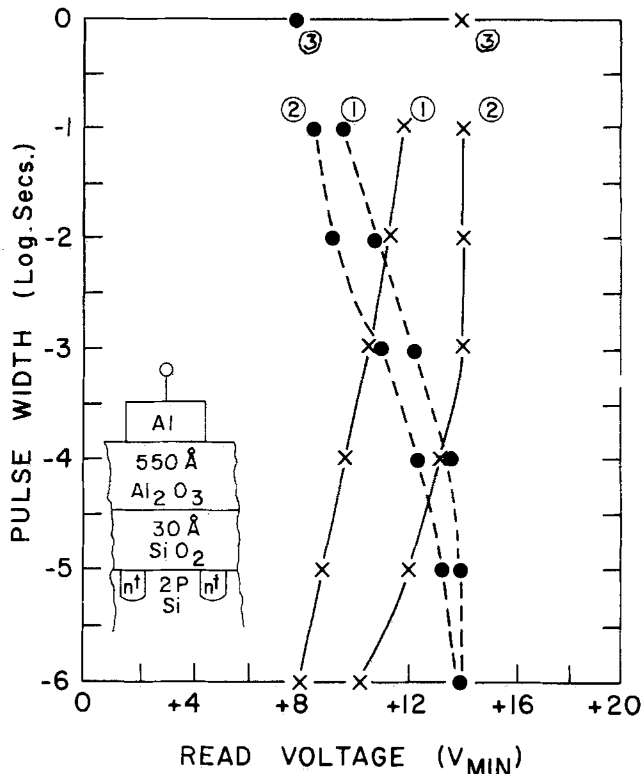

Fig. 14. Charge window with Al_2O_3 storage layer. (1, 25V; 2, 30V; 3, 30V. Saturation erase; 0.1 min read delay).

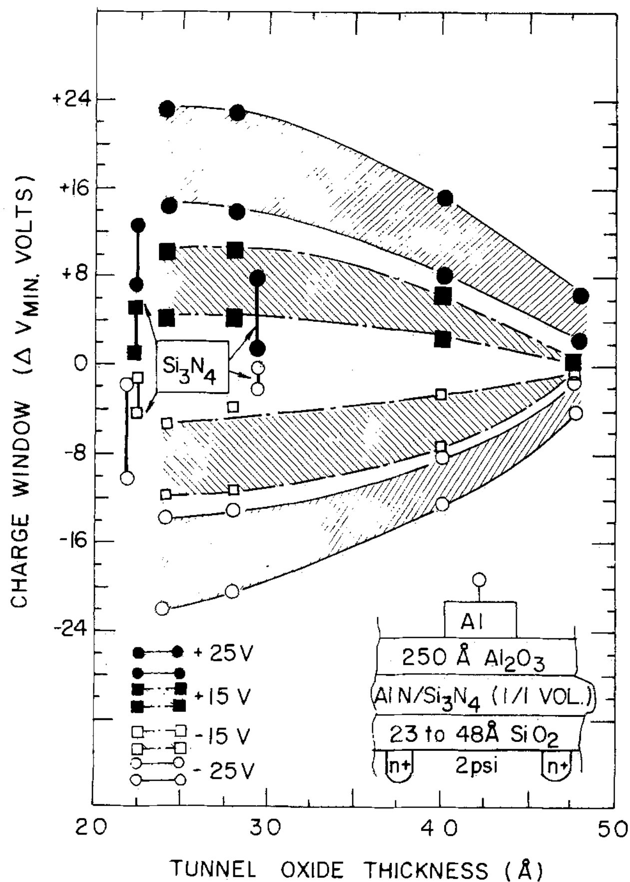

Fig. 15. Absolute magnitude of positive and negative charge windows as a function of SiO_2 thickness. [Write pulse width range: 10^{-5} to 10^{-1} sec; Si_3N_4 data. Ref. (11)].

"erase-write" conditions. Six devices are required since the initial state of charge (in either "write" or "erase" mode) is maintained on long-term test. The pairing of "erase-write" data points result from pulse

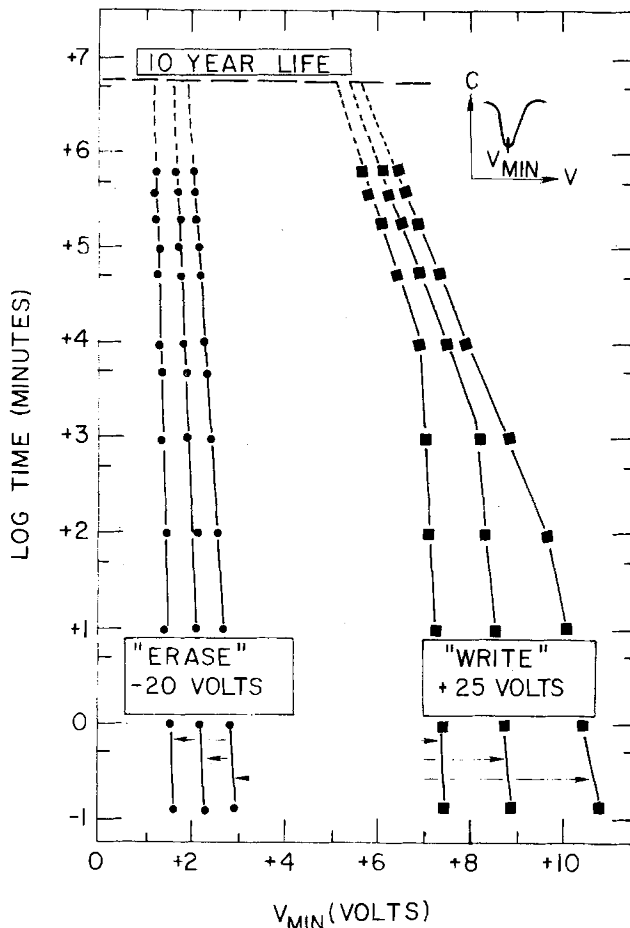

Fig. 16. Long time charge-retention behavior (43Å SiO_2)

width selection during initial charging to yield different windows. The initial "erase" positions differ since saturation pulse widths were not used, otherwise the "erase" data points would merge. It was observed that the discharge behavior is qualitatively similar to that observed for Si_3N_4 (11, 26, 35). The initial discharge rate increases with increased "write" bias, as was also observed with devices made from Si_3N_4 (11). Additionally, when comparing devices of varying tunnel oxide thickness, "writing" to the same charge level yields initial discharge rates that decrease with increased oxide thickness (26). For all initial V_{min} values the shift in V_{min} is linear with $\Delta V_{min}/\Delta ln\ t$, and always in a direction toward shrinkage of the charge window. This, of course, arises from loss of charge through the tunneling oxide to the Si substrate (26). When "erasing" to a negative V_{min} (not shown in Fig. 16), the shift in V_{min} is toward 0V. The time duration of the constancy of the $\Delta min/\Delta ln\ t$ slope, after "writing," varies qualitatively and inversely with the initial value of V_{min}. A discontinuous increase in the $\Delta V_{min}/\Delta ln\ t$ slope then occurs. The net result is eventual convergence of the V_{min} values, even with large differences in the initial written V_{min} values (for constant tunneling oxide thickness). Since this behavior was also observed with Si_3N_4 storage devices (11) the storage behavior of the mixture is most likely governed by the Si_3N_4 matrix within the two-phased structure of the AlN-Si_3N_4 mixture. The data indicated in Fig. 16 for devices with 1/1 volume ratio of AlN/Si_3N_4 and 43Å SiO_2 show that even with initial "read" windows of 5-8V, the final "read" window after 10 years is projected to be of the order of 3-4V. The indicated data points were acquired over a 15 month period.

Discussion

The rise in the Poole-Frenkel conduction slope values ($\beta_{P\text{-}F}$), with increased deposition temperature, can perhaps be reconciled with an increased density of neutral traps, in accordance with the Yeargan-Taylor compensation model (32). With increased deposition temperatures the microstructure (as observed with TEM) tends toward more well-defined grain boundaries and crystallinity (see Fig. 3). We speculate that these higher angle grain boundaries possibly contribute toward increased density of neutral traps. On the other hand, the relative insensitivity of the extrapolated zero-field conduction term (Δ_0), with deposition temperature, would then imply that even with the increase of the neutral traps the total number of traps (neutral plus coulombic) remains essentially the same. Additionally, we postulate that the well-defined crystallinity with increased deposition temperature tends to yield deeper traps, as indicated by the ψ_d values for AlN in Table II.

The $\beta_{P\text{-}F}$ slope values for the Si_3N_4 and mixtures are higher than indicated by the above compensation model and must be reconciled by alternate schemes. The presence of particulates with the lower deposition temperatures (see Fig. 4) may contribute to the excess low field conduction, leading to higher Δ_0 conduction values. The high Δ_0 with deposition at 1100°C could be due to the presence of crystalline Si_3N_4 at and above this temperature (37, 38).

The increasing concentration of Si_3N_4 with the mixtures causes a rapid lowering of the Δ_0 conduction term. The high field conduction behavior, as shown by the $\beta_{P\text{-}F}$ slope values, is similar to that indicated by the Si_3N_4. The conduction behavior of the mixtures, then, appears to be influenced mainly by the enveloping matrix of Si_3N_4 surrounding the AlN grains. This factor is significant regarding the charge storage behavior. We propose the following:

During the charging cycle, the higher $\beta_{B\text{-}F}$ values indicate essentially uniform conduction within the matrix of the Si_3N_4 envelope and AlN grains. Trap filling occurs mostly within the AlN grains and at the AlN-Si_3N_4 interface. With removal of the high external voltage a reversed lower internal field remains due to the high concentration of trapped charge. With the dual dielectric storage structure the trapped charge tends to leak toward the silicon substrate. The rate of discharge is restricted by the Si_3N_4 matrix and the "thick"-tunneling thermal SiO_2.

From energy band considerations, the presence of the Al_2O_3 provides an energy barrier, as shown in Fig. 17, which would cause additional charge pileup at the

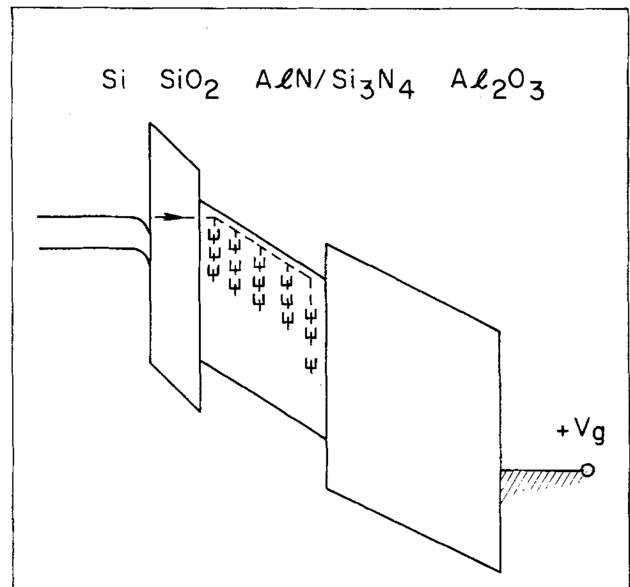

Fig. 17. Energy band diagram for thick oxide charge storage device with AlN-Si_3N_4 mixture within the charge-storage layer (positive write case).

$(AlN-Si_3N_4)-Al_2O_3$ interface. Dual dielectric structures of Si_3N_4 plus Al_2O_3 do not behave differently from single Si_3N_4 charge storage structures (8). This would imply that, perhaps, the mixtures do indeed contain a higher concentration of trapping sites than does Si_3N_4. In addition, high concentration of relatively deep traps with the mixtures (as implied by the larger ψ_d values for the mixtures in Table II) would minimize charge tunneling at the $(AlN-Si_3N_4)-Al_2O_3$ interface into the Al_2O_3 conduction band. This could happen when using Si_3N_4 as a replacement for the Al_2O_3. These devices show smaller charge windows than comparably "written" $(AlN-Si_3N_4)Al_2O_3$ devices.

The influence of varying the tunneling oxide thickness upon the long term discharge behavior is similar to that exhibited by other storage layers (39). Therefore, devices exhibiting long-time charge retention properties, require thick tunneling oxides (between 40 and 50Å).

Summary and Conclusions

The preparation of films of mixtures of AlN and Si_3N_4 has been carried out by the thermal ammonialysis of gaseous $AlCl_3$ and SiH_4. The deposition kinetics and film thickness uniformity is significantly influenced by the $NH_3/(AlCl_3, SiH_4)$ reactants ratio. Some physiochemical properties have been characterized as a function of composition and deposition parameters and compared to those observed with AlN and Si_3N_4. Charge storage structures analogous to MNOS and MAOS devices have been prepared using a dual dielectric storage layer. These devices provide superior electrical performance compared to both MNOS and MAOS devices. The large charge windows obtained with low (under 25V) "write" voltages and the adequate charge retention over long periods of time make these devices potentially useful with read mostly and read only memory devices.

A new concept has been attempted in this work, *i.e.,* the use of a two-phase dielectric layer to enhance charge storage properties. The measurement of several physical properties indicates that the mixed film of $AlN-Si_3N_4$ behaves electrically similarly to Si_3N_4, except that the charge trapping behavior is enhanced due to the addition of the AlN phase. A simple energy band model utilizing a finite width potential well analogue is invoked to qualitatively explain the charge storage behavior of the $(AlN-Si_3N_4)-Al_2O_3$ dual dielectric layer.

Acknowledgments

The authors gratefully acknowledge Dr. A. B. Fowler for his helpful suggestions and continual support of this work, and Drs. P. Arnett and D. DiMaria for stimulating and informative discussions. Additionally, we appreciate Dr. T. Sedgewick's critical review of this manuscript. And finally we wish to acknowledge the experimental support provided by H. Ripke for the electrical apparatus, D. Dong for CVD and ellipsometry support, and J. Kuptsis for electron microprobe analytical support.

Manuscript submitted June 1, 1977; revised manuscript received Oct. 3, 1977. This was Paper 248 presented at the Las Vegas, Nevada, Meeting of the Society, Oct. 17-22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by IBM Corporation.

A Possible Method for the Growth of Homogeneous Mercury Cadmium Telluride Single Crystals

G. Fiorito, G. Gasparrini, and D. Passoni
CISE, Segrate, Milan, Italy

ABSTRACT

A new procedure for preparing homogeneous single crystals of $Hg_{1-x}Cd_xTe$ alloys over a wide range of compositions is proposed. The method, based on a modification of the usual Bridgman technique, promises to overcome variations in composition resulting from the high segregation rate of CdTe with respect to HgTe. During most of the growth period the melt composition is controlled by means of a second solid phase. In particular some results are reported in connection with a composition of significant interest for application as an infrared detector and spin flip laser material.

In recent years the Mercury Cadmium Telluride pseudobinary alloys ($Hg_{1-x}Cd_xTe$) have proved to be uniquely suitable for preparation of high quality medium and far infrared detectors. The reason stems from the various basic material peculiarities (1) such as an energy gap which can be adjusted from 0 to 1.5 eV varying the composition (x). The detector spectral response can be matched to any wavelength in the 1-14 μm range at working temperatures at or above 77°K. In addition to the compositional dependence of the bandgap, $Hg_{1-x}Cd_xTe$ alloys are direct gap semiconductors having high absorption coefficients with low intrinsic carrier concentrations and with high electron mobilities.

Though very high performance photoconductive and photovoltaic detectors have been made for many years, either as single detectors or as arrays, up to now the potentialities of such alloys have been limited by the difficulties of growing crystals with long-range homogeneity of reasonable size. Moreover, to achieve economic fabrication of devices, high yields of useful material are required. For these reasons, present research on the material will be concerned primarily with improved methods of growing large single crystals of adequate compositional uniformity.

To achieve this goal, several techniques have been proposed and used. Most of them are based on the existence of a liquid phase even for thin layer depositions. However most thin layers have been grown by an evaporation-diffusion mechanism, using a close-spaced configuration, or in a mercury plasma using a triode sputtering arrangement. These layers of the compounds have been successfully used for fabricating photovoltaic detectors (2-4).

The main problem in $Hg_{1-x}Cd_xTe$ growth from the melt is the compositional inhomogeneities which result along the growth direction because of strong segregation of its binary components, due to the wide separation of the liquidus and solidus lines in the phase diagram (5, 6). Melt stoichiometry maintenance during the growth is also a problem because of the high mercury vapor pressure in equilibrium with the melt. Moreover a tellurium excess may introduce a remarkable constitutional supercooling (7).

By a modified Bridgman approach, the CdTe segregation with respect to HgTe has been prevented utilizing high speeds of growth (Burton-Prim-Slichter mechanism). Because of the rapid solidification, the resulting ingot contains a dendritic substructure, and a subsequent high temperature anneal must be used to remove such a structure (8). The preparation of suitable crystals has been also attempted by a two-step technique (9) employing a quenching from the liquid state under appropriate conditions followed by heat-treatment for a long time in mercury vapor just below the solidus temperature. Homogeneous crystals have also been obtained by the vertical zone melting method (10), although composition fluctuations are generally observed due to hot-zone instability. The vertical-zone melting method has also been employed for solution growth of $Hg_{1-x}Cd_xTe$ using Te as a solvent (11). Finally, some amount of high quality material has been obtained using a method involving crystallization from a two-phase mixture followed by a solid recrystallization (12).

These methods generally labeled as modified Bridgman techniques, solid-state recrystallization, vertical-zone melting, and "slush" recrystallization have been applied with varying degrees of success. In addition, we propose and have experimentally tested another method for obtaining large single crystal portions having a high composition homogeneity starting from a two-phase system. We have taken advantage of the marked difference between the liquidus and the solidus curves in the HgTe-CdTe pseudobinary system.

Proposed Method and Some Experimental Results

Consider in Fig. 1 the schematic temperature profile of a vertical furnace (not to scale) and the sketch of the phase diagram for the $Hg_{1-x}Cd_xTe$ single pseudobinary alloy system. Assume an ampul filled with an alloy charge of over-all composition x_0 to be placed in the furnace in region 1 (not to scale) at temperature T_0. The charge will be entirely melted since the temperature T_0 is slightly above the liquidus line, as shown in the figure. Assume further that the ampul containing the charge is quickly lowered to region 2 (not to scale) at temperature T, intermediate between liquidus and solidus lines for the x_0 composition. This procedure will produce a liquid and solid two-phase mixture of composition x_L and x_S, respectively. At this point the directional freezing is actuated by lowering the ampul to region 3.

If freezing occurs slowly as it is assumed for the time being, the liquid phase composition remains constant at value x_L as long as the solid phase x_S is present which supplies the liquid marking up for the depletion due to the crystal growth in the ampul tip. As soon as the x_S composition phase is exhausted, normal freezing occurs. In these idealized conditions, what is expected is a crystal with constant composition equal to x_S for a length corresponding to the steady-state region for the melt composition and finally a transient with rapidly decreasing cadmium telluride concentration. This schematic situation occurs only if directional freezing of liquid alloy occurs in equilibrium conditions with complete mixing in the liquid. This condition can be approached by selecting a freezing rate which is small as compared with x_S solid dissolution rate in the liquid

Key words: modified Bridgman, compositional uniformity, infrared material.

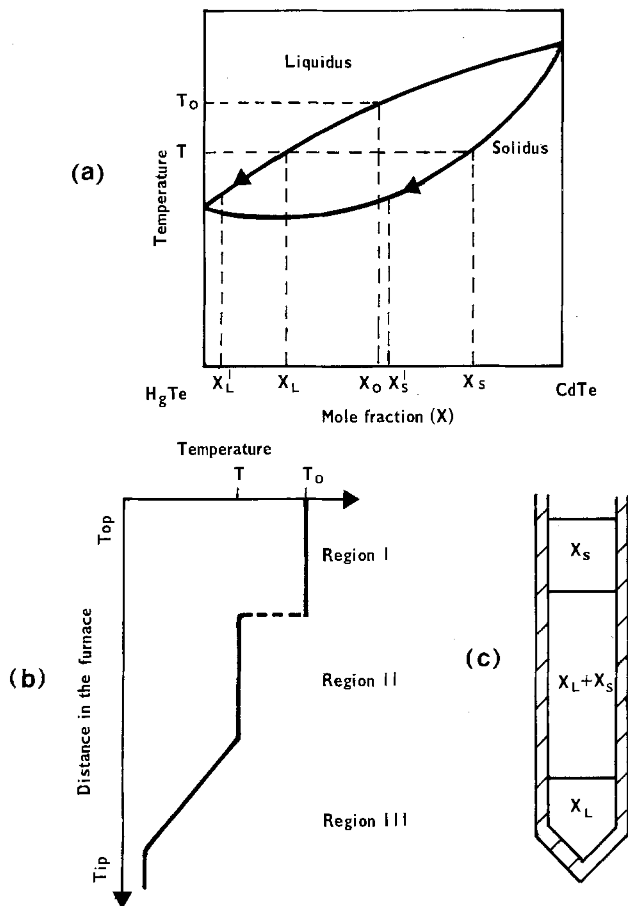

Fig. 1. Sketches of: (a) phase diagram of the pseudobinary alloy system HgTe-CdTe; (b) Temperature profile of growth apparatus; (c) x_L and x_S phase distribution at the growth starting.

and in particular if comparable with the diffusion rate in the liquid.

On the other hand the requirement of producing useful material with high yield at a reasonable rate suggests that the freezing rate be adjusted to a value not very far from the constitutional supercooling limit related to the actual thermal gradient operating at the solid liquid crystallization interface. In this connection, it has already been reported elsewhere (7) that the possibility of constitutional supercooling arising from both segregation of CdTe with respect to HgTe exists as well as the segregation of any Te excess in the melt. This latter effect proved to be the most restrictive as to growth rate, as it appears even at very low growth speeds. It is therefore necessary to assure the melt stoichiometry to get better Te segregation conditions and to be able to approach the limit imposed by the constitutional supercooling.

The speed of 0.5 mm/hr, if used for growths from melts with carefully adjusted metal to Te ratio, may be considered as reasonably close to the mentioned limit which can also be calculated by Tiller's relation (13). In addition to an accelerated growth rate as above described, mixing in the liquid phase is never complete and in particular in our experimental configuration, because of the rather poor actual temperature gradient distribution at the solidification interface (40°C/cm), because of the charge diameter (12-13 mm) and because of the charge length (up to 25 cm).

Finally it is not convenient to keep the x_S solid-phase distribution uniform. In fact the presence of unmelted particles at the growth interface will activate undesirable spurious nucleations with consequent worsening of the crystal quality. The drawback can be avoided if the distribution of the liquid and solid phases occur as schematized in Fig. 1c. This is realized in the actual method by quenching to room temperature the T_0 homogenized charge, taking care that the ampul end, where the directional freezing has to start, be directed upwards. Thus, as the filling coefficient is necessarily less than unity, the solid will not occupy the empty end. The subsequent overturn of the ampul and heating at T temperature will make, by gravity, the liquid phase occupy the lower volume free form the solid phase, as schematized in Fig. 1c. Then it is obvious that at the start of a growth the charge end part will now essentially consist of an extremely spongy self-supporting solid emerging from the liquid. The extension of the liquid zone, free from the solid, is an adjustable parameter depending on the ampul total length to content ratio. Under these conditions, because of poor mixing, the advancing crystal rejects solvent more rapidly than the x_S solid reserve can refill by dissolution and diffusion. As a consequence, the liquid composition at the growth interface tends to become lower than the starting x_L value, reaching after a transient, a $x_L' < x_L$ value. In this case, the solidified crystal will be characterized by an initial composition transient with decreasing solute concentration from the x_S value, a quasisteady-state region with a constant composition, and a final composition transient with rapidly varying solute concentration.

This is just what happens as shown in Fig. 2 for the two different growth runs. The composition values were determined both by measuring the 77°K cutoff wavelengths of a set of photovoltaic detectors prepared by ion implantation (14) on the surface of wafers cut at right angles to the growth direction and by measuring the absorption edges of the same samples at room temperature. The latter analysis method, rather integral, was used once the solidification interface, under the experimental conditions, was proved to be flat (15) and radially symmetric (16) as to allow $\Delta x < 0.01$ composition variations over 80% of the solidification interface diameter.

Table I reports the composition values along a wafer diameter (position 1-12) as obtained from the cutoff wavelengths of a set of photovoltaic detectors (the devices were 200 μm in diam and taken 800 μm apart center-to-center distance). The wafer center corresponds to position 6.

The synthesis of $Hg_{1-x}Cd_xTe$ alloys was accomplished by melting together the appropriate quantities of HgTe and CdTe binary compounds in evacuated thick-walled quartz ampuls with enough excess mercury to maintain a $\simeq$ 16 atm pressure at operating temperature T. Starting materials for binary compound preparations were Cd and Te 6N purity in a stoichiometric mixture to prepare CdTe, Hg, and Te 6N purity with an excess Hg in the case of HgTe. In $Hg_{1-x}Cd_xTe$ alloy synthesis we preferred to start from binary components rather than from single elements to avoid Hg-Cd direct contact, since the amalgama formed readily oxidize. The ampul containing the ternary mixture was first treated at 500°C; then the temperature was carefully raised just above the liq-

uidus line for the actual over-all composition. The melt was then left to homogenize for at least 24 hr. At this point the above suggested procedure could be started. Figure 3 shows an as-grown crystal.

Conclusions

Though several growth techniques have already been proposed and applied for $Hg_{1-x}Cd_xTe$ single crystal production having long-range homogeneity and reasonable size, from the detector manufacturers stand point, the problem is not fully solved. At present the research in the field should be primarily concerned with improved methods of large single crystal growth as well as development of thin-film techniques. In this connection we think that our suggestion, if suitably developed, may lead to positive improvements. The results presented are in fact to be intended more as capabilities rather than as technique limits. On the other hand, the yield obtained can be considered as rather satisfactory for suitable material even if it is too early to be definite in this point. Further work along the described line is now under way.

Transport Phenomena Measurements in Epitaxial Reactors

Vladimir S. Ban*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

The deposition rates and uniformity in CVD reactors are functions of transport phenomena. It is necessary to understand these phenomena as completely as possible in order to design and use reactors properly. In the last few years several, mostly theoretical, discussions of transport phenomena in CVD reactors appeared. In the present study we discuss the results of the experimental measurements of these phenomena by means of flow visualization techniques and temperature and concentration measurements. These measurements suggest a model of flow somewhat different than models suggested by other authors. The importance of entry effects and influences on the development of velocity and temperature profiles are illustrated. Such a model is more complex than models where the fully developed velocity and/or temperature fields are assumed, but it is also more descriptive of the true situation in the reactor.

Today's multiwafer epitaxial reactors must fulfill requirements of satisfactory deposition rates and of stringent thickness and doping uniformity. This means that sufficient and equal amounts of gaseous reactants (*e.g.*, $SiCl_4$, SiH_4, etc.) and dopants (*e.g.*, PH_3, B_2H_6, etc.) must be supplied to all wafers in the reactor. Good understanding of the gas phase transport phenomena is thus important for reactor designers and users.

* Electrochemical Society Active Member.
Key words: CVD, epitaxial reactor, transport phenomena silicon deposition.

In the last few years several theoretical treatments of transport phenomena in epitaxial reactors appeared (1-4). The purpose of this work is to present the results of experimental studies of transport phenomena in a horizontal silicon epitaxy reactor. The apparatus itself and the preliminary results have been described previously (5). Briefly, the somewhat modified laboratory size horizontal reactor (susceptor was 5 $\times$ 15 cm; rectangular quartz tube length was 60 cm, cross section was 7.5 $\times$ 5.0 cm) was equipped with an instrument introduction port. A specially designed mass spectrometric probe was used to determine qualitatively and quantitatively the vapor species present, as well as their spatial distribution. The temperature and its spatial distribution was measured by means of specially designed thermocouples, and the gas flow patterns were observed by means of the TiO_2 smoke visualization. In this work we present some additional results of these studies as well as a brief discussion of these results.

Results

Flow visualization experiments.—The flow visualization experiments provide an insight into the momentum transfer of the gas phase. The nature of flow in epitaxial reactors is difficult to predict. The low values of Reynolds number (typically < 200) suggest a laminar flow, but on the other hand, the steep transverse temperature gradients caused by the hot susceptor imply possible disturbance of the laminar nature. Furthermore, the entry effects must be considered, because susceptors are relatively short and the velocity and thermal profiles might not be completely developed. Sparrow *et al.* (6) studied a similar problem of simultaneous action of buoyancy and viscous forces and devised the Gr/Re^2 ratio as a criterion for assessing the relative influences of the above two forces (Gr = Grashof number; Re = Reynolds number; see Table I for definition). We observed flow patterns by means of TiO_2 smoke for Gr/Re^2 ratios ranging from 0.16 to 12.5 and susceptor temperatures from 500° to 1200°C. The results of these observations are summarized in Fig. 1. At $Gr/Re^2 \geqq 0.5$ one observed a fully developed spiral, and at lower values upward deflection of the streamline was observed. Both of these observations clearly show the effect of buoyancy forces. A spiral flow was also observed by Takahashi *et al.* (7) in their observations of flow in epitaxial reactors. Some fluid mechanics workers report different behavior (8, 9), but in their experiments special effort has been made to eliminate the entry effects.

Temperature measurements.—The temperature and the temperature distribution in the reactor is a function of several variables, such as the gas velocity, the nature of the gas, and the geometry of the reactor. We measured temperature in the x-y plane above the susceptor (x = direction of the gas flow; y = direction perpendicular to the susceptor; $y = 0$ at the susceptor; $y = 3$ cm at upper wall) as a function of those variables.

Table I. Definition of dimensionless numbers

Number	Symbol	Physical meaning	Definition*
Reynolds	Re	Inertia force / Viscous force	$\rho Vl / \mu$
Grashof	Gr	(Inertia force) (Buoyant force) / (Inertia force)^2	$\rho^2 g l^3 \beta \Delta T / \mu^2$
Prandtl	Pr	Momentum diffusivity / Thermal diffusivity	$C_p \mu / h_c$

* Nomenclature: ρ = mass density (g/cm^3), V = flow velocity (cm/sec), l = linear dimension (cm), μ = absolute viscosity (g/cm-sec), g = gravitational constant (cm/sec^2), β = expansion coefficient (liter/°K), and ΔT = temperature difference (°K), C_p = specific heat (cm^2/sec^2°K), h_c = thermal conductivity (g cm/sec^3°K).

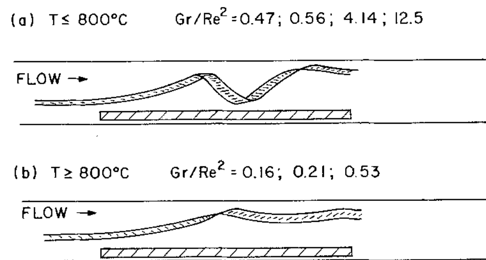

Fig. 1. TiO_2 smoke streamlines observed at various Gr/Re^2 ratios and susceptor temperatures (these drawings were obtained by tracing the actual photograph of the flow patterns).

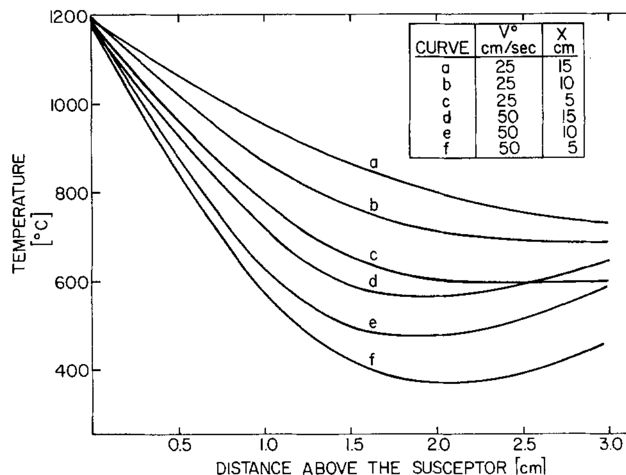

Fig. 2. Temperature profiles in He for various experimental conditions.

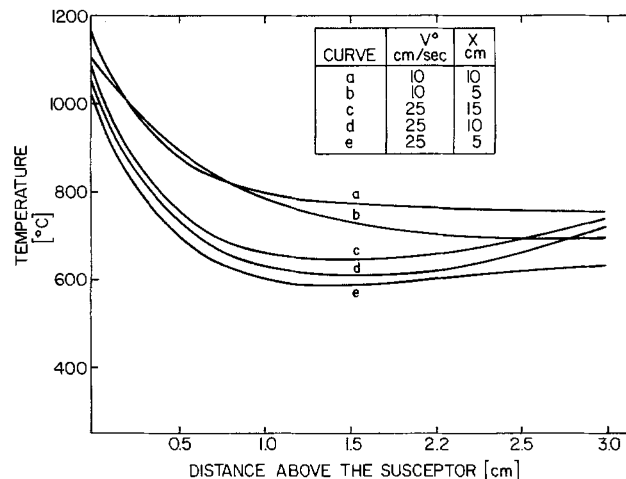

Fig. 3. Temperature profiles in N_2 for various experimental conditions.

Figure 2 shows temperature profiles in the y direction in helium. These profiles were taken at x = 5, 10, and 15 cm. Two different gas velocities were used $V° \approx 25$ cm/sec and ~ 50 cm/sec ($V°$ = velocity at room temperature). The susceptor temperature, T_s, was 1200°C. Figure 3 shows similar profiles taken in N_2. All relevant data are specified in the figure.

There are several things to notice in the above curves: (*i*) There is a steep temperature gradient in the first 1.5 cm above the susceptor, and a practically flat gradient above it; (*ii*) for the same velocity and susceptor temperature, gradients are steeper in N_2 than in He (H_2 behaves similarly to He); and (*iii*) the temperature of the upper portion of the gas increases with x and with decreasing V, thus resulting in shallower gradients under those conditions. Figure 4 shows the isotherms in the horizontal reactor. In this

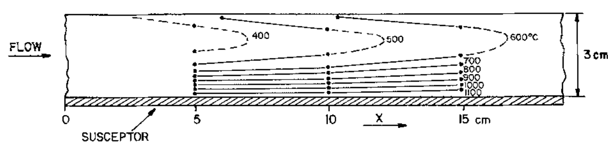

Fig. 4. Isotherms in the horizontal reactor ($V° = 50$ cm/sec; $T_s = 1200$°C).

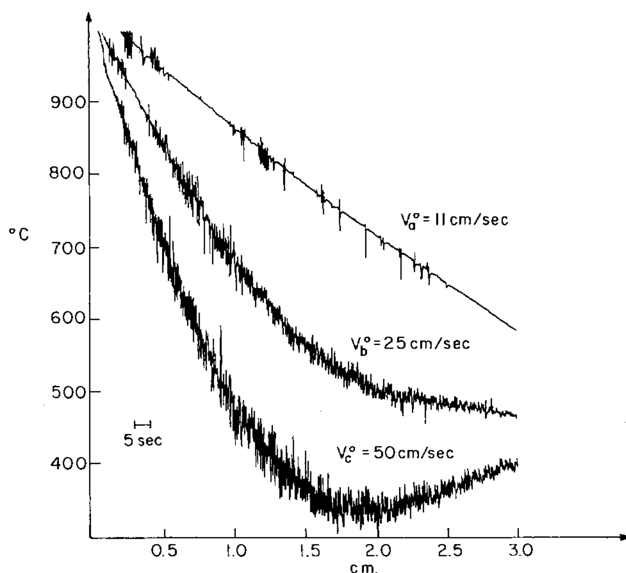

Fig. 5. Direct recordings of temperature profiles in He showing oscillations. $T_s = 1000$°C, $x = 15$ cm.

case $V° = 50$ cm/sec, $T_s = 1200$°C, gas is helium. Again, two different temperature areas are visible.

Another interesting observation in these measurements is the existence of large temperature fluctuations. Figure 5 shows the direct temperature profile recording. The relevant data are specified in the figure. These oscillations have a frequency of about 3-5 Hz and amplitudes as large as ± 30°C. Similar fluctuations were observed by Curtis and Dismukes (10).

Partial pressure measurements.—Mass spectrometric experiments determined the following species in the vapor phase: H_2, $SiCl_4$, HCl, and $SiCl_2$; $SiCl_2$ is at least an order of magnitude less abundant than the other species. The H_2 and $SiCl_4$ are, of course, the input gases, while the HCl and $SiCl_2$ are products of chemical reactions occurring in the system. In addition to the above gases, about 1% of Ar was added to the input mixture; Ar served as an internal standard so that the quantitative measurements of partial pressures of other gases can be made by comparison with the known Ar pressure.

The spatial variation of partial pressures of $SiCl_4$ and HCl in the x-y plane were given in Ref. (5). From these data it is possible to construct the $SiCl_4$ isobars, which are shown in Fig. 6. Again in the upper area a flatter concentration gradient exists than in the lower area, where isobars are closer together. There is also a partial pressure gradient in the x direction, due to the depletion of the reactant. If uncorrected (*e.g.*, by tilting the susceptor) this depletion would cause the downstream wafers to be thinner than the upstream wafers. The HCl isobars would show the opposite tendencies: an increase in pressure close to the susceptor and also in the x direction.

Figure 7 is the direct mass spectrometric recording of the $SiCl_4$ partial pressure profile. Again, one notices fluctuations in the middle section of this curve; the frequency is around 3-4 Hz and the amplitude is about ± 10% of the mean value.

Discussion

The above-described results allow us to make some conclusions on the nature of transport phenomena in the epitaxial reactors. First of all, one deals with not fully developed temperature and velocity profiles. The full development of the temperature field in a horizontal channel heated from below occurs when $x > L = 0.4$ DPe, where D = height of the channel and Pe = Peclet number (Pe = Pr × Re where Pr = Prandtl number) (8). In our case Re ≈ 50, Pr = 0.7, $D = 3$ cm. Therefore, temperature is fully developed when $x > 40$ cm, which is considerably longer than the susceptor itself.

A criterion for the elimination of entry effects from the velocity profiles is that $x > L = 0.029$ ReD. In our case $L \approx 45$, and thus again much longer than the susceptor itself. In the entry region boundary layers start to form on the walls of the channel, but between these layers one has a central core of the fluid with different temperature and velocity characteristics as evidenced by the observed flat temperature and concentration profiles and the recorded oscillations. These oscillations increase with a value of Re, which is consistent with the entry effect explanation presented here. The entry effects disappear when the upper and lower boundary layer met and a fully developed laminar flow velocity profile is formed. The lower layer increases in thickness faster, because the viscosity of the gas increases with temperature. The flat concentration and temperature gradients mean that relatively good mixing occurs in the central core. This mixing is due to the transverse gas movement caused by buoyancy effects, which were observed in the flow visualization experiments. The core can be thus considered a reservoir of reactant gaseous species from which they diffuse through the boundary layer to reach the growth interface. The core itself changes in the x direction. It becomes narrower due to the development of boundary layers, its temperature increases, the partial pressure of reactants decreases and of products increases. These ideas are pictorially presented in Fig. 8, where the qualitative changes in velocity, temperature, and concentration profiles are shown.

It is important to note that the model which emerges from our experiments is more complex than models used in theoretical calculations referenced earlier. In these works either the fully developed laminar velocity profiles and/or the constant temperature in the

Etching of CVD Si_3N_4 in Acidic Fluoride Media

Cheryl A. Deckert*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

The process whereby CVD Si_3N_4 films are etched in acidic fluoride solutions has been investigated at 25° and 60°C by use of a series of well-characterized etchants. The rate law for the dissolution process has been identified and is found to be linear in both [HF] and $[HF_2^-]$, but independent of $[F^-]$. Although the exact magnitude of the etch rates of CVD Si_3N_4 is known to depend on the deposition conditions used, it is thought that the general form of the rate law will remain constant. Comparison between the rate constants for Si_3N_4 and those previously reported for SiO_2 suggests that the etch rate of Si_3N_4 can be increased relative to that of SiO_2 by use of elevated temperatures and very low pH solutions, and by adjustment of the nitride deposition parameters so as to increase the NH_3/Si ratio in the reaction mixture.

Removal of silicon nitride from semiconductor device wafers is usually carried out using a hot (180°C) phosphoric acid etchant (1). As has been pointed out previously (2), this process is rather inconvenient to utilize both because of the high temperature which must be maintained and because water tends to become depleted from the etchant mixture. Etch rates of Si_3N_4 films in buffered hydrofluoric acid and in concentrated HF have been reported; more recently, dissolution studies of Si_3N_4 in various dilutions of HF over a range of temperature have appeared (2, 3). In all these cases, comparison with etch rates of SiO_2 films has been made; the etch rates of nitride are lower than those of oxide in all the cases reported except for very dilute ($\gtrsim$ 0.3%) HF solutions at high temperatures ($\geq$90°C). The implementation of processes based upon such data is hampered by two main difficulties: first, unlike thermally grown SiO_2, which gives readily reproducible etch rates in a given medium, CVD Si_3N_4 displays varying etch rates depending on the exact deposition parameters; and second, the mechanism of etching Si_3N_4 has never been investigated in a series of well-characterized etchants, as has been done for SiO_2 (4), so as to yield a simple rate law based on one or more chemical species.

In this study we have examined the dissolution of CVD Si_3N_4 films of a "typical" formulation in a variety of well-characterized fluoride etchants, in an attempt to deduce the dependence of etch rate on the various chemical species present. Although such a rate law will vary somewhat depending on the film deposition conditions, the general form of the rate equation will most likely be constant and can thus be of general use in nitride patterning processes.

Experimental

The silicon nitride films were prepared by chemical vapor deposition techniques on silicon wafers of [111] orientation. The flow rate of N_2 carrier gas through $SiCl_4$ at ~25°C was 110 cm³/min resulting in transport of 0.21 g/min $SiCl_4$. The flow rate of NH_3 was 600 cm³/min. The nitrogen main flow was 225 liters/min,

* Electrochemical Society Active Member.

Key words: CVD Si_3N_4 films, acidic fluoride solutions, etching.

and the reactor temperature was 875°C. Nitride deposition rate was 120-130 Å/min. Thicknesses of deposited nitride were limited to approximately 2100Å in order to avoid excessive stress buildup. The material was found to dissolve at 10-12 Å/min in a p-etch (30 parts conc. HF, 20 parts conc. HNO_3, 600 parts H_2O). The etching experiments were terminated at about 800Å remaining nitride so that possible occurrence of oxy-nitride species near the Si_3N_4/Si interface would not alter the observed etch rates. The etching tests were conducted in a constant temperature bath controlled to within ±0.5°C. Thicknesses, both before and after etching, were measured by a technique based on relative reflectivity of a monochromatic beam of light (5). Two different wavelengths of light were employed and duplicate samples were tested in each experiment. The usual assumption was made that etch rate is linear with time. Estimated error in etch rates was ±5%.

Either reagent- or electronic-grade chemicals were used throughout the experiments. The NH_4F stock solution was analyzed for % fluorine content by Schwarzkopf Microanalytical Laboratory using a volumetric procedure with La^{3+}.

Results

The etchant solutions were prepared similarly to those of Judge (4). Simplistically, formulation of the etchant solutions can be described as follows: NH_4F was used to control the total fluoride content, HCl to lower the *p*H, and NH_4Cl to bring the total solution ionic strength up to 1M. The composition of the etchant solutions, expressed in terms of formality of reagents added, is given in Table I. The exact concentrations of the various fluoride-containing species were determined from the known dissociation constants for HF in 1M ionic strength media (6)

$$HF + H_2O \rightleftarrows H_3O^+ + F^-$$

$$K_1\ (25°C) = 1.30 \times 10^{-3}$$
$$(60°C) = 6.57 \times 10^{-4} \quad [1]$$

$$HF_2^- \rightleftarrows HF + F^-$$

$$K_2\ (25°C) = 1.04 \times 10^{-1}$$
$$(60°C) = 3.66 \times 10^{-2} \quad [2]$$

The calculated equilibrium concentrations and observed etch rates are given in Tables II and III.

In order to deduce the rate law for Si_3N_4 dissolution, the correlation of etch rate with concentration of the various fluoride-containing species was examined. Simple perusal of the data indicates that etch rate is independent of concentration of "free" fluoride ion, F^-, whereas both protonated fluoride species, HF and HF_2^-, appear to be involved in the rate law. Characterization of the SiO_2 etching process has revealed (4) a linear dependence of etch rate on both [HF] and [HF_2^-]; thus we performed a multiple regression analysis on the data to determine whether a good straight line fit could be obtained using the equation

$$R = A[HF] + B[HF_2^-] + C \quad [3]$$

When R is expressed in Å/sec and concentrations are in molarity, the values of the constants A, B, and C calculated for the Si_3N_4 etching process are those given in Table IV. For comparison, the constants previously reported (4) for SiO_2 are also given. As a check on the assumption that the data would fit the linear Eq. [3], a plot was made of etch rate *vs.* the calculated function for each temperature. These plots are shown in Fig. 1 and 2. It is seen that the data do fall close to the plotted straight lines and that the intercept is very close to the origin in each case (since parameter C is close to zero), thus increasing confidence in the validity of the calculated rate law.

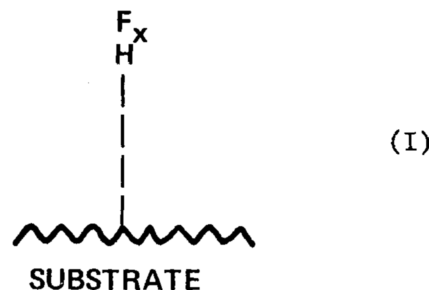
Discussion

It is interesting that the rate laws for etching of SiO_2 and Si_3N_4 are so similar, and that the unprotonated species, F^-, is unreactive in each case. One might hypothesize an etching mechanism which involves an intermediate hydrogen-bonded species (I)



(I)

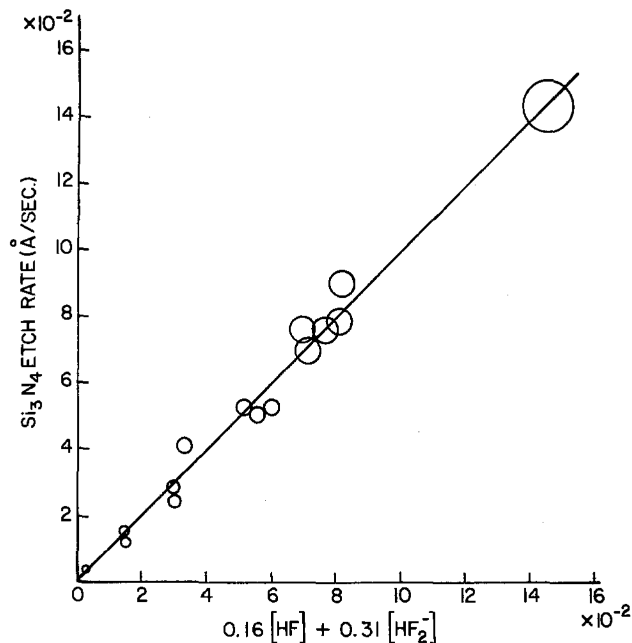


Fig. 1. Si_3N_4 etch rate at 25°C *vs.* the function $\{A[HF] + B[HF_2^-]\}$. The diameters of the circles reflect the experimental error in the etch rates.

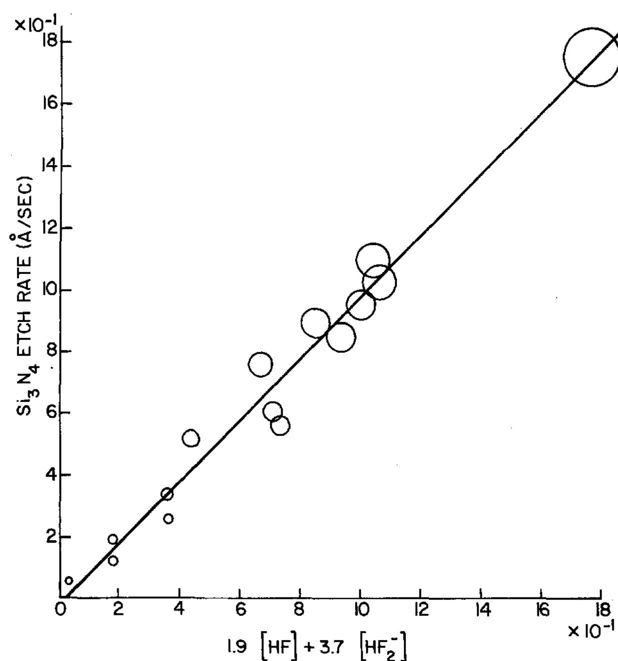

Fig. 2. Si_3N_4 etch rate at 60°C *vs.* the function $\{A[HF] + B[HF_2^-]\}$. The diameters of the circles reflect the experimental error in the etch rates.

Initial formation of such a species might hold the fluorine atoms close to the substrate for a long enough period of time so that they could achieve a favorable orientation and could thus successfully attack the substrate.

Regarding the relative rates of oxide *vs.* nitride etching, it can be seen from the data in Table IV that although at both temperatures studied Si_3N_4 etches much more slowly than does SiO_2, nevertheless the nitride rate constants appear to be increasing somewhat faster with temperature than those of oxide. This behavior indicates higher activation energies for the nitride etching process than for oxide, as is shown graphically in Fig. 3. Since the slopes of these lines are equal to $-E_A/R$, we can calculate the apparent activation energies shown in Table V, in kcal/mole.

Table V

	Si_3N_4	SiO_2
A term (HF dependent)	14	8.0
B term (HF_2^- dependent)	14	9.1

From these activation energies, it can be determined that, although keeping the HF/HF_2^- ratio large (by buffering at a low pH) should favor the nitride etch rate as much as possible, the SiO_2 and Si_3N_4 etch rates in 1M ionic strength etchants will not become equal at temperatures below the boiling point of the etchants. This result is in contrast to those of Harrap (2), who found that under certain conditions, namely at high temperatures (~90°C) and in very dilute hydrofluoric acid solutions, the nitride etch rate could be favored over that of oxide. This difference may be in part due to the particular nitride deposition process used: our process involved a smaller NH_3/Si (Si from $SiCl_4$) molar ratio (22) than did Harrap's (75 or 250, Si from SiH_4), a change which is expected to decrease nitride etch rate. Unfortunately, the fact that Harrap's work was done in solutions of undetermined ionic strength hampers direct comparison of his results and ours. It is quite likely, however, that use of dilute solutions and high temperatures favor HF formation relative to HF_2^-; this would be the case if the 1M ionic strength acid dissociation constants are applicable, and would give qualitative agreement between the two sets of results. However, more detailed comparisons of the two studies, particularly where the more highly concentrated fluoride media are concerned, will require further information concerning higher associated fluoride species and acid dissociation constants.

Analysis of Phosphorus-Diffused Layers in Silicon

Richard B. Fair*

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

Using the Fair-Tsai model of P diffusion in Si, equations have been derived which relate the total P concentration, electron concentration, sheet resistance, and junction depth of a P-diffused layer. Curves are presented which show surface concentration as a function of the $R_S \cdot x_J$ product, percentage of electrically active P as a function of surface concentration, and R_S *vs.* x_J for P-implant doses ranging from 1×10^{14} to 5×10^{16} cm^{-2}.

At high concentrations the diffusion of phosphorus in silicon produces an impurity atom distribution that differs considerably from the Gaussian or complementary error-function distributions. For this reason it has not been known how to calculate curves that relate P surface concentration and electron concentration to the average resistivity ($R_S \cdot x_J$ product) of the layer, etc.

Recently, Fair and Tsai (1) reported on a model of P diffusion in Si which accounts quantitatively for the existence of electrically inactive P, the "kink" and the tail regions of the P profile, and the emitter dip effect. This model is based upon the idea that P diffuses with vacancies in the V^x, V^-, and $V^=$ charge states. In the high concentration surface region ($n \geqq 10^{20}$ cm^{-3}) equilibrium concentrations of $P^+V^=$ pairs dominate. At lower concentrations when the Fermi level is ~0.11 eV below the conduction band, the $V^=$ vacancy gives up an electron, and the 0.3 eV lower binding energy of the resulting P^+V^- pairs enhances the probability for pair dissociation by a factor of 10-35, depending on the temperature. This effect creates a steady-state excess vacancy concentration which flows to the bulk and the surface. The concentration of excess vacancies is proportional to the number of $P^+V^=$ pairs in the surface region times the probability for pair dissociation. These V^- vacancies interact with P to create the enhanced tail diffusion. Three diffusion coefficients are required to describe P diffusion [see Fig. 1 taken from Ref. (1)].

Analysis

In this section simplifying assumptions are introduced into the physics governing P diffusion in Si. In this way approximate expressions are developed for estimating the important profile parameters in P diffusion; sheet resistance, junction depth, and surface concentration. To begin it it necessary to calculate the electrically active P/cm² concentration, Q_{el}, for any diffusion condition.

Total and electrically active phosphorus per square centimeter.—It was shown in Ref. (1) that the implication of the three phosphorus diffusion coefficients means that high concentration phosphorus diffusion yields a profile similar to the one shown in Fig. 2. This profile can be divided into two parts; one associated with the highly doped surface region with total doping per square centimeter of Q_{ST}, and one associated with the tail region with total doping per square centimeter of Q_{TAIL}. Not all of the P in the surface region is electrically active. The inactive doping, Q_{sn}, is in the form of $P^+V^=$ pairs while the active doping is labeled Q_{se}. The total electrically active P/cm² under the profile is

$$Q_{el} = Q_{se} + Q_{TAIL} \qquad [1]$$

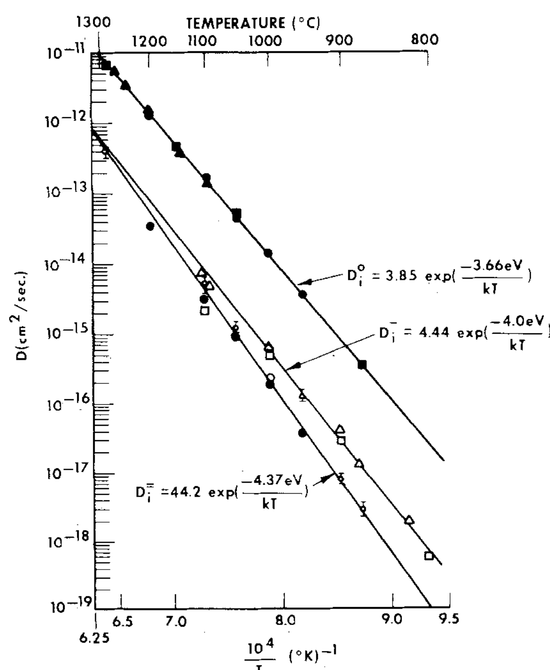

Fig. 1. Intrinsic diffusivities of phosphorus in silicon [after Ref. (1)].

* Electrochemical Society Active Member.

Key words: electrical activity, diffusion in silicon, ion implantation.

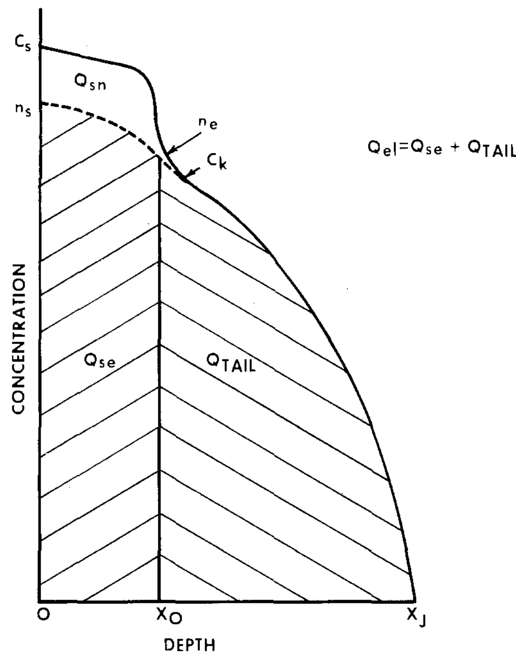

Fig. 2. A typical high concentration phosphorus diffusion profile in silicon.

The tail profile is a complementary error function with a "surface" concentration, C_k, occurring at the profile kink. The integrated concentration of P in the tail is

$$Q_{TAIL} = \frac{2}{\sqrt{\pi}} \sqrt{D_{TAIL} t}\, C_k \quad [2]$$

D_{TAIL} is the tail diffusivity given by

$$D_{TAIL} = D_i^x + \frac{D_i^- n_s^3}{n_e^2 n_i} \left[1 + \exp\left(\frac{0.3 \text{ eV}}{kT}\right) \right] \quad [3]$$

where n_s is the electron concentration at the Si surface, n_e is the concentration at which $P^+V^=$ pairs dissociate to create excess V^- vacancies, and D_i^- is the intrinsic diffusivity of P when diffusion occurs with V^- vacancies. The 0.3 eV term in the exponential refers to the binding energy difference between $P^+V^=$ pairs and P^+V^- pairs. Arrhenius plots of the diffusion coefficients for P are shown in Fig. 1. The data from which these diffusion coefficients were obtained are referenced in Ref. (1) as are values of C_k, n_e, and n_s as a function of temperature.

Making use of the observation that $C_k/n_e \simeq 0.4$ for many profiles and assuming that the second term on the right in Eq. [3] is dominant if $n_s \gtrsim 5 \times 10^{19}$ cm^{-3}, then

$$Q_{TAIL} \simeq \frac{n_s^{3/2}}{2} \sqrt{\frac{D_i^-}{n_i} \left[1 + \exp\left(\frac{0.3 \text{ eV}}{kT}\right) \right] t} \quad [4]$$

At surface concentrations below $n_s = 2 \times 10^{19}$ cm^{-3}, $D_{TAIL} \simeq D_i^x$. In this concentration range neutral vacancies control P diffusion.

In the high concentration surface region it has been observed that the total P/cm² concentration is

$$Q_{ST} = Q_{se} + Q_{sn},$$

$$\simeq \frac{C_s x_o}{2} \quad [5]$$

where Q_{sn} is the number of nonelectrically active P atoms/cm², C_s is the total P surface doping density, and x_o is the depth at which $n \simeq n_e$. An approximate expression for x_o, sometimes referred to as the width of the "flat region," is

$$x_o = 2 \sqrt{D_i^= \left(\frac{n_s}{n_i}\right)^2 ht} \quad [6]$$

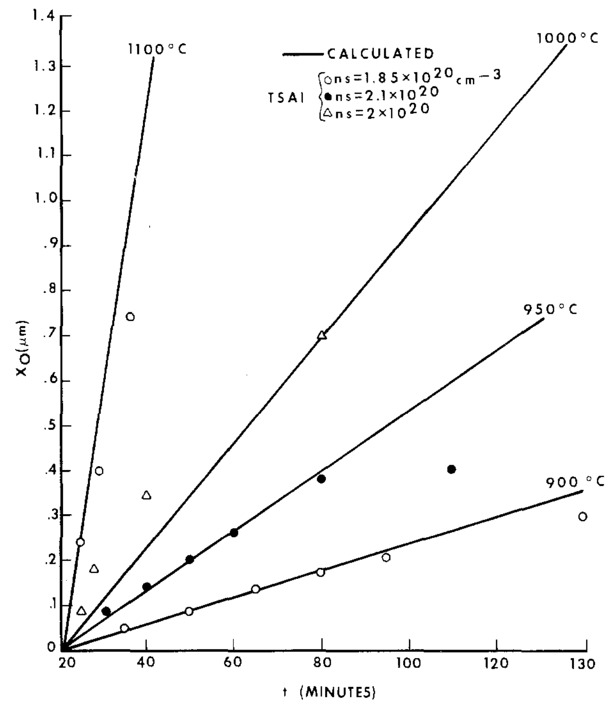

Fig. 3. Calculated "flat" region width of a phosphorus profile vs. diffusion time.

In Eq. [6] $D_i^=$ is the surface region P diffusivity ($P^+V^=$ pair diffusion), and h is the electric-field enhancement factor ($h \simeq 2$). Equation [6] is shown plotted in Fig. 3 for several temperatures. The data are from Tsai (2) and represent the flat region width for P diffusions with $n_s \simeq 2 \times 10^{20}$ cm^{-3}. Good agreement is obtained with these measured data. C_s is related to n_s through the equation (1)

$$C_s = n_s(1 + 2.04 \times 10^{-41} n_s^2) \quad [7]$$

This equation results because at high concentrations a fraction of the P is not electrically active. The "inactive" P is contained in $P^+V^=$ pairs.

Equation [5] can be solved for Q_{ST} in terms of n_s. Adding this result to Eq. [4] for Q_{TAIL} gives the total P atoms/cm² in a diffused profile as

$$Q_T = Q_{ST} + Q_{TAIL} = n_s^{3/2} \sqrt{\frac{t}{n_i}} \left[(1 + 2.04 \times 10^{-41} n_s^2) \sqrt{\frac{D_i^= n_s h}{n_i}} + \frac{1}{2} \sqrt{D_i^- \left(1 + \exp\left(\frac{0.3 \text{ eV}}{kT}\right)\right)} \right] \quad [8]$$

and the electrically active P/cm² as

$$Q_{el} = Q_{se} + Q_{TAIL} = n_s^{3/2} \sqrt{\frac{t}{n_i}} \left[\sqrt{\frac{D_i^= n_s h}{n_i}} + \frac{1}{2} \sqrt{D_i^- \left(1 + \exp\left(\frac{0.3 \text{ eV}}{kT}\right)\right)} \right] \quad [9]$$

Equations [8] and [9] are shown plotted in Fig. 4 where Q_T and Q_{el} *vs.* n_s are the coordinates. The data shown were taken from measured P profiles in which the $POCl_3$ source flow rates were adjusted to achieve different surface concentrations for the 875°C 45 min diffusions (3). Reasonably good agreement is obtained between the data and the calculated curves.

It can be seen that Eq. [8] is of the form $Q_T = \sqrt{KT}$ which agrees with the experimentally observed parabolic law behavior of P predeposition (4). At very

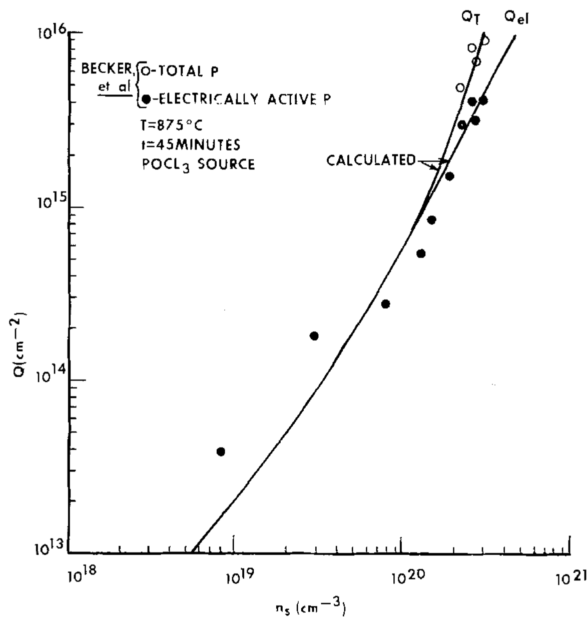

Fig. 4. Total and electrically active P/cm² vs. surface electron concentration.

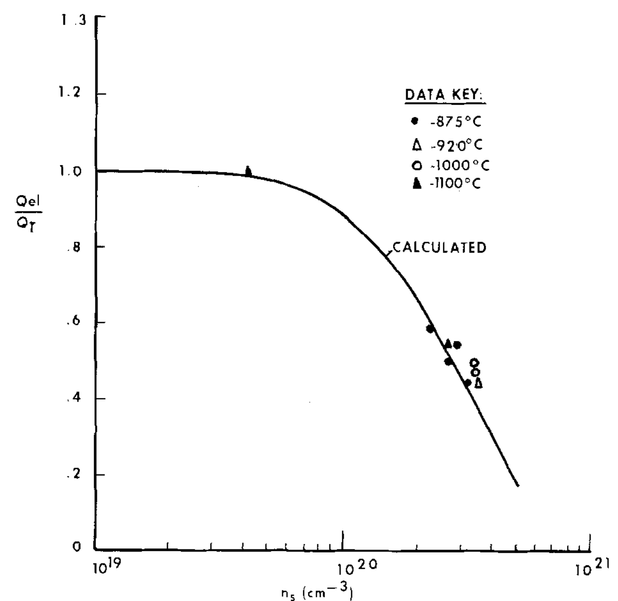

Fig. 5. Electrically active phosphorus fraction vs. surface electron concentration for all diffusion temperatures.

large surface concentrations, Eq. [8] reduces to

$$Q_T = n_s^{3/2}\sqrt{\frac{t}{n_i}}\,(1 + 2.04 \times 10^{-41} n_s^2)\sqrt{\frac{D_{i^=} n_s h}{n_i}} \quad [10]$$

The diffusivity of the $P^+V^=$ pair controls the rate of introduction of P into Si, so that from Fig. 1 with n_s independent of temperature

$$Q_T \propto \sqrt{\exp\left(\frac{-4.37\text{ eV}}{kT}\right) \Big/ n_i^2}$$

$$\propto \exp\left(\frac{-1.49\text{ eV}}{kT}\right)$$

where 1.49 eV is the calculated energy term in the temperature dependence of Q_T. Negrini *et al.* (4) have measured this energy to be 1.1 eV. However, it is evident from their published profiles (5) that for a fixed $POCl_3$ flow rate, n_s is a function of temperature. Also, Eq. [8] for Q_T is only valid for P concentrations below solid solubility, whereas Negrini's work concentrates on the region above solid solubility.

The parabolic constant K can be calculated from Eq. [10] for low $POCl_3$ flow rates. For example, for a 920°C deposition with 0.06% $POCl_3$ in 1.3% O_2 for 27 min, Negrini measures $K = 1.5 \times 10^{32}$ cm^{-4} hr^{-1}. From Ref. (5) this predeposition corresponds to a P profile with $n_s \simeq 2.8 \times 10^{20}$ cm^{-3}. From Eq. [10], the calculated K value is 1.8×10^{32} cm^{-4} hr^{-1}, in good agreement.

Taking the ratio of Q_{el} (Eq. [9]) to Q_T (Eq. [8]) and plotting the result as a function of n_s yields a single curve which is independent of temperature and diffusion conditions (source ambient) etc. This curve is shown in Fig. 5 and is particularly useful in predicting the percent electrically active P following implantation and subsequent diffusion. This curve is only valid for P concentrations below the P solid solubility limit in Si. Care must be taken in comparing this curve with P diffusion data where P precipitation has occurred. The data shown in Fig. 5 (1, 4-6) were selected on this basis and show good agreement with the calculated curve.

Sheet resistance and surface concentration.—The expression for the sheet resistance of a diffused impurity layer in Si is

$$R_S = \frac{1}{q\,\bar{u}\,Q_{el}} \quad [11]$$

where $\bar{u}$ is the effective bulk carrier mobility (cm²/V-sec) given by

$$\bar{u} = \frac{\int_0^{x_J} u\,n(x)\,dx}{Q_{el}} \quad [12]$$

An approximate expression for mobility can be obtained from the data of Mousty *et al.* (7). Thus

$$u = 75 + \frac{1.8 \times 10^{20}}{n} \quad [13]$$

where n is the electron concentration. Substitution of Eq. [13] into Eq. [12] and using the resulting expression for $\bar{u}$ in Eq. [11] yields

$$R_S = \frac{1}{q(75\,Q_{el} + 1.8 \times 10^{20}\,x_J)} \quad [14]$$

The units of electrically active P, Q_{el}, are (atoms cm^{-2}) and x_J is in cm.

By eliminating time from the expression for Q_{el} in Eq. [9] and solving for Q_{el} as a function of x_J, then the $R_S \cdot x_J$ product can be determined from Eq. [14]. The junction depth is the sum of the "flat region" width, x_o, and the depth of the tail region profile

$$x_J = x_o + 2\sqrt{D_{TAIL}t}\,\text{erfc}^{-1}\left(\frac{C_B}{C_K}\right) \quad [15]$$

C_B is the substrate background doping and C_K is the concentration at the kink in the P profile. Thus, Eq. [9] becomes

$$Q_{el} \sim \frac{x_J(1 + 2.04 \times 10^{-41} n_s^2)}{\text{erfc}^{-1}\left(\frac{C_B}{C_K}\right)} \left[3.5 \times 10^{10}\sqrt{\frac{D_{i^=} n_s}{D_{i^-}\left[1 + \exp\left(\frac{0.3\text{ eV}}{kT}\right)\right]}} + \frac{C_K}{\sqrt{\pi}}\right] \quad [16]$$

for $n_s >> C_K$ and

$$Q_{el} \sim \frac{n_s x_J}{\mathrm{erfc}^{-1}\left(\frac{C_B}{n_s}\right)\sqrt{\pi}} \quad [17]$$

for $n_s < C_K$. These equations are valid for the temperature range $T \lesssim 1050°C$. Above 1050°C the kink in the profile disappears.

Equations [16] and [17] have been used in Eq. [14] for estimating the $R_S \cdot x_J$ product for a background doping of 1×10^{17} cm^{-3}. The results are plotted *vs.* total P doping, C_S, and n_s for 800°, 900°, and 1050°C in Fig. 6. The C_S and n_s curves stop at the respective solid solubility limits. Data taken from measured profiles (8) are also included in Fig. 6 to support the calculations. Similarly, for the 1100°-1300°C range average $R_S x_J$ *vs.* C_S and n_s curves are shown in Fig. 7. In this temperature range the resistivity *vs.* surface concentration curves do not show the temperature dependence of the 800°-1050°C curves shown in Fig. 6.

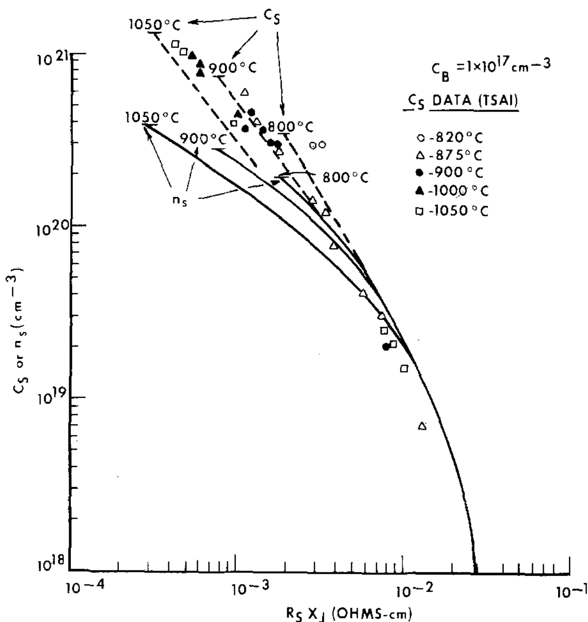

Fig. 6. Total and electrically active P surface concentrations *vs.* average resistivity for the 800°-1050°C temperature range.

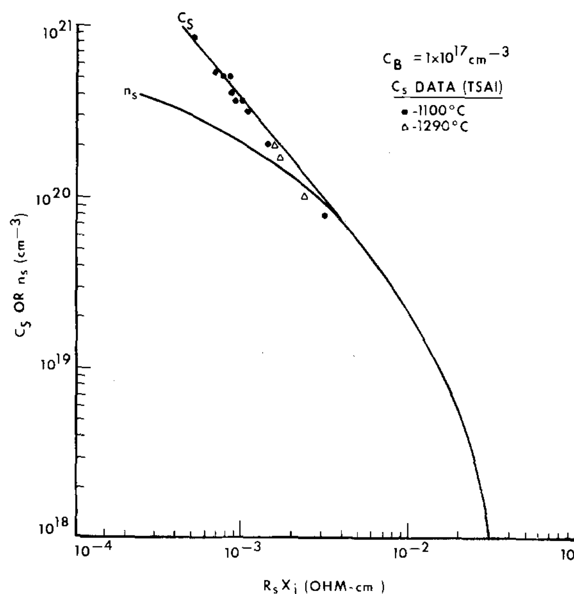

Fig. 7. Total and electrically active P surface concentration for the 1100°-1300°C temperature range.

Drive-in of implanted or predeposited P layers.—In the case of an ion-implanted P layer, the total dose, Q_T, is known. In order to determine R_S as a function of x_J, Q_{el} must be calculated. If the final surface concentration, n_s, is known, then Q_{el} can be determined from Fig. 5 for any diffused P layer in Si, regardless of the diffusion temperature. Rewriting Eq. [14], the sheet resistance becomes (Ω/□)

$$R_S = \frac{8.3 \times 10^{16}(1 - 28.8 R_S x_J)}{Q_{el}} \quad [18]$$

Curves of R_S *vs.* x_J at a background doping of 1×10^{17} cm^{-3} can now be generated. For a given P implant dose, values of n_s can be selected from which Q_{el} (Fig. 5) and $R_S x_J$ (Fig. 6 and 7) can be determined. Equation [18] can then be solved for R_S. Calculated curves which have been averaged over the temperature range of 900°-1300°C are shown plotted in Fig. 8. For example, a 1×16 cm^{-2} P implant with a junction depth of 3 μm will have a sheet resistance of approximately 8.5 Ω/□. The data shown in Fig. 8 were obtained from 50 keV P implants and support the approximate curves for the doses shown. However, these curves do not depend on implant energy since the unique relationship between R_S and x_J is only a function of Q_{el}. This assumes that the initial implant quickly redistributes during thermal processing so that this unique relationship can occur rapidly.

Conversely, the surface concentration can be determined from R_S measurements if the implant dose and diffusion temperature range are known. For example, a 20 Ω/□, 5×10^{15} cm^{-2} P implant diffused in the temperature range $T > 1100°C$ yields $x_J \simeq 1$ μm at 10^{17} cm^{-3}. Thus, $R_S x_J = 2 \times 10^{-3}$ Ω-cm. From Fig. 7, $C_S = 1.2 \times 10^{20}$ cm^{-3} and $n_s = 1 \times 10^{20}$ cm^{-3}.

Discussion

At least one phenomenon in P diffusion has not been treated in this paper, *i.e.*, precipitation on dislocations. Generally, it is found that if the surface concentration is limited to solid solubility values, precipitation is negligible in its effect on diffusion. At higher surface concentrations significant precipitation can occur in the Si, depending to some extent on the initial dislocation density of the Si crystal (9). The effect of P precipitation on dislocations is to introduce nonequilibrium processes into the diffusion mechanisms which can significantly reduce the depth to which

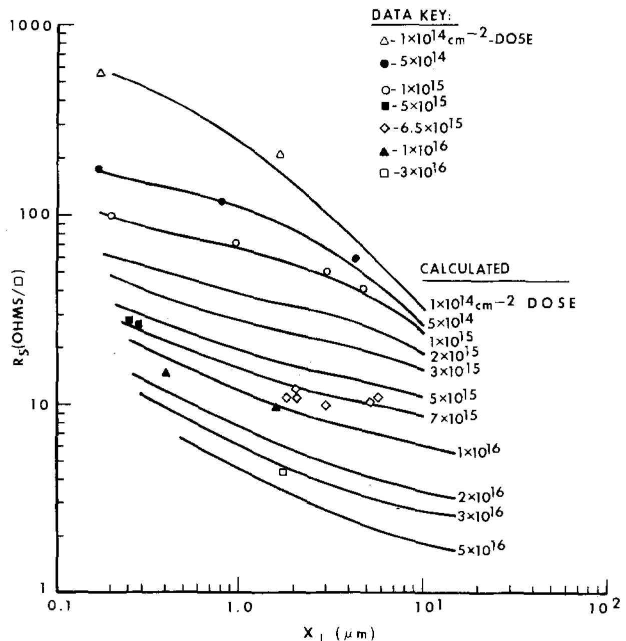

Fig. 8. Sheet resistance *vs.* junction depth at 10^{17}cm^{-3} curves for P implanted-diffused layers in Si.

P diffuses for a given time and temperature. The curves presented in this paper do not account for precipitation. As a result, diffusions with C_S greater than solid solubility will show a smaller junction depth and larger C_S than predicted by the analysis.

Summary and Conclusions

The complex diffusion of phosphorus in silicon has been analyzed in simplified terms. By calculating the relationship between total P/cm^2 and electrically active P/cm^2, curves have been generated which relate P and electron surface concentrations to the average diffused-layer resistivity. For the case of an ion-implanted P layer which is subsequently diffused, it has been shown that well-defined curves of R_S *vs.* x_J can be generated for a particular implant dose, regardless of the diffusion time and temperature.

Characterization of the Gaseous and Solid Products of Aluminum Sulfate Decomposition

Gary F. Knutsen and Alan W. Searcy

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Materials Science and Mineral Engineering, University of California, Berkeley, California 94720

ABSTRACT

Measurements of SO_2^+/SO_3^+ mass spectrometer ion ratios and of weight losses when $Al_2(SO_4)_3$ is decomposed in an effusion cell show that equilibrium is achieved. Measurements of H_2O^+/SO_3^+ mass spectrometer ion intensities as a function of time shows that "anhydrous" aluminum sulfate contains about 0.03 moles of water per mole of sulfate ion. The solid decomposition product in the range of effusion studies, below 600°C, is an amorphous Al_2O_3 which has a surface area of 165 M^2/g and internal pores that average about 100Å in diameter. The experimentally measured decomposition pressures are higher by more than a factor of 4 than would be expected from thermochemical calculations, probably because the heat of formation of $Al_2(SO_4)_3$ is 7-9 kcal per mole more positive than reported.

Many metal sulfates, when heated, decompose to a solid oxide plus a mixture of SO_3, SO_2, and O_2 gases in proportions that depend on the temperature necessary to cause decomposition. Among reactions investigated in our laboratory in recent years were the decomposition of barium and strontium sulfates (1, 2). These reactions yielded SO_2 and O_2 as the primary gas products in both Knudsen (equilibrium) and Langmuir (kinetic) studies. But recently, by means of a combined weight loss, torsion effusion and mass spectrometry study, Lau, Cubicciotti, and Hildenbrand (3) showed that although $CaSO_4$ yields equilibrium SO_2 and O_2 pressures relatively readily, $MgSO_4$ does not. With large orifices the principal gaseous product of $MgSO_4$ decomposition was SO_3. When the orifices of the cell were made sufficiently small or when Fe_2O_3 was added as a catalyst, the principal gaseous products became SO_2 and oxygen.

The temperatures suitable for effusion measurements with $MgSO_4$ are lower than for $CaSO_4$, $SrSO_4$, or $BaSO_4$. It appeared of interest to investigate a sulfate decomposition that occurred at a still lower temperature to determine if, under conditions for which equilibrium decomposition pressures of SO_2, O_2, and SO_3 are calculated to be nearly equal, the equilibrium partial pressures of SO_2 can be obtained.

Key words: sulfur dioxide; sulfur trioxide; aluminum sulfate decomposition; aluminum oxide, amorphous; aluminum sulfate, heat of formation, of; aluminum sulfate, water content of.

From available data (4, 5) it could be predicted that aluminum sulfate decomposition would be suitable for such a study. Furthermore, recent investigations by Beruto and Searcy (6, 7) of the calcium oxide produced by vacuum decomposition of $CaCO_3$ suggest that it should be of particular interest to investigate the crystal structure, morphology, and surface area of the solid product of the reaction sequence $Al_2(SO_4)_3 \cdot 17H_2O_{(s)} = Al_2(SO_4)_{3(s)} + 17H_2O(g) = Al_2O_{3(s)} + 3SO_{2(g)} + 3/2\ O_{2(g)}$.

Vacuum decomposition of $CaCO_3$ yields a CaO that is poorly crystalline, has particles with an internal porosity of more than 50%, and has surface areas of the order of 50 M^2/g. That oxide is much more reactive toward water vapor than is the oxide produced by decomposition of $CaCO_3$ in air or dry nitrogen.

The molar volume of Al_2O_3 formed from $Al_2(SO_4)_3 \cdot 17H_2O$ can be calculated to be only 10% that of the starting material. Thermal decomposition of $Al_2(SO_4)_3$ in air at temperatures less than 750°K yields an alumina that x-ray powder diffraction studies show to be amorphous (4-6). A study by Kalinina and Pori-Koshits (8) shows that $Al_2(SO_4)_3$ decom-

poses to γ-Al_2O_3 at approximately 1170°K and then transforms to the thermodynamically more stable form α-Al_2O_3 at temperatures greater than 1420°K. Therefore analogy with the results of $CaCO_3$ decomposition suggests that the alumina from $Al_2(SO_4)_3 \cdot 17H_2O$ decomposition in vacuum might well be both metastable and highly porous. If so it might, like the oxide produced by calcite decomposition, show unusually high reactivity.

Experimental

The mass spectrometer used to investigate the gaseous products of $Al_2(SO_4)_3$ decomposition was a 24 cm radius, Atlas CH4 magnetic deflection device equipped with a 16 stage, Cu-Be, electron multiplier for use as an ion current detector. Reagent grade $Al_2(SO_4)_3$ powder was purchased from the J. F. Baker Company. The only listed impurities were 0.01% Cl, 0.001% Fe, and 0.001% Pb. The powder, a hydrated form of $Al_2(SO_4)_3$, was heated for 24 hr at 620°K to drive the water off. The product then showed the expected powder x-ray pattern for anhydrous $Al_2(SO_4)_3$.

The dried $Al_2(SO_4)_3$ was stored in a vacuum desiccator until it was transferred to a 99.5% Al_2O_3 effusion cell. The cell was heated in the mass spectrometer by radiation from a 0.025 cm diameter tungsten wire surrounded by a tantalum heat shield. Temperatures were measured with a Pt-Pt 10% Rh thermocouple inserted in the bottom of a platinum cell holder which contained the Al_2O_3 cell.

Experiments were performed with cell lids of three different orifice diameters in order to test whether equilibrium is achieved inside the cells and to correct for nonequilibrium if necessary (9, 10). Orifice diameters were 0.31, 0.51, and 0.78 mm, respectively, and the thickness of each lid was 2.31 mm.

Background pressures below 10^{-7} Torr were established before each run. The intensities of SO_3^+ and SO_2^+ were followed using 70 or 17 eV electrons. In all the decomposition runs the temperature variations were less than 2°K, and the temperatures were stable at the midpoints for long periods of time. The total fluxes of SO_3 + (SO_2 + 1/2 O_2) were calculated from the weight changes produced in known periods of heating. The relative amounts of SO_3 and SO_2 effused were determined by monitoring the mass 80 peak, which corresponds to $S^{34}O_3{}^{16}$, and both the mass 64 which corresponds to $S^{32}O_2{}^{16}$ and the mass 66 peak for $S^{34}O_2{}^{16}$.

The Al_2O_3 that formed on the decomposition of $Al_2(SO_4)_3$ was examined by the powder x-ray diffraction method and a scanning electron microscope was used to determine the characteristic particle sizes and shapes for the $Al_2(SO_4)_3$ and the Al_2O_3 product. The surface area of the Al_2O_3 and the $Al_2(SO_4)_3$ were measured using a Quantasorb surface area analyzer. The samples were out-gassed for 1-2 hr at 625°K prior to surface area determination to desorb water or other contaminates on the surfaces.

Pore size distributions were studied for thoroughly out-gassed samples using a high pressure (60,000 lb) American Instrument mercury porosimeter.

Results and Discussion

It has been reported (11) that fragmentation of SO_3 to SO_2^+ is considerable. In order to determine accurate gas composition data, the ion current ratios were measured at 17 eV (about 5 eV above appearance potentials for both ions). The effective cross section σ_{eff} for a molecule at less than maximum potential values is given by the equation

$$\sigma_{eff} = \frac{(E - AP)\sigma}{(E_{MAX} - AP)}$$

where AP is the appearance potential. For SO_2, σ_{eff} is 0.52 and for SO_3 it is 0.54 based on cross sections by Mann (12) and appearance potentials determined by Lau *et al.* (3). When 17V electrons are used, fragmentation of both SO_2 and SO_3 is minimal, and the vapor effused from orifices of diameters 0.31, 0.51, and 0.78 mm all give SO_2^+/SO_3^+ ratios of 1.8/1 at 673°K. The fact that the ion ratios and calculated total pressures were independent of orifice area shows that equilibrium was attained more readily than for $MgSO_4$ decomposition (3). Fragmentation of SO_3 to SO_2^+ does have a significant effect when 70V electrons are used in studies of decomposition of $Al_2(SO_4)_3$; the SO_2^+/SO_3^+ ratio measured with 70V electrons was 2.7/1 at 673°K.

Our early SO_2^+/SO_3^+ ratios measured at 70 eV were higher than 2.7/1, and a scan of the mass spectrometer peaks showed the H_2O^+/SO_2^+ intensity ratio was approximately 1.1/1. After some 20% of the sulfur oxide had been driven out by heating, the H_2O^+ intensity decreased to about 10-15% of the SO_2^+ intensity. The relative intensities then remained at 1.8/1 until the sulfate was nearly decomposed (Fig. 1).

The initial high H_2O^+ intensity probably resulted from escape of adsorbed water. When the powder was exposed to air for more than 20 min the ratios of SO_2^+ to SO_3^+ measured with 70 eV electrons increased to 5/1. High SO_2^+/SO_3^+ ratios were accompanied by high H_2O^+ intensities and a peak corresponding to $H_2SO_4^+$ which was about 10% of the intensity of H_2O^+. Reaction of water with SO_3 is evidently the cause of the high SO_2^+/SO_3^+ ratios.

At longer times of heating, the intensities of SO_2^+, SO_3^+, and H_2O^+ all decreased at essentially the same rate, until about 95% of the sulfur oxide content of the sample had been exhausted. The intensities then decreased at a faster rate and SO_2^+/SO_3^+ ratios increased as expected when insufficient $Al_2(SO_4)_3$ remains to provide the equilibrium pressures of gaseous products. The gradual decrease in ion intensities that characterized most of the period of a run is probably a consequence of poisoning of the electron multiplier by the sulfur oxides.

The fact that an H_2O^+ peak persisted at some 3% of the SO_2^+ + SO_3^+ intensity throughout sample decomposition appears to mean that water is a significant component of "anhydrous" aluminum sulfate, as usually prepared. This conclusion is consistent with the report by Young (13) that he was unable to lower the water content of $Al_2(SO_4)_3$ below 0.3 weight percent of his sample, or about 2.4 mole percent, of the sulfur oxide content.

Decomposition of $Al_2(SO_4)_3$ in vacuum at 720°K produced a solid product that gave no discernable x-ray pattern, which indicates an amorphous material. Decomposition in vacuum at 1020°K produced a solid that showed only three broad x-ray peaks of

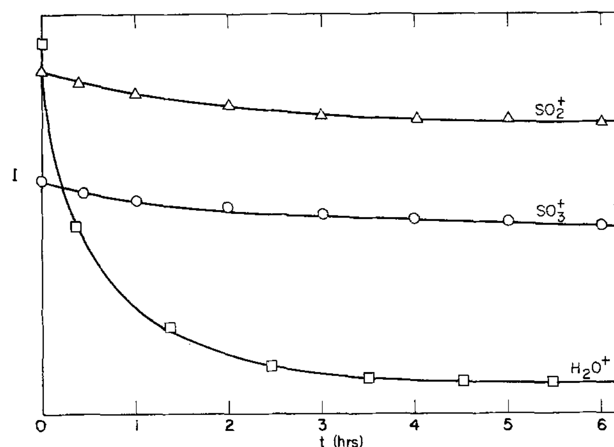

Fig. 1. Ion intensity vs. time at 800°K

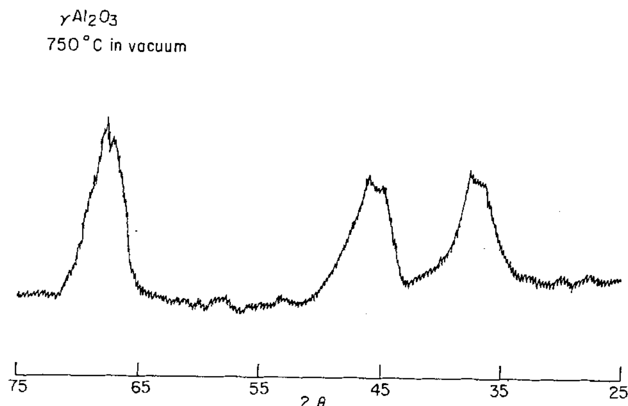

Fig. 2. X-ray pattern of γ-Al_2O_3 from decomposition at 750°C

γ-Al_2O_3 (Fig. 2). Decomposition in vacuum at 1370°K produced well-crystallized α-Al_2O_3. These results are consistent with earlier results for $Al_2(SO_4)_3$ decomposition in air (8).

Total decomposition pressures were calculated from isothermal Knudsen effusion weight loss experiments of at least several hours duration. The vapor was assumed to be a mixture of SO_3, SO_2, and O_2 which was at equilibrium for each temperature and total mass flux. Water, which is estimated to account for less than 2% of total weight losses, was neglected. The equilibrium assumption is supported by the fact that consistent total pressures were calculated from measurements with orifices of three different diameters (Fig. 3).

Because the alumina produced in our experiments was amorphous the corresponding decomposition pressures must be lower than those when γ-Al_2O_3 is the product (14). But our measured pressures are higher than the pressure calculated for decomposition to γ-Al_2O_3 by about a factor of 4 (5, 15). Furthermore, in the $Al_2(SO_4)_3$, the sulfur oxide activities should be reduced by the presence of water by an amount of the order of 3%, in accordance with Raoult's law, regardless of the form in which the water is present.

The heat of formation of $Al_2(SO_4)_3$ has been estimated to be uncertain by 5 kcal. The discrepancy between calculated and measured pressures is accounted for if it is assumed that the true heat of formation of $Al_2(SO_4)_3$ is, in fact, $5 + n$ kcal more negative than reported, where n is the heat of formation of amorphous alumina from γ-Al_2O_3. Probably n is 1-3 kcal.

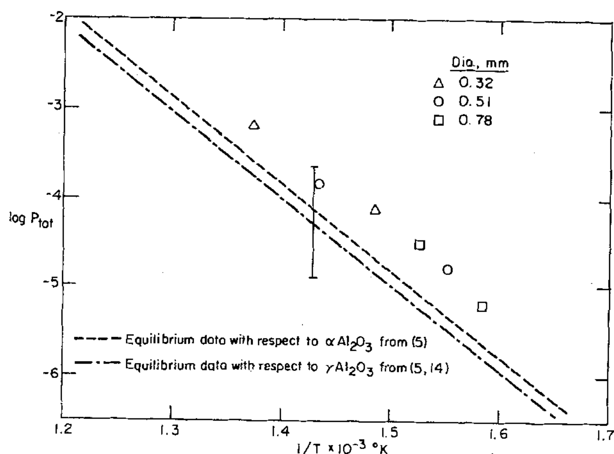

Fig. 3. Variation of p_{tot}, the total equilibrium decomposition pressure in atmospheres, with temperature. 5 kcal error bar is included on γ-Al_2O_3 line.

Table I. Surface areas

Material	Surface areas (M^2/g)
$Al_2(SO_4)_3 \cdot 17H_2O$	1.5
$Al_2(SO_4)_3$	35
Al_2O_3	165

Scanning electron micrographs of $Al_2(SO_4)_3 \cdot 17H_2O$ and Al_2O_3 show the hydrate and product oxide particles to be of the same shapes and dimensions, approximately 20 μm in typical cross section. Molar volume calculations indicate that the alumina particles must have more than 85% internal porosity. The fact that the pores could not be resolved in SEM pictures shows that either their diameters must be less than 0.1 μm or that reaction with water vapor during the short time of exposure to the atmosphere before SEM pictures could be made obscured the pore mouths.

Surface areas were obtained using the dynamic BET method on $Al_2(SO_4)_3 \cdot 17H_2O$, $Al_2(SO_4)_3$, and Al_2O_3. The results are given in Table I. These results coupled with the scanning electron micrographs prove that the alumina particles have very high internal surface areas.

A high pressure mercury porosimeter was used to measure the pore size distribution for the Al_2O_3 (Fig. 4). The average pore size is calculated to be 100Å.

Because the surface area of 165 M^2/g is nearly as high as areas of catalyst supports (16), we have initiated studies to determine if the Al_2O_3 produced from $Al_2(SO_4)_3 \cdot 17H_2O$ decomposition may be an effective reactant for removal of SO_2 and/or SO_3 from gas streams.

Kinetics of the Transformation of Metastable Tin-Nickel Deposits

I. Determination of the Avrami Equation Parameters by DSC or DTA

J. A. Augis and J. E. Bennett

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

Using both differential scanning calorimetry (DSC) and differential thermal analysis (DTA), the kinetics of the transformation upon heating of the metastable tin-nickel alloy were studied. The solid-state reaction proceeds according to a classical Avrami equation. The parameters of the reaction equation were determined, and it is shown that the metastable alloy will not revert to the stable state, for all practical purpose, if kept at temperatures below 100°C. Variations of the kinetic parameters were observed which can explain most of the different stability evaluations reported by different authors.

The electrodeposited equiatomic [approximately 65 weight percent (w/o) Sn-35 w/o Ni] tin-nickel alloy has been used in various practical applications because of its corrosion resistance or passivity and its thermal stability. Its remarkable corrosion resistance (1) has been the subject of several recent studies (2-4). Thermal stability has been reexamined by one of the authors (5). The equiatomic alloy is not an equilibrium phase of the nickel-tin binary system (6) and can only be prepared either by electroplating (7) or from more recent results by sputtering (8). The electroplated and sputtered deposits are metastable and are known to revert upon heat-treatment to the two phases Ni_3Sn_4 and Ni_3Sn_2 which constitute the room temperature equilibrium state of the equiatomic alloy of tin and nickel. The metastable phase is what is normally electrodeposited, and if conditions are such that transformation could occur during service life it is important to be able to predict it. However the morphology of this phase and the reason for its stability are still unknown. In this paper a study of the transformation kinetics was performed to derive a prediction equation. This study also provided information on the mechanism of the transformation which is reported in a companion paper (9).

Using the technique of differential thermal analysis (DTA), the metastable phase was shown to decompose exothermically at around 365°C, when heated at 5°C/min, into the equilibrium intermetallic compounds Ni_3Sn_2 and Ni_3Sn_4 (5). In the same article a brief review of previous work on "SnNi" thermal stability was presented. Some workers observed the decomposition from isothermal annealing at temperatures as low as 250°C (10) while others report stability at temperatures as high as 500°C (11). While Bennett and Tompkins (5) utilized a different method (DTA) from that of previous investigators in their thermal stability study, it was apparent that a more detailed study of the transformation kinetics was needed. By using either a differential scanning calorimeter (Perkin-Elmer Model DSC-1B) or a differential thermal analysis apparatus (CSI, R. L. Stone Company), we determined the parameters for the Avrami equation (12) describing the transformation as well as the range of activation energies observed for different deposits.

Theory and Experiments

DTA is a dynamic technique where the time variable and the temperature variable are intermixed, so that no true isothermal experiment can be performed with DTA equipment. While DTA measures a temperature difference between the investigated sample and a reference material, DSC works on a different principle whereby the apparatus provides heat to either the sample or the reference container in order to keep their temperatures equal. The instantaneous power delivered to sample and reference is available as an analog signal. In a single step reaction the fraction of material transformed *vs.* time is proportional to the quantity of heat evolved or absorbed. Isothermal experiments can be conducted with a differential scanning calorimeter.

Most reactions in solid metallic phases are empirically described by the Avrami equation where x is the fraction of material transformed at the time t

$$x = 1 - \exp[-(kt)^n] \quad [1]$$

n is a dimensionless exponent, k has the dimensions of reaction rate and is generally given by an Arrhenius type of relation

$$k = \nu \exp - \frac{\Delta E}{RT} \qquad [2]$$

where ν = frequency factor, ΔE = activation energy, R = gas constant, and T = Kelvin temperature.

The rate of transformation at any instant is given by differentiating Eq. [1] with respect to time at constant temperature

$$\frac{dx}{dt} = nk^n t^{n-1} (1 - x) \qquad [3]$$

For a given temperature, k is constant and Eq. [3] yields a characteristic rate curve. As mentioned above, isothermal experiments cannot be performed with DTA equipment, but such rate curves can be obtained from isothermal DSC experiments.

Although the DSC equipment measures dx/dt directly, the data can be more conveniently analyzed by the integral of Eq. [3], *i.e.*, Eq. [1] which can be rewritten as

$$\ln \frac{1}{1 - x} = (kt)^n \qquad [4]$$

This expression is used to determine n and k at a given temperature by least squares fitting the natural logarithm of expression [4] to ln t. By repeating the same procedure at different temperatures one can generate k as a function of T. The activation energy and the frequency factor are then determined by the standard method of plotting ln k *vs.* the reciprocal of T.

The advantage of DSC is obvious as one considers Eq. [4]; although all the terms necessary to solve for k in [4] are available in a DTA run there are no unambiguous ways to choose the exponent n since DTA cannot be done isothermally.

In this study DSC measurements were taken on two different deposits in order to determine precisely the parameters, n, ΔE, and ν for these two particular cases. Since no variation of n was found in the DSC experiments, previous DTA results on various other deposits were then used to estimate the range of variation of the parameters ΔE and ν.

The materials used for the DSC runs were a thick electrodeposit (40-100 μm) plated under conditions similar to the ones described in Ref. (5) and a sputtered film (15-20 μm) prepared as in Ref. (8). Both films were deposited on a stainless steel foil and were freed from their substrate prior to the thermal experiments by bending the foil. Both types of samples were first run in the scanning mode (20°C/min) in order to determine the temperature range where transformation could be detected. Several fixed temperatures were selected in these ranges to perform isothermal experiments. During the runs the temperature of the calorimeter was first increased linearly at 40°C/min to the vicinity of the selected temperature. This final temperature was then adjusted manually and the rate curve was traced on a time chart recorder until the vertical deflection remained stable, thus indicating the end of the reaction. A typical rate curve is shown in Fig. 1a. For each temperature, the area under the curve was measured until a given time t by using a planimeter. The amount transformed x, ratio of this area to the total area under the curve was then used in a least squares fitting procedure for Eq. [4]. The "ln-ln plot" of Eq. [4] is shown in Fig. 1b for the rate curve of Fig. 1a.

The procedure for the DTA experiments has been presented previously (5). Numerous DTA experiments were run on "SnNi" produced during different electroplating operations. A typical DTA trace is shown in Fig. 2.

Results

The values of the exponent n and the rate constant k at various temperatures are shown in Tables I and II for the electroplated and the sputtered samples, respectively. The plot of ln k *vs.* T^{-1} is linear in both cases (Fig. 3a and b). From a least squares fit of these data the activation energies and the frequency factors shown in Table III were derived. The parameters are given with their 95% confidence intervals. The value of n is rather constant over the range of temperature investigated which justifies the use of an Avrami type of equation and indicates that probably only one mechanism is operative during the transformation. Although the 95% confidence intervals for the activation energies overlap slightly, the difference in the mean values for ΔE between electroplated and sputtered samples is probably genuine (both ΔE and ν are distinct within the "one sigma" limit); it is only the limited number of isothermal experiments available which leads to such relatively large confidence intervals at the 95% level.

In order to obtain information on the variability of the activation energy for different plating operations we next used the DTA data of Table IV. The platings are identified by their date. The average temperatures T_M at which the peak of the DTA trace occurs, and their confidence intervals are given for the constant

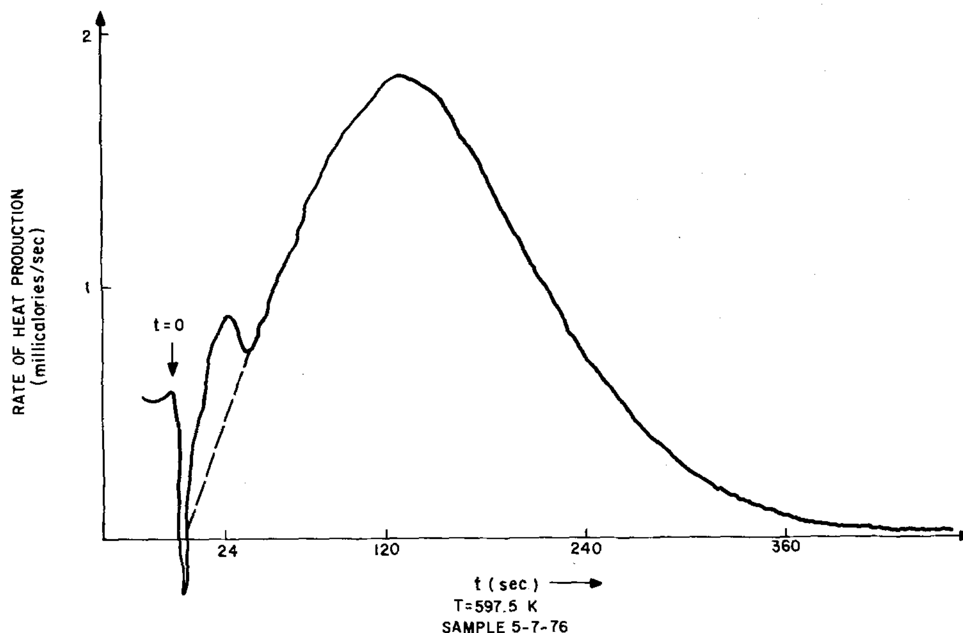

Fig. 1a. DSC rate curve obtained with plated "SnNi" (5-7-76) at 597.5°K. The time is measured from the instant the temperature 597.5°K is reached. The transient behavior seen at the beginning of the curve is due to the calorimeter and is disregarded.

heating rate of 5°C/min. Using a graphical method the activation energies for the different platings were calculated assuming n equal to 2.1 and a constant ν equal to $2 \times 10^{14}\ sec^{-1}$. The results are shown in Table V. The margin of error given in Table V is not a true confidence interval but merely represents the shift in intersection in the graphical solution by using the confidence interval for the various T_M values.

The graphical method employed led us to modify the Kissinger method commonly used for kinetic analysis of DTA data for homogeneous systems (13). This

reported in detail elsewhere (14), is applicable to heterogeneous systems which follow a general Avrami law for any value of n, and enabled us to independently calculate ΔE and ν solely from DTA data. The values obtained ($n = 2.2$, $\Delta E = 56$ kcal/mol, $\nu = 2.3 \times 10^{17}$ sec^{-1}) are in reasonable agreement with our DSC results.

Discussion

The decomposition kinetics of various deposits of "SnNi" can all be described by an Avrami equation (Eq. [1]) with a constant exponent n equal to 2.1. The rate constant follows an Arrhenius equation (Eq. [2]) with a frequency factor of the order of 10^{14} sec^{-1} and an activation energy varying between 42 kcal/mole – 60 kcal/mole (1.83-2.61 eV).

From the values of these parameters and by using Eq. [1] and [2] we can calculate the fraction of transformed material as a function of time at isothermal conditions. Taking the central values in Table III found for the plating (5-7-76), we plotted in Fig. 4 the fraction x of transformed material for various temperatures. It is observed that transformation occurs very rapidly close to 320°C (almost complete transformation in a few minutes). The time to transformation increases rapidly with lowering of the temperature, for example, no detectable amount of material is transformed in one day at 200°C, and about 120 days are required for complete transformation at this temperature. The activation energy of this particular electroplate is the lowest that we have observed, and it is then the least stable of our samples. In Fig. 5 the time necessary to reach 10% (t_{10}) and 90% (t_{90}) decomposition as a function of temperature is shown. We have included in this figure the maximal variation of parameters encountered in this study (cf. Table III $\Delta E/R$ min. $= 2.1 \times 10^4$K^{-1}, $\Delta E/R$ max $= 3 \times 10^4$K^{-1}, ν min. $= 1.2 \times 10^{13}$ sec^{-1}, ν max $= 8.2 \times 10^{15}$ sec^{-1}). Here again one can note that no amount of transformation is expected in 40 yr at temperatures below 125°C.

However, there are wide variations from sample to sample in the time necessary to achieve a certain percentage of transformation; for instance, at 320°C 10% decomposition can be reached in a minimum of 1 min for samples having the lowest ΔE, or a maximum of 4 days for samples having the highest ΔE (sputtered). Regardless of the values of ΔE and ν, t_{90} is roughly four times longer than t_{10}. Ten percent transformation is roughly the minimum amount which can be detected by x-ray means. The variation in activation energy and the consequent variation in t_{10} that we show in this paper are more or less consistent with the reported variations of thermal stability (5) if one excludes the 500°C value of Smart and Robins (11).

Summary

The transformation kinetics of several samples of electroplated or sputtered equiatomic tin-nickel alloy have been investigated. The transformation follows an Avrami law with an exponent n equal to 2.1, an activation energy ranging from 42 to 60 kcal/mol, and a frequency factor ranging from 1.2×10^{13} sec^{-1} to 3.3×10^{16} sec^{-1}. These numbers predict a very steep influence of the temperature on the transformation rate.

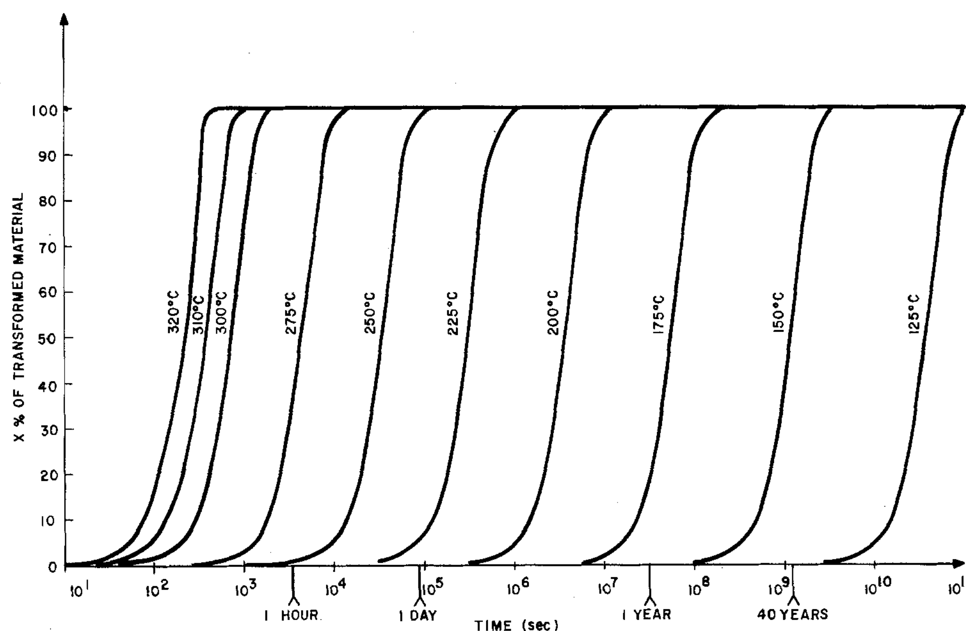

Fig. 4. Sigmoidal curves for the decomposition of sample 5-7-76. The percentage of transformed material is plotted against time for various temperatures (in °C). The plot was generated using the central values determined for 5-7-76.

$$x = 1 - \exp\left[-(kt)^{2.1}\right]$$
$$k = 3.25 \times 10^{14} \exp - \left[\frac{2.30 \times 10^4}{T}\right] \text{sec}^{-1}$$

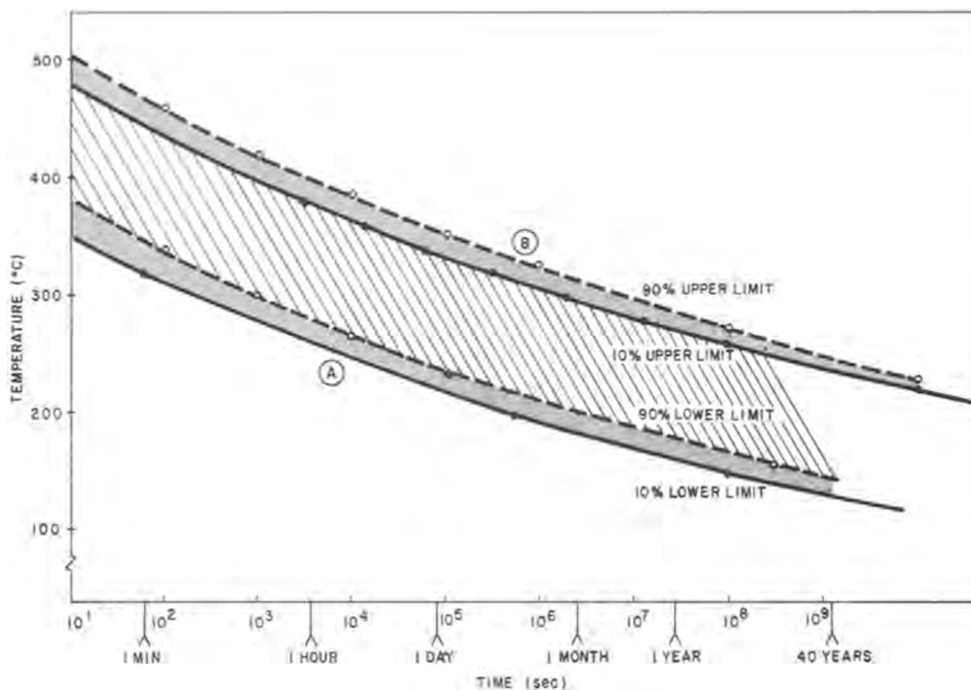

Fig. 5. Time-temperature-transformation curves for the "Sn-Ni" transformation. Curve A corresponds to the lower limits of the scatter of the parameters ΔE and ν, Curve B corresponds to the upper limits of the same parameters. For both A and B the lower curves correspond to 10% transformation (t_{10}) the upper curves to 90% transformation (t_{90}).

While 40 yr at 125°C will be insufficient to lead to transformation, 1 min at 475°C completely transforms all samples. The value of n makes the influence of the observed variations of ΔE and μ large enough to explain most of the varied stability results previously acknowledged.

Kinetics of the Transformation of Metastable Tin-Nickel Deposits

II. Formation and Transformation Mechanisms

J. A. Augis and J. E. Bennett

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

The nature of as plated metastable tin-nickel phase is reexamined. From x-ray, scanning electron microscope studies, and measurement of the enthalpy of transformation of the metastable alloy, it is concluded that the deposited alloy is a metastable extension of the composition range of the equilibrium phase Ni_3Sn_2 and not a distinct low temperature phase. It forms as a result of more favorable nucleation kinetics at the low deposition temperature. Its metastability is due to its morphology, and its decomposition upon heating is interpreted as precipitation and growth of the second equilibrium phase Ni_3Sn_4 from the supersaturated metastable configuration.

In a previous paper (1) the authors found that the solid-state transformation of a metastable equiatomic [approximately 65 weight percent (w/o) Sn-35 w/o Ni] tin-nickel alloy into the equilibrium compounds Ni_3Sn_2 and Ni_3Sn_4 (2) proceeds according to a classical Avrami equation

$$x = 1 - \exp[-(kt)^n] \quad [1]$$

where x is the fraction of material transformed at the time t, and n is a dimensionless exponent. k has the dimensions of reaction rate and is generally given by an Arrhenius expression

$$k = \nu \exp\left[-\frac{\Delta E}{RT}\right] \quad [2]$$

where ν = frequency factor, ΔE = activation energy, R = gas constant, and T = temperature.

Analysis of DSC data, and analysis of DTA data using our modification (3) of Kissinger's method (4), enabled determination of the following values for the Avrami and Arrhenius parameters

$n = 2.1$

$\Delta E = 42\text{-}60$ kcal/mol

$\nu = 1.2 \times 10^{13}\text{-}3.3 \times 10^{16}$ sec^{-1}

While our data allows a prediction for the conditions of the decomposition of "SnNi," the morphology of this nonequilibrium phase and its transformation mechanism are still uncertain. Rooksby (5) considered "SnNi" to be the result of an extension of the composition range of the equilibrium phase Ni_3Sn_2. Such extensions are quite often found during the rapid deposition of alloys by various techniques such as plating (6), sputtering (7), and splat-cooling (8). On the other hand, Dutta and Clarke (9) on the basis of solution calorimetry data argue that the electrodeposit is a new phase which is thermodynamically stable at the temperature of electrodeposition (72°C). To resolve this uncertainty we do reexamine the x-ray data, use SEM examination, and measure the enthalpy of formation of "SnNi."

Experimental Results

X-ray.—The methods and results are similar to those already presented in Ref. (10) and (11). The crystal structures of "SnNi" and Ni_3Sn_2 are very similar and all x-ray diffraction lines of the deposited alloy are nearly coincident with the more intense lines of Ni_3Sn_2. The structure of Ni_3Sn_4 is markedly different (12). In Fig. 1 we show a portion of the x-ray spectra for a powdered sample of electroplated "SnNi" before and after heat-treatment (500°C, 1 hr). We also show

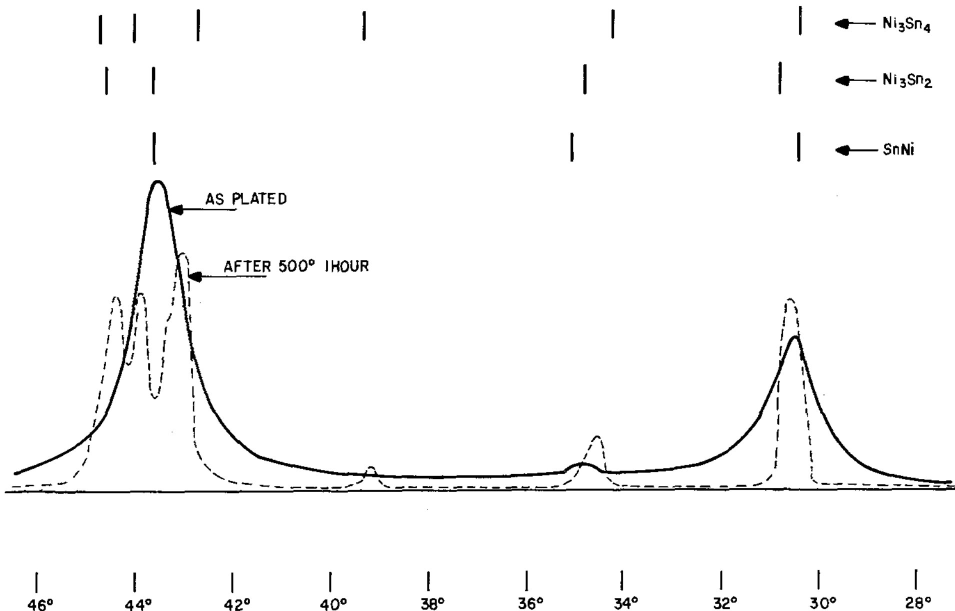

Fig. 1. Part of x-ray diffraction pattern for as-plated and heat-treated "SnNi" powders. Filtered copper radiation 50 kV, 30 mA. Also shown are the positions of the major peaks for "SnNi," Ni_3Sn_2. Ni_3Sn_4.

the characteristic positions of the main diffraction lines (relative intensity greater than 40) for "SnNi," Ni_3Sn_2, and Ni_3Sn_4. Besides the observation that upon heat-treatment the lines of Ni_3Sn_4 become apparent in addition to the lines of Ni_3Sn_2, one can observe the obvious sharpening of the lines. On the as-deposited samples the corrected full width at half-maximum is as large as 1.4×10^{-2} radian. X-ray line broadening is known to be due to small grain size, internal microstresses, and/or lattice defects. While it is not possible in the present case to separate the three factors, the line breadth is nonetheless an indication of small grain size; by assigning all the broadening to this effect and using the Scherrer formula, we predict the main dimension of the crystallites to be around 15 nm.

SEM examination.—To confirm the conclusion of the x-ray work, a metallographic study was attempted. Electrodeposited "SnNi" is known to be passive in respect to attack by most chemicals, and we were unable to reveal any structure by conventional metallographic methods. Better results were obtained by ion etching followed by scanning electron microscopy. Figure 2a shows the etched surface of a "SnNi" sample prior to heat-treatment. Although a nodular structure is present we were unable to detect any grain structure at any magnification, which suggests grain sizes of the order of tens of nanometers.

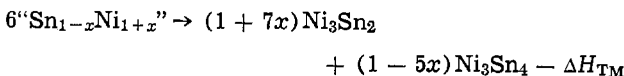
After heat-treatment (500°C, 24 hr) the transformed alloys show grain sizes of the order of 1 μm (Fig. 2b) within the wall of the nodular structure.

Free energy of formation of "SnNi".—The heats of transformation $-\Delta H_{TM}$ were measured using the differential scanning calorimeter on several samples of different deposits. The results and their scatter are shown in Table I along with the results of compositional analyses obtained using wavelength dispersive x-ray analysis and pure metal standards on a scanning electron microscope.

Regardless of the morphology of "SiNi," the transformation can be written

$$6\text{"SnNi"} \rightarrow Ni_3Sn_2 + Ni_3Sn_4 - \Delta H_{TM}$$

or, more exactly, since we have departure from stoichiometry



$$6\text{"}Sn_{1-x}Ni_{1+x}\text{"} \rightarrow (1 + 7x)Ni_3Sn_2 + (1 - 5x)Ni_3Sn_4 - \Delta H_{TM}$$

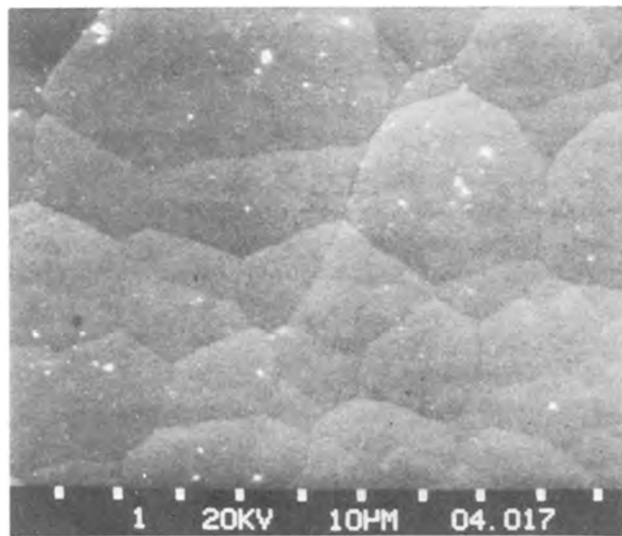


Fig. 2a. Scanning electron micrograph of the surface of an unannealed sample of plated SnNi (5-7-76) after 15 min of argon ion etching. There is no evidence of grain structure; the boundaries shown are those of plating nodules. The interval between the scan marks is 10 μm. 1150×.

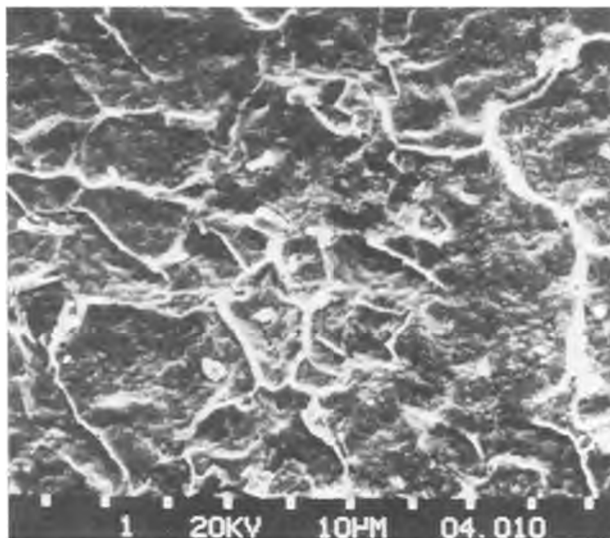

Fig. 2b. The same as Fig. 2a for the same sample after heat-treatment at 500°C for 24 hr. The grain structure is now evident (grain size of the order of 1 μm). 1150×.

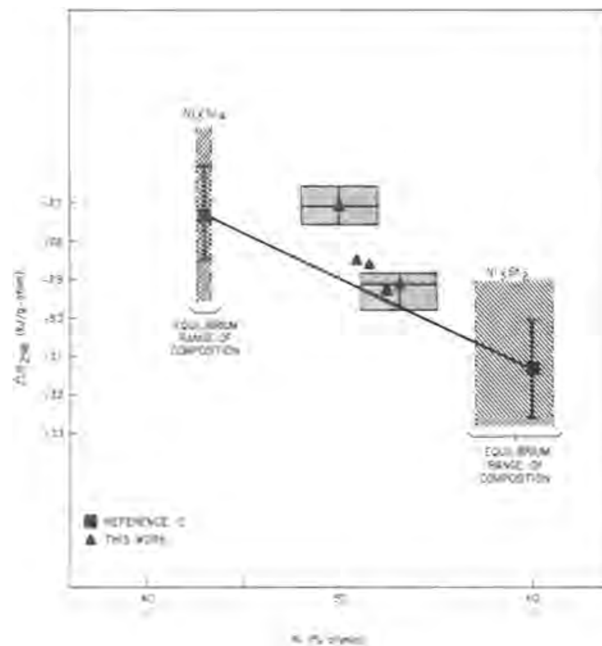

Fig. 3. Calculated standard enthalpies of formation of the "SnNi" alloys as a function of the nickel concentration. The values (△) are derived from the measured heat of reaction. The values for Ni_3Sn_2 and Ni_3Sn_4 are taken from Korber and Oelsen (14).

Using a similar analysis to the one of Dutta and Clarke (9) we can estimate the heat of formation of "$Sn_{1-x}Ni_{1+x}$" as a function of the Ni content.

To convert our experimental $-\Delta H_{TM}$ to the standard convention $-\Delta H_{298}$, we assumed the Kopp-Neuman rule of mixtures (13) concerning the specific heat. The results for our deposits are plotted in Fig. 3

Table I. Measured heats of transformation and composition analysis for several samples

Deposit identification	T_M (°K)	$-\Delta H_{T_M}$ (kJ/g-atom)	Composition (a/o) Ni	Composition (a/o) Sn
2-3-75	636	0.315 ± 0.300	52.5 ± 2	47.5 ± 2
7-2-75	640	0.817 ± 0.290	53.0	47.0
4-28-76	619	1.100 ± 0.160	51.4	48.6
5-7-76	598	1.26 ± 0.160	51.0	49.0
Sputtered	684	3.45 ± 0.465	49.8	50.2

vs. atomic composition, along with the enthalpies of formation of the equilibrium compounds (14). The vertical error bars are due to standard errors both in the calorimetric experiments and the composition analyses. For the composition range of our deposits (which is narrower than that used by Dutta and Clarke) the heat of formation of "SnNi" is not very different from the heat of formation of the corresponding mixture of the equilibrium compounds.

No data are available on the standard entropy of these compounds but if we assume these values to be similar (not too different entropy of mixing, similar vibrational entropy due to similar lattice), the ΔH_{298} values should show the relative positions of the free energy ΔG_{298} values in a free energy diagram. Within the limits of our assumptions, the experimental results do not indicate a substantial lowering of the free energy in the vicinity of the "SnNi" composition. Consequently the existence of "SnNi" as a new equilibrium phase at low temperatures is not indicated. A probable chemical free energy diagram for this system at a given low temperature, near ambient, is sketched in Fig. 4: the wider range of composition of the Ni_3Sn_2 phase (2) is consistent with a shallower free energy curve than that for Ni_3Sn_4.

Discussion

The experimental data have shown that: there is seemingly no minimum in the free energy diagram in the vicinity of the equiatomic composition, the crystal structure of "SnNi" is close to that of Ni_3Sn_2, and the microstructure of the deposit is characterized by very small grains. We will show how these facts are sufficient to consider "SnNi" as an extension of the composition range of Ni_3Sn_2 (5) and not a new low temperature equilibrium phase (9). The chemical free energy of a Ni_3Sn_2-like phase having an equiatomic composition would be represented by the point A, (ΔG_A), in Fig. 4. The equilibrium state for the equiatomic composition would be point B, (ΔG_B), corresponding to a mixture of the two equilibrium compounds (Ni_3Sn_2, Ni_3Sn_4). This diagram shows that, thermodynamically, state B should be more stable than state A, and this is known to be true from metallurgical preparation of the equiatomic composition alloy. However, the diagram in Fig. 4 representing equilibrium conditions cannot be used to ascertain the formation of phases obtained by electrodeposition and sputter-deposition at low temperatures.

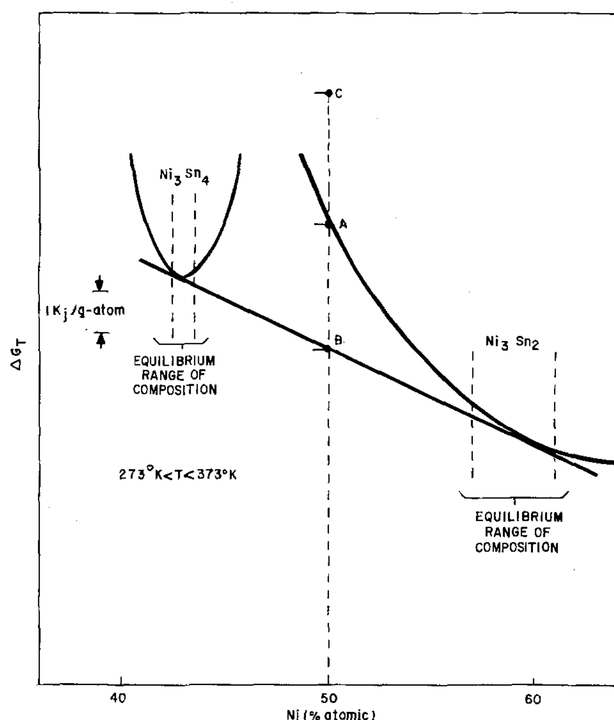

Fig. 4. Probable low temperature chemical free energy diagram for the "Sn-Ni" system between the compositions Ni_3Sn_4 and Ni_3Sn_2. B corresponds to the equilibrium mixture, A to the metastable state, C to the equilibrium state taking into account the grain boundaries energy.

The conditions during deposition are such that nucleating a mixture of the two phases would raise the free energy of the system to $\Delta G_C > \Delta G_A$. Consequently the system chose the metastable state A, with a barrier $\Delta G_C - \Delta G_A$ which can be overcome by heat-treatment to return to the equilibrium state B. The term which raises the free energy from ΔG_B to ΔG_C comes from the elastic energy stored at the grain boundaries.

To form the equilibrium configuration, *i.e.*, Ni_3Sn_2 and Ni_3Sn_4, corresponding to point B in Fig. 2, by electrodeposition would require simultaneous nucleation of these two compounds which have different crystal structures. In an ideal (most favorable) nucleation situation, both phases would differ in composition but have the same lattice structure and parameters. The boundary between two such phases would be coherent, *i.e.*, the structures would meet at an interface whose lattice points are common to both. The interface energy factor in this ideal two-phase situation would tend toward a minimum. Any factor which limits or decreases the degree of coherency, such as crystal structure or lattice parameter differences, leads to appreciably higher values of the interface energy term. Thus, any structural assembly with lower coherency of the boundaries is more difficult to nucleate.

Typical interface energies for incoherent boundaries fall in the range of 0.5-1 J/m^2 while for coherent boundaries the values are between 0.02 and 0.2 J/m^2 (14). For an average grain size of 15 nm the total boundary internal energy can be as large as 4 kJ/g-atom for the incoherent case and as low as 0.08 kJ/g-atom for the coherent one. This additional term makes the total free energy of the equilibrium mixture with small grains higher than that of the metastable phase.

The authors postulate that during electrodeposition (or sputtering) of the equiatomic alloy, nucleation of a metastable supersaturated form of Ni_3Sn_2 is then favored; it is, in essence, an intermediate stage between the aqueous plating bath or sputtering vapor phase and the equilibrium two-phase structure. From classical nucleation theory (15) the free energy of formation of a nucleus in the heterogeneous case is still of the form $W \propto \gamma^3$, where γ is the interfacial energy per unit area. The lower coherency raises the free energy of formation of stable nuclei ($W_B > W_A$), and this barrier to nucleation of the equilibrium configuration is accentuated by the low temperature deposition techniques since nucleation rate is proportional to exp $(-W/kT)$. The metastable phase, although it is less stable ($\Delta G_A > \Delta G_B$), forms preferentially since it can be nucleated at a significantly greater rate at the low temperatures of deposition (345°K) than the equilibrium mixture of Ni_3Sn_4 and Ni_3Sn_2; higher plating temperatures result in two-phased equilibrium deposits. The results of Polesya *et al.* (16) on splat-quenching of liquid nickel-tin alloys showed that this technique of low-temperature rapid crystallization substantially increased the composition range (33.1-54.8 a/o Sn) of the Ni_3Sn_2 phase. Furthermore, even with a melt having the stoichiometric Ni_3Sn_4 composition, they still found Ni_3Sn_2 in the quenched product, which they attributed to the high rate of formation of Ni_3Sn_2 nuclei.

Transformation of the Metastable Structure

The model for "SnNi" proposed in the preceding paragraph must be consistent with the kinetics of its transformation presented in the companion paper (1).

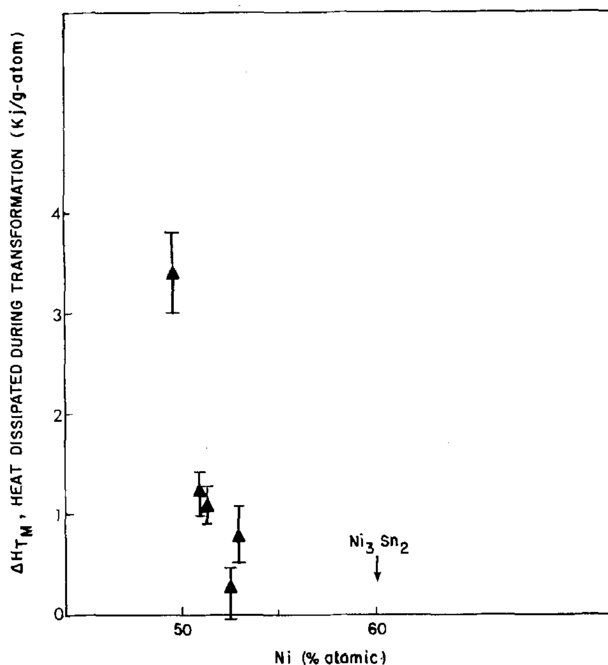

Fig. 5. Heat dissipated during transformation as measured with the DSC. The heat measured close to the temperature of maximum rate of reaction T_M is plotted as a function of the nickel concentration.

Upon heat-treatment of the supersaturated metastable deposit, transformation to the equilibrium configuration becomes feasible and a maximum energy $-\Delta H_{TM}$ is released which is the sum of the difference of enthalpies between state A and state B, and of the contribution due to the boundaries. This model could explain the trend observed in Table I or Fig. 5, where the exothermic heat of transformation increases as the sample composition departs further from the Ni_3Sn_2 stoichiometry. The kinetic data (1) should be consistent with a transformation consisting of a nucleation and diffusion-controlled growth of a second phase (Ni_3Sn_4) from a supersaturated alloy ("extended Ni_3Sn_2").

The Avrami equation for such a precipitation process with a constant nucleation rate has been calculated (17) and can be represented approximately by

$$x = 1 - \exp [-(2.76D^{3/2}It^{5/2})] \qquad [3]$$

where $D = D_o \exp(-\Delta E_D/RT)$ is the diffusion constant with an activation energy equal to ΔE_D and $I = I_o \exp(-\Delta E_N/RT)$ is the nucleation rate with an activation energy equal to ΔE_N.

Equation [3] predicts an Avrami exponent n equal to 2.5; our experimental value of 2.1 is close but indicates a somewhat decreasing nucleation rate (in the absence of nucleation, n should be equal to 1.5) (17). The rate constant of Eq. [2] should be given according to Eq. [3] by

$$k \simeq 1.5D^{0.6}I^{0.4} \qquad [4]$$

which leads to

$$\Delta E = 0.6\Delta E_D + 0.4\Delta E_N \qquad [5a]$$

$$\nu = 1.5D_o^{0.6}I_o^{0.4} \qquad [5b]$$

No values for the diffusion rate of Sn or Ni in "SnNi" or in the equilibrium compounds were found in the literature. An order of magnitude calculation using the diffusion constants of Sn in copper-tin alloys ($\Delta E_D = 50$ kcal/mol [2.17 eV], $D_o = 2400$ cm²/sec) (17), requires the activation energy for nucleation of the second phase to be of the order of 50 kcal/mol to agree with Eq. [5a] and [5b] and our experimental value of the activation energy for the transformation. With this simplified model the rate of nucleation of the second phase would be given using Eq. [5a] and [5b] and $\nu = 10^{14}$ s^{-1} by

$$I \simeq 10^{30} \exp - \frac{2.5 \times 10^4}{T} \qquad [6]$$

Thus, at a typical service temperature (100°C)

$$I = 7.8 \text{ nuclei/cm}^3\text{/s}$$

whereas, at the observed transformation temperature (345°C)

$$I = 2.7 \times 10^{12} \text{ nuclei/cm}^3\text{/s}$$

Our model is evidently not sophisticated enough to hope to be more quantitative in the use of Eq. [6] and to determine the free energy of nucleation or the value of the interfacial energy γ. However, it shows how the nucleation rate increases dramatically between deposition temperature and temperature where the transformation is observable. With the barrier to nucleation overcome, the elevated temperature also favors diffusion to obtain grains of the order of 1 μm as observed in the SEM experiment. Due to the value of the Avrami exponent and the order of magnitudes of the activation energies encountered, the presented model for the morphology of the plated "SnNi" phase is at least not in contradiction with the kinetic data of its transformation.

The morphology of the deposit gives it its metastable character so that the height of the barrier to transformation, ΔE, must be related to this morphology and particularly to the grain size. The elastic energy stored in grain boundaries, which can be released upon heating, is also a function of the grain size. Therefore, a correlation was expected between the heat of transformation, $-\Delta H_{298}$, reported herein and the activation energy, ΔE, reported in a companion paper (1). Our calorimetric procedure was sensitive enough to reveal only a weak correlation.

Summary

The morphology of metastable "SnNi" and the mechanism of its transformation upon heating have been studied. The metastable phase belongs to an extended composition range of the equilibrium Ni_3Sn_2 phase as suggested by Rooksby; it is not a thermodynamically stable low temperature phase as theorized by Clarke and Dutta. The mechanism for the formation of the extended Ni_3Sn_2 morphology was attributed to its more favored nucleation kinetics at the deposition temperature, and the resistance of this deposit to transformation at low temperatures (<100°C) was attributed to the lower energy configuration of the fine grained single phase deposit. The transformation at higher temperature is interpreted as the precipitation and growth of the second phase Ni_3Sn_4 from the supersaturated alloy. The parameters which described the kinetics of this transformation are given.

Acknowledgments

The authors wish to thank B. G. Bagley for the use of the DSC, T. M. Paskowski for diligently taking the DSC data, R. Schroeder and H. G. Tompkins for ion etching of the deposits, and C. C. Lo and M. R. Pinnel for stimulating discussions.

Manuscript submitted June 10, 1977; revised manuscript received Sept. 28, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by Bell Laboratories.

ABSTRACT

The kinetics of the thermal oxidation of (111) and (100) oriented silicon in O_2/H_2O (2-10 v/o H_2O) and O_2/Cl_2 (1-3 v/o Cl_2) mixtures were investigated over the temperature range 900°-1100°C. Effective values of the parabolic and linear rate constants in the general oxidation relationship and therefore over-all oxidation rates were found to increase with increasing concentrations of H_2O. Additions of Cl_2 to O_2 also increased the oxidation rates, but results were more erratic. The experimental oxide thickness-oxidation time data for the O_2/H_2O ambients were compared with those calculated from a relationship involving the simultaneous oxidation of silicon by two independent oxidation species. Since H_2O and Cl_2 are possible reaction products of O_2 and HCl, the results of this investigation were compared with those previously obtained for O_2/HCl silicon oxidations. Reaction mechanisms of the O_2/HCl silicon oxidations, including possible effects due to the presence of H_2O and Cl_2, are discussed.

The addition of a chlorine species to the oxidation ambient used to passivate silicon device structures continues to be an important factor in semiconductor technology (1-3). In a recent paper (4), the thermal oxidation kinetics of (111) and (100) oriented silicon in oxygen containing 0-10 volume percent (v/o) hydrochloric acid were investigated over the temperature range 900°-1100°C. For a given silicon orientation and temperature, the rate of oxidation increased with increasing HCl concentration, and corresponding changes in the effective parabolic and linear rate constants were determined. No detailed mechanisms were devised which would account for the observed rate increases, but it was suggested that water and chlorine, possible reaction products, could well contribute to the change in the oxidation process. These two species may be produced by the reaction of oxygen with hydrochloric acid as follows (5-7)

$$4HCl + O_2 \leftrightarrows 2H_2O + 2Cl_2 \quad [1]$$

The exact equilibrium conditions are not known, especially when possible catalytic effects at the SiO_2 surface are considered.

[1] Present address: Department of Chemical Engineering, University of California, Berkeley, California 94720.
Key words: silicon, kinetics, oxidation, chlorine.

In view of the possible contributions resulting from the presence of either H_2O or Cl_2 to the O_2/HCl oxidation process, a short program was carried out to determine silicon oxidation kinetics in oxygen containing either 2-10% H_2O or 1 and 3% Cl_2. The same temperature range (900°-1100°C) and silicon orientations [(111) and (100)] were employed as in the previous O_2/HCl investigation. It was hoped that the results of these studies would provide a better insight into the mechanisms involved in the thermal oxidation of silicon in O_2/HCl mixtures.

Experimental

The experimental conditions and procedures employed in this program were very similar to those reported previously (4). Silicon wafers were (111) and (100) oriented, 4-6 Ω-cm n-type. The wafers were cleaned following the same procedure described earlier (8). Similarly, the oxidation systems utilized were the same as previously described (8) with the following modifications. For the water additions, initially, oxygen was bubbled through a quartz flask containing deionized water whose temperature was controlled to ±0.1°C. The vapor pressure and thus the percentage of water in the oxygen was controlled by the temperature employed. It was determined, however, that this method was not satisfactory, since

oxidation rates were not reproducible. Also, it appeared that at higher percentages of water (corresponding to $T > 30°C$), the partial pressures of water were much lower than calculated, probably due to condensation in the tubing leading to the furnace. For these reasons, a pyrogenic system involving water generation from O_2 and H_2 was employed for all data reported here. The system was manufactured by Corso-Gray Instruments, Sunnyvale, California, Model D-101. Concentrations of water in oxygen varied from 2 to 10 v/o. Silicon oxides were prepared at 900°, 1000°, and 1100°C.

For the O_2/Cl_2 oxidations, procedures were identical to those reported for the O_2/HCl experiments (4); in addition, chlorine of 99.9% purity was used. Due to severe corrosion of the plumbing and duct work, oxidations were limited to temperatures of 1000° and 1100°C and to concentrations of Cl_2 in O_2 of 1.0 and 3.0 v/o.

In the case of O_2/H_2O oxidations the wafers were pushed rapidly into the furnace after the appropriate O_2/H_2O mixture had been established and was flowing at approximately 2 liters/min (~44 cm/min). The wafers were rapidly pulled from this ambient at the end of the oxidation time. The push-pull conditions for O_2/Cl_2 oxidations were the same as for the O_2/HCl work (4). That is, the wafers were rapidly pushed into the furnace in oxygen, the appropriate Cl_2 flow was started, and when the oxidation was completed, the O_2/Cl_2 flow was stopped, the wafers were purged in nitrogen for 15 min, and the wafers were pulled out of the furnace at ~15 cm/min.

Oxidation times for the O_2/H_2O mixtures at 900°C ranged from 1 to 48 hr; at 1000° and 1100°C times were 0.25-16 hr. For the O_2/Cl_2 mixtures the times were 0.25-7 hr. Oxide thicknesses were measured using a Rudolph Model 436-200E ellipsometer with a helium-neon laser source. Measurement reproducibility was ±3%. Mobile ion concentrations in all oxides, including those produced by the H_2-O_2 system were typically less than 2×10^{10} cm^{-2} as determined by C-V analysis.

Data Evaluation

Following the same procedure as for the O_2/HCl data reported previously (4), the oxidation rate data for the O_2/H_2O and O_2/Cl_2 oxidations were evaluated using the general relationship (9)

$$x_o^2 + Ax_o = B(t + \tau) \qquad [2]$$

where x_o = oxide thickness in micrometers, A = constant in micrometers, B = parabolic rate constant in square micrometers per hour, B/A = linear rate constant in micrometers per hour, t = oxidation time in hours, and τ = correction factor, which accounts for an observed initial accelerated growth rate in dry oxygen, in hours. Equation [2] may also be written in the form

$$\frac{x_o^2 - x_i^2}{B} + \frac{x_o - x_i}{B/A} = t \qquad [2a]$$

where $x_i = x_o$ at $t = 0$, and the other terms are the same as defined in Eq. [2]. The effective rate constants B and B/A were determined from x_o vs. $(t + \tau)/x_o$ plots as described earlier (9).

Since these oxidations were due to more than one reacting gas species (O_2 and H_2O or O_2 and Cl_2) the above relationship is not truly valid. Therefore a combination general relationship was derived based on one reported earlier by Hirabayashi and Iwamura (5). It is as follows

$$t = \frac{1}{E}\left\{ (x_o^2 - x_i^2) + C(x_o - x_i) - D \ln\left[\frac{2Ex_o + F}{2Ex_i + F}\right]\right\} \qquad [3]$$

where $C = (A_1B_1 + A_2B_2)/(B_1 + B_2)$, $D = [B_1B_2(A_1 - A_2)^2]/[2(B_1 + B_2)^2]$, $E = B_1 + B_2$, $F = A_1B_2 + A_2B_1$, and A_1 and B_1 are the constants in Eq. [2] for one oxidation species and A_2 and B_2 the constants for the second species. B_1 and B_2 are proportional to the partial pressure of components 1 and 2 in the oxidation ambient.

In deriving the type of combination oxidation relationship as given by Eq. [3], Hirabayashi and Iwamura assumed that the fluxes of the two reacting species (representing diffusion through the oxide as well as a reaction at the Si-SiO_2 interface) are parallel but independent. This assumption of complete independence may or may not be valid, as will be discussed later. The over-all oxide growth rate is therefore a function of the sum of these fluxes.

An important difference between the relationship derived by Hirabayashi and Iwamura and Eq. [3] above is the inclusion of x_i in Eq. [3]. As indicated, $x_i = x_o$ at $t = 0$, but alternately can take into account the rapid initial oxidation rate observed for dry oxygen oxidation of silicon (9). If this constant ($x_i \sim 200$Å for dry O_2) is not included, then it is almost impossible to analyze the data properly. Not known, however, is how x_i changes as H_2O is added to O_2. In this work a constant value of $x_i = 180 \pm 20$Å was assumed for all mixtures, with values of τ determined from extrapolated linear plots of x_o vs. t.

If the values of A and B in Eq. [3] are known from single-component, oxidation studies, then t can be calculated as a function of x_o and compared with experimental results. As indicated earlier (4), the parabolic rate constants in either Eq. [2] or [2a] and thus Eq. [3] should be independent of silicon orientation, while the linear rate constants B/A should vary with orientation.

Previous work (9) has indicated that the constant in Eq. [2] that is most difficult to determine is τ, and care must be taken to assure that $\tau << t$ for the data used to determine the constants A and B. More recently, Irene and van der Meulen (10) have investigated in detail the application of Eq. [2] to silicon oxidation at lower temperatures.

In order to determine activation energies using an Arrhenius-type expression, the effective rate constants from Eq. [2] had to be used, since Eq. [3] is too complex for this analysis.

Hirabayashi and Iwamura (5) pointed out that if the conditions are such that $A_1 \approx A_2$, then Eq. [3] may be approximated by

$$B^*t = (x_o^2 - x_i^2) + A(x_o - x_i) \qquad [4]$$

where $B^* = B_1 + B_2$. This is the same form as Eq. [2] and experimentally determined effective values of B and A may be compared with those calculated from earlier experimental results of one-component oxidations, assuming B_1 and B_2 are proportional to partial pressures of the two components in the mixture. For O_2/H_2O oxidation of silicon, $A_{O_2} \approx A_{H_2O}$ at 1100°C. Thus, experimental results may be evaluated at this temperature using Eq. [4].

Finally, if the reaction of O_2 and HCl presented in Eq. [1] is valid and is assumed to go primarily to completion (to the right), then 2 moles of HCl will produce 1 mole each of H_2O and Cl_2. The O_2/HCl data can therefore be compared with the results obtained from the equivalent O_2/H_2O or O_2/Cl_2 oxidations.

Results and Discussion

Oxidation rate data.—O_2/H_2O and O_2/Cl_2 mixtures.— As indicated above, oxidation rate data were obtained for O_2/H_2O and O_2/Cl_2 mixtures as a function of silicon orientation, oxidation temperature and H_2O and Cl_2 concentration. Typical results are indicated in Fig. 1 and 2 where plots of log x_o vs. log t at 1000°C for various ambient concentrations and the two silicon orientations are presented. It can be noted that the oxidation rates for all cases increase with increasing

Fig. 2 in Ref. (4) which also are for 1000°C. Similar trends were found for the O_2/H_2O and O_2/Cl_2 oxidations at the other temperatures investigated.

Values of the constants A, B, and B/A were determined as indicated in the previous section. These data for O_2/Cl_2 oxidations at 1000° and 1100°C are tabulated in Tables I and II. Also included for comparison in the tables are the data for 100% dry O_2 and 1% HCl in O_2 oxidations, as well as the values of τ used in these determinations. The significance of τ will be discussed later. The variations of the effective parabolic rate constant B and the effective linear rate constant B/A for O_2/H_2O mixtures with H_2O concentration are indicated by the plots in Fig. 3 and 4. Here, it can be observed that gradual increases of both B and B/A values occur with increasing H_2O concentrations. The trends are somewhat different than those reported for O_2/HCl oxidations (4), where, in the latter case considerable less dependence of B and especially B/A on HCl concentration was found. These differences will be discussed later.

Arrhenius-type plots of log B and log B/A *vs.* $1/T$ were prepared and activation energies determined. For the linear rate constants all activation energies, for both (111) and (100) silicon orientation, ranged from 1.95 to 2.05 eV. This value of approximately 2 eV has been found (9) for both dry oxygen and wet oxygen (95°C H_2O) and is believed to be associated with the Si-Si bond energy: It is therefore expected that all mixtures of O_2 and H_2O would have the same activation energy associated with the linear rate constant.

The parabolic rate constant activation energy for 10% H_2O in O_2 was found to be 0.9 eV, compared to 1.2 eV for dry O_2 and 0.7 eV for wet O_2 (95°C H_2O). Values of 0.93 eV and 1.07 eV were calculated for 5% and 2% H_2O in O_2, respectively. It is apparent that relatively small amounts of water have considerable effect on the activated process associated with the diffusion of the oxidizing species through the oxide; similar effects have been reported by Irene (11). It should be pointed out that, unlike the data for O_2/HCl oxidation (4), all Arrhenius plots for the O_2/H_2O oxidations were straight lines over the temperature range 900°-1100°C.

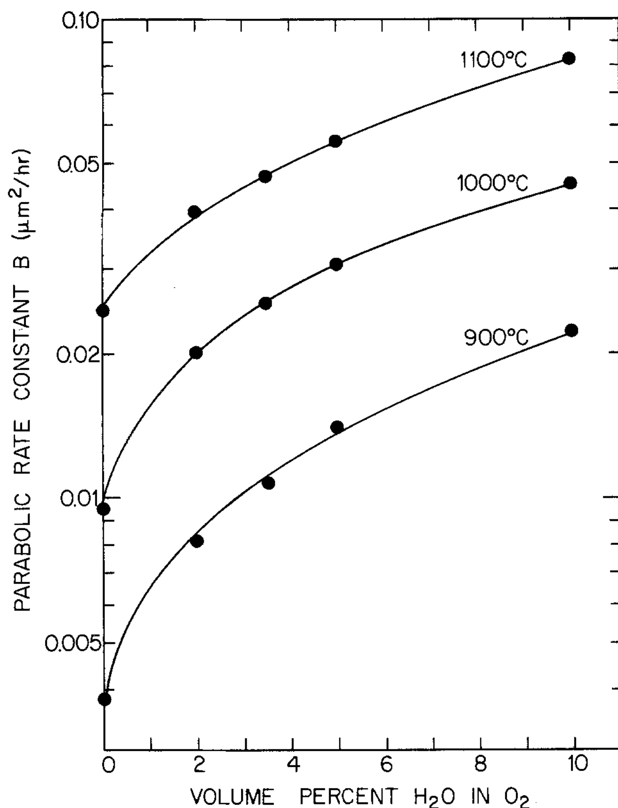

Fig. 3. Parabolic rate constant *vs.* volume percent H_2O in O_2 for oxidation of n-type silicon at 900°, 1000°, and 1100°C. Data are for (111) silicon orientation; values of B for (100) silicon are essentially equal to those of (111) silicon.

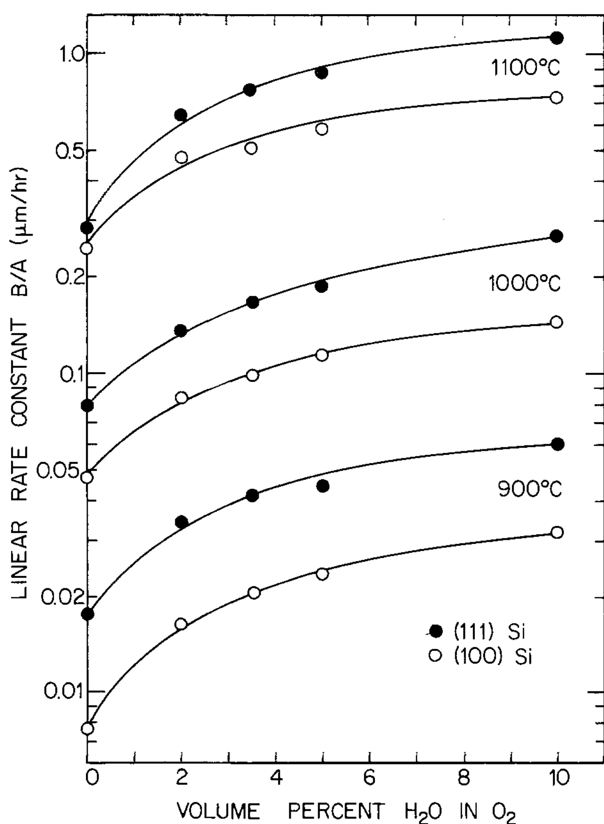

Fig. 4. Linear rate constant *vs.* volume percent H_2O in O_2 for oxidation of (111) and (100) oriented n-type silicon at 900°, 1000°, and 1100°C.

In the previous section a complex relationship (Eq. [3]) for silicon oxidation involving simultaneous oxidation by two reactants was presented. It was noted, however, at 1100°C, the values of A_{H_2O} and A_{O_2} are approximately equal, and thus Eq. [3] takes the form of Eq. [4] with $B^* = B_1 + B_2$. Since B_1 and B_2 in the case of O_2/H_2O mixtures are equal to the B values at atmospheric pressure multiplied by their partial pressures in the mixture, the experimental results of t *vs.* x_o at 1100°C can readily be compared to calculated values. This comparison is shown in Table III, where the times (t) required to obtain particular oxide thicknesses are listed, along with the corresponding times calculated from Eq. [4] for those same oxide thicknesses. Also included in Table III are the times calculated from Eq. [3], and the ratios of the two calculated values of t. Data are included for 900° and 1000°C, in addition to 1100°C. It can be observed that t from the full calculation, Eq. [3], is identical to the t from Eq. [4] at 1100°C, but the agreement becomes worse as the oxidation temperature decreases. Also, in all cases, the experimental time required to obtain a particular oxide thickness is less than that calculated by either equation. This latter finding would imply that some interaction between O_2 and H_2O is occurring which is increasing the oxidation rate compared to that predicted by Eq. [3].

Table III. Comparison of experimental oxidation times (t) and those calculated from Eq. [3] and [4]
[n-type, 4-6 Ω-cm, (111) Si]

Oxidation temperature (°C)	A_{O_2}/A_{H_2O}	x_o (μm)	t_{exp} (hr)	$t_{Eq. [3]}$ (hr)	$t_{Eq. [4]}$ (hr)	$t_{[4]}/t_{[3]}$
900	0.44	0.245	10.0	10.83	11.33	1.046
1000	0.65	0.278	4.0	4.34	4.36	1.005
1100	0.90	0.446	4.0	4.56	4.56	1.000

To determine which rate constant might reflect the above-mentioned acceleration of the oxidation reaction in O_2/H_2O mixtures, experimentally determined values of B and B/A (at 1100°C) are plotted against H_2O concentration in Fig. 5 and 6. Also plotted in

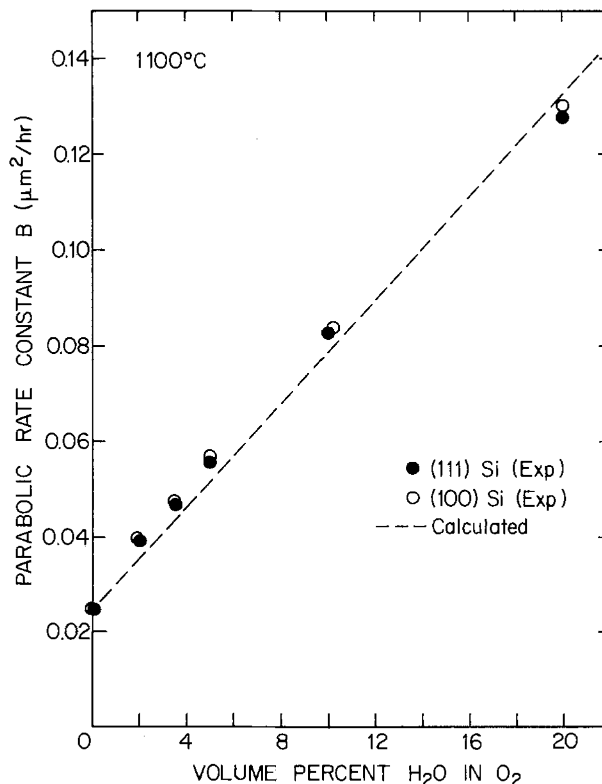

Fig. 5. Comparison of experimental and calculated values of the parabolic rate constant *vs.* volume percent H_2O in O_2 for the oxidation of (111) and (100) oriented n-type silicon at 1100°C. Dashed line represents data calculated using Eq. [4].

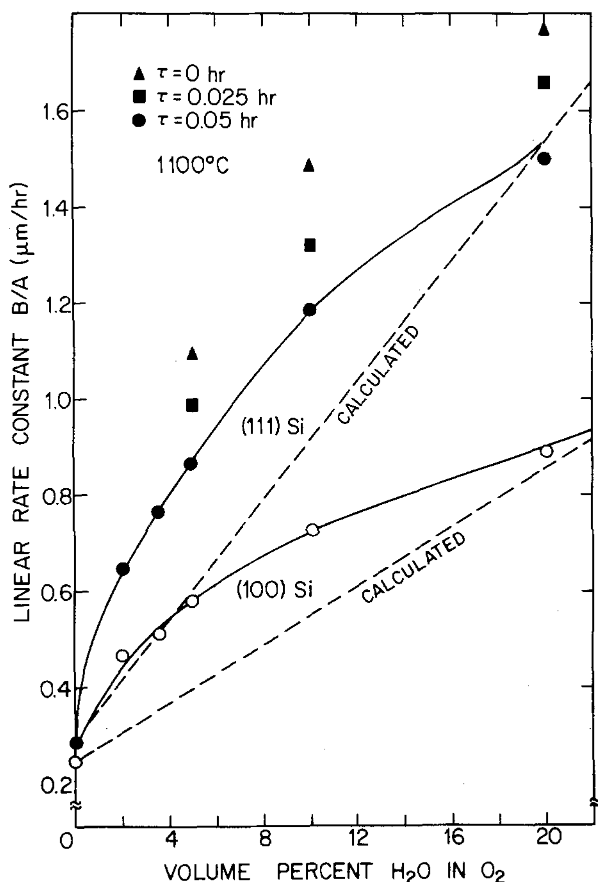

Fig. 6. Comparison of experimental and calculated values of the linear rate constant vs. volume percent H_2O in O_2 for the oxidation of (111) and (100) oriented n-type silicon at 1100°C. Dashed line represents data calculated using Eq. [4]. Also included for selected H_2O concentrations are data for various values of τ in general relationship.

Fig. 5 and 6 are values of B^* and B^*/A, which are obtained from the relationship $B^* = \gamma B_{H_2O} + (1 - \gamma)B_{O_2}$, where γ = mole fraction of H_2O, $(1 - \gamma)$ = mole fraction of O_2, and B_{H_2O} and B_{O_2} are the parabolic rate constants at atmospheric pressure. The values of A are those determined at atmospheric pressure and do not change with concentration. As observed in Fig. 5, the values of B^* and B_{exp} agree quite closely up to 20% H_2O (a 20% H_2O/O_2 mixture was included at 1100°C only). However, there is considerable deviation between experimental and calculated B/A values up to about 20% H_2O. At this concentration, the O_2 contribution is negligible compared to that of the H_2O and above 20% H_2O it is anticipated that the two curves will be the same. Similar results are noted for both (111) and (100) silicon orientations.

Some mention should be made of the value of τ used for the data in Fig. 6. In determining the values of the rate constants B and B/A tabulated in Table III using Eq. [2], τ was set equal to 0.05 hr for the H_2O/O_2 data at 1100°C (a value of τ = 0.04 hr was used for 20% H_2O). Normally the exact value of τ used at the higher temperatures is not critical, especially in regards to its effect on B, the parabolic rate constant, and the over-all oxidation kinetics. However, in plotting the linear rate constant data in Fig. 6, it was observed that A and thus B/A is quite dependent on the value of τ used. For this reason, values of B/A are indicated in Fig. 6 with τ = 0, 0.025, and 0.05 hr. Close examination of the x_o vs. $(t + \tau)/x_o$ plots used to determine the rate constants indicated the true value of t lies between 0.025 and 0.05 hr. Thus, if anything, the difference between experimental and calculated values of B/A in the H_2O concentration range 0-20% is even a little greater than originally determined. The net general trend is the same, with the two curves coming together at about 20% H_2O concentration. As mentioned above, B in Fig. 5 is not dependent to any great extent on τ.

The reason for the accelerated oxidation rate resulting from small additions of water to oxygen is not known. Since the effect is mainly through the linear rate constant B/A, it is possible that a catalytic reaction due to the water affects the breaking of Si-Si bonds. Such an effect apparently does not, however, change the activation energy as indicated above. This would suggest that the enhanced oxidation rate, relative to that calculated, is associated with the pre-exponential term in the Arrhenius expression (12).

Comparison of O_2/H_2O and O_2/Cl_2 oxidation data with O_2/HCl results.—If it is assumed that the reaction of HCl with O_2 (Eq. [1]) goes to completion, *i.e.*, 2 moles HCl produces 1 mole each of H_2O and Cl_2, then the kinetic oxidation results of various concentrations of HCl in O_2 can be compared with those of half the same concentrations of H_2O and/or Cl_2 in O_2.[2] This was done in the case of H_2O by plotting log x_o vs. log t data for 10% HCl in O_2 and 5% H_2O in O_2 at 900°, 1000°, and 1100°C. These plots for (111) oriented silicon are presented in Fig. 7-9. Also in-

[2] Exact calculations indicate that 10% HCl will produce 5.13% each of H_2O and Cl_2 due to a difference in total moles gas produced. Similarly 2.0% HCl produces 1.005% of H_2O and Cl_2.

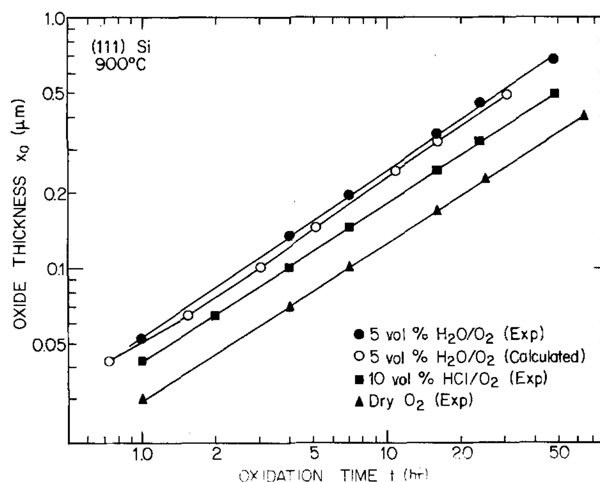

Fig. 7. Oxide temperature vs. oxidation time for the oxidation of (111) oriented n-type silicon at 900°C in 5 v/o H_2O/O_2, 10 v/o HCl/O_2, and dry O_2 mixtures. Also included are data for 5 v/o H_2O/O_2 mixtures calculated from Eq. [3].

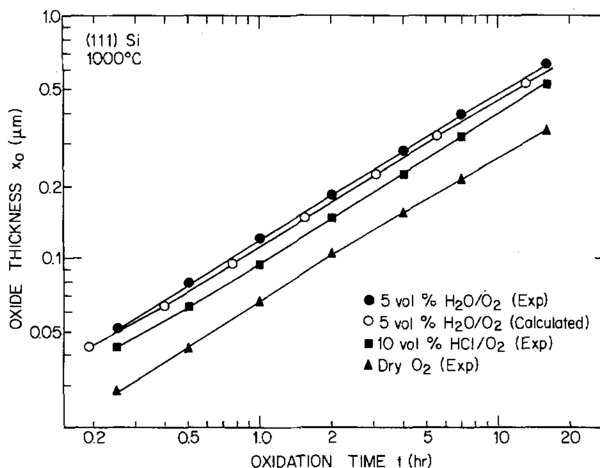

Fig. 8. Oxide thickness vs. oxidation time for the oxidation of (111) oriented n-type silicon at 1000°C in 5 v/o H_2O/O_2, 10 v/o HCl/O_2, and dry O_2 mixtures. Also included are data for 5 v/o H_2O/O_2 mixtures calculated from Eq. [3].

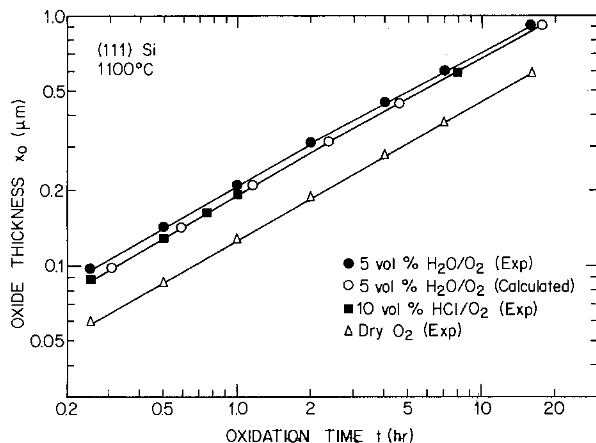

Fig. 9. Oxide thickness vs. oxidation time for the oxidation of (111) oriented n-type silicon at 1100°C in 5 v/o H_2O/O_2, 10 v/o HCl/O_2, and dry O_2 mixtures. Also included are data for 5 v/o H_2O/O_2 mixtures calculated from Eq. [3].

cluded for comparison are the calculated data for 5% H_2O in O_2 using Eq. [3], and previous data obtained for dry oxygen (9). It can be observed that, as indicated earlier, the experimental H_2O oxidation rates are slightly greater than the calculated ones. Also, the 5% H_2O rates are significantly greater than those of 10% HCl, although the difference becomes much less at 1100°C (about 10%) as compared to 900°C (30%).

Another way of comparing O_2/HCl oxidation data with those of O_2/H_2O and O_2/Cl_2 mixtures is to observe variation of oxidation rate constants of the three mixtures as a function of equivalent gas compositions. This comparison is shown in Fig. 10 and 11 where values of B and B/A for O_2/HCl oxidations at 1000°C are plotted for 0-10% HCl concentrations, and corresponding B and B/A values are included for 0-5% H_2O and Cl_2 in O_2. The data in Fig. 10 represent both (111) and (100) silicon orientations, since the parabolic rate constant is independent of silicon orientation. In Fig. 11, separate plots for (111) and (100) orientation are presented, reflecting

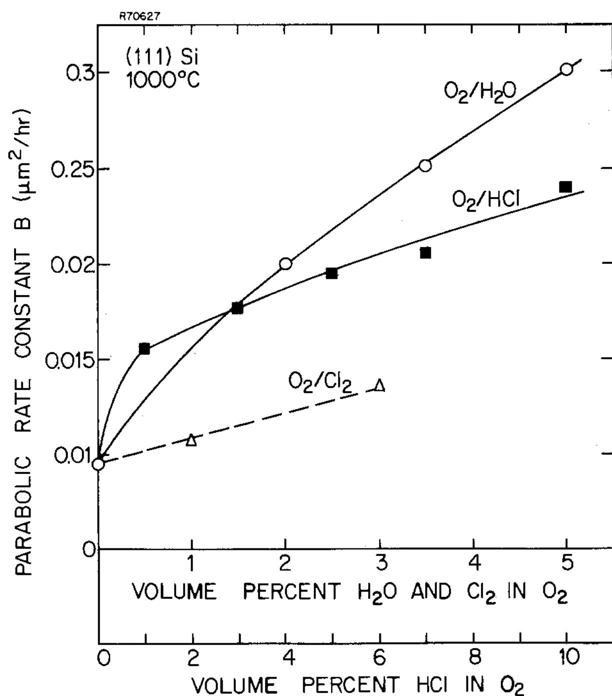

Fig. 10. Parabolic rate constants vs. 0-5 v/o H_2O and Cl_2 in O_2 and 0-10 v/o HCl in O_2 for the oxidation of (111) oriented n-type silicon at 1000°C.

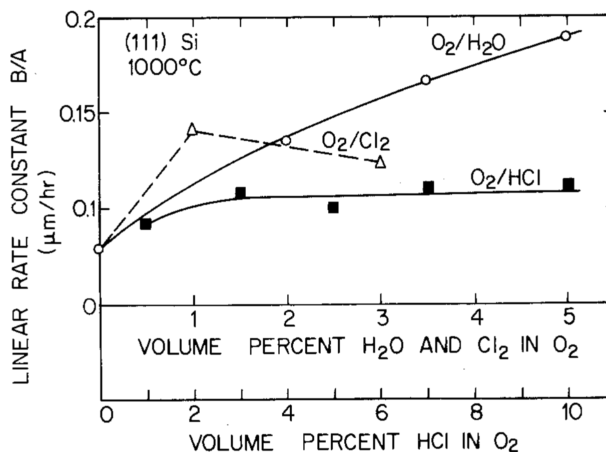

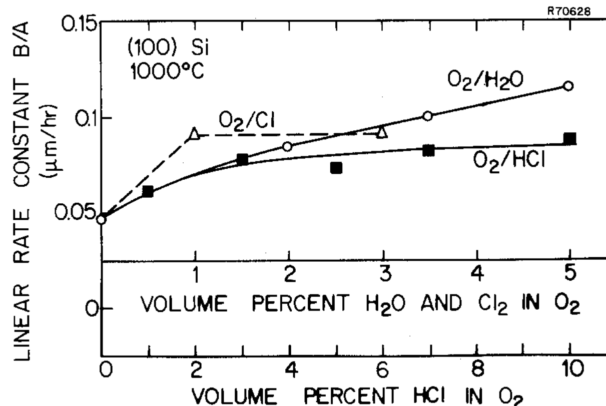

Fig. 11. Linear rate constants vs. 0-5 v/o H_2O and Cl_2 in O_2 and 0-10 v/o HCl in O_2 for the oxidation of (111) and (100) oriented n-type silicon at 1000°C.

the dependence of the linear rate constant on orientation.

Figures 10 and 11 indicate that the 2:1 ratio for HCl:H_2O predicted by the O_2-HCl reaction (Eq. [1]) is too small, at least at 1000°C. It would appear from the parabolic rate constant data (Fig. 10) that a 3:1 ratio at 1000°C would be more likely. From similar 1100°C plots (not shown) the ratio is about 2½:1, while at 900°C it is approximately 5:1. An extrapolation of these data would indicate that the 2:1 ratio might be obtained at about 1250°C. The data for the linear rate constant (Fig. 11) are more confusing, however. For both orientations, and for the other two temperatures, the value of B/A levels off with increasing HCl concentrations. Thus, it is not possible to compare this curve in a quantitative manner with that of the O_2/H_2O oxidation.

The general effects due to B and B/A variations with HCl concentration on the over-all kinetic rate data for O_2/HCl oxidations may be observed in another type of plot. This involves the change of oxide thickness with increasing HCl concentration for a given oxidation time. Such a plot is given in Fig. 12 for O_2/HCl oxidations at 1000°C and for an oxidation time of 2 hr. The HCl concentration in O_2 varies from 0 to 10%. Corresponding data are also shown for O_2/H_2O oxidations, with the equivalent concentration range of H_2O in O_2 being 0-5%.

In the case of O_2/HCl oxidations, it can be observed quite clearly in Fig. 12 that the increase of oxide thickness tends to level off somewhat at an HCl concentration of about 3%. This corresponds to a similar leveling off of the O_2/HCl linear rate constant observed in Fig. 11 for both orientations. Above 6% HCl, the oxide thickness again slowly increases, which corresponds to the increase of the O_2/HCl parabolic rate constant B in Fig. 10. Similar results were observed for other temperatures and oxidation times.

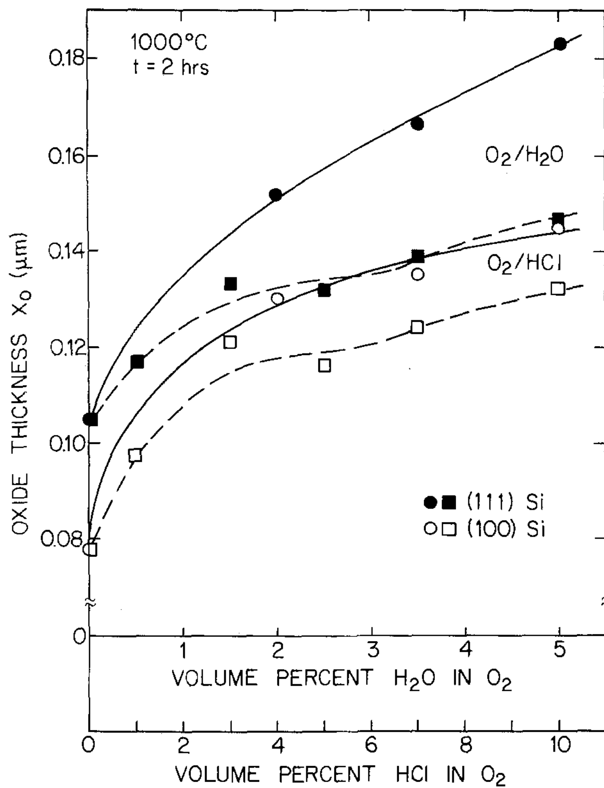

Fig. 12. Oxide thickness vs. v/o H_2O and HCl in O_2 for the oxidation of (111) and (100) oriented n-type silicon at 1000°C for 2 hr.

The O_2/H_2O data in Fig. 12 indicate a regular increasing oxidation rate with H_2O concentration. This trend was noted for all temperatures, times, and both orientations.

It can be observed from Fig. 10 and 11 that the oxidation rate constant data for O_2/Cl_2 mixtures are somewhat erratic. This was also the case at 1100°C (no O_2/Cl_2 data were obtained at 900°C). Thus, no real comparisons with the O_2/HCl results can be made, although speculation of the effect of Cl_2 on the over-all oxidation reaction will be included in the next section.

Mechanism for O_2-HCl silicon oxidation.—The results obtained from the O_2/H_2O and O_2/Cl_2 oxidation experiments seem to provide some insight into the mechanism involved in O_2/HCl silicon oxidation processes. First, the observed effects on the general kinetics due to either H_2O or Cl_2 additions to O_2 (Fig. 1-2) are very similar to those previously obtained for HCl additions (4). Also, the variation of parabolic rate constants B with increased HCl or H_2O content are quite similar [Fig. 3 and Ref. (4)]. Finally, the relationships in Fig. 7-11 also show similarities in effects due to H_2O (and Cl_2) additions as compared to oxidations in O_2/HCl mixtures. The main differences between O_2/HCl and O_2/H_2O results are primarily reflected in the linear rate constant results (Fig. 4 and 11).

If the parabolic rate constant B is first considered, the data indicate that the assumed reaction of 2 moles HCl with 1/2 mole O_2 to produce 1 mole H_2O (*i.e.*, Eq. [1]) goes to completion at some temperature above 1100°C (Fig. 10). Since the parabolic rate constant becomes dominant at higher temperatures [from the general relationship (9)], the assumed 2HCl:1 H_2O relationship becomes more apparent in the over-all oxidation kinetic data, as indicated in Fig. 9. At lower temperatures, however, much less water is produced, and at 900°C the ratio of HCl to H_2O produced was found to be 5:1. Thus, the parabolic rate constant data would predict, as shown in Fig. 7, that the reaction of HCl with O_2 is much more efficient as the oxidation temperature increases.

The ratio of change between HCl- and H_2O-containing oxygen ambients is greater at all temperatures for the linear rate constants B/A than for the parabolic rate constants, especially for higher HCl concentrations. Therefore, effects of the Si-SiO_2 interface reaction on the deviation from the assumed 2:1 HCl:H_2O ratio should be evident at lower temperatures where the oxidation reaction is more surface controlled. Why the B/A values level off with increasing HCl concentrations is not clear. The effect may well be due to the Cl_2 also produced by the O_2/HCl reaction. This species may interact or interfere with the other oxidizing species at the Si-SiO_2 interface where it has been reported to pile up (3, 13), and thus might actually retard the reaction at higher HCl concentrations. In addition, more recent data involving H_2O/HCl oxidations (14) indicate that little or no effect on oxidation kinetics in H_2O is observed due to the HCl. This would agree with earlier reports (15) that higher water concentrations repress the formation of Cl_2 (or at least its presence in the oxide), and thus Cl_2 may not be a factor in the oxidation reaction at higher HCl concentrations in O_2 since more H_2O is produced according to Eq. [1]. Such a mechanism might indicate a maximum effect on the Si-SiO_2 interface reaction occurs somewhere in the 0-10% HCl concentration range. This would tend to complicate even further the already complex mechanism for the O_2/HCl oxidation of silicon.

Much of this discussion has been based on the assumption that at oxidation temperatures the reaction of O_2 and HCl produces H_2O and Cl_2, as per Eq. [1]. The exact amounts of H_2O and Cl_2 produced depend on the equilibrium constant associated with Eq. [1], which can be affected by several factors. In order to verify the above assumption, an oxidation at 1000°C in O_2 containing 2% H_2O plus 2% Cl_2 was carried out. The kinetic results of this oxidation can be compared to those obtained from an oxidation in a 96% O_2/4% HCl mixture, and this is done in Table IV. Also included in the table are the 98% O_2/2% H_2O results. The first part of Table IV gives oxide thicknesses (x_o) after 2 and 4 hr oxidation. It can be observed that the oxide thicknesses for both the 4% HCl and the 2% H_2O/2% Cl_2 ambients are in good agreement for both orientations, while all the 2% H_2O values are significantly higher.

Values of the rate constants at 1000°C, B and B/A, are also listed in Table IV. The 2% H_2O/2% Cl_2 values of B, the parabolic rate constant, are in be-

Table IV. Comparison of silicon oxidation kinetic data at 1000°C in O_2 with 4% HCl, 2% H_2O + 2% Cl_2, and 2% H_2O additions

	Silicon orientation	O_2/4% HCl	O_2/2% Cl_2/ 2% H_2O	O_2/2% H_2O
Oxide thickness x_o (μm) at t = 2 hr	(111)	0.133	0.132	0.152
	(100)	0.118	0.115	0.130
Oxide thickness x_o (μm) at t = 4 hr	(111)	0.202	0.207	0.230
	(100)	0.182	0.186	0.198
Parabolic rate constant B (μm²/hr)	(111)	0.0185	0.0199	0.0200
	(100)	0.0185	0.0197	0.0205
Linear rate constant B/A (μm/hr)	(111)	0.103	0.101	0.135
	(100)	0.0780	0.0743	0.0837

tween those of the 4% HCl and the 2% H_2O mixtures. This is expected if the data in Fig. 10 are examined, since for these concentrations the curves for the two mixtures are fairly close together. On the other hand, values of the linear rate constant, B/A, for the 2% H_2O/2% Cl_2 mixture are very close to those of the 4% HCl ambient, and much lower than the 2% H_2O value.

These results tend to confirm that Eq. [1] is valid for the oxidation of silicon in O_2 with small additions of HCl. Also, the equilibrium of the reaction (Eq. [1]) is approached very rapidly whether starting with either O_2 + HCl or H_2O + Cl_2.

Summary

The kinetics of the thermal oxidation of (111) and (100) oriented silicon in O_2/H_2O and O_2/Cl_2 mixtures have been investigated over the temperature range 900°-1100°C. The concentrations of H_2O in O_2 were varied from 2 to 10 v/o, while those of Cl_2 were 1 and 3 v/o. Effective values of the parabolic (B) and linear (B/A) rate constants in the silicon oxidation general relationship were determined and both increased with increasing H_2O concentration in O_2. Results for O_2/Cl_2 oxidations were more erratic, however, although the addition of Cl_2 to O_2 also increased the over-all silicon oxidation rate. The experimentally determined O_2/H_2O oxide thickness oxidation time data were compared with similar data calculated from a combination general relationship involving simultaneous but independent oxidation of silicon by two species. Good agreement between experimental and calculated values of parabolic rate constants was obtained. However, below 20% H_2O, the experimentally determined linear rate constants B/A were significantly greater than the corresponding calculated values. This implies that some catalytic effect or interaction between H_2O and O_2 occurs at the Si-SiO_2 interface to accelerate the silicon oxidation reaction.

The O_2/H_2O and O_2/Cl_2 oxidation processes described above were studied in part because H_2O and Cl_2 are possible products of the O_2-HCl reaction in this temperature range, and their presence may affect the O_2/HCl silicon oxidation kinetics. A comparison between the results obtained here and those reported previously for O_2/HCl oxidation kinetics indicates that the increases found for parabolic and linear rate constants and over-all oxidation rates with varying H_2O concentrations in O_2 are greater than corresponding increases for equivalent HCl additions. It appears, however, that effective values of the parabolic rate constant B for O_2/H_2O mixtures approach the B values for O_2/HCl oxidations at some temperature above 1100°C. The over-all oxidation rates are also similar for these two systems at 1100°C or above, which is expected, since the oxidation process is controlled primarily by the parabolic rate constant at these higher temperatures. These results suggest that the assumed relationship $4HCl + O_2 \leftrightarrows 2H_2O + 2Cl_2$ may go to completion at higher temperatures. While the O_2/Cl_2 data are somewhat erratic, a reaction or interference by Cl_2 at the silicon surface (where it probably accumulates) may lead to the observed decrease in oxidation rate in O_2/HCl mixtures at lower temperatures, reflected in the lack of dependence of the linear rate constant on increasing HCl concentration.

A special experiment involving silicon oxidation in O_2 with 2% H_2O + 2% Cl_2 gave identical results to those obtained with a 96% O_2/4% HCl ambient. This helps to confirm the assumption that O_2 reacts with HCl to form Cl_2 and H_2O, and also indicates that the equilibrium of the reaction and product species occurs rather rapidly under these oxidation conditions.

The effect of increasing amounts of H_2O produced by higher HCl concentrations on chlorine incorporation in the oxide and thus on the subsequent oxidation kinetics is not known. Accurate chlorine concentration profiles in the oxide for various oxidation conditions would be highly desirable, and should provide additional insight into O_2/HCl oxidation mechanisms

Although several etchants (1-4) exist for gallium phosphide, in general, etch rates are greater than 100 Å/min, and often the resulting surface is not uniform and smooth. A new technique has been developed for etching gallium phosphide which permits a nearly constant etch rate, uniform etching across the sample surface, and a moderately slow etch rate that allows thin layers (a few hundred angstroms) of the sample to be removed in reasonable time. Such an etchant is desirable in order to determine the depth distribution of the dopants in thin layers of ion-implanted gallium phosphide.

The 5 × 5 × 0.5 mm polished gallium phosphide samples were washed separately in trichloroethylene, acetone, and methanol rinses before etching. A coating of black wax was applied to the sample to permit approximately one-half of the sample to be exposed to the etchant. The wax dissolved in the trichloroethylene to reveal the necessary etch step which was measured with a Sloan Dektak Surface Profile Measuring System. Once the sample had been etched, all wax was removed with cleaning solvents; then the sample was glued to a glass microscopy slide which facilitated edge-step measurements. Measurements were made of the step height at four evenly spaced locations across the sample surface.

A mixture of 2g $K_3Fe(CN)_6$, 6 ml 45% KOH, and sufficient deionized water to bring the final volume to 150 ml proved to be a most satisfactory etchant. The etching solution was placed in an ice-water bath 30 min before use in order to stabilize the temperature at a constant 0°C. Since the etch rate varies with temperature this particular temperature was chosen because it is stable and entirely reproducible. Magnetic stirring at 10 Hz was used and our etchant emitted only small amounts of noxious gases when retained at 0°C.

The etched gallium phosphide surfaces were smooth and uniform. Dislocations in the GaP material affect the surface smoothness since these regions etch at a different rate (3) than the uniform material; however, the low temperature and dilute etchant solution minimize this effect. It was found that 150 ml of solution will last ~8 hr with the samples used in our experiments. The etchant must be fresh if stable rates are to be achieved. Sulfur-doped n-type GaP and zinc-doped p-type GaP were etched simultaneously to eliminate variations due to etching conditions. The p-type material was found to etch 37% faster than the n-type material. Table I illustrates the type of GaP used. All samples were oriented along the <100> direction.

Table I. Type of GaP used

Dopant	Carrier concentration (cm^{-3})	Mobility ($cm^2 v^{-1} sec^{-1}$)	Resistivity (Ω-cm)
S	2.3×10^{17}	132	0.207
Zn	1.2×10^{17}	73	0.42

When the etch step was measured, it was found that the center of the sample etched at a slightly slower rate than the edges. Generally, this was found to be ~5% of the total edge step. The Dektak was found to be accurate to better than 1% for ideal samples; however, usually some variation was found in the four measurements made on each GaP sample. This error was found to be negligible in most cases.

Hydrogen Adsorption on Single Crystal Platinum

E. Yeager,* W. E. O'Grady,* M. Y. C. Woo,* and P. Hagans*

Case Laboratories for Electrochemical Studies and Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

Various electrochemists (1-5) have examined the role of surface structure in electrocatalysis but the results have not been highly conclusive. Recently more sophisticated efforts have been made to determine the role of crystal orientation (6-8). This note reports the results of studies of H electrosorption on Pt(111), (100) and (110) as well as the effect of cycling the potential of polycrystalline Pt.

The LEED-Auger-electrochemical system used in these studies has been described elsewhere (6). The Pt surfaces were cleaned by argon ion sputtering at 350eV and annealed at 900°C to obtain sharp LEED patterns. The principal surface contaminant is carbon which diffuses to the surface from the bulk of the Pt. This procedure was repeated a number of times until no further C or other impurity was detectable in the Auger spectrum (sensitive to ∿0.01 monolayer). The same procedure was used for polycrystalline Pt without the LEED examination. The sample was next transferred under vacuum into a second vacuum chamber which was back-filled with ultra-pure argon (99.9999%, further purified by Ti gettering). The sample was then examined electrochemically in a thin-layer cell with an α Pd-H counter electrode in 0.05M H_2SO_4, prepared with ultra-pure acid (Baker Ultrex H_2SO_4) and pyrolyzed water. The Pt was brought into contact with the electrolyte under controlled potential (0.4V vs. RHE) to minimize the possibility of surface reconstruction.

Figure 1 presents the voltammetry curves for Pt(100) and (111) obtained on the first cathodic scan, starting at 0.4V (RHE) and the reverse anodic sweep. H_2 formation is observed in the cathodic sweep at ∿0.05V and the complementary H_2 oxidation peak in the anodic sweep. The (111) surface exhibits a small H peak in the anodic and cathodic sweeps at ∿0.10V. The charge under the anodic peak is estimated to be ∿7μC/cm^2. Assuming 15.0×10^{14}atoms/cm^2 on Pt(111) and one H per Pt atom, this corresponds to a low coverage of ∿0.03. The first sweep on the Pt(110) surface also exhibits a quite small H peak at ∿0.1V and is similar to that for Pt(111). This is not surprising since a (2x1) LEED pattern was obtained for the Pt(110) surface as a result of a reconstructed surface composed of Pt(111) facets (9).

The first sweep for the Pt(100) surface indicates a much larger H peak at ∿0.25V, corresponding to more strongly adsorbed H. Although the anodic and cathodic peaks differ in width, the charge ratio Q(cath)/Q(anod)=∿1 and the charge is ∿50μC/cm^2. Assuming 13.1×10^{14} atoms/cm^2 on the Pt(100) surface, this corresponds to a coverage of ∿0.3. There may also be a small contribution from weakly adsorbed H. The LEED pattern for the clean Pt (100) surface indicated a (5x1) overlayer as reported in the literature (10) but this surface probably reconstructed to (1x1) upon introduction into the electrolyte.

The H coverages on these surfaces are surprisingly low compared to those found in conventional electrochemical experiments on polycrystalline Pt. The 0.3 coverage for strongly adsorbed H on Pt(100), however, compares favorably with flash desorption studies (11) in the gas phase on Pt(100) which also yield coverages of ∿0.3 at room temperature. The low coverage (∿0.03) for the weakly adsorbed H peaks on the Pt(110) and (111) may not be associated with these surfaces but rather edge effects in the thin-layer cell. They may also arise from portions of the surface which are not the orientation indicated by the LEED pattern. The LEED patterns are sharp and up to literature standards but this does not necessarily insure a very high degree of surface perfection. Samples annealed at high temperatures as in the present study, however, usually have relatively defect free surfaces (12). A third possibility is that the low coverage is the result of surface contamination. This is unlikely in view of the extensive precautions to prevent contamination. Reexamination of the surfaces with Auger after the electrochemical measurements was complicated by the non-volatility of the

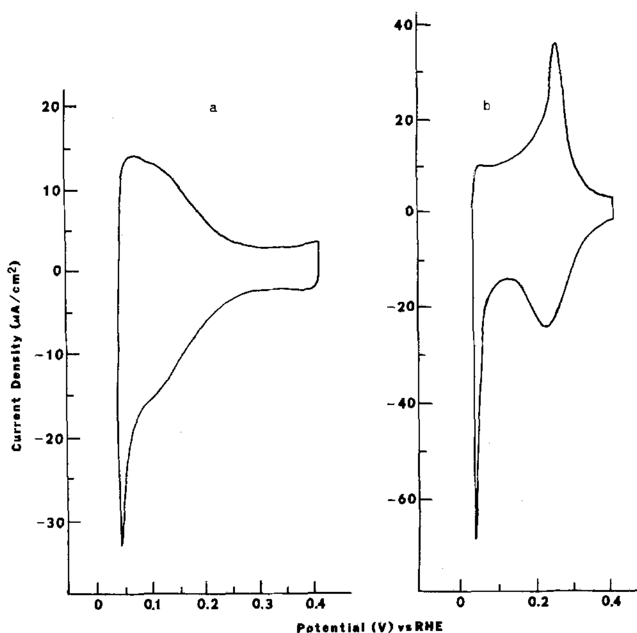

Fig. 1. Voltammograms for a) clean Pt(111) - (1x1) and b) clean Pt(100) - (5x1) in 0.05M H_2SO_4. Sweep rate: a) 100mV/s; b) 50mV/s.

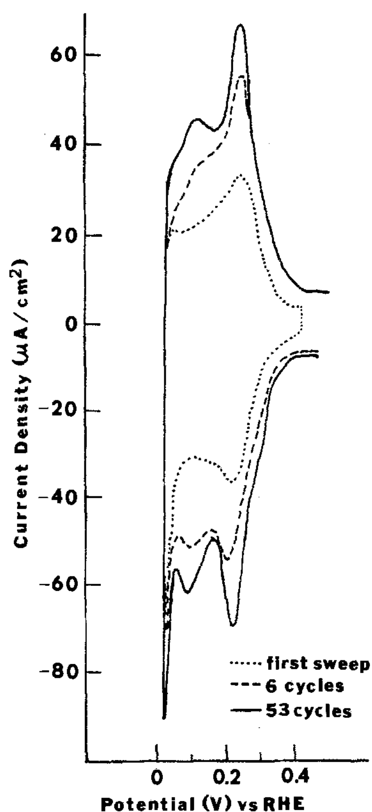

Fig. 2. Voltammograms for polycrystalline Pt in 0.05M H_2SO_4. Sweep rate: 100mV/s.

Manuscript received Nov. 22, 1977; revised manuscript received Dec. 7, 1977.

electrolyte. Post-Auger measurements indicated large sulfur peaks from the sulfate electrolyte and only a minor C peak. On the basis of the ratio of the C to Pt peaks, the C coverage was less than ∿0.1 monolayer.

In Figure 2 is shown the initial scan in 0.5M H_2SO_4 for polycrystalline Pt. The scan was begun at 0.4V and swept cathodically. A predominate H peak appears at ∿0.25V corresponding to stronger adsorbed H with only a minor contribution due to the weakly adsorbed hydrogen. The high temperature annealed polycrystalline Pt resembled quite closely the (100) surface. Cycling of the polycrystalline Pt out to 1.3V in the anodic film region leads to increases in the areas of the H peaks already present as well as the development of additional peaks. After 53 cycles the voltammogram begins to take on the appearance normally found in conventional studies of Pt. The most likely explanation is the reconstruction of the Pt surface.

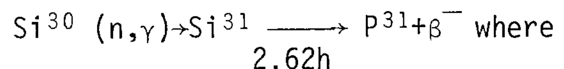
Neutron transmutation doping (NTD) is being applied to convert ingots of high resistivity float-zoned silicon into homogeneously and precisely phosphorus doped n-type material (1-6). Such neutron transmutation doped material is being successfully used in high voltage thyristors and diodes (7,8).

This communication describes the application of NTD to the generation of precisely and homogeneously doped n-type epitaxial layers. Such starting material would result in a greater yield of devices of desired electrical parameters. It would be especially desirable for large area devices consisting of a group of adjacent cells which must all be as identical as possible in order to operate more effectively.

In the method conventionally used, doped silicon is epitaxially laid down on a prepared heated silicon substrate by the decomposition of a flowing gas containing a silicon compound such as silane, dichlorsilane, trichlorsilane or silicon tetrachloride, together with a doping agent such as PH_3. The concentration of the dopant in the epitaxially deposited silicon layer, here phosphorus, is affected by variations in gas flow, by temperature gradients and by autodoping, the pickup of impurities from the doped substrate and their redeposition with the epitaxial silicon. Schuman (9) has published a detailed description of the impurity profile found in a conventionally produced n/n^+ epitaxial wafer, using spreading resistance measurement techniques. He found significant inhomogeneities across the surface as well as in depth of the epitaxial layer.

The process utilizing NTD began with the deposition of an undoped silicon epitaxial layer on a heavily arsenic doped substrate at 1050°C using undoped silane as the silicon source. These wafers were subjected to an irradiation of 250 hours in an in-core position of the Bulk Shielding Reactor at Oak Ridge National Laboratory. The thermal neutron flux was measured as 1.3×10^{13} n cm^{-2} sec^{-1}, the fast neutron flux using a Ni detector was found to be 1.7×10^{12} n cm^{-2} sec^{-1}.

This results in the reaction,



$$Si^{30}\ (n,\gamma) \rightarrow Si^{31} \xrightarrow[2.62h]{} P^{31} + \beta^{-}$$ where

the stable silicon isotope Si^{30} is converted to the stable phosphorus isotope P^{31}, thereby doping the material n-type. The effective decay length for silicon is sufficiently large to limit variation in resistivity due to neutron flux absorption to 1%. The continuously uniform neutron flux at any position in a nuclear reactor permits us by controlling the time of exposure to obtain a reproducibility of doping from lot to lot. Thus reproducibilities and uniformities of ±2% are possible compared to the ±10% normally specified for the resistivity of epitaxial layers prepared by conventional techniques.

The final step in the process consisted of an annealing treatment of 20h at 750°C in dry N_2. This permits the newly created P atoms to take substitutional positions in the silicon crystal lattice and to reduce the lattice damage so that

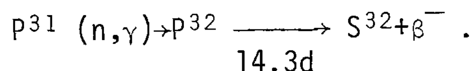
---

*Electrochemical Society Active Member. Key words: neutron irradiation, neutron transmutation doping, homogeneous epitaxial layers, epitaxial wafers.

full electrical activity can be observed (3,5).

Figure 1 illustrates the resistivity profiles obtained before and after neutron bombardment and annealing. The profile was obtained by a spreading resistance probe technique, utilizing a Hartman ε conducting correction. This correction was found to give consistently good agreement with C/V data on n/n^+ epitaxial structures (10). We note that while the deposited silicon varies in resistivity over the range of 20 to 100Ωcm, the neutron bombarded epitaxial resistivity is quite uniform at 2.7Ωcm.

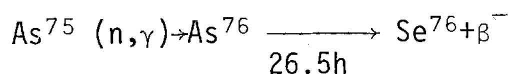
The half-life for Si^{31} of 2.6h insures that the neutron bombarded silicon decays to an undetectable level in 3 to 5 days (5). The doping level required in epitaxial layers are normally one to two orders of magnitude greater than are encountered in power devices prepared by NTD. This raises a question with regard to the P^{31} atoms generated by NTD which are subject to the secondary transmutation,



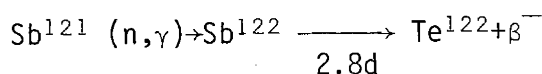
$$P^{31}\ (n,\gamma)\rightarrow P^{32} \xrightarrow[14.3d]{} S^{32}+\beta^- .$$

Because of the longer half-life of P^{32}, there is the possibility of significant residual radioactivity. However, after a 25 day cool down period the unetched wafers were found with a radioactivity of less than $2mRh^{-1}$, well within acceptable safe limits.

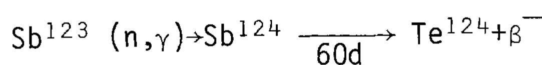
The possible donor substrate dopants are antimony and arsenic. Phosphorus is precluded because of its excessive autodoping tendencies. The neutron transmutations of these elements are given as,



$$As^{75}\ (n,\gamma)\rightarrow As^{76} \xrightarrow[26.5h]{} Se^{76}+\beta^-$$



$$Sb^{121}\ (n,\gamma)\rightarrow Sb^{122} \xrightarrow[2.8d]{} Te^{122}+\beta^-$$



$$Sb^{123}\ (n,\gamma)\rightarrow Sb^{124} \xrightarrow[60d]{} Te^{124}+\beta^-$$

Although As^{75} has a much larger thermal neutron capture cross section than Sb^{121} or Sb^{123}, the much longer half-life of the Sb^{123} (60.2d) precludes its use as a substrate dopant for the neutron fluence of $5x10^{18}$ to $1x10^{20}$ cm^{-2} normally required. The use of As permits radioactive decay in a reasonable period. Similarly, Ga represents an acceptable acceptor type substrate dopant, while B does not, since B^{10} (19.6% abundant) has a large (3,840 barn) cross section, and fissions to introduce He^4 and donor type Li^7.

ACKNOWLEDGMENTS

The authors would like to thank Jay Levine for carrying out the epitaxial deposition, and Dr. Arthur Hochberg and Robert Etchells for the computer program.

Thermal Properties of Battery Systems

H. Frank Gibbard*

Gould Laboratories, Rolling Meadows, Illinois 60008

ABSTRACT

A compact expression is derived for the change in any extensive thermodynamic state variable which accompanies an electrochemical reaction. The distinction between an electrochemical reaction and the complete thermodynamic change in state is clearly drawn. The cases in which every reactant is in a single, pure phase and that in which some reactants are dissolved in solution are discussed. Detailed calculations of ΔH, ΔG, the cell potential, and the thermal efficiency of the lead/acid battery are presented as examples. Practical thermal efficiencies of 11 other systems are calculated and compared, where possible, with theoretical thermal efficiencies. Equations for the rate of heat flow from batteries are developed and applied to a typical duty cycle of a lead/acid battery for vehicular propulsion.

The measurement and calculation of thermodynamic properties of battery systems have many practical applications. For example, engineering analyses of plants for utility load leveling and peak shaving require heat balances. For some military applications, thermal efficiencies for battery discharge must be known. Thermodynamic calculations are straightforward for cell reactions in which each reactant and each product is present in a single, pure, condensed phase. However, the thermodynamics of electrochemical cells in which some of the constituents are dissolved in a liquid solution is more complicated. For both cases, it is convenient to have a simple expression which describes the change in any extensive thermodynamic state function for a given extent of the cell reaction. The purpose of this paper is not only to present the results of some calculations of discharge efficiencies but also to show in some detail how such calculations are done.

Equations for Thermodynamic Properties

The stoichiometry of the net cell reaction is specified by numbering the reactants and products and defining a quantity υ_i which is equal to the stoichiometric coefficient of the ith species, if it is a product, and is equal to the negative of the stoichiometric coefficient of the ith species, if it is a reactant. The amount (in moles) of any substance i present at the beginning of the cell reaction is designated by n_i°. After some extent of reaction has occurred, the amount of substance i present is $n_i^\circ + \upsilon_i\xi$, where ξ is the reaction progress variable for the cell reaction. The υ_i are pure numbers and ξ has units of moles. If X is any extensive state variable, *e.g.*, Gibbs energy G, enthalpy H, or entropy S, then

$$X = \Sigma_i n_i \overline{X}_i \quad [1]$$

where $\overline{X}_i$ is the partial molar X of the ith component, and the summation is taken over all components present, not only those which appear in the cell reaction. For the change from the initial state, taken as $\xi = 0$, to the final state, taken as $\xi = 1$ mole, the change in X is given by

$$\Delta X = \Sigma_i n_i^\circ [\overline{X}_i(\xi = 1) - \overline{X}_i(\xi = 0)] + \Sigma_i \upsilon_i \overline{X}_i(\xi = 1) \quad [2]$$

which is the desired general relation. For reactions in which all of the components are present in single, pure phases, the first summation vanishes, and $\overline{X}_i$ is simply the molar X of pure substance i. For reactions involving solutions, the first summation does not vanish and will include terms for every substance present in the solution, even if some substances do not take part in the chemical reaction.

Here it should be mentioned that the notation "ΔX" in the literature often does not mean the change in X for a finite change in state. It is rather the derivative of X with respect to ξ

$$(\partial X/\partial \xi)_{P,T} = \Sigma_i \upsilon_i \overline{X}_i(\xi) \quad [3]$$

For reactions in solution, generally $\overline{X}_i$ is not the molar quantity of pure substance i, and the substitution of "ΔX" for $(\partial X/\partial \xi)_{P,T}$ is poor nomenclature.

If X is G, then $\overline{X}_i$ is μ_i, the chemical potential of component i, which may be expressed in terms of the activity of i

$$\mu_i = \mu_i^\circ + RT \ln a_i \quad [4]$$

Then Eq. [2] becomes

$$\Delta G = \Sigma_i \upsilon_i \mu_i^\circ + RT \ln \Pi_i [a_i(\xi = 1)]^{\upsilon_i} + RT \ln \Pi_i [a_i(\xi = 1)/a_i(\xi = 0)]^{n_i^\circ} \quad [5]$$

where $\Sigma_i \upsilon_i \mu_i^\circ$ is the so-called "standard Gibbs energy change" for the cell reaction. If X is the enthalpy function H, then

$$\Delta H = \Sigma_i \upsilon_i \overline{H}_i^\circ + \Sigma_i n_i^\circ [\overline{L}_i(\xi = 1) - \overline{L}_i(\xi = 0)] + \Sigma_i \upsilon_i \overline{L}_i(\xi = 1) \quad [6]$$

where $\Sigma_i \upsilon_i \overline{H}_i^\circ$ is the standard enthalpy change for the cell reaction, and $\overline{L}_i$ is the relative partial molar enthalpy of substance i

$$\overline{L}_i = \overline{H}_i - \overline{H}_i^\circ \quad [7]$$

* Electrochemical Society Active Member.

The thermal efficiency of a battery system is defined as the negative of the electrical work divided by the enthalpy change which accompanies the cell reaction. For the case of reversible operation, the thermodynamic thermal efficiency ϵ_{th} is given by

$$\epsilon_{th} = \Delta G/\Delta H \quad [8]$$

in which the change in state to which ΔG and ΔH refer is the discharge of the battery between known initial and final states. Equations [5] and [6] show that ϵ_{th} can be calculated if the activities and relative partial molar enthalpies of each constituent are known. As is shown below, the calculation is simple, provided that careful attention is given to writing the correct over-all change in state.

For most batteries accurate activity coefficients and relative partial molar enthalpies are not known. In these cases Eq. [3] provides an alternate, but usually less accurate, method to find ΔG and ΔH. For an electrochemical cell $\Sigma_i \upsilon_i \overline{G}_i = -n\mathbf{F}E$ and integration of Eq. [3] with respect to ξ gives

$$\Delta G = -n\mathbf{F}\int_0^1 E(\xi)d\xi \quad [9]$$

so that ΔG can be calculated if the open-circuit voltage (taken to be the cell potential E) of the battery is measured during discharge. Values of ΔH can be derived from measurements of the temperature dependence of the cell potential and the Gibbs-Helmholtz equation, written in the form

$$\Delta H = -n\mathbf{F}\int_0^1 [E - T(\partial E/\partial T)_{\xi,P}]d\xi \quad [10]$$

Examples of the use of Eq. [5] and [6] and the alternative Eq. [9] and [10] to calculate thermal efficiencies will be given for the lead/acid battery, for which all of the relevant properties are well known.

For some applications it may be useful to know the "instantaneous thermal efficiency" ϵ'. This quantity, which at any time represents the fraction of total energy[1] output which is electrical work, is defined by

$$\epsilon' = -n\mathbf{F}V_i/(\partial H/\partial \xi)_{P,T} \quad [11]$$

where V_i is the operating voltage of the cell. For the case of reversible operation the thermal efficiency is

$$\epsilon'_r = (\partial G/\partial H)_{P,T,\xi} = (\partial G/\partial \xi)_{P,T}/(\partial H/\partial \xi)_{P,T} \quad [12]$$

which can be computed by using the differential forms of Eq. [5] and [6] or Eq. [9] and [10], which are

$$(\partial G/\partial \xi)_{P,T} = \Sigma_i \upsilon_i \mu_i^\circ + RT \ln \Pi_i [a_i(\xi)]^{\upsilon_i} \quad [13]$$

$$(\partial G/\partial \xi)_{P,T} = -n\mathbf{F}E(\xi) \quad [14]$$

$$(\partial H/\partial \xi)_{P,T} = \Sigma_i \upsilon_i \overline{H}_i^\circ + \Sigma_i \upsilon_i \overline{L}_i(\xi) \quad [15]$$

$$(\partial H/\partial \xi)_{P,T} = -n\mathbf{F}[E - T(\partial E/\partial T)_{\xi,P}] \quad [16]$$

If values of ΔS or $(\partial S/\partial \xi)_{P,T}$ are desired, they may be calculated using the equation

$$\Delta S = (\Delta H - \Delta G)/T \quad [17]$$

or its differential form

$$(\partial S/\partial \xi)_{P,T} = [(\partial H/\partial \xi)_{P,T} - (\partial G/\partial \xi)_{P,T}]/T \quad [18]$$

Calculation of Thermal Efficiencies

Application to the lead/acid battery.—The lead/acid battery provides an excellent example for the calculation of thermal efficiencies, because the solute and solvent activities (1) and relative partial molar enthalpies (2) are known accurately, and the cell potential and its temperature derivative have been measured by various authors (3-5). Also the lead/acid system clearly shows the large role which concentration changes in the electrolyte can play.

To write the complete change in state it is useful to begin with the general equation for the molality of a solute species

$$m_i = (n_i^\circ + \upsilon_i \xi)/(n_1^\circ + \upsilon_1 \xi)M_1 \quad [19]$$

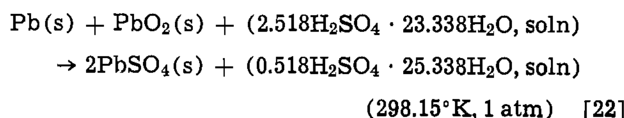
in which n_i° is the number of moles of species i when $\xi = 0$, component 1 is the solvent, and M_1 is the molar mass of the solvent in kilograms per mole. For the special case in which the solvent does not participate in the cell reaction, Eq. [19] reduces to

$$m_i = m_i^\circ + (\upsilon_i/n_1^\circ M_1)\xi \quad [20]$$

The cell reaction for the lead/acid battery may be written

$$Pb + PbO_2 + 2H_2SO_4 \rightarrow 2PbSO_4 + 2H_2O \quad [21]$$

The constituents are numbered as shown in Table I. To write a specific change in state the initial and final molalities of sulfuric acid are chosen as 5.989 and 1.135 mole/kg, which are representative of batteries in the charged and discharged states. Substitution of these values into Eq. [19] and solution of the two equations for n_1° and n_2° gives enough information to write the complete change in state for one mole of reaction



$$Pb(s) + PbO_2(s) + (2.518H_2SO_4 \cdot 23.338H_2O, soln) \rightarrow 2PbSO_4(s) + (0.518H_2SO_4 \cdot 25.338H_2O, soln) \quad (298.15°K, 1\ atm) \quad [22]$$

To calculate ΔG and ΔH for the change in state [22], values for the terms $\Sigma_i \upsilon_i \mu_i^\circ$ and $\Sigma_i \upsilon_i \overline{H}_i^\circ$ are required. From tabulations of the National Bureau of Standards (6) these are calculated to be −394.15 and −315.60 kJ/mole, respectively. The activity of sulfuric acid is $4m^3\ \gamma_\pm^3$, and from the values of $\gamma_\pm$, a_1, $\overline{L}_2$, and $\overline{L}_1$ from Table II for $\xi = 0$ and $\xi = 1$ mole, Eq. [5] and [6] give $\Delta G = -391.05$ kJ and $\Delta H = -378.02$ kJ. Thus the over-all thermal efficiency of the lead/acid battery for the change in state [22] is 1.0345. This value indicates that the lead/acid battery tends to absorb heat during a slow, nearly reversible, discharge.

It is interesting to examine not only the over-all thermal efficiency but also the instantaneous thermal efficiency at each stage of the discharge process. For this reason the data of Table II are given in steps of 0.1 mole in ξ, and Fig. 1 shows the values of ϵ'_{th} cal-

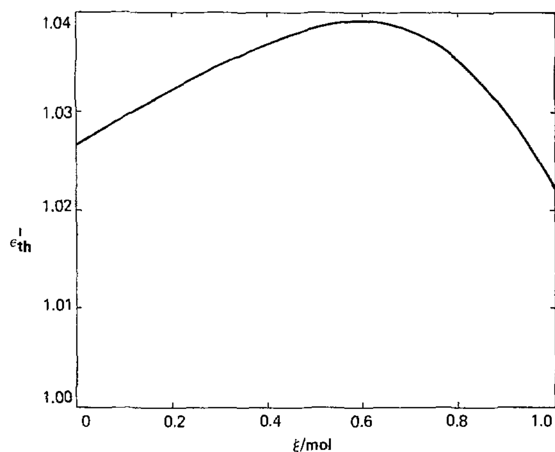

Fig. 1. Differential thermal efficiency of the lead/acid battery at 298.15°K.

culated from Eq. [12], [13], and [15]. The curve shows that the maximum absorption of heat occurs at $\xi = 0.6$ mole, or at a sulfuric acid molality of about 3.0 mole/kg. This sort of plot and its irreversible counterpart might be useful to a battery design engineer if thermal efficiency were important in a particular application; for it clearly shows in which parts of the discharge the greatest and least absorptions of heat occur.

The calculations required to prepare Fig. 1 also permit comparison of the present work with previous studies of the lead/acid battery. Figure 2 shows the cell potential calculated from values of $(\partial G/\partial \xi)_{P,T}$ for the data in Table II, along with measurements on storage batteries and electrochemical cells by Vinal and his co-workers (7). Since the molalities selected for the charged and discharged states in this paper are arbitrary, some of the points for other studies lie outside the range $0 \leq \xi \leq 1.0$ mole. Over the range of the present calculations, the agreement with Vinal and Altrup (7) is within 0.001V, while Craig and Vinal's (5) measurements lie 0.003 to 0.008V higher. The dotted curve shows the mean value of cell potential measurements of Vosburg and Craig (3), Harned and Hamer (4), and Craig and Vinal (5). Integration of the dotted curve serves to determine ΔG for the change in state [22] from cell potentials alone. The value obtained from Eq. [9] is -391.8 kJ, which is 0.19% lower than that determined by Eq. [5]. Integration of the curve for this work yields -391.08 kJ, which shows

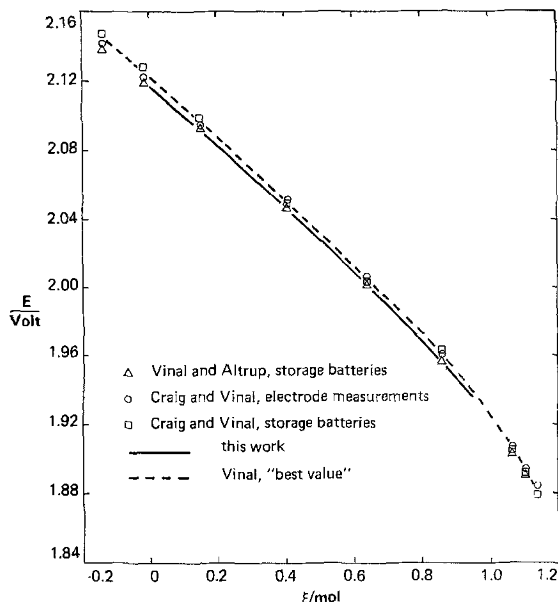

Fig. 2. Cell potential of the lead/acid battery at 298.15°K

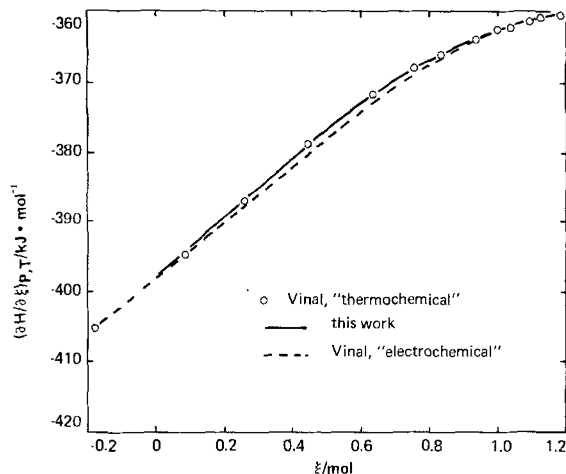

Fig. 3. $(\partial H/\partial \xi)_{P,T}$ for the lead/acid battery at 298.15°K

good consistency of the solute and solvent activities through the Gibbs-Duhem equation.

Figure 3 shows values of $(\partial H/\partial \xi)_{P,T}$ calculated from the $\overline{L_i}$ data in Table II, and the corresponding values determined by Vinal (7) from cell potentials and from the thermal data available to him. The value of ΔH from Eq. [10] for the change in state [22] is -378.45 kJ, which is 0.11% lower than that found from Eq. [6]. Thus the over-all thermal efficiency calculated from cell potentials alone is $-391.08/-378.45$ or 1.0353, and due to a cancellation of errors this differs by only 0.08% from the value obtained from activity and thermal data.

In concluding this section it is important to note that the results for the lead/acid battery are by no means typical of most battery systems. First, the thermal efficiency of most batteries is in the range of 0.8-0.95, while that of lead/acid is greater than unity. Second, for no other practical battery system are data available which are as numerous and precise as those of the lead/acid battery. This is to be expected because of the practical importance, the long history, and the relatively simple and reversible cell reaction of the lead storage battery. However, many advanced battery systems are currently under development for vehicular propulsion, utility off-peak storage, and other applications. The more successful of these will be carefully studied, and it may be expected that the data needed for the calculations presented here will become available for several systems.

Practical Thermal Efficiencies

Results for other systems.—The terminal voltage V_i of any battery being discharged at a finite rate is less than its reversible cell potential E. Because of the dissipative processes in the battery the electrical work must be less than $-\Delta G$. For a battery undergoing discharge at voltage V_i and current I for a period of time t we write

$$\epsilon = -(n\mathbf{F}/\Delta H) \int_0^t V_i(\tau)I(\tau)d\tau \Bigg/ \int_0^t I(\tau)d\tau \quad [23]$$

Equation [23] is a general relation of which Eq. [8] represents the special case of reversible discharge. For constant-current discharge Eq. [23] reduces to

$$\epsilon = -n\mathbf{F}V_i(\text{avg})/\Delta H \quad [24]$$

where V_i(avg) is the average discharge voltage.

Equation [24] is a very convenient form for the calculation of practical thermal efficiencies; all that is needed is a discharge curve and the enthalpy change for the cell reaction. Table III shows the thermal efficiencies of 12 systems, calculated by Eq. [24] with ΔH's from Ref. (6), and the average discharge voltage taken from typical discharge curves in the literature. The exact values obtained for ϵ and V_i(avg) are not

especially significant, because they depend on the discharge rate. However, the systems with high and low thermal efficiencies are readily identified, and the results are easily converted to other observed average voltages by multiplication of the table entry for ϵ by the ratio of the observed average voltage to the average voltage in the table. A detailed treatment of solution effects was possible only in the cases of the lead/acid and H_2/Br_2 systems. A description of the computations for the latter system has been reported elsewhere (8).

To perform the calculations in Table III it was necessary to assume unit coulombic efficiency of each electrode. This is certainly not true for some systems, but it is the only approximation which can be made in the absence of detailed information on the nature and extent of any nonfaradaic reactions. The formalism developed here can be extended to systems in which nonfaradaic reactions occur, as is shown below. Consider the case in which one electrochemical and p chemical reactions occur simultaneously. Then $p + 1$ reaction progress variables $\xi_j (j = 1, \ldots, p + 1)$ are required to specify the state of the battery. Assume that the battery contains m substances; then the jth reaction can be written

$$\sum_{i=1}^{m} \upsilon_i^{(j)} S_i = 0 \quad (j = 1, \ldots, p + 1) \qquad [25]$$

where S_i represents substance i. Of course, if S_k is not a reactant or product of reaction j, then $\upsilon_k^{(j)} = 0$. If one nonfaradaic reaction is the chemical path for the cell reaction, then the reaction must be written twice, with two independent reaction progress variables, to include the effect of self-discharge.

The change in an extensive state variable X is now written

$$\Delta X = \sum_{i=1}^{m} \left(n_i^\circ + \sum_{j=1}^{p+1} \upsilon_i^{(j)} \xi_j \right) \overline{X}_i(\{1, \xi_2, \ldots, \xi_{p+1}\}) - \sum_{i=1}^{m} n_i^\circ \overline{X}_i(\{0\}) \qquad [26]$$

in which $\{\xi_j\}$ represents the set of reaction progress variables, and $\{0\}$ is the set in which each reaction progress variable is zero. If Eq. [26] is written for ΔH, as in Eq. [6], and if each ξ_j is measured for the battery's discharge, then Eq. [23] can be used for the calculation of thermal efficiency. In the practically important case where the only significant chemical reaction is self-discharge, the result is simply the replacement of ΔH for $\xi = 1$ mole by the ΔH for $\xi = (\epsilon_C)^{-1}$ mole, where ϵ_C is the coulombic discharge efficiency.

Rates of Heat Flow in Battery Systems

To the battery engineer a quantity which may be more useful than the thermal efficiency is the rate of heat flow during charge and discharge. The rate of heat flow $-q'$ from the battery to its surroundings can be written as a derivative either with respect to the reaction progress variable or with respect to time. We write

$$-q'_\xi = \begin{cases} -dq/d\xi \text{ for discharge } (d\xi > 0) \\ dq/d\xi \text{ for charge } (d\xi < 0) \end{cases} \qquad [27]$$

where

$$-dq/d\xi = -T(\partial S/\partial \xi)_{P,T} + n\mathbf{F}(E - V_i) - C_p dT/d\xi \qquad [28]$$

and C_p is the average constant-pressure heat capacity of the battery, or

$$-q'_t = -dq/dt = I\,[-(T/n\mathbf{F})(\partial S/\partial \xi)_{P,T} + E - V_i] - C_p dT/dt \qquad [29]$$

with the convention that $I > 0$ for discharge and $I < 0$ for charge.

Several special cases of Eq. [28] and [29] are of interest. For reversible, isothermal operation the second and third terms of Eq. [28] vanish, and $q'_\xi = T(\partial S/\partial \xi)_{P,T}$. Figure 4 shows, for example, the reversible absorption of heat by the lead/acid battery at 298°K as a function of state of charge.

For isothermal operation the heat capacity terms drop out of Eq. [28] and [29], and the net heat flow depends on the intrinsic entropy change and the overpotential. In Fig. 5 the rate of heat flow $-q'_\xi$ for iso-

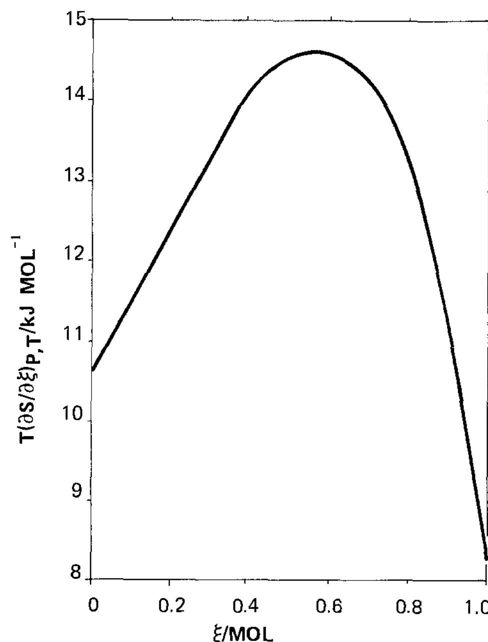

Fig. 4. Absorption of heat for reversible operation of the lead/acid battery at 298°K.

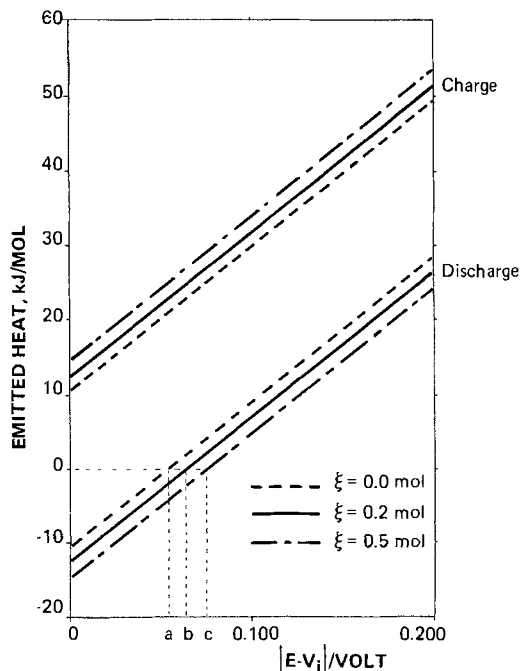

Fig. 5. Dependence of heat flow from the lead/acid battery on overpotential at 298°K.

thermal operation of the lead/acid battery is shown as a function of overpotential. This figure clearly illustrates the facts that the lead/acid battery evolves heat at all potentials on charge, while on discharge heat may be absorbed or emitted. At a certain overpotential which depends on the state of charge the battery neither absorbs nor emits heat. This "thermoneutral" overpotential is shown for three states of charge by the abscissas a, b, and c in Fig. 5. For most other battery systems $T(\partial S/\partial \xi)_{P,T} < 0$, so the relative positions of the charge and discharge lines in Fig. 5 are reversed, and the thermoneutral overpotential applies to the charge mode of the battery.

A final limiting case of interest is the adiabatic one, in which the left-hand sides of Eq. [28] and [29] are zero. Here the internal energy which would flow to the surroundings in isothermal operation remains in the battery, and the temperature rises accordingly. Figure 6 shows the change in temperature calculated from Eq. [29] for a fully charged 281 A·hr (3 hr rate) battery subjected to the load cycle shown. This current profile resembles that observed in a test of electric vehicles for postal service (9). Repetition of the 1 min cycle in Fig. 6 leads to an adiabatic heating rate of 2.64°K/hr; for a half-discharged battery the rate is

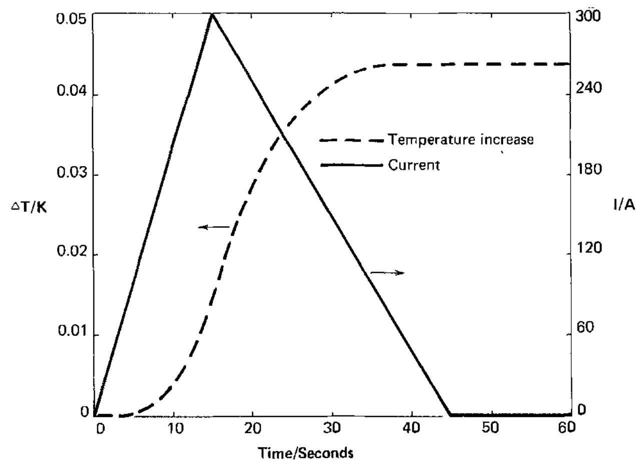

Fig. 6. Calculated temperature rise in an adiabatically insulated lead/acid battery subjected to a vehicular propulsion load cycle.

3.56°K/hr and at the end of discharge it has risen to 4.10°K/hr. Temperature rises of the magnitude calculated are actually observed for the first few hours of service in vehicular propulsion applications (10), before heat loss to the surroundings brings about a steady state at 45°-50°C.

For purposes of comparison we note that the thermodynamic treatment of Gross (11, 12) can be expressed in terms of the formalism developed here. His "enthalpy voltage" $E_{\Delta H}$ is given by

$$E_{\Delta H} = E - (T/n\mathbf{F})(\partial S/\partial \xi)_{P,T} \qquad [30]$$

Gross (11) treated the case of more than one electrochemical reaction and discussed alternatives to the thermodynamic approach for the study of thermal energy in battery systems. He did not give a detailed treatment of solution effects.

Electrochemical and Optical Properties of Thin Oxide Layers Formed on Fresh Titanium Surfaces in Acid Solutions

D. Laser, M. Yaniv, and S. Gottesfeld

Institute of Chemistry, Tel-Aviv University, Ramat Aviv, Israel

ABSTRACT

Optical properties and thicknesses of thin oxide layers formed electrochemically on Ti surfaces which were exposed by abrasion *in situ* were evaluated according to results of ellipsometric and reflectometric measurements. It is shown that the optical as well as some other physical properties of the thin ($d < 100$Å) oxide films are close to those of bulk Ti oxides and, hence, deviations of their electrochemical characteristics from those of bulk TiO_2 are most probably due only to their small thicknesses. Electroreduction of such films was also traced by the optical means and could be shown to result, under certain conditions, in some thinning and, especially, in the increase of the extinction coefficient of the film. The effect of such a reductive treatment on the electrochemical characteristics of the oxide layer is also discussed.

The physical properties of TiO_2 films formed electrochemically on Ti substrates are of interest in relation to the stability of Ti in corrosive environments. Furthermore, since the activity of TiO_2 as a photoanode has become the subject of intensive recent efforts, analysis of such properties and their bearing on the electrochemical and photoelectrochemical reactivity of the Ti/TiO_2/electrolyte system seems to be of importance. In this work thin TiO_2 films ($d < 150$Å) were grown on fresh Ti surfaces exposed by the abrasion *in situ* of Ti electrodes in aqueous H_2SO_4 solutions. While the films formed by anodization of Ti in appropriate solvents may be much thicker (1), the formation of such thin films following exposure of the fresh metal surface probably simulates the process of film repair at sites of protective film failure. The optical properties (thickness and complex refractive index) were determined according to combined reflectometric and ellipsometric measurements taken for films formed anodically following abrasion, as well as for the same films after their partial reduction. The optical-electrochemical cell was equipped with an arrangement for the abrasion *in situ* of the Ti surfaces, which allowed the monitoring of the films optically (*in situ*) immediately following abrasion. The unit employed for the abrasion *in situ* was an improved version of the system originally developed by Ambrose and Kruger (2). A combination of the optical measurements with various electrochemical measurements of the capacity and the behavior of some redox systems, as well as the photooxidation of water at the Ti/TiO_2/electrolyte interface, should allow some insight into the relationship between thickness and optical properties of such films and their electrochemical characteristics.

Experimental

Experiments were carried out with the L119 Gaertner ellipsometer at a wavelength of 5460Å, using a 150W tungsten lamp as a power source, a Bausch and Lomb high intensity monochromator, a mica quarter-wave plate as a retarder prior to the sample, and a Hamamatsu Type R585 photomultiplier. Power suppliers to the lamp and photomultiplier were, respectively, Kepco Model JQE 36V/15A and J. Fluke Model 412B. The photomultiplier output current was converted by a current to voltage converter and monitored on an X-Y recorder. The cylindrical electrochemical cell which served for *in situ* ellipsometric and reflectometric measurements has been employed before (3) and was made of Teflon with a brass envelope in which quartz windows were mounted for an angle of incidence of 65°. A Teflon lid with a central hole for the electrode holder was clamped to an X-Y-Z micrometer positioner attached to the ellipsometer base. The flat surface Teflon electrode holder was attached to a glass tube passing through the lid's central hole, thus allowing rotation around the optical axis.

The *in situ* abrasion unit attached to the optical-electrochemical cell is shown schematically in Fig. 1. A shaft (made of steel with a front Kel-F part) was rotated by an a-c motor at a speed of 300 rpm, as determined by the radius of the large transmission wheel. A linear motion bearing at the center of the large wheel allowed the free linear motion of the shaft along its axis. The rotating shaft (front Kel-F part)

entered the electrochemical-optical cell through a Teflon bearing (braided Teflon permeated with Kel-F oil) and carried on its end the polishing head. To produce an efficient and durable polishing head, which allowed numerous consecutive efficient abrasions before replacement while leaving specularly reflecting metal substrates and clear solutions, a 3μ diamond paste (Struers Scientific Instruments) was applied to a suitable polishing cloth (Struers DP cloth Type DUR) and thermally treated (1-2 hr at 100°C). The thermal treatment left the diamond powder embedded in the cloth and active for 20-50 consecutive abrasions of Ti electrodes. This impregnated cloth was glued by silicon rubber cement to a silicon rubber support casted in a Kel-F hollow cone. The threaded apex of this conical "cushion" holder could be connected to the rotating shaft and, thus, the whole polishing head easily replaced without misalignment.

While rotating the shaft, the polishing head could be pressed against the metal electrode sample, applying a controllable pressure by means of an electroproportional solenoid. After the completion of the abrasion the polishing head could be quickly retracted by applying a strong knock to the rotating shaft along its axis by means of a fast solenoid. To allow the fast retraction, the electroproportional solenoid was switched off simultaneously, the "on" and "off" commands to the pair of solenoids being appropriately synchronized by an electronic unit. By using this approach for retracting the rotating shaft, the optical path was found to be completely cleared within 0.5 msec after the termination of polishing. Thus optical readings of film growth on exposed metal surfaces could be taken in the millisecond time scale. The possibility of following such early stages of film growth is significant (2), and the resulting advantages of faster retraction will be demonstrated in a forthcoming contribution.

The Ti specimens were prepared by cutting disks 6 mm in diameter from Ti rods (99.7% pure, Ventron, Alfa Products, Beverly, Massachusetts) and were mounted by pressure in a Teflon holder exposing a single surface to the solution. Samples within the holder were mechanically polished prior to the electrochemical experiments with silicon-carbide paper grades 300 and 600 followed by diamond paste size 15 and 3μ successively, using ethanol as lubricant. After polishing the samples were immersed in sulfochromic acid solution and then thoroughly rinsed and soaked in an ultrasonic triply distilled water bath. The working solution was 0.5M Na_2SO_4 with pH adjusted to 1.7 with H_2SO_4. A commercial saturated calomel electrode with a sealed porous glass bridge served as a reference electrode. The assembled cell, containing the mounted sample but without solution and windows, served for the alignment procedure according to McCrackin *et al.* (4). Allowance was made for window birefringence.

Samples were abraded in the cell under controlled potential, preselected as described in the next section. Δ and Ψ null readings were taken when the current, under potentiostatic conditions, has attained a steady state. Continuous changes in the reflectivity were recorded in linear potential scanning experiments by monitoring the exit beam intensity with the ellipsometer set at P = A = 0° or P = A = 90° for variations in reflectance at parallel and perpendicular polarization, respectively. Continuous variations of Δ were recorded in such experiments as off-null intensity transients. The off-null settings of the ellipsometer were selected according to the criteria described elsewhere (5), but the variations of Δ followed in this work were too large to allow a perfectly linear dependence of $\delta I_{\rm refl.}$ on $\delta\Delta$ at constant off-null settings. Further calibrations of such off-null intensity curves were, therefore, performed by separate constant voltage growth experiments, in which the same off-null settings were used. Changes of the exit beam intensity due to the application of several constant anodic voltages were fitted to the shifts of Δ measured at the same applied voltages by the regular method of nulling. This fitting yielded the required (slightly nonlinear) $\delta\Delta$ *vs.* $\delta I_{\rm refl.}$ curve, which is suitable for the specific film/substrate system under the off-null settings employed. (The growth of films with identical optical properties in constant voltage and in linear scanning experiments is assumed in such a calibration.) The convention: $\hat{n} = n - ik$ will be used throughout for the presentation of the complex refractive index.

Results and Discussion

Ellipsometric and reflectometric measurements of oxide film growth on titanium.—The initial state of the "film free" Ti surface.—The nature of the "clean Ti surface," left in contact with an acid solution following the abrasion *in situ*, was first examined. Figure 2 shows the current-potential curve recorded while the abrasion of a Ti electrode immersed in an acidic Na_2SO_4 solution (pH adjusted to 1.7 with H_2SO_4) was taking place. The corrosion potential, V_c, is identified as the potential at which zero net current is observed for the fresh exposed Ti surface. According to previous reports (6, 7), the net current in the whole region shown in Fig. 2 is expected to be the sum of partial cathodic and anodic currents. The cathodic processes involved may be H_2 evolution and Ti hydride formation (8), while the anodic processes are the electrooxidation of Ti to some soluble products and to the surface oxide. The overlap of the oxide and hydride stability regions (7) means that, in principle, it should be impossible to obtain at equilibrium in solution a Ti surface which is perfectly free of any adsorbed (or absorbed) species by a combination of abrasion and cathodic polarization. However, for the wavelength employed (5460Å) the optical effects due to the H surface layer could be shown to be negligible in the potential range covered. For the polished Ti surface no significant change in any optical parameter could be detected as the voltage was scanned between V_c and the cathodic limit set by the beginning of H_2 evolution. (Onset of gas evolution could be identified optically by very unstable readings due to the bubbles formed in the light path.) The optical effects caused by adsorbed H layers on other metals in the visible

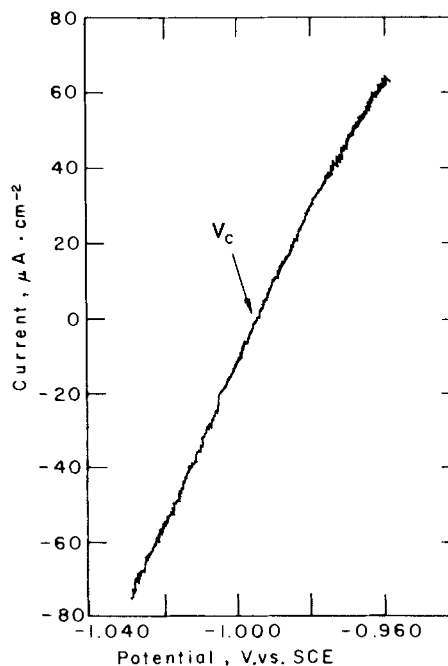

Fig. 2. Current-voltage curve for a Ti electrode taken during mechanical polishing *in situ*. Solution: 0.5M Na_2SO_4, 0.075M H_2SO_4 (pH = 1.65).

region are already known to be at least an order of magnitude smaller than the effects due to similar coverages of oxygen (9). It was thus concluded that, as far as the optical reference state is concerned, the existence of some form of H coverage prior to oxide formation had probably a very minor influence at 5460Å. [Stronger optical effects due to H ad- or absorption may be obtained at shorter wavelengths (10).]

Abrasion under cathodic polarization seems, according to these results, to produce a Ti surface which is quite suitable to serve as the reference "film-free" substrate. The apparent optical properties of such substrates were measured ellipsometrically, taking null readings for abraded Ti electrode surfaces, which, following abrasion, were kept at potentials between V_c and the H_2 evolution region. The results obtained at 5460Å were: $n_{Ti} = 2.7\text{-}2.8$; $k_{Ti} = 3.20\text{-}3.25$.

The large scatter in the results reported in the literature for $\hat{n}_{Ti}$ has been discussed by Smith (11). The last author obtained at 5460Å for a mechanically polished polycrystalline Ti sample which was carefully cleaned in vacuum: $n_{Ti} = 3.1$; $k_{Ti} = 3.4$.

The fit between the results for Ti surfaces as obtained by abrasion *in situ* and those given by Smith for samples cleaned in vacuum is not perfect, but the deviation is not large when compared with the scatter found in some sets of experimental data for "clean metal substrates" quoted in the literature. This order of deviation is most probably a result of a slightly different "damaged layer" which is left on the metal surface in each of the cases, as a result of mechanical polishing, although a residual H or O coverage cannot be completely ruled out. In some cases mechanical polishing outside the cell prior to the optical measurements left a relatively rough surface, which could not be improved by abrasion *in situ* with cathodic applied potentials. This was manifested by the value of Δ_0, measured at -0.9V following abrasion, being several degrees lower than usual. In such cases, it was found that abrasion under anodic applied potentials (0.0V) had a favorable effect, apparently caused by the electropolishing of the exposed metal surface under the positive applied potential. Following such a treatment the smoothed surface exhibited the higher regular Δ values at -0.9V.

Electrochemical and optical results recorded during film growth.—The combination of ellipsometric and reflectometric measurements was shown in previous contributions to constitute an effective tool for following the growth and evaluating the properties of thin films (12). Figure 3 shows the dependence on potential of the current and of three optical parameters Δ, $R_{||}$, and $R_{\perp}$, for a Ti electrode to which a triangular potential scan was applied following abrasion *in situ*. (The most reproducible optical and electrochemical results, as well as simple and regular growth kinetics, were obtained when such continuous linear changes of the potential were employed.) The continuous recording of the changes in Δ was performed with off-null settings of the ellipsometer. The pair of symmetrical intensity transients obtained at two symmetrical off-null settings [curves a and b in Fig. 3 indicate that transients thus recorded closely approximate the variation of Δ as a function of applied potential (5).] Any deviation from linearity in the dependence of $\delta I_{refl.}$ was further corrected, however, prior to the computer analysis, according to the procedure described above (see Experimental). In the anodic branch of the current cycle a "dissolution peak" is first observed, followed by a region of film growth in which the current is practically constant during the linear potential scan. The beginning of the change in optical properties can be observed to occur at the foot of the "dissolution peak," as the net current becomes positive. In the constant current range all three optical parameters seem to change linearly with applied potential. For the thin

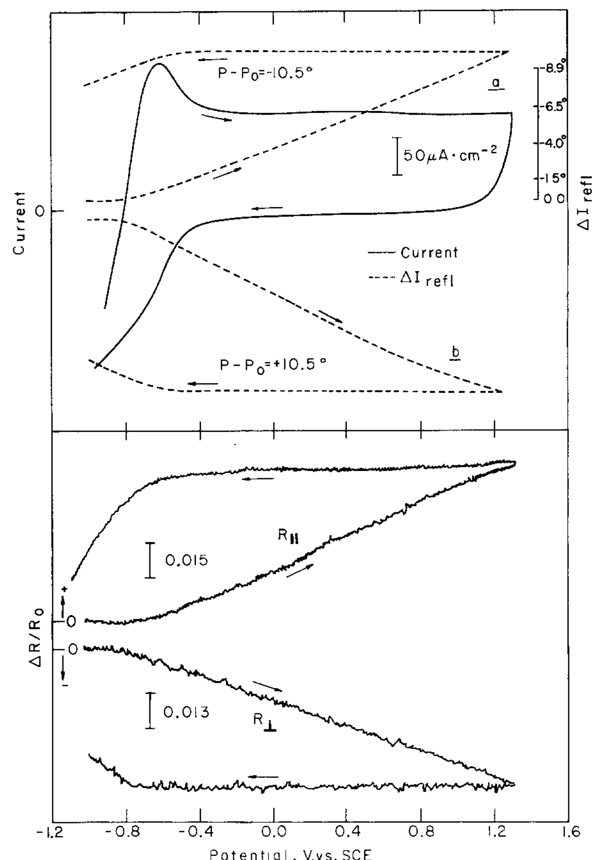

Fig. 3. Current-voltage curve and the associated optical changes recorded during oxide film growth and its subsequent reduction in a triangular potential scanning experiment: a and b, light intensity changes recorded at two symmetrical off-null settings: the scale in the upper right-hand corner shows the calibration of curve a in terms of changes in Δ (see Experimental). Solution as in Fig. 2; scan rate, 15 mV sec^{-1}; $\lambda = 5460$Å.

films involved, this immediately proves the linear dependence of thickness on applied potential, and, more significantly, it proves the growth of a film with practically uniform properties in the potential range covered in this figure. As shown in some previous contributions on combined ellipsometric-reflectometric measurements (12), if the optical properties of such a film change with thickness this would cause appreciable changes in the ratio $\delta\Delta/(\delta R/R)$, which were not observed here in practice.

In the cathodic half-cycle very low currents were recorded and no change in the optical properties of the film-covered Ti surface could be observed until a potential of ~ -0.5V was reached (see Fig. 3). A cathodic current then started to develop and was accompanied by appreciable changes in the thickness and properties of the oxide. These changes are discussed later.

Analysis of the optical properties of the film.—Two approaches were attempted in the analysis of the optical properties for thin films produced on Ti in the potential region -0.9 to $+1.5$V in the acidic solutions employed. In the first approach (method 1) it was assumed that the Ti surface kept under cathodic polarization following abrasion *in situ* is indeed a perfect film-free substrate and may be, therefore, taken as an ideal optical reference state for film growth. Results of combined ellipsometric and reflectometric measurements taken at different potentials were fitted to a uniform film growth model by a minimization computer program (13). A minimum for the function

$$F = \Sigma \{ (\delta\Delta_{meas} - \delta\Delta_{calc})^2 + (\delta\Psi_{meas} - \delta\Psi_{calc})^2 + [(\delta R/R)_{||, meas} - (\delta R/R)_{||, calc}]^2 + [(\delta R/R)_{\perp, meas} - (\delta R/R)_{\perp, calc}]^2 \} \quad [1]$$

was searched, assuming that a film-free Ti surface, with optical properties calculated according to the Δ_0 and Ψ_0 readings following abrasion, indeed existed at -0.9V.

Another computational approach (method 2) was also tested, the use of which allowed the avoidance of the rigid assumption of a perfectly film-free surface in the initial state. If it was assumed, rather, that an initial very thin film did exist on the surface following abrasion (and prior to anodization), the parameters of the substrate became two additional unknowns. These could be solved, however, if it was further assumed that the optical properties of the "initial film" resembled those of the film grown by anodization. (This approach is capable, in principle, of avoiding the complications when the buildup of some surface film is very fast at any applied potential following abrasion, *i.e.*, due to the overlap of oxide and hydride stability regions, thus making the state of a perfectly clean substrate unachievable.) A total $4 + j$ unknowns: n_{metal}, k_{metal}, n_{film}, k_{film}, and j thicknesses including that of the initial film, could be solved according to the ellipsometric and reflectometric readings taken at each point during anodization, using the same minimization computer program (13). Since for thin films such as those investigated here an interplay between the optical properties of substrates and film may yield different local minima, the (Δ_0, Ψ_0) readings taken at -0.9V were always used for the initial guess of the metal's properties in such a search for a minimum of F.

Both isotropic and nonisotropic uniform film models were tested. In the nonisotropic model different values were assumed for n_{film} in the direction normal to the surface, $(n_f)_n$, and parallel to it, $(n_f)_t$, with the same k_f in both directions. Results of the computer analysis based on a growth experiment extending up to 1.5V are summarized in Table I. It can be seen that method 2 of computation generated a better fit, *i.e.*, that solving the substrate is to be preferred to an assumption of film-free surface at any potential. It also shows that an absorption coefficient slightly different than zero in an isotropic film could be "traded-off" for a slightly anisotropic but transparent film. The refractive index evaluated is similar to that reported recently for much thicker anodic oxide films on Ti, the structure of which was shown to be that of crystalline anatase (40).

Figure 4 demonstrates the fit between the solution obtained for the single isotropic film model and the experimental optical results of another growth experiment conducted with a series of constant applied voltages. The curves in Fig. 4 which gave the best fit were due to the following optical properties of substrate and film: $n_{Ti} = 2.80$; $k_{Ti} = 3.25$; $n_{oxide} = 2.43$; $k_{oxide} = 0.0$. Some difference in the properties of the film as a function of the method of growth (linear potential scanning or large potential steps) can be seen to occur.

Since metal dissolution may have occurred to a small extent during the anodic scans employed (see current peak in Fig. 3), changes in the morphology of the metal substrate which could affect the optical parameters were possible in principle. The results obtained revealed, however, that film growth was not accompanied by appreciable changes in the optical properties of the Ti substrate surface under the experimental

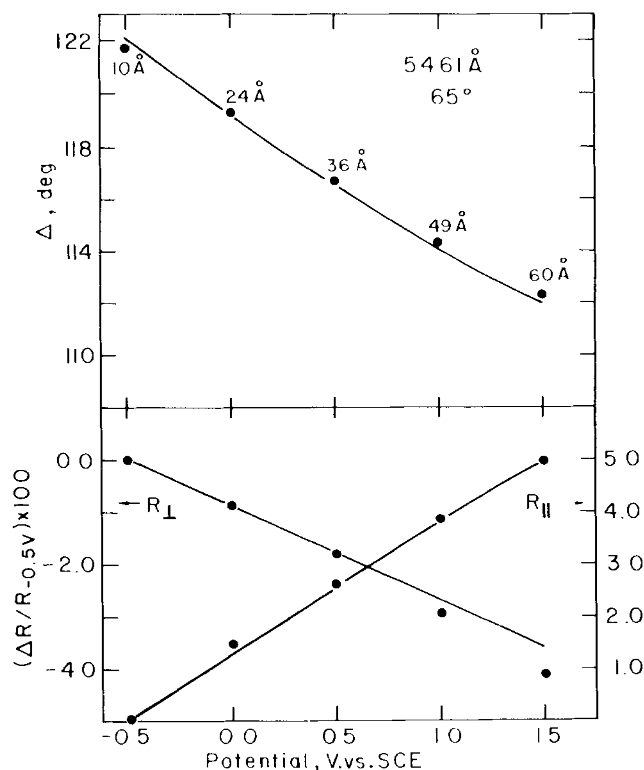

Fig. 4. Experimental and calculated optical changes during film growth. Points = experimental readings, solid lines = the computer solution for a single isotropic film model fitted according to all the optical measurements, with $\hat{n}_{film} = 2.43-0.0i$, $\hat{n}_{Ti} = 2.80-3.25i$.

conditions described above. Smoothing of the surface, which is to be expected when metal dissolution occurs simultaneously with oxide growth, should have brought about an increase of both $R_{||}$ and $R_{\perp}$, while in fact $R_{\perp}$ was found to decrease regularly (see Fig. 3). Any other type of a significant change in the optical properties of the metal substrate during anodization should have caused severe difficulties in the fitting of results of combined ellipsometric and reflectometric measurements to a model of single uniform film growth. Thus it seems that, under the experimental conditions employed, the optical effects must have been almost exclusively determined by the process of oxide growth, the contribution from a simultaneous limited metal dissolution process being minor.

The analysis of the optical results as presented above shows that "as-grown" thin TiO_2 films are found to be uniform and to have optical properties close to those of much thicker TiO_2 layers (1, 14, 40). Deviation of the electrochemical behavior of such thin films from that of bulk TiO_2 samples must be traced, therefore, to the sole effect of thickness. This is true provided, however, that the film has not undergone any further treatment following its growth (see below).

** X = measured parameter; X' = calc parameter; σ = experimental precision.

Evaluation of some physical properties of the thin films and kinetic parameters related to their growth according to the combined electrochemical and optical results.—For a mechanism of ionic migration under a high field, the current due to oxide growth depends on the field strength inside the film through Eq. [2], the theoretical foundation of which was given by Verwey (15) and Mott and Cabrera (16)

$$i = A \exp(\beta E) \quad [2]$$

where A and β are constants characteristic of the film, and E is the electrical field within the film. The parameters A and β could be solved according to the combined electrochemical and optical results obtained in linear scan experiments in the constant current region. Since in this region both the current and the growth rate (determined optically) were found to be constant, it could be safely assumed that the current efficiency for oxide growth was practically 100%. Furthermore, according to Vetter (17) a constant current implies no change in the potential drop across the oxide-electrolyte interface, and, hence, the total change of V apparently falls across the film. Therefore, in the region of constant current obtained in the linear potential scan experiments, the field across the film is given by

$$E = \frac{\Delta V}{\Delta e} = \frac{(dv/dt)\Delta t}{\int kidt} = \frac{(dv/dt)\Delta t}{ki\int dt} = \frac{dv/dt}{ki} \quad [3]$$

where dv/dt is the scan rate and k is the factor relating charge density to film thickness. The value of k could be easily determined according to film thicknesses obtained and the corresponding measured anodic charges. (Since uniform film growth was established optically, this implied a constant k, and, therefore, it could be taken, together with the constant measured current i outside the integral which appears in the denominator.) The final form of Eq. [3] implies that growth actually occurs under constant field conditions in the region in question, and Eq. [2] becomes

$$i = A \exp\left(\beta \frac{dv/dt}{ki}\right) \quad [4]$$

and a plot of ln i *vs.* $[(dv/dt)/i]$ gives β/k as the slope. Having determined k, β can be thus evaluated and A is computed next from Eq. [4]. Growth under constant field conditions could also be confirmed by some complementary constant current experiments shown in Fig. 5 in which the practically linear change with

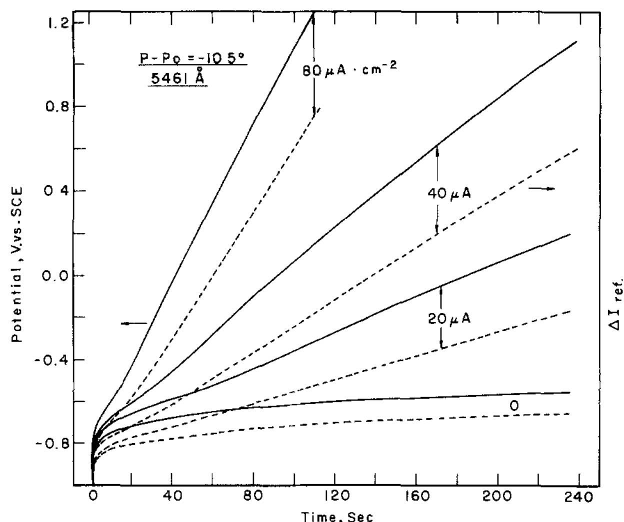

Fig. 5. Changes of the potential and of the light intensity under off-null settings in galvanostatic experiments of oxide growth on Ti (solution as in Fig. 2). The value of constant current applied in each case is designated in the figure.

time of both potential and thickness testify to this behavior. If k is known, two properties of the films grown may be further estimated: the density and the thickness of a monolayer

$$d \text{ monolayer} = kQ \text{ monolayer} \quad [5]$$

$$\rho \text{ film} = \frac{M}{n\mathrm{F}k} \quad [6]$$

where M is the molecular weight assumed for the surface compound (the value for TiO_2 was used) and Q monolayer may be taken as 880 μCb (4e process per Ti atom). The kinetic and physical parameters calculated from our measurements in thin oxide films may be compared to values given in the literature for thicker TiO_2 films, according to Table II.

Capacity measurements and the dielectric constant of the film.—Combined impedance and (optical) thickness measurements yield the dielectric constant of the film. Assuming that the admittance of the interface is due to the oxide film alone (*i.e.*, that the capacity of the Helmholz layer is much larger), it is given by

$$Z^{-1} = \omega\epsilon''\epsilon_0/d + i\,\omega\epsilon'\epsilon_0/d \quad [7]$$

where d is film thickness, ω is the angular frequency, ϵ', ϵ'' are the real and imaginary parts of the complex dielectric constant, and ϵ_0 the permittivity of free space. For a parallel circuit presentation

$$Z^{-1} = R_p^{-1} + i\,\omega\,C_p \quad [8]$$

hence

$$C_p = \epsilon'\epsilon_0/d \quad [9]$$

and a linear dependence of $1/C_p$ on d is expected.

C_p was determined for different stages of film growth as $(1/\omega)I_m(Z^{-1})$. A lock-in amplifier equipped with a phase-sensitive detector was used for this measurement to determine the component of the current at 90°C to the (10 mV ptp) sinusoidal voltage perturbation. The plot of $1/C$ *vs.* d (where d was found from the optical measurements) is given in Fig. 6. The linear dependence obtained is quite satisfactory, lending support to the optically evaluated thicknesses. It could be shown (Fig. 6) that $1/C_p$ was dependent on ω even at such low frequencies, which meant that the measured $\epsilon'(\omega)$ was somewhat lower than the static dielectric constant, due to some very slow dielectric relaxation processes in the film. The measured slope at ω = 100 Hz (Fig. 6) gave: ϵ' = 47. This value is inside the range quoted earlier for thicker TiO_2 films (1).

Electron transfer through the TiO_2 film.—Since it is not expected that thin films of TiO_2 such as those analyzed in this work should exhibit electron transfer properties identical with those of much thicker semiconductor (SC) films, and since the ease of electron transfer through the film may be an important condition for the interaction of the (TiO_2 covered) Ti metal with different oxidizing or reducing components of the electrolyte, possible deviations from the behavior predicted for thicker TiO_2 layers seemed worth looking into.

Rectification properties of thick anodic oxide films were observed long ago (20). While oxidation reactions appear to be inhibited by the oxide, H_2 evolution as well as some other reductions were found to proceed through the film (21, 22). The essential requirement for charge transfer between various redox sys-

tems in solution and the bands of a thick SC electrode is the energetic overlap between the SC bands at the surface and the so-called "Fermi level in solution" [which, to a first approximation, coincides with the standard redox potential of the relevant couple in solution (23)]. The energetic overlap condition and the magnitude of the potential gradient in the Helmholtz layer are expected to determine together the characteristics of thick n-type SC-aqueous electrolyte systems, which are expected to exhibit the following behavior (24): (*i*) Redox couples with standard potentials more negative than the flatband potential (FBP) should be able to exchange electrons with the conduction band of the SC in both directions, under small applied overvoltages. [The FBP nearly coincides with the energetic location of the SC conduction band relative to the reference electrode used (25).] (*ii*) Redox couples with nobler standard potentials (*i.e.*, energetically located within the SC bandgap) should not be able to exchange electrons with a n-type SC unless potentials more negative than the FBP are imposed, at which a cathodic process may occur. No anodic process is expected, however, for the last type of redox systems at a thick n-type SC electrode.

All the above-mentioned arguments have been put forward and shown to apply for thick n-type SC electrodes (26), including n-TiO_2 (27) [diagrams of electron energy levels in TiO_2 and in various redox couples in solution are given in Ref. (27)]. From recent measurements the value of the FBP has been evaluated for the single crystal TiO_2 as -0.3 ± 0.1V *vs.* SCE (28) and may be assumed as a first approximation to apply to the TiO_2 films dealt with here as well.

It was found in this work that any species which is known to be reducible at a gold or Pt electrode could be reduced also through the thin oxide films grown on the Ti electrodes (by the injection of electrons from the conduction band of the SC). Since this can be achieved only at electrode potentials more nega-

tive than the FBP, an "overvoltage" for such reactions was always found for systems with standard redox potentials more positive than -0.3V *vs.* SCE. This behavior, as presented for the reduction of $Fe(CN)_6^{-3}$ in Fig. 7 was found to be independent of film thickness for $d > 20$Å, and is consistent with the general behavior of bulk n-TiO_2 electrodes. It could also be shown that a couple such as Cd/Cd^{+2}, with a standard redox potential of -0.75V (more negative than the FBP), indeed exhibited both the reduction and oxidation current peaks at the TiO_2 film electrode, while cupric and silver ions (E° of 0.05 and 0.34V, respectively) were reduced at the Ti/TiO_2 electrode but the corresponding metals were not oxidized (Fig. 8).

Deviations from the regular behavior predicted for thick SC electrodes were also found, however, as presented for example by the oxidation of I^- ($E°_{I^-/I_2}$ = 0.5) in Fig. 9. Such oxidations were found to take place through the thin TiO_2 films, although they were shifted to higher anodic potentials with the increase of film thickness. Similar behavior was also found for oxidations of the $Fe(CN)_6^{-2}$ ion and of hydroquinone, both of which are not expected to undergo oxidation at thick TiO_2 electrodes. The effect of film thickness has an important role in such charge transfer processes, which apparently do not involve an electron transfer to the conduction bandedge, but rather the tunneling of an electron through the thin film to the Ti substrate. Such effects were observed before at highly doped SC electrodes with a narrow space charge region (29). It seems, therefore, that the oxidation of Ti_{aq}^{+3} at a TiO_2 (thin film) covered Ti electrode (30), which was shown to have a possible role in the self-repair mechanism of Ti, is not unique, and other oxidations may also take place through such thin TiO_2 films, although they are not expected to occur at thicker TiO_2 layers.

Oxide film reduction.—Recent contributions have dealt with changes in the optical properties of oxide films on metal electrodes, such as W (31), Mo (32), V (33), Ni (34), and Ir (35), which can be induced by modulation of the electrode potential. Such changes in the apparent optical properties indicate some changes in composition and structure of the oxide which may have a significant bearing on its electrochemical characteristics, including, possibly, its corrosion resistance (33). Figure 3 reveals that as the potential of the Ti electrode covered by an anodically grown TiO_2 film is scanned in the negative direction a reduction current appears at ~ −0.5V and the optical parameters start to change. The negative change of $R_{||}$ (the reflectivity at parallel polarization) associated with the cathodic current is found to be more pronounced than the changes of either Δ or $R_{\perp}$. This testifies to an increase of light absorption in the film as one of the results of the cathodic process, since oxide dissolution alone should return all the parameters evenly toward their original values while the increase of κ_{film} is expected to affect more strongly the value of $R_{||}$. The current recorded during a second anodic sweep, following the cathodic process (Fig. 10), shows, however, that reductive dissolution does occur to some extent: The current in the second anodic sweep is quite small at first, rising steeply at some voltage which is found to depend on the potential and duration of the cathodic treatment. This shows that the film has reached a smaller thickness by cathodic dissolution. As the voltage corresponding to that thickness is passed in the next anodic sweep, the field strength in the film exceeds the value required for renewed growth, resulting in the sudden increase of the anodic current.

In order to characterize completely the changes in the optical constants of the film caused by the reductive process, oxide films were grown at steady applied potentials of 3.0 or 4.0V, then reduced at −0.9V, further reduced at −1.2V, and at the end the electrode returned to the original anodic growth potential. The film's optical constants and thicknesses at each potential were determined according to the measured changes of the pair of ellipsometric and pair of reflectometric parameters. Table III illustrates results of two experiments of this kind. At −0.9V an increase of the refractive index is observed and at the more cathodic potential of −1.2V a significant increase in the absorption coefficient occurs. As may be seen, the reduction is also accompanied by some film dissolution.

Thermal reduction of TiO_2 (films or single crystals) by hydrogen has been reported to convert the TiO_2 from intrinsic to n-type semiconductors. This was explained by partial reduction of the TiO_2 to form a nonstoichiometric compound ("n-type TiO_2") in which the excess of Ti atoms acts as electron donors to the conduction band. The same effect was obtained by heating a vapor-deposited TiO_2 film in vacuum (36). On the other hand, the annealing of vapor-deposited TiO_2 in air was shown to increase its refractive index and specific gravity (14). This was explained by the conversion of the film from polycrystalline to the crystalline rutile form. It seems that electrochemical reduction of the oxide causes the same apparent changes as those which result from a combination of heat-treatment and thermal reduction.

The electrochemical reduction of the oxide and the associated increase in light absorption may most probably be explained in terms of a double-injection mechanism, such as that suggested by Faughnan, Crandall, and Heyman (31) to explain the electrochromism of WO_3:H^+ ions are injected into the oxide

from the aqueous solution and electrons from the metal. Thus H atoms are introduced into the oxide and are probably bound to $O^{=}$ ions to form OH groups. Such incorporated H atoms lower the valence of some of the Ti ions to +3. The mixed valence oxide formed may exhibit either an intervalence transfer absorption or free carrier absorption, depending on the extent of the delocalization of the electrons due to the incorporated H atoms (31).

Figure 11 shows that electroreduction of the TiO_2 film resulted in a significant increase of its activity in the photooxidation of water (36). This result is quite understandable, since the increase in defect concentration as well as in the number of conduction electrons, both of which may cause the recorded increase of κ_f, is believed to assist in the photooxidation process (28, 37). It has to be noticed, however, that the anodic photocurrent obtained following film reduction is quite low for potentials smaller than 0.3V: curve b in Fig. 11 has a sigmoidal shape rather than increase quite steeply from 0.0V (38). This behavior depends on the applied potential and duration of the oxide film reduction and is probably associated with excessive trapping of photocarriers, as described in more detail elsewhere (39).

Anodic Polarization Behavior of Fe-Cr Surface Alloys Formed by Ion Implantation

B. S. Covino, Jr.,* B. D. Sartwell, and P. B. Needham, Jr.

Bureau of Mines, U.S. Department of the Interior, College Park Metallurgy Research Center, College Park, Maryland 20740

ABSTRACT

A new class of alloys has been fabricated by implantation of 25 keV chromium ions into the surface regions of iron in doses ranging from 1.0×10^{16} to 4.0×10^{16} Cr atoms/cm^2. The aqueous corrosion characteristics of these "surface alloys" have been studied under conditions of anodic polarization at 30°C in a helium-deaerated, sodium borate-buffered boric acid solution at a pH of 8.5 containing 2400 ppm Cl^-. The active-and passive-region corrosion characteristics are shown to be comparable to those of nominally equivalent standard bulk alloys. In addition, the electrochemical properties of one of the Fe-Cr surface alloys are compared with those obtained for the equivalent Fe-Ni surface alloy, and the results are interpreted as indicating that these corrosion characteristics are not due to defect production during implantation.

The formation of alloyed regions near the surfaces of metals using ion implantation is being investigated by the Bureau of Mines as a means of providing corrosion resistance while realizing a substantial reduction in the consumption of expensive alloying materials that are in limited supply (1). To date, these "surface alloys" have been fabricated by implanting chromium, nickel, aluminum, and cadmium ions into iron and by implanting aluminum ions into titanium. The concentrations of the alloy elements in the surface region have ranged from 3 to 30 atomic percent (a/o). These surface alloys have been tested for gaseous, electrochemical, and galvanic corrosion characteristics.

The surface alloys described in this paper were fabricated by implantation of the desired total implant dose, D, of 25 keV chromium ions into polycrystalline iron targets. In order to facilitate comparison of the anodic polarization characteristics of the implanted samples to those of standard bulk alloys, we have designated the surface alloys by the average chromium implant concentration a/o over the depth, δ (cm), containing 95% of the implanted chromium. The chromium depth distributions were determined experimentally using proton-excited x-ray analysis (PEX) coupled with argon-ion sputtering. From these distributions, δ was determined and the surface-alloy designation was calculated from N (atoms/cm^3) $= D/\delta$ and written as Fe-X(s)Cr where $X(a/o) = (N/8.5 \times 10^{22}) \times 10^2$ for iron.

Reported in this paper are anodic polarization results comparing the corrosion resistance of Fe-6(s)Cr, Fe-10(s)Cr, and Fe-19(s)Cr surface alloys with Fe, Fe-5%Cr, Fe-12%Cr, and Fe-18%Cr bulk alloys. The corresponding measured total ion doses for these surface alloys were 1.25×10^{16}, 2.20×10^{16}, and 4.0×10^{16} ions/cm^2, respectively. In addition, in order to make a preliminary determination as to whether the observed electrochemical corrosion characteristics were due to the formation of an alloy structure or to the production of radiation damage-type defects during the implantation process, the polarization characteristics of an Fe-Cr surface alloy are compared with those for an Fe-Ni surface alloy.

Experimental Techniques

The surfaces of the iron samples used in the fabrication of the surface alloys and the surfaces of the iron and iron-chromium bulk alloys used for anodic polarization studies were prepared using identical techniques. Each sample was cut from a high purity (99.95%) 1.5 mm thick sheet, polished through 600 grit paper, stress relieved at 600°C for 2 hr in an argon atmosphere, and then water quenched to prevent grain boundary precipitation of carbon. The samples were then cleaned in a dilute solution of sulfuric acid, rinsed thoroughly in distilled water, electropolished in a 9:1 ratio of glacial acetic acid/70% perchloric acid, rinsed in 18 MΩ water, and dried in a stream of dry nitrogen. The iron samples intended for implantation were immediately transferred to the vacuum chamber. The iron-chromium alloy samples intended for anodic polarization were placed into the electrochemical cells within minutes of the electropolishing step.

The polycrystalline iron samples were implanted in a vacuum chamber that had a base pressure of 1.33×10^{-6} Pa. During implantation, the pressure was $<6.6 \times 10^{-5}$ Pa. Twelve 2.5 cm diam samples were mounted on a carousel that continuously rotated through the 1.3 cm diam ion beam during implantation, resulting in a laterally uniform implanted strip. The samples were maintained at +150V for suppression of secondary electrons, and the total number of ions implanted into the samples was determined by an integrating current digitizer. Following implantation, at least two of the twelve samples were analyzed for residual carbon, oxygen, and other surface impurities using PEX prior to both the profiling and the electrochemical studies.

The composition depth profiles of the surface alloys were obtained using a technique, designated PEX-IS, that combined PEX with 1 keV argon ion sputtering. The argon ions were incident at an angle of 30° with respect to the sample surface, and 180 keV protons were used to excite Cr-K x-rays from the chromium implant region. This profiling technique has been described in detail elsewhere (2).

The anodic polarization characteristics of the surface alloys and bulk alloys were studied using standard electrochemical cells (3) modified to permit maximum agitation of the solution in front of the working electrode. The solution was 0.15N boric acid (H_3BO_3) buffered to pH 8.5 with sodium borate ($Na_2B_4O_7 \cdot 10H_2O$) and containing 2400 ppm Cl^- (as NaCl). The solution, consisting of reagent-grade chemicals mixed with 18 MΩ water, was maintained at a temperature of 30°C. High purity helium was bubbled through the solution at a rate of 6 liters per min to deaerate the solution and to minimize, by agitation, the effects of diffusion on the anodic polarization results. The surface and bulk alloys were mounted in Lexan compression-type holders using Viton O-rings with only

Key words: ion implantation, anodic polarization, pitting potential, surface alloys, Fe-Cr.

0.8 cm^2 of the implant region exposed to the solution. The electrochemical parameters were measured using a Wenking 70TSI potentiostat, a Keithley 165 multimeter, and an X-Y recorder. Potentials were measured using a saturated calomel electrode/Luggin probe combination and are reported here *vs.* the normal hydrogen electrode (NHE).

The anodic polarization measurements were performed identically for iron, the bulk alloys, and the surface alloys. Prior to beginning the potential scan, the sample was cathodically reduced using the potentiostat in the galvanostatic mode. A cathodic current density of 5×10^{-4} A/cm^2 was used to reduce the air-formed oxide film on the metal surface. The sample was then allowed to achieve a steady-state open-circuit rest potential (E_R) for 10-15 min, following which the anodic polarization test was initiated at -100 mV with respect to E_R with the potential scanned at a rate of 10 mV/min.

Results

Prior to performing the anodic polarization measurements, representative surface alloy, bulk alloy, and electropolished iron samples were analyzed by PEX (1) to characterize the surface impurities. These measurements indicated that, for the electropolished iron and bulk alloys, the residual carbon coverage was approximately 1×10^{16} atoms/cm^2 (equivalent to about 9Å as graphite) and that the air-formed oxide film was less than 12Å thick.

After implantation, the surface alloys had residual carbon, silicon, and chlorine surface impurities as shown in Table I. These impurities were a result of neutrals drifting into the vacuum chamber from the ion source assembly in the ion-implantation system. The silicon originated in the silicon-based fluid used in the ion-implantation system oil diffusion pump. From the composition depth-profiling measurements, it was determined that about one-half of the measured carbon impurity concentration was actually distributed throughout the implant region, presumably due to recoil implantation of surface carbon atoms resulting from collisions with the incident ions. The chlorine and silicon, on the other hand, were found only on the sample surface.

Figure 1 shows the chromium implant profile obtained experimentally using PEX-IS for Fe-10(s)Cr ($D = 2.2 \times 10^{16}$ ions/cm^2) with the concentration plotted as a function of the sample depth in angstroms. The depth scale in angstroms was obtained by normalization of the experimental sputtering charge (*i.e.*, microcoulombs of incident argon ions) scale with an appropriate sputtering yield (4) for the sputtering of iron by 1.0 keV argon ions.

Figures 2-4 show the anodic polarization behavior of the Fe-6(s)Cr, Fe-10(s)Cr, and Fe-19(s)Cr alloys individually compared to all of the bulk metals and alloys. Each curve represents the average of six samples polarized at 10 mV/min. The electrochemical data presented in this report, relating surface alloys to bulk alloys, are interpreted under the boundary condition that an equivalent i_c means equivalent general corrosion resistance, an equivalent E_p means equivalent pitting corrosion resistance, and that these interpretations hold true only as long as the alloyed surface region remains intact. These three figures indicate that, in general, increasing the chromium content of both the surface and bulk alloys causes a decrease in the critical corrosion current, i_c, and shifts the pitting potential, E_p, toward more positive potentials. A comparison of Fe-6(s)Cr with Fe-5%Cr, Fig. 2, indicates that in the region generally attributed to anodic dissolution the alloys are quite similar electrochemically. The i_c's were identical, although the E_p for the Fe-5% Cr alloy was more positive. At

the potentials associated with the transpassive region, the electrochemical behavior of the Fe-6(s)Cr was quite similar to that of iron.

In Fig. 3 and 4 the implantation of chromium ions to a concentration greater than 6 a/o is shown to not only shift the crossover potential, E_o, in the positive direction but to completely eliminate the region of anodic dissolution. For metals exhibiting this type of behavior, we have taken E_p as being equivalent to E_o. Compared with the bulk Fe-Cr alloys the surface alloys appear to be more protective at potentials negative with respect to the E_o's of the surface alloys. In addition, the sharp rise in current density associated with the surface alloys is attributed to the rapid pitting of the thin surface alloyed region while the bulk alloys exhibit a wide, low current density passive region.

Both the Fe-10(s)Cr, Fig. 3, and Fe-19(s)Cr, Fig. 4, indicate the onset of pitting corrosion without a prior region of anodic dissolution. Both alloys exhibit a pitting potential more negative than that of the Fe-12%Cr bulk alloy, implying a lower resistance to pitting corrosion. As the polarization proceeded into the transpassive region, the Fe-19(s)Cr shows a dissolution rate many orders of magnitude higher than the Fe-18%Cr; at a potential of +0.5V *vs.* NHE, the Fe-19(s)Cr dissolution rate is significantly higher than even that of the Fe-12%Cr.

Several iron and surface alloy samples were anodically polarized to +0.30V and then removed from the electrochemical cells for analysis by scanning electron microscopy (SEM). Figure 5 shows the resulting SEM analyses of iron and an Fe-10(s)Cr alloy. For iron, the dissolution occurred over the entire surface, whereas the dissolution of the Fe-10(s)Cr occurred only as a result of pit nucleation and propagation at inclusions, defects, and grain boundaries. Using an x-ray attachment on the SEM, it was determined that the chromium concentration outside the pits was the same as that for an unpolarized sample. No chromium was detected inside the pits.

Discussion

In Fig. 1 we have compared the experimentally determined chromium depth profile for the implanted iron samples to that predicted by the theory of Lindard, Sharff, and Schiott (LSS) (5). In using the LSS theory we have made a slight modification in the method of calculation in order to include the effects of sputtering of the iron samples by the chromium ions during implantation (1). Although for the present case of chromium this tends to shift the predicted distribution somewhat closer to the surface than is observed experimentally, for the case of nickel the method resulted in excellent agreement (2). From the experimental profile, the depth δ required in the calculation of the surface alloy concentration was determined to be 250Å.

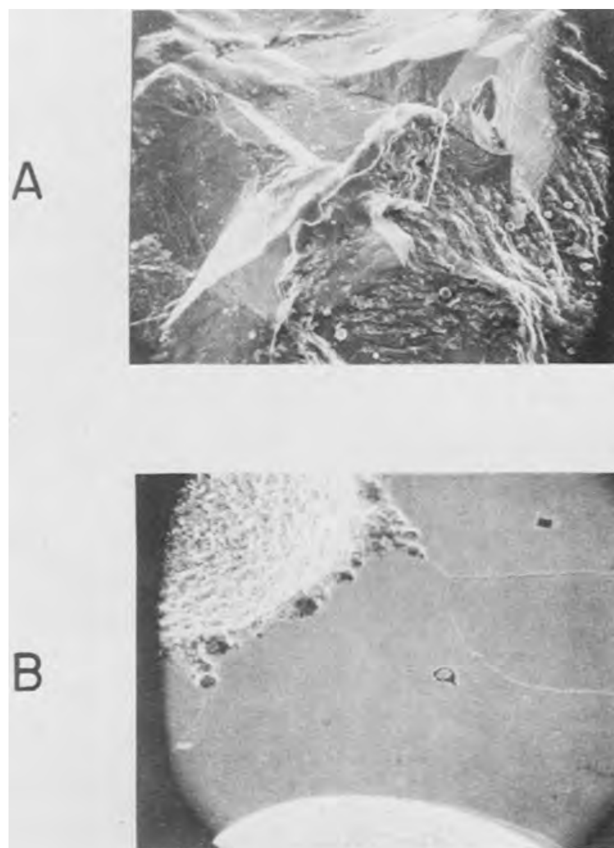

Fig. 5. SEM photomicrographs of (A) iron (magnification 600×) and (B) Fe-10(s)Cr alloy (magnification 1200×) polarized to +0.3V vs. NHE in a borate-buffered pH 8.5 solution with 2400 ppm Cl^- addition.

The polarization curves shown in Fig. 2 and 3 for the Fe-6(s)Cr and Fe-10(s)Cr alloys are shifted, with respect to iron, by an amount that is very close to that for the respective equivalent bulk alloy. The major difference is, as might be expected, their behavior in the high potential transpassive regions where dissolution resulting from pit nucleation at defects and grain boundaries has largely destroyed the nearby regions of the 250Å implant, with resulting dissolution kinetics approximating those of iron. The Fe-19(s)Cr is only slightly lower in pitting potential than the Fe-12%Cr, and the subsequent transpassive dissolution currents are substantially different than those of either Fe-12%Cr or Fe-18%Cr. The large difference between the pitting potential of Fe-19(s)Cr and Fe-18%Cr and the fact that the current density of Fe-19(s)Cr rises rapidly to that of pure iron indicate that the effect of the implanted chromium is, as might be expected, rapidly negated when the pits progress beyond the implanted region. Thus, in terms of pitting corrosion, the implanted chromium improves the resistance to pitting corrosion, but the amount of improvement cannot be directly correlated with nominally equivalent bulk alloy compositions. Since the definition used here for the surface-alloy concentration is somewhat arbitrary, caution must be exercised in making direct correlations between the observed corrosion characteristics for the surface and bulk alloys. From preliminary observations on the depth profiles, a more logical correlation may be between the amount of chromium in the first few tens of angstroms and the bulk alloy chromium concentration. The implication of such a correlation would be that substantially lower ion beam energies and smaller implant dosages would yield the same elec-

trochemical results as reported here. Such investigations are continuing.

In addition, the residual surface impurities present on the surface alloys should be taken into account in any interpretation of the anodic polarization results. The results presented here have indicated that the over-all corrosion resistance of the surface alloys increased with increasing chromium concentration. On the other hand, the quantities of the surface impurities were not a function of ion beam dose D, and, as shown in Table I, varied considerably for each type of surface alloy studied. It was concluded, therefore, that the corrosion resistances of the surface alloys were due principally to the effects of the implanted chromium and that the effects of the initial impurity coverages were at least minimal.

Finally, since other laboratories have demonstrated that corrosion behavior can be altered by radiation damage due to high rate, high dose ion implantation (6), it is desirable to determine whether the increased corrosion resistance obtained in these experiments was due to the formation of a specific alloy structure or was simply due to the production of defects caused by the collisions between the incoming ions and the lattice atoms. The ion current densities used in these studies have been kept below 500 nA/cm^2 to minimize the production of "dose-rate"-caused defects. Figure 6 compares anodic polarization data obtained for Fe-6(s)Cr to that obtained for Fe-6(s)Ni under identical electrochemical conditions. The Fe-6(s)Ni alloys were fabricated with 8.5×10^{15}, 25 keV Ni^+ $ions/cm^2$. If the shift in the effective pitting potential resulting from the implantation process was due to defect production, the Fe-6(s)Cr and Fe-6(s)Ni data would be expected to be essentially identical since defect production rates for Cr^+ and Ni^+ ions of the same energy are about the same (5). Clearly,

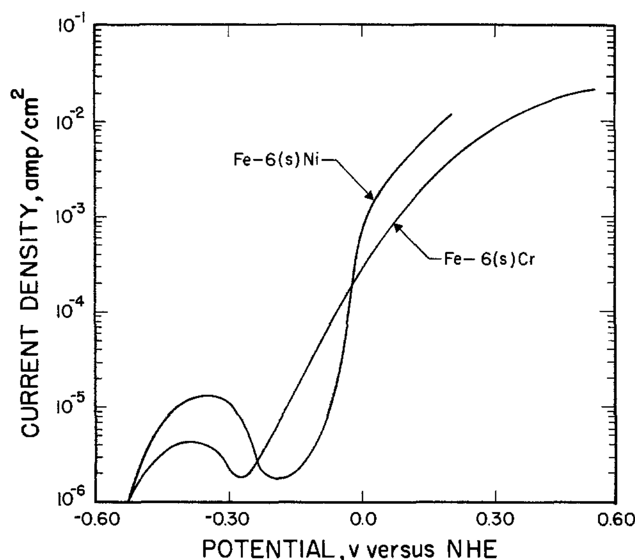

Fig. 6. Anodic polarization behavior (in a borate-buffered pH 8.5 solution with 2400 ppm Cl^- addition) of Fe-6(s)Cr compared to Fe-6(s)Ni.

the chromium and nickel surface alloys exhibit substantial differences in both the values of the i_c and E_p. We have attributed these differences to some, as yet undefined, alloy characteristics.

Summary

Surface alloys have been fabricated using the implantation of energetic chromium and nickel ions into the surface region of iron. The composition depth profiles of the Fe-Cr surface alloys have been compared to theoretical profiles modified to include sputtering of the iron during implantation.

Anodic polarization studies at 30°C in a borate-buffered boric acid solution (pH 8.5) containing 2400 ppm Cl^- to enhance pitting corrosion have demonstrated that electrochemical corrosion characteristics comparable to those of bulk Fe-Cr alloys are obtained through fabrication of Fe-Cr surface alloys. The mechanism of corrosion for the surface alloys was shown to be pit nucleation and propagation at crystal defects or grain boundaries, a result similar to that for bulk alloys. In the transpassive regions where pitting corrosion had largely destroyed the implant regions, however, the surface alloys, particularly the Fe-19(s)Cr, exhibited dissolution currents significantly higher than those of the equivalent nominal bulk alloys.

The results of a comparison of the anodic polarization behavior of Fe-6(s)Cr and Fe-6(s)Ni alloys have been interpreted as demonstrating that the improved corrosion characteristics obtained by surface alloying are due primarily to some unspecified alloy characteristics and are not due to the production of radiation damage-type defects.

Anodic Polarization Behavior of Fe-Ni Alloys Fabricated by Ion Implantation

B. S. Covino, Jr.,* P. B. Needham, Jr., and G. R. Conner*,[1]

Bureau of Mines, U.S. Department of the Interior, College Park Metallurgy Research Center, College Park, Maryland 20740

ABSTRACT

Surface alloys have been fabricated by implantation of 25 keV nickel ions into polycrystalline iron to doses ranging from 8.5×10^{15} to 3.4×10^{16} ions/cm^2. Their aqueous corrosion characteristics have been studied under conditions of anodic polarization at 30°C in a helium-deaerated sodium borate buffered boric acid solution (pH 8.5) containing 2400 ppm chloride ion. The pitting- and general-corrosion characteristics are comparable to nominally equivalent bulk commercial alloys and are superior to those of pure iron. A high strength maraging steel is shown to exhibit an increase in pitting-corrosion resistance due to the implantation of chromium ions.

Ensuring an adequate supply of critical materials such as nickel to meet national economic and strategic needs is a goal of the Bureau of Mines metallurgy research program. Ion implantation offers the potential of extending the usefulness of our supply of critical materials without sacrificing chemical or physical properties.

A group of iron-nickel alloys has been fabricated by the implantation of low energy metallic ions into the surface regions of polycrystalline iron. These alloys have been designated as surface (s) alloys (1) since the alloyed region extends only to a depth of 200Å below the iron surface. A potentiodynamic study of the characteristics of these alloys has been conducted in order to determine their characteristic critical current densities (i_c) and pitting potentials (E_p). These two parameters are an indication of the relative general- and pitting-corrosion resistances, respectively, and can be compared to equivalent parameters determined for commercial bulk alloys of known corrosion resistance. E_p is an operational parameter measured in an identical manner for all of the data reported here and is equivalent to the "critical breakdown potential" reported by other authors (2).

The surface alloys were prepared by implanting 25 keV nickel ions into 99.99% purity polycrystalline iron samples. The details of the technique have been extensively described elsewhere (3), and only a few brief remarks are made here. Prior to implantation, the iron surfaces were prepared using mechanical grinding, electropolishing, and high vacuum treatments that also have been described elsewhere (1, 4). The result of these surface preparations was a residual oxide coverage less than 10Å in thickness and a residual carbon surface impurity coverage of less than 1×10^{16} atoms/cm^2. The 25 keV nickel ions had a mean penetration depth of 38Å, and the final implant depth distribution was shown experimentally to be essentially Gaussian in character, with approximately 99% of the nickel located within the first 150Å (3). The surface alloy concentration has been defined, therefore, as the average concentration over this 150Å implant region. Implantation of nickel ions was used to fabricate surface alloys of 6 atom percent (a/o) (a dose of 8.50×10^{15} Ni^+ ions/cm^2), designated as Fe-6(s)Ni, and 25 a/o (a dose of 3.40×10^{16} Ni^+ ions/cm^2), designated as Fe-25(s)Ni. Tertiary surface alloys containing 15 a/o Ni (a dose of 2.05×10^{16} Ni^+ ions/cm^2) and 10 a/o Cr (a dose of 2.08×10^{16} Cr^+ ions/cm^2), designated as Fe-10(s)Cr-15(s)Ni, also were fabricated and studied. A commercial maraging steel, Vascomax 250 (V-250), was implanted with 25 keV chromium ions to a total dose of 2.08×10^{16} Cr^+ ions/cm^2. This resulted in an average concentration of 10 a/o chromium over the first 200Å.

The potentiodynamic polarization studies of both the surface and the bulk alloys were conducted in a high purity boric acid solution buffered to pH 8.5 with the addition of sodium tetraborate decahydrate and containing 2400 ppm Cl^- (as NaCl). The solutions were deaerated with helium, and the area in front of the electrode was rapidly stirred with the same gas to minimize the effects of diffusion on the polarization results. The polarization tests were conducted in standard 1-liter glass polarization cells that were cleaned with boiling HNO_3. The planar electrodes (test alloys) were mounted in an O-ring sealed Lexan electrode holder. The tests were conducted at 30°C with a polarization scan rate of 10 mV/min. The initial applied potential was −100 mV with respect to E_R, where E_R was the rest potential recorded after the electrode had stabilized following a cathodic reduction process. The electrode potential was maintained using a Wenking 70TSI potentiostat and was scanned with a Wenking VSG72 scan generator.

Results

The surface alloys, bulk alloys, and metals reported here were studied under identical electrochemical con-

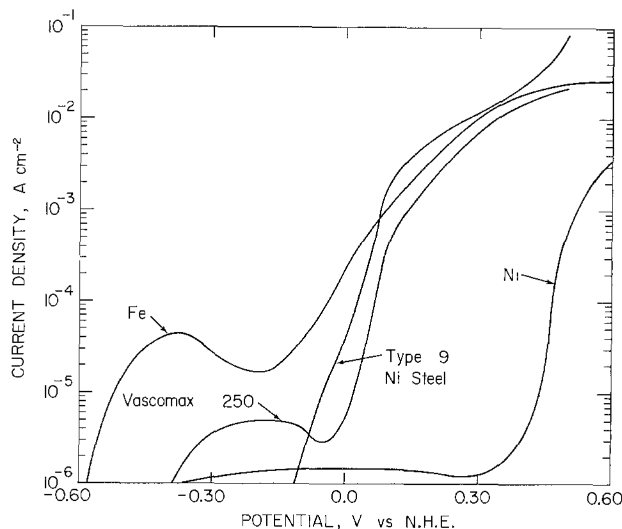

Fig. 1. Anodic polarization behavior (in a borate-buffered solution with 2400 ppm Cl^- addition) of polycrystalline iron and nickel and two commercial alloys.

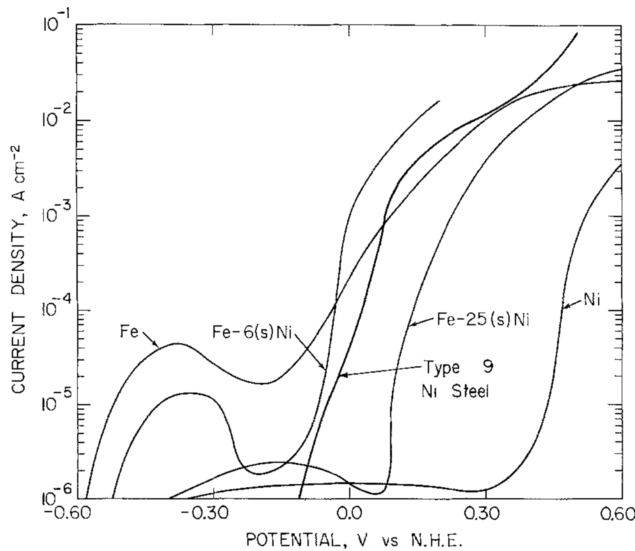

Fig. 2. Anodic polarization behavior (in a borate-buffered solution with 2400 ppm Cl$^-$ addition) of the surface alloys Fe-6(s)Ni and Fe-25(s)Ni compared with that for polycrystalline iron and nickel and one commercial alloy.

ditions. Figure 1 shows the results obtained for polycrystalline iron (99.99%), nickel (99.5%), V-250 (18% Ni), and Type 9 nickel steel (9% Ni) under these specific conditions. Each curve in this figure and in subsequent figures represents the average of a minimum of four tests. Figure 2 shows the results obtained for the Fe-6(s)Ni and Fe-25(s)Ni alloys compared with those obtained for pure iron, nickel, and Type 9 nickel steel. The electrochemical behavior of iron in a borate-buffered solution of pH 8.5 without the presence of Cl$^-$ indicates an i_c of 1-3 $\times$ 10^{-5} A/cm^2 with a definite passivation region extending from -0.20 to $+1.10$V *vs.* NHE (5, 6), the normal hydrogen reference electrode. The addition of 2400 ppm Cl$^-$ reduces the length of the passive region, increases i_c to 4.5 $\times$ 10^{-5} A/cm^2, and shifts E_p to -0.14V *vs.* NHE. E_p was determined graphically for each alloy by the intersection of tangents drawn from the passive region and the region of the current density *vs.* applied potential curve that exhibited the steepest slope. For those polarization curves that did not exhibit active dissolution regions, E_p was determined as the potential at which the current density was equal to 1 $\times$ 10^{-6} A/cm^2, generally the lowest measurable current density in these experiments. A comparison of the results obtained for iron with the results obtained for the Fe-Ni surface alloys shows three effects due to the surface alloying: (*i*) a substantial reduction in i_c; (*ii*) a shift of the crossover potential, E_o, toward the noble direction; and (*iii*) a shift of E_p toward the noble direction. The values for these parameters obtained directly from the curves in Fig. 2 are summarized in Table I.

Figure 3 contains the results for the Fe-10(s)Cr-15(s)Ni alloy, 316 L stainless steel (18% Cr, 12% Ni), Inconel 625 (61% Ni, 21.5% Cr), and the iron and nickel data from Fig. 1. The electrochemical parameters of interest are summarized in Table II and again indicate that the resistance to pitting corrosion is enhanced by surface alloying. In Fig. 4 results are shown

Table I. Electrochemical parameters from Fig. 2 where i_c ≡ critical current density, E_o ≡ the crossover potential, and E_p ≡ the pitting potential

Metal	i_c (A/cm^2)	E_o (V *vs.* NHE)	E_p (V *vs.* NHE)
Iron	4.5 × 10^{-5}	−0.58	−0.14
Fe-6(s)Ni	1.3 × 10^{-5}	−0.52	−0.12
Type 9 Ni steel	<<10^{-6}	−0.12	−0.12
Fe-25(s)Ni	2.5 × 10^{-6}	−0.40	0.08
Nickel	1.5 × 10^{-6}	−0.36	0.41

for the electrochemical behavior of V-250 + 10(s)Cr, as compared with V-250 and pure iron. The relevant electrochemical parameters are summarized in Table III.

Discussion

The implantation of nickel ions into polycrystalline iron has been shown (Fig. 2) to produce results similar to those previously reported for Fe-Cr surface alloys (1). These results indicate a general trend, similar to those observed for Fe-Cr and Fe-Ni bulk alloys, for E_p to become more noble with increasing concentration of the alloying element. A similar type of behavior in bulk alloys has been interpreted by many in-

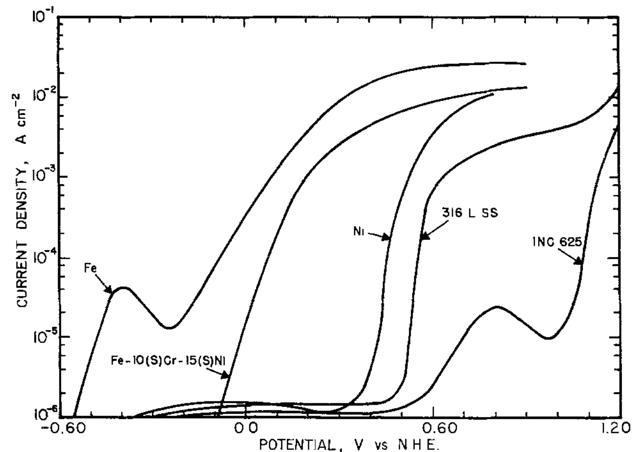

Fig. 3. Anodic polarization behavior (in a borate-buffered solution with 2400 ppm Cl$^-$ addition) of a tertiary surface alloy, Fe-10(s)Cr-15(s)Ni, compared with that for polycrystalline iron and nickel and two commercial alloys.

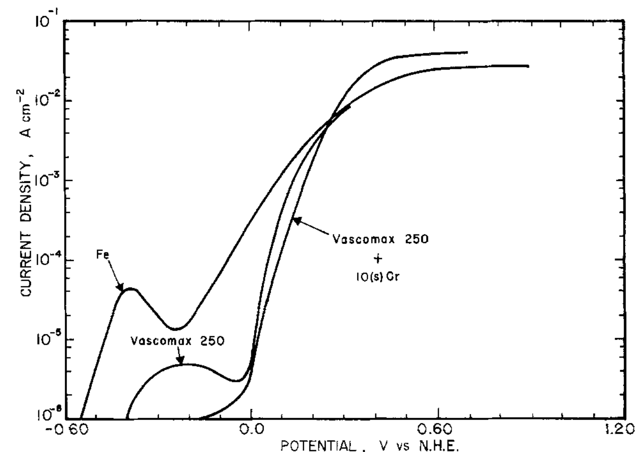

Fig. 4. Anodic polarization behavior (in a borate-buffered solution with 2400 ppm Cl$^-$ addition) of a maraging steel, after implantation of 25 keV Cr$^+$ ions to an average concentration of 10 a/o.

vestigators (2, 7, 8) to indicate an increase in the resistance of the alloy to pitting corrosion. Increasing the resistance to general corrosion by increasing either the nickel and/or the chromium concentration in bulk alloys is a well-known phenomenon. The electrochemical data reported here for the Fe-Ni surface alloys are interpreted as indicating that, since the active, passive, and transpassive regions for the surface alloys are similar to those for the equivalent bulk alloys, the over-all corrosion behavior could be expected to be the same. It has been reported previously (1) that the electrochemical results for an Fe-5% Cr bulk alloy were essentially identical to those for an Fe-6(s)Cr alloy up to a potential of +0.20V *vs.* NHE. At more anodic potentials, the implanted region was completely dissolved and the subsequent electrochemical behavior of the Fe-6(s)Cr alloy resembled that of pure iron. This was interpreted as indicating that as long as the alloyed surface region remains intact, the over-all corrosion resistance properties are the same. Similar conclusions are reached in this paper for the Fe-Ni surface alloys.

Table I shows that there is a decrease in i_c and an increase in E_p with increasing nickel implant concentration. The i_c approached a limiting value of 1.5×10^{-6} A/cm^2, the same value measured for pure nickel. The effect of the implanted nickel can be seen also as a shift of E_0 toward the same value as that for pure nickel. The decreasing i_c reflects the decreasing anodic dissolution; the increasingly more noble E_p reflects an increased resistance to pitting corrosion. The Fe-25(s)Ni alloy exhibits a more noble E_p than that measured for an Fe-19(s)Cr alloy (1) and has a pitting-corrosion resistance approximately equal to that of an Fe-12% Cr bulk alloy (1) (assuming that the surface alloyed region remains intact).

Two Fe-Ni commercial alloys, V-250 and Type 9 nickel steel, were tested. In addition to iron and nickel, the V-250 contains significant amounts of Co, Mo, Mn, and Ti. These additional alloying elements are probably detrimental to the over-all corrosion resistance since i_c for the V-250 was higher than that for the Fe-25(s)Ni alloy and the E_p was less noble than that for the surface alloy. The addition of the chromium, via implantation into the V-250, resulted in a decrease in i_c and a more noble value of E_p. The results for the V-250 + 10(s)Cr are interpreted as indicating a region of anodic dissolution, followed by pitting (indicated by the rapid rise in current density). The i_c was determined as the highest current density measured before the applied potential reached the value of E_p. A comparison of the results for the Fe-6(s)Ni alloy with those for the Type 9 nickel steel shows that the surface alloy exhibited a substantially higher i_c than the Type 9 nickel steel (which in fact exhibited no i_c at all). Also, the Type 9 nickel steel had an E_p slightly greater than that of the Fe-6(s)Ni alloy.

The commercial alloys, Inconel 625 and 316 L stainless steel (with an i_c of approximately 1.0×10^{-6} A/cm^2), each exhibited a much more noble E_p than the Fe-10(s)Cr-15(s)Ni alloy. The results for this multiple implant are comparable to those for the Type 9 nickel steel and the Fe-19(s)Cr alloy (1).

The implantation of nickel and chromium ions into iron and steels has been shown to have the potential for fabricating alloys with good general- and pitting-corrosion characteristics. In addition, high strength steels such as V-250 can have their surfaces alloyed to increase resistance to corrosion while at the same time retaining their designed bulk strength characteristics.

HPLC Analysis of the Stereoisomers Obtained by Electrohydrodimerization of *p*-Hydroxybenzaldehyde

David F. Tomkins and John H. Wagenknecht*

Monsanto Company, Corporate Research Department, St. Louis, Missouri 63166

ABSTRACT

In contrast to previous reports, high pressure liquid chromatographic analysis (HPLC) of the 4,4′-dihydroxyhydrobenzoin formed by the electrohydrodimerization of *p*-hydroxybenzaldehyde showed that the ratio of *dl*- and *meso*-isomers did not vary significantly with various reduction mediums, the cathode material, or the concentration of aldehyde.

The electrochemical reduction of aldehydes and ketones in a divided cell leads to glycol/pinacol dimers in good yield under a variety of conditions (1, 2). Aldehydes and nonsymmetrically substituted ketones dimerize to form a mixture of stereoisomers and, by varying the reaction conditions, the ratio of *dl*/*meso*-isomers can be varied (1, 2). Also, the use of an

* Electrochemical Society Active Member.
Key words: electrohydrodimerization, *p*-hydroxybenzaldehyde, high pressure liquid chromatography, *dl*/*meso* ratio, glycol formation.

optically active solvent allows the *d* to *l* ratio to be varied (3).

The *dl*/*meso* ratio of the glycols from aromatic aldehydes can be varied over a small range with many aldehydes. However, *p*-hydroxybenzaldehyde seems unique in that it is reported to give pure *meso*-dimer in aqueous base (4, 5) and nearly pure *dl*-dimer in acidic solution (6). Our results with *p*-hydroxybenzaldehyde indicated that a nearly equal amount of *dl*- and *meso*-isomers of 4,4'-dihydroxyhydrobenzoin was formed under a wide variety of conditions, including those previously reported. However, an important difference was in the sample workup. Previous workers isolated the dimers before analysis; we developed a high pressure, liquid chromatographic procedure for analysis of the catholyte. The fact that no isolation was required eliminated possible preferential loss of one of the isomers (which have quite different solubility properties) during workup.

Experimental

The electrolyses were carried out in a glass frit divided H cell with a platinum foil anode and SCE reference electrode. The cathode materials are listed in Table I. Electrolyses at constant potential were carried out with a Wenking Model PCA 72H Potential Control Amplifier. Constant current electrolyses were carried out with a Lambda Model LP-412A-FM power supply. NMR spectra were obtained on a Varian T-60 spectrometer.

The HPLC was carried out with a du Pont Model 830 high performance, liquid chromatograph equipped with a gradient elution accessory and u.v. (254 nm) detector. The system was modified by the addition of a Waters Model U6K injector system and coupled with a Hewlett-Packard 7132A recorder and Autolab System IV (Spectra-Physics) integrator. The column was a μ-Bondapak C_{18} analytical (Waters Associates) reversed-phase column (4 mm ID × 30 cm). μ-Bondapak C_{18} is an octadecyltrichlorosilane permanently bonded to μ-silica particles. A mobile-phase gradient from pH = 3 H_2O—adjusted with H_3PO_4 (initial) to 50% MeOH pH = 3 H_2O (final)—using the concave gradient No. 3 at 5%/min was utilized for the determinations. The flow rate was adjusted to 2 ml/min. The suggested conditions for analysis required modification (reduced final methanol composition) depending upon column performance.

Analytical

An internal standard solution was prepared by the addition of 100 ml acetone to 1 liter methanol. The same internal standard solution was used for standards and samples.

A standard solution was prepared by accurately weighing 18 mg *p*-hydroxybenzaldehyde, 2 mg *p*-hydroxybenzoic acid, 9 mg *p*-hydroxybenzyl alcohol, and 40 mg 4,4'-dihydroxyhydrobenzoin and dissolving the mixture in 10 ml of 10% acetone/methanol solution (internal standard solution) and adding 2 ml of glacial acetic acid.

The sample reaction products were determined by pippeting a 1 ml sample into a 15 ml screw-capped vial and adding 10 ml internal standard solution and 2 ml glacial acetic acid.

The determination was accomplished by injecting 5 μl of standard solution, starting the gradient, and monitoring the effluent at 254 nm. The integrator was set to measure the peak areas accurately. The sample solution (5 μl) was injected after an approximately 15 min reequilibration time. The calculations were made utilizing the System IV integrator with established procedures employing the internal standard.

Reagents.—Solvents used for HPLC were methanol (u.v. grade "distilled in glass" [Burdick and Jackson]), water (obtained from Mili-Q system [Millipore Corporation]) acidified to pH 3.0 with H_3PO_4, acetone (reagent grade), and glacial acetic acid (reagent grade). Eastman *p*-hydroxybenzaldehyde was used for the electrolyses.

Electrolysis procedure.—The electrolyses carried out at Hg (6 cm^2) were stirred with a very small magnetic stirrer which did not cause large waves on the Hg surface which would give widely varying values of cathode potential because of the changing distance between the SCE and the Hg pool. The volume of the catholyte was 75 ml and the composition is listed in Table I. Electrolyses were carried to completion under N_2 and the quantity of electricity passed was measured by an in-series d-c motor attached to an odometer. Approximately 1**F** of electricity per mole of aldehyde was passed in each case. Analyses of the products formed in 80% ethanol were carried out at partial conversion, because at complete conversion the *meso*-isomer precipitated from solution, thus complicating the analyses. Analysis of the *dl*/*meso* ratio at periods throughout the electrolyses in aqueous base showed that no change in ratio occurred during the electrolyses.

The electrolyses at constant current (see Table I) were carried out with 30 ml of weil-stirrd, deaerated catholyte for sufficient time to dimerize 85% of the aldehyde. The only physical product isolation carried out is indicated below.

Product isolation and characterization.—The optimum product isolation from an electrolysis of 0.8*M* *p*-hydroxybenzaldehyde carried to completion in 1*M* NaOH was achieved by adjusting the pH to 9.0 with acetic acid and cooling the solution to 5°C. About 80% of the 4,4'-dihydroxyhydrobenzoin present will precipitate, giving a solid with a *dl*-*meso* ratio of approximately 0.45. The *dl*-*meso* ratio in the original solution was 0.77. Analysis of the filtrate by HPLC showed that the *dl*-isomer predominated in that solution. The dried solid melted at 215°C as observed by Allen (4). Recrystallization from pyridine gave *meso*-isomer, mp 242°C [lit. mp 244°-245° (5)]; NMR (pyridine d_5) δ 5.33 (s, 2, CHOH) and 7.42 (m, 8, aromatic). The tetraacetate of this isomer melted at 176°-177°C; NMR ($CDCl_3$) δ 2.00 (s, 6, OAc), 2.26 (s, 6, OAc), 6.05 (s, 2, CHOAc), and 7.13 (m, 8, aromatic) and had the proper elemental analysis. A sample of *meso* 4,4'-dihydroxybenzoin was neutralized with NaOH in water. The solution was concentrated until crystals formed. The assignment of the *meso* structure to this isomer was verified by x-ray crystallography. The full crystal structure will be published elsewhere.

A predominately *dl*-isomer of 4,4'-dihydroxyhydrobenzoin was obtained from the filtrate of the original isolation by concentrating the solution. Several recrystallizations and reprecipitations did not yield pure *dl*-isomer. However, by comparison with the spectrum of the *meso*-isomer it could be determined that the

Table I. Electrochemical hydrodimerization of *p*-hydroxybenzaldehyde

NMR absorption for the benzylidyne hydrogens in the *dl*-isomer occurs at $\delta = 5.14$ in pyridine d_5. We were unable to obtain the *dl*-tetraacetate free of *meso*-isomer by recrystallization; however, the predominately *dl*-tetraacetate had a satisfactory elemental analysis, and, by comparison with the NMR spectrum of the *meso*-tetraacetate, it could be determined that the NMR spectrum of the *dl*-tetraacetate in $CDCl_3$ was δ 2.08 (s, 6, OAc), 2.24 (s, 6, OAc), 6.03 (s, 2, C*H*OAc), and 7.04 (m, 8, aromatic).

Results and Discussion

The electrochemical reduction of *p*-hydroxybenzaldehyde was carried out under a variety of conditions. The results of the individual experiments are shown in Table I. The ratio of *dl/meso* was within an experimental error of 0.79 in all experiments carried out in 1*M* NaOH. In less basic media, the ratio was significantly higher. Although the change in ratio at various pH's was the same order of magnitude as reported by Stocker and Jenevein (7), the direction was opposite. The fact that changing electrode material and aldehyde concentration did not change the *dl-meso* ratio, and changing *p*H did, was consistent with previously reported results (3, 7).

A small effect on the *dl/meso* ratio was observed when tetrabutylammonium hydroxide was used in place of NaOH. The change is opposite in direction and much smaller, compared to the result obtained by Puglisi *et al.* (8), when quaternary ammonium ions were added to the electrolyte during reduction of benzaldehyde in acidic solution. Our results do not allow one to determine whether these dimerizations occur in the immediate vicinity of the electrode-solution interface or in the bulk solution, but they should eliminate the use of *p*-hydroxybenzaldehyde as an example of a highly stereoselective reaction.

A major difference between our results and those reported by others (4-6) seemed to be related to the new sample workup. The different solubilities of the *dl*- and *meso*-isomers caused separation of isomers during sample workup. Our analytical procedure (high pressure liquid chromatography) avoided separations prior to the analysis. The procedure is described in the Experimental section, and a sample chromatogram is shown in Fig. 1.

A reversed-phase system was employed using a nonpolar (octadecyltrichlorosilane) stationary phase with a polar solvent in the gradient elution mode. The *p*H of the initial H_2O solution was adjusted to *p*H 3 with H_3PO_4 to suppress the ionization of the phenolic compounds, thus enhancing the partition between the stationary and mobile phases. This ion-suppression technique increased the retention characteristics of the reaction products and allowed complete separation of components of interest using the gradient elution mode. Water, free of organic contaminants, was used to prevent extraneous peaks in the reversed phase mode.

The column needed special care to maintain separation efficiency. Useful column life was normally limited to approximately one month of continuous operation before resolution was irreversibly lost. During use, the column packing settled, producing a void at the column head and causing loss of efficiency. This void was refilled with μ-Bondapak C_{18} packing and the column was restored to nearly original efficiency.

Acetone was used as the internal standard of choice because its elution was in an area that was free from interferences. The high volatility and low absorbance of acetone limit its use as an internal standard, but other compounds tested as internal standards, including phenol and *o*-chlorobenzoic acid, were more affected by interferents and *p*H changes. These compounds, when used on an efficient column, also were satisfactory internal standards.

The pure *meso*-isomer was isolated and the tetraacetate prepared; however, the pure *dl* mixture could not be isolated. Pyridine d_5 proved to be an excellent

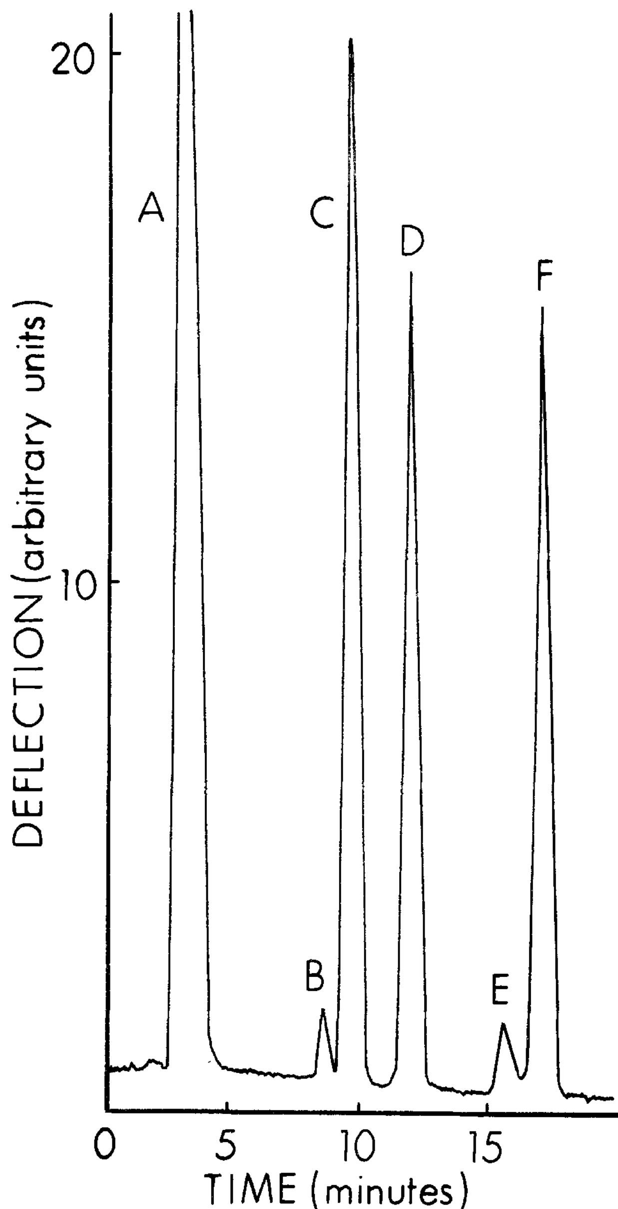

Fig. 1. HPLC analysis of the products of the electrohydrodimerization of *p*-hydroxybenzaldehyde. A, acetone (internal standard); B, *p*-hydroxybenzyl alcohol; C, meso-4,4'dihydroxyhydrobenzoin; D, *dl*-4,4'-dihydroxyhydrobenzoin; E, *p*-hydroxybenzoic acid (impurity in *p*-hydroxybenzaldehyde); F, *p*-hydroxybenzaldehyde.

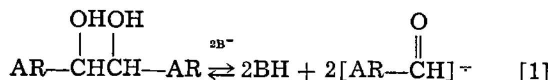
solvent for NMR analyses of the dimers [as suggested by Snowden (2)] because of the widely differing chemical shifts of the benzylidyne hydrogen of the *dl*- and *meso*-isomers.

It has been shown previously (9) that when pinacols are treated with strong base the molecule may cleave to form two ion radicals (reaction [1]). If that reaction were to occur in aqueous base, it could explain the constant



$$\text{AR—}\overset{\text{OH}}{\overset{|}{\text{C}}}\text{H}\overset{\text{OH}}{\overset{|}{\text{C}}}\text{H—AR} \underset{}{\overset{2B^-}{\rightleftarrows}} 2BH + 2[\text{AR—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{H}]^{\dot{-}} \quad [1]$$

dl/meso ratio in basic electrolyses. This was tested by warming the *meso*-isomer in 1*M* NaOH followed by HPLC analysis. No *dl*-isomer was detected in the sample.

We concluded from our results that changing the electrolysis conditions does not grossly affect the stereochemistry of the dimeric product obtained from the electroreduction of *p*-hydroxybenzaldehyde. The use of HPLC to analyze the products was an extremely useful tool for this type of study because isomer

losses in product isolation and/or derivatization were avoided.

Semiconductor Electrodes XV. Photoelectrochemical Cells with Mixed Polycrystalline n-Type CdS-CdSe Electrodes

Rommel N. Noufi,* Paul A. Kohl,* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Solid solutions of CdS and CdSe of different compositions were prepared by sintering pressed pellets and vacuum evaporation. The bandgap of the mixtures varied monotonically with percent composition between that of CdS and CdSe. Studies of the photoassisted oxidation of sulfide with these electrodes with a 1*M* Na_2S, 0.1*M* NaOH electrolyte showed that the flatband potentials (V_{fb}) of the mixtures were shifted toward negative potentials with respect to pure CdS and CdSe. Solar cells using these electrodes formulated as (x)n-CdS $(1 - x)$CdSe/1*M* Na_2S, 0.2*M* S, 0.1*M* NaOH/Pt are described. When $x = 0.9$, for a sintered pellet electrode, a power efficiency of 9% at a cell voltage of 202 mV (irradiation with 577 nm light of 1 mW/cm^2 intensity) was obtained.

There has been much recent interest in the application of n-type cadmium chalcogenide (CdX, where X = S, Se, or Te) electrodes to the construction of photoelectrochemical cells for the conversion of solar to electrical energy (1-14). These materials have bandgap energies (E_g) which are small enough ($\leq$2.4 eV) to capture a reasonable fraction of the solar spectrum and can be operated for long time periods with little or no decomposition of the semiconductor electrode in suitable electrolytes (*e.g.*, S^{2-}/S_x^{2-}). Cells with solar energy power conversion efficiencies ($\eta_{p,s}$) of 7-8% (9) and monochromatic light efficiencies ($\eta_{p,m}$) of 9-10% (4) using single crystal CdX electrodes have been reported.

The maximum efficiency of a photoelectrochemical cell utilizing a redox couple with an equilibrium potential, V_{redox}, for conversion of light to electrical energy with no over-all change in electrolyte composition depends upon the flatband potential of the semiconductor, V_{fb}. For a cell with an n-type semiconductor photoanode, the more negative the value of V_{fb}, the greater the possible output voltage (which has a maximum value $V_{redox} - V_{fb}$) and the larger the maximum efficiency. Thus optimization of the semiconductor-electrolyte characteristics involves variation of E_g for optimum match with the solar energy spectrum (15) and V_{fb}. Other semiconductor characteristics of importance include the doping level, which governs the material resistivity and the thickness of the space charge region at a given bias, the minority carrier lifetime in the bulk and at the surface, and the location and properties of intermediate levels within the gap region. We report here studies of electrodes produced by forming solid solutions of CdS and CdSe of different compositions prepared from sintered, pressed pellets or by vacuum evaporation and used as photoanodes in S^{2-}/S_x^{2-} electrolytes. The effect of composition and sample preparation on V_{fb}, E_g, efficiency and stability were of particular interest.

Experimental

The pellet semiconductor electrodes used in this study were prepared from high purity, reagent grade polycrystalline CdS and CdSe powder (Ventron, Beverly, Massachusetts). Mixtures of the two compounds, which are known to form solid solutions after sintering (16), were milled in acetone for 30 min prior to use. The 0.5 mm thick pellets were pressed at 5000 psi, sintered in a nitrogen atmosphere at 450°C for 12 hr, and then heated in a hydrogen atmosphere for 5 min. The densities of the pellets were about 87-89% of single crystal densities. An ohmic contact was made to the rear of each pellet with gallium-indium alloy. The resistance between the two faces of the pellet after sintering was generally less than 100Ω.

Electrodes were also prepared in a vacuum evaporation apparatus by vacuum deposition of the pure compounds and their mixtures on Pt and SnO_2-

coated glass substrates (donated by Texas Instruments, Dallas, Texas). Before the deposition, the Pt substrates were boiled in concentrated nitric acid for 5 min followed by several rinsings with water and then with ethyl alcohol. The SnO_2-coated glass substrates were soaked in alcoholic KOH for 1 hr and rinsed several times with distilled water, followed by baking in an oven at 200°C for 2 hr. The semiconductor films, which were about 1.5 μm thick as determined by weighing the electrode before and after deposition, were annealed first in a nitrogen atmosphere at 400°C for 2 hr and then in a hydrogen atmosphere at 400°C for 5 min. The resistance between the film surface and conducting substrate was less than 1Ω.

A copper wire was attached to the electrodes with conducting silver epoxy cement (Allied Chemicals, New Haven, Connecticut). The back and sides of the electrodes were insulated with epoxy resin cement (Devcon Corporation, Danvers, Massachusetts). The exposed areas of the electrodes were 0.25-1.0 cm^2. The electrodes were etched in 6M HCl prior to use. The etching times for the sintered and film electrodes were about 15 and 5 sec, respectively. Both polycrystalline CdS and CdSe electrodes show a comparable increase in photocurrent after a similar etching step.

The semiconductors were used as the working electrode in a conventional three-electrode cell with a platinum foil counterelectrode and an aqueous saturated calomel reference electrode (SCE). The semiconductor electrodes were irradiated through an optically flat Pyrex window. The two-electrode, single compartment solar cell contained a platinum foil counterelectrode (about 10 cm^2) which was spaced about 0.5 cm from the semiconductor electrode. With this cell the current was measured as a function of load resistance under irradiation with no external power source.

The electrolyte solution (1M Na_2S, 0.2M S, and 0.1M NaOH) was yellow in color and a correction for absorption of the incident radiation by the solution was performed when calculating efficiencies.

For voltammetric measurements, a PAR (Princeton Applied Research, Princeton, New Jersey) Model 173 potentiostat and Model 175 universal programmer were employed. The current-voltage (i-V) curves were recorded using IR compensation on a Houston Instruments (Austin, Texas) Model 2000 X-Y recorder for scan rates less than 1 V/sec. Current-voltage curves at greater than 1 V/sec, obtained for capacitance measurements, were recorded on a Nicolet (Madison, Wisconsin) digital oscilloscope. An Oriel Corporation (Stamford, Connecticut) 450W xenon lamp and Model 7240 grating monochrometer were used to illuminate the electrodes. The radiant power was measured with a Model 550-1 Radiometer/Photometer (E.G. & G., Salem, Massachusetts).

ESCA and Auger electron analysis of the electrodes were carried out with a Physical Electronics Model 548 (Eden Prairie, Minnesota) instrument. The relative amounts of S and Se were determined from the area of the Se $3d_{5/2}$ peak at 54.18 eV as the amount of S increased in the mixture. Small amounts of carbon impurities were detected in the mixtures by Auger electron analysis. The x-ray diffraction spectrum (obtained with a Norelco x-ray diffractometer) of the mixed compound electrodes gave no lines characteristic of either of the pure components, indicating the mixtures were substitutional solid solutions.

Results

Electrode composition.—The composition of the electrodes prepared by sintering was known from the relative quantities of CdS and CdSe employed. The composition of the vacuum-deposited material was known approximately from the amounts of CdS and CdSe used as the source material and the known relative evaporation rates (16); the CdS content of the films was always higher than its relative amount in the source material. These films were analyzed by ESCA and x-ray diffraction, and the results, reported in Table I, are probably accurate to within 5% of the values listed. In general, the electrochemical behavior of sintered and vacuum-evaporated film electrodes of about the same composition was very similar, except where noted.

[a] For solution of 1.0M Na_2S and 0.1M NaOH under irradiation with white light.

E_g and V_{fb}.—The bandgap energy was determined by noting the longest wavelength (λ) which produced a photoanodic current with the electrode held at potentials 0.60-0.95V positive of V_{fb}. V_{fb} was estimated from the i-V curves and was taken as the potential for the onset of the photoanodic current. Typical i-V and i-λ curves for a film electrode are given in Fig. 1 and the rising portion of the photocurrent-V curves as a function of electrode composition is shown in Fig. 2. The shapes of the i-V curves were similar in solutions of 1M Na_2S and 0.1M NaOH, with and without dissolved sulfur. Values of E_g and V_{fb} for the
