different electrodes are given in Table I; the variation of V_{fb} with electrode composition is shown in Fig. 3. Butler (17) has recommended that V_{fb} be determined not from the potential of onset of the photocurrent but from the extrapolated value of a plot of V *vs.* (photocurrent).[2] The trend in such extrapolated values with composition generally is the same as that in Fig. 3 but displaced to more positive values. Similar i-V behavior was observed in 0.1*M* NaOH alone, with the onset of photooxidation shifted in a positive direction by about 0.5V compared to the sulfide-containing solutions. In these solutions the electrodes underwent photodissolution to Cd^{2+}, S, and Se (with the appearance of a yellowish film in the case of CdS-containing electrodes and a gray film on the CdSe electrode) and the photocurrent decreased with time.

The dark anodic curent in 0.1*M* NaOH at the film electrodes appeared at potentials positive of 0V *vs.* SCE and bubbles were observed forming on the electrode surface. No dark anodic current was found at the sintered electrodes until potentials well positive of +1.0V *vs.* SCE. A cathodic current in 0.1*M* NaOH was observed at potentials just negative of V_{fb}, occurring at slightly more positive potentials at the film electrodes. Attempts to determine V_{fb} from Mott-Schottky plots (18), with the capacitance determined by cyclic voltammetry (19) over a potential range where no dark faradaic current was observed led to intercepts that were frequency dependent. The slopes of these plots showed doping levels between 10^{18} and 10^{20} cm^{-3}.

Efficiency and solar cells.—The quantum efficiency for electron flow, Φ_e, defined as the number of electrons flowing in the external circuit divided by the number of photons impinging on the electrode, was 100 ± 2% for all electrodes maintained at −0.70V *vs.* SCE. The open-circuit voltages, V_{oc}, of the two-electrode solar cells (x)n-CdS $(1 - x)$CdSe/1*M* Na_2S, 0.2*M* S, 0.1*M* NaOH/Pt measured between the illuminated sintered semiconductor electrode and the platinum cathode are listed in Table I. The maximum value of V_{oc} is $V_{fb} - V_{redox}$, where V_{redox} is −0.7V *vs.* SCE (4, 20-23). The trend in V_{oc} with electrode composition followed very closely that of V_{fb} determined from the i-V curves, with a maximum with an electrode composition of about 90% CdS-10% CdSe (Fig. 3). The open-circuit photopotentials were dependent on light intensity. For example, in the case of the measurement made using the 67% CdS-33% CdSe, when white light from the 450W xenon lamp was reduced by 50%, the open-circuit potential, V_{oc}, decreased from 0.75 to 0.66V; at intensities reduced to 10 and 1%, V_{oc} was 0.58 and 0.45V, respectively. Similar dependence was observed when measuring the potential drop through a 1000Ω resistor. This dependence on light intensity was also evident when measuring solar cell efficiencies. The $\eta_{p,s}$ of the 90% CdS-10% CdSe sintered material electrode was measured to be about 1% for solar intensities of about 75 mW·cm^{-2} compared to 5.9% with an attenuated solar intensity (using neutral density filters) of 1.1 mW·cm^{-2}. A similar decrease of efficiency with increasing irradiation intensity was also observed by Wrighton *et al.* (3, 4) in CdS and CdSe cells. The monochromatic light power efficiency, $\eta_{p,m}$, of the photoelectrochemical cell, defined as the ratio of the output power across the external load resistor to the incident radiant power, was determined with 577 nm light (12 nm bandpass) with an intensity of 1 mW·cm^{-2}. For the 90% CdS-10% CdSe sintered pellet with a 1000Ω load resistor, the output voltage was 202 mV and the current was 0.45 mA·cm^{-2}, yielding $\eta_{p,m}$ = 9%. The maximum value of $\eta_{p,m}$ found with the film electrodes was with the 60% CdS-40% CdSe material on Pt substrate with an 800Ω load resistor, and incident power of 0.4 mW·cm^{-2}. $\eta_{p,m}$ was 7% with an output voltage of 157 mV. The measured $\eta_{p,m}$ and $\eta_{p,s}$ values were quite vari-

able from electrode to electrode; this can be attributed to the high and variable internal resistance of the sintered electrodes and the poor adhesion of the vacuum evaporated films to the substrates, particularly the SnO_2-coated glass. Separate experiments in which the sintered electrodes were used as photoanodes in stirred solutions containing 1*M* NaS, 0.2*M* S, and 0.1*M* NaOH for periods (about 14 hr) which would have been sufficient to dissolve all the electrode material by photooxidation of the lattice showed weight loss of about 1%. This small loss was attributed to surface erosion of the pressed pellets during the long periods of stirring and soaking of the electrode. The stability of the cell current was dependent on the sulfide-polysulfide concentration. For example, when the solution contained 1*M* S and the initial current density was 16 $mA \cdot cm^{-2}$ (100Ω load) the current dropped to about 55% of its initial value in 14 hr. With 0.2*M* S, the current dropped to 26% of its initial value after the same period of time. Furthermore, when illumination was interrupted for several minutes and then resumed the onset current would reach a value slightly smaller than its initial value. After a 10 sec etch in 6*M* HCl, the current would attain almost its initial value.

Discussion

The mixtures (x)CdS $(1 - x)$CdSe gave the expected monotonic variation of E_g as the composition was changed from pure CdS to pure CdSe (16, 24). It is particularly interesting that the variation of V_{fb} with x shows a maximum (Fig. 3) with the mixture where $x = 0.9$ having a V_{fb} *ca.* 0.2V more negative than either pure CdS or CdSe. To seek the reason for this behavior let us consider the factors that affect V_{fb}. These include the electron affinity of the semiconductor (EA), the potential drop through the Helmholtz layer (V_H), the potential drop across the diffuse double layer (V_d), and the difference between the Fermi level and the conduction band ($E_F - E_C$); to put V_{fb} on a scale relative to a given reference electrode using the absolute EA (in eV), a constant term, E_{ref}, usually taken as *ca.* 4.75 eV for the SCE *vs.* the vacuum level (25) is used. The following equation, which is an extension of one given by Butler and Ginley (26), can then be written

$$V_{fb} = \frac{EA}{e} - \frac{E_{ref}}{e} - (V_H + V_d) + \frac{(E_F - E_c)}{e} \quad [1]$$

Taking $E_F - E_c$ as 0.10 eV, $E_{ref} \simeq 4.75$ eV, and assuming a negligible drop across the diffuse double layer ($V_d \sim 0$) this can be written

$$V_{fb}(V) \simeq \frac{EA}{e} - 4.7 - V_H \quad [2]$$

The values of V_{fb} for CdS and CdSe in NaOH and in the presence of S^{2-} taken from various sources are shown in Table II. The V_{fb} values for CdS and CdSe in sulfate media are independent of *p*H (4, 27) and the relative values agree quite well with those predicted from E_g and the intrinsic Fermi level ($E_F{}^i$) calculated by Nethercot (28) from electronegativities. In the latter case $E_F{}^i$ is calculated from the Pauling electronegativities for the atoms A and B (χ_A and χ_B) using the equation (28, 29)

$$E_F{}^i = 2.86(\chi_A\chi_B)^{1/2} \quad [3]$$

If one takes EA as the difference in energy between the conduction bandedge and vacuum (26), then

$$EA = E_F{}^i - E_g/2 \quad [4]$$

Calculated EA values are shown in Table II. When these values are used in Eq. [2], a V_H of about 0.9 (±0.1)V is obtained for both CdS and CdSe in the NaOH medium. The addition of S^{2-} causes the V_{fb} values to shift toward negative values by about 0.5V for CdS and 0.7V for CdSe (4) presumably because specific adsorption of S^{2-} causes a change in the voltage drop across the Helmholtz layer (to about 1.4 and 1.6V for CdS and CdSe, respectively).

Thus the change in V_{fb} with composition could be ascribed to changes in the EA or specific adsorption (V_H). The fact that the same sort of maximum of V_{fb} with composition is observed for NaOH solutions in the absence of S^{2-} suggests that this variation can be attributed to changes in the EA and that the introduction of small amounts of CdSe into the CdS lattice yields a material with a significantly smaller EA. However it is also possible that the composition of the surface layer of these electrodes changes upon immersion or operation in the sulfide electrolyte medium. Under these conditions a junction potential could arise between the surface layer and the bulk semiconductor which would affect the observed V_{fb} values obtained under illumination. Investigations of the changes in the electrode surfaces by ESCA and Auger electron spectroscopy are currently underway in this laboratory.

It is of interest to consider in a general way how the efficiency of a photoelectrochemical solar cell varies with E_g and V_{fb}. For irradiation with light of energy equal to that of the bandgap the maximum efficiency, or the so-called open-circuit voltage efficiency (15), is

$$\eta_{p,m}(\max) = \frac{(V_{redox} - V_{fb})e}{E_g} \quad [5]$$

Thus both the maximum output voltage and efficiency depend upon V_{fb}. When one considers the solar energy efficiency of a threshold semiconductor device the ultimate power efficiency, η_{ult}, depends upon the value of E_g [as given in Ref. (15), Eq. [2], and Fig. 3]. Thus, considering the variation of both V_{fb} and E_g, the maximum (open-circuit voltage) efficiency for solar irradiation is $\eta_{p,m}(\max)\ \eta_{ult}$; typical curves showing the efficiency (for AM1 sunlight) are given in Fig. 4. With these curves and the V_{fb} and E_g values

Table II. Characteristic data for CdS and CdSe

	V_{fb} (0.1 *M* NaOH) (V *vs.* SCE)	V_{fb} (1.0*M* Na_2S) (V *vs.* SCE)	$E_F{}^i$ [d] (eV)	E_g [e] (eV)	EA [f] (eV)

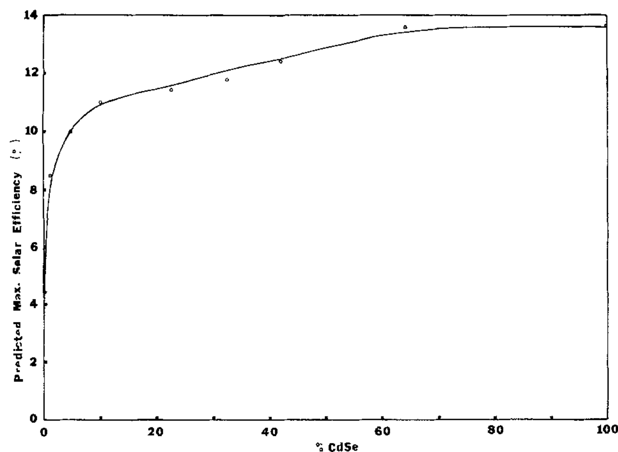

Fig. 5. Predicted maximum solar efficiency vs. composition for the (x)CdS $(1 - x)$CdSe system with S^{2-}, S_x^{2-} electrolyte.

of the various CdS-CdSe mixtures a plot of maximum solar efficiency as a function of composition can be derived (Fig. 5). The results suggest that the addition of only a small amount of CdSe greatly improves the maximum efficiency of a CdS electrode. Although the efficiency in this case is smaller than that of CdSe alone, this principle when applied to other systems could, by suitable manipulation of V_{fb} and E_g, yield higher efficiencies than the pure compounds.

Solid solutions such as (x)CdS $(1 - x)$CdSe may also be utilized in preparing a film electrode with a gradient composition, *i.e.*, an increasing CdSe content with depth. This would allow one to take advantage of the negative shift in V_{fb} at the solution interface (with high CdS content), and to absorb a greater fraction of the visible spectrum further into the space charge region (with the higher CdSe content). Work is currently being carried out in our laboratory to improve the conductivity of the pellets and extend the concept of solid-state solutions to other semiconductor systems.

Coulostatic Deposition of Metals at Underpotential

I. Potential Relaxation in the Absence of Chemical Reactions

D. F. Untereker,*[,1] W. G. Sherwood,*[,2] and Stanley Bruckenstein*

Chemistry Department, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

Under commonly occurring conditions, coulostatic processes can lead to underpotential deposition of a metal on a foreign metal substrate. These deposition processes are described quantitatively in terms of the isotherm for underpotential metal deposition, the double layer capacitance of the electrode surface, and the initial potential of the electrode. Coulostatically controlled underpotential deposition is demonstrated for silver on gold and platinum and for mercury on gold.

The process of underpotential deposition (UPD) of metals has been studied by a number of workers (1) since the original studies of Haissinsky (2) and Rogers (3). An understanding of UPD can give insight into the nature of the interactions occurring at the interface between two metals. Such insight can be used for a variety of purposes, such as to produce electrocatalytic surfaces of controlled activity. Thus, it is important to know when UPD has occurred. To date, UPD phenomena have been assumed to occur only when charge flows in the external circuit and no recognition was given to the possibility of unsuspected UPD processes occurring under zero current conditions. Several years ago we discovered a zero current UPD phenomenon in the course of rotating platinum ring-platinum disk electrode studies. It was noted (4) that some shielding of Ag^+ ion could be detected at the ring electrode of a rotating platinum ring-disk electrode when it was immersed in $\sim 10^{-5}M$ Ag^+ dissolved in 0.2*M* H_2SO_4, even though the disk electrode was at open circuit. In addition, after the shielding ceased, electrooxidation of the disk produced a collection current at the ring for a species having the properties of Ag^+. As is shown below, these phenomena are the result of UPD of silver occurring via coulostatic discharge of the double layer capacitance.

The purpose of this work is to quantitatively describe the coulostatic mechanism of UPD. Our theoretical description has been confirmed using the rotating ring-disk electrode (RRDE) on the systems Ag^+/Ag on Pt, Ag^+/Ag on Au, and Hg^{2+}/Hg on Au.

Theoretical

Coulostatic discharge processes for the electrochemical reaction

$$A \pm ne = B \quad [1]$$

are well understood when A and B are both soluble species. However, no treatment exists for the case where A is soluble and B deposits on a solid electrode surface in a uniform layer such as occurs in UPD of metals.

Let us carry out a coulostatic experiment at a solid electrode in the presence of M^{n+} which can deposit at underpotential. Assume that the isotherm for UPD of M is given by curve 1 of Fig. 1 and is represented by Eq. [2]

$$\theta = \mathbf{F}(E) \quad [2]$$

At potentials anodic to $E_{\theta=0}$, the surface coverage, θ, of M is zero and at potentials more cathodic than $E_{\theta=0}$, θ increases to one at $E_{\theta=1}$. We make no assumptions concerning the net charge on the UPD species other than it lies between n and 0. If the electrode potential is set originally so that $\theta = 0$, and then it is stepped to E_i, UPD of M will eventually occur if $E_i < E_{\theta=0}$. However, if before any significant UPD can take place, this electrode is disconnected from the external circuit, only coulostatic processes can be operative. The key points of our argument are that once the potential of the electrode is made more cathodic than $E_{\theta=0}$, and the electrode is disconnected from the circuit: (*i*) UPD of M must occur on the electrode by removal of cathodic charge from the double layer capacitance and (*ii*) the electrode will reach equilibrium when θ and E correspond to some point on the UPD isotherm. These points are formulated below, first without specifying any particular model and second for a linear combination model.

The charge in the double layer capacitance, Q_{E_i}, at the instant of disconnect is

$$Q_{E_i} = AC_{E_i,\theta=0}(E_{\theta=0}{}^* - E_i) \quad [3]$$

where A is the microscopic electrode area, $C_{E_i,\theta=0}$ is the integral (double layer) capacitance per unit area at the potential E_i of the substrate metal electrode before any UPD of M has occurred, *i.e.*, the surface coverage of M, θ, is zero, and $E_{\theta=0}{}^*$ is the point of zero charge (pzc) of the substrate metal.

As UPD of M proceeds, the relationship between E and θ is governed by Eq. [4]

$$Q_{E_i} = AC_{E,\theta}(E_\theta{}^* - E) + q_{E,\theta} \quad [4]$$

where $C_{E,\theta}$ is the integral capacitance per unit area. $C_{E,\theta}$ is defined with respect to the θ-dependent potential of zero charge, $E_\theta{}^*$, and is a function of E and θ. $q_{E,\theta}$ is the charge required by the UPD process to pro-

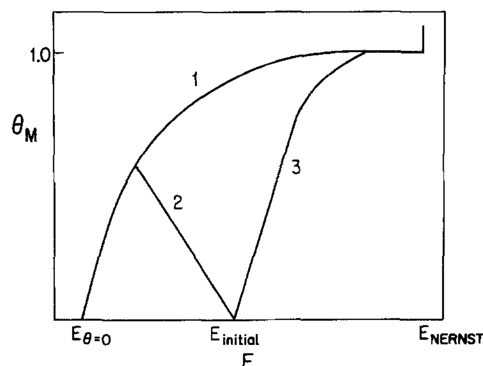

Fig. 1. Hypothetical θ-E relaxation responses for coulostatic UPD phenomenon. Curve 1, UPD isotherm for metal M on substrate; curve 2, response where relaxation path has a negative slope at point of intersections with UPD isotherm; curve 3, response where relaxation path has a positive slope at point of intersection with UPD isotherm. It is assumed $E_{\text{Nernst}} = E_{\theta=1}$.

Key words: coulostatic, underpotential deposition.

duce coverage θ at a potential E, starting from E_i where $\theta = 0$.

The particular functional form of $C_{E,\theta}$, E_θ^*, and $q_{E,\theta}$ depends on the model chosen. However, it is not necessary to specify a particular model in order to discuss the potential path taken as θ increases. For E_i more cathodic than $E_{\theta=0}$ the coulostatic discharge process will change the electrode potential, for example, along the path shown by curve 2 of Fig. 1, or perhaps along the path taken by curve 3. All of the possible paths are described by Eq. [4], which can be rewritten as

$$\theta = \mathbf{G}(E, Q_{E_i}) \quad [5]$$

The potential of the electrode will change according to the path described by Eq. [5] until Eq. [2] is also satisfied

$$\mathbf{G}(E, Q_{E_i}) = \mathbf{F}(E) \quad [6]$$

i.e., until the coulostatic relaxation path and the UPD isotherm intersect. At the intersection point of curves 1 and 2 the system is in equilibrium for path 2.

Curve 3 of Fig. 1 represents that path followed when the change in E_θ^* and/or $C_{E,\theta}$ with θ as such that it overcomes the tendency of $q_{E,\theta}$ (the charge taken from the double layer capacitance in the reduction case of Eq. [1]) to shift the electrode's potential anodic. In this situation, even after E and θ correspond to a point on the UPD isotherm, the electrode's potential will spontaneously shift cathodically along the isotherm until the Nernst potential is reached $(\theta = 1)$.

The RRDE technique provides data of the form of Eq. [5]; thus, we use this functional form to compare the experimental data with the predictions arising from a specific model. A remarkably simple one leads to good agreement with experiment. In this model: (*i*) The electrode is assumed to consist of two electrode regions, of area θA for the UPD material and $(1 - \theta)A$ for the substrate metal, where A is independent of θ; (*ii*) the integral double layer capacitance per unit area and the point of zero charge of each area are assumed to be unique and independent of θ; and (*iii*) $q_{E,\theta}$ is assumed to be given by

$$q_{E,\theta} = kA\theta \quad [7]$$

where k still may be a function of θ and E. k represents the charge per square centimeter required by the UPD process to produce a coverage, θ, starting at coverage $\theta = 0$. Then the expression equivalent to Eq. [4] is

$$Q_{E_i} = AC_S(1-\theta)(E_S^* - E) + A\theta C_M(E_M^* - E) + kA\theta \quad [8]$$

where the subscripts S and M refer to the substrate region and UPD region coated with M, respectively. At $\theta = 0$, $E = E_i$ and

$$Q_{E_i} = AC_S(E_S^* - E_i) \quad [9]$$

Thus, equating Eq. [8] and [9] yields

$$\theta = \frac{C_S(E - E_i)}{k + [C_M(E_M^* - E) - C_S(E_S^* - E)]} \quad [10]$$

as the explicit form of Eq. [5]. Now, the terms in the braces in the denominator tend to be of the same magnitude and can cancel each other. Then, when M^{n+} is discharged as M, k will be the predominant term in the denominator. Thus, not infrequently, a limiting form of Eq. [10] may hold, *i.e.*

$$\theta = C_S(E - E_i)/k \quad [11]$$

The actual oxidation state of the UPD species cannot be determined from electrochemical data unless a model is chosen. This can be seen by writing Eq. [4] in the form

$$Q_{E_i} = AC_{E,\theta}([E_\theta^* + k\theta/C_{E,\theta}] - E) \quad [12]$$

by substituting Eq. [7] into Eq. [4]. Since E_θ^* and k may both be functions of E and θ, there is no model-free way to distinguish E_θ^* from k.

A model, such as that used to derive Eq. [10], permits evaluating k, and thus $q_{E,\theta}$. The value of $q_{E,\theta}$ yields the average charge, $\bar{a}$, carried by a single UPD species. In principle, for the reduction case of Eq. [1], $0 \leq \bar{a} \leq n$. We prefer to interpret nonzero values of $\bar{a}$ as signifying an underpotential deposit consisting of a mixture of zero valent (adatom) and ionic metal species (adion), although we recognize that others prefer to regard such a result as evidence for a single surface species carrying a partial ionic charge. No experimental evidence exists which has distinguished between these two models. Theoretical arguments favoring the single surface species have not considered the possibility of stabilization of surface ions by solvent interactions and we regard the choice between these two views still to be a matter of personal preference.

Experimental

Chemicals.—Supporting electrolyte solutions were prepared from triply distilled water and Baker analyzed reagent grade sulfuric acid. Mercuric and silver sulfate stock solutions were prepared by dissolving the appropriate Mallinckrodt reagent grade sulfates in $0.2M$ H_2SO_4. The stock solutions were diluted to the working concentration just before an experiment was performed.

Equipment.—Standard laboratory equipment was used for these experiments. The rotator, electrochemical cell, and potentiostat are all of conventional design. The digital data acquisition and control system is described elsewhere (5). The rotating ring-disk electrodes were constructed in our laboratory (6).

Data acquisition.—A six-step digital data acquisition sequence was used to acquire data for the zero current experiments in $2.0 \times 10^{-5}M$ Hg^{2+} solution with a gold RRDE. In the first step the disk electrode potential was scanned at 100 mV/sec between -0.4 and $+1.6$V for 3 min at $\omega = 2500$ rpm. Simultaneously, the ring electrode was potentiostated at 1.0V. The disk electrode potential was then stepped to 0.0V at $\omega = 0$ rpm for 10 sec to ensure complete reduction of gold oxide formed during the previous step. Then the electrode rotator was started ($\omega = 2500$ rpm) and the disk electrode was potentiostated at 1.05V for 20 sec. At this potential, no mercury deposits and no gold oxide forms. Simultaneously, the ring electrode was potentiostated at 0.0V. Finally, the disk electrode potential was stepped to the desired initial potential for 0.2 sec, after which the current was set to zero and data acquisition was begun.

The Ag^+/Ag data on gold and platinum were obtained by a similar procedure using manual techniques.

In all cases it was possible to begin the zero current part of the experiments before any significant UPD could occur via a conventional faradaic mechanism. All potentials are reported *vs.* the saturated calomel electrode (SCE).

Au double layer capacitance determination.—To determine the capacitance of a gold electrode, a stationary gold disk electrode was scanned from 1.0 to 0.0V in $0.2M$ H_2SO_4 to obtain the *i-E* curve from which the charge-potential (*q-E*) plot was calculated. The *q-E* plot was normalized to the microscopic electrode area (see below) and the average integral double layer capacitance of the gold electrode over this potential region was calculated to be 57 $\mu F/cm^2$. Values for the pzc of Au and Hg in dilute sulfuric acid have been given in the literature as -0.042 and -0.442V (*vs.* SCE), respectively (7), and these are the values used in our model.

Determination of the isotherm for UPD metal on Au and Pt.—The quantity of UPD metal that was de-

posited on the substrate (Au or Pt) at a particular potential was determined as follows.

The gold electrode was first pretreated according to the sequence described above in the section on Data acquisition. Explicitly, the final steps in these experiments were to step to the UPD potential of interest and initiate rotation at 2500 rpm. After 10 min when UPD was complete the electrode was oxidized by means of a linear anodic potential scan at 100 mV/sec. The Hg^{2+} produced in this anodic scan was collected at the ring electrode. The charge required to oxidize the UPD deposit from the gold disk electrode was measured and compared with the simultaneously acquired ring electrode data. From these two sets of data, both θ and the fraction of θ that exists as adatoms were estimated as a function of potential. These techniques were also used after coulostatic experiments to determine the coverage of Hg on the Au surface.

Similar experiments were also performed to determine the UPD isotherm for Ag^+ on Pt. The situation of Pt is somewhat more complicated than on Au, in that part of the Ag on Pt isotherm superimposes on the Pt oxidation region in 0.2*M* H_2SO_4. Also, as is the case for Hg(II) on Au, there is adsorption of Ag(I) on Pt, and $\bar{a} \neq 0$ in the potential region of interest. Separate charge balance experiments were used to estimate the amount of Ag(I) which adsorbs. At 0.64V, the rest potential attained after the Pt disk was open-circuited at 0.2V, the fraction of total adsorbate present as Ag(I) was about 0.5 ($\bar{a} \approx 0.5$). In the Ag^+/Ag on Au system, the silver deposited almost entirely as Ag(O).

Microscopic electrode area.—The microscopic area of gold disk electrode was determined in order to permit charge density calculations required to interpret the coulostatic relaxation experiments performed in Hg^{2+} and Ag^+ solutions. After potentiostating a pretreated and reduced stationary Au disk electrode at 1.20V for 5 min the charge required to reduce the oxidized surface was used as a measure of the true microscopic Au area. This method has been described elsewhere (8). The microscopic area of the platinum disk electrode was calculated from hydrogen adsorption curves, assuming hydrogen adsorbs to the extent of 210 $\mu C/cm^2$ (9).

Results and Discussion

Coulostatic relaxation experiments involving Hg^{2+} were performed using a rotating gold ring-gold disk electrode, and both gold-gold and platinum-platinum ring-disk electrodes were used in the Ag^+ experiments. Representative disk potential-time (E_D-t) responses for these cases are shown in Fig. 2. In each case, following pretreatment, the electrode was open-circuited at an initial potential, E_i; E_D drifted anodically and finally reached its equilibrium potential, E_{eq}. Although not shown in this figure, E_{eq} depends on E_i. Note that the E_D-t curves for Hg^{2+} and Ag^+ on a Au are linear, while the Ag^+ on Pt curve has two linear parts and has a definite change in slope at about 0.5V.

Ring electrode shielding responses for each system show that metal ion is being consumed at the disk electrode while E_D drifts anodically. The ring electrode current, i_R, returns to the unshielded value at the time the E_D drift ceases. The ring electrode shielding curves also show that metal ion consumption occurs at a convective-diffusion controlled rate during most of the E_D relaxation. Also, the Ag^+/Ag on Pt system is diffusion controlled over at least the Ag^+ concentration range of 10^{-5}-$10^{-7}M$.

Hg^{2+}/Hg on Au.—The ring electrode shielding curve corresponding to the Hg^{2+}/Hg on Au E_D-t curve in Fig. 2 is shown in Fig. 3. The ring electrode in Fig. 3 is potentiostated at 0.0V. When the disk electrode is open-circuited the ring electrode becomes shielded (see Experimental section) until the disk electrode reaches E_{eq}. The shaded area represents Hg(II) that has deposited both as adatoms and adions on the disk

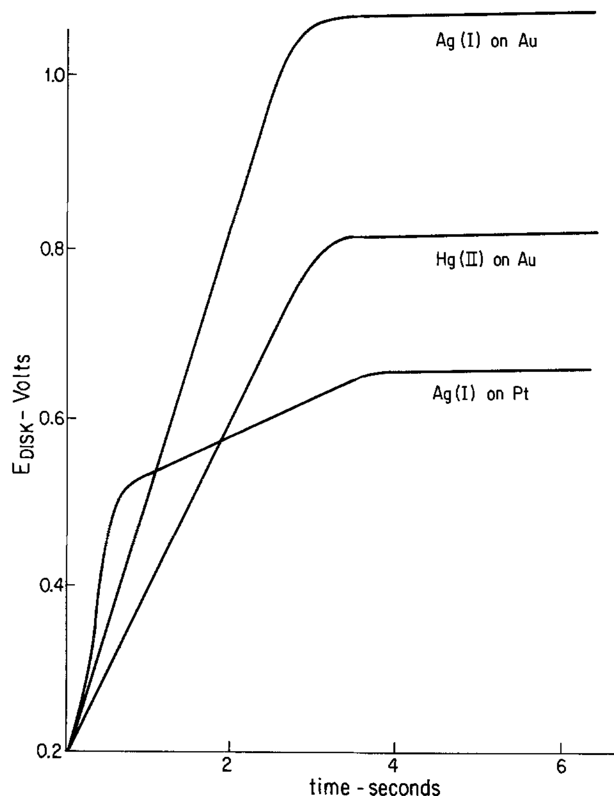

Fig. 2. Coulostatic potential-time curves for three UPD systems. $C_{M^{n+}} = 2 \times 10^{-5}M$, $\omega = 2500$ rpm, 0.2M H_2SO_4, geometric area of disk electrode = 0.46 cm^2. $E_{initial} = 0.2V$ in each case.

electrode surface. 54 $\mu C/cm^2$ of Hg(II) did not reach the ring electrode because the equivalent of this amount (2.8×10^{-10} g·atoms/cm^2) of Hg species adsorbed on the disk electrode. Analogous i_R-t curves were observed in each system studied.

If, after attaining E_{eq}, the disk electrode is swept in the anodic direction, oxidation peaks identical to those obtained for stripping conventionally prepared UPD deposits of Hg (5, 6) are observed.

Ring electrode shielding data of the kind shown in Fig. 3 were used to determine the UPD coverage of Hg as a function of E for various E_i's. The time integral of i_R, divided by the collection efficiency, N, of the RRDE yields the total quantity of Hg(II) species consumed at the disk as a function of time (and thus E_D). The maximum adsorbate that can be formed is determined in a separate potentiostatic RRDE experiment performed a few tenths of a millivolt anodic of the Nernst potential. At $\theta = 1$, 2.0×10^{-9} g·atom/cm^2 of total mercury adsorbate forms, of which only 87% is present as Hg(0). Using this maximum value we calculate θ as a function of E. Three of these E *vs.* θ

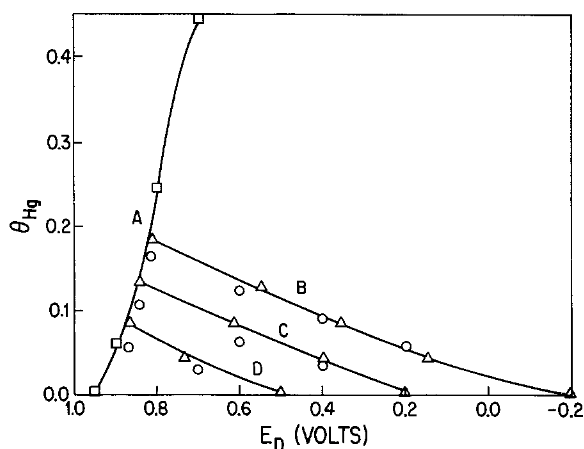

Fig. 4. θ_M vs. E plots for the Hg(II)/Hg on Au system. Three initial potentials −0.2, +0.2, and +0.5V vs. SCE. ω = 2500 rpm, 0.2M H_2SO_4, $C_{Hg(II)} = 2 \times 10^{-5}M$. Curve A experimental UPD isotherm, curve B is the theoretical θ-E path for E_i = −0.2V, curve C is the theoretical path for E_i = 0.2V, curve D is the theoretical path for E_i = +0.5V. △ are experimental points, ○ are calculated points using Eq. [11].

plots (curves B-D) are shown in Fig. 4 for the Hg^{2+}/Hg on Au systems. Note that as E_i is made more cathodic, θ at E increases and, also, that the slope of the E-θ plots appear to be independent of E_i. It can be seen from the plots shown in Fig. 4 that the θ-E behavior is consistent with Eq. [1]-[4]. Note that each of the θ-E paths terminates within experimental error, at the isotherm, curve A. These plots are similar to path 2 in the example discussed in the Theoretical section and, as shown below, are consistent with the view that adatom formation, by reduction of Hg(II) using charge stored in the double layer, is the main potential-determining process.

The experimental θ-E plots calculated from the coulostatic data agree well with Eq. [11]. As stated above, this would be the case when the bracketed term in the denominator of Eq. [10] is insignificant with respect to k. Thus, the bracketed term in Eq. [10] must be almost zero, and

$$C_M \simeq C_S(E_S^* - E)/(E_M^* - E) \qquad [13]$$

Values of C_M, calculated from Eq. [13], range from 30 to 40 $\mu C/m^2$ for nearly all the experimental data if E_M^* is taken to be equal to that of bulk mercury. Thus, the value of C_M is surprisingly similar to that of mercury at anodic potentials.

The value of k in Eq. [11] (as determined coulometrically) is 295 $\mu C/cm^2$ in the UPD coverage range of mercury, $0.06 \leq \theta \leq 0.2$. This coulometric value was calculated from the charge required to oxidize the UPD mercury from the disk electrode. The value of k calculated from the "straight" lines plots in Fig. 4 were: curve B, 300 $\mu C/cm^2$ and curves C and D, both 295 $\mu C/cm^2$. Thus, the predictions of the coulostatic relaxation mechanism agree well with independent coulometric data for Hg(II) UPD as Hg(0).

Ag^+/Ag on Au and Pt.—Two other systems were studied to investigate the generality of the coulostatic UPD phenomena. The E_D-t curve shown in Fig. 2 for the Ag^+/Ag system on Au and Pt shows that coulostatic deposition occurs on these two metals. For the Ag^+/Ag on Au system, the UPD isotherm is very steep in the range $0 \leq \theta \leq 0.3$, and E_{eq} was observed to be nearly independent of E_i. Ag^+ does not appear to absorb on Au appreciably in the potential range studied and Eq. [11] adequately describes the E-θ paths. The Ag^+/Ag on Pt system shows more complex behavior than the other systems during coulostatic relaxation experiments. The isotherm for Ag on Pt is shown in Fig. 5. These data are presented in terms of microcoulombs per square centimeter of Ag(I) consumed at the disk in order to clarify the discussion that follows.

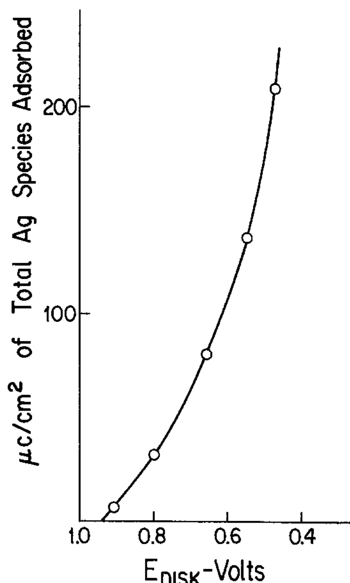

Fig. 5. UPD isotherm for Ag(I)/Ag on Pt in 0.2M H_2SO_4

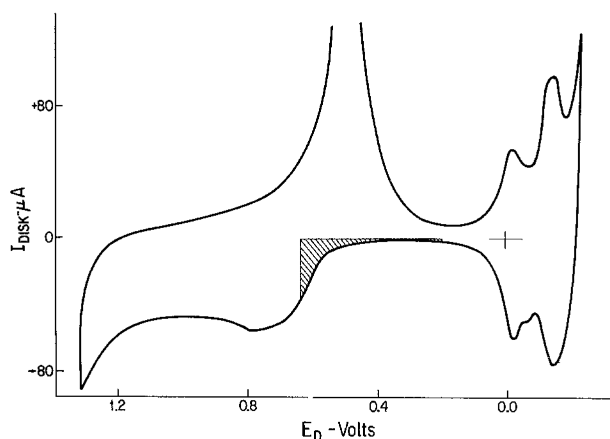

Fig. 6. Current-potential curve for Pt disk electrode in 0.2M H_2SO_4. Area of disk = 0.46 cm^2, roughness factor = 1.6, dE_d/dt = 100 mV/sec.

A comparison of the isotherm with the current-potential curve for platinum in 0.2M H_2SO_4 (Fig. 6) indicates that a significant quantity of a silver species exists on the platinum surface in the potential region where some surface oxidation has occurred.

Figure 7 represents the charge-potential curve calculated from the anodic current-potential scan in Fig. 6. In going from 0.2 to 0.64V, 90 $\mu C/cm^2$ are required for double layer charging and electrode oxidation. A RRDE experiment, conducted during a coulo-

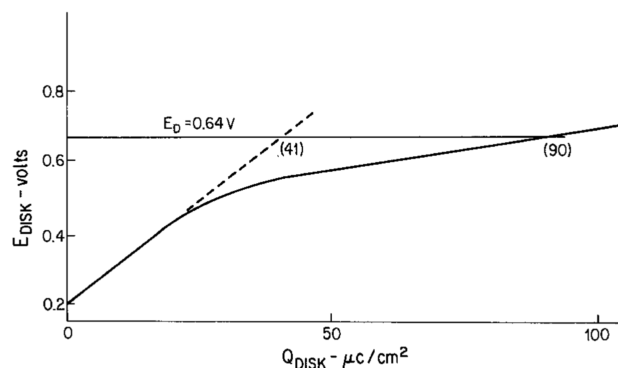

Fig. 7. Charge-potential curve for anodic portion of Fig. 6

static relaxation experiment in $2 \times 10^{-5}M$ Ag^+ in $0.2M$ H_2SO_4 (Fig. 2), showed that 88 $\mu C/cm^2$ of Ag^+ was consumed at the disk between 0.2 and 0.64V. The agreement between the amount of Ag^+ consumed and the charge data in Fig. 7 is most simply explained by the reduction of Ag^+ to Ag(0) on platinum during the coulostatic relaxation. The charge required for this reduction was supplied from the double layer and by electrochemical oxidation of the platinum surface, just as is the case when anodic charge flows in the external circuit.

It should be noted that the fraction of the platinum surface that may be oxidized at E_{eq} is not large. However, the conclusion that some platinum surface oxidation occurs as a result of the couples

$$Ag^+ + Pt + e \rightarrow Ag_{UPD}$$

$$Pt \rightarrow Pt(oxidized) + e$$

is an indication of the strength of the interaction between UPD silver and surface platinum atoms.

Conclusion

The coulostatic process can lead to significant surface coverages of species which can be underpotentially deposited. Thus, when an open-circuited electrode is immersed in a solution containing metal ions which can underpotentially deposit, the electrode potential will drift to a potential determined by the UPD isotherm for the metal ion/substrate system. Changing the concentration of the metal ion present in solution will then produce another shift in potential to a new point on the UPD isotherm. This phenomenon provides a mechanism that explains how "noble" metal electrodes such as platinum and gold can act as indicator electrodes in potentiometric titrations involving certain metal ions, such as Ag^+. Also, given the UPD isotherm for a particular metal ion at different metal substrates, the coulostatic theory predicts which metal substrate will yield the largest change in end-point potential during a potentiometric titration. The coulostatic UPD process also provides another way to alter the characteristics of electrocatalysts by (unsuspected) trace metal ion impurities and should be added to the catalog of mechanisms by which electrode processes can be unintentionally inhibited or accelerated.

Coulostatic Deposition of Metals at Underpotential

II. The Effect of Heterogeneous Chemical Reactions on the Potential Relaxation Process

W. G. Sherwood,*[,1] D. F. Untereker,**[,2] and Stanley Bruckenstein**

ABSTRACT

The coulostatically controlled underpotential deposition (UPD) processes Ag(I) + e = Ag on gold and platinum and Hg(II) + $2e$ = Hg on gold have been shown to lead to anodic potential excursions (1). Chemical reactions that precede and/or accompany coulostatic underpotential deposition can produce two other kinds of potential relaxation. For example, the potential of an oxidized gold electrode, on being open-circuited in Hg(I) solutions, shifts continuously to a more cathodic potential until equilibrium is reached. The Hg(I) reduces the gold oxide and then produces a UPD mercury layer on the gold surface through the disproportionation reaction

$$(Hg(I))_2 + Au \rightarrow Au\text{-}Hg + Hg(II)$$

The potential shift ceases when the Nernst potential is reached. The potential of a reduced gold electrode, on being open-circuited in a Hg(I) solution, initially shifts anodically and then shifts cathodically until equilibrium is reached. The initial anodic shift is due to a conventional coulostatic deposition mechanism while the subsequent cathodic shift is due to the disproportionation mechanism given above.

In a previous paper dealing with potential relaxations occurring at open-circuited metal electrodes, a theory for coulostatic underpotential metal deposition (UPD) was developed (1). Experimental evidence was given for zero-current UPD in the systems Ag^+/Ag on Pt, Ag^+/Ag on Au, and Hg^{2+}/Hg on Au. In these systems, the coulostatic process causes a monotonic anodic potential excursion that stops when the UPD surface coverage and electrode potential reach the UPD isotherm for the system. In this paper, two

Key words: coulostatic, underpotential deposition, heterogeneous reaction.

situations are considered that exhibit cathodic potential excursions, both taking place in dilute Hg(I) solutions in $0.2M\ H_2SO_4$. In the first case, an oxidized gold electrode is open-circuited, and in the second case an oxidized gold electrode surface is electrochemically reduced and then open-circuited at a cathodic potential. The (initially) anodically poised system exhibits a monotonic cathodic potential excursion, while the (initially) cathodically poised system first undergoes an anodic potential shift, which is then followed by a cathodic potential excursion. The concepts developed previously (1) are valid in these more complicated systems where heterogeneous chemical reactions also occur.

We show below that: (*i*) when an oxidized gold electrode is open-circuited in a Hg(I) solution, the electrode surface is first reduced by the oxidation of Hg(I) to Hg(II), and then covered with UPD Hg resulting from the disproportionation reaction

$$(\mathrm{Hg(I)})_2 + \mathrm{Au} \rightleftharpoons \mathrm{Au\text{-}Hg} + \mathrm{Hg(II)} \qquad [1]$$

and (*ii*) when a reduced gold electrode is open-circuited in a Hg(I) solution, coulostatic UPD of Hg first shifts the potential anodically then the disproportionation reaction shifts the potential cathodically. In both cases the potential relaxation ceases when the Nernst potential is reached.

Theoretical

Double layer charging in the presence of surface chemical reactions.—If an electrode is potentiostated at a potential, E_i, and then open-circuited, and a chemical process occurs to produce or remove a monolayer film of coverage, θ, the equilibrium electrode potential will correspond to a point on the isotherm of the adsorbate being formed or removed. The charge in the double layer may be expressed by

$$Q_{E_i} - q_{E,\theta} = AC_{E,\theta}\,(E_\theta{}^* - E) \qquad [2]$$

where Q_{E_i} is the charge in the double layer at the potential of disconnect, E_i, A is the microscopic electrode area, and $C_{E,\theta}$ is the integral double layer capacitance per unit area. $C_{E,\theta}$ is defined with respect to the θ-dependent potential of zero charge, $E_\theta{}^*$, and is a function of E and θ. $q_{E,\theta}$ is the charge injected into or removed from the double layer on "adsorbing" one or more solution species in going from E_i to E. A part of $q_{E,\theta}$ may involve one or more species detectable at the ring electrode of a ring-disk electrode. When this is the case, it becomes possible to quantitate the change in the flux of these species to or from the disk electrode surface and to describe these flux changes in terms of adsorption. Using disk electrode charge data obtained in experiments subsequent to the open-circuit (coulostatic) experiment and making assumptions concerning the double layer capacitance, the net charge of the adsorbate can be estimated.

Interpretation of ring electrode currents.—The ring-disk electrode is used to determine the presence, generation, or removal of the Hg(I) and Hg(II) species.

At $E_R = 1.0\text{V}$, the reaction

$$(\mathrm{Hg(I)})_2 \rightleftharpoons 2\mathrm{Hg(II)} + 2e^- \qquad [3]$$

occurs, while at $E_R = 0.0\text{V}$, the reactions

$$(\mathrm{Hg(I)})_2 + 2e^- \rightleftharpoons 2\mathrm{Hg} \qquad [4]$$

and

$$\mathrm{Hg(II)} + 2e^- \rightleftharpoons \mathrm{Hg} \qquad [5]$$

occur. Thus, ring electrode current measurements at $E_R = 1.0\text{V}$ and 0.0V allow us to determine the disk electrode surface concentrations of Hg(I) and Hg(II) in a Hg(I) solution, using the fundamental definition of the collection efficiency, N, at both ring electrode potentials.

In the discussion that follows, $C_{II}{}^S$ represents the concentration of Hg(II) at the disk electrode surface and $C_I{}^S$ and $C_I{}^b$ represent the disk electrode surface and bulk concentrations of $(\mathrm{Hg(I)})_2$, respectively.

For $E_R = 1.0\text{V}$, the flux of Hg(I) to the ring equals the flux of Hg(I) from solution plus the flux of Hg(I) from the disk, or

$$\frac{(i_R)_{1.0}}{2\mathbf{F}} = \beta^{2/3} L C_I{}^b - NL(C_I{}^b - C_I{}^S)$$

and

$$(i_R)_{1.0} = -2\mathbf{F}L\{(\beta^{2/3} - N)C_I{}^b + NC_I{}^S\} \qquad [6]$$

where L is the Levich constant relating flux and species concentration (2), $\mathbf{F}$ is the Faraday, $\beta^{2/3}$ the ratio of the convective-diffusion controlled ring to disk electrode currents when the ring operates in the absence of a disk current, and $(i_R)_{1.0}$ is the ring electrode current when $E_R = 1.0\text{V}$.

For $E_R = 0.0\text{V}$, the flux of Hg(II) to the ring electrode is the RRDE collection efficiency times the flux of Hg(II) leaving the disk electrode; hence the part of the ring current at $E_R = 0.0\text{V}$ due to reduction of Hg(II) is

$$(i_{R,II})_{0.0} = 2\mathbf{F}LNC^S{}_{\mathrm{Hg(II)}} \qquad [7]$$

The Hg(I) flux balance leads to

$$\frac{(i_{R,I})_{0.0}}{2\mathbf{F}} = \beta^{2/3} < C_I{}^b - NL(C_I{}^b - C_I{}^S)$$

or

$$(i_{R,I})_{0.0} = 2\mathbf{F}L\{(\beta^{2/3} - N)C_I{}^b + NC_I{}^S\} \qquad [8]$$

where $(i_{R,I})_{0.0}$ is the part of the ring current at $E_R = 0.0\text{V}$ due to Hg(I) reduction. Equation [8] describes the Hg(I) shielding process. The observed ring current, $(i_R)_{0.0}$ in a solution containing $(\mathrm{Hg(I)})_2$ and in which Hg(II) is generated at the disk is

$$(i_R)_{0.0} = (i_{R,II})_{0.0} + (i_{R,I})_{0.0}$$

or

$$(i_R)_{0.0} = 2\mathbf{F}L\{(\beta^{2/3} - N)C_I{}^b + N(C_{II}{}^S + C_I{}^S)\} \qquad [9]$$

where it is assumed that $D_I = D_{II}$, as observed to a very good approximation (3).

Experimental

Reagents.—Supporting electrolyte solutions were prepared from triply distilled water and Baker Analyzed Reagent Grade sulfuric acid. Stock $0.1M\,(\mathrm{Hg(I)})_2$ was prepared according to a procedure described elsewhere (4, 5). The solution was initially standardized using Pugh's method (4) and was later restandardized via amperometric titration with standard chloride solution.

Equipment.—Standard laboratory equipment was used for these experiments. The rotator, electrochemical cell, potentiostat, and the digital data acquisition and control system have been described elsewhere (6).

Data acquisition.—The data acquisition sequence used to obtain data for zero current experiments initiated on reduced gold electrodes ($0.9\text{V} > E_i > -0.2\text{V}$) is identical to that described previously for the Hg(II)/Hg on Au system (1). However, for the Hg(I) system it was necessary to perform rotating ring-disk electrode experiments with the ring electrode potentiostated at two ring potentials, *i.e.*, at 0.0V where both Hg(II) and Hg(I) are reduced at convective diffusion control and at 1.0V where Hg(I) is oxidized and can be selectively monitored in the presence of Hg(II).

The data acquisition sequence for zero current experiments initiated on an oxidized electrode was similar to the one described in Ref. (1). Following pretreatment of the gold disk electrode, the potential was stepped to 1.2V and maintained there for 5 min at $\omega = 0$ rpm. After potentiostating the ring electrode at the appropriate potential (1.0 or 0.0V), the electrode was rotated at $\omega = 2500$ rpm, the disk electrode current was set to zero, and the disk electrode potential-time and the ring electrode current-time responses were simultaneously recorded.

The charge required to electrochemically reduce the oxidized gold electrode surface formed at 1.2V was determined by separate linear voltage scan experiments and was related to the microscopic surface area according to the procedure of Brummer and Makrides (7). The value of the "real" surface area was needed to relate experiments done using different electrodes, since the electrode roughness determines both the double layer capacitance and the charge corresponding to one monolayer of UPD mercury.

Results and Discussion

Zero current reduction of oxidized gold: $E_D > 0.95V$. —*Disk electrode potential-time curves.*—Coulostatic relaxation experiments in the presence of Hg(I) were performed at an oxidized gold electrode poised at an initial potential, E_i, of 1.2V. The zero current disk electrode potential-time, E_D-t, response obtained is shown in curve A of Fig. 1.

After open circuiting the oxidized gold electrode, the potential rapidly shifts cathodically from 1.2 to 0.95V. Gold oxide reduction occurs at these potentials, and, therefore, the initially oxidized gold surface must be undergoing reduction. Hg(I) is oxidized at potentials where the gold oxide surface is reduced (3). Therefore, oxidation of Hg(I) by surface gold oxide is a thermodynamically spontaneous process. Since the Au electrode is open-circuited, it is plausible that reduction of the oxide occurs via the heterogeneous chemical reaction

$$[Hg(I)]_2 + Au\ (oxidized) \rightleftarrows 2Hg(II) + Au\ (reduced) \quad [10]$$

Since 0.95V is slightly anodic of the UPD isotherm, no UPD Hg deposition can occur (1, 8).

Ring electrode current-time curves.—The ring electrode current-time responses accompanying the cathodic disk potential drift of Fig. 1, curve A, are shown in Fig. 2. The shielding response curve for Hg(I) (E_R = 1.0V, curve A) shows that it is being consumed at all disk potentials more anodic than ~0.4V (times less than 75 sec). However, the ring electrode collection current for Hg(II) and Hg(I) (E_R = 0.0V, curve B) is initially greater than its unshielded value. It returns to the limiting value about the time the Au disk electrode potential drops below ~0.95V, the potential corresponding to complete reduction of gold oxide. The i_R-t curves are consistent with reaction [10] since the Hg(I) ring shielding response shows that it is consumed quantitatively at the disk electrode. If reaction [10] is quantitative, $C_I^S = 0$. Thus according to Eq. [6], the change in ring current in going from a surface concentration of zero, when there is reaction according

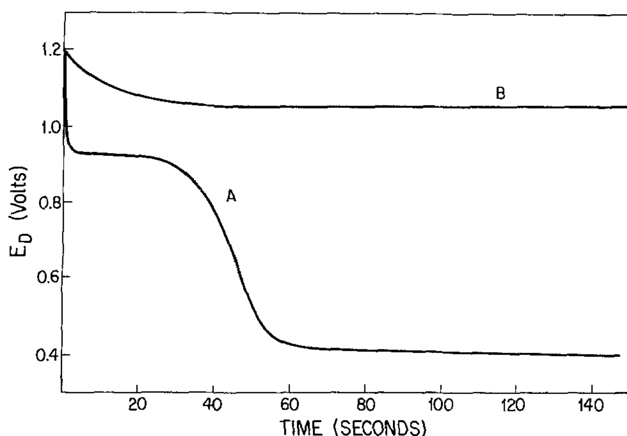

Fig. 1. Zero current potential-time responses at an oxidized gold disk electrode in: curve A. 0.2M H_2SO_4-2.0 × 10^{-5}M Hg_2^{2+}; and curve B, 0.2M H_2SO_4. ω = 2500 rpm.

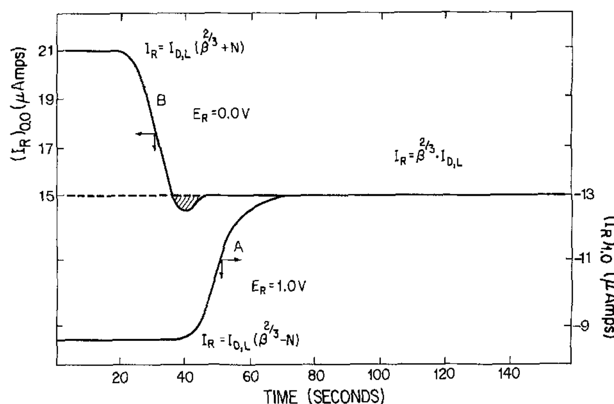

Fig. 2. Ring electrode current-time responses accompanying curve A of Fig. 1, curve A, E_R = 1.0V; curve B, E_R = 0.0V. I_{DL} is the appropriate disk-limiting current.

to Eq. [10], to a value of C_I^S when there is no reaction, is

$$(\Delta i_R)_{1.0} = 2\mathbf{F}LNC_I^S$$

The disk electrode limiting current for the oxidation of Hg(I) to Hg(II) (reaction [3]) is

$$(i_L)_{1.0} = -2\mathbf{F}LC_I^S$$

Hence

$$(\Delta i_R)_{1.0} = -N(i_L)_{1.0} \quad [11]$$

The average value of Δi_R for 10 experiments of the kind shown in Fig. 2, curve A, was 4.9 ± 0.2 μA. The value of $(i_L)_{1.0}$ was −14.2 and N = 0.341, yielding 4.8 μA for the product $N(i_L)_{1.0}$, in good agreement with the observed values of Δi_R. Note that the experimental value of $(i_L)_{1.0}$ is only 90% of the theoretical value. This low value of $(i_L)_{1.0}$ also occurs at platinum electrodes (7), appears to be associated with kinetic complication in the oxidation of Hg(I), and in no way affects our interpretation.

The ring collection response shows a cathodic current greater than the unshielded Hg(I) reduction current when $E_D > 0.95V$, *i.e.*, during the reduction of oxidized gold. We calculate the change in ring current, $(\Delta i_R)_{0.0}$, when the reaction given by Eq. [10] occurs as compared to when there is no reaction, as follows. Initially in the absence of reaction, the surface concentrations of Hg(I) and Hg(II) are C_I^b and 0, respectively, and they are 0 and C_I^S, respectively during the reaction. Thus

$$(\Delta i_R)_{0.0} = 2\mathbf{F}NL(C_{II}^S - C_I^b)$$

If Eq. [8] is quantitative, and $D_I = D_{II}$, $C_{II}^S = 2C_I^b$, and

$$(\Delta i_R)_{0.0} = 2\mathbf{F}NLC_I^b \quad [12]$$

The cathodic disk limiting current for reduction of Hg(I) to Hg is

$$(i_L)_{0.0} = 2\mathbf{F}LC_I^b$$

thus

$$(\Delta i_R)_{0.0} = N(i_L)_{0.0} \quad [13]$$

We found Δi_R = 5.9 ± 0.4 μA from 10 experiments of the type shown in Fig. 2, curve B. The value $(i_L)_{0.0}$ is 16.0 μA and N = 0.341 yielding a calculated value for the product of $N(i_L)_{0.0}$ of 5.5 μA, in satisfactory agreement with the assumption that reaction [10] occurs quantitatively at an oxidized gold electrode.

Charge balance.—The open-circuit potential relaxation must simultaneously satisfy Eq. [2] and the isotherm for oxygen coverage on gold. Since Q_{E_i} is constant and $C_{E,\theta}$ and E_θ are predetermined (but unknown) functions of E and θ, $q_{E,\theta}$ must adjust to satisfy the requirements of Eq. [2]. Therefore, charge balances between the quantity of gold oxide existing on the electrode surface and the various mercury species were made at 1.2V. All our experiments started at 1.2V, and it

was assumed that $\theta = 1$ for oxygen coverage (2.1×10^{-9} g-atoms O/cm^2), as stated by Brummer and Makrides (7).

Writing the reduction reaction as

$$AuO + (Hg(I))_2 + 2H^+ = Au + H_2O + 2Hg(II) \quad [14]$$

we see that $N_O = N_{(Hg(I))_2} = -\frac{1}{2}N_{Hg(II)}$, where N is the number of gram-atoms of the subscript species consumed. Eight replicate coulostatic relaxation experiments were performed in $2.0 \times 10^{-5}M$ $(Hg(I))_2$ solution. Ring electrode experiments at $E_R = 0.0$ and 1.0V showed that in going from 1.2 to 0.95V (oxidized to reduced surface) $4.0 \pm 0.1 \times 10^{-9}$ g-atoms/cm^2 of Hg(II) were produced and $2.1 \pm 0.2 \times 10^{-9}$ g-atoms/cm^2 of $(Hg(I))_2$ were consumed. Any discrepancies between these values and the number of O atoms on the initially oxidized gold surface (2.1×10^{-9} g-atoms/cm^2) are within experimental error, and there is no evidence for any Hg species contributing to the value of $q_{E,\theta}$ (Eq. [2]) in the potential range 1.2-0.95V.

Formation of UPD mercury by disproportionation of (Hg(II))$_2$.—In the material that follows we will demonstrate that during the disk potential relaxation process that occurs after the reduction of AuO ($E < 0.95$V), the surface concentrations of $[Hg(I)]_2$ and Hg(II) are in quantitative agreement with Eq. [1], and also that the amount of UPD Hg deposited agrees with the stoichiometry required by Eq. [1].

Ring current responses.—After the gold oxide surface is reduced, curve A of Fig. 1 shows that E_D shifts cathodically to 0.40V, the equilibrium potential we found for a Hg-covered gold electrode in the solution used. The accompanying ring current responses are given in Fig. 2. At 1.0V, the ring current remains completely shielded, as it was during the reduction of the oxidized gold surface. Clearly, Hg(I) continues to be removed at the disk electrode surface. Also, at $E_R = 0.0$V, the cathodic ring current changes in a direction corresponding to a decrease in the reducible flux reaching the ring electrode. Both ring current responses agree with the quantitative surface disproportionation of Eq. [13].

As shown above, if $C_I^S = 0$, Eq. [6] predicts a shielded ring current given by Eq. [11], and there should be no change in i_R between 0.95 and 0.40V since Eq. [1] continues to hold $C_I^S = 0$.

Further according to Eq. [1] and assuming $D_I = D_{II}$

$$C_{II}^S = C_I^b$$

Substituting this result and $C_I^S = 0$ into Eq. [9], the expression for the ring current at 0.0V is

$$(i_R)_{0.0} = 2FL\beta^{2/3}C_I^b$$

or

$$(i_R)_{0.0} = \beta^{2/3}(i_L)_{0.0} \quad [15]$$

In a $2.7 \times 10^{-5}M$ $(Hg(I))_2$ solution, $(i_L)_{0.0} = 21.6$ μA. Using the value, $\beta^{2/3} = 0.94$, we calculate the product $\beta^{2/3}$ $(i_L)_{0.0}$ to be 20.3 μA (9 experiments), in agreement with Eq. [15].

Thus the ring current responses at 1.0 and 0.0V are in quantitative agreement with the assumed heterogeneous disproportionation reaction.

Anodic stripping behavior.—Equation [1] also predicts that UPD mercury will deposit on the electrode surface. Curve A, Fig. 3, is an anodic current-potential curve seen on a gold disk electrode that has relaxed from 1.2 to 0.4V at open circuit. It yields anodic stripping peaks not found on a bare gold electrode. Ring electrode collection curves at $E_R = 1.0$V (not shown) and 0.0V (curve B, Fig. 3) demonstrate the collection of a species whose electrochemistry is that of Hg(II). Identical behavior is found for UPD Hg on Au.

The amount of UPD Hg assumed to be stripped was calculated from the disk anodic charge. In one particular experiment this charge corresponded to 1.7×10^{-9} g-atoms/cm^2, while 2.0×10^{-9} g-atoms/cm^2 of Hg(II) were formed, as calculated from the ring electrode collection. The discrepancy between the disk stripping and ring collection values is caused by adsorption of a charged Hg species at the disk (see below).

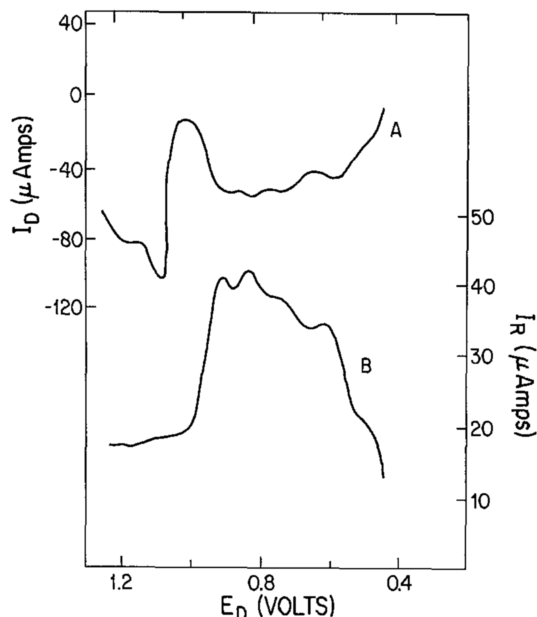

Fig. 3. Disk electrode stripping (curve A) and ring electrode collection response (curve B) obtained during anodic potential sweep after the zero-current experiment of Fig. 1, $\omega = 2500$ rpm, $E_R = 0.0$V.

The spontaneous formation of UPD mercury by Eq. [1] is not really surprising despite the unfavorable thermodynamics for this process at a bulk mercury surface. The strong interaction of Hg with Au on the formation of UPD mercury supplies the necessary driving force. The disproportionation reaction should cease when the UPD mercury surface becomes the same as that of bulk mercury. This proves to be the case since the "equilibrium" potential of a gold electrode in $[Hg(I)]_2$ solutions is the same as that of a bulk mercury surface (5). Note that the effect of the disproportionation reaction on the potential of the Hg/$(Hg(I))_2$ interface is negligible under our experimental conditions.

In eight replicate experiments at $E_R = 1.0$V, it was found that $1.9 \pm 0.2 \times 10^{-9}$ g-atoms/cm^2 of $[Hg(I)]_2$ were consumed in going from 0.95 to 0.40V (bare gold electrode to Hg-coated electrode). The stoichiometry of the disproportionation reaction (Eq. [1]) requires that $N_{(Hg(I))_2} = N_{Hg(UPD)}$. This relationship is consistent with the ring electrode collection data obtained during anodic stripping of UPD Hg, 1.9×10^{-9} g-atoms/cm^2 (3). The discrepancy between the quantity of Hg stripped from the disk electrode (1.7×10^{-9} g-atom/cm^2) and the quantity consumed at open circuit and collected at the ring electrode during the disk electrode anodic stripping experiment can again be attributed to the adsorption of a charged mercury species on the disk electrode surface (8). The small shielding response at $E_R = 0.0$ immediately after gold oxide reduction (shaded area, curve B, Fig. 2) is also consistent with the adsorption of a charged mercury species on the disk electrode since neither Eq. [1] nor Eq. [10] predict electrode shielding when $E_R = 0.0$V. The area of the shaded portion of curve A corresponds to only 1.6×10^{-10} g-atoms/cm^2 of adsorbed mercury species, compared to a difference between ring electrode collection and disk electrode stripping values of 5.4×10^{-10} g-atoms/cm^2. The additional charged mercury species adsorbed on the electrode surface at open circuit may be produced via a coulostatic discharge (oxidation) process, indicating that $q_{E,\theta}$ (Eq.

Table I. UPD Hg coverage for $0.95 > E_D > 0.40V$ obtained using $E_R = 1.0V$ data ($\theta_{1.0,R}$)

0.50	0.78	0.76
0.40	0.97	1.00

[2]) has a nonzero value in the potential range 0.95-0.40V.

Hg coverage vs. E.—The coverage of gold with UPD Hg after reduction of the oxidized gold should, according to Eq. [2], obey the E-θ isotherm for UPD Hg. Table I shows the coverages determined at various intervals in the potential range $0.95V > E_D > 0.40V$ using $E_R = 1.0V$ data.

The isotherm coverage, θ_{iso}, (column 3) determined independently (8) agrees well with that obtained using the ring electrode. This result confirms that the disproportionation reaction determines the potential relaxation response during the cathodic shift at potentials between 0.95 and 0.40V.

Potential relaxation of a reduced Au electrode $+0.9V > E_i > 0.2V$.—If a reduced gold electrode potentiostated at 1.0V is stepped to a potential in the region +0.9 to −0.2V, and then open-circuited the electrode potential initially relaxes anodically and then relaxes cathodically, stopping at 0.40V in a $2 \times 10^{-5}M$ $(Hg(I))_2$ solution. Typical experiments are shown in Fig. 4.

Our interpretation of this relaxation response is: (*i*) During the anodic potential shift, coulostatic discharge of $(Hg(I))_2$ occurs, producing UPD mercury on the gold electrode surface. The explanation of this process is identical to that given earlier (1) in Hg(II) solutions. (*ii*) The anodic potential excursion ceases when θ_{Hg} and E correspond to the UPD isotherm for Hg on Au. (*iii*) The cathodic potential excursion proceeds via the disproportionation reaction of Eq. [1].

Anodic potential shift region.—As the electrode potential shifts from E_i to a maximum anodic value, the i_R-t curves show that $[Hg(I)]_2$ is quantitatively consumed at the disk electrode and no Hg(II) is produced (Fig. 5). We calculate the electrode coverage with mercury species from the total amount of shielded Hg(I) (Fig. 5, curve A), and calculate θ assuming that 2.0×10^{-9} g-atom/cm^2 of total mercury species corresponds to $\theta = 1$ (3). Typical E_i-$\theta_{R,0.0}$ data are reported in columns 1 and 3 of Table II. The maximum anodic disk potential (E_D^P, column 2) obtained during the potential-time relaxation should correspond to a point on the UPD-Hg isotherm, if the mercury species being produced is UPD mercury. The last column of Table II corresponds to the value of θ_{iso} according to the previously determined UPD-Hg isotherm (8). The agreement between θ_{iso} and $\theta_{R,0.0}$ data is excellent and thus confirms the mechanism of the coulostatic discharge process. Note that as E_i is made more anodic, E_D^P becomes more anodic and the coverage obtained by coulostatic deposition decreases. At $E_i = 0.9V$, the anodic excursion and resultant coulostatic coverage are nearly zero, implying that all UPD-Hg is formed according to the disproportionation reaction, Eq. [3].

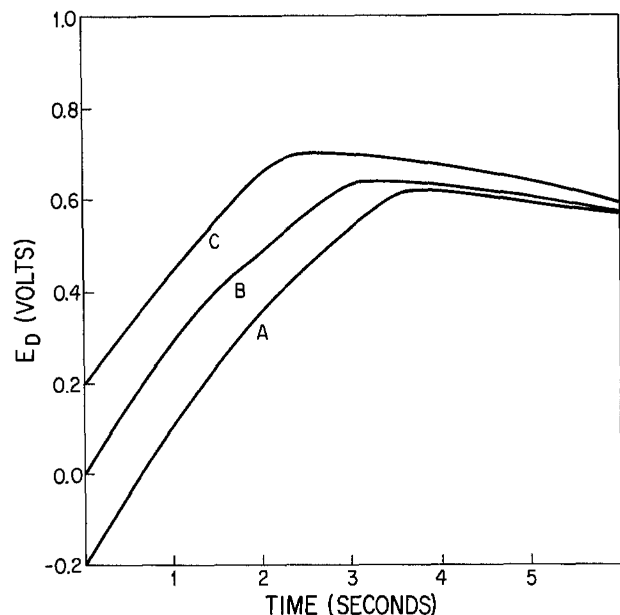

Fig. 4. Coulostatic E_D-t responses in 0.2M H_2SO_4-$2.0 \times 10^{-5}M$ Hg_2^{2+}. Curve A, $E_i = -0.20V$; curve B, $E_i = 0.0V$; curve C, $E_i = 0.20V$. $\omega = 2500$ rpm.

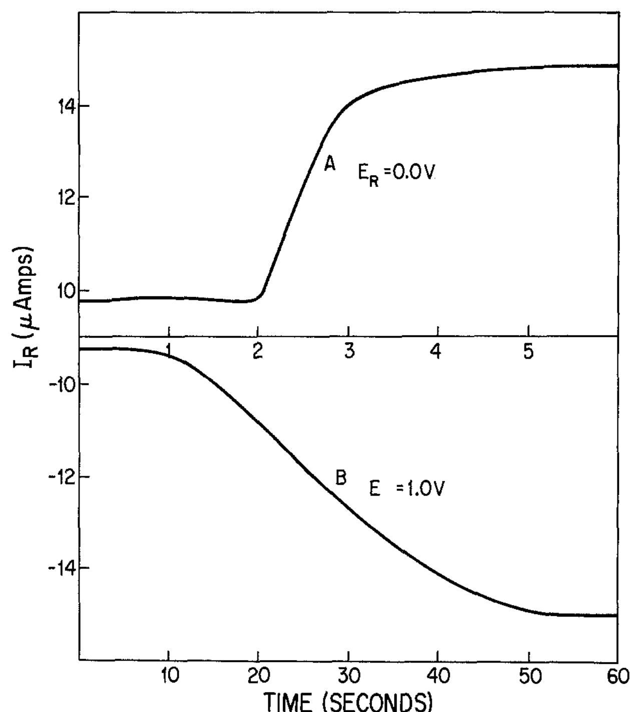

Fig. 5. Ring electrode current-time responses accompanying curve B of Fig. 4. Curve A, $E_R = 0.0V$; curve B, $E_R = 1.0V$.

Cathodic potential shift region.—Table III presents cathodic E-θ data obtained for an electrode initially potentiostated at 0.5V. The electrode potential first shifts anodically to a maximum of 0.78V, and then shifts cathodically. The potentials observed during this cathodic excursion E_D^C, are given in column 1 of Table III. Column 2, $\theta_{1.0,R}$, is the coverage calculated from ring data at $E_R = 1.0V$, and the third column, θ_{iso}, is the value of coverage taken from the previously determined isotherm (8). Again, agreement between $\theta_{1.0}$ and θ_{iso} is excellent, confirming that the dispropor-

tionation mechanism governs the cathodic part of the open-circuit discharge process that follows the initial anodic potential excursion.

Conclusions

The occurrence of two independent processes, namely, spontaneous reduction of gold oxide by $(Hg(I))_2$ and disproportionation of $(Hg(I))_2$, produces a cathodic potential shift on an initially oxidized gold disk electrode under open-circuit conditions. When open-circuit experiments are performed on an initially reduced gold disk electrode, there is first an anodic potential excursion, during which UPD Hg deposits coulostatically, and then there is a cathodic potential excursion as the UPD Hg coverage increases via disproportionation of $(Hg(I))_2$ along the UPD isotherm. The point at which the potential excursion changes direction corresponds to a UPD mercury coverage relationship of the UPD isotherm. The final mercury coverage obtained for all initial potentials of open circuiting was $\theta = 1$, as predicted from the theory developed in Ref. (1).

ABSTRACT

The kinetics of the Fe(II)-Fe(III) and of the hydroquinone-quinone reaction were investigated on smooth rhodium covered with oxygen to the extent of $\theta = 0$ to 1.5 monolayer charge equivalents (2 electrons per oxygen atom). For the Fe(II)-Fe(III) system the apparent rate constant varies systematically from $k_a^o = 4.60 \times 10^{-4}$ cm sec^{-1} at $\theta = 0$ to $k_a^o = 2 \times 10^{-5}$ cm sec^{-1} at $\Theta = 1.40$ and it does not seem to decrease significantly after that. The charge transfer coefficient is 0.55 ± 0.04 independent of θ. For the hydroquinone-quinone system, $k_a^o = 2.42 \times 10^{-4}$ cm sec^{-1} at $\theta = 0$ and $k_a^o = 1.87 \times 10^{-5}$ cm sec^{-1} at $\theta = 0.75$ and it varies only little for $\theta \geqq 0.75$. The charge transfer coefficient is 0.53 ± 0.07. Data are interpreted on the basis of a blocking effect, the charge transfer rate on oxygen-covered rhodium being negligible as compared to that on the free surface.

There is ample evidence in electrochemical literature that materials adsorbed on electrode surfaces can substantially influence the rate of electrochemical reactions (1). Several possible mechanisms for this influence have been discussed (2-5). The effect may arise from a simple geometric blocking effect in which the electrochemical reaction occurs only at the free surface, or from a field effect in which the adsorbed material alters the potential at the outer Helmholtz plane, or, alternatively, changes the position of the plane in the double layer at which reaction occurs.

One of the most common materials adsorbed on electrode surfaces is oxygen. The adsorbed oxygen or oxide film on a metal electrode generally inhibits the rate of an electrochemical reaction. It causes passivation on some metals, inhibiting metal dissolution reactions (6), and prevents electron transfer reaction on others, *e.g.*, oxalic acid oxidation on platinum (7). But while this effect of adsorbed oxygen is widely acknowledged, its mechanism is not well understood. It was our intent in the present study to focus upon the quantitative features of oxide film inhibition of charge transfer reactions and the mechanism responsible for the effect.

Previous efforts in this direction are those of Schmid and co-workers (8, 9), who studied the effect of adsorbed oxygen on the gold dissolution reaction and on the Ce(III)-Ce(IV) reaction kinetics at a gold electrode. They point out that the amount of adsorbed oxygen on a noble metal electrode can be controlled

* Electrochemical Society Active Member.
Key words: electrode kinetics, oxygen coverage, double layer, blocking effects.

and determined through its charge equivalent upon electroreduction. Moreover, the oxygen adsorption-desorption behavior at such electrodes exhibits a hysteresis which makes it possible to have various coverages on the surface at a fixed potential. This allows the kinetics of a charge transfer reaction to be studied as a function of oxygen coverage alone, all other experimental conditions being held constant. However, Bonewitz and Schmid's (9) choice of gold as the test electrode limited the scope of their study in two respects. Firstly, oxygen adsorbs on gold only at a potential above 1.2V *vs.* NHE, and the number of simple electron transfer reactions with equilibrium potentials in the range of 1.2-1.4V is small. Secondly, relative to the oxygen adsorption curves of gold, the equilibrium (formal) potential of the Ce(III)-Ce(IV) couple is such as to permit kinetic data to be taken only at coverages equivalent to or greater than about 0.6 of a monolayer. Trends at $0.6 \leq \theta \leq 1$ indicate the possibility of a more dramatic rate change in the $\theta = 0$ to $\theta = 0.6$ range of coverage.

In the present study rhodium was chosen as the test electrode material. Although the hysteresis of oxygen adsorption on rhodium is not as pronounced as on gold, the potential range over which adsorption occurs begins at 0.6V, making it possible to choose some simple redox couples whose rates can be studied as a function of oxygen coverage in the $\theta = 0$ to $\theta = 1$ range. Accordingly, the test systems chosen were the Fe(II)-Fe(III) and hydroquinone-quinone couples, the kinetics of which have been thoroughly studied by other workers and are well known to be free of undue complications (6).

Experimental

Solutions and materials.—The water employed throughout this work was distilled once from alkaline permanganate, then twice more in an all-quartz still. The 1.0*M* $HClO_4$ was made up directly from standardized reagent grade 70% $HClO_4$ solutions. 0.1*M* ferrous and ferric perchlorate stock solutions were prepared in 1.0*M* $HClO_4$ from the reagent grade salts once recrystallized from 1.0*M* $HClO_4$. The ferrous and ferric ion concentrations were determined by titrating aliquots of each solution with standard permanganate, both with and without prereduction with stannous chloride. When kept in closed flasks, periodic restandardization showed the 0.1*M* ferrous solutions to be stable with respect to air oxidation over the two to three week periods of usage. All hydroquinone and quinone test solutions were prepared gravimetrically from the reagent grade materials without further purification.

The all-Pyrex electrochemical cell was of standard design and contained in the main compartment a rhodium wire test electrode (Englehard Industries) of 0.100 cm^2 apparent surface area and a large-area platinum wire gauze auxiliary electrode. The main compartment was connected via a Haber-Luggin capillary to a side compartment containing a saturated calomel reference electrode. The capillary contained a normally closed ground glass stopcock to prevent chloride contamination of the test solution. In addition, the cell was fitted with gas lines to allow purging of dissolved oxygen from the test solutions with helium. The lines were made of Pyrex glass and 5/16 in. Teflon tubing connected with Teflon Swageloks.

Experimental procedures.—At the outset of this work, the test electrode was cleaned by brief immersion in aqua regia followed by washing with copious amounts of water. Thereafter, and preceding each run, the electrode was cleaned by immersion in chromosulfuric cleaning solution for 10 min and then thoroughly rinsed with water. To purge the test solutions of oxygen, a constant stream of helium (99.99% pure) was bubbled through the cell for at least 8 hr prior to and during a run. Solutions were stirred with a magnetic stirrer.

The oxygen coverage of the test electrode was determined by constant current cathodic stripping. To determine the ascending coverage (*i.e.*, coverage established coming from more cathodic potentials) the electrode was first set to 0.25V, where the surface is free of adsorbed oxygen, for at least 5 min using a Wenking Model 70TS1 potentiostat. The electrode was then set to a value in the range of 0.65-1.65V and held there for 10 min to allow for the oxygen coverage to reach steady state. The potentiostat, which was bucking the current from a Kepco Model ABC 40-0.5M power supply, was then disconnected from the circuit using a Potter and Brumfield mercury-wetted relay, which simultaneously triggered a storage oscilloscope (Tektronix, Model 564B). The potential-time function produced by the stripping current was displayed on the oscilloscope screen. "Transition times" were read from inflection point to inflection point and the charge calculated as the product of stripping current and time. For determination of the descending coverage (*i.e.*, coverage established coming from more anodic potentials) the electrode was held at 0.25V and then at some value in the 0.65-1.65V range for 5 and 10 min, respectively. The potential was then lowered to a value between 1.65 and 0.40V and held there for another 10 min, after which stripping was carried out as above. The constant stripping current from the power supply was found by measuring the potential drop across a standard resistor with a Hewlett Packard 425A electrometer.

Apparent exchange currents, i_o^a, for the Fe(II)-Fe(III) and hydroquinone-quinone reactions were obtained at various equilibrium potentials and various oxygen coverages of the electrode and were computed from the slopes of low overpotential *vs.* current density data. Prior to the application of overpotentials about a given equilibrium potential the oxygen coverage was always established as described above. Overvoltages were applied in steps of ±5 and ±4 mV about the equilibrium potentials of the hydroquinone-quinone and Fe(II)-Fe(III) systems, respectively, with the total applied overvoltages for the two systems being ±15 and ±16 mV, respectively. Again, the currents were determined by measuring the potential drop across a standard resistor with a Hewlett Packard 425A electrometer. Typical plots are shown in Fig. 1.

Results and Discussion

Cathodic stripping.—In the cathodic stripping of rhodium in acidic solutions, the removal of adsorbed

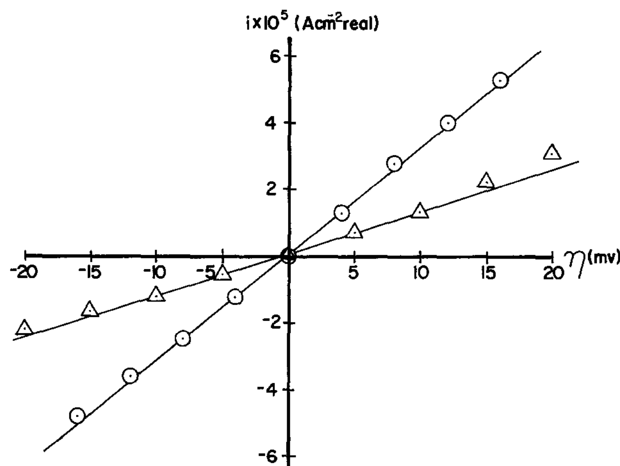

Fig. 1. Typical plots of current density *vs.* overpotential. ○: Fe(II)-Fe(III) reaction ($5.41 \times 10^{-3}M$ Fe(II), $1.786 \times 10^{-3}M$ Fe(III), $E_{eq} = 0.731V$, $\theta = 0.76$); △: hydroquinone-quinone reaction ($1.010 \times 10^{-3}M$ H_2Q, $0.1303 \times 10^{-3}M$ Q, $E_{eq} = 0.616V$, $\theta = 0.26$).

oxygen is followed by the adsorption of hydrogen. The potential of oxygen removal is more negative the higher the potential at which the coverage is established and the larger the stripping current density, making it increasingly more difficult to separate oxygen removal from hydrogen adsorption (10, 11). However, no major difficulties were encountered with current densities of less than 10 mA cm^{-2}. In the experiments reported here the stripping current density was 5 mA cm^{-2}. The results are shown in Fig. 2. The hysteresis frequently found for oxygen adsorption on noble metals is evident, *i.e.*, the coverage depends on the highest potential reached prior to stripping. It is assumed, as in the case of gold (9), that the change in slope of the ascending curve at +0.95V indicates the point at which a monolayer of oxygen atoms is adsorbed on the surface. The charge corresponding to this break is 2700 $\mu C\ cm^{-2}$ apparent. Taking 560 $\mu C\ cm^{-2}$ real (two electrons per rhodium surface atom and 1.74×10^{15} atoms cm^{-2}), the roughness factor calculated is approximately 5, a value not unreasonable for an etched electrode. Fractional coverages, θ, were calculated using 2700 $\mu C\ cm^{-2}$ apparent as representing monolayer coverage. All kinetic parameters reported in this paper are reported in terms of real area using a roughness factor of 5.

A charge of 560 $\mu C\ cm^{-2}$ real for a monolayer and a roughness factor of 5 agree well with the results of other workers. Thus, Böld and Breiter (10) find a charge of about 1.3 mC cm^{-2} apparent with oxygen uptake starting at 0.55V in acidic solution. Icenhower *et al.* (11) report approximately 0.5 mC at 1.0V *vs.* RHE in acidic solution on what appears to be a smooth Rh wire of 0.4 cm^2 apparent area. Will and Knorr (12) show a change of slope of the oxygen uptake curve at about 0.9V and a charge of about 0.4 mC cm^{-2} in good agreement with the results presented here.

The Fe(II)-Fe(III) reaction.—Ten ferrous-ferric mixtures, varying from 5.35×10^{-4}M to 5.41×10^{-3}M in Fe^{++} and 4.82×10^{-4}M to 5.73×10^{-3}M in Fe^{+++} (Table I), all 1.0*M* in $HClO_4$, were used in studying the reaction kinetics of this system. The equilibrium potentials showed good Nernstian behavior.

For each solution the apparent exchange current, i_o^a, was determined as a function of oxygen coverage of the electrode in the range of $0.3 \leq \theta \leq 1.6$ by appropriate selection of the initial anodic potential of the electrode. The experimental data are listed in Table I. A representative plot is shown in Fig. 3. Typically, i_o^a decreased linearly with increasing θ down to a coverage of $\theta = \sim 1.3$, beyond which point i_o^a appeared to decline at a much slower rate.

Values of the apparent charge transfer coefficient, α, and the standard rate constant, k_o^a, were obtained at various oxygen coverages by using the expression (13)

$$\ln (i_o^a/c_o) = -(n\mathbf{F}\alpha/RT)E_{eq} + \ln n\mathbf{F}Ak_o^a$$

where c_o is the concentration of the oxidized species, in this case Fe(III). Thus, α values were calculated from the slopes and k_o^a values from the intercepts of plots in $\ln (i_o^a/c_o)$ *vs.* E_{eq}, keeping the coverage of adsorbed oxygen constant for any one plot. Such plots were made for oxygen coverages of $\theta = 0$, 0.25, 0.50, 0.75, 1.00, 1.25, and 1.50 with the appropriate i_o^a values being obtained by interpolation or extrapolation from the i_o^a *vs.* θ plots. Two representative plots are shown in Fig. 4. The slopes and intercepts were obtained by a least squares analysis, assuming E_{eq} to be known precisely. The results are summarized in Table II, from which it can be seen that α remains fairly constant with oxygen coverage $0 \leq \theta \leq 1.5$. Figure 5 shows the plot of the least

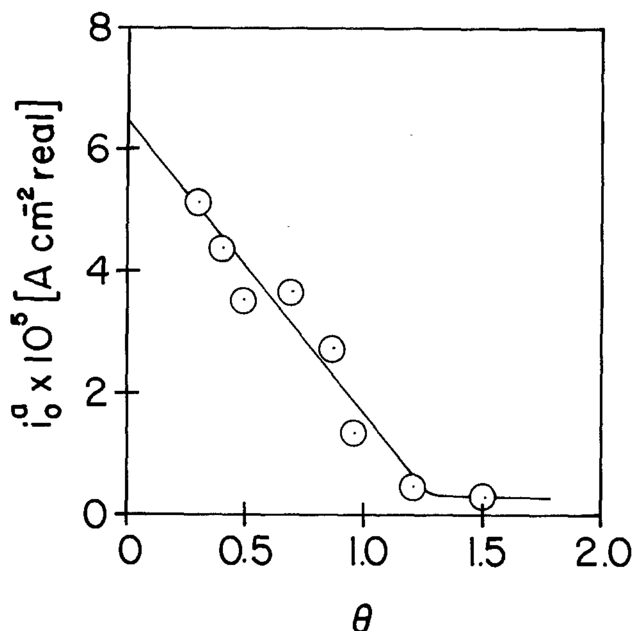

Fig. 3. Effect of θ on i_o^a for the Fe(II)-Fe(III) reaction. Solution 1.0M in $HClO_4$, 5.41 × $10^{-3}M$ in Fe^{++}, and 0.659 × $10^{-3}M$ in Fe^{+++}.

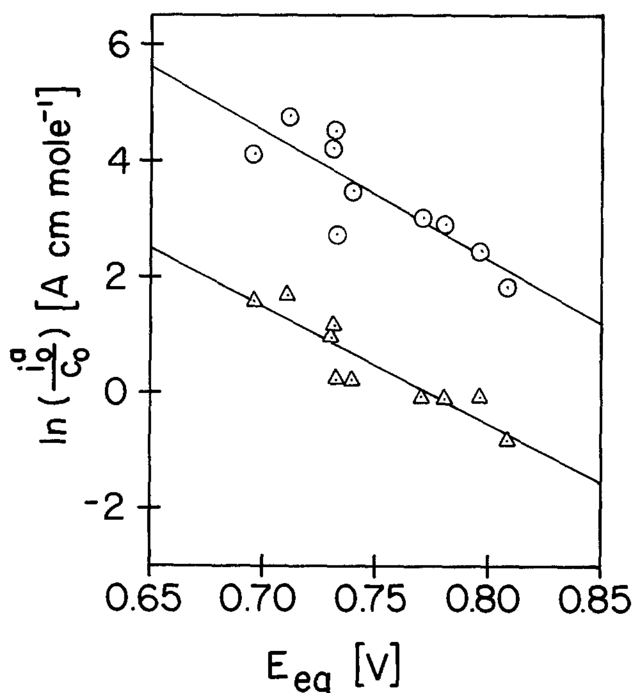

Fig. 4. Plots of $\ln(i_o^a/c_o)$ vs. E_{eq} for the Fe(II)-Fe(III) reaction. ⊙: $\theta = 0.5$; △: $\theta = 1.5$.

squares k_o^a values *vs.* oxygen coverage. k_o^a decreases linearly up to $\theta = 1.4$, but then seems to diminish much more slowly.

Standard rate constants quoted in the literature for the Fe(II)/Fe(III) reaction in both 1M $HClO_4$ and 1M H_2SO_4 on Pt are generally between 5 × 10^{-3} and 2 × 10^{-2} cm sec^{-1} and are thus higher by a factor of 6-10 than the values reported here (14-19). On glassy carbon in $HClO_4$ they are > 10^{-2} cm sec^{-1} (20), on carbon paste in H_2SO_4 ~10^{-5} cm sec^{-1} (21, 22). In view of the dependence of the rate on electrode material the k_o^a for Rh at $\theta = 0$ is quite reasonable. The values of α are in good agreement with Stulikova's and Gerischer's work (14, 20) on Pt in H_2SO_4 and $HClO_4$.

The hydroquinone-quinone reaction.—Five different hydroquinone-quinone solutions varying from 8.57 × $10^{-5}M$ to 1.06 × $10^{-2}M$ in hydroquinone and from 9.26 × $10^{-5}M$ to 4.46 × $10^{-3}M$ in quinone were used in studying the kinetics of this reaction. Apparent exchange currents were determined in the same way as for the Fe(II)-Fe(III) system, with values being obtained for oxygen coverages ranging from $\theta = 0$ to $\theta = 1.65$. Table III contains these data for all solutions. A typical plot of i_o^a *vs.* θ is shown in Fig. 6, and indicates a linear variation of i_o^a with oxygen coverage over the range of $\theta = 0$ to $\theta = $ ~0.7. At higher values of θ, i_o^a is constant within experimental error.

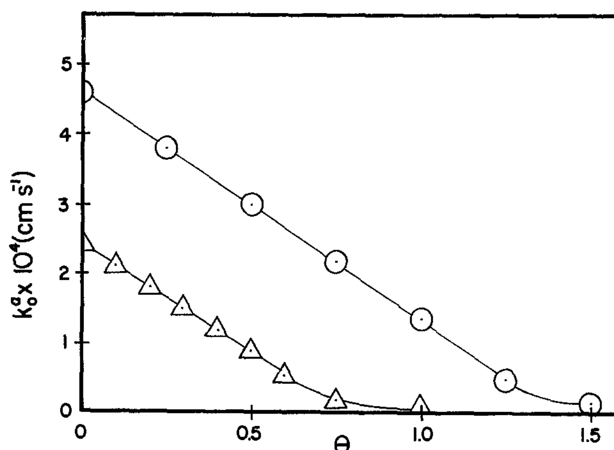

Fig. 5. Effect of θ on k_o^a. Data from Table II. ○: Fe(II)-Fe(III) reaction; △: hydroquinone-quinone reaction.

Values for α and k_o^a at various oxygen coverages were obtained using the same procedures employed for the Fe(II)-Fe(III) system. Plots of ln (i_o^a/c_o) *vs.* E_{eq} were constructed for oxygen coverages of θ = 0.0, 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.75, 1.00, 1.25, and 1.50. The plots at $\theta = 0$ and $\theta = 1.0$ are shown in Fig. 7. Table II lists the least squares values of α and k_o^a obtained from these plots. Over the entire range of coverages α is reasonably constant although a slight downward drift is noted in the $\theta = 0$ to $\theta = 1.0$ segment. In the k_o^a *vs.* θ plot given in Fig. 5, the decline in k_o^a is seen to occur in the $\theta = 0$ to $\theta = 0.75$ region of coverage. The decrease is parallel to the one observed for the Fe(II)-Fe(III) system, where it occurs over the more extensive range $0 \leq \theta \leq 1.40$.

According to Vetter (23) and to Hale and Parsons (24), the hydroquinone-quinone reaction is a two one-electron step reaction, with approximately equal activation energy for each step. In acetonitrile the reaction is one two-electron step (25) and there is evidence in the literature that this is so in aqueous solutions also (26). At pH 3.9, Parsons (24) finds α

= 0.58 and a standard rate constant, k_o^a = 1.4 × 10^{-3} cm sec^{-1}, about six times larger than the one reported here on oxygen-free rhodium.

Interpretation of Results and Conclusions

The dominant and most interesting feature of the charge transfer rate data presented in this paper is that most of the inhibitive effect produced by oxygen adsorption occurs during the buildup of the first monolayer of coverage. This behavior could be attributed to (*i*) a change in the reaction mechanism, which would cause changes in both α and k_o^a; (*ii*) a double layer field effect; or possibly (*iii*) a simple geometric blocking effect.

Possibility (*i*) can be excluded because α is essentially independent of oxygen coverage in the range in which the major decrease occurs in k_o^a both for the Fe(II)-Fe(III) and the hydroquinone-quinone reaction systems.

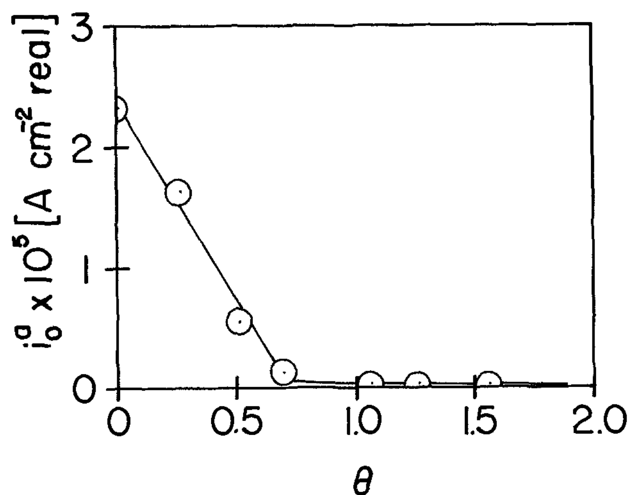

Fig. 6. Effect of θ on i_o^a for the hydroquinone-quinone reaction. Solution 1.0M in $HClO_4$, 1.010 × 10^{-3}M in hydroquinone and 0.1303 × 10^{-3}M in quinone.

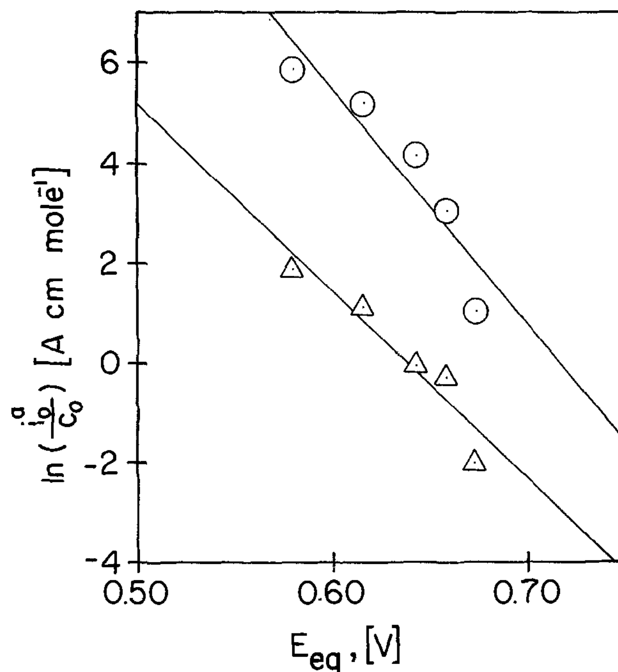

Fig. 7. Plots of $\ln(i_o^a/c_o)$ vs. E_{eq} for the hydroquinone-quinone system. ⊙: θ = 0.0; △: θ = 1.0.

The field effect explanation (*ii*) of the data involves the assumption that the presence of adsorbed oxygen on the electrode surface causes, at constant electrode potential, a change in ϕ_c, the potential drop across the compact double layer with a concomitant change in ϕ_2, the potential drop across the diffuse double layer. This changes the electric field at the site of the reaction, affecting k_o^a but not α. The change in ϕ_2 caused by a monolayer of oxygen coverage can be estimated by assuming that there is an apparent standard rate constant for the oxygen-covered surface, $k_{o}^{a}{}_{,\theta=1}$ and one for the bare surface, $k_{o}^{a}{}_{,\theta=0}$. We can then write (13)

$$k_{o}^{a}{}_{,\theta=0} = k_o^t \exp[-(z_R + \alpha)(F/RT)\phi_{2,\theta=0}]$$

and

$$k_{o}^{a}{}_{,\theta=1} = k_o^t \exp[-(z_R + \alpha)(F/RT)\phi_{2,\theta=1}]$$

where k_o^t is the true standard rate constant and z_R is the charge of the reduced species. Therefore, for a given reaction

$$k_{o}^{a}{}_{,\theta=0}/k_{o}^{a}{}_{,\theta=1} = \exp[-(z_R + \alpha)(F/RT)\Delta\phi_2]$$

where $\Delta\phi_2 = (\phi_{2,\theta=0} - \phi_{2,\theta=1})$ is the change sought. For the Fe(II)-Fe(III) couple, $k_o^a{}_{\theta=0}$ = 4.60 × 10^{-4} cm sec^{-1}, $k_{o}^{a}{}_{,\theta=1}$ = 2 × 10^{-5} cm sec^{-1} (at θ = 1.40), and $\Delta\phi_2$ = (−)32 mV. For the hydroquinone-quinone couple, $k_{o}^{a}{}_{,\theta=0}$ = 2.42 × 10^{-4} cm sec^{-1}, $k_{o}^{a}{}_{,\theta=1}$ = 1.87 × 10^{-5} cm sec^{-1} (at θ = 0.75), and $\Delta\phi_2$ = (−)124 mV. The discrepancy between the $\Delta\phi_2$ values for the two reaction couples, 32 *vs.* 124 mV, is too great to be rationalized on the basis of the difference in θ (1.40 *vs.* 0.75). Alternatively, the presence of adsorbed oxygen could cause changes in the plane of closest approach of the reactants, *i.e.*, changes in the value of the activity coefficient of the activated complex (2). This requires $\ln(k_{o}^{a}{}_{,\theta}/k_{o}^{a}{}_{,\theta=0})$ to be linear in θ. Such plots are convex for Fe(II)-Fe(III) and sigmoid in shape for the hydroquinone-quinone system. The results strongly argue that over the θ = 0 to θ = 1 coverage range, the data cannot adequately be explained as due to a double layer field effect.

The geometric blocking model (*iii*) together with the assumption that charge transfer is much more rapid at free rhodium than at oxygen-covered rho-

dium accounts particularly well for the marked linearity of the k_o^a *vs.* θ plots and for the fact that they are parallel for the two systems studied. Furthermore, these plots show that while for the Fe(II)-Fe(III) system the major decline in rate occurs over the $\theta = 0$ to $\theta = 1.4$ coverage range, the corresponding decline for the hydroquinone-quinone system occurs over only half that range, from $\theta = 0$ to $\theta = 0.75$. At $\theta = 0.75$, the rate for the Fe(II)-Fe(III) reaction is about half its value at $\theta = 0$, indicating that at $\theta = 0.75$ the remaining free rhodium surface atoms are sterically accessible to ferrous and ferric ions. In the hydroquinone-quinone system, however, the rhodium atoms that are still uncovered at $\theta = 0.75$ are apparently sterically inaccessible to hydroquinone and/or quinone molecules. If the planar quinone (or hydroquinone) molecule must lie flat on the free electrode surface to react, then its dimensions (5.5Å from oxygen to oxygen) require a free surface equivalent to that provided by at least two adjacent free rhodium surface atoms, and this is a very unlikely occurrence beyond $\theta = 0.75$. Organic compounds containing ring systems are frequently found to lie flat on electrode surfaces (28). Apparently in order to be blocking the Fe(II)-Fe(III) reaction the film must be slightly thicker than a monolayer.

In both reaction systems charge transfer occurs at greater than monolayer coverage, albeit at a much slower rate. Generally, the data indicate that at coverages beyond $\theta = 1.40$ for the Fe(II)-Fe(III) couple and beyond $\theta = 0.75$ for the hydroquinone-quinone couple, the charge transfer rate is not much affected by increasing oxygen coverage. This is especially obvious in the hydroquinone-quinone system, and is in agreement with Bonewitz and Schmid's observations (3) for the Ce(IV)-Ce(III) reaction on gold from $\theta = 1$ to $\theta = 2$.

Summary

Oxygen coverages on rhodium in 1M $HClO_4$ were determined as a function of potential. Working with increasing potential, the uptake begins at 0.65V, has reached a monolayer, $\theta = 1$ at 0.95V and $\theta = 1.8$ at 1.55V. The uptake is linear with potential. Hysteresis is pronounced; when working with decreasing potentials rhodium becomes oxygen free at potentials from 0.65 to 0.35V as the highest potential reached varies from 0.65 to 1.55V.

Apparent rate constants, k_o^a, and charge transfer coefficients, α, were measured for the Fe(II)-Fe(III) system for solutions having equilibrium potentials 0.809 to 0.696V as a function of oxygen coverage $0 \leq \theta \leq 1.5$. At $\theta = 0$, $k_a^o = 4.60 \times 10^{-4}$ cm sec^{-1} and shows a systematic decrease to $k_a^o = 2 \times 10^{-5}$ cm sec^{-1} at $\theta = 1.40$, decreasing only slightly to $\theta = 1.50$. In the range $0 \leq \theta \leq 1.5$ α has values $0.59 > \alpha > 0.49$, generally decreasing slightly with θ. It is considered to be constant over the range studied.

For the quinone-hydroquinone system, solutions had equilibrium potentials 0.580-0.674V. At $\theta = 0$, $k_a^o = 2.42 \times 10^{-4}$ cm sec^{-1}, decreasing to 1.87×10^{-5} cm sec^{-1} at $\theta = 0.75$. The decrease in k_a^o at $\theta > 0.75$ is minor. A decrease is apparent in α which varies from 0.61 at $\theta = 0$ to 0.49 at $\theta = 1.5$. The mean is 0.53 ± 0.07 and α is considered constant, the variation not being consistent enough to justify the assumption of a coverage dependence. The approximate constancy of α indicates that the reaction mechanism is independent of θ.

The effect of oxygen coverage on the apparent rate constant could be caused by a double layer effect. Accordingly $\Delta\phi_2$ potentials were calculated for the two systems, $\Delta\phi_2 = \phi_{2,\theta=1} - \phi_{2,\theta=0}$. The values are 37 mV for Fe and 124 mV for quinone. The two values seem inconsistent with each other, even taking into account the difference in the values of θ at which blocking is at its maximum.

The assumption of a blocking effect is consistent with the observed variation of k_a^o with θ and with the steric requirements of the reactants at the rhodium surface.

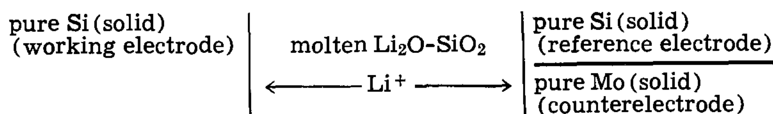
Electrochemical Determination of Interdiffusivity of Cations in Liquid Li_2O-SiO_2 System at 1100° to 1350°C

M. Kawakami,* K. Nagata,[1] and K. S. Goto

Department of Metallurgical Engineering, Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT

An electrochemical polarization method was proposed to obtain the interdiffusivity in molten binary ionic melts at high temperature. The following galvanic cell was constructed using molten Li_2O-SiO_2 as an electrolyte



A small direct current was supplied for a very short time through the left silicon electrode and pure molybdenum electrode, while the overpotential was measured between both silicon electrodes. The overpotential induced at the left silicon electrode was related to the interdiffusion of Li_2O-SiO_2 at the electrode interface. From the time dependency of the overpotential, the interdiffusivities at definite composition were obtained as follows:

For 20 weight percent (w/o) Li_2O-80 w/o SiO_2

$D = 7.2 \times 10^{-3} \exp(-33 \times 10^3/RT$ (cm²/sec) 1100°-1350°C

For 30 w/o Li_2O-70 w/o SiO_2

$D = 3.0 \times 10^{-3} \exp(-29 \times 10^3/RT$ (cm²/sec) 1200°-1350°C

These results are quite reasonable compared with other interdiffusivity data in other molten binary silicates obtained by the conventional method.

The experimental technique of high temperature electrochemistry has been developed extensively since a discovery of very stable solid electrolytes by Kiukkola and Wagner (1) in 1957. Many papers have been published on thermodynamic studies at 500° ~ 1600°C with the aid of these zirconia- and thoria-based electrolytes. Recently, Fischer and Janke (2) documented all the papers up to 1975 in their comprehensive monograph. The studies were exclusively made on thermodynamic properties up to 1967. However, Rickert and Steiner (3) in 1966 and Pastorek and Rapp (4) in 1969 used the solid electrolytes to determine the diffusivity of oxygen dissolved in silver and copper, respectively. The principle of the measurement is based on the electrical current limited by the diffusion of oxygen dissolved in the metallic electrode. The same principle was used by Sasabe and Goto (5) to determine the diffusion of molecular oxygen dissolved in liquid oxide mixtures. As another application of this principle the present authors (6, 7) proposed the method of determining the interdiffusivity of ions in liquid oxide mixtures from the variation of the potential or current with time. In this method, the current is supplied to the following type of the cell

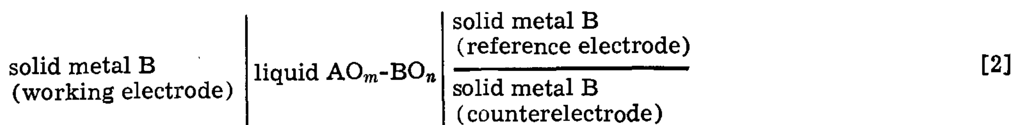
$$\text{solid metal, B/liquid } AO_m\text{-}BO_n\text{/solid metal B} \quad [1]$$

where A and B mean metals, and the liquid oxide mixture AO_m-BO_n has an exclusive cationic conduction by A^{2m+} and AO_m is thermodynamically much stabler than BO_n. The details of the measurement are given in the following section, but the principle is based on the current limited by the interdiffusion of cations of A^{2m+} and B^{2n+} in the oxide melts. A similar idea has been proposed also by Nowak and Schwerdtfeger (8).

This new principle does not need cumbersome analyses of the oxide mixture quenched after a diffusion run. Further, this method suffers from no effect of the convection in the oxide melt, because the diffusion distance is very limited from the surface of the solid electrode. Thus it seems very interesting to prove its universal applicability to many oxide melts. The present paper reports the results on the system of Li_2O-SiO_2.

Experimental Method of Determining the Interdiffusivity

Principle.—The following cell is constructed using molten oxide itself as an electrolyte



Essential requirements for the interdiffusivity measurement are: (*i*) the transference number of A^{2m+} should be unity (*ii*) the standard free energy of formation of AO_m should be much smaller than that of BO_n, and (*iii*) activity data in the molten AO_m-BO_n are available.

Wagner (9) derived a general equation for electromotive force of any galvanic cells in terms of the chemical potential of electrically neutral species, based on only two assumptions of local equilibrium and of electrical neutrality throughout the cell,

$$E = -\frac{1}{\mathbf{F}}[-\tilde{\mu}''_{[B]} + \tilde{\mu}'_{[B]} + \Sigma_\alpha \int t_\alpha d\tilde{\mu}_{\alpha B} - \Sigma_{\beta=e} \int t_\beta d\tilde{\mu}_{A\beta}$$

$$+ \int (\Sigma_{\beta=e} t_\beta) d\tilde{\mu}_{AB} + \int t_e d\tilde{\mu}_{[B]} + \Sigma_\gamma \int t^*_\gamma d\mu_\gamma] \quad [3]$$

* Electrochemical Society Active Member.
[1] Present address: Centro de Ingenierial y Computacion, I.V.I.C., Caracas, Venezuela.

Key words: polarization, galvanostat, alkali, silicates.

where $\tilde{\mu}$ is the chemical potential per equivalent, t is transference number, α and β denote cation and anion, respectively. The prime and double prime show different electrode interfaces. The other symbols are the same as those in Ref. (9). Equation [3] is appropriate to apply to the expression of electromotive force or potential difference in ionic solutions at high temperature such as molten oxides and molten halides, because the local equilibrium condition is very easily satisfied and no other arbitrary conventions are needed. In the present case of molten binary silicates with the transference number $t_{A^{2m+}}$ of unity, the equation can be simplified as

$$E = \frac{RT}{4\mathbf{F}} \ln \frac{P''_{O_2}}{P'_{O_2}} - \frac{RT}{2m\mathbf{F}} \ln \frac{a''_{AO_m}}{a'_{AO_m}} \quad [4]$$

At each electrode interface in the above cell, P_{O_2} is determined by the following reaction equilibrium as long as AO_m is much stabler than BO_n

$$B(\text{solid}) + \frac{n}{2} O_2 = BO_n(\text{molten oxide}) \quad [5]$$

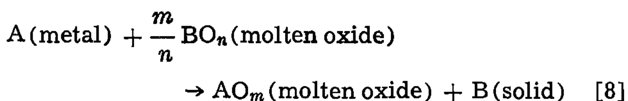
Further, the activity of pure metal B is taken as unity. Then, P_{O_2} in Eq. [4] can be replaced by the activity of BO_n in the molten oxide

$$E = \frac{RT}{2n\mathbf{F}} \ln \frac{a''_{BO_n}}{a'_{BO_n}} - \frac{RT}{2m\mathbf{F}} \ln \frac{a''_{AO_m}}{a'_{AO_m}} \quad [6]$$

When the whole of the cell is in equilibrium before supplying a current, the potential differences between three electrodes should be zero.

When a finite cathodic current is supplied to the working electrode, the following series of reactions will take place

$$A^{2m+} + ame \rightarrow A(\text{metal}) \quad [7]$$



$$A(\text{metal}) + \frac{m}{n} BO_n(\text{molten oxide}) \rightarrow AO_m(\text{molten oxide}) + B(\text{solid}) \quad [8]$$

because the transference number of A^{2m+} is unity and AO_m is much stabler than BO_n. As the result, the concentration of BO_n is reduced and that of AO_m is enriched at the interface with the bulk composition unchanged. Conversely, when an anodic current is supplied

$$O^{2-} \rightarrow \frac{1}{2} O_2 + 2e \quad [9]$$

$$B(\text{solid}) + \frac{n}{2} O_2 \rightarrow BO_n(\text{molten oxide}) \quad [10]$$

The composition of the molten oxide at the interface changes conversely. The fact that such kinds of reactions really take place was proved in the previous paper (6) by the microanalyses of oxides after the current supply in the molten CaO-SiO_2-Al_2O_3 system, where CaO and Al_2O_3 are much stabler than SiO_2. Therefore, the virtual cell reaction induced by the current supply can be summarized as

$$B(\text{solid}) \rightleftarrows B^{2n+} + 2ne \quad [11]$$

as long as AO_m is much stabler than BO_n. The overpotential η is induced by the difference of the composition between the interface and the bulk and can be expressed in terms of the activities of constituent oxides in each phase

$$\eta = \frac{RT}{4\mathbf{F}} \ln \frac{a_{BO_2}{}^{i}}{a_{BO_2}{}^{b}} - \frac{RT}{2\mathbf{F}} \ln \frac{a_{AO}{}^{i}}{a_{AO}{}^{b}} = \frac{RT}{4\mathbf{F}} \ln \left\{ \left(\frac{a_{BO_2}}{a_{AO}{}^2} \right)^{i} \Big/ \left(\frac{a_{BO_2}}{a_{AO}{}^2} \right)^{b} \right\} \quad [12]$$

where m and n are assumed as 1 and 2, respectively, for brevity.

$\ln(a_{BO_2}/a_{AO}{}^2)$ can be empirically expressed as a linear function of weight percent of BO_2, if the change of BO_2 concentration induced by the current supply is relatively small

$$\ln(a_{BO_2}/a_{AO}{}^2) = a + b[\text{w/o } BO_2] \quad [13]$$

where constants a and b can be obtained graphically using the activity data. Then Eq. [12] can be simplified as

$$\eta = \frac{bRT}{4\mathbf{F}} ([\text{w/o } BO_2]^{i} - [\text{w/o } BO_2]^{b}) \quad [14]$$

When the current is supplied galvanostatically, the time dependency of BO_2 concentration at the interface can be given, assuming unidirectional diffusion in a semi-infinite medium and under the following conditions

$$c_{BO_2}{}^{i} = c_{BO_2}{}^{b} \qquad 0 \leqq x, \quad t = 0$$

$$-D_{AO\text{-}BO_2} \frac{dc_{BO_2}}{dx} = \frac{i}{4\mathbf{F}} \ (\text{const.}) \qquad x = 0, \quad t > 0$$

$$c_{BO_2}{}^{b} = \text{const.} \qquad x = \infty, \ t > 0 \quad [15]$$

Consequently, the equation of Fick's second law is solved as

$$c_{BO_2}{}^{i} - c_{BO_2}{}^{b} = \frac{i}{2\mathbf{F}\sqrt{\pi D_{AO\text{-}BO_2}}} \sqrt{t} \quad [16]$$

where c_{BO_2} is molar concentration (mole/cm^3), i is current density (A/cm^2), $\mathbf{F}$ is Faraday constant (C/equiv.), $D_{AO\text{-}BO_2}$ is the interdiffusivity (cm^2/sec), and t is time (sec). Molar concentration can be converted to weight percent with density data of the system. Substitution of Eq. [16] for Eq. [14] will give the time dependency of η as

$$\eta = \frac{100 b i M_{BO_2} RT}{8\mathbf{F}^2 \rho \sqrt{\pi D_{AO\text{-}BO_2}}} \sqrt{t} \quad [17]$$

where ρ is the density and M_{BO_2} is the molar weight of BO_2. Thus, the interdiffusivity will be obtained from the slope of plots of η against $\sqrt{t}$.

In reality, A^{2+} and B^{4+} would migrate, satisfying the electrical neutrality condition by the movement of O^{2-}. However, the micromechanism of the diffusion process in ionic melts is not yet clarified. Thus, the interdiffusivity is simply written as $D_{AO\text{-}BO_2}$ in the present paper. The diffusivity is determined in the external coordinate frame of reference, whose origin was taken at the electrode interface of B. Therefore, the diffusivity would be slightly different from that determined by Matano-Boltzmann method from the penetration curves. However, the difference would be much smaller than the error estimated in the subsequent section.

Under the potentiostatic condition, on the other hand, the diffusion equation will be solved under the boundary condition that molar concentration of BO_2 at the electrode interface is kept constant, to give the time dependency of current density as

$$i = 4\mathbf{F}j = 4\mathbf{F}(c_{BO_2}{}^{i} - c_{BO_2}{}^{b}) \sqrt{\frac{D_{AO\text{-}BO_2}}{\pi}} \frac{1}{\sqrt{t}} \quad [18]$$

Again, converting molar concentration to weight percent, substitution of Eq. [14] for Eq. [18] will give the following equation

$$i = \frac{16\mathbf{F}^2 \rho}{100 b M_{BO_2} RT} \eta \sqrt{\frac{D_{AO\text{-}BO_2}}{\pi}} \frac{1}{\sqrt{t}} \quad [19]$$

The interdiffusivity will be obtained from the slope of plots of i against $1/\sqrt{t}$.

This principle can be applied to obtain the interdiffusivity in any binary or quasibinary ionic solutions, regardless of liquid or solid oxides (or halides), as long as the above requisitions are fulfilled. Among silicate systems, CaO-SiO_2, CaO-SiO_2-Al_2O_3, Li_2O-SiO_2, etc., are considered as the appropriate systems, because SiO_2 is very unstable in all cases with unit transference number of Ca^{2+} and Li^+.

In the present paper, Li_2O-SiO_2 was taken because no interdiffusivity data was reported on the system. A measurement of transference number on this system was carried out by Bockris *et al.* (10). From the measurement, the present authors concluded the transference number of Li^+ as unity. The experiment was carried out under galvanostatic condition. Then, with appropriate numerical values, Eq. [17] was simplified as

$$\eta = 8.69 \times 10^{-7} \frac{biT}{\rho \sqrt{D_{Li_2O\text{-}SiO_2}}} \sqrt{t} \qquad [20]$$

Experimental procedure.—As shown in Fig. 1, the cell assembly consisted of molten oxide contained in a dense alumina crucible, into which a working electrode W, a counterelectrode C, and a reference electrode R were dipped. The working electrode was a rod of pure silicon with 1.5 mm diam and 30 mm length. The upper end of the rod was connected with a molybdenum wire used as lead wire. A piece of molybdenum sheet was immersed so as to cover the sidewall of the crucible and was used as the counterelectrode, which is not necessarily made of silicon as seen in Eq. [2]. Another rod of pure solid silicon with about 3 mm diam was immersed in the molten oxide and used as the reference electrode. The cell assembly and lead wires were shielded by an earthed iron net from the noise induced by the stray electric field. Argon containing 10% hydrogen was introduced into the furnace tube at 500 cm^3/min in order to prevent oxidation of silicon rods. The temperature was measured at the surface of the molten oxide with a Pt-13% Rh·Pt thermocouple. The crucible was placed so that the temperature at the upper part was a few degrees higher than at the bottom in order to avoid thermal convection in the molten oxide phase.

Compositions of the oxide were 70 w/o SiO_2-30 w/o Li_2O and 80 w/o SiO_2-20 w/o Li_2O by charge. The

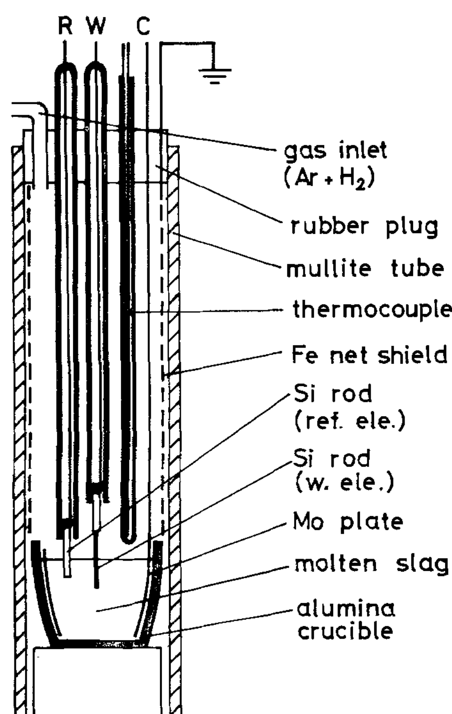


Fig. 1. Schematic diagram of cell assembly

commercial 99.9% silica powder (Merck, Kieselgel 60) was heated at 1000°C to obtain a constant weight. The commercial >99.0% lithium carbonate powder was kept at over 200°C for several days to obtain a constant weight. These powders were mixed to have the above composition and were melted in the alumina crucible. The molten oxide solution was carefully mixed and quenched on a water-cooled copper plate. The quenched oxide was crushed finely, mixed carefully, and then served for the experiment. Dissolution of the alumina crucible into the molten oxide was negligibly small, because the solidified oxide could be easily split away from the crucible, showing no reaction between them.

A constant current was generated with a commercial potentiostat and a known resistance and was supplied between the working and counterelectrodes. The potential difference between the working and reference electrodes was measured by a commercial potential recorder with input impedance of 2 MΩ. When the current was supplied for a very short time, the potential change was followed by a memory-type oscilloscope. The electrical circuits to generate a rectangular single pulse of current and to measure the potential changes over a very short time were detailed in Ref. (7).

After the oxide powder was remelted in the cell assembly the working and reference electrodes were dipped into the molten oxide. The surface level was detected by taking electrical connection between the counter and above electrodes. The depth of the electrodes were fixed to the desired position from the surface. After dipping the electrodes, it took several hours to obtain steadily zero potential difference between the working and reference electrodes. The constant current was supplied to the working electrode thereafter. Since the value of b in Eq. [20] was estimated as 0.110 for 80 w/o SiO_2 and 0.147 for 70 w/o SiO_2 from the activity data (11), and the value of ρ was obtained at the experimental temperature from published data (12), the interdiffusivity was obtained using Eq. (20).

Experimental Results

When the current was supplied, the potential jumped immediately corresponding to the *IR* drop. Then, the potential changed parabolically with time. Figure 2 shows three examples of the potential change with time recorded by the oscilloscope for different time scales. A circuit for the *IR*-drop compensator was used to record only the parabolic potential change in the scope on a large scale. Although the *IR* drop could not be estimated with sufficient accuracy from the figure, it could be obtained accurately by plotting the potential against square root of time and extrapolating to zero. In Fig. 3, subtracting the *IR* drop from the potential change, the overpotential η was plotted against square root of time with different anodic and cathodic current densities. It is seen that the time dependency of the potential was well expressed by Eq. [20], regardless of current directions and densities. In Fig. 4, the slope of the above lines were plotted against current densities, showing a very good proportionality. Thus, Eq. [20] was proved to be satisfied by the experiments with respect to current density. Figure 5 shows the change of the slope with the depth of the working electrode keeping a constant current density. At smaller depths the slope increases with the depth, but over 10 mm, it seems virtually constant. When the depth is small, a part of the current would be consumed by a side reaction such as

$$H_2 \text{ (in gas)} \rightleftarrows 2H^+ + 2e \qquad [21]$$

at the three-phase boundary of gas-molten oxide-electrode. Over 10 mm depth, however, the effect of the above reaction can be neglected. Therefore, the interdiffusivities were estimated from the data for over

10 mm depth. The diffusion distance from the interface would increase with duration of current supply. If there exists a convection in the molten oxide and, further, if the distance exceds the diffusion boundary layer, the time dependency of the potential would be changed with the duration of current supply. The duration was changed from 100 msec to 10 sec. Results are shown in Fig. 6. The slope of η *vs.* $\sqrt{t}$ plot is vir-

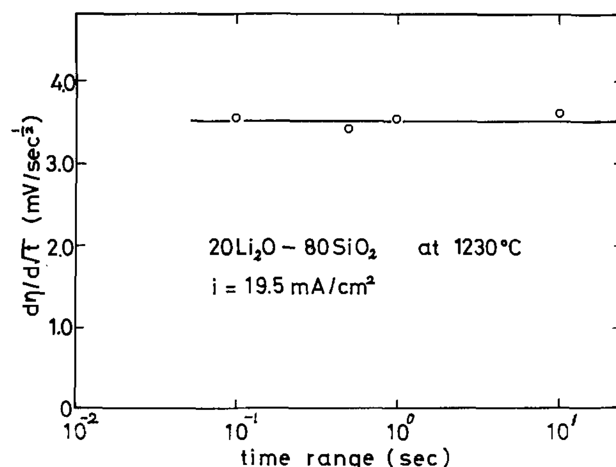

Fig. 6. Plot of the slope of overpotential over square root of time against electrolysis time range.

tually constant regardless of the duration, showing no effect of convection on the polarization.

By these precautions, it was proved that the time dependency of the overpotential was completely due to the unsteady interdiffusion in the stagnant molten oxide. Thus, the interdiffusivities were estimated from 31 polarization curves for $30Li_2O$-$70SiO_2$ and 21 curves for $20Li_2O$-$80SiO_2$ at different temperatures, using Eq. [20]. They are plotted against reciprocal of absolute temperature in Fig. 7 and are formulated by a least squares method as follows:

For 20 w/o Li_2O-80 w/o SiO_2

$$D_{Li_2O\text{-}SiO_2} = 7.2 \times 10^{-3} \exp(-33 \times 10^3/RT) \quad (\text{cm}^2/\text{sec}) \quad 1100°\text{-}1350°\text{C}$$

For 30 w/o Li_2O-70 w/o SiO_2

$$D_{Li_2O\text{-}SiO_2} = 3.0 \times 10^{-3} \exp(-29 \times 10^3/RT) \quad (\text{cm}^2/\text{sec}) \quad 1200°\text{-}1350°\text{C}$$

The standard deviation for activation energies were 1.6 kcal/mole for $20Li_2O$-$80SiO_2$ and 2.7 kcal/mole for $30Li_2O$-$70SiO_2$, respectively. Higher Li_2O content gave higher interdiffusivity within the experimental temperature range, but lower activation energy.

Discussion

Estimation of errors.—The "mean error" of the determination of the interdiffusivity can be defined as the following equation

$$\left|\frac{\Delta D}{D}\right| = \sqrt{\left|\frac{\Delta(\eta/\sqrt{t})}{\eta/\sqrt{t}}\right|^2 + \left|\frac{\Delta I}{I}\right|^2 + \left|\frac{\Delta A}{A}\right|^2 + \left|\frac{\Delta T}{T}\right|^2 + \left|\frac{\Delta b}{b}\right|^2} \quad [22]$$

where I is the total current and A is the interfacial area. The largest error was included in the estimation of the value of b, *i.e.*, $\Delta b/b = \pm 10\%$. The next largest were $\Delta A/A$ of $\pm 5\%$ and $\Delta I/I$ of $\pm 5\%$. The slope of the overpotential *vs.* square root of time has a very small error of $\pm 1\%$ as seen in Fig. 3. Measurement of temperature has also a very small error of $\pm 1\%$. The mean error, then, can be estimated as $\pm 13\%$.

Although the electrode had cylindrical geometry, a planar interface was assumed on solving the diffusion equation. The solution for cylindrical coordinates under the same initial and boundary conditions as those of Eq. [15] is given for a short time as

$$c_{BO_2}{}^i - c_{BO_2}{}^b = \frac{i}{4F}\left(\frac{t}{D_{AO\text{-}BO_2}}\right)^{1/2} \left[\frac{2}{\sqrt{\pi}} - \frac{1}{2}\left(\frac{D_{AO\text{-}BO_2}t}{a^2}\right)^{1/2} + \ldots\right] \quad [23]$$

where a is the radius of the electrode (13). Comparing Eq. [16] with [23], the error induced by the assumption of the planar interface geometry is given as

$$\left[\frac{1}{2}\left(\frac{D_{AO\text{-}BO_2}t}{a^2}\right)^{1/2} + \ldots\right] \quad [24]$$

Using the largest $D_{AO\text{-}BO_2}$ value of 4×10^{-7} cm²/sec, the radius of the electrode of 0.05 cm and the longest time of 20 sec in Eq. [24], the error is estimated as 2.8×10^{-2}, which corresponds to 2.5% of $2/\sqrt{\pi}$. Consequently, the error from the assumption of the planar interface geometry was estimated less than 2.5%.

The activity data (11) was estimated at 1400°C from the measurement of vaporization rate of Li_2O (14). Therefore, the use of such data would cause a certain error, but the magnitude of it could not be estimated in the present work. If more accurate data were available, the interdiffusivity obtained would be more accurate, because the slope of η *vs.* $\sqrt{t}$ was obtained very accurately in the present experiment.

Comparison of the present data with those of others.—Interdiffusivities in other molten binary silicates are cited in Fig. 8 together with the present data. Number 1 shows the interdiffusivities of Li_2O-SiO_2 obtained in the present work, numbers 2-5 for Na_2O-SiO_2, number 6 and 7 for K_2O-SiO_2, and finally, number 8 for PbO-SiO_2.

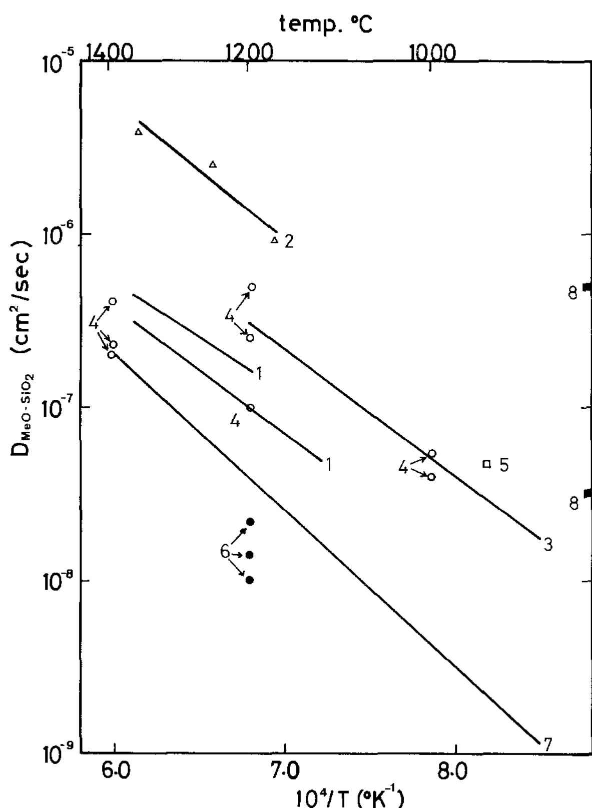

Fig. 7. Interdiffusivities in molten binary silicates. Li_2O-SiO_2: 1, the present work. Na_2O-SiO_2: 2, Shurygin *et al.* (17); 3, Hlavac and Nademlynska (18); 4, Schwerdtfeger (16); 5, Kreider and Cooper (19). K_2O-SiO_2: 6, Schwerdtfeger (16); 7, May and Wollast (20). PbO-SiO_2: 8, Kosaka *et al.* (14).

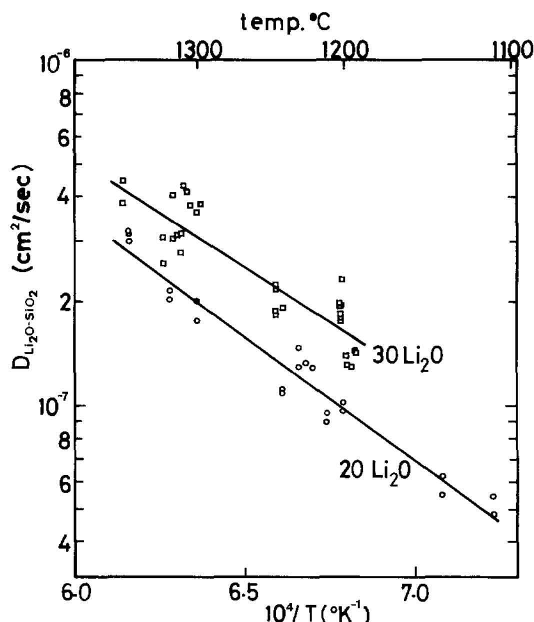

Fig. 8. Interdiffusivities of Li_2O-SiO_2 obtained in the present work

May and Wollast (20) reported no composition dependency of the interdiffusivity from their experiments on K_2O-SiO_2 system at SiO_2 mole fractions from 0.74 to 0.84. Schwerdtfeger (16), however, suggested that the diffusivity would decrease by a factor of 2 from SiO_2 mole fraction of 0.77-0.88 in K_2O-SiO_2 system at 1200°C. On Na_2O-SiO_2 system, Schwerdtfeger (16) suggested large decrease by a factor of 5 from SiO_2 mole fraction of 0.65-0.75. Kosaka *et al.* (15) reported a large decrease of an order of magnitude on the PbO-SiO_2 system at 850°C. In the present work, small dependency by a factor of 1.5 from 0.54 to 0.67 SiO_2 mole fraction was obtained at 1200°C. As a whole, it might be concluded that there exists a moderate dependency of the interdiffusivity on SiO_2 mole fraction, *i.e.*, by a factor of 2 ~ 3 from 0.60 to 0.80 SiO_2 mole fraction at 1200°C.

In the present work, the activation energy was obtained 33 and 29 kcal/mole for 0.67 and 0.54 SiO_2 mole fraction, respectively. The others reported about 35 kcal/mole, although SiO_2 mole fractions are different. Thus, it might be concluded that the activation energy for the interdiffusion in molten alkali silicate is 30-40 kcal/mole, regardless of alkali element and compositions.

Conclusion

The interdiffusivity of Li_2O-SiO_2 in molten binary Li_2O-SiO_2 was determined by an electrochemical polarization method from 1100° to 1350°C. Li_2O-SiO_2 was selected because of no data on the diffusivity and because SiO_2 is stabler with unit transference number of Li^+. The results are summarized as follows.

For 20 w/o Li_2O-80 w/o SiO_2

$$D_{Li_2O\text{-}SiO_2} = 7.2 \times 10^{-3} \exp(-33 \times 10^3/RT) \quad (cm^2/sec) \quad 1100°\text{-}1350°C$$

For 30 w/o Li_2O-70 w/o SiO_2

$$D_{Li_2O\text{-}SiO_2} = 3.0 \times 10^{-3} \exp(-29 \times 10^3/RT) \quad (cm^2/sec) \quad 1200°\text{-}1350°C$$

The interdiffusivity is larger by a factor of 1.5 for $30Li_2O$-$70SiO_2$ than for $20Li_2O$-$80SiO_2$ at 1200°C. The activation energies are 33 and 29 kcal/mole for $20Li_2O$-$80SiO_2$ and $30Li_2O$-$70SiO_2$, respectively.

These results are quite reasonable compared with published interdiffusivity data in other molten binary silicates. Thus, the present method was proved to be applied successfully to determine the interdiffusivity in molten Li_2O-SiO_2 system.

Manuscript submitted April 18, 1977; revised manuscript received Sept. 12, 1977. This was Paper 241 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by K. S. Goto.

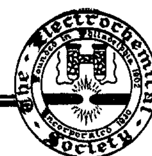
Technical Notes



The Four-Point Bend Test for Measuring the Ductility of Brittle Coatings

C. C. Lo

Bell Laboratories, Columbus, Ohio 43213

Electroplated metals are often much harder and less ductile than the same metals obtained from the melts. One of the primary causes for the reduction of ductility is the codeposits of gaseous and other impurities in many electroplates. ASTM recommends (1) that the

Key words: ductility, brittle coatings.

ductility (the strain to fracture) be determined by a bend test for brittle plates on a substrate, and a tensile test for ductile plates with the substrate removed.

The procedure of the bend test (1, 2) is to press the specimen onto a series of mandrels of various diameters with the substrate side against the mandrel. When visible cracks are observed under a 10X magnifier, the ductility is then calculated over a range from the two adjacent mandrel diameters and the specimen thickness. This technique is simple. However, with the 10X magnifier one can never be sure about the occurrence of cracks until they are extensive. Other major deficiencies of this method are the uncertainty with the rate and the force distribution during the bending.

The bulge test has also been used in determining the ductility of electroplates (3). However, the bulge is not shaped like a spherical cap as frequently assumed (4), hence the uncertainty arises from the strain calculation based on the bulge height measurement, particularly if the bulge height is small as is the case for a brittle material. Because the biaxial stress in a bulge test resists necking which is seen in a conventional uniaxial tensile test for a ductile material, the bulge test has been used successfully for obtaining the stress-strain relationship over the large plastic strain region. The strain to fracture obtained in a bulge test usually is much larger than that of the uniaxial tensile test.

A different, simple bend test method is presented here, which avoids the problems just described. The technique is sometimes called the four-point method as used by the ceramic industry, where the specimen, without a substrate, is bent and fractured into two or more pieces. This tester can be used to evaluate the ductility of a brittle coating with a strain to fracture between 0 and 2%. Cracks are revealed under an optical microscope at 50X with oblique illumination. Cracks as revealed by this optical technique are also compared with those by two other techniques commonly used for porosity testing: HNO_3 vapor and electrography.

Four-Point Bend Test

The basic mechanisms of the four-point bend test include a simply supported beam subjected to two loads, symmetrical over the central span (Fig. 1). Since the bending moment is constant between the two loads, the plastic hinge is not likely to develop. Samples are placed on two tool steel knife edge supports located 50.8 mm apart. Two line loads are applied by two 3.2 mm diam steel cylinders spaced 12.7 mm apart, or 19.1 mm from the supports, and controlled by a micrometer which indicates the displacement. After every 0.1 mm increment (or any selected distance) of the loading cylinders, the specimen is removed from the testing frame and examined at 50X magnification under oblique dark field illumination. If the specimen is bent at a rate of about 0.1 mm in 1 or 2 sec, we obtain a strain rate of about 10^{-4}/sec, which can be considered as a static rate The rod which connects the loading cylinders and the micrometer can be made long enough that the specimen can be placed inside an oven while the micrometer is outside for measuring the ductility at elevated temperatures.

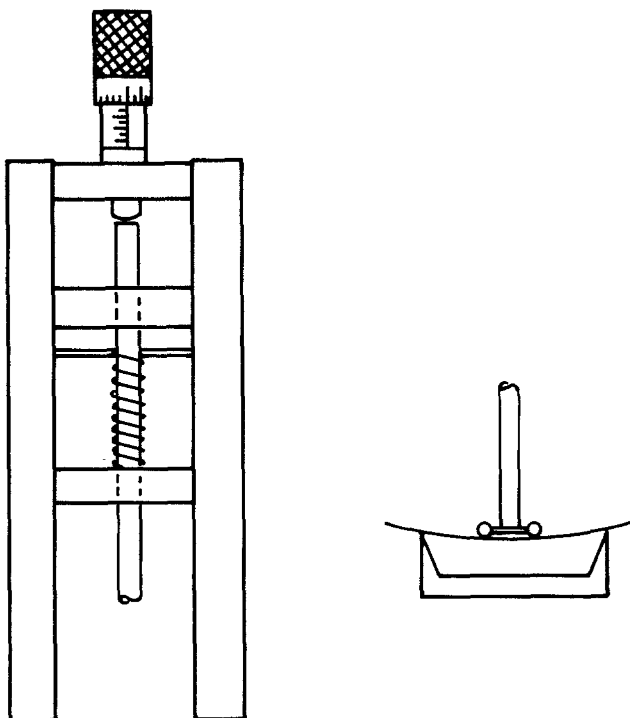


Fig. 1. Schematic of the four-point bend test apparatus

The errors of the measurement depend on whether the two loading cylinders are parallel to the knife edge supports, are making contact at the same time, and are at the right positions, and whether the specimen has a uniform thickness and width, as discussed by Hoagland *et al.* (5) for the elastic bending case. To evaluate the reliability of the four-point bend test, they compared the Young's modulus of a steel beam measured in the bend test with tests in uniaxial loading. The difference was only about 1%. The single most important error in the bend test is that due to the twisting action when the specimen is not flat so that the supporting edges and the loading cylinders do not make the initial parallel contact with the specimen simultaneously. This error is inversely proportional to the beam deflection. The typical deflection for a brittle coating on a metallic substrate is much larger than that for a ceramic specimen, hence the error for the former is smaller. In conclusion, it seems to be reasonable to assume that, with standard laboratory precaution, the total error can be kept within 5%.

For brittle nonmetallic materials without the substrate the strain to fracture obtained by the four-point bend method appears to be 15-30% higher than that obtained by a tensile test (6, 7). This can be explained by the fact that all the flaws in the tensile specimen are subjected to the maximum tensile stress to cause crack initiation and growth, while in the bend test only the flaws near the tensile side surface of the specimen are. A statistical treatment of this case was given in Ref. (6). For a thin coating on a ductile substrate, all the flaws in the coating can nucleate cracking for both the tensile test and the bend test, so the strain to fracture should be the same for both tests. However, an experimental proof is still needed.

Strain to Fracture

After cracks appear, the ductility can be determined from the measured displacement at the loading cylinders. If the substrate material is within its elastic limit and the distance between the two loads is 1/4 of the span, the maximum strain in the specimen is

$$= \frac{16}{3}\frac{h\delta}{l^2} \quad [1]$$

where h, l and δ are the total thickness, distance between the two supports, and the displacement under the loads, respectively. If the ductility of the coating is less than 0.5%, it is advantageous to choose a substrate with a high yielding strain so that Eq. [1] can be used. One of the suggested substrates is a phosphor bronze strip 10 mm wide and 0.3-0.4 mm thick. The coating thickness can vary between 5 and 20 μm.

However, if the substrate material deforms plastically, the strain cannot be calculated easily. First, the stress-strain curve for the substrate should be obtained from a tensile test machine. Then the displacement-strain curve is usually obtained by a tedious numerical integration method. As an alternative, an approximate simple solution was given in Ref. (8) for maximum strains of 1-2%, depending on the stress-strain curve. For a half-hard copper substrate, the strain-displacement curves based on this nonlinear theory (8), as well

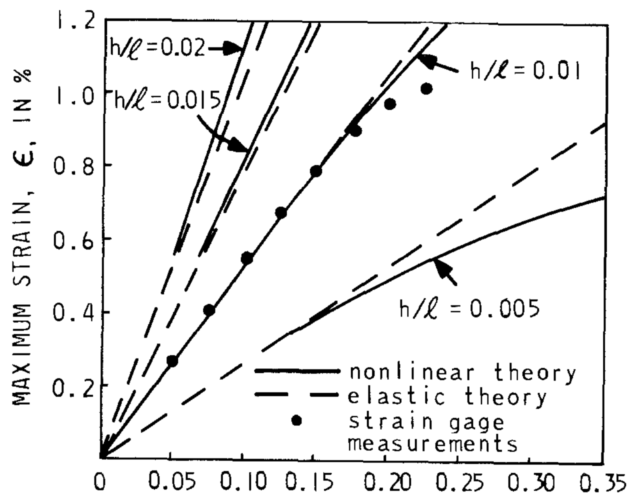

Fig. 2. Strain-displacement curves for a half-hard copper substrate.

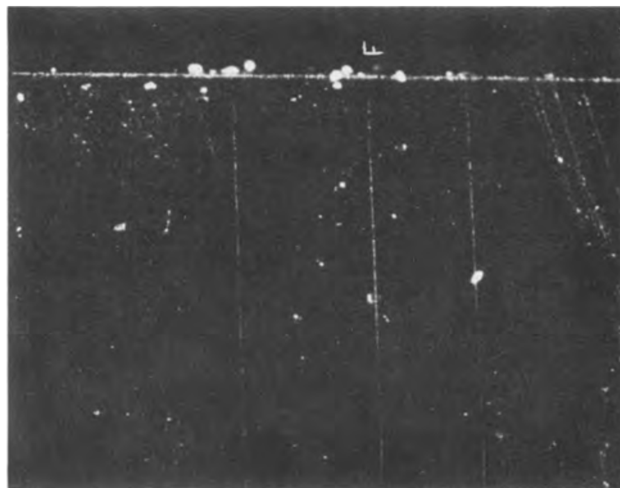

Fig. 3. Cracks on a 10 μm NiSn plate as revealed at 50X under oblique illumination.

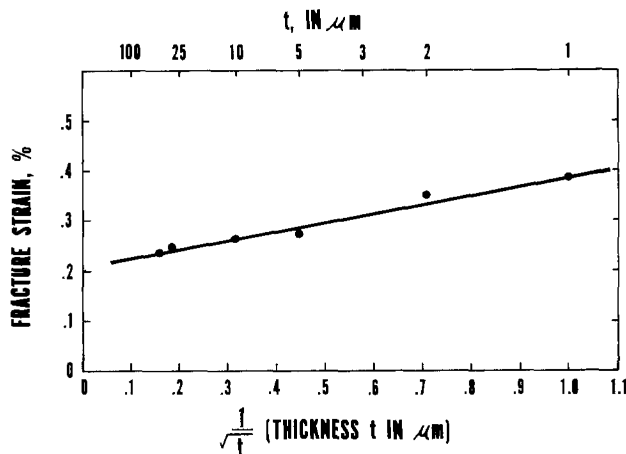

Fig. 4. Ductility of NiSn plate versus the plate thickness

as that based on the simple elastic theory, are shown in Fig. 2. It is interesting to note that, when the ratio of the total thickness (coating and the substrate) to the distance between the two supports is about 0.01, the strain obtained from the simple theory of Eq. [1] is nearly the same as that obtained from the nonlinear theory for strains up to 1%.

The displacement-strain curve can also be calibrated experimentally by measuring the strain optically. However, none of the optical techniques is simple or readily available. The strain gauge method is not desirable because it affects the stiffness of the sample, so that plastic hinges are likely to develop which will lower the measured strain. To prove this point, we used the smallest strain gauge available, which had a thickness of less than 25 μm, on a 0.5 mm half-hard copper strip. The displacement *vs.* strain curve based on these strain gauge measurements is shown in Fig. 2 as dots (h/l = 0.01). At about 0.9% strain, plastic hinges started to appear, and the measured strain became smaller than the calculated value.

Methods to Reveal Cracks

Oblique illumination.—In this study, we chose NiSn alloy (9) coating as an example because it is rather brittle and resistant to most etching chemicals. NiSn alloy was electrodeposited on both sides of a half-hard copper strip, 12.5 mm wide and 0.5 mm thick. The copper strip was not polished; its surface scratches were also apparent on the plated surface. The NiSn plate had a nonuniform thickness varying from about 15 μm at the edge to 7 μm near the center. When a cracked specimen was placed under a microscope at 50X with oblique lighting perpendicular to the cracks, cracks could be seen easily. The internal oblique illumination provided by some microscopes does not reveal the cracks as clearly as an external light can. When the incidence angle was low, the background was dark, and cracks were shown as fine straight lines perpendicular to the edges, whereas the scratches were seen as coarse lines at random orientations as shown in the upper right corner of Fig. 3. It is also interesting to see that the ductility for NiSn varies linearly at a low slope with the reciprocal of the square root of the plate thickness over 1-40 μm as shown in Fig. 4. The dependence of ductility on the coating thickness has long been suspected (2). For brittle coatings, this can be explained by the increased number of flaws in the coating with thickness as discussed earlier.

Though fine cracks can be seen easily using oblique dark field illumination, the same cracks can be seen only at much higher magnifications under normal incidence bright field illumination. At high magnification, it becomes difficult to distinguish cracks from scratches. Under normal incidence illumination, both the resolution and the perception limits are proportional to the ratio of the wavelength of light to the numerical aperture of the microscope. On the other hand, under the oblique dark field illumination, perception depends only on the total light reflected from the cracks (10).

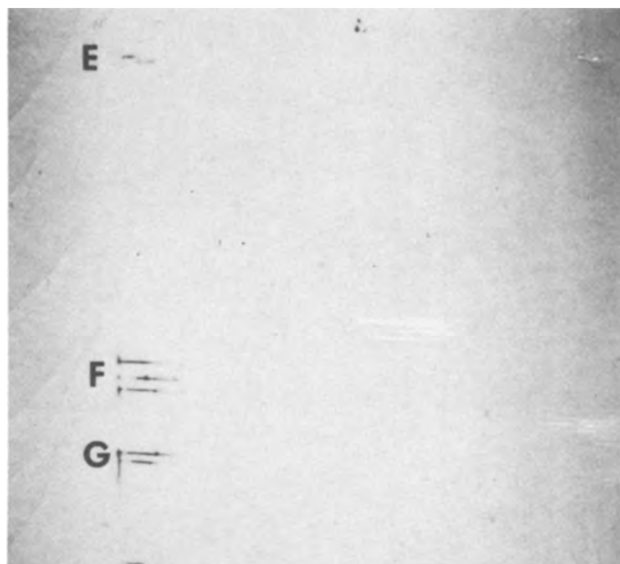

Fig. 5. Cracks on a 10 μm NiSn plate as revealed by electrographic technique, 5X.

Electrography.—After a specimen was examined using a microscope with oblique illumination, the same sample was tested by the electrographic technique (11-13). Kodak Type F dye transfer paper was cut into strips 2 by 7 cm and soaked for 15-45 min in a solution of 20 g/liter of disodium salt of dimethylglyoxime and 20 g/liter of NaCl. A roller was used to remove the excess solution from the printing paper. The specimen was held firmly against the printing paper between two aluminum electrodes which were pressed together in a hydraulic press. A current was passed through the specimen and paper for 1 min at a constant voltage of 2.0V. The result is shown in Fig. 5. The electrographic method in this case has revealed about 1/3 of cracks found by oblique illumination. Other samples with plating thicknesses from 4 to 40 μm of NiSn alloy gave similar results. Unrevealed cracks indicate that the electrolyte does not fill all cracks but depends on the crack dimension, the NiSn plating thickness, and the wetting angle between the alloy and the solution. Figure 5 shows that the electrographic technique revealed some cracks near the edge, but none in the center area even though the former had a plating thickness twice as large as the latter. The electrolyte used here is effective for revealing pores in a gold plate. However, it is possible that some other electrolytes may be more effective for NiSn alloy plates due to different wetting angles.

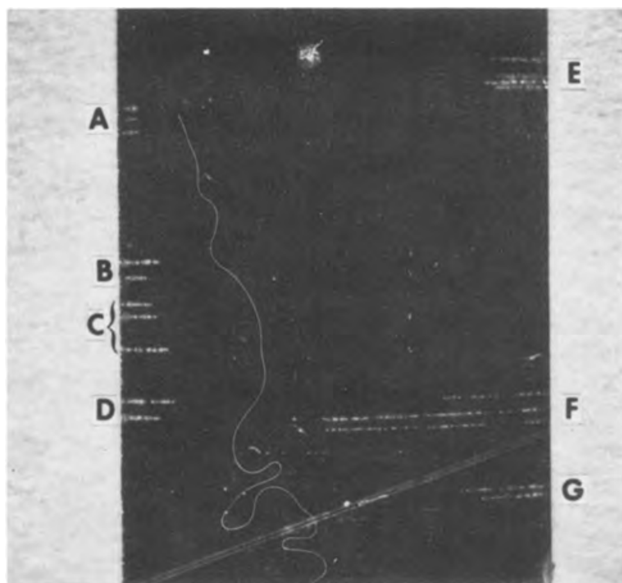

Fig. 6. Cracks on a 10 μm NiSn plate as revealed by HNO_3 vapor, 5X.

HNO_3 vapor.—After the electrographic test, samples were placed in a desiccator over a pool of HNO_3 of 70% concentration for 1 hr. Cracks were manifested by copper corrosion products as shown in Fig. 6 at 5X. In Fig. 6, cracks were marked as areas A to G so that they may be compared to the same cracks shown in Fig. 3 and 5. Cracks revealed by HNO_3 vapor were identical to those revealed by oblique illumination.

Surface Composition of Equiatomic Electrodeposited Tin-Nickel Alloy

G. C. Nelson

Sandia Laboratories, Albuquerque, New Mexico 87115

The surface passivity of an equiatomic tin-nickel alloy has been studied with Auger electron spectroscopy by Tompkins and Bennett (1). They conclude that the air-formed surface layer is tin rich. However, due to the escape depth of the Auger electrons used for the analysis, it was not possible to clearly state whether the layer is devoid of nickel. They do conclude however, that the least complex model consistent with their results is a tin oxide containing no nickel. To clarify this point, the surface composition of equiatomic electrodeposited tin-nickel alloy has been determined by low energy ion-scattering spectroscopy. Since this technique is more surface sensitive than Auger electron spectroscopy, it is possible to unambiguously determine the composition of the first few monolayers.

Key words: tin-nickel alloy, surface passivity, equiatomic.

Experimental Results

The ion-scattering spectrometer used for these measurements is a modified commercial instrument. A 2 keV $^4He^+$ beam was used for the analysis and for obtaining a sputter profile of the near surface region. The ion beam was rastered over a 4 mm^2 area with only the signal originating in the center 1 mm^2 accepted in the pulse-counting system. The 1 μm thick tin-nickel samples were obtained from Tompkins and Schubert and were electroplated on Cu and stainless steel, respectively. Rutherford backscattering was used to deter-

mine the composition of the films at a depth of 1000Å. This composition was considered to represent that of the bulk. It was found that the composition of these samples deviated slightly from being equiatomic. The sample on stainless steel was found to contain 51 a/o (atomic percent) Sn while the one on Cu contained 45 a/o Sn. By using these bulk composition values and the relative Ni/Sn peak height obtained from the sputter profiles, sensitivity factors for Ni and Sn were obtained. With the sensitivity factors, the depth profile data were converted to a concentration profile. These data for Sn/Ni on Cu are shown in Fig. 1. The initial rise in the Sn signal is due to the removal of carbonaceous material and the tin oxide layer as discussed by Tompkins (1). The delay in the Ni signal clearly indicates that the Ni is absent in the surface region. By measuring the current density and estimating the sputtering yield, the depleted surface layer was found to be 5-10Å thick which is in agreement with the value of 5Å reported by Tompkins. Similar results were obtained from the sample electroplated on stainless steel. These results confirm the speculation of Tompkins and are consistent with the idea that since tin is more readily oxidized than nickel, a tin oxide will form on the surface. It should be pointed out, however, that a tin-rich surface may also form in the absence of oxygen due to differences in surface-free energies (2).

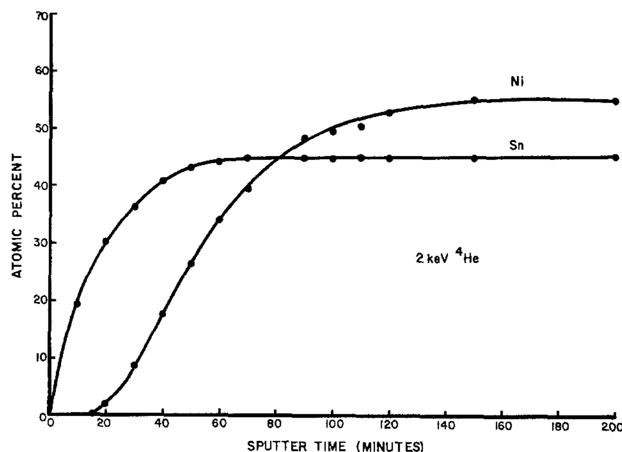

Fig. 1. Depth profile of electrodeposited tin-nickel sample. The absence of Ni in the surface region is clearly evident.

Acknowledgments

The author would like to thank H. G. Tompkins and R. Schubert for supplying the samples and J. A. Borders for the RBS measurements. This work was supported by the U.S. Energy Research and Development Administration.

Oxygen Reduction on Platinum in Trifluoromethane Sulfonic Acid

A. J. Appleby*

CNRS Bellevue, Laboratoire d'Electrolyse, 92-Bellevue, France

and B. S. Baker*

Energy Research Corporation, Danbury, Connecticut 06810

In strongly acidic solution, the rate of the electrolytic reduction of oxygen on oxide-free platinum appears to be determined by the heat of adsorption of the product of the rate-determining step, which may be identified with the primary electron- and atom-transfer process (1-3)

$$O_2 + H^+ + e^- \rightarrow O_2H_{(ads)}$$

A further effect on the rate may result from the coverage of adsorbed molecular oxygen initially present on the electrode surface (2, 3), which may be a function of the heat of adsorption of the anion in the solution.

Acid fuel cells, which currently operate at temperatures on the order of 150°-180°C to ensure adequate reaction rates, use concentrated orthophosphoric acid as the electrolyte. This material has not only poor mass-transport properties (oxygen solubility and diffusivity together with ionic conductivity) but also very low exchange currents for oxygen reduction at temperatures less than *ca.* 100°C (2, 4) when comparison is made with, *e.g.*, perchloric acid (1) or sulfuric acid. The latter acids are insufficiently stable for use in fuel cells at temperatures above about 80°C. Consequently, starting in 1971, a search was made for other possible acid electrolytes with higher stability than perchloric and sulfuric acids, and improved kinetics for oxygen reduction compared with orthophosphoric acid. At that time, trifluoromethane sulfonic acid was examined; it was later shown elsewhere that it demonstrated improved kinetics for hydrocarbon oxidation compared with orthophosphoric acid (5). After initial work on oxygen reduction kinetics and performance of trifluoromethane sulfonic acid in a fuel cell, less volatile higher homologs were examined, particularly tetrafluoroethane 1-2 disulfonic acid (6). The kinetics of the oxygen reduction process on platinum in trifluoromethane sulfonic acid solution are described in this paper.

Experimental

A 10% solution of trifluoromethane sulfonic acid (Eastman Kodak) in distilled water was used. This corresponded to a molarity of about 1.1M. The electrochemical cell was of conventional 3-compartment type, and was fitted with a platinum-black fuel cell electrode

* Electrochemical Society Active Member.

Key words: oxygen reduction, electrocatalysis, platinum, trifluoromethane sulfonic acid.

on a tantalum exmet screen as counterelectrode, a dynamic hydrogen reference electrode (7) which used a similar cathode (area 1 cm^2) together with a smooth platinum anode in a compartment fitted with a Luggin capillary, and a bright platinum working electrode 2 cm^2 in area. The polarizing current for the dynamic hydrogen electrode was 1 mA and its potential was determined to be +5 mV with respect to a bubbling hydrogen electrode in the same electrolyte. This value was independent of temperature in the range studied. The cell contained a further electrode in the working electrode compartment which was identical with the counterelectrode and was used for preelectrolysis of the trifluoromethane sulfonic acid solution.

The solution as first prepared had a pale straw color which slowly cleared as oxygen was bubbled through the cell. A slight precipitate formed during this period. Accordingly, all solutions were first pretreated using this procedure for a period of about 48 hr after which the solution was filtered and preelectrolysis was started. Stable electrochemical results were obtained after 60-72 hr of preelectrolysis at 1 mA-cm^{-2}. Shorter periods than this were insufficient to remove oxidizable impurities and resulted in considerable deactivation of V-log i curves for oxygen reduction (see below). Oxygen (ultrapure grade) was bubbled through the solution during the preelectrolysis period. After preelectrolysis, the platinum-black anode was removed from the solution in the working compartment and the oxygen flow was reduced. The working electrode, prepared as in previous work (2), was then lowered into the cell. It was activated by the anodic and cathodic pulsing procedure described earlier (2). After the final cathodic pulse into the hydrogen adsorption region, a galvanostatic current of the value desired was applied and the electrode was allowed to reach the potential corresponding to this value. Since relatively rapid deactivation of the bright platinum electrode due to adsorption of impurities occurred [*cf.* Ref. (2)] the maximum potential registered was taken to be that corresponding to the reduction of oxygen on the clean, oxide-free platinum surface. Potentials and currents were measured using a Wenking potentiostat with digital voltmeter readout.

Results were obtained on two bright platinum working electrodes, which were consistently within 5 mV of each other. All results reported below refer to a single electrode. The Tafel plots shown could be traced forwards and backwards fairly reproducibly (±5 mV). Temperatures were maintained to ±0.3°C using a water or ice bath.

Results

Tafel plots after 72 hr of preelectrolysis at 0°, 20°, 36°, and 62°C are shown in Fig. 1. Open-circuit poten-

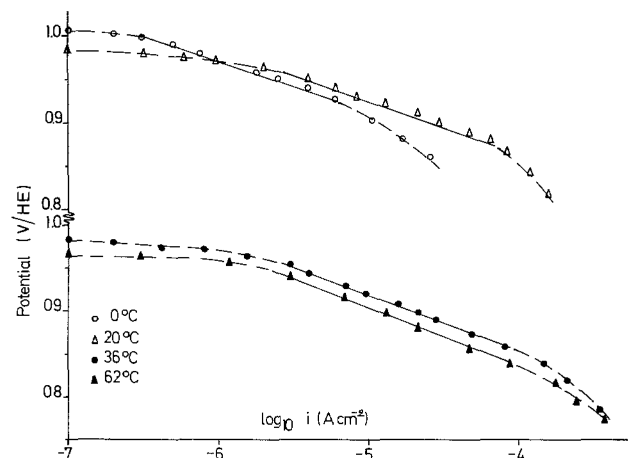

Fig. 1. Tafel plots for oxygen reduction on smooth oxide-free platinum in 1.1*N* trifluoromethane sulfonic acid solutions (after 72 hr preelectrolysis).

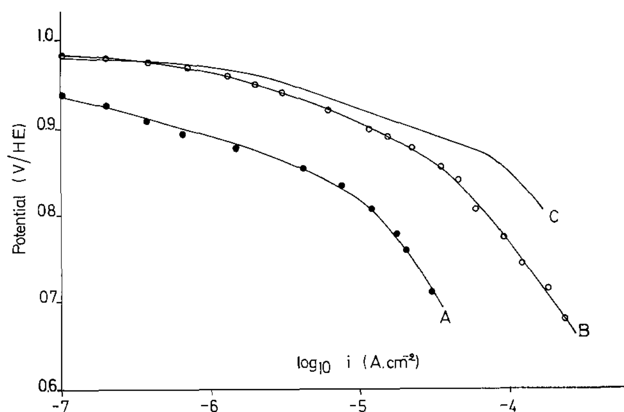

Fig. 2. Tafel plots as in Fig. 1, as a function of preelectrolysis time. A, no preelectrolysis; B, 12 hr; C, 72 hr.

tials (measured after completion of the Tafel plots) varied from 1025 mV *vs.* hydrogen at 0°C to 990 mV at 62°C. Figure 2 shows the effect of preelectrolysis on the results obtained at 20°C. Tafel slopes in the potential range above 920 mV (at 0°C) and 850 mV (at 62°C) appear to be close to $RT/\mathbf{F}$ (54-66 mV/decade depending on temperature). At lower potentials, just before the limiting current region, higher slopes seem to occur. Although this secondary Tafel range is never long enough for accurate slope determination, results may be on the order of 2 $RT/\mathbf{F}$, as has been observed elsewhere (8, 9). The Tafel slopes have been extrapolated back to the calculated reversible oxygen electrode potentials [taking into account the temperature and the gas and water-vapor partial pressures (2)] to obtain the apparent exchange current values shown in Table I. Values shown are for 1 atm oxygen partial pressure, the extrapolated values from the Tafel plots being corrected as necessary for the effect of water vapor pressure, assuming the oxygen reduction reaction to be first order (1, 2).

An Arrhenius plot of the exchange current density values is shown in Fig. 3. Experimental activation energy is 12.6 (±2) kcal/mole under 1 atm oxygen pressure conditions.

Discussion

The Tafel slope observed, as in other acids (1, 2, 9), is $RT/\mathbf{F}$. This suggests that the same rate-determining step occurs as in perchloric and orthophosphoric acids (1, 2). While support from order of reaction determinations is required for a positive confirmation, evidence points to the primary electron transfer step

$$O_2 + H_3O^+ + e^- \rightarrow O_2H_{(ads)}{}^+ H_2O$$

as rate-limiting. Due to the presence of adsorbed —OH or —O radicals derived from the oxidation of water, which have a heat of adsorption that is linearly dependent on coverage (1) (Temkin conditions), the environment of adsorption of the reaction intermediate is affected (10). When coverage of reversibly adsorbed —OH or —O radicals is low (*i.e.*, when Langmuir adsorption occurs) the characteristic slope of $RT/\beta\mathbf{F}$, where β is the symmetry factor, should be observed [*i.e.*, 2 $RT/\mathbf{F}$, or about 120 mV, with a typical value for β equal to ½ (8, 9)]. This is consistent with the results obtained.

The probable 25°C exchange current for reduction of oxygen at 1 atm pressure is 9 × 10^{-11} A/cm^2. The

Table I. Exchange currents for oxygen reduction in 1.1*N* CF_3SO_3H

Temp, °C (±0.3)	Calculated theoretical $E°$ (mV *vs.* H_2)	i_o, A/cm^2 (1 atm O_2)
0	1248	8.0 × 10^{-12}
20	1231	6.0 × 10^{-11}
36	1216	1.7 × 10^{-10}
62	1192	5.8 × 10^{-10}

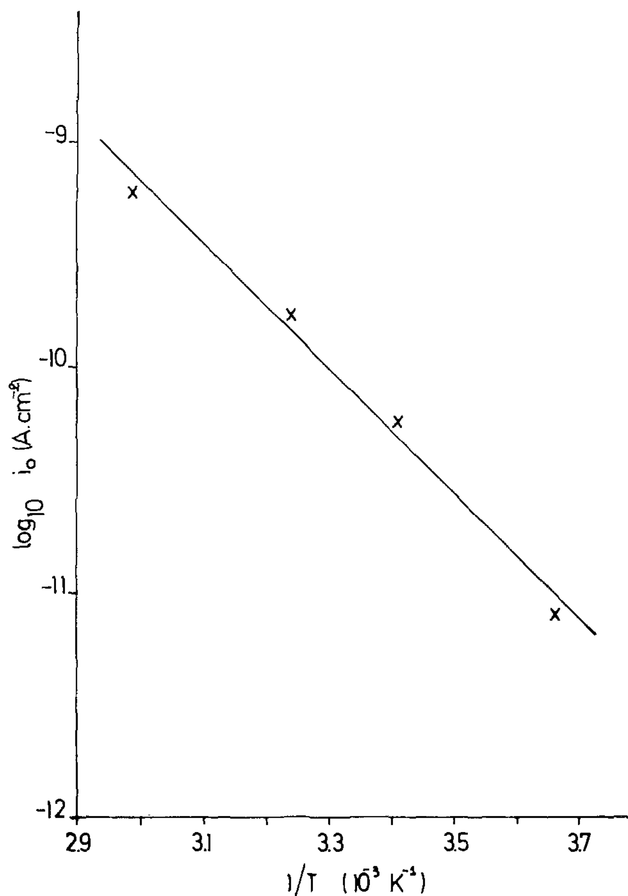

Fig. 3. Arrhenius plot for extrapolated exchange current densities (1 atm O_2).

corresponding value in perchloric acid (0.1N) is about 8×10^{-11} (1), whereas that in 85% orthophosphoric acid (14.5M) is about 4×10^{-13} A/cm^2 (2). A compensation effect between the activation energy and the Arrhenius preexponential term is noted for oxygen reduction on bright platinum in trifluoromethane sulfonic and orthophosphoric acids. The corresponding preexponential terms for the exchange currents are -0.94 and $+2.17$, respectively, when expressed as $\log_{10} i_o$ (A/cm^2). The temperature at which the oxygen reduction reaction has the same rate in both acids is about 135°C, the i_o value being *ca.* 2×10^{-8} A/cm^2.

Conclusions

1.1M trifluoromethane sulfonic acid shows an exchange current density for oxygen reduction at 1 atm pressure and ordinary temperature that is about 2 orders of magnitude greater than that in 85% orthophosphoric acid, the electrolyte normally used in acid fuel cells. It shows a particularly low activation energy (about ~10.3 kcal/mole less than that in orthophosphoric acid) which renders it particularly interesting for use at lower temperatures. This difference in activation energy probably results from the combined effect of heat of adsorption of anions and differences in the heat of solution of oxygen. As noted elsewhere for oxygen reduction in acid solution, a compensation effect (3) is observed between the Arrhenius preexponential terms and activation energies in the two acids, with an extrapolated crossover temperature of about 135°C. Such compensation effects may be of great theoretical significance for oxygen electrode processes.

Photoanodic Behavior of n-type Cadmium Sulfide in Acetonitrile Solutions Containing Iodide Ion

Kenji Nakatani,[1] Shigeyuki Matsudaira, and Hiroshi Tsubomura

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka, Japan

The conversion of light energy to electrical and chemical energy in electrochemical systems equipped with semiconductor electrodes has attracted wide attention. Unfortunately, many semiconductors having appropriate bandgaps, *e.g.*, CdS, GaP, etc., are subject to undesirable dissolution or decomposition by photoelectrochemical reactions in aqueous solutions (1). Recently, some photoelectrodes, *e.g.*, CdS, CdTe, have been reported to be stabilized in aqueous solutions containing reducing agents such as ferrocyanide, sulfide, and selenide (2).

We thought that the dissolution or decomposition could be prevented, or suppressed by employing nonaqueous solvents. It turned out that the photoanodic dissolution of CdS could not be fully avoided in various organic solvents, such as acetonitrile, nitromethane, and dimethylformamide. But the onset potential for the anodic dissolution current of CdS was found to change with solvent basicity (3). In this paper, we report the results on stable CdS photocells using nonaqueous solution containing iodide ion. The photoelec-

[1] Present address: Teijin Limited, Central Research Institute, Hino, Tokyo, Japan.

Key words: semiconductor, photocell, photocurrent, solar energy conversion.

tric behavior of semiconductor electrodes in nonaqueous solutions has also been extensively studied by Bard *et al.* (4).

Experimental

The structure of the electrochemical photocell and the measuring devices used are of a conventional type, reported in our previous paper (5). In some cases, a two-compartment cell separated by an agar bridge was used. Some of the experiments were made under the potentiostatic conditions using a Hokutodenko HA 101 potentiostat. CdS single crystal electrodes with the (0001) face polished with alumina abrasive and etched in a 3M HCl solution for 5 sec were used together with a platinum plate counterelectrode. Acetonitrile and nitromethane were purified according to the literature (5, 6). Lithium perchlorate (0.1 mole · $liter^{-1}$) was used as a supporting electrolyte. A 250W high pressure mercury lamp combined with Toshiba glass filters, UV-35 and UB-46, or a 500W halogen lamp monochromatized by an MC-20 monochromator of Ritsu Oyo Company Limited was used as the light source, and the light intensity was measured with an Eppley thermopile. The intensity of the light incident upon the sample is *ca.* $1.40 \cdot 10^{-2}$W cm^{-2} for the former and $1.20 \cdot 10^{-4}$W cm^{-2} at λ: 475 nm for the latter.

In order to check the dissolution of CdS after the passage of photocurrent under potentiostatic conditions (0V *vs.* SCE), solutions were ashed with a suitable amount of concentrated nitric acid and analyzed for Cd^{2+} by either colorimetry with dithizone (7) or atomic absorption method. The differential capacitance of the electrode was measured with an a-c bridge at 1 kHz.

Results and Discussion

No steady photocurrent was obtained between an illuminated CdS electrode and a directly connected counterelectrode in an acetonitrile solution containing only $LiClO_4$. The surface of the CdS electrode became rough and yellow by the anodic photocurrent, owing to the deposition of sulfur. The amount of the Cd^{2+} ion produced, measured by the colorimetric analysis, was almost equivalent to the electrical quantity passed (0.3-18C, for periods of 20 min to 9 hr).

The decomposition of CdS was prevented by addition of sodium iodide into the solution even for the case of strong illumination, and a photocurrent as shown by curve a in Fig. 1 was obtained. The solution became yellow by passage of the current, suggesting the oxidation of I^- ion on the surface of the electrode to I_3^-. By employing an H-shaped cell, with the cathode and anode being separated, the formation of I_3^- was confirmed from the absorption spectrum of the solution in the CdS half-cell. The amount of I_3^- calculated from the absorbance and the molar extinction coefficient of I_3^-, 2.9×10^4, agreed well with the theoretical value obtained according to the following reaction

$$3I^- + 2p \rightarrow I_3^- \quad [1]$$

When the photocurrent experiments were carried out using an H-shaped photocell containing I^- in both sides, with oxygen bubbled into the cathodic (Pt) half-cell and nitrogen into the anodic (CdS) half-cell, the photocurrent under the short-circuit condition increased, as shown by the dotted curve in Fig. 1, probably because of the reduction of oxygen. No effect was observed by bubbling oxygen into the CdS half-cell.

With more than 10^{-4} mole · $liter^{-1}$ of I_2 added into the cathodic half-cell, the photocurrent was not affected by oxygen. The initial drop of the photocurrent as shown by curve a of Fig. 1 was avoided by addition of I_2 in the solution before illumination (curve b, Fig. 1), I_2 being mostly changed to I_3^-, owing to the large equilibrium constant for $I^- + I_2 \rightleftarrows I_3^-$ (8). These results arise undoubtedly by the reaction at the cathode

$$I_3^- + 2e \rightarrow 3I^- \quad [2]$$

With an undivided cell, the intensity of the I_3^- absorption band in the solution did not change even after long illumination, showing that equal amounts of I^- and I_3^- are generated at the anode and the cathode, respectively.

Quantitative analysis of the Cd^{2+} ion was carried out for the photoreacted acetonitrile solution containing various quantities of sodium iodide, and the "dissolution ratio," that is, the ratio of the observed Cd^{2+} concentration *vs.* that calculated from the total electric quantity of the photocurrent was plotted against the NaI concentration (Fig. 2). When the concentration of NaI was above 0.2 mole · $liter^{-1}$, the Cd^{2+} ion concentration in the solution became very small as found from colorimetric and atomic absorption analysis, and no weight loss of the CdS electrode was detected even after long illumination with an intensity of up to 0.135 W/cm^2.

Honda *et al.* (2) reported that the photoanodic dissolution of CdS in aqueous solutions could not be fully avoided by addition of I^-. The present favorable result can be attributed to the following two reasons. Firstly, the photodissolution current of CdS arises only at a more positive potential (− 0.3 ~ − 0.6V *vs.* SCE) in acetonitrile than in water (3). Secondly, the redox potential of I^-/I_3^- in acetonitrile (+ 0.03V *vs.* SCE) is more negative than that in water (+ 0.29V) (9), probably because of the smaller solvation energy of I^- in acetonitrile than in water. According to these

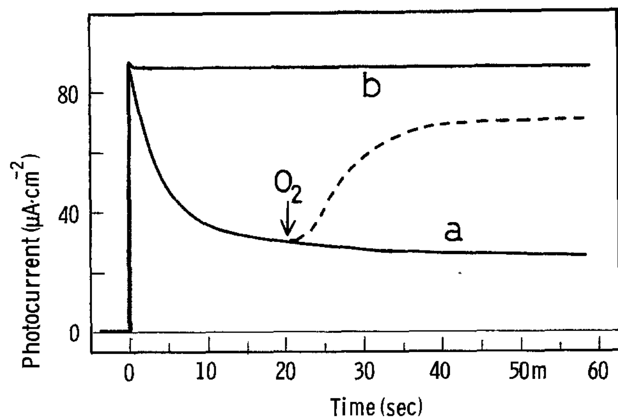

Fig. 1. Photocurrent curves *vs.* time under nitrogen gas bubbling. *a*, CH_3CN solution containing 0.285M NaI and 0.1M $LiClO_4$ (------: O_2 bubbling started at 20 sec); b, CH_3CN solution containing 0.285M NaI, 6×10^{-4}M I_2, and 0.1M $LiClO_4$.

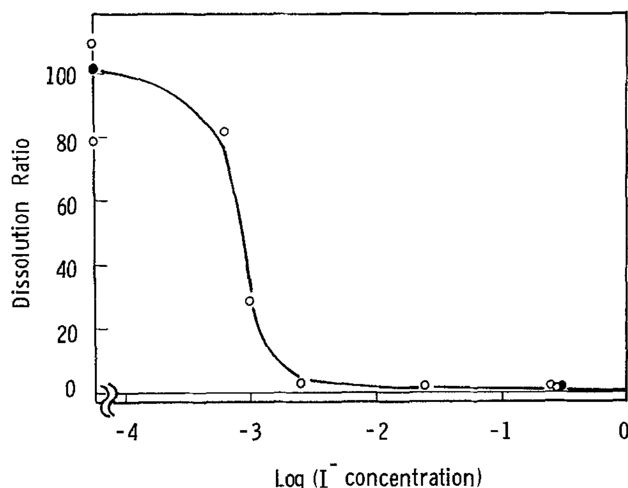

Fig. 2. "Dissolution ratio" for a CdS electrode under light from a filtered mercury lamp at various concentrations of NaI in acetonitrile solutions of $LiClO_4$. ○, By the colorimetric analysis: ●, by the atomic absorption analysis.

two reasons, CdS becomes stable in acetonitrile in the presence of an I^-/I_3^- couple.

An attempt was made to use nitromethane instead of acetonitrile, which was expected to stabilize CdS electrodes by its weak basicity (3). This was unsuccessful due to the small solubility of NaI in nitromethane. Even when a saturated solution of NaI was used, *ca.* 6% of the photocurrent arose from the dissolution of CdS.

The above-mentioned satisfactory result for acetonitrile solutions has led us to check the efficiency of the conversion of light to electrical energy by the photocell <CdS|NaI-acetonitrile|Pt> with variable load resistance (R) inserted into the external circuit and with light from a Xe lamp monochromatized at 475 nm. The acetonitrile solutions of NaI/I_2 redox couple, in spite of their yellow color, have little effect of retarding light coming toward the CdS electrode, as shown in Fig. 3.

Van den Berghe *et al.* reported that the etching of the electrode is very important for getting a large photocurrent (10). We have also observed that the photocurrent was enhanced by etching in a 3M HCl solution for 3 min (Fig. 4). Longer etching caused no further increase. The best power-conversion efficiency (electrical power, $i_p \cdot V_p$, produced divided by incident light power) obtained was 9.5% at $R = 100$ kΩ with an output potential of 0.70V and the highest photocurrent quantum efficiency (number of electrons in the short-circuit current ($R = 0$) divided by number of incident photons) was 69%, both for incident monochromatic light, 0.120 mW cm^{-1} at wavelength 475 nm. The dissolution of CdS was inhibited by I^- irrespective of the etching time.

The etching has been found to influence the differential capacitance in acetonitrile (Fig. 5). The $1/C^2$ *vs.* potential plot for a sufficiently etched (for 10 min) CdS electrode resulted in a straight line, while the plots for insufficiently etched CdS electrodes deviated from it. As the capacitance of the Helmholtz layer is thought to be much larger than the capacitance measured ($< 0.3\ \mu F/cm^2$), the observed capacitance should have arisen mostly from inside the semiconductor. The result in Fig. 5 shows that a part of the capacitance is brought about by a surface layer which can be removed by the etching. It is therefore concluded that the improvement of the photocurrent by etching is due to the removal of the current-retarding interfacial material.

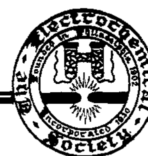
Brief Communication



Persistent Polarization of Polyelectrolyte Membranes in an Aqueous Environment

G. A. Bornzin and I. F. Miller*

Bioengineering Program, University of Illinois, Chicago, Illinois 60680

Over the past several years, a number of attempts have been made to model neural excitation and conduction phenomena using a dipole orientation and stabilization model (1-4). Evidence for the involvement of dipole orientation comes from measurements of axonal surface charges (5), birefringence changes (6, 7), and infrared emission measurements during action potential propagation (8).

Although the dipole orientation and stabilization models used are considered to be heterocharged electret models, there are important differences between axonal membranes and the systems usually used in electret studies. Most experimental studies of heterocharged electrets have involved dry electrical insulators and workers have postulated their formation to involve electron trapping (9) in some cases or displacement of ionic impurities in other cases (10). Such electrets have been shown to involve volume polarization (11) and have been shown to decay by mechanisms of dielectric relaxation (12, 13). Of course, axonal membranes are highly swollen with water, contain mobile ions, and cannot be considered to be electrical insulators.

Recently, we reported on a system in which strong heterocharged electrets were shown to exist in polyelectrolyte membranes (14-17). These membranes were electrical conductors and, in fact, it was shown that the amount of persistent polarization actually increased with electrical conductivity. The process involved was modeled by assuming mobile ion displacement down the electric field and stabilization of the dipoles thus induced by hydrogen bonding. The polyelectrolyte membranes contained sodium polystyrene sulfonate and polyvinyl alcohol, were studied in vacuum, and were dry.

* Electrochemical Society Active Member.

Key words: electret, polarization, polyelectrolyte, nerve, water.

In using the results of various electret studies to model the neural axon membrane, the role of water must be taken into account. Water swelling of dielectric membranes would destabilize any electret present. Similarly, if hydrogen bonding is involved, as apparently occurs in the polyelectrolyte systems, water should also have a disruptive effect here, unless water is excluded from the hydrogen bonding regions as probably occurs in certain polypeptide systems (18).

In this work, we have attempted to assess the effect of water and aqueous solution swelling on polarization stability in a polyelectrolyte membrane system. In the membrane formulation studied, the components were sodium polystyrene sulfonate (PSSNa), (Dow SA-1291.1, avg. mol. wt. $\simeq$ 2-4 $\times$ 10^6), polyvinyl alcohol (PVA) (Dupont Elvanol 71-30), crosslinked by hexamethoxymelamine (American Cyanamid Cymel 303). In addition, a small amount of *para*-toluenesulfonic acid (p-TSA) was added as an acid catalyst. All ingredients were washed several times and dialyzed against distilled water for purification purposes. The ingredients were dissolved in a methanol-water mixture, cast on glass plates, and cured at 70°C in a circulating oven. The finished membranes were clear, flexible, and fairly tough, had thicknesses ranging from 0.05 to 0.07 mm, and had an ion exchange capacity averaging 1.08 Mequiv./dry gram. They also could absorb substantial amounts of water. When dry, the membranes contained 15.2 weight percent (w/o) PSSNa, 30.9 w/o PVA, 51.7 w/o Cymel, and 2.2 w/o *p*-TSA. This formulation corresponds to a mole fraction of 0.08 in sulfonate groups.

Thermoelectrets were formed in these membranes by the methods reported earlier (14), except that the membranes and electrodes were previously coated with purified colloidal graphite to reduce contact resistance (17). Polarization was carried out at 65°-75°C in vac-

uum for at least 24 hr. After cooling to room temperature, four different experiments were carried out:

(*i*). The first, a control experiment, involved a removal of the charging field and a reheating of the membrane (following a capacitive discharge) to 15°C above the charging temperature, while monitoring the discharge current with a Keithley 610C electrometer. Integration of the discharge current over time yielded the total charge stored.

(*ii*). This was similar to (*i*) above, except that after cooling the charged electret to room temperature, the seal was broken, the electrode removed, and the membrane exposed to 100% relative humidity air at 20°C for 24 hr. The electrode was then replaced and the chamber resealed, evacuated, and thermally discharged.

(*iii*). This was similar to (*ii*) above, except that instead of exposure to high humidity air, the membrane was soaked in distilled water for 2 min.

(*iv*). This was similar to (*ii*) above, except that the membrane was soaked in 0.2M KCl solution for 24 hr, followed by a distilled water wash.

The results of these experiments are shown in Table I. As may be seen from the data, exposure to humid air or aqueous solution leads to substantial water swelling of the membranes. However, apparently it does not significantly destabilize the thermoelectrets formed. In fact, the water swelling appears to lead to substantially more charge storage than the control experiments (it should be noted that the control numbers are essentially the same as those reported by Linder (14) for a similar system). This is even true for the experiments in which the membrane is soaked in salt solution.

It is possible to explain the role of water in apparently stabilizing the electrets formed by considering its effect on the local field surrounding an electret forming group. In forming a heterocharged electret, the local field opposes the polarization, and anything that can reduce the effect of the local field within the membrane should lead to enhanced electret stability. When water enters the membrane, its polarization vector is in the same direction as the local electric field, thereby reducing the local field. Another effect of the water might be to reduce the attractive forces between separated charges in any induced dipoles present. This effect is, of course, counterbalanced by the disruptive effect of the water on the hydrogen bonding which stabilizes the separated charges.

Table I

	Experiment	Charge-stored C/cm² × 10⁸ two experiments
(*i*)	Control—negligible water content	0.052, 0.026
(*ii*)	Humid air—18.0% water (by weight)	0.92, 0.42
(*iii*)	Distilled water—20.2% water (by weight)	0.10, 0.26
(*iv*)	0.2M KCl—24.4% water (by weight)	0.14, 0.15

Thus, one might expect that there is an optimum amount of water that will maximize electret stability beyond which the electrets become less stable. The possibility of such an optimum may be inferred from the data reported, but the data is too sparse to reach a firm conclusion. If these reported effects also occur in neural axon membranes, perhaps it is easier to understand how persistent polarization can occur in a membrane so heavily loaded with water and mobile ions.

In the axon membrane, of course, ionic permeability changes accompany polarization changes. An attempt (using K^+ as the permeant) to determine if significant permeability changes occur in the polyelectrolyte membranes as a function of charge storage and degree of water swelling resulted in no significant changes being observed.

The Effect of SO_2 and NaCl on High Temperature Hot Corrosion

D. W. McKee, D. A. Shores,* and K. L. Luthra*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Sea salt ingested into gas turbines in a marine environment may result in the transient deposition of NaCl in a Na_2SO_4 film on hot gas path components under certain conditions. It has been found in laboratory studies that the corrosion behavior of high temperature alloys, such as IN 738, IN 713C, IN 100, and Ni-30Al (NiAl), toward such salt deposits is strongly influenced by the chemical composition of the gaseous environment. When SO_2 is present together with small concentrations of NaCl in Na_2SO_4 in an oxidizing atmosphere, these alloys are rapidly attacked at around 750°C, whereas much less corrosion occurs when either SO_2 or NaCl is absent. It appears that gaseous chlorine formed during sulfation of NaCl plays an important role in initiating attack which is subsequently propagated by the presence of a liquid phase.

The role of NaCl in the hot corrosion of gas turbines operating in a marine environment has been the subject of several investigations (1-7) and was discussed extensively in a recent conference (8). The controversy is not over the effect of NaCl, its ability to accelerate Na_2SO_4-induced attack has been demonstrated repeatedly, but whether NaCl is a relevant species in a gas turbine environment and by what mechanism it can accelerate attack by a predominantly Na_2SO_4 deposit.

In a marine environment NaCl is ingested into a gas turbine predominantly as an aerosol of sea salt along with the intake air. With normal engine operation and low-to-moderate salt levels, thermodynamic calculations predict that NaCl should not condense on first stage buckets; indeed, NaCl should be converted to Na_2SO_4 by reaction with SO_2 in the combustion gas (9, 10). However, because of the short residence times of the combustion gases, kinetic limitation of the sulfation and evaporation reactions may allow some NaCl particles from the compressor deposits to survive long enough to reach the first stage buckets (3, 11, 12). Thus, according to these arguments, NaCl may deposit by impaction along with Na_2SO_4 and other salts on turbine blades, but will be removed eventually by evaporation or sulfation. Operation of the gas turbine at low or moderate power will enhance the likelihood for the deposition of NaCl particles and, because of the lower blade temperatures, the average residence time of a deposited NaCl particle will be longer than at high power. Unfortunately, it has proved to be difficult to confirm the existence of NaCl on turbine blades. Careful chemical analysis of deposits or corroded regions on turbine blades only rarely reveals chlorides (13), but this may be simply a reflection of the transient nature of the deposited NaCl particle owing to sulfation and evaporation or, as others have proposed, due to the formation of volatile products by reaction with components of the scale (1-7). The deposition of NaCl particles under particular circumstances such as low power operation, appears likely but not well substantiated.

Earlier published work, especially by Hancock *et al.* (4, 5) and Condé (1, 3), has demonstrated that Cr_2O_3-forming alloys are particularly susceptible to attack in the presence of NaCl, with corrosion rates generally increasing with temperature. By contrast, Al_2O_3-forming alloys and aluminide coatings without Cr were reported to be much less affected by chloride. These observations were made using the dynamic vibration modulus technique (5, 14, 15), hot stage microscopy (4) and salt-sprayed specimen testing in atmospheres of air or oxygen to which NaCl was introduced (3). Recently, burner-rig data have been presented which show quite a different pattern of behavior for MCrAlY-type coatings and high temperature alloys such as IN-738 and Nimonic 105 (8). In these cases, when SO_2 was present in the gaseous combustion products, the alloys and coatings showed much more extensive chloride-induced corrosion at 750°C than at 900°C.

The present report concerns the role of NaCl in the mechanism of Na_2SO_4-induced hot corrosion attack of several alloys at moderate temperatures (700°-800°C). In particular, the synergistic effect of SO_2 and NaCl, reported previously (16), is considered in some further detail. Another mechanism of attack at moderate temperatures, which is dependent on SO_2 and SO_3 but not NaCl, will be described in a subsequent paper.

Experimental Procedure

Three kinds of kinetic experiments have been carried out: (*i*) studies of the interaction of Na_2SO_4-NaCl mixtures with O_2 and $O_2 + SO_2$ environments, (*ii*) studies of the oxidation of IN-738 and Ni-30Al in O_2 and in $O_2 + Cl_2$ mixtures, and (*iii*) crucible-type hot corrosion tests of several alloys in Na_2SO_4, NaCl, and Na_2SO_4-NaCl mixtures with various environments. The kinetics of evaporation and sulfation of NaCl in Na_2SO_4-NaCl mixtures were measured wtih a Mettler

* Electrochemical Society Active Member.

Thermoanalyzer-2 balance. This instrument recorded weight changes as a function of time at various temperatures in a controlled environment. The sensitivity of this balance could be varied over a wide range up to maximum sensitivity of $\pm$ 5 μg for a 5g load. The salt mixtures were prepared from Fisher Certified A.C.S. grades of NaCl and anhydrous Na_2SO_4, and were premelted at 900°C in air for 1 hr, then cooled, ground, and thoroughly mixed before use. Experiments were carried out at temperatures from 600° to 1000°C in O_2 (dried by passage through Drierite) or in various O_2-SO_2 mixtures. Gas mixtures (analyzed grade) were prepared by Union Carbide Corporation (Linde Division) from gases of the following purity: oxygen 99.6%, sulfur dioxide 99.9%, chlorine 99.5%, and hydrogen chloride 99%. Because of the expected slow attainment of equilibrium between SO_2, O_2, and SO_3 at moderate temperatures, a few corrosion tests were carried out in the presence of a Pt catalyst. This was accomplished with the specimen and salt contained in a Pt crucible which was covered with a few layers of Pt gauze. The Ni-30Al (NiAl) alloy was prepared by induction melting and casting in argon 1 in. diam bars from which rectangular coupons were cut. Similar specimens of superalloys were machined from cast ingots which had been given the appropriate heat-treatments as suggested in the literature (17). The compositions of the alloys used in the hot corrosion experiments are listed in Table I. The alloy specimens for both the oxidation and hot corrosion tests were polished through 600 grit SiC paper and degreased with alcohol and acetone before use. Oxidized and corroded specimens were examined metallographically and with the scanning electron microscope.

In the hot corrosion tests alloy coupons (typically 6.4 $\times$ 12.8 $\times$ 1 mm) were placed in small, glazed porcelain crucibles containing 1.0g of either Na_2SO_4, NaCl, or premelted mixtures containing small concentrations of NaCl in Na_2SO_4. In this configuration the specimen was about half-immersed in the salt. For those conditions in which the salt melted, the upper half of the specimen was also covered with a thin film of salt because of capillarity. The crucible and contents were placed in the Chevenard thermobalance previously described (18) and brought to temperature within an hour in a flowing stream of the desired environment, which included O_2, $O_2 + SO_2$, $O_2 + Cl_2$, or O_2 + HCl. Many of the runs were carried out in 76%O_2-0.1%SO_2-bal N_2 which simulates the chemical potentials of oxygen and sulfur typical of the combustion products in a gas turbine operating at 5 atm with a 50:1 air/fuel ratio, and this composition will be referred to subsequently as simulated combustion gas (SCG). Since evaporation and sulfation of the salt were significant under some conditions, the measured weight changes were corrected by data from blank runs under identical conditions but containing no specimen. The sensitivity of the Chevenard balance was approximately $\pm$ 0.2 mg. Hot corrosion tests were carried out at a variety of temperatures between 600° and 950°C on Ni-30Al, IN-738, IN-713C, and IN-100. Some of the alloys were preoxidized in O_2 at 700°-900°C before the hot corrosion test. No appreciable corrosion of the glazed porcelain crucibles by the Na_2SO_4-NaCl melt could be detected during the duration of the experiments.

Results

Gas/salt interactions.—The combustion gas produced by burning petroleum-based fuels in a gas turbine contains N_2, O_2, CO_2, H_2O, small amounts of nitrogen oxides, CO, SO_2, hydrocarbons, and various airborne or fuel-borne impurities. The interaction of these various impurities with O_2, SO_2, and H_2O are significant to hot corrosion. Thus, the study of the effect of NaCl on hot corrosion under conditions which simulate a gas turbine environment necessarily involve evaporation and sulfation reactions

$$NaCl(c) = NaCl(g) \quad [1]$$

$$2NaCl(c) + SO_2 + O_2 = Na_2SO_4(c) + Cl_2 \quad [2]$$

and

$$2NaCl(c) + SO_2 + H_2O + \tfrac{1}{2} O_2 = Na_2SO_4(c) + 2HCl \quad [3]$$

and

$$Na_2SO_4(c) = Na_2SO_4(g) \quad [4]$$

The rate at which reactions proceed to the right under our experimental conditions was measured by TGA in some preliminary runs. In slowly flowing dry O_2 at 800°C a Na_2SO_4-10 w/o NaCl melt lost weight steadily as a result of evaporation and no Cl_2 could be detected in the exhaust gas. With $O_2 + SO_2$ or $O_2 + SO_2 + H_2O$ the melt either lost weight less rapidly or gained weight indicating that sulfation was taking place concurrently with evaporation. Analysis of the exhaust gas for the $O_2 + SO_2$ run revealed copious amounts of Cl_2 as expected from Eq. [2]. As will be shown later, Cl_2 can have a substantial influence on rates of hot corrosion.

At lower temperatures the rates of evaporation and sulfation were reduced, but the same response was observed, *i.e.*, weight losses due to evaporation in O_2 and weight gains in $O_2 + SO_2$. Even at the highest temperature used in the hot corrosion tests, 950°C, a major portion of the NaCl remained after 6 hr. In Table II are reported analyses of Na_2SO_4-NaCl mixtures after

Table I. Composition of alloys

* The gas flow rate was 250 ml/min with a 1g sample.

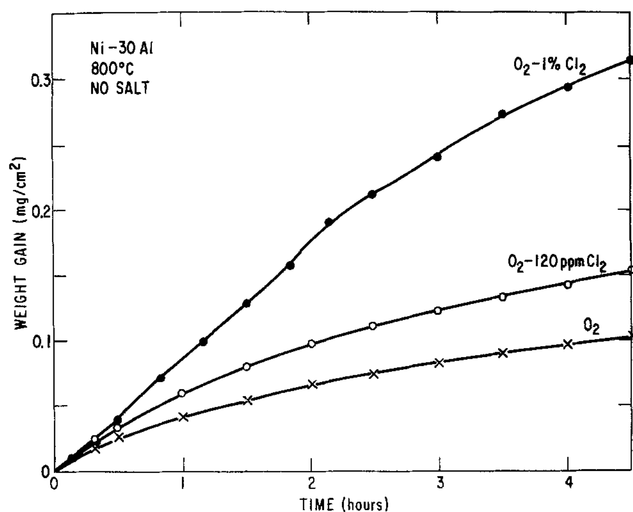

Fig. 1. Effect of gaseous Cl_2 on oxidation rate of Ni-30Al in O_2 at 800°C. Weight gains vs. time.

heating in atmospheres containing O_2 + SO_2 (but not H_2O) at three temperatures.

Oxidation.—IN-738 and Ni-30Al are resistant to oxidation at 800°C in pure O_2; however, for Ni-30Al the addition of a small amount of Cl_2, 120 ppm, to O_2 resulted in a measurable increase in the rate of weight gain, as shown in Fig. 1. With the addition of 1% Cl_2 the rate of weight gain was further increased. For IN-738 120 ppm Cl_2 also produced a slow but steady weight gain, but when the oxygen contained 1% Cl_2, the sample of IN-738 developed an oxide scale yet it lost weight steadily (Fig. 2), indicating the formation of a volatile product. However, of greater significance is the effect of Cl_2 on the integrity of the protective scale. With pure O_2 IN-738 formed a dense, protective scale at 800°C with an overgrowth of fine crystallites as shown in the SEM photographs in Fig. 3. Another specimen, exposed under identical conditions except that the gas contained 1% Cl_2, developed a much different scale morphology that was badly cracked and spalled as shown in Fig. 4. The appearance of the latter sample is very similar to that in Fig. 5 which is typical of a sample exposed in the crucible test to Na_2SO_4-1% NaCl in the SCG at 750°C.

Hot corrosion tests.—Some preliminary crucible-type tests were carried out with IN-738 in pure NaCl at 750°C in various environments, and the results are shown in Fig. 6 and 7. These tests were not intended to simulate conditions in a gas turbine, but rather to provide information on alloy/NaCl interactions. With pure O_2 IN-738 gained weight very slowly, but at a rate

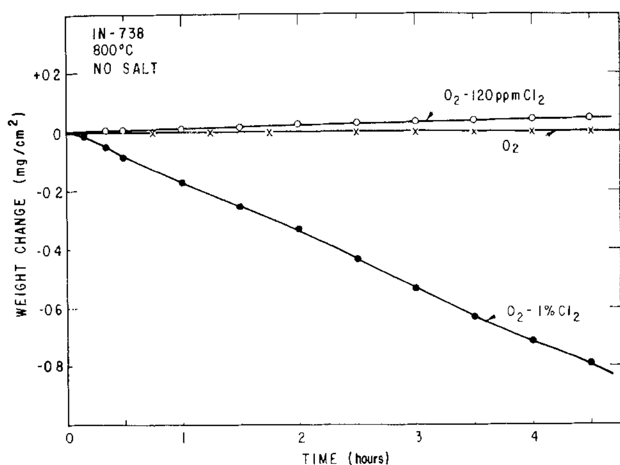

Fig. 2. Effect of gaseous Cl_2 on oxidation of IN-738 in O_2 at 800°C. Weight change vs. time.

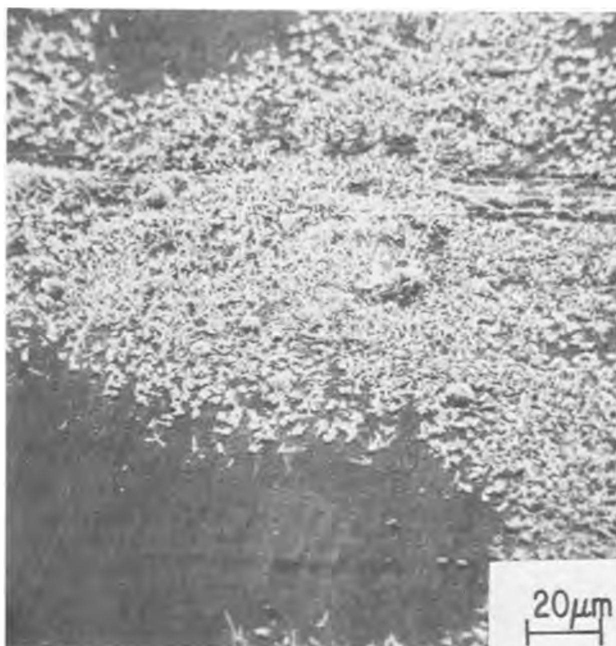

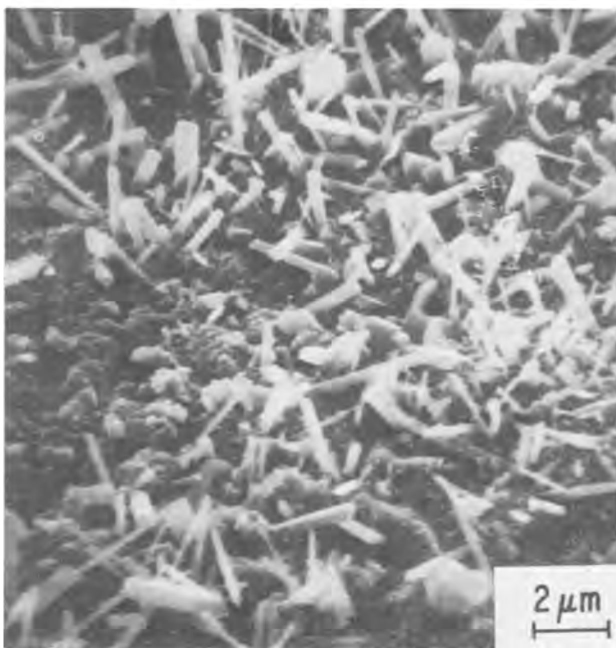

Fig. 3. SEM micrographs of the surface of IN-738 after oxidation in O_2 for 120 hr at 800°C.

somewhat faster than for simple oxidation. Although the salt was not melted at this temperature, the normally protective oxide scale was cracked and spalled, probably by NaCl vapor. Hancock *et al.* (4) have demonstrated that NaCl vapor will crack the protective oxide scale on Ni-base superalloys. With the addition of 120 ppm Cl_2 to O_2 IN-738 initially lost weight but subsequently was attacked considerably faster than in O_2. Very rapid rates of attack were observed in O_2-60 ppm HCl and in O_2-1% Cl_2. To distinguish the effect of NaCl vapor from that due to condensed NaCl in contact with the specimen, two runs were carried out with specimens suspended over, but not in contact with, NaCl. These data are reported as dashed curves in Fig. 6. In both O_2 and in O_2-1% Cl_2 the rate of attack in these tests was much lower than that when condensed NaCl was in contact with the specimen.

Although the test temperature was ~ 50°C below the melting point of NaCl, a liquid phase may have

formed in the crucible tests with O_2 + Cl_2 by the interaction of condensed NaCl with transition metal chlorides, which themselves are formed by the reaction of Cl_2 with components of the oxide scale. As is shown later some transition metal chlorides are thermodynamically stable in the presence of relatively high oxygen activities. Atomic absorption analysis revealed significant quantities of water soluble Ni and Co in the salt which is evidence for the formation of $NiCl_2$ and $CoCl_2$ during the test.

The presence of small concentrations of SO_2 in place of Cl_2 invoked a similar response of IN-738 in pure NaCl at 750°C, *e.g.*, 0.1% SO_2 approximately doubled the corrosion rate and in O_2-1% SO_2 the weight increases were linear and about an order of magnitude faster than in pure O_2. These data are reported in Fig. 7. One important effect of SO_2 is to convert NaCl to Na_2SO_4 and to generate Cl_2. The concentration of Cl_2 at the sample surface would be difficult to estimate because the rate-limiting step for reaction [2] is unknown. Nevertheless, in O_2 + 1% SO_2 the value of the activity of Cl_2 corresponding to thermodynamic equilibrium was estimated to be 0.16 atm when the activity of Na_2SO_4 was 1. Thus, it seems not unreasonable to suppose that at the specimen surface fairly high levels of Cl_2 were possible which could crack the oxide scale. In addition, the reaction of SO_2 with NaCl produces Na_2SO_4, again by Eq. [2], which eventually could form an aggressive liquid NaCl-Na_2SO_4 eutectic melt. In the present tests with either O_2-SO_2 or O_2-Cl_2 environments the bulk of the salt did not melt, but it appeared that the salt grains in contact with the sample had formed a small amount of liquid phase. From the runs in which the specimen was suspended above the salt (thereby excluding the possibility of a liquid phase) it was apparent that NaCl vapor together with Cl_2 in the presence of O_2 was insufficient to induce rapid attack.

A series of crucible tests have been carried out with several alloys in Na_2SO_4-NaCl mixtures, and the rate of attack was found to be strongly dependent on temperature, SO_2 in the gas and concentration of NaCl in the salt. In Fig. 8 are shown weight gain *vs.* time data for IN-100 at 750°C. In O_2 the rate of attack in

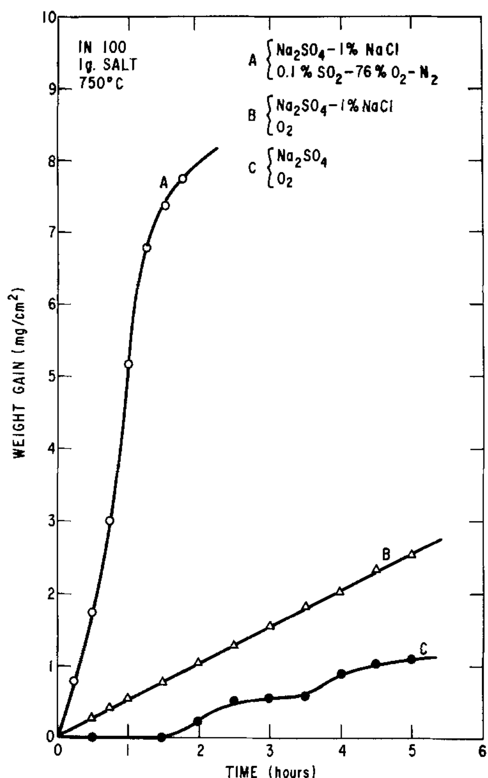

Fig. 8. Effect of NaCl and SO_2 on Na_2SO_4-induced corrosion in the crucible test of IN-100 at 750°C. Weight gains vs. time with Na_2SO_4 and Na_2SO_4-1% NaCl in O_2 or simulated combustion gas.

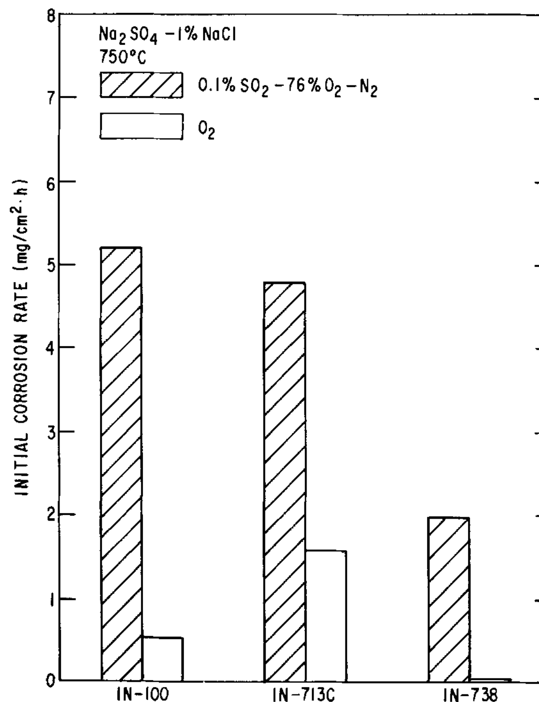

Fig. 11. Comparison of initial corrosion rates of several alloys in Na_2SO_4-1% NaCl melts at 750°C.

Na_2SO_4-1% NaCl was increased over that in Na_2SO_4 alone; when SO_2 was added to the environment a further substantial increase in the rate of attack occurred. IN-713C responded in a similar way at both 750° and 900°C, as shown in Fig. 9 and 10. The latter data also demonstrated that as little as 100 ppm SO_2 with NaCl in the salt was able to accelerate the rate of attack over that in O_2. Both of these alloys have been shown to have rather poor resistance to Na_2SO_4-induced hot corrosion at elevated temperatures (19). Figure 11 shows a comparison of the initial corrosion rates (during the first hour of exposure) of the three superalloys in Na_2SO_4-1% NaCl at 750°C. In both oxygen and simulated combustion gas, IN-738 was the most resistant.

More extensive crucible tests as a function of temperature and composition of the environment were car-

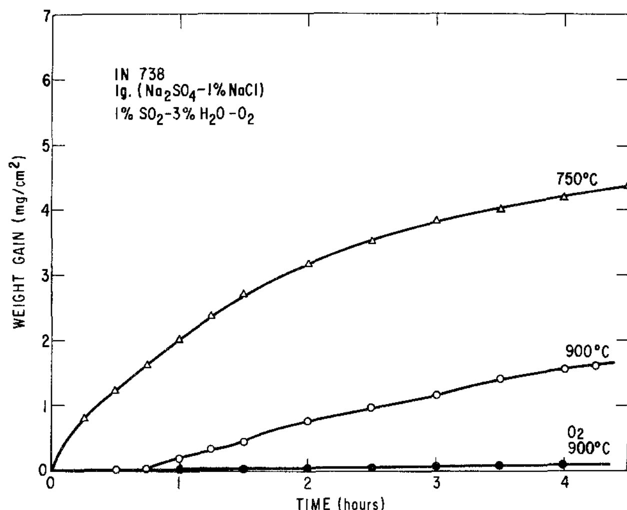

Fig. 12. Corrosion of IN-738 in the crucible test by Na_2SO_4-1% NaCl in O_2 and 1% SO_2-3% H_2O-O_2. Weight gains vs. time at 750° and 900°C.

ried out in Na_2SO_4-1% NaCl mixtures with IN-738. Figure 12 shows that environments containing O_2-SO_2-H_2O (which generate HCl by reaction with NaCl via Eq. [3]) also accelerated the rate of attack. Under these conditions the attack was faster at 750° than at 900°C. In a series of tests at temperatures between 600° and 900°C in the SCG the rate of attack of IN-738 became noticeable at 600°C, reached a maximum at about 750°C, and declined at higher temperatures. The data from these runs are summarized in Fig. 13 as a plot of initial corrosion rate (averaged over the first 1-2 hr) *vs.* temperature. Although most tests lasted only 5-6 hr, a 48 hr test at 850°C in O_2-SO_2 maintained a reasonably uniform rate of attack for the entire duration. Thus, the lower rates of attack between 800° and 900°C are not the result of a prolonged incubation period; rather, they represent steady-state corrosion under those test conditions. A similar, but less intense, peak in corrosion rate was found with O_2-100 ppm SO_2. For comparison Fig. 13 also shows that the rates of attack were relatively low over that temperature range when the test involved either 1% NaCl in O_2 or Na_2SO_4 in O_2-0.1% SO_2; only when both SO_2 and NaCl were present together were high rates achieved.

In a separate series of crucible tests at 750°C with IN-738 a Pt catalyst was used with SCG to insure a p_{SO_3} close to the equilibrium value. In these tests IN-738 was attacked by Na_2SO_4 alone and at a substantially faster rate by Na_2SO_4-10% NaCl. The effect of chloride was still marked in the presence of O_2-SO_2-SO_3 at 750°C. In the previously described tests without a Pt catalyst p_{SO_3} was unknown but was somewhat less than the equilibrium value. The main effect of SO_3 was to enhance attack by Na_2SO_4 at moderate temperatures but by a different mechanism which will be discussed in a subsequent paper.

Alloy coupons that had been intensely corroded by Na_2SO_4-NaCl-SO_2 at 750°C exhibited a flaky, spalled surface scale shown previously in the SEM photograph in Fig. 5. Metallographic examination of that specimen revealed a thick nonprotective oxide scale and numerous internal Cr_xS precipitates (Fig. 14a). On the other hand, when SO_2 was absent, a test in Na_2SO_4-1% NaCl at 750°C produced only a thin, dense scale with no internal precipitates (Fig. 14b).

With Ni-30Al the combined effects of NaCl and gaseous SO_2 again produced a maximum in the rate of attack at intermediate temperatures. Figure 15 summarizes the results of several crucible tests on Ni-30Al in a variety of Na_2SO_4 mixtures over a range of temperatures. With 1% NaCl the maximum rate occurred at about 850°C, but with higher concentrations of NaCl the maximum shifted to lower temperatures. The rates of attack in the range of 700°-850°C were extremely rapid (note that the ordinate in Fig. 15 encompasses a range more than ten times that of Fig. 13). Under these conditions the samples gained weight linearly with time and formed thick, porous, layered scales as shown in Fig. 16. As with IN-738, crucible tests with Na_2SO_4 alone yielded relatively low rates of attack. Preoxidation was effective in delaying the onset of rapid attack,

as shown in Fig. 17, but could not prevent it. This appeared to be a general effect for all the alloys tested and has been observed before (3, 4). The rapid attack of Ni-30Al in the presence of NaCl and SO_2 is in contrast to previous generalizations that alloys forming Al_2O_3 scales are less susceptible to chloride-induced attack. However, the synergistic effect of NaCl and SO_2 was not recognized previously.

Discussion

There seems to be wide agreement that the principal role of small concentrations of NaCl in hot corrosion induced by Na_2SO_4-NaCl mixtures is to crack or break the protective oxide scale, thereby drastically reducing the initiation or incubation period (1-7). When the salt mixture gains direct access to the alloy beneath the oxide scale, the subsequent rapid hot corrosion reactions proceed much as if access were accomplished by any other alternate mechanism; such as by cracking from thermal cycling or by fluxing. Corrosion morphologies and corrosion reaction products from deposits containing small concentrations of NaCl are much the same as in the absence of NaCl, Cl is usually not detected among the corrosion products (6). There is, however, much less concurrence on explanations of how NaCl breaks the protective scale.

In the present work attention has been focused on the role of Cl_2, and in particular on Cl_2 generated by the interaction of SO_2 in the environment with NaCl in a salt mixture. (HCl is expected to have a similar effect.) Chlorine has been found to play a much more aggressive role in hot corrosion than NaCl; *e.g.,* in corrosion tests with small concentrations of NaCl, low Cl_2 activities produced low rates of attack whereas high Cl_2 activities produced aggressive attack. In fact, Cl_2 was able to crack oxide scales whether or not NaCl was also present. A detailed explanation of the mechanism of Cl-induced cracking of oxide scales cannot be offered at present. However, some possible reactions involving chlorine and oxides are discussed below. It should be recognized, however, that in some laboratory tests, as well as in marine gas turbines, mass transport through salt layers or through gas boundary layers may limit the activities of some species at the reaction site.

At the usual temperatures for hot corrosion testing (900°-1000°C) rapid rates of attack can be sustained because a liquid film of salt prevents the formation of a barrier oxide at the alloy surface. For the same reason it is quite likely that a liquid salt is also a necessary (but perhaps not sufficient) condition for rapid attack at lower temperatures. Consider the kinetic data for IN-738 in pure NaCl at 750°C, which is about 50°C below the melting point of the salt. When a sample was exposed to only gaseous reactants, O_2-1% Cl_2 plus NaCl vapor, the rate of attack was rather low (Fig. 6). However, when the run was repeated with essentially the same activities of reactants, except that the specimen was in contact with condensed NaCl, rapid attack occurred. If it is presumed that a liquid film is required, the question then becomes how a molten phase can occur at temperatures below the melting point of pure NaCl. The possibility of forming low melting eutectics between NaCl and transition metal chlorides was examined by first calculating the thermodynamic stability of several transition metal chlorides which might form by reaction of Cl_2 with components of the oxide scale. These results, which are summarized in

Table III. Calculated partial pressures of O_2 and Cl_2 in O_2-Cl_2 mixture in equilibrium with liquid NaCl-M Cl_x mixtures at 750°C

System	Stable oxide	Liquid phase	MCl_x activity in melt	p_{O_2} (atm)	p_{Cl_2} (atm)**

*** Activity of $CrCl_3$ assumed equal to that of $AlCl_3$ because of similar liquid phase.
† Based on ideal behavior of MCl_x and NaCl in liquid.
‡ Activity coefficient was estimated from the phase diagram (20).

Table III, reveal that only $NiCl_2$ and $CoCl_2$ are sufficiently stable in an oxidizing environment to be possible candidates. Second, the NaCl-$NiCl_2$ and NaCl-$CoCl_2$ phase diagrams (20) reveal low melting eutectics and, equally importantly, the uptake by NaCl of relatively small amounts of these chlorides is sufficient to cause melting at 750°C. Thus, liquid could form where NaCl crystals contact the samples, and subsequent cracking of the oxide by Cl_2 could provide access for the liquid phase to attack the alloy.

Evidence for the formation of such transition metal chlorides was obtained by analysis of salt that had been in contact with IN-738 during a crucible test. Atomic absorption analysis of the salt revealed significant concentrations of water-soluble Ni and Co and very low concentrations of Cr and Al in agreement with the thermodynamic estimates in Table III. It is noted that runs in pure O_2 (Fig. 6), where transition metal chlorides would not be stable, produced quite low rates of attack. In principle, the same arguments apply to Na_2SO_4-NaCl mixtures. However, because the concentrations of NaCl were low and because most of the tests were run above the Na_2SO_4-NaCl eutectic temperature, the effect of $NiCl_2$ or $CoCl_2$ (if present) is expected to be very small. All the data are consistent with the proposal that a liquid phase is necessary to sustain rapid attack.

In a series of tests with Na_2SO_4-NaCl mixtures over a range of temperatures a maximum in the corrosion rate was found at intermediate temperatures when the environment contained O_2 and SO_2 (Fig. 13 and 15). In contrast to this, low corrosion rates were found over the whole temperature range with Na_2SO_4-NaCl mixtures in O_2 or with Na_2SO_4 in O_2 and SO_2. Both an Al_2O_3-forming alloy (Ni-30Al) and a Cr_2O_3-forming alloy (IN-738) exhibited this pattern. For Ni-30Al the maximum corrosion rate shifted from about 850°C to about 700°C as the concentration of NaCl was increased from 1 to 10%. It is proposed that these observations can be rationalized in the following way.

According to the phase diagram the Na_2SO_4-NaCl system forms a simple eutectic with a melting point of about 625°C. There is negligible solid solubility of NaCl in Na_2SO_4 (20). Therefore, aside from any possible interactions with the oxide, in tests above 625°C some liquid salt would be present, the amount increasing at higher temperatures. In addition, those environments containing SO_2 will generate Cl_2, which can accelerate the attack in the presence of liquid salt by cracking and disrupting the oxide scale. However, the activity of Cl_2 so generated will be strongly dependent on temperature, as indicated by the estimates from thermodynamic considerations in Table IV. Clearly the activity of Cl_2 could be quite high at the lower range of temperatures but will decline with increasing temperatures to rather low values at 900°C.

Thus, it is proposed that the corrosion rate is affected by two opposing factors: with increasing temperature the increasing amount of liquid tends to accelerate the rate, but at the same time the declining activities of Cl_2 tend to lower the rate, approaching

Table IV. Calculated pressure of Cl_2 in equilibrium with Na_2SO_4-NaCl mixtures*

Temperature (°C)	Mole fraction NaCl	Pressure Cl_2 (atm)**	Pressure Cl_2 (atm)†

‡ Mole fraction of NaCl was obtained from the phase diagram (20).

that in Cl_2-free environments above 900°C. As the test temperature increases from the eutectic temperature, the effect of the increasing amount of liquid is offset by the declining activity of Cl_2, and the rate passes through a maximum. Although the liquid is initially rich in NaCl, with increasing temperature the concentration of NaCl diminishes; however, the consequences of this appear to be less important than the declining activity of Cl_2. The activity of Cl_2 at the alloy surface may be further limited by diffusion when the sample is covered by a continuous film of liquid salt or is submerged in a melt. Chlorine transport through a liquid salt is likely to be slow, as is thought to be the case with O_2 in Na_2SO_4 (21). Hence, at high temperatures the liquid may effectively shield the specimen from Cl_2, and thereby further contribute to a reduction in corrosion rate.

Increasing the concentration of NaCl from 1 to 10% in $O_2 + SO_2$ environments shifted the maximum corrosion rate of Ni-30Al to lower temperatures (see Fig. 15). This behavior is understandable because the amount of liquid formed at a given temperature will increase as the concentration of NaCl is increased; or to put it another way, as the NaCl concentration is raised the minimum amount of liquid for substantial attack will be formed at lower temperatures. At a given temperature the liquid phase will have the same composition whether the over-all concentration of NaCl is 1 or 10%. By the same reasoning, complete coverage by a liquid film will occur at lower temperatures with high NaCl concentrations, and hence the decline of corrosion rates will commence at lower temperatures. Thus, the entire curve of corrosion rate *vs.* temperature will be shifted to lower temperatures with increasing NaCl concentrations, as shown in Fig. 15.

Chlorine and NaCl vapor have been shown to be effective in cracking oxide scales on alloys, but the mechanism by which this occurs is not known. Because alloys forming Cr_2O_3 scales were found to be more susceptible to Cl-induced hot corrosion than those forming Al_2O_3 scales (3-7), the evolution of volatile chromium chlorides or oxychlorides has been sug-

gested as a means of lifting and breaking the oxide scale. However, the vapor pressures of these species are considerably less than 1 atm in the temperature range where chloride effects are observed. On the other hand, the boiling points of $AlCl_3$ and $TiCl_4$ are quite low, and these species could generate considerable pressure if they were to form in a region of low oxygen activity at the metal/scale interface.

For example, at the alloy/scale interface (choosing $a_{Ni} = 0.65$, $a_{NiO} = 1$, $a_{Al_2O_3} = 1$) the chlorine activity required to generate 1 atm of $AlCl_3 + Al_2Cl_6$ is only 0.0025 atm. However, as mentioned before, with p_{Cl_2} at the oxide/salt interface on the order of 0.16 atm (for $p_{SO_2} = 0.001$ atm, $a_{NaCl} = 1$ and $a_{Na_2SO_4} = 1$), clearly a $p_{AlCl_3} + p_{Al_2Cl_6}$ greater than 1 atm is feasible. Thus, if cracking is due to mechanical lifting by gaseous chlorides, Al or Ti chlorides are more feasible. On diffusing out of cracks in the scale into a region of high oxygen activity, both $AlCl_3$ and $TiCl_4$ would be quickly converted to their respective oxides leaving little evidence of Cl in subsequent analysis.

Conclusions

The present studies, which were designed to elucidate the corrosive effects of NaCl in Na_2SO_4 deposits, have shown that it is important to include the active components of the combustion environments. In particular:

(*i*) Small concentrations of Cl_2 in O_2 produced extensive fracturing and spalling of oxide scales in the absence of a salt deposit.

(*ii*) The reaction of SO_2 with NaCl in a deposit can produce substantial partial pressures of Cl_2.

(*iii*) In the presence of a liquid salt phase, cracking of the oxide scale by gaseous halogens is accompanied by rapid attack.

(*iv*) With a Na_2SO_4 deposit containing small (1-10%) concentrations of NaCl, the corrosion rate attained a maximum at temperatures around 750°C when SO_2 was present. This behavior was observed with a binary alloy and three superalloys which included both Al_2O_3 and Cr_2O_3 formers; IN-738 was the least affected. When either SO_2 or NaCl was absent the rates of attack were much lower on all the alloys in this temperature range.

Some possible reasons for the observed behavior have been discussed.

Contact Resistance of Tin-Nickel Alloy Electrodeposits

M. Antler

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

The atmospheric corrosion resistance of equiatomic tin-nickel alloy having the weight percent composition, 65Sn-35Ni, increases with time due to the growth of a protective oxide. Tin-nickel is used as a material for wiping electric contacts, usually as an underplate for gold, and during use can become exposed as the gold is worn through. In this study, the contact resistance of tin-nickel was found to be initially low and to change on aging as the oxide forms at a rate which depends on relative humidity and temperature. Contact resistance increases very slowly in dry air and quickly in humid air with little rate difference between 15 and 88% relative humidity. The increase of contact resistance when tin-nickel is in contact with water has the same kinetics initially as when it is aged in humid air, but resistance continues to grow with time well beyond the air-limiting value. The initial kinetics of contact resistance increase at 100°C are the same as at room temperature, although much higher levels are attained on prolonged aging at 100°C. The contact resistance of tin-nickel is also inversely related to its surface roughness.

Electrodeposited tin-nickel alloy is a single phase equiatomic intermetallic compound (SnNi) having the weight percent composition, 65Sn-35Ni. It is considered to be thermodynamically unstable, since it does not appear in the phase diagram for the two metals (1). Practical experience, however, has shown SnNi to be kinetically stable, transforming rapidly to Ni_3Sn_4 and Ni_3Sn_2 only above *ca.* 300°C (2-5). Coherent electrodeposits that are mixtures of SnNi, Ni_3Sn_4, and Ni_3Sn_2 with chemical and physical properties similar to those of the single phase plating have also been prepared (6).

Tin-nickel can be corroded by HNO_3 vapor and other reagents if it is exposed immediately after removal from the electroplating bath (7). However, it quickly becomes corrosion resistant in air, a characteristic which improves on continued air exposure for several thousand hours, after which there is no further change (7). This long recognized (8) chemical stability is due to a protective oxide (9, 10) that grows on its surface to a limiting thickness, believed to be about 30Å, and to consist of tin oxide mixed with some tin and nickel hydroxides (11).

Among the applications of SnNi are its use as a chemical etch resist for the fabrication of printed wiring boards from copper-clad laminate (12, 13). When the board has electric contacts along its edge which engage separable connectors, a gold overplating is usually applied to lower contact resistance, and even thin (less than 1 μm) gold is effective for this purpose. Furthermore, the corrosion resistance of gold on SnNi is equivalent to that of SnNi alone, because a galvanic couple does not persist at pores and other discontinuities in the gold once the protective oxide is formed (6, 7). When in service as a contact material, the gold plate may gradually become worn through by the wiping of the opposing contact thereby exposing the SnNi underplate. As the area of exposed SnNi enlarges and as it becomes oxidized, contact resistance increases and can become unacceptable. It is, therefore, of interest to determine environmental factors which affect the growth of the oxide and thereby its contact resistance.

The objective of this investigation was to determine whether the contact resistance of SnNi is controlled by the relative humidity (RH) of the air in which it is aged. This work is an expansion of a preliminary study (7) of the dependence of contact resistance with time of aging which was conducted at 15-20% RH. Experiments with SnNi in contact with water or in air at elevated temperature were also made. In this work, the SnNi samples were etched in HCl to assure that they were free of films prior to aging. Observations were also made of the contact resistance of unetched SnNi that had been aged for up to 10 years. The dependence of contact resistance of SnNi on its surface roughness was examined.

Key words: passivation, oxidation, corrosion resistance, electric contacts.

Experimental

Sample preparation.—Electropolished, oxygen-free copper panels, 3.8 cm square by 0.16 cm thick, were plated with 12 μm of SnNi from a fluoride bath (14). Samples were etched in 18% HCl (1:1 mixture of water and concentrated HCl, sp gr = 1.18) to remove any air-formed film that was present, washed well in distilled water, blown dry with nitrogen, and inserted immediately into various controlled environments, described below, in which they were aged. A few samples were not etched, including some that had been prepared by abrasion of the substrate surface rather than by electropolishing. One of these panels was brass plated with 15 μm of SnNi.

The completeness of removal of air-formed oxide could be determined by contact resistance measurement after etching. Treatment for a minimum of 1 min with 18% HCl at room temperature was adequate to reduce contact resistance to a low and reproducible level of 5-6 mΩ (7) when measured in a prescribed way, discussed later. Some samples were etched in HCl for less than 1 min, which gave a contact resistance intermediate to the initial value and 5-6 mΩ. Their change of contact resistance on air aging was then determined.

Additional samples, obtained from commercial sources, were printed wiring boards having 5 or 12 μm of SnNi on copper substrates without a gold overplate and were plated from a fluoride bath (14). These samples were not etched prior to plating.

Roughness was measured with a diamond stylus instrument; the polished panels were too smooth to give meaningful readings and are presumed to have been below *ca.* 0.03 μm center line average (CLA). The printed wiring boards had comparably smooth surfaces.

Aging.—Panel samples in loosely covered petri dishes were aged at room temperature and ambient conditions (25-60% RH) or in an oven at 100°C. The samples aged at controlled RH and room temperature were in sealed desiccators over slurries in water of CP salts: 15% RH, LiCl; 51% RH, $Ca(NO_3)_2$; 88% RH, $BaCl_2$. Silica gel, which leaves 0.03 mg residual water/liter air at 30.5°C (15), was also used (0% RH). The water-aged sample was immersed in deionized water in a sealed vessel. The SnNi-plated printed wiring boards were aged in laboratory air without humidity control.

The panel samples were removed periodically for contact resistance measurement and then were returned to their aging environments. The water-aged sample was dried in nitrogen prior to probing. The RH of the room air in which probing was done was 15-20%.

Contact resistance.—An automated contact resistance probe ("Autoprobe") (16) was used. The probe was a 3.2 mm diam smooth hemispherically ended solid gold rod. Open-circuit voltage was 0.03V. Nine or more measurements were made on each sample at each time interval with load continuously increasing from 0 to 200g.

Observations and Discussion

Aging in air at room temperature.—Figure 1 is a plot of the median contact resistances at 100g from etched samples aged at 0, 15, 51, and 88% RH including 9000 hr data for an 88% RH aged panel. The bands include 95% of all of the measurements that were made; *i.e.*, 5% of the determinations were outliers. Shown also in Fig. 1 are the median contact resistances for unetched samples aged for 3, 6, 8, 18, 72, and 120 months at ambient conditions. Newly plated, unetched samples had about the same contact resistance, 5-7 mΩ, as freshly etched specimens. These contact resistance determinations were made within 10 min of removal from the plating bath or etching solution.

The maximum resistance value from the 500 determinations made with all samples was 15Ω. Contact resistances at loads other than 100g are not presented because the trends were the same, with only the absolute values being different. This is illustrated in Fig. 2, typical median contact resistances at 25, 50, 100, and 200g for the etched sample in Fig. 1 which was aged at 15% RH.

The data in Fig. 1 can be grouped into two categories, resistances for etched samples aged at 0% RH, and those from etched samples aged at 15-88% RH. Resistance increases with air aging, but much more quickly when water vapor is present, attaining values of 1-10Ω in several thousand hours. There is no significant difference in rate of resistance change in aging at 15, 51, and 88% RH. It is possible that etched SnNi attains a limiting contact resistance which is the same as that for as-plated samples. This trend in contact resistance parallels an increasing ability of SnNi on air aging to resist attack by corrosive environments (7).

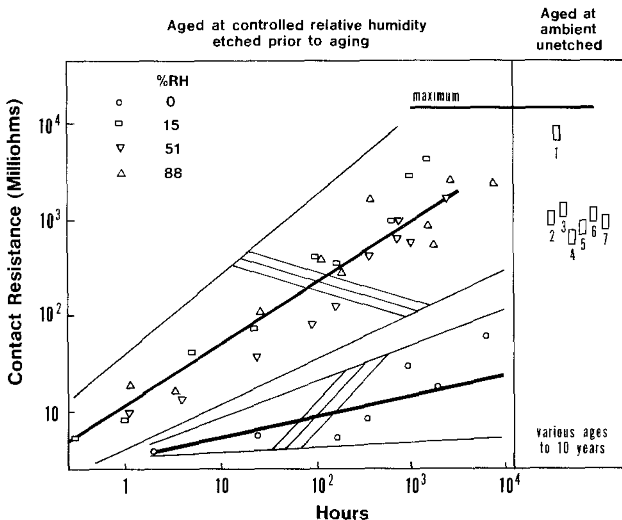

Fig. 1. Contact resistance at 100g of smooth SnNi electrodeposits. Left: Aged in air at room temperature and controlled RH. Samples were 12 μm thick on copper. Etched in 18% HCl prior to aging. Right: Aged indoors at ambient uncontrolled RH. Samples 1, 2, 3, and 7 were coupons of 12-15 μm SnNi on copper or brass; 4, 5, and 6 were printed wiring boards with 5-12 μm SnNi on copper. Not etched. Sample 1, 3 months old; sample 2, 6 months old; sample 3, 8 months old; sample 4, 18 months old; sample 5, 18 months old; sample 6, 72 months old; and sample 7, 120 months old. Probed with a hemispherically ended gold rod. Each point is the median of 9 or more measurements. 95% of all measurements are within the bands, with a maximum value of 15Ω from 500 determinations.

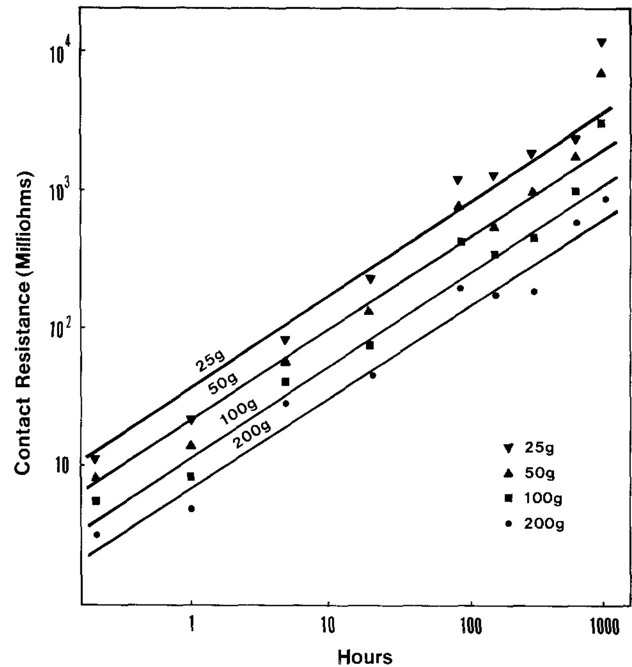

Fig. 2. Typical dependence of contact resistance on load. Etched SnNi aged in air at room temperature and 15% RH. Data at 100g are replotted from Fig. 1.

The sample aged at 0% RH was observed for 7000 hr during which contact resistance slowly increased. Nevertheless, contact resistance was still relatively low, only 0.01-0.1 of the value in humid air.

The different rates of contact resistance change between aging SnNi in water vapor and aging in dry air suggest either that different films formed or that the film at anhydrous conditions grew less quickly. Earlier work (17) in which SnNi had been freed of its air-formed film by sputtering, then exposed to dry oxygen, showed that a different film (believed to be a mixture of anhydrous nickel stannate [$NiSnO_3$] with oxides of tin and nickel) formed and grew more rapidly than the one produced in humid air. Additional experiments are necessary to determine whether the contrasting contact resistance behaviors of the dry air and humid air grown films in the present work are attributable to differences in film thickness or in their mechanical and electrical properties.

Aging in water.—Contact resistance data for the etched sample aged in deionized water are given in Fig. 3, including the range of values at each time interval and the median contact resistances. The contact resistance after about 100 hr of immersion was within the range observed for SnNi aged in humid air, but on longer immersion the median contact resistances attained higher values and the spread was larger than in the air-aged case, with some resistances greater than 1000Ω.

The film on the water-aged sample after 1000 hr was mottled gray, unlike the thin, invisible films on all of the other specimens. It is likely that the film formed in water was heterogeneous as well as different in composition from those obtained on air exposure. Apparently, water can slowly corrode SnNi that does not have its "natural" passive layer.

The rate of contact resistance change depends on the water content of the environment, increasing from dry air, to humid air, to water immersion. These observations, as pointed out earlier, can be explained by assuming that the primary determinant of contact resistance is film thickness and that the rate of growth of films on SnNi is markedly different in these environ-

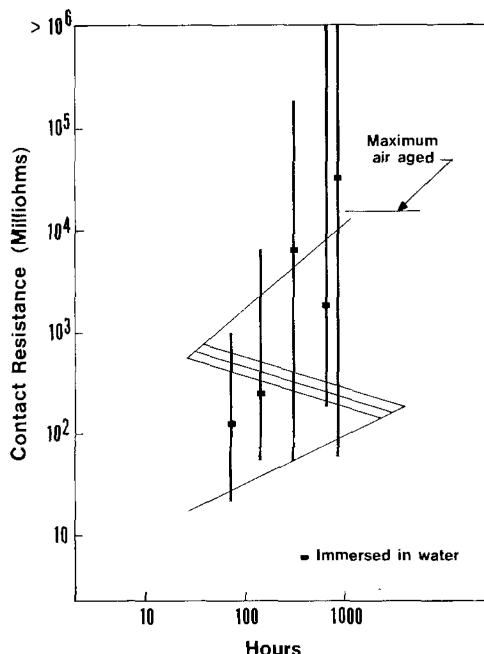

Fig. 3. Median contact resistance of smooth SnNi electrodeposit, 12 μm thick, on copper. Aged in deionized water. Etched in 18% HCl prior to aging. Probed at 100g with a hemispherically ended gold rod. Nine measurements at each time interval. The range of values is indicated by the vertical lines. The band encompasses 95% of all points obtained on air aging from 15-88% RH (see Fig. 1).

ments. Differences in film resistivity, attributable to different film compositions, may be a contributing factor.

Air aging of partially etched tin-nickel.—It was of interest to determine the contact resistance change with time of SnNi having a natural air-formed film which was incompletely removed by brief etching in 18% HCl, sufficient to lower contact resistance partially from its initial value. Figure 4 is a plot of contact resistance on aging at 51 and 88% RH for two specimens having initial (1 hr aged after etching) median contact resistances, respectively, of 240 and 550 mΩ. Contact resistance increases in this case, achieving the same value in approximately 100 hr as that of oxide-free SnNi after several thousand hours.

These observations cannot be explained by assuming that abbreviated etching removed only part of the air-formed film, which then reformed to its initial state on resumption of air aging. It has been found (18) that the initial decrease in contact resistance on brief etching is not accompanied by a change in mass. Perhaps chemical changes of the films were promoted by contact with HCl, which in turn altered its electrical characteristics.

Aging at 100°C.—A sample was etched and then aged at 100°C in the laboratory atmosphere having a RH calculated to be 1-2% at this temperature. Figure 5 shows that the contact resistance dependence closely parallels that for aging at room temperature from 15-88% RH for 1000 hr. Heating was continued for 2200 hr and a median contact resistance greater than 1000Ω was obtained. All values of resistance were greater than 15Ω, the largest value attained by both etched and unetched room temperature aged SnNi (Fig. 1).

These results can be understood by assuming that the kinetics of early growth and the electrical-mechanical characteristics of the film at 100°C are similar to those for the room temperature films, but that it grows thicker on prolonged aging.

Dependence of contact resistance on surface roughness.—Most oxide films have low plasticity and strains sufficient to rupture then on probing can increase the extent of metallic contact of the two surfaces. Film fracture is roughness dependent, demonstrated in studies with various materials (19-22). In the present work, surfaces were very smooth which accentuates the effects of films on contact resistance.

It is useful, however, to illustrate the contact resistance dependence on roughness of SnNi, and Fig. 6 shows this relationship with unetched specimens aged in excess of 50 months having three different roughnesses, polished (less than 0.03), 0.06, and 0.38 μm CLA. At 100g the median contact resistance was 130 mΩ for the rough sample compared to 1000 mΩ for the polished specimen. As suggested earlier (20), rough sur-

faces can probably be designed for base metal contacts which will permit them to be utilized in practical connector applications, probably with nonwiping designs to avoid high sliding friction and wear.

With conventional wiping contacts made of gold on a SnNi underplate, the contribution to contact resistance by SnNi through a worn gold layer can also be expected to depend on surface roughness.

Summary and Conclusions

It is necessary to understand factors which control the contact resistance of metals in order to be able to use them as contact materials. The SnNi system was chosen for study because of its unusual corrosion stability and its acceptance as a material for separable contacts, in most cases with a thin (0.1-1.0 μm) gold overplate. If the gold becomes worn through during use, the SnNi is exposed and its contact resistance characteristics contribute to the behavior of the system. Tin-nickel develops a self-limiting oxide film in air which is responsible for the increase in its contact resistance as well as its passivity.

In this study, it was determined that the contact resistance of SnNi, freed of oxide by etching in HCl, depends on the RH of the air in which it is aged. In dry air at room temperature, contact resistance rises very slowly for 7000 hr or more; in humid air (from 15-88% RH), contact resistance rises more rapidly and achieves a value of 1-10Ω at 100g for polished surfaces against a gold probe in several thousand hours. The contact resistance of unetched SnNi aged in air for up to 10 years likewise is in the range, 1-10Ω. The limiting contact resistance is less with rough surfaces, typically 0.1-0.2Ω with a finish of 0.4 μm CLA. The contact resistance increase of etched SnNi immersed in water or heated in air at 100°C follows the same initial kinetics as in humid air at room temperature, but ultimately attains much higher levels. The contact resistance of SnNi whose natural oxide is incompletely removed by brief etching in HCl is slowly restored to its equilibrium level when re-exposed to air.

Acknowledgments

The cooperation of C. F. Hornig, P. T. Woodberry, Hewlett-Packard Company, Singer Business Machines, Incorporated, and the Tin Research Institute, Incorporated is acknowledged for providing the SnNi samples used in this study. Valuable discussions were had with K. F. Bradford and J. H. Thomas, III. M. Drozdowicz obtained most of the experimental data.

Composition, Chemical Bonding, and Contamination of Low Temperature SiO_xN_y Insulating Films

Gordon Wood Anderson, William A. Schmidt,* and James Comas

Naval Research Laboratory, Washington, D. C. 20375

ABSTRACT

The stoichiometry and contamination of low temperature SiO_xN_y layers grown by the pyrolytic decomposition of silane in an ammonia- and oxygen-rich atmosphere on InSb and Si substrates are reported. The chemical composition and chemical bonding properties of the films have been analyzed by Auger, nuclear reaction analysis, optical, Rutherford backscattering, and SIMS techniques. Capacitors were fabricated on Si and InSb substrates, and the electrical characteristics were measured. The layers exhibited physical characteristics similar to those of thermally grown SiO_2 layers. Analysis of the SiO_xN_y films indicated a uniform distribution of Si and O throughout the films. The N concentration measured in the films ranged from 1 to 3% of the O concentration, depending on the growth parameters. The optical results indicated some evidence of small amounts of Si-N and N-H bonding. All films grown on Si substrates in the presence of InSb or on InSb substrates had In and Sb contamination throughout, with the In and Sb content increasing from the film/substrate interface to the SiO_xN_y surface.

Significant interest currently exists in developing high quality metal-insulator semiconductor (MIS) devices using narrow bandgap semiconductors as substrates, in particular InSb, for utilization in infrared imaging systems (1-6). Typically, the insulating films for MIS capacitors on InSb contain Si, O, and N and are grown at low temperatures (200°-250°C) by the pyrolytic decomposition of silane in the presence of oxygen, nitrogen, and ammonia. Low temperature processing is necessary in the case of InSb because the material is thermally unstable above 400°C (7). The electrical properties of these MIS devices have been studied extensively (1-5), but no efforts have been made to characterize the stoichiometric, chemical, and other physical properties of these low temperature insulating films. It is the purpose of this paper to present the results of a series of spectroscopic studies of these SiO_xN_y insulating films on both InSb and Si substrates, including Auger, nuclear reaction analysis, optical, Rutherford backscattering (RBS), and secondary ion mass spectroscopy (SIMS) techniques. These studies are the first extended effort to characterize the stoichiometric, chemical bonding, and structural properties of these technologically important, low temperature SiO_xN_y films.

Insulator Growth

Processing.—The low temperature (200°-250°C) silicon-oxy-nitride (SiO_xN_y) system for insulator growth is conventional in design and similar to those used by others (1-5). A schematic of the reaction system is shown in Fig. 1. A Matheson gas mixture of 3% silane in nitrogen was used as the silane source. The silane mixture, oxygen, and ammonia used were ultrahigh purity "electronic grade" gases. Boil-off from a liquid nitrogen tank was the source for the nitrogen carrier gas. Flow rates were controlled by manually set needle valves and monitored by mass flowmeters. The silane mixture was further diluted with nitrogen in a mixing manifold prior to being introduced into the reaction chamber. Nitrogen, ammonia, and oxygen were combined in a second mixing manifold before introduction into the chamber.

The reaction chamber was enclosed by a stainless steel base plate and a Pyrex bell jar which was O-ring sealed to the base plate (Fig. 1). Substrates were supported on a rotating (~20 rpm) carbon platen which rested on a resistively heated aluminum block.

* Electrochemical Society Active Member.

Key words: silicon-oxy-nitride films, chemical vapor deposition, film composition and contamination, optical, spectroscopic properties.

Numerous other designs were tried, but this design gave the most reliable service.

InSb samples were prepared for passivation by chem-mechanical polishing on a Pellon cloth pad with a solution of bromine in methanol, etching in a solution consisting of 50 parts lactic acid, 8 parts HNO_3, and 2 parts HF, and briefly dipping in HF. Silicon wafers were used as delivered from the manufacturer after cleaning with organic solvents followed by a short HF dip. Low Na content electronic grade reagents and high resistivity water rinses (18 MΩ-cm) were used. Cleaned, polished samples were loaded onto the carbon platen, and the system was flushed with nitrogen for 30 min. The samples were then heated for 20 min in a nitrogen atmosphere to achieve thermal stability at the growth temperature. The reactive gases then were turned on to initiate growth. After a preselected time, the heat and reactant gases were shut off simultaneously, terminating growth.

The temperature of the stationary heated block was measured with thermocouples mounted directly in the block. Under growth thermal conditions but with no growth reaction taking place, substrate surface temperatures were measured optically and with phase altering indicators. These temperature values were compared with the block thermocouple readout. Because of difficulties in making substrate surface temperature measurements during film growth, this procedure was used to estimate substrate surface tem-

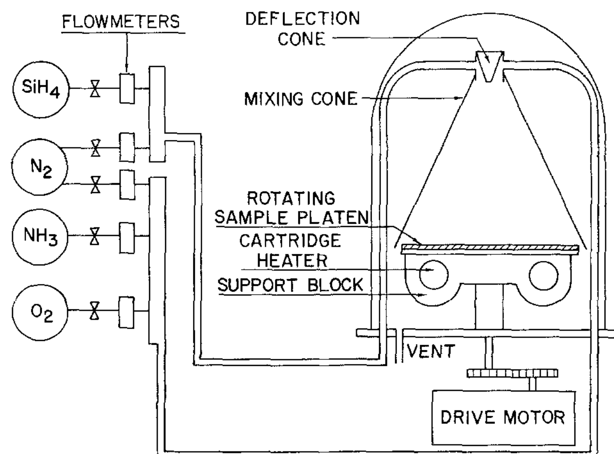

Fig. 1. Schematic illustration of sample preparation system

peratures during growth. This procedure indicated that substrate surface temperatures during growth were 23° ± 4°C lower than the temperature of the stationary block.

Processing variations.—Layer thickness uniformity was such that only one interference color extended over the entire surface of a 38 mm diam Si wafer. Sample thickness, growth rate, rotation rate of the sample holder, and uneven heating were the major factors affecting the thickness, uniformity, and reproducibility of the films. The growth rate decreased with increases in the nitrogen carrier gas flow rate. Variation of other parameters including temperature, ammonia, oxygen, and silane gas flow rates, and rotation rate had less predictable effects on the growth rate because of competing effects. Typical growth conditions were: temperature, 250°C; nitrogen carrier gas and 3% silane in nitrogen introduced into one mixing manifold at flow rates of 1700 and 275 cm^3/min, respectively, and the mixture introduced into the chamber; and nitrogen carrier gas, oxygen, and ammonia introduced into a second mixing manifold at flow rates of 1700, 50, and 50 cm^3/min, respectively, and the second mixture introduced into the chamber separately from the first mixture.

The growth rate using the conditions listed above was about 50 Å/min. Growth rates were insensitive to ±70% variations of the oxygen flow rate. Variations of the remaining parameters about the values listed above caused significant changes in the film characteristics. Increasing or decreasing the silane flow rate resulted in an increase or decrease, respectively, in the film growth rate. With an increase of as little as 25% in the silane flow rate, growth occurred throughout the chamber, and an excessive amount of particulates were formed which caused spots and defects in the films. With an equivalent decrease in the silane flow rate, film growth was effectively stopped.

The variation of the growth rate with the ammonia flow rate was nonlinear (Fig. 2). The growth rate changed from about 160 Å/min at a flow rate of 20 cm^3/min to about 15 Å/min at a flow rate of 130 cm^3/min. While the film growth rate increased sharply at lower flow rates, at flow rates below about 15 cm^3/min the film growth was uncontrollable, and the growth resulted in the formation of whiskers, platelets, and other irregularly shaped structures.

Variation of the substrate temperature also had a significant effect on the growth rate. A 20°C decrease in temperature effectively stopped growth on the substrate, while a similar temperature increase resulted in an increase in the growth rate by a factor of 3-5.

Etching techniques have been developed (8) which permit a comparison of the quality of SiO_2 and SiO_xN_y

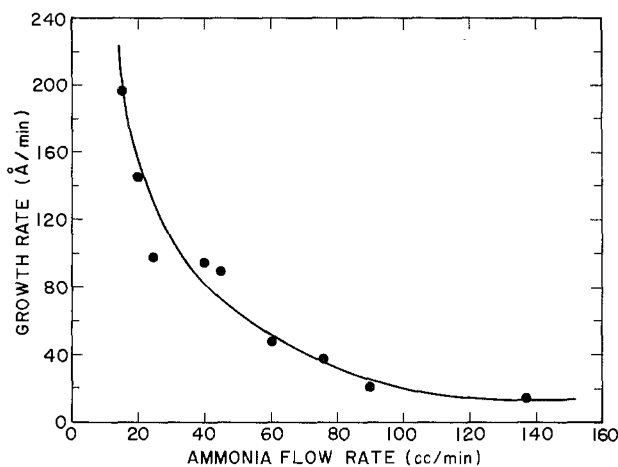

Fig. 2. Relation of film growth rate to ammonia flow rate during film growth for the typical growth conditions listed in the text.

films grown by various processes. The "P" etch used in the work discussed below consisted of 15 parts HF, 10 parts HNO_3, and 300 parts H_2O. Films grown under the conditions listed above had etch rates of 20 Å/sec. This etch rate is similar to that for undensified SiO_2 films grown at 405°C. In comparison, SiO_2 films grown by the thermal oxidation of Si at 1000°C are etched at a rate of 2 Å/sec. There was no significant variation in the etch rates for different SiO_xN_y films etched with "P" etch. Variation of the film growth rate by as much as a factor of 5 by means of ammonia flow rate adjustments did not affect the density of the films as determined by the etching measurements.

No adverse reactions were detected with any of the materials used for substrates. Uniform, insulating films were grown on a range of different substrate materials including quartz, metal wafers, and various elemental, III-V, and II-VI semiconductors. Excellent results were achieved with normal photoresist and etching processes on films used as dielectric isolation layers in devices where low temperature processing was required.

Diagnostic Techniques

Auger.—Auger electron spectroscopy measurements were made to determine the N content of the SiO_xN_y films utilizing a Physical Electronics Industries system. An SiO_2 film implanted to a peak N concentration of 10^{21} ions/cm^3 was used as a standard. The depth distributions in the films were obtained by sputter-etching the samples with a 5 keV Ar ion beam and simultaneously recording the Auger energy spectrum. An Si_3N_4 sample and a dry thermal oxide were also examined for comparison with the N-implanted SiO_2 film and the SiO_xN_y grown films. The limit of sensitivity of the Auger technique is approximately 0.1 atomic percent (a/o)

Nuclear reaction analysis.—Nuclear reaction measurements were made for both N and O in the SiO_xN_y films. A 900 keV deuteron beam from the Naval Research Laboratory (NRL) 5 MV Van de Graaff accelerator was incident on the film, and protons and alpha particles were detected. In the case of N, a $^{14}N(d, \alpha)^{12}C$ reaction was analyzed, and, in the case of O, a $^{16}O(d, p)^{17}O$ reaction was analyzed. The areas under the N and O reaction curves are directly related to the number of atoms in the layer for a given sample. The ratio of these areas for a given sample is directly related to the composition of the film. Comparisons between samples were made on the basis of the values of these ratios. A Si surface barrier detector was used with an 0.059 mm Ni foil placed in front of the detector to absorb elastically scattered deuterons.

Optical.—Optical transmission experiments were made utilizing two spectrophotometers, a Beckman IR-7 and a Perkin-Elmer 521, in the range of 250-4000 cm^{-1} (40.0-2.5 μm). The measurements were double beam measurements, and a beam condenser was used for small samples. Attenuated total reflection (ATR) experiments were made in the same range using the Perkin-Elmer instrument. Ellipsometry measurements were made at 6328Å using a Rudolph 43702-200E ellipsometer. All measurements were made at room temperature.

RBS.—RBS techniques were used to determine the major constituents and to evaluate the thickness of films grown on both Si and InSb substrates. Due to the irregular surfaces on InSb substrates, mechanical and ellipsometry measurements of film thicknesses on these substrates were difficult to obtain. The RBS system employed 2 MeV He ions from the NRL 5 MV Van de Graaff accelerator and a Si solid-state detector. The depth resolution for these films utilizing this technique was ~150-200Å. Reviews of the technique and its usefulness for analysis of insulating films are given elsewhere (9, 10).

SIMS.—Profiles of Si, SiO, SiO_2, Sb, and In were measured by SIMS techniques using a Cameca IMS-300. SIMS experimental techniques and instrumentation details are described elsewhere (11). Due to surface-related effects associated with the SIMS analysis, data from the near surface region (~100Å) were omitted. Depth scales were established from thickness measurements of the SiO_xN_y films. SIMS depth measurements and atomic concentration profiles were reproducible within about 25% for a given sample.

To ensure that the SIMS signal at mass 115 was due to In contamination and not a Si-type complex, the isotopic ratios (113 and 115) of In in the films and substrates were measured. It was established using this approach that the films grown on InSb substrates or in the presence of InSb contained In. The N content in these films could not be determined by the SIMS technique due to competing signals from Si and its complexes. Impurities in SiO_xN_y films grown on Si were determined by mass spectra analyses.

Electrical.—Electrical evaluations of these layers were made by measuring *C-V*, *G-V*, and *I-V* characteristics of MIS test capacitors having chromium-gold gates and back side contacts. Measurements were made using either probes or gold wires bonded to individual pads. Gate areas were 2×10^{-3} cm². All samples with d-c leakage currents greater than about 10^{-13}A at +1V gate bias (~10^5 V/cm) at 80°K were discarded. The discarded samples included approximately 50% of all samples and generally exhibited shorts associated with bonding problems or pin holes. *C-V* and *G-V* measurements for Si substrate capacitors were made at 295°K and 80°K and for InSb substrate capacitors at 80°K. These samples were bonded to transistor headers. To eliminate extraneous lead capacitance and enhance cooling efficiency, the InSb chips were mounted on gold-plated beryllium oxide heat sink pads on headers which in turn were mounted directly to a cold finger. High frequency (1 MHz) *C-V* measurements were made with a Boonton capacitance meter, and lower frequency *C-V* and *G-V* measurements were made using a PAR 129A lock-in amplifier. Leakage current measurements were made using Keithley 602 and 616 electrometers.

Diagnostic Results

Auger.—An estimate of the N concentration in the SiO_xN_y films, based on the comparison of the N Auger signals from the SiO_xN_y films and the reference N-implanted, thermally grown SiO_2 film, gave a value of <5 a/o throughout the layers. The N content estimated from the Auger data was in qualitative agreement with the nuclear reaction results.

Nuclear reaction analysis.—The nuclear reaction results were utilized to give a quantitative measurement of the amount of N incorporated in the insulating films. A portion of the same N-implanted, thermally oxidized Si wafer discussed above was used as a reference. The results are shown in Table I in the next to last column for several films. These films included the reference sample and several SiO_xN_y films grown on both Si and InSb substrates. The major point of these data is that the total amounts of N incorporated in the SiO_xN_y films grown in this study were over a factor of two less than the amount implanted in the reference thermal oxide. If the N implanted in the thermal oxide were of uniform concentration through the oxide, that concentration would be approximately 5% of the O concentration on an atomic basis. Thus, the N concentrations in the SiO_xN_y films were low, about 1 to 2% of the O concentration on an atomic basis.

Optical.—Optical transmission experiments were carried out on a series of samples including thermal oxides grown on Si substrates and SiO_xN_y films grown on both InSb and Si substrates. The transmission spectra of the SiO_xN_y films grown on Si were very similar to those of thermal SiO_2 films grown on Si; the spectra of the SiO_xN_y films on InSb differed from those of the thermal oxides on Si primarily in the effects of the different substrates on these spectra. The results for two typical SiO_xN_y films, one deposited on a Si substrate and the other on an InSb substrate, are shown in Fig. 3, and results for all spectra are

briefly summarized in Table II. The four major bands observed in bulk SiO_2 glass and thermally grown films on Si were observed in the SiO_xN_y films as well (8, 12-17). The broad shoulder on the high energy side of the major 1080 cm^{-1} band at about 1160 cm^{-1} was not as pronounced in the spectra of films on InSb because of the onset of the fundamental absorption edge (Fig. 3).

The very broad 930 cm^{-1} band observed in the SiO_xN_y films was at the energy at which bands have been observed in some bulk SiO_2 glasses and thermal oxide films and may be a SiO_2 band (14, 15, 17). In addition, the weak 560 cm^{-1} shoulder was observed in the SiO_xN_y films on Si but not clearly observed in films on InSb. This band very likely was the Si LO + TA combination band (18), though a weak band at this energy also has been observed in some bulk SiO_2 glasses (14, 15). The weak band near 3500 cm^{-1} was observed in the SiO_xN_y films on Si substrates but not in the thermal oxides.

ATR spectra of SiO_xN_y films grown on Si exhibited several bands in the range 1300-4000 cm^{-1} (Fig. 4 and Table II). Only the bands at 3255 and 3600 cm^{-1} may be related to N in the films. Four of the eight other bands previously have been assigned to SiO_2, Si-H, or SiH . . . O type bonding as indicated in Table II (19-23). The unreported and/or unidentified bands are described briefly below.

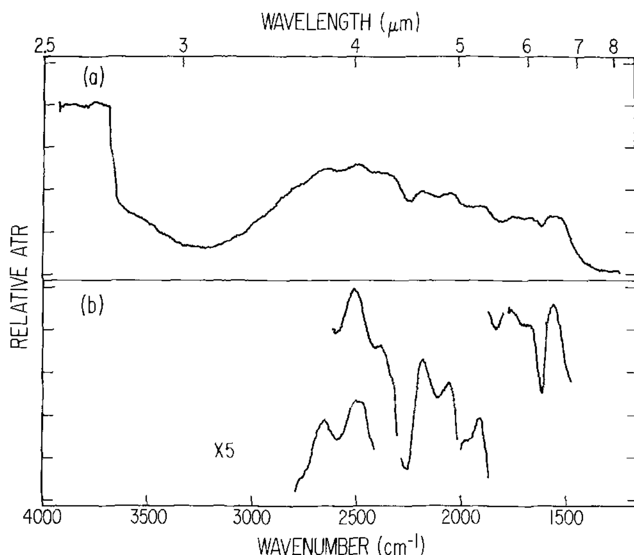

Fig. 4. Typical ATR spectra of SiO_xN_y films on Si. (a) Relative ATR spectra. (b) Scale expansion factor ×5. Vertical position of each section in (b) is relative to itself. Vertical position of different sections in (b) cannot be compared quantitatively. Room temperature measurements.

The very weak and previously unreported band at 1700 cm^{-1}, if real, is thought to be a SiO_2 band. The 1830 cm^{-1} band is shifted to a position lower in energy than that observed in thermal SiO_2 probably due to the different composition and stoichiometry of the two types of films (19). The 2115 and 2415 cm^{-1} bands appear to be satellites of the main 2260 cm^{-1} Si-H band (20-23) and are thought to be Si-H or SiH . . . O type bands, the 2415 cm^{-1} band being slightly removed in energy from the position of the atmospheric CO_2 band. The origin of the 2590 cm^{-1} band is not known.

Values of the thickness and real part, n, of the index of refraction of films on Si substrates determined by ellipsometry at 6328A are given in Table I. It was assumed that the value of the imaginary part of the index of refraction of the films was zero in calculating these results from the ellipsometry data.

RBS.—The RBS spectra for SiO_xN_y films on Si substrates were very similar to those of thermal oxides on Si substrates. In addition, the absence of a resolvable N peak in the RBS data in films on Si substrates demonstrated that the N content of the films was very low (less than 5% of the O content atomically).

The film thickness values obtained from RBS, mechanical (Dektak), and ellipsometry techniques are presented in Table I. It should be noted that the RBS measurements are presented as qualitative comparisons of the films, and it was assumed for the thickness analyses that the films were of uniform and equal density, an assumption substantiated by the chemical etch rates of films on Si substrates. The unimplanted SiO_2 thermal oxide film was used as a reference to estimate the film thicknesses from the RBS data in order to compare these values with the mechanical (Dektak) and ellipsometry measurements. In the cases of films grown on InSb substrates, corrections for dE/dx of the He ions were made to determine the thicknesses from the energy shifts of the edge of the onset of scattering as shown in columns 3 and 4 of Table I. These energy shifts were with reference to the position of the edge for a clean InSb substrate with no film on its surface.

The RBS data include results obtained from three pairs of samples, one substrate being Si and one InSb for each pair. The films were grown simultaneously on the two substrates of each pair. These RBS results indicated that for films grown simultaneously on InSb and Si substrates, the films on InSb substrates contained more mass as shown in column 3 of Table I.

SIMS.—The SIMS data obtained from an SiO_xN_y film are shown in Fig. 5. The results indicate a uniform distribution of Si and O throughout the SiO_xN_y film. Films grown on InSb also had uniform distributions of Si and O throughout. In addition, the SIMS Si:SiO:SiO_2 ion sputtering yield ratios for individual

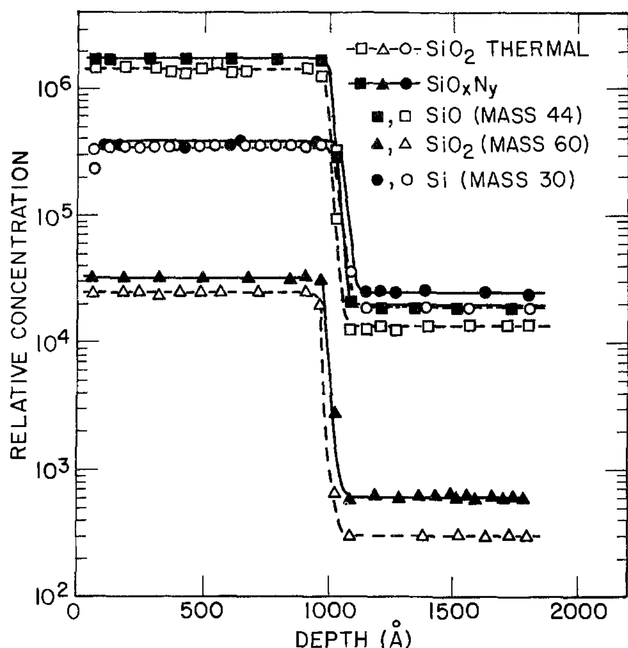

Fig. 5. Relative concentrations of SiO (■, □)-atomic mass 44, SiO_2 (▲, △)-atomic mass 60, and Si (●, ○)-atomic mass 30 in SiO_xN_y (closed data points) and thermal SiO_2 (open data points) films on Si substrates determined by SIMS. Steps at about 1000Å depth represent insulator-substrate interfaces. Samples grown at same times and in same chambers with sample 1 NRL and thermal SiO_2 standard (unimplanted).

SiO_xN_y films on Si substrates and for individual thermal SiO_2 films were similar (Fig. 5). These ratios were also within 25% or better of the ratios of yields of films grown on InSb substrates. Thus, the stoichiometry of SiO_xN_y films grown on both InSb and Si substrates and of thermal SiO_2 films was similar. The Si, SiO, and SiO_2 signals decreased beyond the film/substrate interface due to the decrease in the secondary ion yields in Si as compared to those in SiO_xN_y and SiO_2 (Fig. 5).

The atomic profiles of In in SiO_xN_y films grown simultaneously on Si and InSb substrates are shown in Fig. 6. Films grown on InSb substrates had a significantly higher In content than films grown simultaneously on Si substrates. Films subsequently grown on Si substrates in the absence of InSb showed

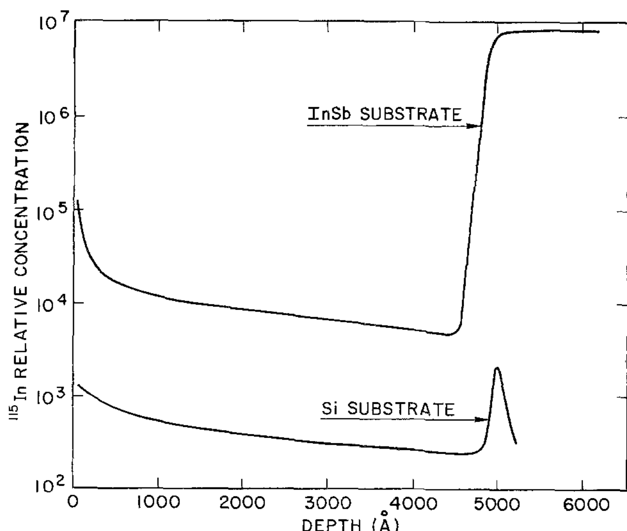

Fig. 6. Relative concentrations of In in SiO_xN_y films grown simultaneously on Si and InSb substrates. Steps at about 5000Å represent insulator-substrate interfaces. Growth conditions similar to those of samples 5 NRL and 6 NRL.

significantly less In content. An estimate of the ^{115}In concentration in the SiO_xN_y films grown on InSb substrates was approximately 10^{16}-10^{17} cm^{-3}. This estimate was based on a comparison between the SIMS ^{115}In signals from a ^{115}In implanted reference sample and from the SiO_xN_y films. To investigate the possibility of decomposition of InSb from the back surface during film growth, several samples were coated on the back surface with sputter-deposited Si_3N_4 prior to being placed in the reactor which had been cleaned and flushed. The SIMS analysis of the films grown in this manner indicated a significant decrease in the In and Sb content. Antimony was also detected and showed the same general behavior as In, although the concentration levels were not determined.

Mass spectra analyses of two classes of samples were carried out to determine the relative Na concentrations in the two classes. One class, samples of which were rejected for further measurements because of anomalously broad hysteresis loops (7-15V) in their C-V curves, had at least three orders of magnitude more Na content than the second class, samples which were retained for further electrical measurements. The Na concentration as a function of depth in the films could not be determined due to the high mobility of Na in insulating films subjected to ion bombardment (24). All films analyzed contained traces of hydrocarbons, K, and Ca.

Electrical.—The dielectric constant determined by correlating the measured values of gate oxide capacitance, insulator thickness, and gate area for given MIS capacitors was typically about 3.3 for the low temperature SiO_xN_y films. Though the measured values were in a range 2.2-4.6, increased with film thickness, and varied from film to film, they generally were less than 3.9, the dielectric constant of thermally grown SiO_2. These measured values are believed to be correct within about 20%. In addition, the dielectric constant values of the low temperature SiO_xN_y films were consistently less than the range 4-9 reported for higher temperature SiO_xN_y films with various x/y ratios (12, 13).

The *C-V* curves for capacitors on Si and InSb substrates showed that the flatband voltage values typically were -1 to -2V [Fig. 7(a) and (b)]. Hysteresis was observed for about 95% of the samples measured, and hysteresis of both clockwise and counterclockwise sense was observed. An example of a *C-V* curve with essentially no hysteresis is shown [Fig. 7(c)]. The flatband voltage could be varied by applying a negative bias voltage at room temperature and cooling the samples to 80°K under bias. Flatband voltage shifts as large as +5V have been observed when samples were cooled under negative bias voltage, and this process was reversible.

Discussion

The results of the experiments indicate that the low temperature SiO_xN_y films were very much like thermal SiO_2 films but with a very small N concentration, about 1-2% of the O concentration on an atomic basis. The spectroscopic results for samples prepared in this study and for industrial samples (2, 3) were very similar for each technique employed. The value of the real part of the index of refraction of the SiO_xN_y films was the same as that of dry, thermal SiO_2 films. This value was not intermediate between that of SiO_2 and that of Si_3N_4 as in the case of higher temperature SiO_xN_y films which contain significant amounts of nitrogen (25).

The optical results also demonstrated that there was very little N present in the low temperature SiO_xN_y films. The major 1080 cm^{-1} band did not shift to lower energy for these films, as observed for higher temperature SiO_xN_y films (12, 13), indicating little or no evidence of Si-N bonding. The Si-N band reported at ~ 475-500 cm^{-1} was not observed with certainty in the present work (22, 26).

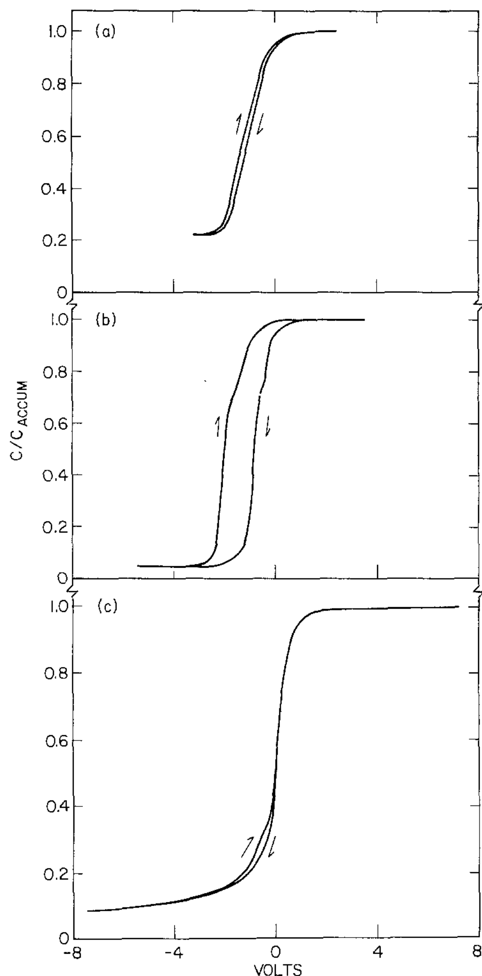

Fig. 7. One MHz C-V curves for three MIS capacitors having SiO_xN_y insulating films. (a) InSb substrate measured at low temperature. (b) Si substrate measured at room temperature. (c) Si substrate measured at 80°K. About 5% of capacitors tested exhibited essentially no hysteresis as shown in (c).

The weak band observed at about 880 cm^{-1} may be due to Si-N type vibrations. The sharpness of this band in comparison to those observed at this energy in other studies of SiO_xN_y films deposited at higher temperatures and of Si_3N_4 (12, 13, 22, 26), however, casts some doubt on this identification.

The 3255 and 3600 cm^{-1} ATR bands and the 3500 cm^{-1} transmission band, which probably is the same as the 3600 cm^{-1} ATR band, may be either N-H type or O-H type vibrational bands as reported for thermal oxides, Si_3N_4 films, and higher temperature SiO_xN_y films (20-23). It is reasonable to postulate that the 3600 cm^{-1} band may be an O-H type vibrational band and the 3255 cm^{-1} band an N-H type band (20-23). The N-H band reported (22, 23) at about 1200 cm^{-1}, if present in these films, was obscured by the strong SiO_2 type bands at 1080 and 1160 cm^{-1}.

The optical evidence for little N bonding and the close similarity of the spectra to those of thermal SiO_2 films are consistent with the general observation that little N is present in these low temperature films and that the films are like SiO_2 in many observable respects. Thus, the role of the ammonia in the film growth reaction is not clear. The presence of the ammonia in the reaction chamber was necessary, however, or uniform and controllable film growth would not occur. The growth rate variations indicate that the primary role of the ammonia may be that of a modifying agent in retarding the low-temperature pyrolytic decomposition rate of the silane in the presence of oxygen (Fig. 2).

The SIMS results (Fig. 5) also demonstrated that the low temperature SiO_xN_y films are uniform in composition and similar to thermal SiO_2 films. Because the concentrations of In and Sb impurities detected in films grown on InSb substrates or on Si substrates in the presence of an InSb substrate increased with distance away from the semiconductor-insulator interface (Fig. 6) and because significantly less contamination was present in films grown on InSb substrates having the back sides coated with Si_3N_4 prior to film growth, it is believed that this contamination resulted from the decomposition of InSb at the back surface of the InSb substrates.

The hysteresis observed in many C-V measurements could have been due to one or more of several causes (27-32), and hysteresis of both cyclic senses was observed in different samples. At present it is not possible to identify which one or more of these potential causes were responsible for the hysteresis.

The thickness values of films on Si substrates as determined mechanically, by RBS, and by ellipsometry were in agreement within 13.5% or better (Table I). The RBS data, however, indicated that the SiO_xN_y films on InSb substrates had more mass and thus were thicker or denser or both than the corresponding films deposited simultaneously on Si substrates. This observation is not understood at present. The etching rate values described in the processing section indicated, in addition, that the SiO_xN_y films were less dense than dry, thermal SiO_2 films grown on Si substrates, and the measured dielectric constant values were consistent with this observation.

Thus, it has been demonstrated that low temperature SiO_xN_y films successfully grown on InSb and Si substrates are uniform in composition, are very much like thermal SiO_2 films grown on Si substrates, and contain only small amounts of N. The SiO_xN_y films, moreover, show significant promise for use in electronic devices.

On Thermally Stimulated Space-Charge Decay in Sn^{2+}-doped Sodium Chloride and Potassium Chloride Crystals

Ah Mee Hor*,[1] and P. W. M. Jacobs

Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7, Canada

ABSTRACT

When quenched crystals of NaCl:Sn^{2+} or KCl:Sn^{2+} are warmed at a constant rate and the voltage appearing across platinum electrodes in contact with the crystal is monitored, as in a thermal depolarization experiment, large d-c currents are measured even when the crystals have not previously been polarized. This charge release is believed to be associated with the crystallization of precipitates of $SnCl_2$ within the crystal. The appearance of depolarization currents of the "wrong" sign during heating of previously polarized crystals is commented upon briefly.

The purpose of this brief paper is to report on the strange behavior of quenched NaCl:Sn^{2+} and KCl:Sn^{2+} crystals during thermal depolarization. RbBr:Sn^{2+} crystals (1) behave "normally," that is to say, whereas untreated crystals or crystals annealed at 250°C for 20 hr display no depolarization currents, crystals annealed at 500°C for 4 hr and then at 400°C for 13 hr prior to quenching in liquid nitrogen, exhibit after polarization and warming at a steady rate of 4°K/min a characteristic double peak in the temperature range 182°-212°K. If the polarization temperature T_p is low enough (215°K) this is the only peak observed. With higher polarization temperatures a more-or-less complicated series of depolarization bands are observed on the high temperature side of the 182°-212°K double peak. The structure of these bands depends on T_p and hence on the polarization current. The bands have tentatively been assigned to the release of macroscopic space charge associated with electrode processes occurring during polarization. The double peak is ascribed to the occurrence of Sn^{2+}-cation vacancy complexes. Broadly similar behavior occurs in RbBr:Ba^{2+} (1), RbCl:Sr^{2+} (2), and in many other doped alkali halides.

The behavior of NaCl:Sn^{2+} and KCl:Sn^{2+} is quite different and includes a feature we believe not to have been previously reported. An unpolarized NaCl:Sn^{2+} crystal which had not received any thermal pretreatment showed zero "depolarization" current j on warming from 100°K to room temperature. j was similarly negligible if this crystal was subjected to a polarization voltage of 200V at 255°K. The same behavior was observed after annealing for 16 hr at 360°K but if T_p was increased to 295°K a sharp inverted peak occurred at 255°K (Fig. 1).

During polarization the top platinum lead was connected to the input of a Cary 401 electrometer and the lower platinum electrode resting on the sapphire insulator was connected to the + terminal of a Hewlett Packard 6100 A d-c voltage supply (see Fig. 2). During depolarization the top electrode remained connected to the input of the electrometer and the bottom electrode was grounded. Both surfaces of the crystal in contact with leads were coated with silver paint to en-

Key words: thermal depolarization, ionic thermoconductivity, doped alkali halides.

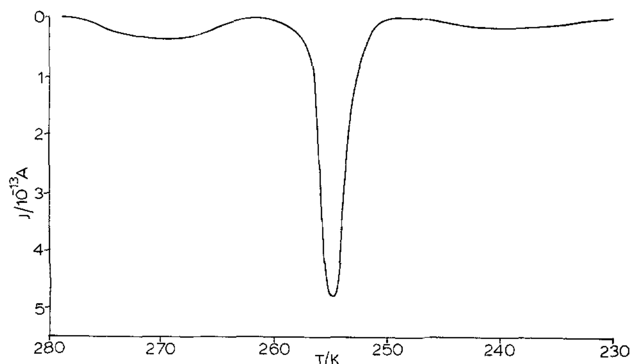

Fig. 1. Large "inverted" peak in the $j(T)$ depolarization curve for a NaCl:Sn^{2+} crystal that had been polarized at 295°K. Two broad smaller peaks are also found at 239° and 269°K, respectively.

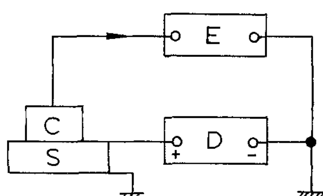
(a) During polarization



(b) During depolarization

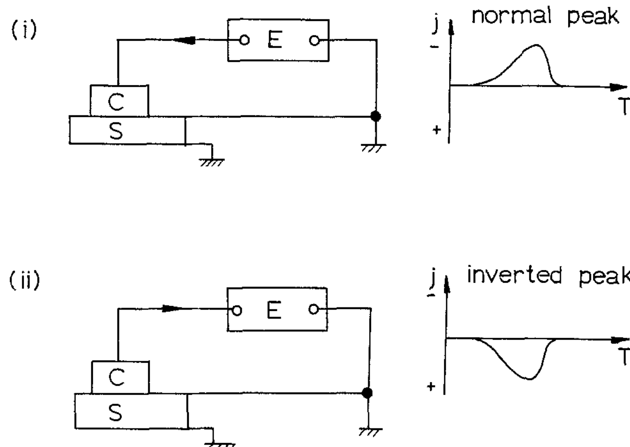


Fig. 2. Schematic circuit diagrams for (a) polarization; and (b) depolarization measurements. C = crystal; E = electrometer; D = d-c power supply; S = sapphire insulator. Arrows show direction of flow of positive current through the external circuit. In (b):(i) the direction of current flow is as expected, and obtained, for randomization of dipoles and the depolarization current peak is referred to as "normal"; (ii) For "inverted" peaks the electrometer records a positive voltage instead of a negative one, *i.e.*, the current flow through the external circuit is in the same direction as that during polarization. The terms "normal" and "inverted" have their same significance even when the polarization voltage $V_p = 0$.

sure good electrical contact with the platinum leads. During depolarization both sides of the sapphire insulator were grounded. One anticipates, and normally measures, a negative voltage with the electrometer due to the reorientation of dipoles aligned preferentially in the d-c field during polarization. An "inverted peak" means that the polarity of the voltage across the crystal was positive instead of negative. Inverted peaks have been observed previously during thermally stimulated depolarization measurements and have generally been ascribed, rather loosely, to precipitates or space charge. However, a space charge consisting of carriers that have piled up in front of one or both of the electrodes should, as it decays, yield a "normal" depolarization current in the opposite direction to that flowing during polarization. In alkali halides at or below room temperature and particularly in these Sn^{2+}-doped crystals we anticipate an excess of cation vacancies and that an excess of vacancies will have accumulated adjacent to the (lower) positive electrode during polarization. The migration of these vacancies to restore the equilibrium distribution should give a normal (negative) depolarization peak.

However, the above facile explanation of a space charge peak overlooks the possibility that the potential distribution in the crystal may be more complicated than just described. In unpolarized crystals the potential is not uniform due to the Frenkel (3) space charge. If the polarized crystal contains specifically adsorbed carriers plus diffuse double layers of neutralizing charge, then the perturbation of these double layers by the polarizing field could result in a nonequilibrium charge distribution whose relaxation would give a current flow in the opposite direction to that associated with the randomization of dipoles. Specific detailed models of the decay of macroscopic space charge during thermal depolarization in ionic crystals, including the occurrence of inverted peaks, have not yet been developed although the existence and importance of the macroscopic space charge has been pointed out, for example, by Kessler (4). Possibly, double layers at precipitates, as well as at surfaces and dislocations, contribute to the space charge.

A second NaCl:Sn^{2+} crystal was annealed for 31 hr at 400°C, quenched in liquid nitrogen, and then allowed to warm to room temperature before mounting in the polarization cell. The crystal was shorted at room temperature, cooled to ~100°K, and then warmed at a constant rate of 4°K/min. No polarizing voltage had been applied, yet substantial inverted peaks were observed in the 205°-250°K range. The cooling and warming sequence was repeated twice without any application of a voltage to the crystal. No depolarization was observed on cooling but on each warming cycle a small inverted peak followed by large "normal" peaks were observed. Figure 3 shows that this behavior is qualitatively reproducible in the same crystal. The maximum currents are large: 1.5 and 2.3 $\times$ 10^{-12}A, respectively, and are much larger than would normally be observed in the thermally activated randomization of M^{2+}-cation vacancy dipoles, for instance (~3 $\times$ 10^{-14}A).

A possible explanation of this phenomenon is that during cooling of the crystal from room temperature to 100°K, Sn^{2+}-cation vacancy dipoles aggregate but maintain the NaCl structure. On warming recrystallization to $SnCl_2$ precipitates takes place with ejection

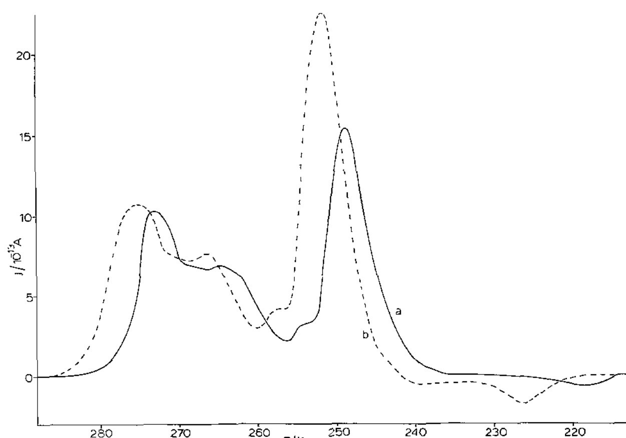

Fig. 3. Large "depolarization" currents observed on warming a previously annealed and quenched NaCl:Sn^{2+} crystal from ~ 100°K to room temperature. (a) Second warming cycle; (b) third warming cycle. No polarizing field has been applied to this crystal.

of cation vacancies. The concentration of cation vacancies now locally exceeds the equilibrium value and is reduced by the diffusion of vacancies to sinks (dislocations). The net displacement current is the vectorial sum of all the microscopic current flows. It would be entirely fortuitous if this sum were zero. Clearly it might have either sign depending upon the actual dislocation structure of the crystal. This tentative explanation requires an unusually high mobility for Sn^{2+} ions in NaCl, which we know to be so because of the relative rapidity with which precipitation occurs in freshly quenched crystals of NaCl: Sn^{2+} compared to, say, RbBr: Sn^{2+}.

Broadly similar behavior was observed for KCl: Sn^{2+}. Figure 4 shows the TD curve on warming a crystal that had been quenched in liquid nitrogen after 2 hr at 550°C, allowed to warm to room temperature, and then cooled to ~100°K in the polarization cell without any application of a polarization voltage. There was no current flow during cooling but in the heating cycle strong inverted peaks occurred in the range 230°-280°K. The crystal was then polarized at 215°K (V_p = 300V) when it showed a qualitatively similar charge release on the warming cycle. This implies either that this charge release has little to do with the attempt to polarize the crystal or that the crystal was

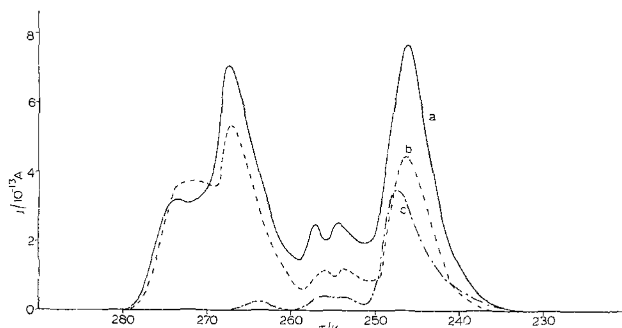

Fig. 4. Depolarization currents observed on warming a previously annealed and quenched KCl: Sn^{2+} crystal from ~ 100°K to room temperature. (a) First run V_p = 0V; (b) second run, V_p = 300V, T_p = 215°K; (c) third run, after annealing for 3 hr at 313°K, V_p = 0V (× 3.33).

somehow self-polarized prior to the first run. It is known (5) that freshly cleaved ionic crystals may contain nonuniform charge distributions but the resulting voltage across the crystal is of the order of magnitude of hundreds of millivolts rather than hundreds of volts. Thus self-polarization seems to be unlikely. This crystal was then annealed at 310°K for 3 hr, cooled to ~100°K without further polarization, and warmed at a constant rate. There was no charge release during cooling but in the warming cycle a small (j_{max} ~ 10^{-13}A) inverted peak occurred in the same temperature region as the large peak in the previous run. This behavior is of a similar nature to that observed for NaCl: Sn^{2+} and the explanation is probably similar.

It seems likely that related effects to those discussed here may have been observed by other research workers in the field but not pursued because of their complexity and irreproducibility. Indeed, the high temperature side of the dipole relaxation peaks has been referred to in the literature (2) as "dielectric chaos." We trust that these modest beginnings may encourage the more detailed investigation of a region of the dielectric behavior of ionic crystals that is important in aiding our knowledge and understanding of dipole aggregation, precipitation, and electrode processes.

Gate Oxide Thinning at the Isolation Oxide Wall

T. T. Sheng and R. B. Marcus

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Transmission electron micrographs of cross sections of MOS devices have shown thinning of the gate oxide at the isolation oxide wall. It is shown that the thinning is related to the slope of that wall which is in turn affected by the time of overetch in BHF during window photolithography. A 7 min overetch produces a thinning of ~25% and cases of 30% thinning have been found in device samples. The thinning is caused by the wall acting as a partial barrier to local oxidation at that site.

During the transmission electron microscope study of cross sections of MOS test devices, it was noticed that gate oxides were sometimes thinned by 20-30% in regions very close to the field oxide wall. Some experiments were carried out to help understand the origin (and control) of this anomalous thinning, and results are reported in this paper.

Key words: MOS devices, gate oxides, oxide wall.

Experimental

The main method used to study the profile of gate oxides was to prepare thin film sections orthogonal to the isolation oxide wall and sample surface, and study these samples by transmission electron microscopy (TEM). A number of authors have described cross-sectional techniques for preparing simple (*e.g.*, non-device) semiconductor structures for TEM study (1-3).

Table II. Processing of tester samples

1. Clean
2. Oxidize 1050°C wet O_2 10,000Å
3. Window photolithography
4. 7 min BHF, Resist strip | 14 min BHF, Resist strip
5. Oxidize 1000°C dry O_2 500Å | Oxidize 1000°C dry O_2 1500Å

Sheng and Chang (3) described a method for sectioning device samples where particular device features need to be examined; their technique was used to prepare samples for the present study. Samples were either CMOS device structures or structures specifically prepared for this study. All samples were (100) orientation and contained ~1μ field oxide formed by wet oxidation at 1050°C and 500-1500Å gate oxide formed by dry oxidation at 1000°-1100°C. The samples are listed in Table I.

The structures specifically prepared for this study were designed to test the effects of variations in window wall geometry on the occurrence of anomalous thinning. They were formed according to the processing scheme shown in Table II. 7 min BHF was needed to clear windows down to the Si substrate; some wafers received a 14 min etch to produce a change in slope of the side wall (see below). Gate oxides were grown to 500 and 1500Å thicknesses to test the effect of gate oxide thickness on anomalous thinning.

Results

Representative transmission electron micrographs of cross sections are shown in Fig. 1 and 2. The electron beam is normal to a (110) surface. The angle formed between the isolation oxide wall and the horizontal surface at the base of the wall are shown in the figures. This angle changes only slightly before and after gate oxidation (compare Fig. 1a with 1c and Fig. 2a with 2c). The relationship between wall angle and percent gate oxide thinning obtained from these measurements is shown in Fig. 3. It can be seen that ~25% thinning occurs on samples which have been 100% overetched (samples J, K) whereas samples which received no overetch (samples G, H) show very little or no thinning. Of the five device samples examined, two (C and D) show 20% gate oxide thinning; these samples probably received a severe overetch in BHF. The percentage oxide thinning is not correlated with gate thickness over the range 500-1500Å (compare J with K and G with H).

The gate oxide thinning is apparently due to the geometrical effect of the isolation oxide wall acting as

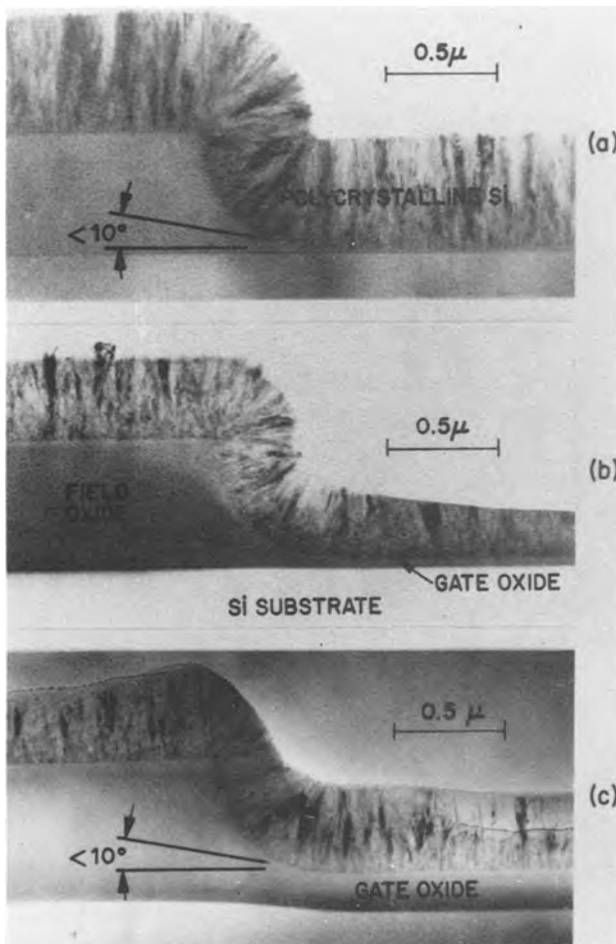

Fig. 1. TEM photos of cross sections of tester samples with 7 min BHF. Sample F, no gate oxide (a); sample G, 500Å SiO_2 (b); sample H, 1500Å SiO_2 (c).

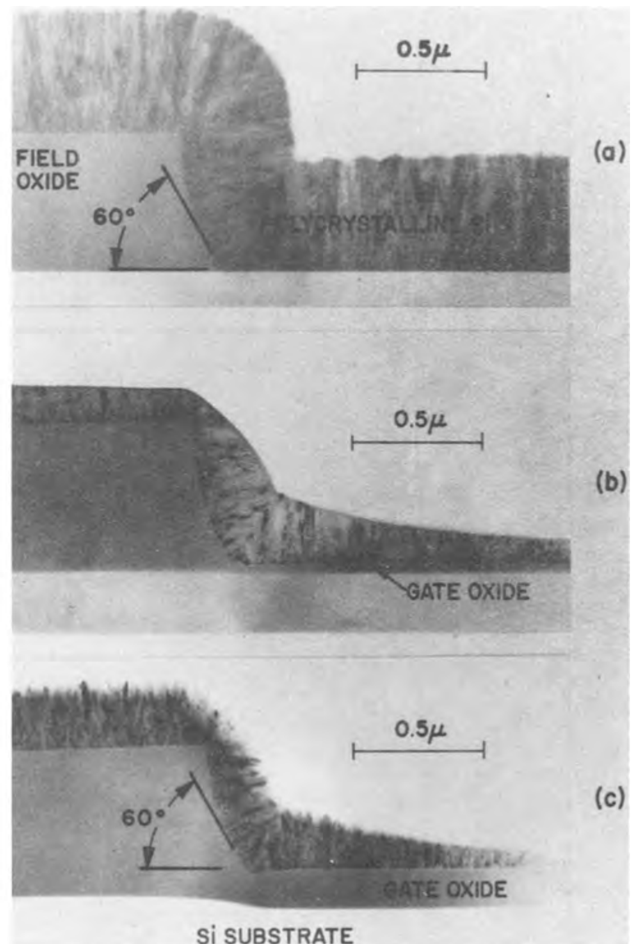

Fig. 2. TEM photos of cross sections of tester samples with 14 min BHF. Sample I, no gate oxide (a), sample J, 500Å SiO_2 (b); sample K, 1500Å SiO_2 (c).

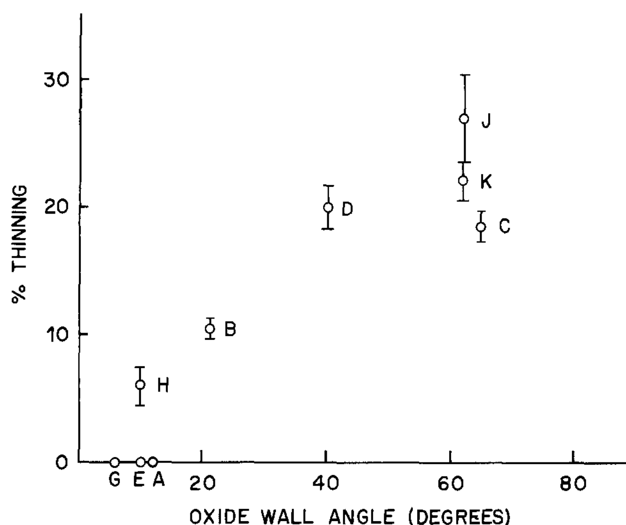

Fig. 3. Relation between angle at base of isolation oxide wall and gate oxide thinning.

a partial barrier which limits the oxidation rate in that local region. This mechanism is now being mathematically modeled. It is clear that as long as oxide thickness and oxide etch rate nonuniformities occur among the wafers in a lot undergoing processing and overetch is required, gate oxide thinning will occur. Assuming a linear relation between time of overetch, isolation oxide wall slope, and gate oxide thinning (Fig. 3), it would appear that $\lesssim$ 10% thinning would occur if the overetch time of thermal oxide in BHF could be kept less than 2 min (~30% overetch). Tighter requirements would occur for faster etching oxides.

Thermally Stimulated Depolarization Studies of PVC Polymer Electrets

I. M. Talwar and D. L. Sharma

Department of Physics, Punjab Agricultural University, Ludhiana-141004, India

ABSTRACT

Thermally stimulated depolarization (TSD) of polyvinyl chloride thermoelectrets prepared at polarizing temperatures of 80°, 100°, and 120°C with field strengths 10, 12.5, and 15 kV/cm has been studied. A very sharp peak appears at 97°C. The activation energy associated with the trap at a depth of a 0.44 ± 0.03 eV has been calculated by the initial rise method. The characteristics of the TSD spectra are in agreement with the theory and are explained on the basis of theoretical predictions.

The thermally stimulated depolarization (TSD) of polar dielectrics usually shows several bands or peaks, indicating thereby that the depolarization of thermoelectrets is realized by several different processes. Two of these processes that are well known are the relaxation of aligned impurity-point defect complexes (1) and the relaxation of a space charge caused by mobile defects accumulated at the electrodes (2, 3). But there are still unidentified processes which cause TSD peaks (1, 4), and one of the fundamental aims of TSD studies is to establish a correspondance between the observed peaks and the specific polarization processes.

Polyvinyl chloride (PVC) has been selected as a typical example to study the conduction mechanism in polymers. The electret behavior (5, 6) and isothermal electrical conductivity (7) of this polymer have already been reported. The present communication deals with nonisothermal thermally stimulated conductivity of PVC thermoelectrets.

Theory

TSD studies are generally carried out by heating a polarized sample of thickness d and area of cross section a to measure the depolarization current $I_d(t, T)$. The measured current density $i_d(t, T) = I_d(t, T)/a$ is equal to the sum of the charge transport rate density $e \cdot j(x, t)$ and the displacement current density $dD(x, t)/dt$ at any arbitrary cross section of the sample. The current measurement is generally carried out by a sensitive current-measuring device keeping no bias voltage, *i.e.*

$$V = \int_0^d E(x, t)\, dx = 0 \quad [1]$$

and without any charge transfer to the electrodes, so that

$$j(0, t) = j(d, t) = \text{zero} \quad [2]$$

Consequently, the measured current density is simply the displacement current density due to the redistribution of charges inside the sample

$$i_d(t, T) = \frac{dD(x, t)}{dt} \quad [3]$$

Of various different mechanisms of polarization only the following two are important: the polarization due to an accumulation and/or depletion of mobile defects (8) and the depolarization due to the orientation of dipoles. Both of these processes are heat dependent. The rate of depolarization current i_d for such processes is expected to be proportional to some charac-

Key words: thermally stimulated depolarization, thermoelectret, activation energy, trap depth, initial rise method.

teristic rate constant $K(T) = K_0 \exp(-U/kT)$ with a pertinent activation energy U, and to some driving force $F(t)$ (9), *i.e.*

$$i_d \propto K(T)\ F(t) \quad [4]$$

where temperature T is a function of time t, *i.e.*, $T = \phi(t)$.

These conditions satisfy the requisites of Bucci's dipolar theory. If the instantaneous polarization of the sample is P, the decay rate can be expressed as

$$P = P_0 \exp\left(-\int_0^t \frac{dt}{\tau}\right) \quad [5]$$

where τ is the relaxation time and depends on temperature and hence time. If the initial polarization P_0 is due to electric field E_p and temperature T_p, then for freely rotating dipoles

$$P_0 = \frac{N\,b^2\,E_p}{3\,k\,T_p} \quad [6]$$

where N is the dipole volume density and b the dipole moment of the dielectric. The current density is due to redistribution of charges and dipoles. For dipolar solids, such as PVC, the relaxation of polar side group is given by

$$\tau = \tau_0 \exp(U/kT) \quad [7]$$

where τ_0 is a constant. When the dielectric is heated at a linear rate the depolarization current density is given by

$$i_d(T) = \frac{N\,b^2\,E_p}{3k\,T_pT_0} \mathrm{Exp} \left| -\frac{U}{kT} - \frac{1}{\beta\,\tau_0}\int_{T_0}^{T} \exp(-U/kT)\,dT \right| \quad [8]$$

Discharge current from the release of charge carriers from traps has the similar expressions, except for the preexponential factor.

The temperature (T_m) at which maximum current (i_m) occurs can be obtained by differentiating Eq. [8] with respect to T and putting $d\ i_d/dT = 0$. This gives

$$\tau_0 = k\,T_m^2/\beta U \exp(U/kT_m) \quad [9]$$

where β is the heating rate. According to the initial rise method (10), the low temperature tail of i_d can be written as

$$\ln i_d(t) = \text{const.} - U/kT \quad [10]$$

Experimental

The electret material (polyvinyl chloride) used in the present investigation was in the form of a sheet 0.092 cm thick procured from M/S Bhor Industries, Bombay. In addition to containing PVC resin the material had certain copolymers, stabilizers, plasticizers, lubricants etc., which certainly affect the dielectric properties. The glass-transition temperature T_g of PVC is reported to be 80°C, however T_g is drastically affected by the plasticizers, etc. The material does not melt, however; its softening range was 90°-100°C (5) and it gets roasted above 140°C. After 120°C thermal decomposition of the material may possibly set in, as evidenced by disproportionately large current, so only three temperatures 80°C (T_g), 100°C (softening-range temperature), and 120°C (above softening range) were selected. The specimen used was 1 × 1 cm² and was fitted tightly in a 1 × 1 cm² cavity in a 6 × 4 × 0.9 cm³ mica holder. Copper foil was used for electrodes. Two electrodes 1 × 1 cm² were placed one each above and below the specimen. In order to have an ohmic contact, as far as possible between the dielectric and the electrodes they were sandwiched between two glass slabs. The glass slabs were further held between four iron strips and tightened by four screws. So as to ensure a uniform pressure the screws were tightened to the same number of threads. After each set of observations a look at the specimen revealed that the electrodes had left permanent impressions on its faces. Moreover, there was no visible sputtering (as seen under a microscope × 430) on the surfaces of either the electrodes or the dielectric. This rules out the possibility of air-gap breakdown. One of the protruding terminals of the electrodes was earthed, while the other was connected to a d-c power supply capable of giving 500-1500V. The electret assembly was placed in a thermostat capable of measuring 250°C to an accuracy of ± 1°C. In order to control the temperature precisely, the thermostat was maintained at the required temperature for ½ hr and then the field was switched on. After 3 hr of heating the specimen was brought to room temperature in 1 hr. The controlled rate of heating ensured uniform polarization. The specimen was then kept in a shorted position overnight at room temperature to eliminate the frictional and stray charges. The polarizing field was 10.0, 12.5, and 15.0 kV/cm.

The electret was then heated in the same assembly at the uniform rate of 1°C/min by adjusting the input to the thermostat. The electrometer and thermometer readings were taken after every 5 min. For noting the discharge current an electrometer amplifier Model EA 812 manufactured by M/S Electronics Corporation of India, Hyderabad was used. This can measure current of the order of 10^{-12}A to an accuracy of ± 2%. A new specimen was made for every run.

Results

The curves of discharge current *vs.* temperature were plotted to obtain position of current maximum (i_m). The current was measured from 30° to 140°C. Only one peak which is very sharp at 97°C is observed (Fig. 1). The peak temperature (T_m) does not shift with temperature and field. However, the value of i_m increases with field (Table I). The charge is calculated from the area under the curve using a planimeter and is plotted as a function of field along with i_m (Fig. 2). The activation energy was calculated by plotting i_d *vs.* $1000/T$, employing a least squares fit. These values are shown in Table II along with those obtained from Takamatsu *et al.* (12) and Pillai *et al.* (13) through TSD studies and those of Matsuka *et al.* (14) obtained with dielectric measurement on PVC. The values obtained here are in close agreement with those obtained from the dielectric

workers. Takamatsu *et al.* used films prepared by hot pressing, whereas Pillai *et al.* made use of pure resin. The material used here for the present studies had a complex composition.

Discussion

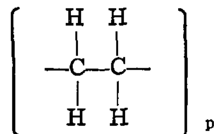
The sharp peak at 97°C corresponds to primary relaxations, as suggested by Takamatsu (12). As already seen, there is no shift of T_m with E_p and T_p (except a slight shift in the 120°C series). Moreover, the shape of curves is identical as per the prediction of Eq. [8]. A space-charge polarization is ruled out because in such cases T_m is strongly T_p dependent, as shown by several workers for the electrets of ionic crystals (15), ice (16), and certain polymers (17). While the results of TSD current show many of the characteristics expected for dipolar disorientation, this cannot be the major component of heterocharge. This is evident from the following observation:

From Eq. [6], the charge is given by

$$P_o \equiv Q_{cal} = N\,b^2\,E_p/3kT_p$$

for $E_p = 10$ kV/cm and $T_p = 357°K$ the charge calculated by finding the area under the curve comes out to be 4.98×10^{-8}C. Assuming dipole moment to be 1.73*D* (11), the volume density of dipoles is found to be 2.18×10^{23} dipoles/cm^3. Taking approximate molecular weight of PVC as 60,000 (18) and calculated density as 1.41 g/cm^3, we get 1.41×10^{19} molecules/cm^3, which corresponds to 15,600 dipoles/molecule.

The structure of polyvinyl chloride can be represented as



The molecular weight of each monomer of polyvinyl chloride (*i.e.*, vinylchloride) is 62.5, therefore the number of monomers in one polymer of PVC is approximately 1000, thus giving 15.6 ($\approx$16) dipoles per monomer of PVC which is about three times the number of bonds available.

So the depolarization current cannot be explained solely by thermal disorientation of aligned dipoles. As suggested by Perlman (19), ions trapped in the defects or dislocations in crystalline regions present in the amorphous structure of PVC could give rise to heterocharge and the associated current.

However, the thermally stimulated depolarization current may be qualitatively explained by the stepwise superposition of various phenomena responsible for persistent polarization in electrets (20). When heating is started space charges of opposite polarity combine to give rise to depolarization current. Then the current is contributed by the disorientation of dipoles and the release of ionic charges from the defects or dislocations. As the thermal treatment is carried on the charge carriers injected on the dielectric surfaces, the electrodes also disappear and become the source of TSD current.

In order to know the cause of depolarization current, work is going on in our laboratory. To differentiate between the space-charge polarization and uniform polarization due to dipoles, it is one of the future plans to study the TSD current spectra of vacuum-formed films of different thicknesses. Such studies have already been undertaken by Fischer and Rohl (21).

Structure and Stability of Anodic Films Formed on Aluminum Containing Dispersed Al_3Fe Phase

J. Zahavi

and M. Metzger*

University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

Al-Fe alloys containing Al_3Fe particles of micron size were anodized at 5 mA/cm² in 2.4M H_2SO_4 and film growth was studied by electron microscopy. It was deduced that the particles were removed by pitting of the matrix progressing preferentially around their margins followed by reanodization of the pit to form a loose pocket of film around the particle. The particle may fall out or be retained depending on the geometry.

The structure and mechanisms of formation of films on alloys containing a finely dispersed phase have not received much attention. This question is particularly pertinent to the behavior of commercial aluminum alloys which are able to form stable films and which exhibit passive behavior despite the presence of numerous microconstituents and (usually) precipitates or zones providing strengthening. Some attention to this question has been given at a relatively macroscopic level for anodizing. However, questions of local film character and its relation to heterogeneities in the substrate and to breakdown processes will require high magnification microscopy and related tools. The authors have employed electron microscopy to study film stability and breakdown models during anodic film growth on single phase 99.999% Al in sulfuric acid (1). In the present work, this approach is applied to alloys containing dispersed Al_3Fe phase. This constituent was of interest for a first study in part because there is some disagreement in previous work as to whether it dissolves, anodizes, or passes into the film unchanged. An attractive feature of the Al-Fe system is that there is limited solid solubility so that the extensive results on high purity aluminum (1) should be applicable to the behavior of the matrix in the alloy.

Previous work on the behavior of Al_3Fe in sulfuric acid involved large, sometimes massive (20 μm), particles and thick films ($\gtrsim$20 μm) in which sections through particle and film were prepared for optical, SEM, or electron-microprobe examination. Keller *et al.* (2) reported that this constituent tended to dissolve but sometimes appeared in the coating, which they explained as the result of an effective cessation of the dissolution when the growing film happened to electrically isolate the particle from the substrate. Wood and Brock (3) found that Al_3Fe particles were incorporated into the oxide without apparently being oxidized or dissolved. Cote *et al.* (4) found that Al_3Fe "oxidized" (*i.e.*, anodized) at about the same rate as the aluminum matrix. They explained Wood and Brock's result (for which the anodizing conditions were not very different) on the electrical isolation model. This was not a strong explanation since the former's sample contained an 8 μm particle which would, on Cote *et al.*'s model, have had substantial time to anodize before becoming isolated.

For the present work, observation of localized processes was sought and the requirement was for small particles and thin films growing up to the depth to which the particles were embedded so that processes in particle and matrix would be visible simultaneously side by side. Procedures were directed toward particle sizes near 1 μm and films of no more than a few microns. Anodizing conditions were the same as in the authors' previous electron-microscopic studies, and this meant that current densities and cell voltages were substantially lower than those employed in the previous studies of Al_3Fe.

Experimental

Alloy preparation.—Binary 0.4 and 1.0% Fe alloys were prepared by melting 99.999% Al and 99.99% Fe in a high purity graphite mold degassed at $\leq 10^{-5}$ Torr and sealed in a Vycor capsule. This was quenched in water to speed solidification. The 2.5 cm diam ingots were swaged to 1.2 cm, recrystallized at 500°C, and cold rolled with one intermediate anneal to 1.0 mm sheet. This procedure was devised to yield Al_3Fe particles of suitable size near 1 μm. Blanks were cut with a working area 20 × 5 mm and a narrow tab and these were annealed in air at 645°C for 6 hr and cooled in an air stream. The final high temperature anneal was given to dissolve any tiny precipitates and promote a more homogeneous matrix (solid solution of 0.05% Fe). A check by optical emission spectroscopy of the impurities in the Fe alloys showed only small increases from the original 99.999% Al, which was from the lot used in authors' previous studies (1), Table I.

Surface preparation.—An initial surface was required which was smooth and undeformed and in which the Al_3Fe intermetallic particles were retained. Three electrochemical treatments were found to yield acceptable particle retention (in each case the oxide film formed during annealing was first etched off with 10% HF): (*i*) electropolishing in 20 volume percent (v/o) 70% $HClO_4$ in ethanol at 0.1 A/cm² for 10 min at −10° to −15°C and rinsing with a jet of ethanol (treatment A of Ref. 1); (*ii*) electropolishing in 33 v/o

70% HNO_3 in methanol at 0.15 A/cm^2 at −30°C for 20 min and rinsing in a jet of methanol (treatment F); (*iii*) chemical polishing in a solution containing 150 ml of 96% H_2SO_4, 800 ml of 85% H_3PO_4, and 50 ml of 70% HNO_3 at 85°-90°C for 6 min and rinsing in water (treatment D of Ref. 1).

Anodizing.—As in the authors' previous studies (1), films were formed at 5 mA/cm^2 in 2.4M H_2SO_4 at 25.0 ± 0.2°C with a ~50 cm^2 Pt cathode. Anodizing times of 25-2700 sec were used with more attention to 84-300 sec when the film was still thin enough to be examined in transmission.

Microscopy.—The synthesis of information from a variety of techniques including scanning, transmission, and replica microscopy was found essential for investigating the film and particle geometries. Carbon replicas preshadowed at ~35° with platinum were employed. In these two-phase alloys a serious particle retention problem also arose in the question to what degree the particles present after anodizing were attacked and altered during the chemical treatments employed to detach the film for either observation in transmission or preparation of a film-underside replica. For film detachment from the substrate, both 0.3% $HgCl_2$ solution and 10% iodine in methanol at ~50°C (5) were employed with results as discussed later.

The shapes and sizes of particles were examined by SEM of as-polished specimens and also by TEM after preparing thin foils of the alloy by conventional jet thinning and electropolishing in sulfuric acid-ethanol and perchloric acid-ethanol solutions. The particles were retained, mostly protruding from the foil and opaque to the electron beam with a sharp silhouette. The particles in the 1% Fe alloy were found to be mainly well distributed euhedral crystals of lath or rod shape with minimum lateral dimensions typically 1-1½ μm and lengths up to ~5 μm and with edges and corners faceted. The particles in the 0.4% Fe alloy were less geometric and more equiaxed with typical dimensions from ~½ to 1½ μm, and they lay preferentially in bands. Diffraction patterns were consistent with the crystallography of Al_3Fe (6); the analysis is described below for particles in detached anodic films.

Results and Discussion

The cell voltage measured with respect to the platinum cathode showed at 5 mA/cm^2 substantially the same variation with time for the two-phase 1% Fe alloy as for single phase 99.999% Al. This is shown for chemically polished specimens (treatment D) in Fig. 1. It was also true for electropolished specimens (treatment A or F) and for chemically polished Al-0.4% Fe.

SEM observations.—Scanning electron microscopy was used for a preliminary survey of the behavior of the Al_3Fe particles during anodizing. Figure 2 shows the backcattered electron image of the surface as chemically polished. The particles appear as light patches (due to greater electron scattering than the matrix). The particles protruded various distances above the matrix surface as indicated by the variation of the "shadow" in the adjacent matrix where the particle shielded backscattered electrons from the collector. The dark patches were cavities at the locations of particles removed during chemical polishing. Figure 2 shows that a minor but significant fraction of the particles at the surface were removed during surface preparation, presumably those less deeply embedded. For electropolishing treatment F, this fraction was about the same as shown in Fig. 2; for the perchloric acid-ethanol electropolish (A), the fraction removed tended to be somewhat larger. The nature of the phenomena occurring during surface preparation or subsequent anodizing appeared to be the same for all treatments.

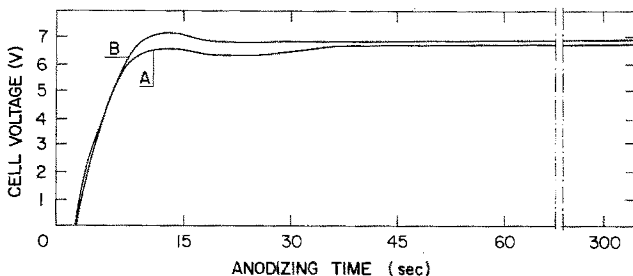

Fig. 1. Cell voltage vs. time for anodizing chemically polished specimens in 2.4M H_2SO_4 at 5 mA/cm^2. A. Al-1% Fe alloy; B. 99.999% Al.

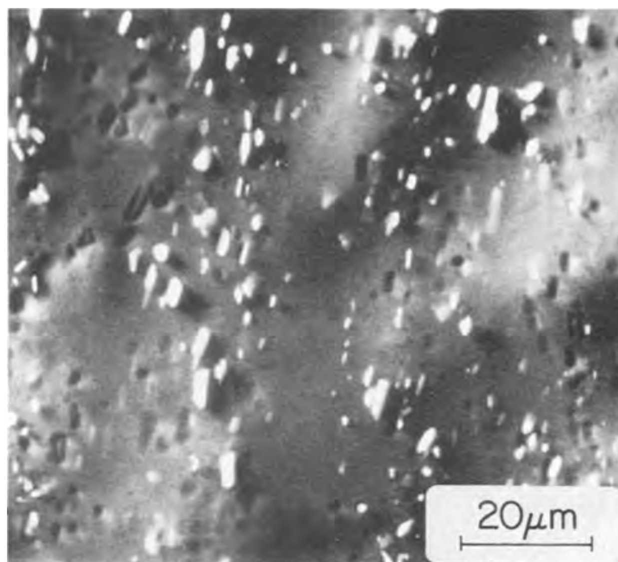

Fig. 2. Scanning electron micrograph showing Al_3Fe particles and cavities in chemically polished Al-1% Fe specimen. Backscattered electron image.

In the course of anodizing, the particles at the surface were gradually removed leaving cavities in the surface, as illustrated in Fig. 3. It was noted that the particles did not continuously shrink in size, which would point to a dissolution process, but appeared to remain at their original size and to be substantially unaffected so long as they were present. A process consistent with this observation would be undermining of the particles by some type of localized or crevice corrosion at their margins. Examination of the surface at higher magnification did reveal that some particles were partially bordered by dark strips that were not shadowing effects, but the resolution of SEM was far below that required for closer study.

TEM observations.—Films examined by transmission electron microscopy after having been detached from the substrate in aqueous $HgCl_2$ or I_2-CH_3OH solutions usually showed structures as in Fig. 4a, b, and c. Some rounded fully anodized cavities, such as in Fig. 4a, are thought to have been cavities present before anodizing from a particle removed during the polishing treatment. More typical was a dark band surrounding a strip of thin film with a gap in the center, occasionally with an almost complete thin film window, Fig. 4b and 4c. These are thought to have represented the sites of particles still attached during anodizing. Since it appeared that an anodic film was forming around the particle, one would expect that some of the many particles visible in SEM would be held by this film and would be seen in the detached film, as in an extraction replica. This was rarely the case. Evidence indicated that either of the solutions used to dissolve the Al substrate and so detach the film also attacked the Al_3Fe phase although at a lower rate.

The residual intermetallic particles in the film were examined, as follows. Figure 5 shows a scanning transmission electron micrograph of a field in which two cavities are visible. In one cavity, the particle had evidently been removed earlier during anodizing since

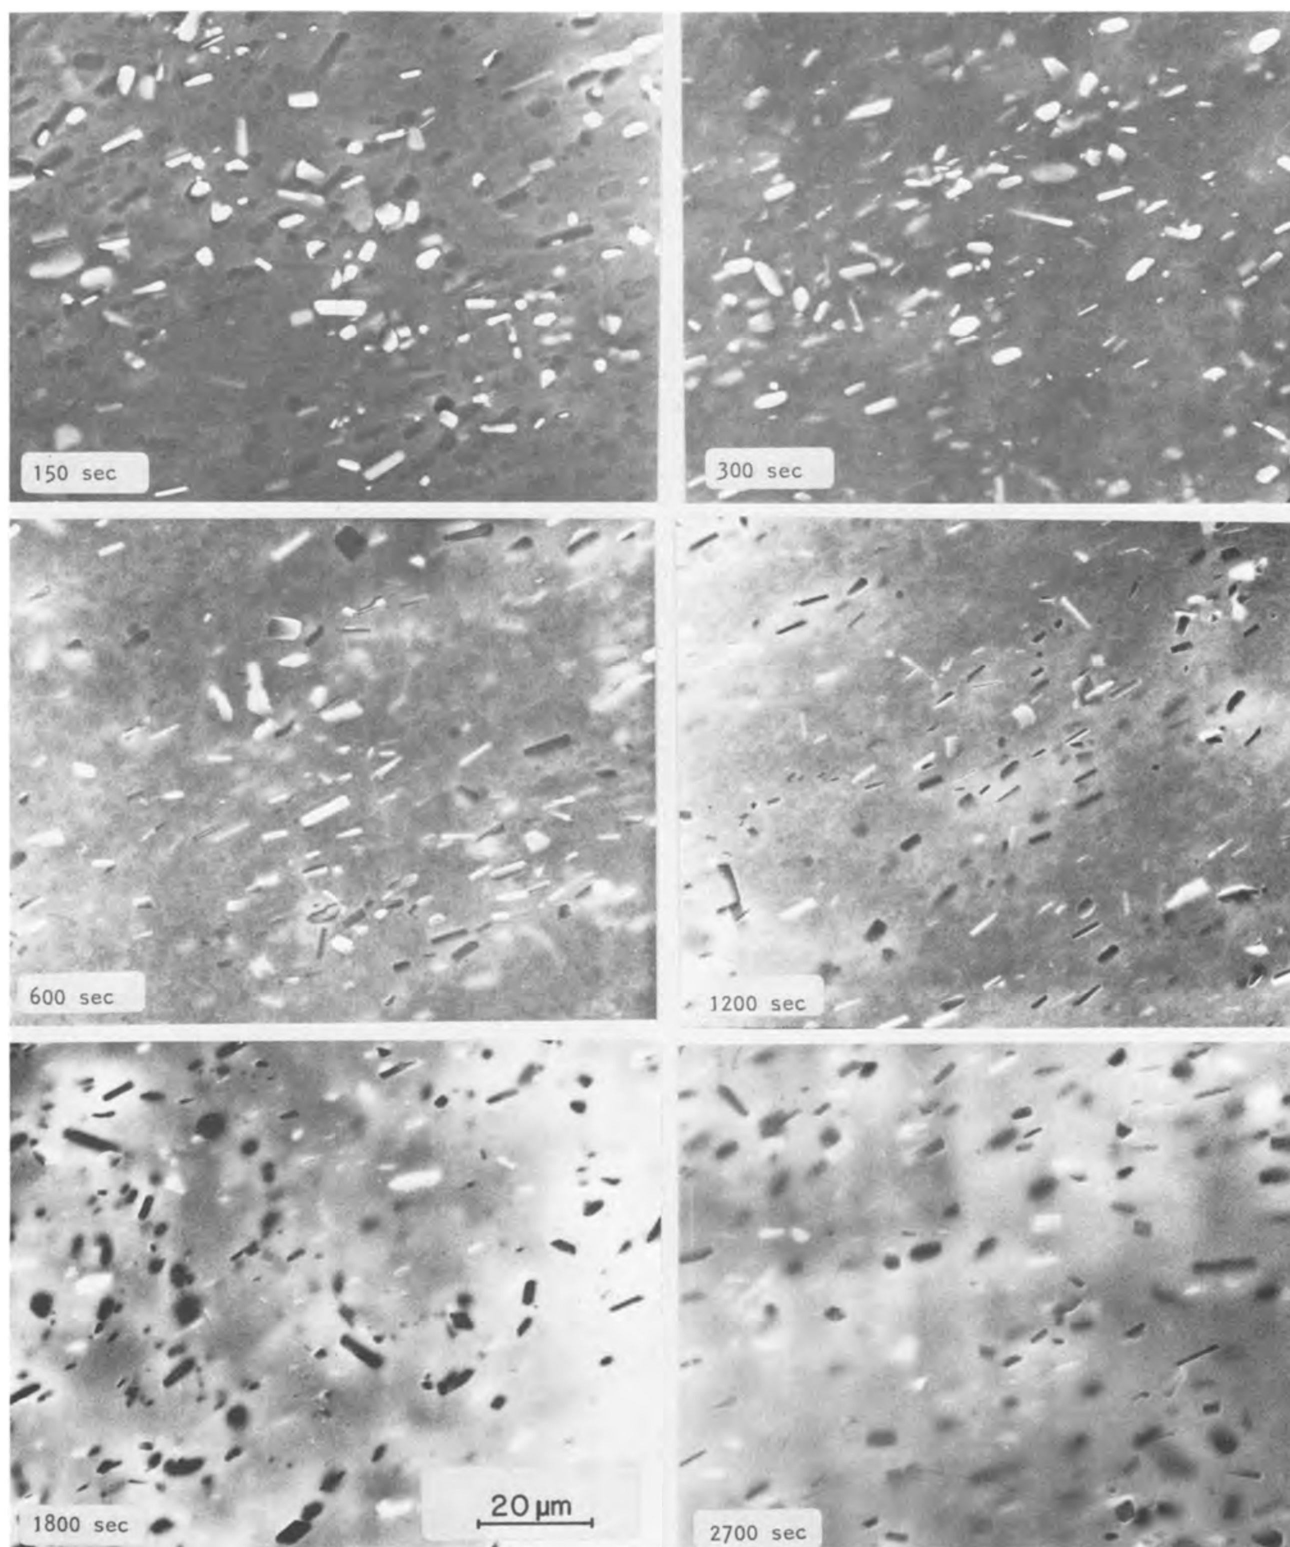

Fig. 3. Progressive removal of Al_3Fe particles during anodizing of chemically polished specimens of Al-1% Fe. Secondary electron images.

the cavity shows the pattern of small dark patches seen throughout this field. This pattern was the result of the micropitting phenomenon which is prominent in single phase aluminum at about this time of anodizing (1) (this pattern was present in the two-phase alloys of the present work but was normally much less prominent). The second cavity contained what was thought to be an incompletely dissolved particle and selected area diffraction did yield a few spots indicating the presence of material other than the amorphous film. Similar results were obtained for the dark cavity (P) in the center of Fig. 4b. Figure 6 shows a case in which an incompletely dissolved particle gave a substantial transmission diffraction pattern when the film was appropriately tilted, Fig. 6b. With a tilt-rotation stage, patterns from this particle in the 1% Fe alloy and one in the 0.4% Fe alloy were analyzed. These were found to be consistent with the monoclinic structure of Al_3Fe as given by Black (6) with $a = 1.5489$ nm, $b = 0.8083$ nm, $c = 1.2476$ nm, and $\beta = 107.14°$. A set of diffraction patterns was recorded while tilting around an axis found to be the normal to $(11\bar{1})$. Each pattern could be analyzed and

its zone normal found. The angles between the different zone normals were calculated and found to be in close agreement with the actual increments of tilt. These checks seemed sufficient to conclude that these particles were Al_3Fe phase and neither artifacts introduced in film preparation nor the metastable orthorhombic Al_6Fe phase which can form in the Al-Fe system (7). The sides of the particle in Fig. 6a appear to be parallel to the (001) plane. The wavy top and bottom edges of

the particle silhouette and the thickness fringes are interpreted as the result of atack by the $HgCl_2$ solution used to detach the film. The conclusion that this attack occurred during film detachment and not during anodizing was not drawn from this photograph but from the SEM observations plus the surface replica observations discussed below.

A film was presumed present on the particle during anodizing. It was thought that this film would, like the anodic film on the aluminum matrix, resist dissolution during the detachment process. This film could not be identified in the transmission micrographs, perhaps because it was not thick enough or strong enough to survive.

A typical "cavity" in transmission, *e.g.*, Fig. 4c or *T* in Fig. 4b, had a dark rim, a patch of thin film window, and a gap in the center. The origin of the contrast was deduced with the aid of the replica observations discussed below.

Replica observations.—It is to be noted that replicas of the film underside are made after detaching the film, and since the particle is generally removed during this process the replica will show a gap over the region where the particle was still attached to the substrate after anodizing. On the other hand, surface replicas are made without further treatment of the specimen and a particle present at the surface after anodizing will be replicated. Some surface-replica micrographs are given in Fig. 7. Figure 7a shows for the 0.4% Fe alloy particles at the surface which appear substantially complete, *i.e.*, no evidence of substantial dissolution in 10 min of anodizing. Figure 7b shows for the 1% Fe alloy a particle peeking out from under a flap of anodic film, and this also appears substantially unattacked after 30 min of anodizing. These observations support the interpretation given above of the transmission micrographs, *i.e.*, there were many regions where substantially complete particles had been present after anodizing but had been completely removed or partly dissolved in the process of film detachment.

The interpretation of thin film windows in the transmission micrographs was that a shell of anodic film was growing around the particles. If so, the film-underside replicas should show the steeply inclined sides of this shell with a more or less flat bottom if the shell were complete. If the shell were incomplete at the termination of anodizing, there would be a hole in the replica where the particle had been dissolved out in the

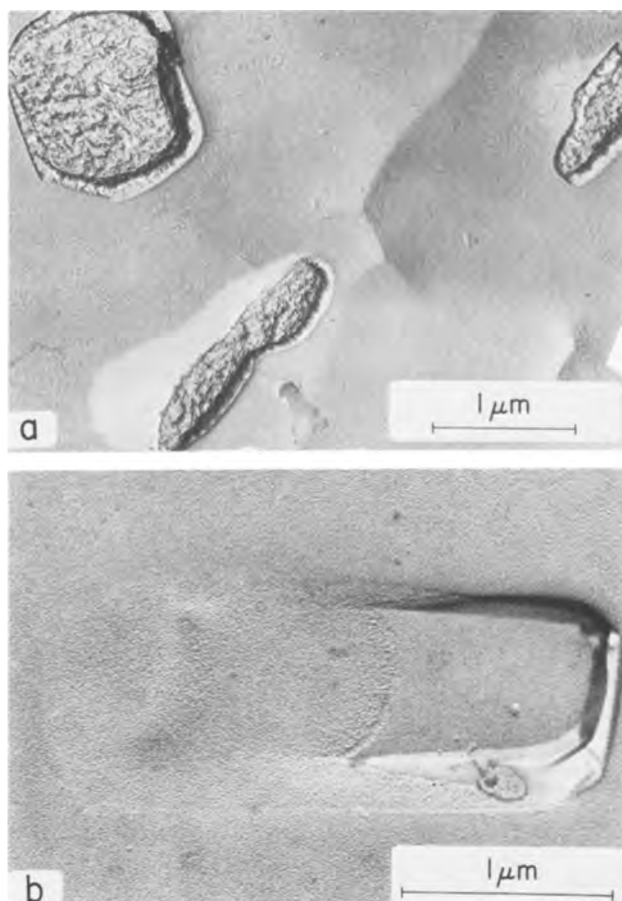

Fig. 7. Surface replicas of specimens anodized after chemical polishing. a. Ditching around particles in 10 min specimen of Al-0.4% Fe; b. Particle lying at a small angle to the surface perhaps detached but retained by overlying film. Al-1% Fe, 30 min.

film-detachment operation. The underside replicas of the 0.4% Fe alloy in Fig. 8 show the sides of the shell of film as a dark ring, sometimes with a considerable shadow. The cell-base pattern of the classical pore structure visible in the background of these micrographs is visible on the flat bottoms of the shells in Fig. 8a, *i.e.*, these were complete. In Fig. 8b and c, gaps in the center of the shells indicate that the bottoms of the particles were still partly attached to the substrate at the termination of anodizing. From these and many other fields of observation, the topography of the film and the nature of contrast in the replicas was deduced to be that presented schematically in Fig. 9 for a partially detached particle. In the center is shown the anodic film containing a particle around which a shell of anodic film is forming progressively during anodizing. It is suggested that this occurs by pitting of the matrix following the particle margins with reanodization of the pit surface behind the pit front; this is discussed further below and the main concern at this point is the contrast in the micrographs. When the film underside replica, shown below in Fig. 9, is prepared, the particle is not present as noted above. The steeply inclined part of the replica around the particle appears thick to the electron beam even without help from shadowing by Pt and so gives a full dark ring as in Fig. 8a, b, and c. Where the film extends over the bottom surface of the particle, the replica is sloping only gently and the density in the micrograph will be comparable to that of the background.

It is to be noted that the scheme of film topography in Fig. 9 is consistent with the typical contrast in the transmission micrographs, *e.g.*, Fig. 4c or *T* in Fig. 4b. There will be a gap where the particle had been removed during film detachment, a thin film window will be visible at the leading edge of the shell of film when the particle axis lies at an angle to the film normal, and this will be surrounded by a dark ring from the steeply sloping part of the shell of film around the particle.

The scheme presented in Fig. 9 of a pitting which tended to follow particle margins is not intended to be specific or unique as regards pit geometry, which varied in detail as well as could be ascertained. As to the size of the gap between the particle and the shell of anodic film, direct observation could be made only at the external surface, as, for example, in Fig. 7a and b. Some use could be made of the observation that many anodized cavities where the particle had been removed during anodizing were quite uniform with widths approximately the same as the typical particle width. This indicated that in these cases the gap had been only a fraction of the particle width. However, the geometry of the transient pitting and thus the extent and shape of the shell of repair film was frequently larger or less regular than represented in Fig. 9. Evidence of this was, for example, the broad shell of repair film in the underside replica of Fig. 8c (*cf.* Fig. 8a and b) or in the transmission micrograph of Fig. 4d, where instead of the relatively uniform dark ring of the typical cavity there was an irregular spreading dark patch. One also notes the large darkish patch in Fig. 4b, which included a number of cavities clustered near one another. None of these observations contradicted the conclusion that there was a strong tendency for the pitting to follow particle margins.

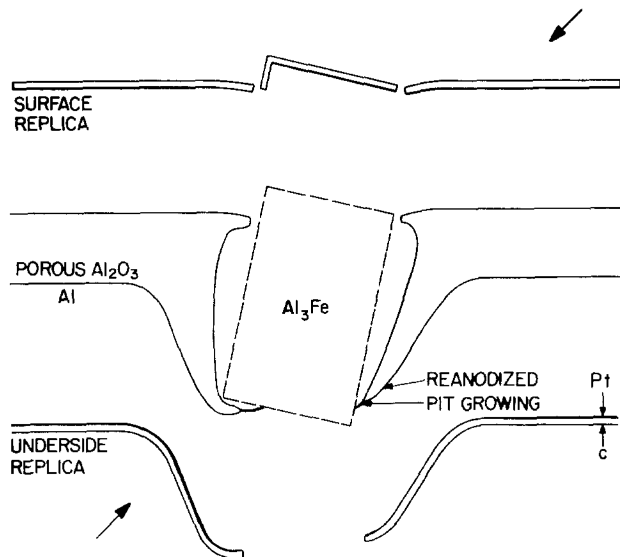

Fig. 9. Schematic of film configuration produced by excavation process illustrating the origin of the contrast. The preshadowed surface and underside carbon replicas are shown. The particle was absent during examination of film in transmission or during preparation of the underside replica.

According to the analysis presented above, the Al_3Fe particles were excavated and undermined by preferential pitting of the adjacent matrix. The continuation of the process represented in Fig. 9 would lead to a configuration in which the particle is only loosely held in a pocket of anodic film and can fall out during anodizing or be removed during subsequent rinsing. Note that the surface geometry might be such that the final configuration would include a flap of film preventing the undermined particle from falling out of its pocket. The particle in Fig. 7b may be such a case. Presumably many of the particles remaining in the film after long anodizing times (Fig. 3) were retained in this manner. A particle initially buried and exposed in the course of anodizing would of course be trapped in the film.

Further Discussion

Electrochemical considerations.—The electrochemical processes implied by the present results and conclusions are examined briefly below for plausibility and consistency.

The conclusion that the Al_3Fe particles did not suffer substantial corrosion during anodizing required that this phase be passive under the conditions employed. An independent examination of the behavior of this phase is in order and has been initiated.

The result that the voltage-time curves for the two-phase alloys were substantially the same as that for single phase aluminum required that those anodic currents associated with the presence of the particles were small. In principle, these currents included (*i*) the ion current of film growth or dissolution of the Al_3Fe particles; (*ii*) the electron current going to the production of oxygen at the surface of the film over the particles; and (*iii*) the local pitting current on the matrix at the particle margins. The first of these was small, as concluded above. A rough check for the presence of a significant oxygen evolution current was made by observing the bubble evolution on the specimen with a $40\times$ microscope during anodizing of the 1% Fe alloy. Very little bubble evolution was noted. The absence of a substantial oxygen evolution current in this alloy at potentials far above the oxygen reversible potential implies that the film over the Al_3Fe phase was a poor electronic conductor, as is the film over the aluminum matrix. The magnitude of the third current, the local pitting current, was viewed as follows. The excavation of the particles by local pitting took place over a time interval of many minutes so that on a time-average basis this particular pitting current need not have been large. A rough estimate for the 1% Fe alloy is as follows. If, say, at most 10 μm^3 of matrix had to be dissolved to excavate a particle and if this took on average only 10 min, then the $\sim 10^6$ particles exposed over 1 cm^2 of the alloy surface needed to draw local pitting currents totaling at most ½ mA/cm^2 to effect the excavation. This current was thus at most 1/10 of the applied current, *i.e.*, it was significant but perhaps not large enough to produce a substantial decrease in cell voltage. The argument given in this paragraph shows that it was not implausible that the

presence of the particles had little effect on cell voltage.

Nature of the local pitting.—The microscopic observations did not give a clear indication of the nature of the pitting around the particle. If the growth of the pit around the margin of the particle is continuous and slow, this cannot be active-mode pitting at low potential with no film. The process might then be a type of high potential pitting perhaps similar to the one suggested earlier by the authors in which dissolution occurs through a soluble film (referred to in a general way as an electropolishing-type film) (1). The presence of some film over the dissolving surface is suggested in Fig. 9. An alternative possibility is that the pit growth is intermittent and the relatively slow time-average growth of the pit around the particle is the result of short periods of rapid partly active pitting interrupted by repair. Such a scheme has the attractive feature that it is analogous to the micropitting phenomenon, *i.e.*, repeated breakdown-pitting-repair events, known to occur over the surface of the matrix. A possible scheme for particle excavation by such a process is given schematically in Fig. 10. After a short initial period of film growth, breakdown occurs at the margin of the particle and a very short period of active-mode pitting gives the geometrical situation shown in Fig. 10b. The active-mode pitting is presumed unstable so the pit surface becomes reanodized. A subsequent breakdown and short period of pit growth, Fig. 10c, starts a repetition of the cycle. This process would produce the geometrical features required to explain the micrographs. It is to be noted that the particle is not necessarily inert as was represented for simplicity in Fig. 10.

Figure 10 represents a geometrical interpretation of particle excavation employing the previous interpretation of the micropitting phenomenon as the point of departure. The special feature introduced here is the assumption of preferential film breakdown or pit initiation at the particle margin. No specific explanation for this is proposed. Local stresses in the anodic film, also transient breakdown or slow dissolution of the particle are conceivable contributing factors. Although it was deduced that the particle was passive at the high potential of its external surface, a different behavior at points within a cavity where the potential was temporarily lower was not precluded. Studies which have been initiated of the behavior of isolated Al_3Fe phase may provide guidance in these matters.

Relation to other work.—Previous work on Al_3Fe involved larger particles and higher cell voltages than used here, and little information was available to indicate how these differences should be taken into account. It was noted that in the 0.4% Fe alloy, which had slightly smaller particles than the 1% Fe alloy, particle removal during anodizing progressed somewhat faster, consistent with the model. Among a few observations made after anodizing at 10 mA/cm^2 (plateau voltage 10-11V, about the same as for 99.999% Al), a check was made on the conclusion that the Al_3Fe did not dissolve. The solution was analyzed for dissolved Fe after anodizing 1 hr. The charge passed here was sufficient to oxidize to the +3 state a layer of alloy contributing 0.67 ppm Fe to the solution if the Al_3Fe dissolved, but there was no increase in dissolved iron within the accuracy of measurement, 0.1 ppm.

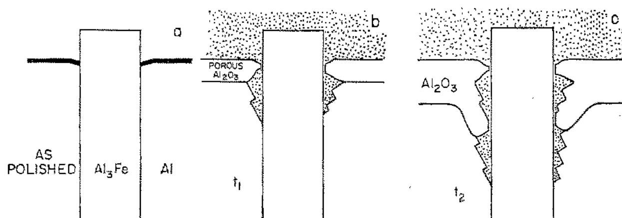

Fig. 10. Schematic of particle excavation by an intermittent local breakdown-pitting-repair process analogous to the micropitting phenomenon.

The larger particles used by previous workers would have required longer anodizing for excavation and they would have been less likely to fall out especially if the gap between particle and pocket of film was narrow as in the present work. Thus, according to the present model, these workers would have tended to observe the particles retained in the film, as noted by Wood and Brock (3). With the light microscopy they employed, Wood and Brock would not have detected a narrow gap between particle and film indicating the excavation process. The present results can thus be reconciled with theirs although a reconciliation is not strictly required since their cell voltages were substantially higher—19.1-19.8V at 25 mA/cm^2. For the same reason, since Cote *et al.* (4) anodized at 16V, their observation that Al_3Fe anodized at the same rate as the matrix is not necessarily incompatible with the present results although their disagreement with Wood and Brock remains to be clarified. In general, it seems not unlikely that the processes occurring will often be more complex than encompassed in the simple alternatives of particle dissolution, anodization, or "inert" behavior and that detailed observations with higher resolution need to be made at various stages of film growth instead of limiting the studies of constituent behavior to thick films.

Lanthanum and Yttrium Halo-Silicate Phosphors

W. Lehmann* **and Th. J. Isaacs**

Westinghouse Research and Development Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

Lanthanum and yttrium halo-silicates of the approximate composition $LnSiO_3X$ (Ln = La, Y; X = F, Cl, Br) have been discovered as new chemical compounds and as phosphor host materials. Luminescence activators are some of the trivalent rare earth elements. The crystallographic symmetry of $LaSiO_3F$ has tentatively been identified.

Halo-silicates, *i.e.*, silicates containing halide ions as essential part of their crystal structures, are relatively little known in general, and as phosphor host materials in particular. Burrus, Nicholson, and Rooksby (1) report Eu^{2+} emission in a material of the approximate composition $Sr_2Si_3O_8 \cdot 2SrCl_2$. Wanmaker and Verriet (2) describe luminescence due to Pb^{2+} and Eu^{2+} in $CaSiO_3 \cdot CaCl$. Wilke, Albers, and Mannheim (3) report $CaSiO_3 \cdot 2CaF_2$ and $CaSi_2O_5 \cdot 2CaF_2$ activated by Pb^{2+}, Bi^{3+}, and Mn^{2+}. A magnesium fluoro-silicate of the approximate composition $MgSiO_3 \cdot 2MgF_2$ activated by Ti^{4+} and Mn^{2+} is described by Ranby and Henderson (4). We want to report about structural and luminescent propertiese of lanthanum and yttrium halo-silicates which, to the best of our knowledge, have not been reported before. The composition of these materials is approximately $LaSiO_3X$ or $YSiO_3X$, respectively (X = F, Cl, Br). The luminescent properties of the lanthanum compounds were observed to be superior to those of the corresponding yttrium compounds. Hence, most experimental work was limited to lanthanum halo-silicates.

Preparation

The materials are prepared by conventional firing. The technique is described below using (La, Ce) SiO_3Cl as an example.

A uniform blend of La_2O_3, CeO_2, a slight excess of silicic acid, and a somewhat larger excess of NH_4Cl is slurried in water to obtain the reaction

$$La_2O_3 + 2NH_4Cl \rightarrow 2LaOCl + 2NH_4OH$$

A typical molar ratio between La, Ce, Si, and Cl to be used may be about 0.85:0.15:1.1:1.5. The slurry is dried in air. The dry powder is fired first in loosely capped quartz tubes surrounded by a slightly reducing atmosphere (*e.g.*, 99% N_2 + 1% H_2) at 1200°C for about 1 hr. It is then ground to a fine powder and refired in open quartz boats for 15 min at 1200°C, again in a reducing atmosphere. The material is then washed in water to remove any traces of water-soluble halides which may remain after the second firing. The final phosphor is a free-flowing white powder of particles in the 5-20 μm size range. It is stable in air and water although attacked by strong mineral acids.

Lanthanum can be replaced by yttrium. Chlorine can be replaced by fluorine or bromine, but not by iodine. SiO_2 appears to be unique; it cannot be replaced by GeO_2, SnO_2, ZrO_2, or by ½ $AlPO_4$ and ½ BPO_4.

Structural Properties

Microscopic examination of a phosphor prepared as described above reveals irregularly shaped particles which do not display crystal faces. Illumination by ultraviolet shows the particles to be uniformly luminescent throughout. Hence, the phosphor is not a heterogeneous halide-silica system as reported elsewhere for different materials (5).

Powder x-ray diffraction spectra show two different patterns depending on the halide used. Materials containing chlorine or bromine are almost identical, having very small changes in lattice spacings, but they differ from those containing fluorine. We were not able to identify either line pattern by comparison with published data of known materials (6).

Attempts to grow single crystals from the melt of lanthanum chloro-silicate failed; the halide escapes at the melting temperature (~ 1550°C) leaving lanthanum silicate behind. Some success was achieved with lanthanum fluoro-silicate, however, although there was still an appreciable loss of the added halide which escaped as SiF_4. Portions of the boule were pulverized and the x-ray powder diffraction pattern was seen to be essentially the same as that of $LaSiO_3F$ phosphor powder. While the boule itself was not a single crystal, we were able to chip from it small pieces (> 1 mm) which were single crystals. These were studied by the Burger precession method using Mo k α radiation. The compound is orthorhombic. Extinction conditions give the diffraction aspect Pn*n, with the possible space groups being Pnmn or Pn2n. The lattice parameters are: $a = 8.828 \pm 0.005$Å; $b = 13.121 \pm 0.005$Å; $c = 5.397 \pm 0.005$Å. The number of molecules per unit cell was determined to be eight. The density was measured by means of a pycnometer and found to be 4.86 g/cm³. The calculated density based on the formula $LaSiO_3F$ is 4.97 g/cm³.

The molecular formula is still somewhat uncertain. The materials were made with the expectation of obtaining $LaSiO_3X$ (X = F, Cl, Br), giving a La:Si:X ratio of 1:1:1. We used somewhat different proportions in the raw mix to allow for the unavoidable loss of volatile halide and, possibly, silicon (as silicon halide) during firing. The ratio of La:Si:X in the final phosphor therefore differs from that used in the raw mix.

We tried to determine the exact composition by wet chemical analysis. The melt-grown boule mentioned above gave a La:Si:F ratio of 1:0.48:0.19, whereas a normal lanthanum chloro-silicate phosphor powder gave a La:Si:Cl ratio of 1:1.1:0.61. Although the 1:1 ratio between La and Si was essentially maintained in one case, the halide content was appreciably lower in both cases, and the two differed from each other.

We believe that the ideal composition of our halo-silicates is given by the formula $LaSiO_3X$ although the materials appear to tolerate appreciable deviation. This conclusion is supported by the close agreement between the theoretical and measured density mentioned above.

Luminescence Due to Various Activators

Cerium.—Pure lanthanum halo-silicates are white powders without significant luminescence under either 254 or 365 nm u.v. radiation. Replacement of about 15-20% of the La^{3+} by Ce^{3+} produces a phosphor which luminesces efficiently in the near ultraviolet under excitation by short-wave ultraviolet. The emission and optical absorption spectra of fluoro- and chloro-silicates differ from each other (Fig. 1 and 2) reflecting the different crystal structures of the mate-

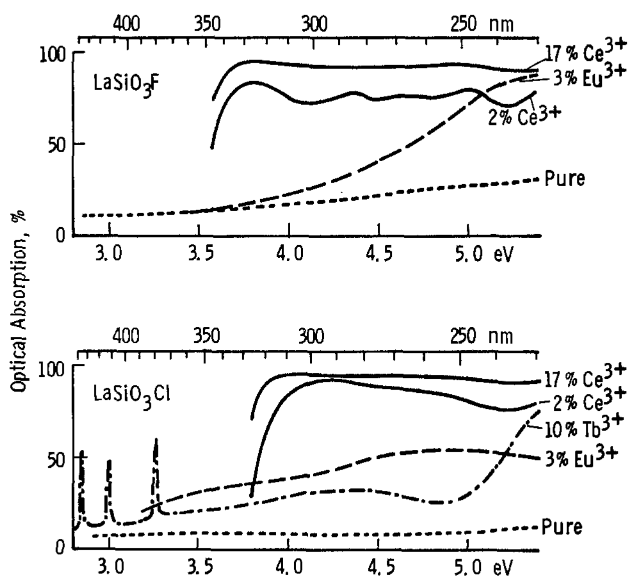

Fig. 2. Optical absorption spectra of lanthanum halo-silicate phosphors containing different activators.

rials. The spectra obtained on bromo-silicates are identical to those of chloro-silicates. Corresponding emission spectra of yttrium halo-silicates (Fig. 3) differ slightly from those of the lanthanum compounds. Two overlapping emission bands about 0.2 eV apart, reflecting recombination into the two ground states $^2F_{5/2}$ and $^2F_{7/2}$ of the Ce^{3+} ion, are frequently discernible. All emission spectra depend somewhat on the mode of excitation; they are shifted to higher energies in cathodoluminescence (Fig. 1). We do not as yet understand the reason of this effect.

Terbium.—The Tb^{3+}-emission in these halo-silicates consists of the usual pattern, a strong line group in the green at about 543 nm corresponding to the $^5D_4 \rightarrow {}^7F_5$

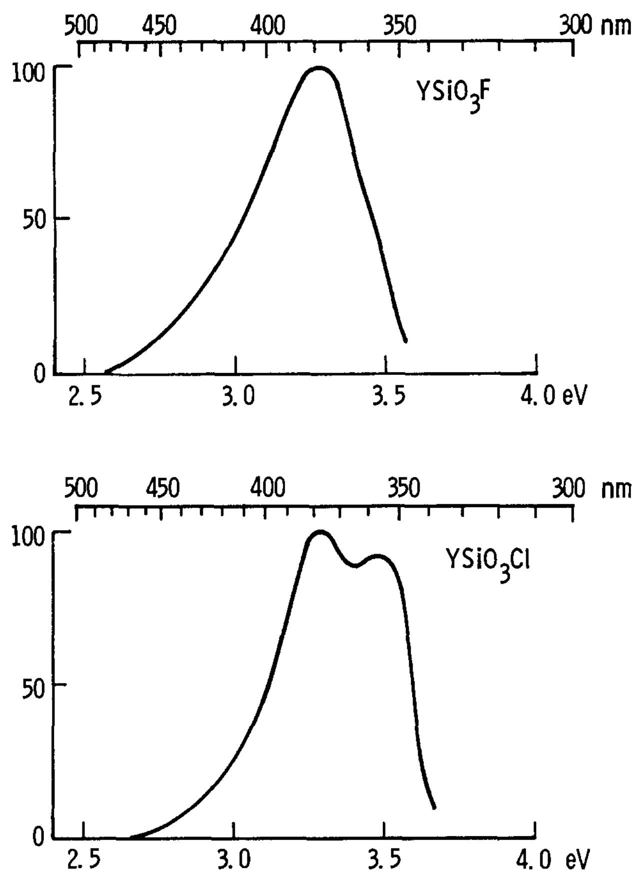

Fig. 3. Emission spectra of Ce^{3+} in yttrium halo-silicates. Excitation by 254 nm u.v.

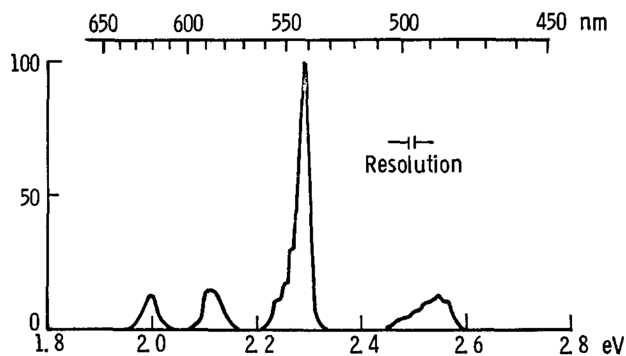

Fig. 4. Emission spectrum of La(0.7), Ce(0.2), Tb(0.1) SiO_3Cl. Excitation by 254 nm u.v.

electron transition, and several weaker ones to both sides (Fig. 4). It is not well excited by either 254 or 365 nm ultraviolet because of the absence of strong optical excitation at these wavelengths (Fig. 2). However, the Tb^{3+} is very efficiently sensitized for 254 nm excitation by Ce^{3+}. The obvious reason of this perfect energy transfer, $Ce^{3+} \rightarrow Tb^{3+}$, is the spectral overlap of the Ce^{3+} emission with several strong absorption lines of the Tb^{3+} (Fig. 1, 2, 3). The quantum efficiency (ratio of emitted/absorbed quanta) of La(0.7) Ce(0.2) Tb(0.1) SiO_3Cl phosphor under excitation by 254 nm ultraviolet was determined (by comparison to NBS-1021) to be about 90% (we believe the efficiency of the ultraviolet Ce^{3+} emission in a similar phosphor without Tb at least as high). The energy efficiency of cathodoluminescence is less impressive, however. We obtained ~4-5% under steady excitation by 10 kV electrons of low current density. This phosphor tolerates very high cerium concentration. While the optimum efficiency requires ~15-20% cerium and 10% terbium, replacement of all lanthanum by cerium,

[*i.e.*, Ce(0.9) Tb(0.1) SiO_3Cl] still gives a phosphor measured to have a quantum efficiency of the Tb^{3+} emission of about 70% under 254 nm excitation.

Samarium and dysprosium.—Both Sm^{3+} and Dy^{3+} in lanthanum and yttrium halo-silicates require sensitization by Ce^{3+} to respond to 254 nm ultraviolet. The energy transfer is not good, however. We observed quantum yields of about 5% for Sm^{3+} and about 30% for Dy^{3+} emission in (La, Ce) SiO_3Cl. These phosphors show the typical line emission and colors of the respective activator ions, *i.e.*, Sm^{3+} orange and Dy^{3+} yellowish-white.

Europium.—As in many other materials, trivalent europium requires an oxidizing atmosphere during preparation of halo-silicates to prevent reduction to Eu^{2+}. Thus we cannot sensitize Eu^{3+} with Ce^{3+}, as the latter requires a reducing atmosphere. Spectra showing the red Eu^{3+} emission in $LaSiO_3X$ are given in Fig. 5. They differ upon the halide used, which reflects the difference in structure. These spectra show relatively many lines between ~580 and 630 nm. The $^5D_0 \rightarrow {}^7F_2$ electron transition obviously is responsible for the strongest emission between ~610 and 620 nm, but a detailed line identification has not yet been possible. The optical absorption spectra due to Eu^{3+} in the lanthanum halo-silicates are relatively flat over a wide spectral range. We measured quantum yields of photoluminescence of ~25-30% for $LaSiO_3F$ and ~45-50% for $LaSiO_3Cl$, both materials containing an optimum europium concentration of about 3%. For reasons which we do not understand, we were unable to obtain Eu^{3+} emission in yttrium halo-silicate phosphors. The latter persistently showed only the Eu^{2+}, not the Eu^{3+}, emission.

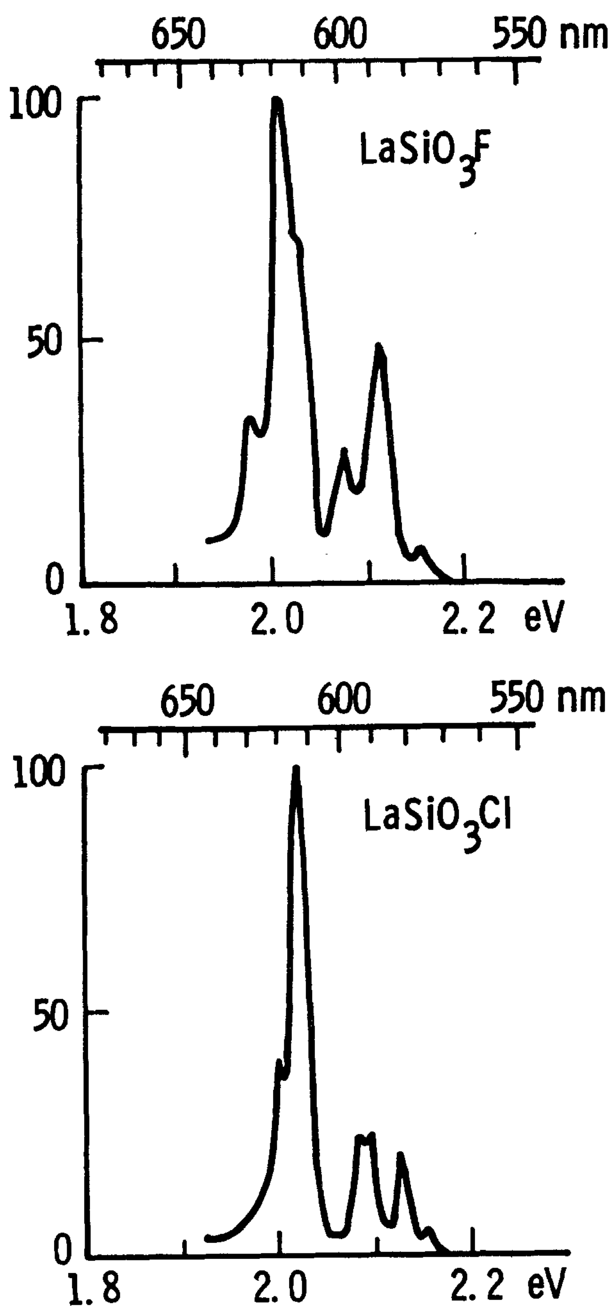

Fig 5. Emission spectra of Eu^{3+} in $LaSiO_3F$ and $LaSiO_3Cl$. Excitation by 254 nm u.v.

Luminescence due to Eu^{2+} in the halo-silicates consists of two diffuse emission bands suggestive of Eu^{2+} ions incorporated in two different lattice sites. A narrow band in the blue to violet dominates, while a very broad band centered in the green is weaker in intensity. Representative spectra of some chloro- and bromo-silicates are shown in Fig. 6. We were not able to obtain unambiguously similar spectra of fluorosilicates because of possible presence of Eu^{2+}-activated fluorides which, being insoluble in water, cannot be removed by washing. Attempts of charge compensation (*e.g.*, Eu^{2+} + Th^{4+} replacing two La^{3+}) had no visible effect on the phosphors. The optical absorption spectra of the materials contain a strong and very broad absorption band from close to the narrow emission band to below 220 nm in the shorter ultraviolet.

Discussion

Lanthanum and yttrium halo-silicates have been prepared and demonstrated as host materials of phosphors. The crystallographic symmetry of $LaSiO_3F$ has tentatively been identified to be orthorhombic. We believe the symmetries of the other compounds of this family to be not much different. More details of the crystal structures of the new compounds are not yet certain. The appearance of two emission bands due to Eu^{2+} activation (Fig. 6) suggests that the lattice provides two different sites with different symmetries for the Eu^{2+} to occupy and, consequently, the same two different sites conceivably are available also for RE^{3+} ions. Although this is far from certain, it seems to be supported by the numerous emission lines observed in the Eu^{3+} spectra (Fig. 5) which may easily be a superposition of emissions from Eu^{3+} ions on two different sites. The Tb^{3+} emission (Fig. 4) is much less sensitive to differences in site symmetry and does not show this line proliferation. More conclusions appear to be too speculative at the moment.

The usefulness of the new halo-silicates as phosphors is relatively limited since only two activators, Ce^{3+} and Tb^{3+} (the latter in combination with Ce^{3+}), provide efficiencies high enough to warrant application in lamps, etc. A systematic evaluation in this respect is not yet available.

Very Thin Silicon Nitride Films Grown by Direct Thermal Reaction with Nitrogen

Semiconductor Laboratory, Fujitsu Laboratories Limited, 1015 Kamikodanaka, Kawasaki, Japan

ABSTRACT

Very thin uniform silicon nitride films less than 100Å have been obtained on silicon wafers by direct thermal reaction with nitrogen at temperatures ranging from 1200° to 1300°C. Small amounts of water or oxygen in reaction mixture caused vapor etching which gave rise to local crystallization. By eliminating both from the reaction ambient to less than 1 ppm, amorphous silicon nitride films can be deposited. These films have been found to have properties similar to those of CVD Si_3N_4 by investigations of Auger electron spectroscopy, infrared spectroscopy, and ellipsometry. Remarkable masking effects of the films against oxidation and phosphorus diffusion have been found.

Silicon nitride films have been widely used in integrated circuit processing as dual dielectric gate films, local oxidation masks, and surface passivation films. This is because silicon nitride has a higher dielectric constant, a higher density, more resistance to radiation, and a higher barrier against alkali-ion migration than silicon dioxide. However, it is well known that the films directly deposited on silicon cause interfacial instabilities between silicon nitride and the substrate (1).

Direct nitridation of silicon wafers was thought to be a profitable technique to obtain a good interfacial structure. Knoop and Stickler (2) examined thermal reaction of silicon wafers packed in quartz ampule with gases containing nitrogen. Brown patches, whiskers, and aggregates of silicon nitride appeared on the wafers. Hu (3) reported that direct nitridation of silicon at temperatures ranging from 1300° to 1400°C yielded polycrystalline silicon nitride in the form of either small or microcrystals. Frieser (4) also observed that directly nitrided silicon films in nitrogen were polycrystalline and were a mixture of α and β Si_3N_4. Electrical properties of these films could hardly be measured because they were nonuniform.

The reasons why it was difficult to react silicon with nitrogen by direct thermal reaction are as follows: binding energy of nitrogen molecules is fairly large, diffusion of nitrogen atoms in silicon or silicon nitride is very slow, and standard free energy of reaction between silicon and nitrogen is small. However, we thought this process would be feasible at a lower temperature than ones mentioned above and uniform thin films of silicon nitride might be obtained if oxidizing impurities in a reactor tube were effectively eliminated. Our efforts were primarily directed at obtaining uniform films of silicon nitride by improving conditions of reaction.

* Electrochemical Society Active Member.

Key words: thermal nitridation, elimination of oxidant, surface morphologies, masking effects.

In this paper, we describe thermal reaction conditions for uniform thin silicon nitride films. The films were characterized using Auger electron spectroscopy (AES), infrared transmittance spectroscopy (IRS), and ellipsometry, and masking effects against oxidation and phosphorus diffusion were studied.

Experimental

Wafer treatment procedure.—Silicon p-type (100) or (111) oriented CZ wafers with boron doping concentrations of 1×10^{15}-2×10^{16} cm^{-3} were used as a starting material. The wafers were chemically cleaned by degreasing, etching in hydrofluoric acid, and rinsing with deionized water. They were then dipped into 48% hydrofluoric acid for 1 min, dried by nitrogen gas flowing, loaded on a silicon carbide-coated susceptor in a nitrogen atmosphere, and inserted into a quartz reactor tube heated at a temperature ranging from 1200° to 1300°C. This process seems to be useful to remove natural oxide on silicon. Vapor etching with hydrochloric or hydrogen gases is also effective to remove the natural oxide, but it is not appropriate to this experiment because some mixture of these gases with nitrogen cause nonuniformities on the surfaces.

Growth apparatus.—The ambient nitrogen gas, flowing continuously through the reactor tube, was highly purified using a specially constructed purifier with catalysis. The experimental apparatus is shown in Fig. 1. Amounts of water and oxygen contained in the nitrogen gas were measured at the outlet of the reactor tube by a dew point meter and an oxygen detector, respectively. Flow rates of the nitrogen were measured with a flowmeter.

Measurement.—Both film thicknesses and refractive indexes were measured by an ellipsometric technique. These values were self-consistently calculated by a computer. Film properties were analyzed by AES and infrared spectroscopy. AES spectra were taken with a cylindrical mirror analyzer. Further, masking effects

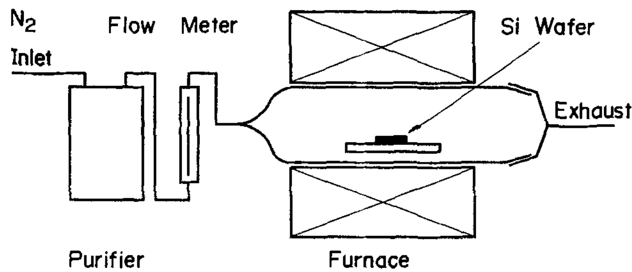

Fig. 1. Apparatus for directly thermal nitridation of a silicon wafer.

of the films grown on silicon wafers against oxidation and phosphorus diffusion were examined. Thermally nitrided silicon wafers were oxidized step by step in an oxidation tube heated at 1010°C. Film thicknesses on the wafers were measured after each oxidation. Donor concentration profiles after diffusing phosphorus into silicon masked by thermally grown silicon nitride films were determined by measuring sheet resistivities of surface layers and step-by-step etching after anodic oxidation.

Results

Growth conditions.—Figure 2 shows boundary conditions in which different surface morphologies are specified. In this case, the ambient nitrogen gas contained no more than 1 ppm water and 0.1 ppm oxygen. The reaction was tried at temperatures ranging from 1200° to 1300°C. The recovery time of the susceptor was nearly 15 sec at those temperatures and is shown as a broken line in the figure. The growth conditions for uniform silicon nitride films with smooth surfaces were restricted to a region between the solid line and the broken one. Rough surfaces with a crystalline morphology were observed for reaction times above the solid line. Small spots just like shallow etch pits appeared for reaction times near the line. If the purity of the ambient is improved, uniform films might be obtained in a wider region than that one shown in Fig. 2. To the contrary, if it contains more water or oxygen, uniform silicon nitride films would hardly be obtained.

Various surface morphologies of the silicon nitride films grown under conditions corresponding to three different regions in Fig. 2 are shown in Fig. 3. These wafers were nitrided at 1250°C for 10, 3, and 1 min, respectively. (a) shows the surface morphology of a partially crystallized silicon nitride film. Such a pattern has previously been reported by others (4). (b) shows a small spots pattern. These small spots seem

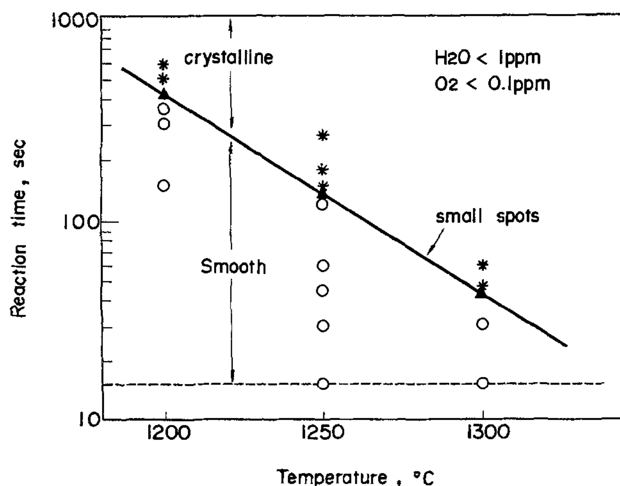

Fig. 2. Reaction conditions in which various surface morphologies of the grown films are specified. Experimental conditions are indicated as star, triangular, and open-circle marks, respectively.

to act as nuclei for crystallization. Figure 4 is an electron micrograph of the surface of the small spots sample (b) in Fig. 3, taken by a carbon replica technique. These small spots seem to grow in 3 dimensions. The surrounding plain region is as smooth as a silicon surface chemically etched by a conventional method. It exhibits no extra structural textures. This smooth region corresponds to the surface of the sample (c) in Fig. 3.

Figure 5 shows a relation between the film thickness and the reaction time at a temperature of 1250°C. Nitrogen gas of 5 liters/min flows continuously through the reactor tube. The growth rate varied up to 2.8Å/

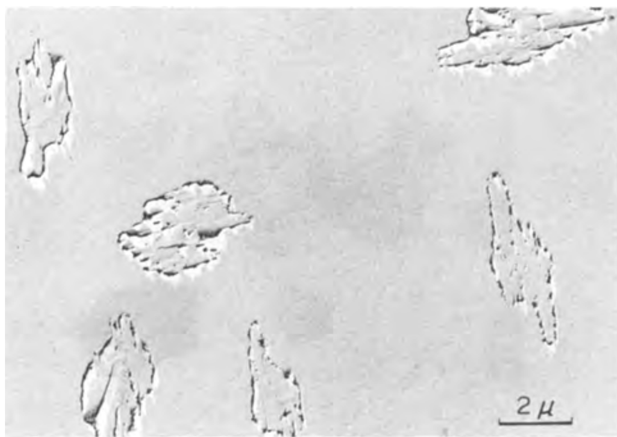

Fig. 5. Relation between film thickness and reaction time

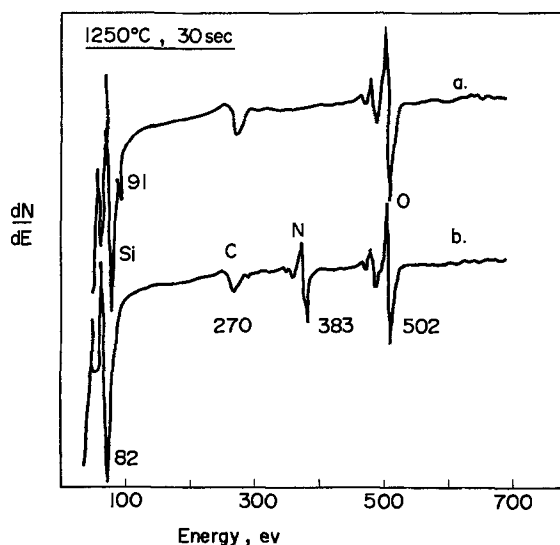

Fig. 6. AES spectra of films grown in different ambient gases. (a) Water, 5 ppm; oxygen, 4 ppm; (b) 1 ppm, 0.1 ppm, respectively.

sec and uniform films with thicknesses less than 100Å could be obtained. Refractive indexes of these films ranged from 2.0 to 2.3, which are slightly higher than those of the CVD materials. This shows a little deviation of stoichiometry of silicon nitride.

Film structural analysis.—Figure 6 shows Auger spectra of typical silicon nitride films. Both wafers were nitrided at a temperature of 1250°C for 30 sec. The upper spectrum (a) is of a film grown in nitrogen gas containing 5 ppm water and 4 ppm oxygen. The lower (b) is 1 ppm and 0.1 ppm, respectively.

The only detectable contaminants in these silicon nitrides are carbon and oxygen, which appear at 270 and 502 eV, respectively. In the upper spectrum, little nitrogen is detected and an elemental silicon peak still remains at 91 eV. This surface seems to be partly oxidized and to have partly remained bare silicon. In the case of improved ambient, the intense nitrogen KLL peak at 383 eV appears and the elemental silicon peak at 91 eV disappears. The chemically shifted silicon peak at 82 eV is believed to be associated with silicon nitride.

Figure 7 shows infrared absorption spectra of samples with different surface morphologies. These wafers were isothermally nitrided at 1250°C for 2, 2.5, and 4.5 min, respectively. Peaks at wavelengths of 9 and 16.4 μm seemed to be attributed to the substrate because they were noticed even in a bare silicon and did not change after the film growth. The surface of the 1 min sample was fairly uniform. But some small spots appeared on the 2.5 min sample and a crystalline pattern generated in the 4.5 min sample. These aspects have been mentioned in Fig. 3. A noticeable peak was recognized at 11.2 μm. The peak height increased with the reaction time.

For samples with the small spots or the crystalline pattern, a peak at 11.8 μm appeared and then overwhelmed the 11.2 μm. The 11.8 μm peak is due to stretching vibration of Si-N bond (5) and seemed to be associated with undesirable crystallization of silicon nitride, because the peak height increased with increasing the crystalline size. A shift of an absorption peak in silicon oxinitride was previously reported by Brown *et al.* (1, 6). According to their data, this uniform silicon nitride film, which only shows the absorption peak at 11.2 μm, would have a composition of 85% nitride and 15% oxide on the average if the band shift could be used in composition calibration. According to electron diffraction the uniform films showed a halo pattern and Kikuchi Lines reflected from the substrates as shown in Fig. 8. These films were surely amorphous.

Masking effects against oxidation and diffusion.—Direct thermal nitrided silicon wafers were inserted into a dry oxidation tube. Figure 9 shows a typical relation between the change of the film thickness on the silicon substrate and the oxidation time at a temperature of 1010°C. The thickness of the initial film, which was silicon nitride, was 75Å. It gradually increased with the oxidation time. After 5 hr the change was less than 50Å.

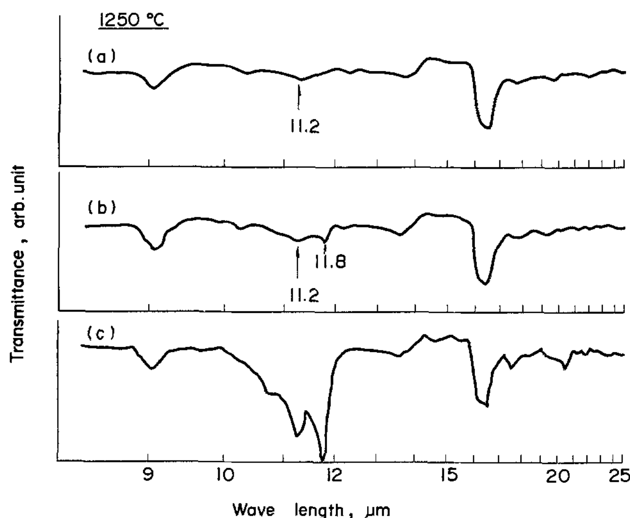

Fig. 7. Infrared absorption spectra of samples with different surface morphologies. (a) Uniform; (b) with small spots; (c) crystalline.

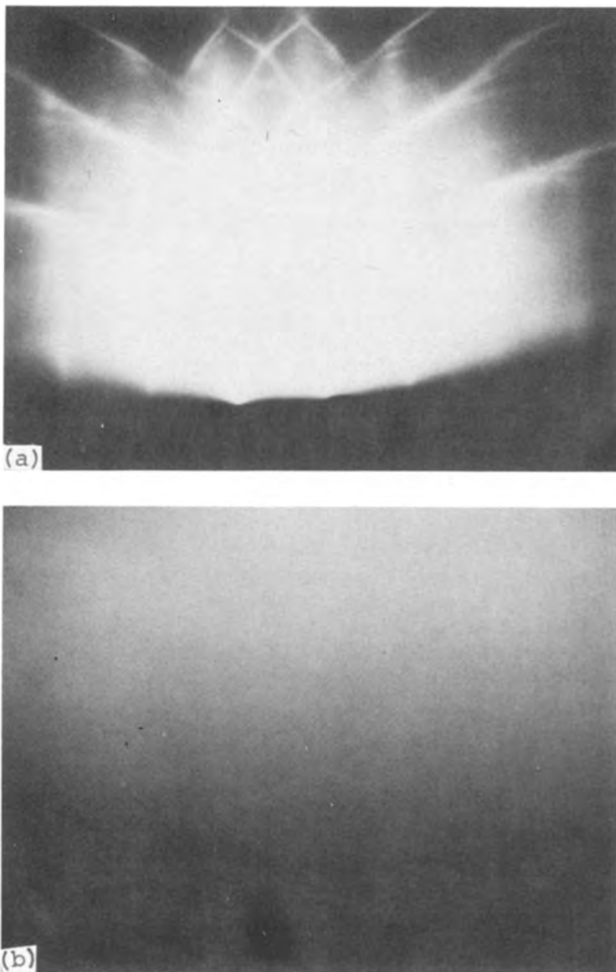

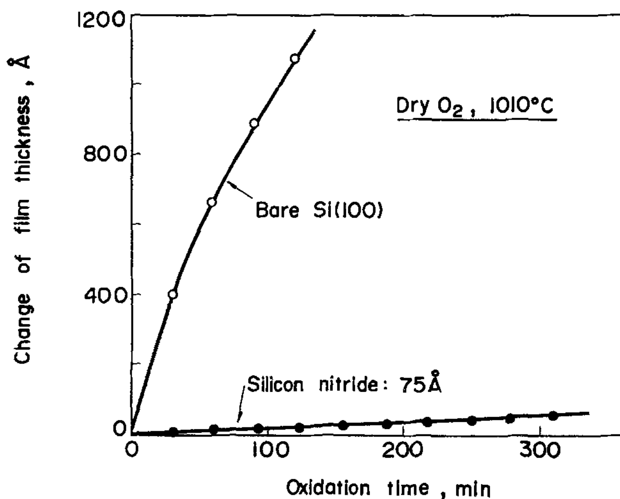

Fig. 8. Electron diffraction patterns. (a) Si surface etched; (b) directly nitrided Si surface.

Fig. 9. Change of film thickness vs. oxidation time. The silicon wafers with the silicon nitride film were heated in dry oxygen.

The mean oxidation rate is about 10Å per hour. For a comparison, a bare silicon wafer was also oxidized under the same conditions. The growth of silicon dioxide on the wafer is indicated as open circles in the figure.

Figure 10 shows carrier concentration profiles after diffusing phosphorus into p-type silicon substrates. Silicon nitride films with film thicknesses of 34 and 92Å were grown on silicon wafers. Subsequently a

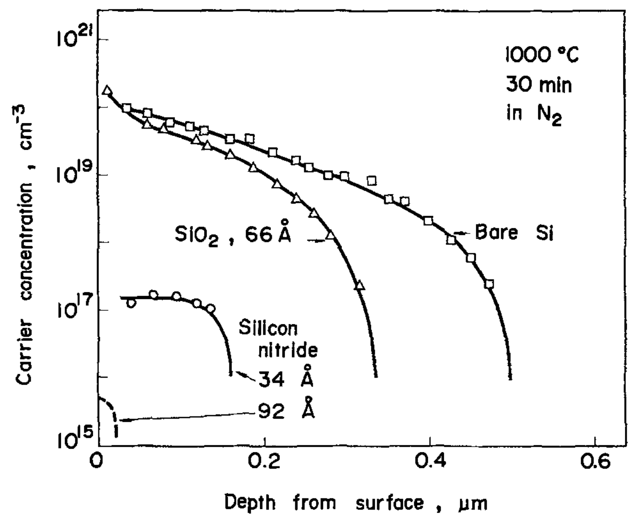

Fig. 10. Phosphorus diffusion profiles in silicon wafers with different protection-masks.

CVD phosphosilicate glass film was deposited by oxidation of silane and phosphine at a temperature of 450°C. Phosphorus concentration was 1.5 weight percent (w/o) and the film thickness was about 1000Å. The diffusion was carried out at 1000°C for 30 min in pure nitrogen ambient. The phosphorus doping profiles were compared with those of diffusions into bare silicon and thermally oxidized silicon with 66Å silicon dioxide. The depths after diffusing through the silicon nitride films are much smaller than those of the references. Especially, the silicon nitride film with 92Å thickness acts almost perfectly as a mask against the diffusion.

Figure 11 shows dependencies of surface-carrier concentrations on mask film thicknesses. The phosphorus diffusion was carried out under the same conditions as that in Fig. 10 and the diffusion times were 30, 60, and 120 min, respectively. The surface-carrier concentrations increase with increasing the diffusion time. However, all of the experimental values in Fig. 11 are smaller than that of a reference sample using a 66Å silicon dioxide film. Comparing one of silicon nitride samples with the reference at the same mask film thickness and under the same diffusion time, this silicon nitride film has more than four orders smaller values than the silicon dioxide film.

Discussion

The object of this work is to obtain stoichiometric silicon nitride films by direct thermal nitridation with

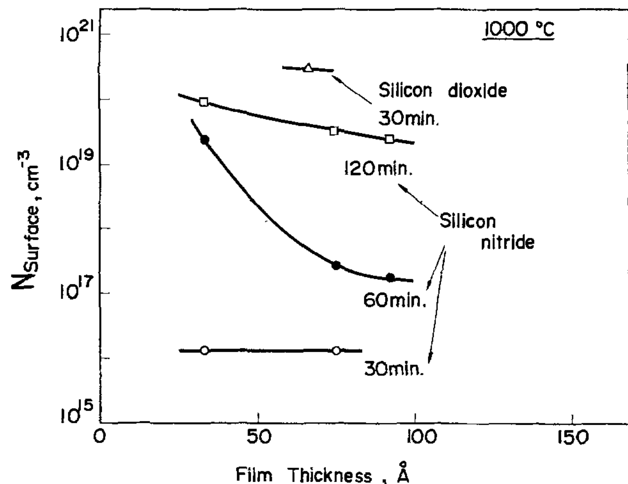

Fig. 11. Carrier concentrations at silicon surfaces vs. mask film thicknesses.

nitrogen. Since oxidation of silicon is thermodynamically more feasible than nitridation, it is necessary to reduce the amount of oxidant such as oxygen and water in reaction ambient. Those amounts have been reduced to less than 1 ppm water and 0.1 ppm oxygen measured at the outlet of the reaction tube, if absorbed gases in the wall of the quartz tube were fully taken out and the above-mentioned experimental conditions were established. However silicon nitride films obtained here have appeared to contain unintentional oxygen by the observations of AES and IRS. To attain the stoichiometry of Si_3N_4 it is necessary to improve further the experimental conditions. The origins of oxygen contained in the films are thought to be backstreaming of air while inserting wafers, penetrating through a quartz tube, and unremoved natural oxide on silicon surfaces besides impurities in the ambient reactive gas. Influences of these oxidants in the reaction process are observed in Fig. 5 which shows the film growth. The growth rate of silicon nitride increases with the increase of reaction time till the film thickness is nearly 100Å. We had expected that the process would obey a self-limiting reaction because the diffusion of nitrogen in silicon nitride is very slow. However the present result does not seem to support it. This is probably because the initial growth would be influenced by natural oxide on silicon and a backstreaming of air from the outlet. These would cause vapor etching of the silicon surface as the wafer temperature gradually elevates. The vapor etching would be caused by silicon monoxide structure.

After the initial reaction occurs, nitridation would become easier than the earlier, even though the nitrogen diffusion becomes slower. The refractive indexes of the films were a little higher than that of chemically vapor-deposited silicon nitride films. This seems to be caused by excess silicon atoms in the film because films grown in less pure ambient had refractive indexes ranging from 2.5 to 3.5. This ambient would cause much vapor etching of silicon and then, more excess silicon would remain in the grown film. The Auger electron peak of bare silicon in Fig. 6 also shows the existence of free silicon. Excess silicon atoms and oxidants contained in the film would become nuclei for local crystallization as indicated in Fig. 3(a). These regions have been ascertained to act hardly as masks against oxidation and impurities diffusion.

Chemically deposited silicon nitride films generally deviate from the expected Si_3N_4 stoichiometry over a wide range of deposition conditions. Johannessen *et al.* (7) analyzed them by AES and reported that an approximately 20% excess of silicon would be the general trend. According to Holloway and Stein (8), oxygen concentrations in various CVD silicon nitride films were observed to range from 0.4 to 7 atomic percent (a/o), where carbon was below the detection limits. Considering these results, some deviations from the stoichiometry in the grown nitride might become less important to certain applications. Deviations of film thicknesses of uniform silicon nitride among wafers and over a wafer were less than 5%, respectively.

Recently, Vromen (9) described that enough nitrogen could penetrate over a 52.6 nm oxide film at a temperature of 1050°C in 20 min to generate a large defect density. The degradation in dielectric strength was due to the generation of defects rather than to a change in intrinsic dielectric strength. Raider *et al.* (10) also reported nitrogen gas diffused to an oxide silicon interface, where it chemically reacts with silicon at elevated temperatures. They found that nitrogen would degrade the electrical properties of structures with the oxide during annealing. Further, Kooi *et al.* (11) observed the formation of some nitride at the silicon surface along the selective oxidation edge by steam oxidation. These phenomena did not show any feasibility in improving surface properties of silicon. However, the directly nitrided silicon films reported here would have far different properties from some nitrides examined by above-mentioned authors, and they would have some important advantages. For example, for the high performance of a short channel MOS transistor in LSI, the thinner gate insulator with a large dielectric constant is effective in eliminating so-called short channel effects and in decreasing the area. A further advantage of the films as a gate insulator is that a poly-Si gate can be highly doped without any impurities diffusing through the film to the channel region.

Conclusions

Very thin uniform silicon nitride films have been obtained by direct thermal reaction with nitrogen at temperatures ranging from 1200° to 1300°C. The film thicknesses were limited to less than 100Å because the reaction was inhibited by the growth of dense silicon nitride films. Small amounts of water or oxygen cause vapor etching and then give rise to local crystallization of the films, so that it has been found to be especially important to control them in ambient nitrogen to less than 1 ppm. The film properties have been investigated by AES, infrared spectroscopy, and ellipsometry. The very thin silicon nitride films had properties similar to those of a thick chemically vapor-deposited one. However, they appeared to contain a little excess silicon and oxygen. Masking effects of the films against oxidation and phosphorus diffusion were remarkable. This very thin silicon nitride film and the direct thermal nitridation process may be used in various integrated circuit technologies.

Oxidation of Silicon in the Presence of Chlorine and Chlorine Compounds

B. R. Singh[1] **and P. Balk***

Institute of Semiconductor Electronics/SFB 56 "Festkörperelektronik"
Technical University, 5100 Aachen, Germany

ABSTRACT

The need for higher manufacturing yields and improved operational reliability of semiconductor devices and circuits has led to a continuing scrutiny of all processing steps. Topic of the present paper is the effect of addition of chlorine or one of its compounds during silicon oxidation. After discussing oxidation kinetics in the presence of halogens and the metallurgical aspects of the process, a comprehensive review of the electrical effects is given. Attention is paid to the elimination of oxide charge centers and interface states, surface stabilization and enhanced dielectric behavior in MOS structures, and to the increased minority carrier lifetime in the silicon substrate. The improvements in device characteristics which have been attained using this method are summarized.

Adequate control of the threshold voltage and the breakdown strength of the gate insulator are essential conditions for the successful manufacture of field effect transistors. A decade ago alkali ions were found to be a major cause of instability of the surface potential in MOS structures; thus elimination of this form of oxide contamination was imperative (1-5). Since working under ultraclean manufacturing conditions presented some practical problems, the PSG stabilization process was developed where the impurities are gettered in a thin phosphosilicate glass layer directly at the metal electrode (6-9). Another possible solution is sealing off the SiO_2 film with a Si_3N_4 layer which is impenetrable to alkali ions (10-11). In both cases the breakdown behavior of the gate insulator is also improved, however, at the price of obtaining a polarizable (PSG) or an electronically somewhat unstable (SiO_2-Si_3N_4) system.

Given this situation the discovery that the addition of chlorine-containing species to the oxidation ambient during growth of the gate oxide may lead to improved stability and breakdown strength of the straightforward MOS structure was of considerable importance. In addition, lowering of the interface state density, elimination of stacking faults, and improvement in the minority carrier lifetime in the substrate on using these processes have been reported. Because of the great technological interest of the method different chlorine-containing species have been explored. However, these do not always lead to the same results.

It is the purpose of the present paper to review our level of understanding of the technique and of the mechanism involved in these processes. Discrepancies in the results and areas requiring further investigation are identified.

Chemistry of Chlorine Processes

Kinetics of oxide growth.—The thermal oxidation of silicon in the presence of O_2 or H_2O for SiO_2 thicknesses beyond 20 nm is generally described by a combined linear-parabolic equation which can be written as (12, 13)

$$\frac{x^2 - x_o^2}{k_{par}} + \frac{x - x_o}{k_{lin}} = t$$

where x is the oxide thickness, t the oxidation time, and k_{par} and k_{lin} are the parabolic and linear rate constants, respectively. For thin films the growth rate is determined by the reaction at the Si/SiO_2 interface. After an initial phase, characterized by the oxide thickness value x_o, the process proceeds at constant rate, yielding a linear increase of oxide thickness with time. For larger oxide thicknesses the growth is determined by the diffusion of the oxidizing species through the oxide layer and thus a parabolic rate equation results. Chlorine oxidation[2] also follows a linear-parabolic law (14-19). However, the values of the constants and their temperature dependences are affected by these additions to the O_2 ambient (Table I) (15): x_o appears to increase in all cases; k_{lin} increases strongly on addition of Cl_2 but is only weakly dependent on p_{HCl}; k_{par} increases with p_{HCl}, whereas the effect of p_{Cl_2} depends on the temperature.

The results for k_{par} with O_2/HCl at 1100°C were confirmed by Hirabayashi and Iwamura (16, 20). However, for k_{lin} these authors found the opposite trend as Van der Meulen and Cahill (15). At least at 1150°C Cl_2 has a stronger effect on growth rate than HCl (Fig. 1). In virtually all cases of practical interest thicker films are obtained with chlorine or chlorine compounds than without. Similarly, addition of trichloroethylene (TCE) to the oxidation ambient causes the rate to increase (Fig. 2) (17, 19, 21, 22).

To interpret the effect of chlorine and its compounds one has to keep in mind that the compounds will at least partially react with oxygen to form Cl_2 and H_2O (19, 23). For example, as may be seen from Fig. 3, a 5% HCl/O_2 mixture will yield approximately 3.5% HCl, 0.7% H_2O, and 0.7% Cl_2 according to the reaction

$$4HCl + O_2 \rightleftharpoons 2Cl_2 + 2H_2O$$

at 1100°C (23). At lower temperatures, the equilibrium shifts slightly to the right. Similarly, at 1100°C the reaction

[2] Here and in the following we will designate the oxidation in an ambient containing Cl_2 or a chlorine compound by "chlorine oxidation." Similarly, "chlorine oxide" designates the film obtained in such a process. To refer to specific processes (oxides) we will use the term Cl_2, HCl, or TCE oxidation (oxides).

Key words: chlorine oxidation, Si/SiO_2 interface, MOS, gettering.

Table I. Dependence of x_0 and of parabolic and linear rate constants on temperature (15)

Oxidant	T (°C)	k_{par} (nm²/min)	k_{lin} (nm/min)	x_o (nm)
O_2	900	39.4	0.220	6.4
	1000	169.0	0.805	19.2
	1100	414.0	3.25	33
O_2 + 4.5% HCl	900	64.2	0.217	11.4
	1000	440.0	1.02	25
	1100	540.0	?	?
O_2 + 0.5% Cl_2	900	18.46	0.31	17.5
	1000	180.0	0.83	24

$$4C_2HCl_3 + 9\,O_2 \rightarrow 2H_2O + 6Cl_2 + 8CO_2$$

$$2H_2O + 2Cl_2 \rightleftharpoons 4HCl + O_2$$

will yield for a 1% TCE/O_2 ambient approximately 0.95% HCl, 0.05% H_2O, and 1.0% Cl_2. Again, at lower temperatures somewhat more Cl_2 and H_2O are being formed.

Originally it was thought that the water formed in the above reaction would be responsible for the enhanced oxidation rates in the O_2/HCl system. However, the effect is larger than that which one would expect in a comparable O_2/H_2O ambient (14). It appears that the Cl_2 formed will also affect the oxidation process (particularly k_{lin}) as may be seen from the O_2/Cl_2 data (Table I). Furthermore, an enhanced diffusion of O_2 and H_2O during chlorine oxidation cannot be ruled out (16, 20). On the other hand, at least at 900°C the effect of the O_2/HCl ratio on k_{lin} is negligible (Table II). It would appear that in this area more extensive studies are required.

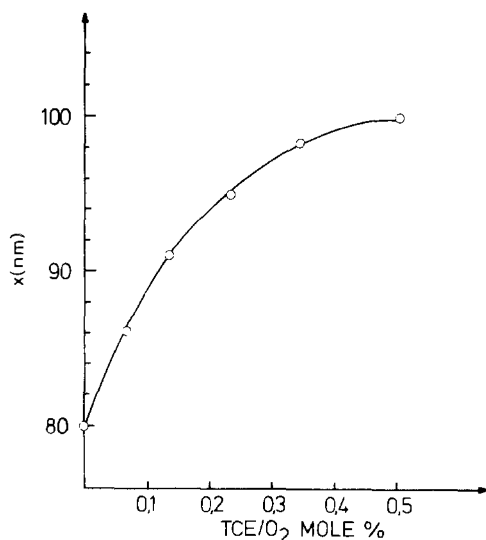

Fig. 2. Oxide thickness vs. TCE concentration (n-type Si, <100>, 4-5 Ωcm; T, 1200°C; t_{ox}, 11 min) (21).

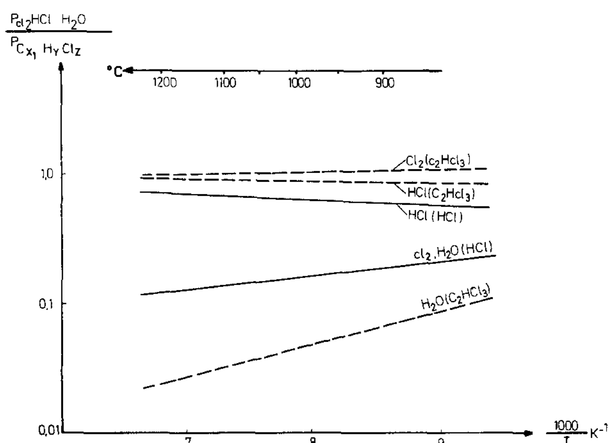

Fig. 3. Relative concentrations of Cl_2, HCl, and H_2O in O_2/HCl and O_2/TCE oxidation ambients at various temperatures. Values have been normalized with respect to the HCl and TCE input concentrations (23).

Chlorine distribution.—To gain insight in the chlorine incorporation and the distribution of this element in chlorine oxides, different analytical experiments using secondary ion mass-spectroscopy (24), Auger (25, 26), x-ray fluorescence (XFS), nuclear back scattering (NBS) (27-29), and electron microprobe analysis (EMA) have been performed. Of all the techniques employed, EMA was found to be the most sensitive, but detailed results are only available from the NBS technique which also yields the chlorine profile in a quantitative and nondestructive manner as a function of depth. A comparison of the amounts of chlorine detected in differently grown chlorine oxide films using various analytical methods is presented in Table III. Even though there may be some doubt about the quantitative nature of the results, almost all analytical techniques show large chlorine concentrations very near to the Si/SiO_2 interface and low concentrations in the rest of the oxide (24-29). The Auger data of Fig. 4 are an example of an experimentally found profile. In this case the Cl tail in the silicon may be an artifact of the Auger analysis method. The profile has the same shape regardless of SiO_2 thickness, growth temperature, and chlorine concentration in the gas phase (28, 29). From the observed large chlorine concentration at the Si/SiO_2 interface it appears that incorporation of chlorine takes place at the oxidation front. As the reaction proceeds, chlorine is expected to be slowly released and perhaps replaced by oxygen. The direct formation of Si-Cl instead of Si-O bonds at the interface has been proposed by Kriegler (26).

In Cl_2 oxides, the chlorine profile was found to be broadly peaked and more homogeneous compared to

Table II. The effect of additive concentration on x_o and on parabolic and linear rate constants during oxidation at 900°C (15)

Oxidant	k_{par} (nm^2/min)	k_{lin} (nm/min)	x_o (nm)
O_2	39.4	0.220	6.4

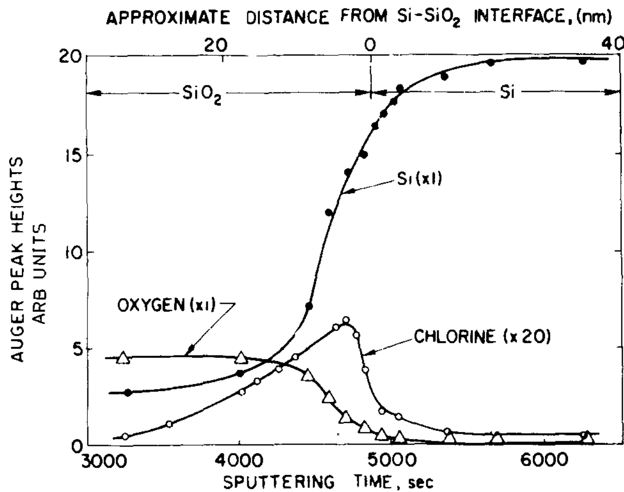

Fig. 4. Chlorine distribution in HCl oxide film determined by sputter etching. The silicon and oxygen profiles have also been indicated (25).

HCl oxides. Also, a higher level of chlorine incorporation was observed in comparison to HCl oxides for comparable concentrations of chlorine in the gas phase (28). Sequential growth studies in which a chlorine species was added during the later part of the oxidation process indicate that in Cl_2 oxides significant chlorine concentrations occur only near the Si/SiO_2 interface, whereas in regular Cl_2 oxides (Cl_2 added throughout the oxidation process) the element was distributed over a much wider range. In HCl oxides the same sequence yields chlorine profiles similar to those for regular HCl oxides. During N_2 annealing at 1200°C a slow chlorine removal takes place in Cl_2 oxides, whereas a rapid loss (to approximately 50%) and a change in the chlorine profile were found in HCl oxides. The above-mentioned differences in chlorine profiles for Cl_2 and HCl oxide and their behavior under annealing may be caused by H_2O which is only present during HCl oxidation. Both with Cl_2 and with HCl as a chlorine source average chlorine concentrations of the order of 10^{20} atoms/cm^3 can easily be achieved (27).

In spite of these differences, a number of similarities in the behavior of both Cl_2 and HCl oxides have also been observed. In both types of chlorine oxides chlorine is reported to be completely removed during further steam oxidation (26, 28, 30). However, some chlorine was found in oxides grown in regular steam/HCl ambient at 1200°C (31). Vacuum annealing at 100°C for about 60 min and also annealing at 1000°C in N_2 ambient do not result in any significant loss in chlorine concentration for both types of oxides.

Metallurgical Characteristics

Surface roughening.—The SiO_2 films grown in large concentrations of chlorine and chlorine compounds, or at smaller concentrations for longer duration show a grainy appearance when viewed through an optical microscope (16, 24, 26). Transmission and scanning electron microscopy results indicate that this is caused by roughening of the Si/SiO_2 interface. It has been suggested that development of smooth rounded bumps takes place and that their height and diameter increase with the HCl concentration (24).

Elimination of stacking faults.—Chlorine oxidation will cause suppression of stacking fault generation. The elimination or shrinkage of stacking faults which were already present have also been realized (32-37). This improvement has been attributed to interaction of these defects with vacancies probably created by removal of silicon atoms during high temperature chlorine oxidation. The diffusion of phosphorus and boron takes place at a reduced rate in O_2/chlorine ambients (38). Such studies related to stacking fault elimination have recently gained considerable importance because of the possible correlation of these defects with dark current spikes in CCD's (39). The existence of a strong correlation has been confirmed by Declerck *et al.* (37, 40).

Optimizing the process may cause some difficulty since the elimination of stacking faults which are already present requires growth conditions (1150°-1240°C, 3-6%) which will result in surface roughening and degradation of other beneficial properties like the attainment of low interface state density, high dielectric breakdown strength, and good stability under room temperature bias. These adverse effects are avoided by working at somewhat more moderate temperatures (1100°-1150°C) and concentrations (3-4% HCl), but under these conditions only generation of new stacking faults is prevented. Thus combination with other methods, like the POGO technique [gettering of defects using a phosphorus or Si_3N_4 deposition on the back of the silicon wafer (41-43)] or damaging the back by ion implantation (which has a similar gettering effect) may be necessary to eliminate the stacking faults (37).

Electrical Properties

In this section the effect of chlorine oxidation on different electrical properties of MOS structures, silicon substrates, and devices are discussed and a comparison between oxides grown in different chlorine-containing species made. In general, all chlorine species tend to have similar effects in improving the Si/SiO_2 interface properties. Nonetheless, some important differences have been observed for typical growth conditions.

Interface state density.—It is now well established that a one order of magnitude reduction in interface state density can easily be obtained in the case of chlorine oxides as compared to oxides grown in chlorine-free atmospheres (Fig. 5) (44-47). In TCE oxides the effect reverses for TCE/O_2 mole ratios of more than 0.6%, where an increase in interface state density is obtained (17). It has been suspected that the reduction is due to the presence of highly active hydrogen or OH^- groups produced during HCl or TCE oxidation which tie up some or all of the dangling bonds at the interface (44, 46, 48, 49). The reduction in interface state density has also been attributed to the gettering of the chemical impurities (21).

The orientation dependence of the interface state density for samples oxidized in O_2 with 3%HCl is similar to that for oxides grown in a chlorine-free atmosphere (47). The results indicate a higher density of states for <111> than for <100> oriented surfaces. Upon postmetallization annealing in N_2 at 525°C the densities reduce for both orientations to the same small value (47). There is no information on the dependence of the state density on the temperature and HCl additive concentration.

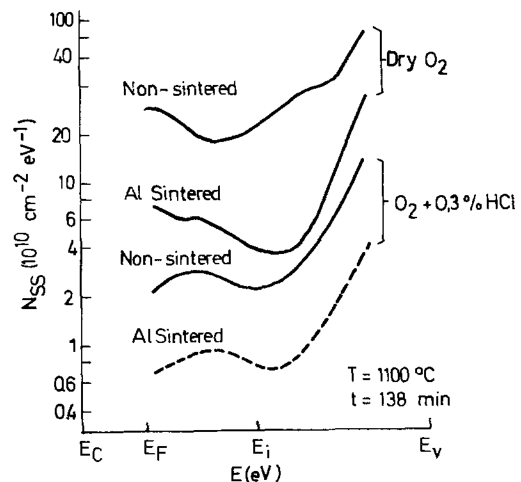

Fig. 5. Surface state distribution at the Si/SiO_2 interface for <111> oriented silicon oxidized in dry O_2 and in HCl ambients (44).

Fixed oxide charge density.—Most authors agree that chlorine oxides do not show significantly reduced fixed oxide charge densities (14, 21, 44-46, 50). However, for TCE the situation is not quite clear (51). Recently a detailed analysis of the dependence of the flatband voltage on the TCE concentration has been conducted. Minimum oxide charge was observed for TCE concentrations of 0.3-0.4% (22). The charge density was found to increase for higher TCE concentrations.

Cleaning effect.—Alkali ion contamination, mainly in the form of sodium ions introduced during high temperature processing of semiconductor devices, results in erratic turn-on voltages and instability of device parameters under operational stresses. These ions move through the insulator film under operational stresses and accumulate at the Si/SiO_2 interface, inducing an equal amount of negative charge in the silicon.

It has been observed that the addition of chlorine during high temperature oxidation has a significant effect in removing sodium ions by forming volatile chlorides (21, 26). Clean oxides have also been obtained by simply oxidizing the wafer in O_2 or steam in a furnace tube which has been precleaned by prolonged exposure to an O_2/chlorine mixture. In this case, the cleaning effect might have been caused by the release of trace amounts of chlorine from the furnace tube into the oxidizing ambient during further oxidation in the chlorine-free atmosphere. However, the fact that the same level of stability was observed for oxides grown in chlorine-free atmosphere (after 15 hr O_2/HCl and 30 min steam purge) and regular HCl oxides (6% HCl, after 15 hr O_2/HCl purge) indicates that prevention of contamination from the tube is the essential point (Table IV). It is also shown in this table that oxidations in 6% HCl/O_2 and in 0.75% TCE/O_2 (which yields approximately the same Cl_2 concentration, see Fig. 3) are comparable in their effectiveness in reducing the mobile ion density (21, 26). This suggests that pure Cl_2 will be equally or perhaps more effective than hydrogen-containing chlorine compounds in this respect.

From the significant reduction in the radiation-induced oxide charge obtained for steam/HCl oxides at 875°C it may be concluded that even under these conditions clean oxides can be obtained (52). This radiation-induced charge buildup is believed to be due to the liberation during irradiation of neutral sodium (not mobile with BT stress) bonded with coulombic forces to oxygen vacancies (53). A similar reduction in the amount of radiation-induced oxide charge was observed by Aubuchon *et al.* (54) in oxides grown in an HCl-purged furnace. On the other hand, oxides with high chlorine concentration show an increased radiation-induced charge. This may be partly due to chlorine migration during irradiation.

In thermally grown oxide, sodium is present both as ionic and as neutral species (4). The instability due to incorporated mobile Na^+ ions caused by involuntary Na^+ contamination, observed after "standard furnace cleaning" (Table IV) appears to be in sharp contrast with the findings of Revesz and Evans (13). After intentionally doping the SiO_2 films with 10^{20} Na atoms cm^{-3} during oxidation, they observed no significant instability. Their oxidation conditions and those in Ref. (21, 26) appear to be quite similar. It thus appears that in Revesz and Evan's films, Na was incorporated in an immobile form, whereas in the experiments of Table IV this element was in mobile form. Most likely a transition between these two forms may occur, but it is not clear under which conditions. The question still remains unanswered if the cleaning effect is due to the formation of volatile chloride or to the neutralization of Na^+ ions during chlorine oxidation.

Passivation effect.—As discussed in the previous section, the incorporation of sodium ions can be prevented either by precleaning the furnace tube or by simply adding a small percentage of chlorine to the oxidation ambient. By definition, the cleaning action of chlorine cannot extend beyond the thermal oxidation step. However, for the fabrication of devices a number of additional steps, like photolithography and metallization, are required which can again introduce significant amounts of sodium and result in device degradation.

It has been observed that chlorine oxides grown under appropriate conditions, *i.e.*, at a reasonably high temperature with a fairly large chlorine concentration and for a sufficient length of time, can effectively alleviate the undesirable electrical effects of sodium even if the contaminant is introduced after high temperature oxidation (24, 26, 55, 56). This will most likely result in the high chlorine concentration near the Si/SiO_2 interface which is apparently necessary to passivate the SiO_2 film, *i.e.*, to neutralize Na^+ ions at the interface. The conclusion about Na^+ neutralization at the Si/SiO_2 interface is based on radiotracer and C-V data obtained on intentionally contaminated chlorine oxide films (6% HCl at 1150°C) after BT stress. The radiotracer data show a relatively high sodium concentration near the interface (Fig. 6) (56). The C-V characteristics measured on identical devices show no appreciable shift. This indicates that sodium ions lose their charge after interacting with chlorine already present at the Si/SiO_2 interface and that the charge must be transferred to the silicon electrode. Once sodium ions lose their charge, they are believed to be strongly trapped or bonded with chlorine. Van der Meulen *et al.* (27) are of the view that sodium ions after interacting with chlorine may be neutralized, but that they are not necessarily immobile. The exact mechanism of charge transfer to the silicon electrode is not understood (26, 55, 57).

The development of passivation takes place suddenly in a narrow range of HCl concentrations between 3 and 4% for devices having sodium contamination levels of the order of 10^{12} ions/cm^2 (Fig. 7). A significant incorporation of chlorine (10-15 $\times$ 10^{14} atoms/cm^2) particularly for 3-4% HCl at 1200°C has recently been observed and its possible correlation with threshold behavior in passivation discussed (Fig. 8) (58). This indicates that passivation is achieved once a certain minimum level of chlorine is incorporated in the SiO_2 film. However, this thresholdlike behavior of passivation is not understood. A similar thresholdlike behavior has been found for TCE oxides (17). Kriegler (24) observed that the passivation efficiency is independent of the sodium contamination level up to a value of 4 $\times$ 10^{12} ions/cm^2. The findings of Van der Meulen *et al.* (27) for higher contamination levels (10^{12}-10^{14} ions/cm^2) indicate that only one-third of the total so-

Table IV. Effect of HCl (26) and TCE (21) on mobile ion density in thermally grown SiO_2

HCl — 1200°C, 2-10-2 min dry-wet-dry cycle, N_2 anneal, 10 min

Sample description	Ion density (ion/cm^2)
No HCl, grown after standard (HF rinse, 6 hr steam purge at 1200°C) cleaning of furnace tube	26×10^{10}
6% HCl, grown without any previous exposure of tube to HCl	12×10^{10}
6% HCl, grown after 15 hr purge with 6% HCl/O_2	1.2×10^{10}
No HCl, grown after further 30 min steam purge	1.4×10^{10}

TCE — 1100°C, 30 min dry oxidation, N_2 anneal, 10 min

Sample description	Ion density (ion/cm^2)
No TCE, grown after standard (HF and H_2O rinse) furnace tube cleaning	3×10^{10}
No TCE, grown after 30 min purge with 0.75% TCE/O_2	10^{10}
No TCE, grown after 2 hr purge with 0.75% TCE/O_2	$3\text{-}6 \times 10^{10}$
No TCE, grown after 15 hr purge with 0.75% TCE/O_2	2×10^{9}

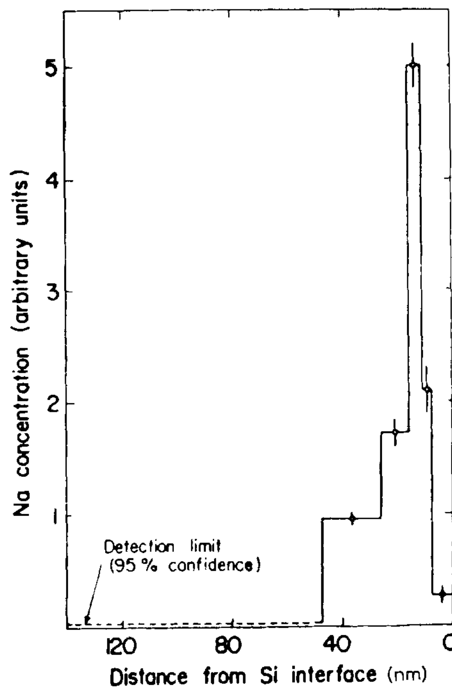

Fig. 6. Radiatracer data on Na^{22} distribution in a 6% HCl oxide after BT stress (56).

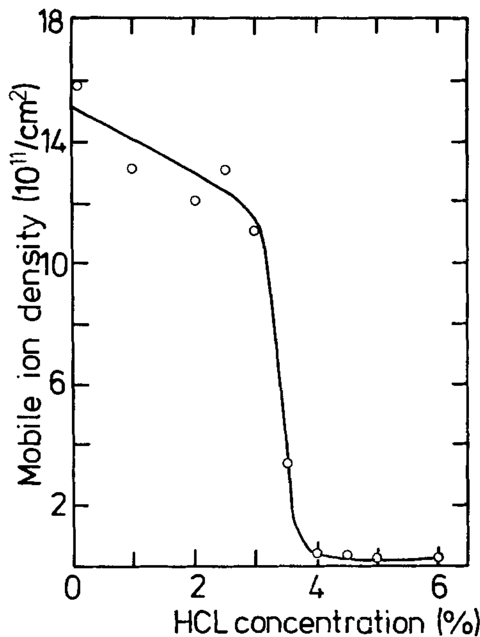

Fig. 7. Dependence of effective mobile ion density in Na-contaminated HCl oxide films on HCl concentration added during oxidation (T, 1150°C; t_{ox}, 34 min) (24).

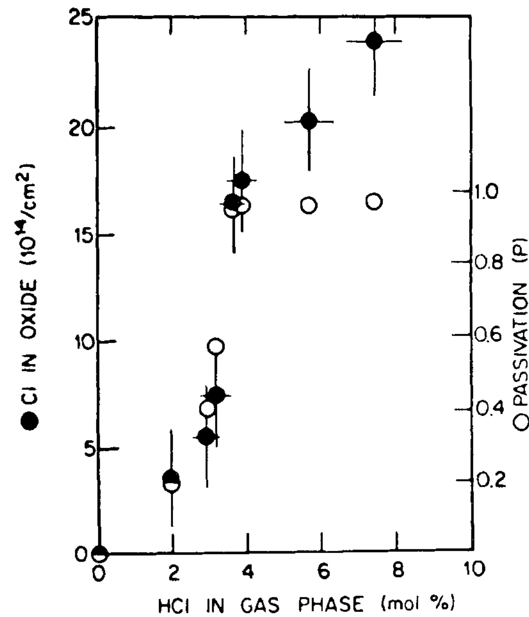

Fig. 8. Dependence of chlorine concentration (solid circles) and sodium passivation (open circles) on HCl concentration added to O_2 ambient during oxidation (T = 1200°C; t_{ox} = 30 min; contamination level, 3×10^{12} Na ions/cm^2). $p = (N_{Mob} - N_{fc})/N_{Mob}$. N_{Mob}, mobile ion density; N_{fc}, number of unneutralized Na^+ ions after BT stress (58).

dium ions are immobile in the SiO_2 films with high chlorine concentrations ($\gtrsim 10^{20}$ atoms/cm^3, 1150°C, 9% HCl). It thus appears that complete neutralization and immobilization of sodium ions are possible only up to a certain level of contamination ($\approx 10^{12}$ ions/cm^2) and that at higher Na^+ levels the effectiveness of the chlorine in the film to trap Na^+ drops off markedly. The observation that TCE oxides are not effective at high levels of contamination ($>10^{12}$ ions/cm^2) can be attributed to this fact (21). A systematic study with different chlorine and sodium concentrations would be required to obtain better understanding of the phenomenon.

The same order of equivalent ion density, which is indicative of the level of passivation, can be achieved for HCl and Cl_2 at a given temperature and oxidation time when the total amount of chlorine in the gas phase is the same (Table V). A minimum temperature larger than 1050°C is required to obtain any effect at all. Raising the temperature to 1150° or 1200°C does not result in a significant improvement in passivation property at least for devices having a sodium ion density of the order of 10^{12} ions/cm^2 (Table VI) (26).

Room temperature bias instability.—At very high fields (>5 MV cm^{-1}) chlorine oxide films exhibit instability of a magnitude not found for the oxides grown in a chlorine-free atmosphere (28, 59, 60). O_2/HCl grown layers exhibit only negative flatband voltage shifts for negative gate voltages (Fig. 9) along with a distortion of the C-V curves indicating generation of surface states (28-59). These effects show a pronounced dependence on the stressing field and on the chlorine concentration (28, 60).

More complex shifts have been reported for Cl_2 oxide (Fig. 10). They occur for both polarities of the

Table V. Effectiveness of HCl and Cl_2 concentrations on the passivation characteristics of the oxide films grown at 1150°C for 30 min on <100> Si. Na^+-contaminated aluminum electrode. Stressing condition: 250°C, 5 min, 5×10^5 V/cm (26)

stressing voltage and their direction depends on that of the bias, suggesting that both negative and positive charges must be present. However, NBS measurements on such samples failed to show any changes in the Cl profiles on stressing. At very high fields (8 MV cm^{-1}) again interface states are being generated (28, 59). The mechanism behind these shifts is as yet unknown. A similar but less pronounced instability has been observed in TCE oxides (22).

Minority carrier lifetime.—It is now well established that many high temperature processing step in silicon device fabrication result in decreased minority carrier lifetimes. This adversely affects device characteristics like storage time and leakage currents. The reduction in minority carrier lifetime is believed due to the presence of heavy metal impurities, *e.g.*, Au, Cu, Fe, and Mg, which create recombination generation centers in the forbidden energy gap of silicon. Different gettering techniques with KCN, V_2O_5, boron, or phosphorus have been used to control this parameter (61-63).

Recent studies have shown that the minority carrier lifetime can be improved by two to three orders of magnitude using a chlorine oxidation technique (64-67) (Fig. 11). This process probably removes the metallic impurities in the form of volatile chlorides. Cl_2 (2%) is more effective than HCl (3%) in removing the metals (Fig. 11). The significant effect of TCE can be concluded from storage time data. This parameter is found to increase from seconds to minutes after TCE oxidation (19, 22).

Results of experiments with a HCl oxidation source indicate that the improvement can be retained during oxidation in a chlorine-free atmosphere once the impurities are removed by HCl oxidation (Fig. 12). Sequential growth studies, *i.e.*, growth of oxide in chlorine-free atmosphere (25 nm) followed by HCl oxidation have shown improvements similar to those observed in oxides grown completely with O_2/HCl. However, annealing of oxide films grown in chlorine-free atmosphere (50 nm) in 3% HCl/N_2, *i.e.*, in an oxygen-free ambient, leads to short inversion times. An increase in lifetime was observed with the increase in oxidation temperature from 850° to 1150°C and additive concentration from 1 to 6% HCl (66). However, a low additive concentration is desirable to have good control over oxidation rates and to prevent surface roughening.

Ronen and Robinson (65) have suggested that the above-mentioned improvements can only be realized when good quality bulk crystals with low oxygen content are being used to begin with. This point deserves further study. Also, the optimization of the process temperature and of the additive concentration for different compounds is still to be carried out.

Dielectric breakdown.—Oxide defects and alkali ion contamination are the main factors responsible for poor breakdown characteristics of MOSFET gates. While studying the effects of different process variations on oxide defects, *i.e.*, spots with low breakdown strength, it was first observed that the defect density is considerably reduced by oxidizing the silicon wafers in a mixture of HCl and O_2. Even prior cleaning of the furnace tube with 6% O_2/HCl at 1150°C, followed by oxidation, results in a 60% reduction of the defect density (68, 69).

A detailed study using different halogen-containing species like HCl, Cl_2, TCE, HBr, and CCl_4 has been carried out by Osburn (69). All additives lead to reduced defect densities. A minimum defect density was observed for the oxides grown in a 3% HCl ambient (Fig. 13). This ambient gives a pronounced effect at 1%. In general, the results indicate that for all additives the lowest defect density can be achieved at concentrations about a factor of two below those which produce nonuniform films. Figure 14 indicates the improvement observed in the statistical distribution of the breakdown voltages for oxides grown in 3% HCl or 2% Cl_2.

Analogous to oxides grown in chlorine-free atmosphere, the defect density in HCl oxide increases with

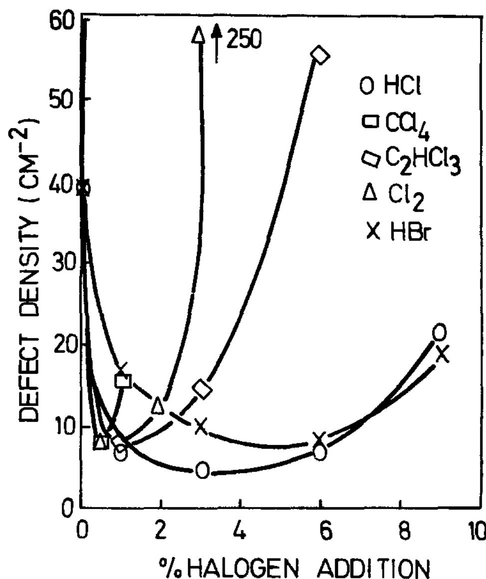

Fig. 13. Effect of halogen concentration during oxidation on defect density of SiO_2 films (T, 1000°C) (69).

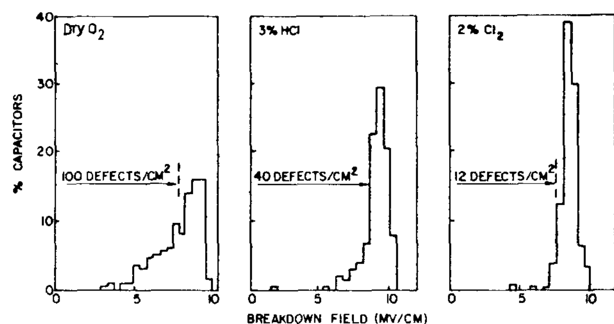

Fig. 14. Distribution of dielectric breakdown strength in HCl and Cl_2 oxides grown at 1000°C (69).

oxidation temperature, as can be seen from the Fig. 15. This enhancement in defect density becomes very pronounced at 1150°C; HCl oxides grown at this temperature or higher lose their favorable breakdown characteristics (69).

For 2% HCl oxides accelerated breakdown tests have shown an increase in wear-out time of up to two orders of magnitude over those grown in pure O_2 at 1000°C. Also, the spread in failure times is reduced. This increase in wear-out times is believed to be due to a retardation of the so-called electrochemical-type degradation during accelerated stressing (69).

Cl_2 oxides grown at 1000 C showed shorter wear-out times than oxides grown in a chlorine-free atmosphere. This result is somewhat surprising because Cl_2 oxides are superior to HCl oxides with regard to improving the initial breakdown characteristics (69).

Investigations of the dependence of the wear-out time on the additive concentration have shown that this dependence is almost linear up to 3% HCl. The positive dependence continues up to 6% HCl and saturates only at this concentration. The wear-out time also increases with oxidation temperature. To obtain any improvement at all an oxidation temperature above 850°C is required. At the same temperature (850°C) a minimum defect density (Fig. 15) is observed. In contrast, the films grown at 1150°C show poor initial breakdown characteristics but maximum wear-out times. This indicates that these two parameters are influenced differently by the presence of HCl in the oxidation ambient (69).

In general, additives like HBr and C_2HCl_3 which contain both halogen and hydrogen improve the dielectric integrity of the SiO_2 films. On the other hand, Cl_2 and CCl_4 also cause adverse effects like shorter wear-out times. It seems reasonable to suspect that the difference between the two groups of additives is due to the presence of the reaction product H_2O in the ambient for the first group of materials. This may reduce the attack of chlorine on the silicon surface. As expected, chlorine oxidation also yields improved breakdown characteristics in devices intentionally contaminated with sodium (69).

Device performance.—In this section we summarize the improvements in characteristics observed for devices fabricated using chlorine oxidation. Mesa-type epitaxial SOS bipolar transistors have shown low leakage current, improved forward and reverse characteristics, and increased breakdown voltage. This effect is probably due to the removal of metallic impurities which results in increased minority carrier lifetimes, as demonstrated in Fig. 16. The low frequency gain of the devices was increased by a factor of two to ten after chlorine oxidation. A significant increase in the base transit time and the minority carrier lifetime has also been noted (65).

Al- and Si-gate MOS transistors have been fabricated to compare the over-all performance of chlorine-oxidized devices with those with oxides grown in a chlorine-free atmosphere and also to see the possible effect of further processing on properties of chlorine oxides. The devices having chlorine gate oxides were found to be more stable (23).

Three phase polysilicon CCD's, delay lines, analog memories, and image sensors using TCE oxide/Si_3N_4 as a gate insulator exhibit improved performance (40). CCD's fabricated with TCE oxide as a gate insulator show significantly higher storage time (by one to two order of magnitude) than oxides grown in a chlorine-free atmosphere (70). The increase in bulk generation lifetime to 300-350 μsec and the low surface generation velocity (0.3-0.4 cm/sec) results in dark currents as low as 5 nA/cm^2 for normal CCD operation. Dark current spikes are considerably reduced.

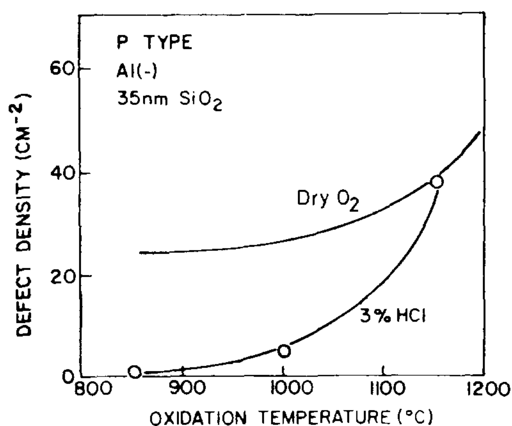

Fig. 15. Dependence of defect density on oxidation temperature for dry and HCl oxide (69).

Conclusions

The wide improvement observed in Si/SiO_2 interface properties using HCl with the oxidation process clearly indicates its superiority over other chlorine-containing species. Even though Cl_2 is one of the more effective gettering agents, its large reactivity toward the silicon surface even at moderate temperatures and concentrations is a drawback. The corrosive nature of HCl and the problems with handling this material have instigated the search for more manageable chlorine additives with similar properties. Here TCE appears to be rather attractive since it is much easier to handle, contains sufficient chlorine to show effective gettering, and also provides a source of hydrogen. However, the available data on TCE oxidation are still rather limited.

It may be seen from this review that it is impossible to optimize the process conditions for all parameters at

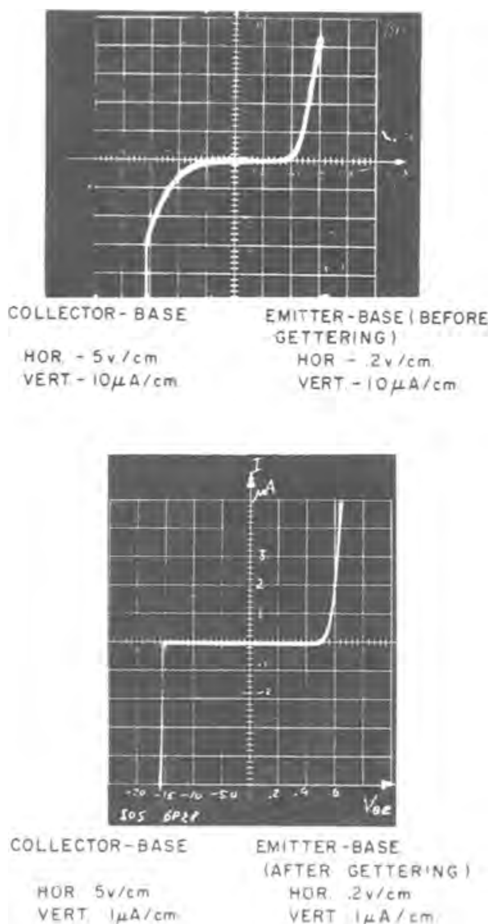

Fig. 16. Improvement in the *I-V* characteristics of collector-base and emitter-base junctions in SOS bipolar transistor after HCl_2 gettering (1% Cl_2, 2 hr at 950°C) (65).

the same time. Specifically, rather different growth conditions are required for achieving good dielectric breakdown characteristics and for passivation and elimination of as-grown stacking faults or defects. Here one has to compromise depending on the nature of the devices. Except for the last two effects, all possible improvements can be realized to a reasonable extent by growing the oxide at 1100°C with 3% HCl. Furthermore, one may expect that if the furnace tube has been precleaned and relatively little contamination will occur during further processing, addition of 4-5% HCl at the same temperature may yield a reasonably good passivation.

With TCE all improvements could be realized in the temperature range of 1100°-1200°C and at concentrations of 0.3-0.4% TCE. Only the high process temperature is a disadvantage of this chlorine compound.

Note added in proof.—Since this manuscript was completed a few publications pertinent to the subject matter of this review appeared. References (71-73) present more extensive data on the effect of Cl_2 and HCl on oxidation kinetics, roughening of the silicon surface, and negative bias instability, respectively. Particularly interesting is the conclusion of Monkowski *et* al. (74) that a second phase is formed near the Si/SiO_2 interface during chlorine oxidation. A study by Pearce and Rozgonyi (75) appears to indicate that the effectiveness of chlorine in suppressing or eliminating oxidation-induced stacking faults is mainly due to the gettering of interstitial oxygen from the bulk of the silicon by this element.

Acknowledgments

The authors wish to thank Dr. G. J. Declerck, Katholieke Universiteit, Leuven, Belgium, for useful discussions and also for making available some of his unpublished results. They are indebted to Dr. C. M. Osburn, IBM Research Center, Yorktown Heights, New York, for bringing to their attention some very recent publications on chlorine oxidation.

Manuscript submitted June 27, 1977; revised manuscript received Oct. 26, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by the Technical University of Aachen.

Electrical Activation of Implanted Arsenic in Silicon during Low Temperature Anneal

Hidetoshi Nishi, Teruo Sakurai, and Tsuneo Furuya

Fujitsu Laboratories Limited, 1015 Kamikodanaka, Nakaharaku, Kawasaki 211, Japan

ABSTRACT

The correlation between the electrical activation of implanted As in Si and the recrystallization of the amorphous layers during low temperature anneals at 440°-650°C is studied by Hall effect measurements and glancing incidence channeling analysis. The results show that the activation process is described well by a simple epitaxial regrowth model. Implanted As atoms are electrically activated during the recrystallization with an activation energy ~2.7 eV. The electrical activation depends strongly on the crystal orientation of the wafer. In (100) oriented wafers the activation rate is highest, and we can achieve almost complete activity. However, in (110) and (111) oriented wafers, about 20 and 35% of As atoms are unactivated, respectively. It is confirmed from channeling analysis that lattice disorder remains in (110) and (111) oriented wafers. It is speculated that these defects act possibly as carrier compensating centers, thereby reducing the electrical activity.

Many investigators have been interested in a detailed understanding of the correlation between electrical activation of implanted dopants and the reordering of lattice damage created by ion implantation after annealing (1-4). For high dose implantation, if a continuous amorphous layer to the surface is formed during implantation, this layer will regrow epitaxially on the underlying crystalline substrate during annealing at temperatures around 600°C (5). A simultaneous reduction of the sheet resistivity is observed in this temperature range, indicating that the implanted dopants are incorporated onto lattice sites (6).

Channeling effect measurement is a useful tool for directly observing reordering of lattice disorder. Recent works of Csepregi *et al.* show that the regrowth of amorphous Si layers formed by self-ion (Si^+) im-

Key words: ion implantation, orientation dependence, epitaxial regrowth, recrystallization.

plantations is linear with time with an activation energy of 2.3 eV (7). It has also been observed that there are marked differences in the regrowth behavior depending on the crystal orientation of the wafers (8). It is reasonable to believe that the orientation-dependent regrowth behavior will affect the electrical activation of an implanted dopant, and will also be reflected in the annealing behavior at high temperature around 1000°C (9).

The purpose of the present paper, then, is to study the electrical activation of high dose implanted As in Si during the recrystallization process and the effect of crystal orientation on electrical activation. The electrical evaluation of the implanted layers, such as annealing characteristics of sheet carrier concentrations or carrier profiles, were made by Hall effect measurements. Glancing incidence channeling analysis was employed to observe recrystallization occurring some hundreds of angstroms beneath the surface for comparison with the electrical activation behavior. The glancing incidence channeling technique has recently been demonstrated by Williams to be a powerful method for investigating disorder distributions with a depth resolution of a few tens of angstroms (10).

First we discuss the electrical activation behavior which can be explained by a simple epitaxial regrowth model. Next, we discuss the effect of crystal orientation of the wafers on the electrical activation.

Experimental

The samples used in the present work were epitaxially grown p-type Si with resistivities of 1-5 Ω-cm. The crystal orientations of the wafers were (100), (110), and (111). The As implantations were carried out at 100 keV with substrate at room temperature. The implanted dose was 1×10^{15} cm^{-2}, and the dose rates ranged from 0.5 to 1.0×10^{12} cm^{-2} sec^{-1}. The critical dose for forming an amorphous layer by 100 keV As implantation is around 3×10^{14} cm^{-2} (6), so the dose studied in these experiments was sufficient to create continuous amorphous layers. Annealing of the implanted specimens was done in a dry nitrogen atmosphere at temperatures ranging from 440° to 650°C.

Electrical evaluation of the implanted layer was made using Hall effect and sheet resistivity measurements using a van der Pauw structure. Before As implantation the electrical contact areas for the Hall measurements were formed by a phosphorus diffusion with a surface concentration of 1×10^{20} cm^{-3} and a junction depth of about 1.5 μm. Carrier profiles were then determined from Hall effect and sheet resistivity measurements utilizing anodic oxidation and HF stripping methods. The thickness of anodic oxides was estimated by ellipsometry. The conversion ratio from SiO_2 thickness to etched layer thickness was determined using a Talystep and was found to be 0.58 ± 0.03.

The glancing incidence backscattering and channeling analysis were performed using 1.5 MeV He^+ ions. The incident direction of a beam was aligned with the <101> axis of a (110) oriented sample by tilting the sample 60° away from the <110> axis along the $(\bar{1}11)$ plane. The backscattered ions through an angle of 165° (of about 75° with respect to the surface normal) were detected by a solid-state detector. The directions of the <110> axes of the (110) samples deviated 5° at maximum from the surface normal of the samples. The energy resolution of the measuring system was about 13 keV. Corresponding depth resolution depended on the deviation of the direction of <110> axis from that of the surface normal and was 90-65Å. The thickness of the amorphous layers was determined using the stopping power data by Ziegler and Chu (11).

Results and Discussions

Recrystallization of amorphous layers.—Recrystallization behavior of the amorphous layers created by 100 keV As implantation to a dose of 1×10^{15} cm^{-2} was observed using glancing incidence channeling analysis. The upper part of Fig. 1 shows the backscattering spectra resulting from 1.5 MeV He ions directed along the <101> axis of (110) oriented specimens. Data indicated by the open circles and by + marks correspond to the spectrum obtained after anneals at 500°C for 60 and 200 min, respectively, and the closed circles correspond to as-implanted. The aligned spectra for <110> directions of the same samples were also measured and the results are shown in the lower part of Fig. 1 for comparison. As can be seen from the figure, the amorphous layer on the underlying crystalline substrate is characterized by a steplike shape. The thickness of the amorphous layer can be estimated from the energy width at half-height of the step using the stopping power data (11).

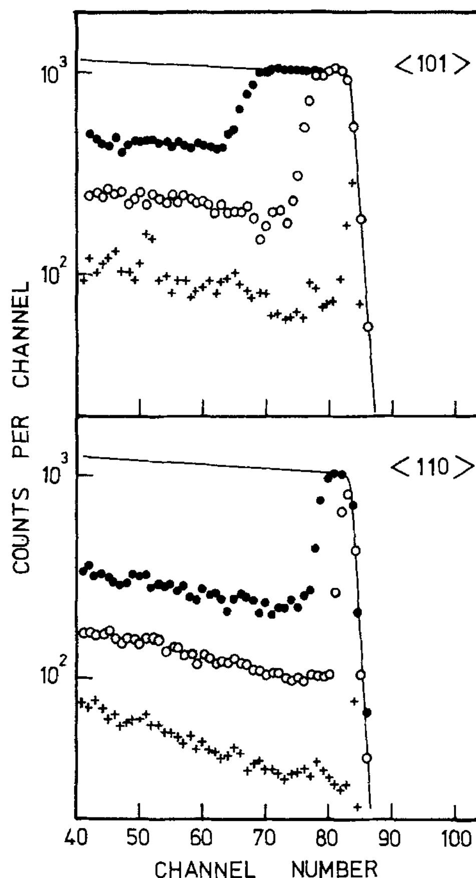

Fig. 1. Backscattering energy spectra for 1.5 MeV He ions directed along the <101> (upper) and the <110> (lower) of the (110) oriented Si. The spectrum indicated by the closed circles corresponds As 1×10^{15} cm^{-2} as-implanted. The open circles and + marks show the spectra after anneal at 500°C for 60 and 200 min, respectively.

The improvement of the depth resolution offered by utilizing the glancing incidence channeling technique can be easily seen by comparing the two corresponding spectra shown in the upper and the lower parts of Fig. 1. For example, in the <110> spectrum for the 60 min annealed sample, the surface peak does not coincide with random yield, however, in <101> spectrum we can clearly observe that a thin amorphous layer still remains.

From the spectrum indicated by the closed circles in Fig. 1, it is seen that a continuous amorphous layer of thickness 1100 ± 90Å was formed due to the implantation. After the anneal for 60 min at 500°C, this amorphous layer was reduced to 440 ± 70Å, indicating that the amorphous layer regrew epitaxially from the crystalline substrate to the surface with a regrowth velocity of about 11 Å/min. The amorphous layer is fully annealed as shown in the spectrum for 200 min anneal, however, the spectrum still indicates that a small frac-

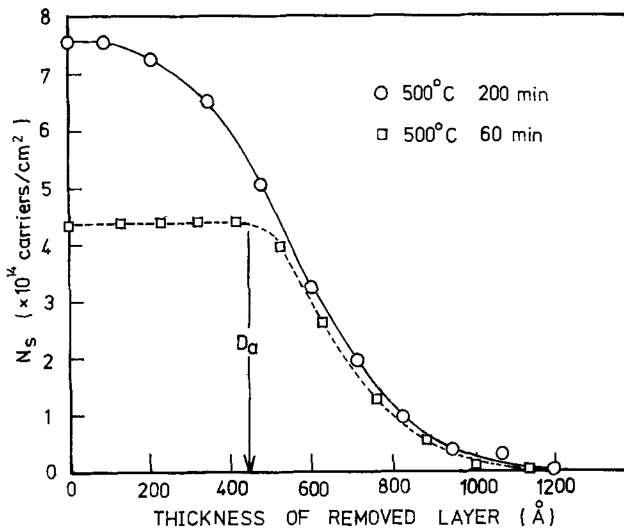

Fig. 2. The variations of the measured N_S's for the (110) oriented samples annealed at 500°C for 60 min (□) and for 200 min (○) as a function of the etched depth. The thickness of the residual amorphous layer after the 60 min anneal is indicated by D_A.

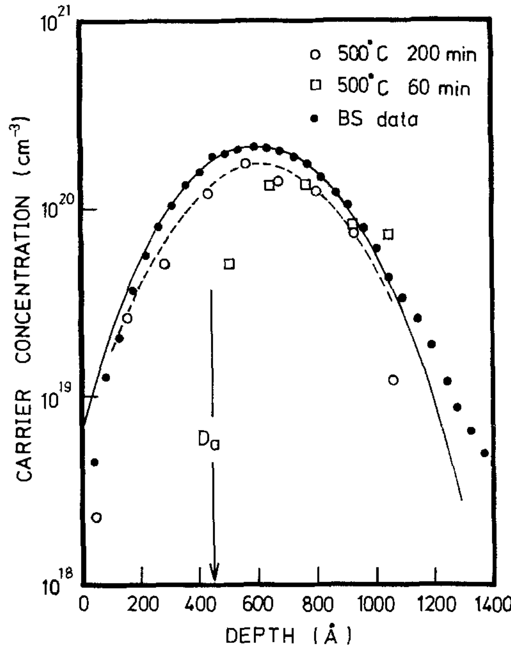

Fig. 3. Carrier profiles obtained from the data shown in Fig. 2. The depth distribution of As atoms is also shown indicated by the closed circles. The solid line represents the Gaussian profile with R_p 600Å and ΔR_p 240Å.

tion of disorder remains in the recrystallized layer; this is mentioned in a later section relating to the orientation-dependent electrical activity.

Carrier profiles were obtained from the same set of samples used in the channeling analysis. In Fig. 2, the measured N_s's are plotted as a function of the etched depth. The resulting carrier profiles are shown in Fig. 3 together with the depth distribution of As atoms obtained by the glancing incidence backscattering analysis. In both figures the data indicated by the squares and the open circles represent the results for 60 and 200 min anneals, respectively. As is seen in Fig. 2, the measured N_s's for the 60 min annealed sample exhibited no change from the surface to a depth of around 440Å, denoted by D_A in the figure. In the region deeper than 440Å, however, the N_s's for the 60 min annealed sample coincide well with that of the 200 min annealed sample. Considering that the amorphous layer regrew to a reduced thickness of about 440Å after the 60 min anneal at 500°C, it is seen that the ionized carriers exist only in the recrystallized layer, with the activation occurring from the amorphous/crystalline interface to the surface corresponding to the regrowth of the amorphous layer. We now introduce an epitaxial regrowth model and compare it with the electrical activation behavior.

Epitaxial regrowth model.—Based on the conclusion, as described above, that electrical activation of implanted As atoms occurs only in the recrystallized layer, we make the following three assumptions: (*i*) electrical activation ratio, η (the number of carriers in unit area per implanted dose), is constant throughout a recrystallized layer; (*ii*) amorphous layer created by As implantation regrows with a constant velocity, v, at annealing temperature, T_A; and (*iii*) v is independent of As concentrations. Therefore, for an As atom distribution with a Gaussian profile represented by the range parameters R_p and ΔR_p, the sheet carrier concentration, $N_s(t)$, after an anneal for time t at a temperature T_A is described by the following equation

$$N_s(t) = \frac{\Phi\eta}{\sqrt{2\pi}\Delta R_p}\int_{\infty}^{D_A} \exp\left\{-\frac{(x-R_p)^2}{2\Delta R_p^2}\right\} dx \quad [1]$$

where $D_A = D_O - vt$, Φ is the implanted dose, and D_O and D_A represent the thicknesses of the amorphous layer after the implantation and the anneal, respectively.

To compare this model with experimental results, the range parameters, R_p and ΔR_p, were estimated from the glancing incidence backscattering data shown in Fig. 3 indicated by the closed circles. The solid line in the figure represents a Gaussian profile with R_p 600Å and ΔR_p 240Å. These values agree well with those reported by Sigmon *et al.* (12). The distribution of As atoms fits well to the Gaussian profile except close to the surface and the region deeper than 1000Å.

Comparison of the experimental results with the calculated ones for a (100) oriented sample annealed isothermally at 460°C is shown in Fig. 4. The calculated curve (solid line) was derived from Eq. [1] using range parameters, R_p = 600Å and ΔR_p = 240Å, which were determined by the glancing incidence backscattering analysis and by using other parameters such as D_O = 1400Å, η = 0.95, and v = 3.5 Å/min. The value of η depends strongly on the crystal orientation of the wafer; this is described in the next section. In every calculation η was determined from the saturation value of N_s obtained after a sufficiently long anneal. The value of D_o used in every calculation is about 300Å

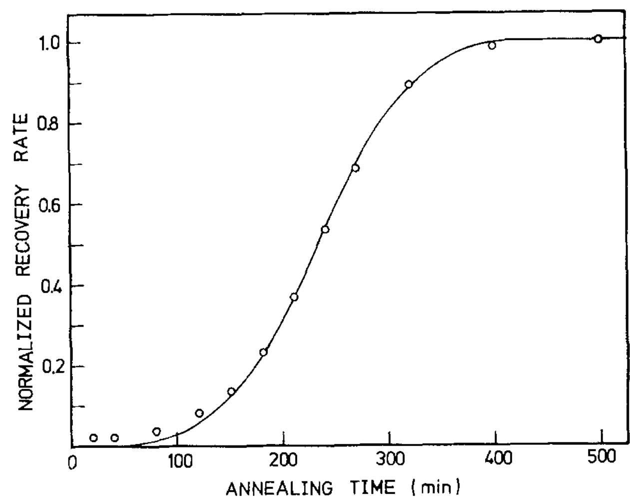

Fig. 4. Comparison of the experimental results with the calculated using the epitaxial regrowth model. The sample was (100) oriented and annealed at 460°C

larger than that obtained by glancing incidence channeling analysis; this is also discussed later. Agreement between the experimental and calculated values are quite good, except at the initial stage of the annealing.

For the epitaxial regrowth model, we adopt the assumption that As atoms are activated with a constant activation ratio in the whole regrown layer. To justify this assumption we examine (111) oriented wafers in which the activity, η, is only about 65% as is described in the next section. The results for annealing at 500°C are shown in Fig. 5. The solid line in the figure represents the calculated result from Eq. [1] with the condition that η is 0.65 and v is 1.3 Å/min. Calculation was also made for the assumption that the carrier concentration is limited to a certain value. To obtain the same activity, 65%, for the whole recrystallized layer, we assume that this limit is 1.2×10^{20} cm^{-3} and the activity is 100% for As concentration below this limit. The calculated result is shown by the dashed line in Fig. 5. The solid line fits the experimental results better than the dashed line, proving that the activation ratio is constant in the whole region and no observable saturation of carriers occurs for the dose of 1×10^{15} cm^{-2}.

Calculations were also made using the equation based on the epitaxial regrowth model and compared with the experimental results for (100), (110), and (111) oriented wafers annealed isothermally in the temperature range 440°-650°C. Good agreement was obtained in every case using the parameter $D_O = 1400$Å while only changing the assumed value of the epitaxial regrowth velocity, v, and assuming η to be equal to the final activity obtained when the regrowth is completed. The value D_O used in every calculation is about 300Å larger than that observed by glancing incidence channeling analysis. The regrowth velocity is actually dependent on impurity concentration (13), therefore, it is reasonable to assume that the v used in the calculations reflects the regrowth velocity in highly As-doped layer. In the initial stage of annealing, the amorphous layer regrows with slower velocity than that used in the calculations because of low As concentrations. This effect, together with a fact that a small number of implanted As atoms are located beyond the amorphous region (see the As distribution in Fig. 3), leads to a smaller calculated value than the experimental ones in the initial stage of annealing as can be seen in Fig. 4 and 5. Furthermore, the quantity η may not be constant throughout the whole regrown layer; however, this factor is not sufficiently large to be detected in the experiments studied here.

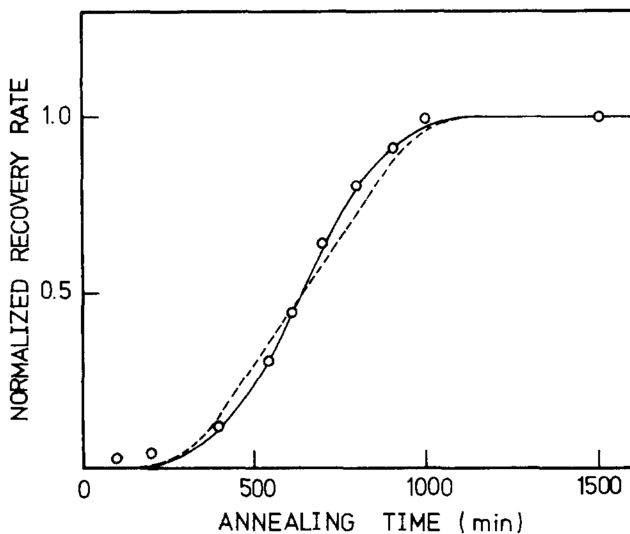

Fig. 5. Comparison of the experimental results with the calculated for the (111) oriented sample annealed at 500°C. The solid and the dashed curves represent the calculated results assuming that the activity is constant in the whole recrystallized layer and that the carrier concentration is limited at 1.2×10^{20} cm^{-3} and the activity is 100% below this value, respectively. In both calculations v is taken to be 1.3Å/min.

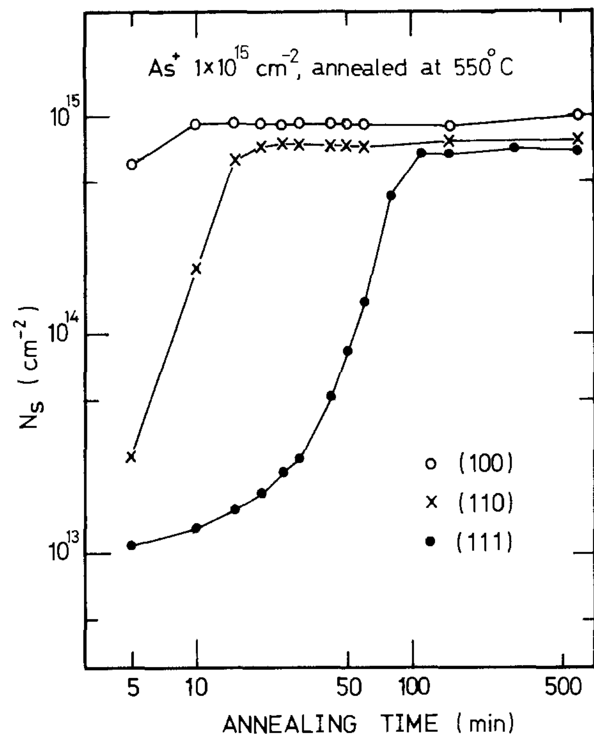

Fig. 6. Orientation dependence of isothermal annealing behaviors of N_S's at 550°C.

Crystal orientation dependence.—In this section we study the effect of crystal orientation of a wafer on the electrical activation of As implanted in silicon.

Isothermal annealing characteristics of the measured N_S's are shown in Fig. 6, comparing the results for (100), (110), and (111) oriented samples. Implanted dose was 1×10^{15} cm^{-2}, and annealing was carried out

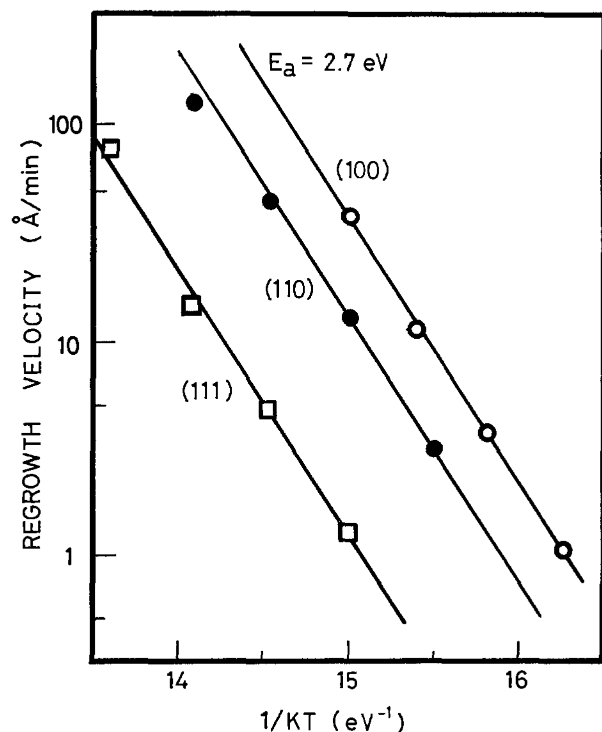

Fig. 7. Arrhenius plot of a regrowth velocity used in the calculations based on the epitaxial regrowth model.

at 550°C. It can be seen from the data that both the activation rate and the final activity are strongly dependent on the crystal orientation of the wafer. For the (100) oriented wafer, the electrical activation progresses most rapidly and results in almost complete activity, however, it progresses most slowly and results in the lowest activity (~65%) for the (111) oriented wafer. The (110) oriented sample exhibits an intermediate characteristic to the (100) and the (111) oriented samples. For 1×10^{14} As ions cm^{-2} implanted Si, the annealing characteristics of measured N_s's did not depend on the crystal orientation of the wafer, indicating that the orientation dependence is due to the formation of the amorphous layer by As implantation. Activation behavior showed similar tendencies at the other annealing temperature studied (440°-650°C).

Figure 7 shows Arrhenius plot of v used in the calculations of the previous section. It is found from this figure that v is about 3 and 29 times higher for (100) wafers than for (110) and (111) oriented wafers, respectively. The orientation dependence of the activation rate is, therefore, attributed to the difference in the regrowth velocity for the various orientations. The activation energy was determined from the data to be 2.8 ± 0.2 eV for (100), 2.6 ± 0.3 eV for (110), and 2.7 ± 0.2 eV for (111) oriented samples. The activation energy for the three different orientations can be regarded to be equivalent, ~2.7 eV. The value obtained from this work is close to the activation energy for the regrowth of intrinsic amorphous Si (2.3 eV) measured by Csepregi *et al.* (7).

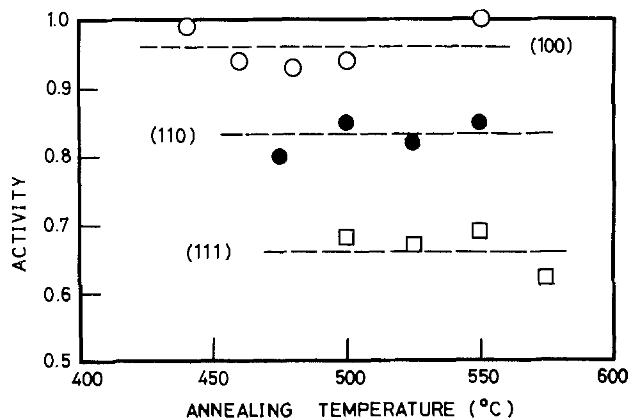

Fig. 8. Temperature dependence of the final activity obtained when the regrowth completes at each temperature.

Figure 8 shows the temperature dependence of the final activity obtained after an anneal sufficiently long so that the regrowth is completed at each temperature. It can be seen from the figure that the electrical activity depends only on the crystal orientation. In (100) oriented wafers nearly complete activity (0.96 ± 0.04) can be achieved, however, the activities are fairly low in (110) and (111) oriented wafers, 0.83 ± 0.04 for (110) and 0.66 ± 0.04 for (111). To compare with these results, the crystalline properties of the recrystallized layers were examined by channeling analysis.

Backscattering spectra for 1.5 MeV He^+ ions incident on <100> for (100) oriented, <110> for (110) oriented, and <111> for (111) oriented samples are shown in Fig. 9A, B, and C, respectively, along with that of an unimplanted sample. All the samples were annealed at 500°C for a sufficiently long time so that the regrowth proceeded to completion as shown in Table I. Data for the recrystallized layers are indicated by the closed circles and the solid lines represent the aligned spectra for the unimplanted samples. The surface peak for the unimplanted samples around the channel number of 84 corresponds to native silicon dioxide. In the (100) oriented sample (Fig. 9A) we cannot observe any difference between the aligned spectra for the recrystallized and unimplanted layers. The aligned spectrum for the recrystallized (110) oriented sample (Fig. 9B) exhibits a slightly higher scattering yield than for the unimplanted, except the surface peak. Discrepancy between the aligned spectra of the recrystallized and the unimplanted samples is quite remarkable for (111) oriented samples as is seen in Fig. 9C. This spectrum shows that lattice disorder remains in the recrystallized layer of (111) oriented sample. The surface peak of the spectrum is larger than the unimplanted sample, indicating that ~1.6×10^{16} displaced Si atoms per cm^{-2} exist at the surface layer.

The minimum yields for these samples are determined from the channeling spectra shown in Fig. 9A, B, and C, and are listed in Table I together with the measured N_s's for the same samples. The minimum yield listed is the averaged value corresponding to a depth 500-600Å beneath the surface. In the (100) oriented sample the minimum yield is equivalent to that of the unimplanted sample. For the (110) orientation the difference in the minimum yield between the recrystallized and unimplanted samples is within ex-

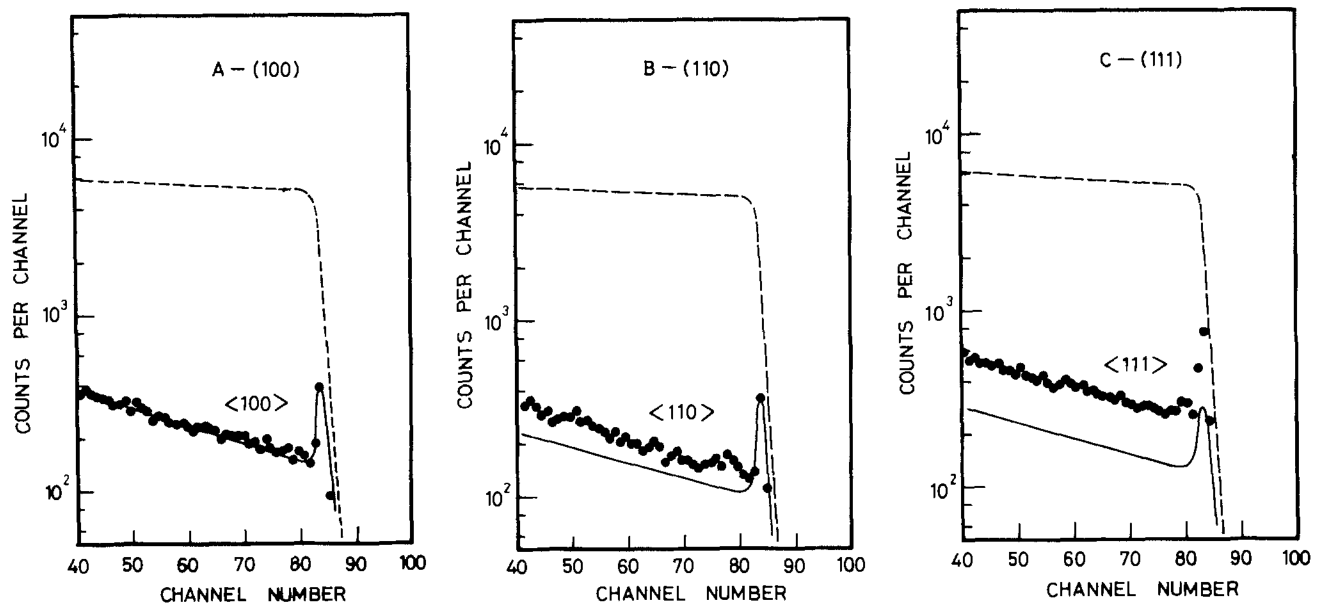

Fig. 9. Comparison of the aligned spectra between the recrystallized and the unimplanted samples. The results for the (100), (110), and (111) oriented samples are shown in A, B, and C, respectively.

Table I. Comparison of the minimum yields for channeling with the measured N_S.
The minimum yields are obtained at the depth 500-600A

Sample orientation	Axis	x_{min} (%) Implanted	x_{min} (%) Unimplanted	N_s (cm^{-2})	Annealing
(100)	<100>	3.1 ± 0.3	3.1 ± 0.5	9.5 × 10^{14}	500°C 85 min
(110)	<110>	2.7 ± 0.3	2.2 ± 0.2	8.4 × 10^{14}	500°C 200 min
	<101>	6.1 ± 0.3	2.0 ± 0.3		
(111)	<111>	5.1 ± 0.4	2.5 ± 0.6	6.8 × 10^{14}	500°C 1500 min

perimental error. However, the result from the glancing incidence channeling analysis clearly show that lattice disorder remains in the recrystallized (110) layers. This can be seen because of the improvement of sensitivity in detecting lattice disorder available using the glancing incidence technique (10). The minimum yield for the recrystallized (111) oriented sample is about twice as large as for the unimplanted sample. Increase in the scattering yield due to lattice disorder observed at the surface of (111) oriented sample is calculated to be less than 10^{-3} according to the single scattering model (14). Therefore, the difference in minimum yields is caused by disorder remaining in the recrystallized layer. The minimum yield for <110> channeling for the recrystallized (111) oriented sample was also measured and it showed about twice as large a value as for the unimplanted sample. The orientation dependence observed in the minimum yield corresponds well with that of the N_S's listed in Table I. The lattice location of implanted As atoms might be different in the differently oriented samples, however, the correlation between the channeling measurements and the activation of implanted As in samples of different orientation indicates that the lower activity for (110) and (111) oriented samples could be due to carrier compensation by residual defects remaining in the recrystallized layers.

Summary

The electrical activation behavior of implanted As in Si during recrystallization of amorphous layers has been studied. The results obtained in this study are summarized as follows:

1. The activation behavior is described well by the epitaxial regrowth model. The activation occurs from the amorphous/crystalline interface to the surface corresponding to the regrowth of the amorphous layer.
2. The activation energy of implanted As is ~2.7 eV, close to that reported for the regrowth of intrinsic amorphous Si.
3. The activation rate depends on the crystal orientation of the wafer, being highest for (100) orientation (about 3 and 29 times larger than for (110) and (111), respectively). This is attributed to the difference in the regrowth velocity for the orientations.
4. Lattice disorder remains in the recrystallized amorphous layer on (111) and (110) wafers, and these residual defects possibly act as carrier compensating centers, thereby reducing the electrical activities by about 17 and 34% in (110) and (111) oriented wafers, respectively.

Acknowledgments

The authors would like to express their thanks to Dr. T. Oshida and Dr. O. Ryuzan for their encouragements throughout this work, to T. Hisatsugu, S. Hashimoto, and T. Kaneda for valuable discussions and comments on this work. They also thank T. Sato, S. Tatsuta, T. Inada, and H. Kawata for their experimental help, and to S. Yamamoto for Talystep measurements. One of the authors (H.N.) would like to thank Dr. A. Revesz for helpful comments on this work.

Channeling experiments were performed using the 2.0 MeV Van der Graaff accelerator at Government Industrial Research Institute, Osaka. The authors greatly appreciate I. Fukui and M. Sato for affording the use of the facility.

Manuscript submitted May 13, 1977; revised manuscript received Oct. 17, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by Fujitsu Laboratories Limited.

Controlling the Interfacial Oxide Layer of Ti-Al Contacts with the CrO_3-H_3PO_4 Etch

T. A. Shankoff, C. C. Chang, and S. E. Haszko

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The cause of high resistance contacts between Al integrated circuit metallization and subsequently applied Ti/Pt/Au beam leads has been evaluated by direct measurement of the surface Al-oxide thickness at various steps in the processing sequence. The Al-oxide layer thicknesses were estimated using Auger electron spectroscopy and gravimetric measurements and were correlated with Hg-probe voltage breakdown observations. Processed MOS wafers incorporating ethylene glycol-buffered HF cleans typically contain 50-60Å of Al oxide in bonding pad regions just prior to Ti deposition. It was demonstrated that the Ti nullifies about 45Å of the oxide by interfacial reaction; therefore, products having >50Å oxide will be yield-limited by high resistance beam-to-Al contacts. A dielectric breakdown strength of 0.09 V/Å was found for the surface Al oxide obtained during processing, and the effective electron tunneling distance was estimated to be 12Å. A convenient method of eliminating surface Al oxide just prior to Ti deposition was demonstrated. An Al-oxide etchant containing CrO_3-H_3PO_4-H_2O removes Al oxide, leaving only an equilibrium final film of 25-30Å thickness, and does not attack underlying Al metal. The effectiveness of such a surface treatment has been confirmed by the excellent contact yields obtained with two MOS split device lots.

Electrical contact to Al metallization in Si integrated circuits is sometimes difficult to establish because of the rapid growth of a surface oxide layer during processing. If this oxide is sufficiently thick, a contact will be open until enough voltage is applied to cause dielectric breakdown.[1] Two approaches that can be considered as potential solutions to this problem are backsputtering and chemical etching. Backsputtering has the advantage that the oxide thickness can in principle be reduced to zero if the subsequent metallization is applied without exposure to air. The disadvantages include: possibility of radiation induced MOS damage; potential for contamination of the sputtering system; redeposition of previously sputtered material, especially from the substrate table; and the need for frequent monitoring of system cleanliness. The chemical etch procedure does not have these disadvantages, but the oxide thickness can never be reduced to zero.

We show below that because of a finite electron tunneling distance and because a Ti film deposited onto Al will effectively consume a certain amount of Al oxide, it is not necessary to reduce the oxide thickness to zero to obtain Ti-Al contacts with zero breakdown voltage. The present study was conducted in order to carefully define Al-oxide thickness tolerances for subsequent Ti metallization, and to optimize a chemical etching procedure based on the CrO_3-H_3PO_4-H_2O Al-oxide solvent system (1). Oxide thicknesses were determined using Auger spectroscopy and gravimetric measurements, while breakdown voltages were obtained using the Hg probe. We describe our model of the Ti-Al contact, and the procedures for preparing Ti-Al contacts with zero breakdown voltage, using the chemical treatment.

Experimental

The Al test films used in this work were 1.5 μm thick, deposited on oxidized 3 in. Si wafers by E-gun evaporation without intentional substrate heating. The Al was doped with 1 weight percent (w/o) Cu. Patterning was accomplished using negative photoresist and A-30 stripping (Allied Chemical proprietary solvent system). Several wafers were also examined after removal from MOS device lots at appropriate points during processing. The Al processing sequence investigated for this work is shown on the left-hand side of Table I.

Ti dots were filament evaporated onto the Al surface through a shadow mask for the experiments on the effect of Ti on the surface Al-oxide. Other methods of Ti dot preparation for this evaluation (evaporated and sputtered Ti patterned by photolithography and chemical or plasma etching) resulted in data that were difficult to interpret, apparently owing to etching residues from the interaction of the Al-oxide surface with the uniformly deposited Ti.

Oxide breakdown voltages were measured using a Hg probe, which was simply a drop of Hg, about 1 mm in diameter, held over the position of interest by a Pt wire loop. The Pt wire also served as part of the electrical circuit for the probe. Contact to the Al film was established by pushing a second Pt wire directly into the Al. The breakdown voltage was obtained from *I-V* curves, generated on a Tektronix 576 curve tracer. A sufficient number of measurements were made (between 5 and 10) so that the standard deviation was less than ±5%.

The etchant used for surface Al-oxide removal is the CrO_3-H_3PO_4-H_2O system. Although the effect of this etch on both Al and Al-oxide surfaces has been extensively investigated (1, 2), the effects on actual LSI MOS circuits was not known, and the useful

Table I. Aluminum oxide thicknesses during processing*

Processing step	Al-oxide thickness (A)
1. Deposit Al	20-30
2. Al photolithography, A-30 resist strip	25-35

4. 30 min, 450°C hydrogen anneal	40-80
5. EG:BHF:H_2O clean 2	40-60
6. O_2 plasma clean	
7. Plasma silicon nitride window etch (plasma)	40-60
8. EG:BHF:H_2O clean 3	40-60
9. Ti deposition	

* The processing sequence tabulated here is incomplete in the sense that steps not directly relevant to the Al-oxide problem have been deleted.

** EG:BHF:H_2O is an equivolume mixture of ethylene glycol, 7:1 buffered HF, and water.

[1] For example, contact failures on some MOS devices were characterized by open Al-Ti contacts detected with 1-1.5V test voltage, which "healed" when the voltage was raised to 2-3V, indicating a thin dielectric barrier.

etchant compositions and thickness variations of the final, equilibrium Al oxide over different areas of a given device chip have not been previously measured. Therefore, we investigated these factors to determine the optimum process conditions for the present applications.

One of the methods used to determine the amount of surface Al oxide was an extension of an established ASTM gravimetric procedure (3) wherein a sample is weighed, exposed to a CrO_3-H_3PO_4-H_2O solution to dissolve the oxide surface, and is reweighed. Since it has been established (3) that the equilibrium loss of Al metal in the etchant is about 2 Å/min, the weight loss is due to etched Al oxide once correction for Al loss is made. In the ASTM method, typical weight losses in the milligram range corresponded to Al-oxide thicknesses in the micrometer range. We have been able to extend the method into the angstrom range by measuring weight losses of less than 100 μg. The assumptions made in applying this method to our case include: (*i*) that the mechanism of the CrO_3-H_3PO_4-H_2O Al-oxide clean is such that all of the initially present surface Al oxide is removed and an equilibrium final film containing both Cr and P is then formed [this is in general agreement with earlier observations (1)]; (*ii*) that although the density range of Al oxide can be from 2.5 to 4.0 g/cm^3, the surface oxide we are dealing with which was formed in solution, probably is a form of alumina with a density close to 3.0 [note that the ASTM method clearly defines a density of 3.0 for Al oxides determined using the gravimetric method as does previous work at Bell Laboratories (4) regarding Al oxide formed in water]; and (*iii*) that the equilibrium Al etch rate of 3 Å/min found in this work is applied against the weight loss found for each sample. A solution containing 2g CrO_3, 5 ml 85% H_3PO_4, and 100 ml of water was used for 5 min at 80°C. As with the Hg probe data, a sufficient number of readings were taken for each weighing until the results were statistically meaningful (usually 20). Extreme care had to be taken to ensure neither the addition of, nor the removal of, material from the 3 in. Si wafer used as the Al film substrate, because of the small weight losses being measured.

The surface compositions and oxide thicknesses were also determined using Auger analysis (5, 6). Oxide thicknesses were estimated using the chemically shifted Auger peaks (6) so that ion mill depth-profiling was not necessary. The Auger apparatus was a Varian cylindrical mirror analyzer with a 10 kV electron gun and comparatively high energy resolution (0.25%) which enabled the chemically shifted Auger peaks to be effectively resolved. The spatial resolution of this technique is limited by the incident electron beam diameter and was less than 10 μm.

Results and Discussion

Typical oxide thicknesses.—The right hand portion of Table I shows typical Al-oxide thicknesses at various stages of Al processing. An important point to note is that, as processing of as-deposited Al proceeds, the oxide thickness can increase. Unless one is acutely aware of the effect of each processing step on the surface Al-oxide thickness, reasonable amounts can build up which later make electrical contact of a subsequent metallization difficult or impossible. The Auger thickness data in Table I are supported by the gravimetric and Hg-probe data as shown in Table II.

Table II. Surface aluminum oxide thickness by various methods

Sample	Thickness in Å found by Hg-probe	Auger	Weight loss
1	51	56	58 ± 18
2	47	47	39 ± 18

Note: Close agreement between Auger and Hg probe data is expected because the latter was calibrated using Auger thickness data. However, it is to be pointed out that the resultant dielectric breakdown strength for the Al-oxide turned out to be almost exactly the value for bulk Al-oxide which provides an independent confirmation of the correctness of the calibration.

An attempt to check the thickness data given in Table II with yet another technique, ellipsometry (7), resulted in data indicating significantly thicker films (>100Å) compared to the other three methods. It should be noted that the samples used for Table II were processed through a final cleaning solution containing one part ethylene glycol, one part 7:1 buffered-HF (7 parts 40 w/o NH_4F in water to 1 part 49% HF) and one part water (EG:BHF:H_2O). For most other processing treatments ellipsometric results tended to be in good agreement with the Auger values. We consider it unlikely that all of the other methods could be in error by the amount indicated by the ellipsometric results. Moreover the ellipsometric data can be sensitive to the exact degree of oxide hydration, porosity, and physical surface structure (*i.e.*, platelet, filamentary, crystalline, etc.) (8). Therefore, we have based the present investigation on the Auger, gravimetric, and Hg-probe results, which are quite self-consistent, and sufficiently understood.

As discussed above, the Al surface which is obtained in the EG:BHF:H_2O solution proved the most difficult to reconcile among the four measurement techniques. This solution affords a convenient means of etching and cleaning dielectrics (SiO_2, Si_3N_4, Al_2O_3) in the presence of Al metal without significant attack on the metal (9). This treatment was recently being evaluated for routine MOS processing as a preplasma SiN clean. Recent Auger analysis showed that Al surfaces treated with an EG:BHF:H_2O solution contain besides Al and O, significant amounts of F, and trace amounts of N, suggesting the possibility of an Al-oxyfluoride surface compound rather than a simple Al oxide. The underlying Al film tends to be slightly attacked and roughened. These factors are probably responsible for the discrepancy between ellipsometric data and the other measurements.

Dielectric breakdown strength of oxide on aluminum.—The dielectric strength of the oxides of interest here were determined using the Hg probe, and the results are presented in Fig. 1. Al-oxide thicknesses were all determined using the Auger method except for the two gravimetric points (1G and 2G). We obtained a dielectric breakdown strength of 0.09 V/Å, which is typical of good quality dielectrics, *e.g.*, SiO_2 is ~0.08 V/Å. The zero intercept for the straight line plotted in Fig. 1 corresponds to an effective electron tunneling distance of 12Å.

Effect of titanium.—One of the practical objectives of the present study was to prepare an Al surface to which Ti (the initial metal in the trimetal beam lead process) can make proper contact. Thus, the next area considered was the effect of Ti on the Al-oxide breakdown voltage. A sample of Al having 90Å surface oxide (Auger) that was grown in 60°C water was used; Ti dots were filament evaporated through a shadow mask. The 90Å thickness was selected to ensure residual Al oxide after surface interaction with the Ti, since the goal of the experiment was to accurately determine the decrease in effective dielectric thickness of the Al oxide upon Ti deposition. Prior to Ti deposition the oxide breakdown voltage was measured with the Hg probe to be 7.5V, which as can be seen from point 9 in Fig. 1 is in excellent agreement with the 90Å Auger thickness value. After Ti deposition, the uncovered Al areas were still found to break down at 7.5V, whereas the Ti areas required only 3.5V, corresponding to the annihilation of about 45Å of Al oxide. This conclusion is valid because the Ti dot surface does not contribute to the breakdown voltage as evidenced by

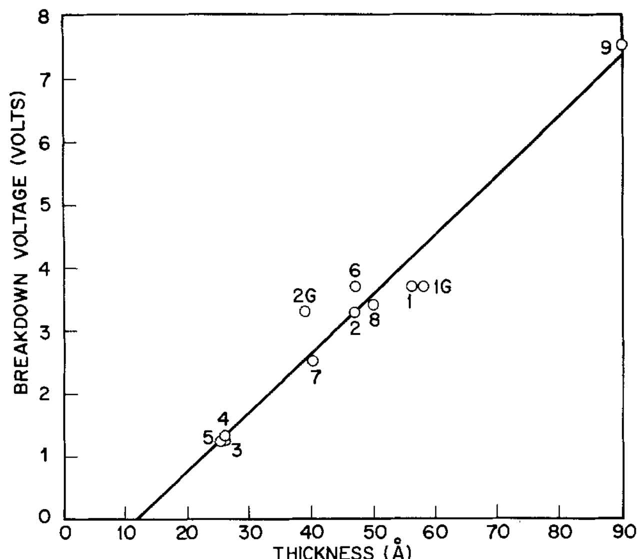

Fig. 1. Breakdown voltage (Hg probe) vs. Al-oxide thickness (Auger and gravimetric). The slope of the straight line gives a dielectric breakdown strength of 0.09 V/Å, and the zero intercept gives an electron tunneling distance of 12Å. Sample numbers are indicated at each data point and correspond to the following processing:

No.	Thickness	Processing sequence (see Table I)
1.	Auger	No. 1, 2, 3, 4, 5
1G.	Gravimetric	No. 1, 2, 3, 4, 5
2.	Auger	No. 1, 2, 3, 4, 5
2G.	Gravimetric	No. 1, 2, 3, 4, 5
3.	Auger	Sample 1 + CrO_3-H_3PO_4 + 15 min in air
4.	Auger	Sample 3 + 30 hr in air
5.	Auger	Sample 2 + CrO_3-H_3PO_4 + 15 min in air
6.	Auger	No. 1 + 30 days
7.	Auger	No. 1, 4
8.	Auger	No. 1, 4, 5
9.	Auger	No. 1 + 60°C H_2O; sample used in Ti expt

the zero breakdown voltage found between a Hg probe and a large area Ti film. The following Al-oxide reduction reaction can be noted

$$Ti + Al_2O_3 \rightarrow \alpha Ti(O) + Al$$

where the O is in solid solution in Ti. Note that the solid solubility of O in the αTi phase is about 33% (10). If the 12Å tunneling range found earlier is added to this 45Å, then it is suggested that Al films having about 55Å of surface oxide will make ohmic contact to Ti metal on a statistically marginal basis. It is clear that the processing sequence of Table I produces an Al surface whose average oxide thickness is close to the marginal value (step 8). Therefore, it is not surprising that the final aspect of this program involved developing a chemical treatment which effectively reduces the Al-oxide thickness to "safe" low values.

The CrO_3-H_3PO_4-H_2O Al-oxide etching system.—It has been reported (1) that the aqueous CrO_3-H_3PO_4 solution passivates the Al surface first by dissolving the surface oxide and then by subsequent reaction with the metal to form a thin surface layer. Estimates of the thickness range of this passivating layer fall in the 10-30Å range (1, 2). In Ref. (1), an estimate of 10-20Å was obtained by use of radioactive CrO_3 and H_3PO_4 to label the thin Al surface film. It was found that the atomic concentration ratio of P to Cr was 0.85 ± 0.2. Using the assumption of a mixed Al-Cr phosphate surface compound having a density about that of $AlPO_4$ (2.6 g/cm^3), it was concluded that a typical film would be 10-20Å thick. Several other results (1) of interest include: (*i*) a 5 min treatment of an Al surface at 85°C is sufficient to establish an equilibrium film condition; (*ii*) the equilibrium dissolution rate of the underlying metal is no more than 2 Å/min (we found 3 Å/min); (*iii*) the initial Al-oxide thickness prior to CrO_3-H_3PO_4-H_2O treatment has little effect on the final thickness of the passivation layer.

Application of the CrO_3-H_3PO_4-H_2O etchant as described in the literature (5 v/o H_3PO_4, 2 w/o CrO_3 at 80°-85°C) showed that certain regions of every device chip on MOS wafers developed a brownish coloration, suggesting a form of electrochemical corrosion. Clearly the above composition is not an optimum one for obtaining the thinnest possible surface film for our application. Therefore, additional experiments whose results are set out in Table III were performed to determine this optimum composition and also to minimize the browning attack. In addition, actual device wafers processed up to step 8 of Table I were treated, and individual contact pads were surveyed, in order to determine the pad-to-pad Al-oxide thickness differences.

In Table III, samples no. 1-18 were full-surface Al films with a 60Å surface oxide grown in 40°C water. Etchant composition, solution temperature, and etch times were varied, and the resultant oxide thicknesses were measured using Auger spectroscopy. Samples no. 1 and no. 2 show that the browning is caused by CrO_3. The brown coloration was visually impossible to discern with any of the remaining full surface samples. The table also shows that the etch composition is clearly not an important variable over a wide range. The solution temperature is obviously important, although the effect of a lower temperature can be compensated by an increased etch time. In general, the more dilute solutions with respect to CrO_3 produced thinner surface films. However. sample no. 1, 17, and 18 show that Al attack and dissolution become severe if the CrO_3 content is too low.

An approximate calculation of the surface atomic composition using the Auger data indicated no large differences in surface composition as a function of the variables investigated. However, some variation was noted as a function of depth. The surface composition in the outer half (~10Å) of the surface layer was in good agreement with the literature (1) in that P and Cr amounts are consistent with mixed phosphates and oxide of trivalent Al and Cr. How-

Table III. The H_3PO_4-CrO_3-H_2O etch

Starting material was an Al film with 60Å of surface oxide for the full surface samples, while device chips were after step 8 of Table I and had typically 50Å of oxide.

The H_3PO_4 was an 85% solution and all etches were prepared by mixing the listed contents with 100 ml of water.

ever, the remaining 10Å or more appeared to be deficient in P and Cr and was therefore essentially Al oxide. This result explains why the thicknesses we measured are somewhat larger than those previously calculated (1) assuming a single Al-Cr phosphate-oxide layer. With these initial results, then, some actual device chips were treated and the oxide thicknesses on the bonding pad areas were measured.

The device chosen was a MOS code processed up to step 8 of Table I, when typical oxide thicknesses should be near 50Å; for example, the thicknesses over devices from two different lots were 54 and 60Å. The results are displayed in no. 19-24; all of the experiments were performed using chips taken from the same wafer. For the last sample, all 42 pads were examined; while for the remaining samples, the two pads at the pad locations in no. 24 which evidenced the thickest films, were measured. The distribution of oxide thicknesses on the pads of sample no. 24 is shown in Fig. 2. The thicknesses ranged from 24 to 29Å with a sharp distribution peak at 27Å. Note that the data from only 35 of the 42 pads could be obtained; all of the remaining 7 pads were floating pads (not connected to the Si substrate), and data could not be obtained from them because of electrostatic charging problems caused by the incident electron beam. For this etch procedure then, the oxide thickness was about 27 ± 3Å which is considerably less than the marginal value of 55Å we determined earlier. Therefore, this etch should be quite acceptable for routine application because of the rather large safety margin of a factor of two in oxide thickness.

The brown coloration due to the presence of CrO_3 was more easily seen on the device chips than on full surface Al films because of the preferential coloration over certain areas in the metallization pattern. Coloration was clearly evident within the Al circuitry (although not on contact pads) for no. 22, perhaps present for no. 23, and not discernable at all for no. 24. Therefore, CrO_3 concentrations below that used for no. 22 appears requisite if all discoloration is to be avoided.

Based on the aforementioned quantitative surface oxide thickness data and on qualitative (gas evolution, surface attack) and quantitative (etch rates) observations regarding Al attack, we decided that the optimum Al-oxide etchant contains 3.5-10 ml 85% H_3PO_4 and 0.25-0.50g CrO_3 for each 100 ml of water. Typical etching times are between 2 and 10 min at 80°C. Reduction of CrO_3 below 0.2g encourages Al attack by H_3PO_4, while amounts of CrO_3 in excess of 0.5g results in visible browning of various portions of the integrated circuit metallization pattern. Quantities of CrO_3 well in excess of 0.5g (5-15g) appear to have little effect on electrically floating Al metal.

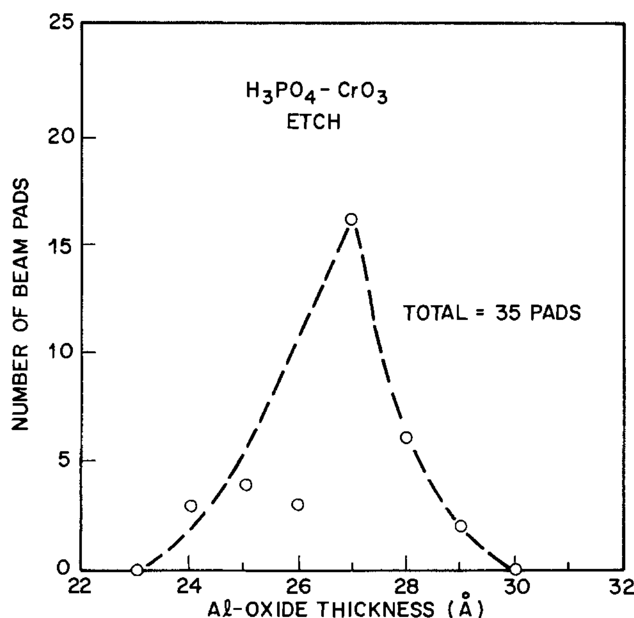

Fig. 2. Al-oxide thickness distribution over 35 contact pads on one integrated circuit chip. The distribution is fairly narrow (±3Å) and is sharply peaked at 27Å.

Split-lot testing of the CrO_3-H_3PO_4-H_2O system.—As a final test, a solution containing 5 ml 85% H_3PO_4, 0.30g CrO_3, and 100 ml of water was used for 5 min at 80°C to clean one-half of the wafers in each of two device lots designated for in-process split-lot evaluation of the CrO_3-H_3PO_4 etchant. Split lot no. 1 consisted of 7 MOS device wafers that had been processed through step 8 of Table I. Three wafers were cleaned as described above immediately prior to Ti deposition, while 4 control wafers received no extra treatment. The contact yield data for the 7 wafer lot are presented in Table IVA. The number of contact failures in the control half of the lot was fairly typical of the standard product processed according to Table I. An over-all contact yield of 94% was found for the etched group *vs.* 78% for the controls.

The second split lot also involved MOS devices, but in this instance the control group was comprised of wafers that received a backsputter etch treatment prior to Ti deposition. The backsputter clean was done in one unit prior to Ti sputter-deposition in a second unit, thus resulting in air exposure of the samples. A typical Auger analysis of this type of Al surface indicates 30-40Å of Al oxide. In addition to the change in controls for this lot, the EG:BHF:H_2O cleans were also omitted for all of the wafers. The resultant contact yields are presented in Table IVB. The backsputtered control group yield of 91.8% can be compared to the 90.8% yield for the CrO_3-H_3PO_4-H_2O cleaned half of the lot. Note that all contact yields quoted here are probably somewhat low since other factors (*e.g.*, closed beam to Al via holes and photolithographic defects) can limit contact yield. Thus, those yields between 90-100% probably reflect contact yields of nearly 100%.

The split lot data show that CrO_3-H_3PO_4-H_2O treatment furnishes an Al surface to which subsequent Ti metallization can make good electrical contact after normal device line processing. The second split lot data suggest little difference between the etching treatment and *ex situ* backsputtering (*i.e.*, use of a separate sputtering unit for cleaning prior to Ti deposition in a second unit). The results from lot no. 1 imply that the CrO_3-H_3PO_4-H_2O treatment can be used successfully even in the Table I Al processing sequence which contains the EG:BHF:H_2O clean-

Table IV. Split lot contact yields in evaluation of the CrO_3-H_3PO_4-H_2O etch

ing procedure. It seems safe to conclude that the availability of the CrO_3-H_3PO_4-H_2O etching system relaxes the requirement of "acute awareness" of the Al metal surface condition during each processing step as long as the etchant is used immediately prior to Ti deposition in the beam lead process.

Summary and Conclusions

We have evaluated the Al metal surface during its processing in integrated circuit manufacture by monitoring the thickness of the surface oxide as a function of various processing steps. It is clearly shown that Al oxide can become too thick for ohmic contact to subsequent metallization if the Al surface is not properly treated during processing. It was found that when the Al-oxide thickness is in the 50-60Å range, contacts between Al and Ti are marginal, and Al-Ti contact failures become a prime cause for poor device yields. We estimate that the critical tolerable Al-oxide thickness is about 55Å which is the sum of the estimated electron tunneling distance (12Å) and the amount of dielectric that is "nullified" by the Ti upon deposition (~45Å). The dielectric breakdown strength for the surface Al oxide during processing was found to be 0.09 V/Å.

A practical method of avoiding Al contact problems involves use of a treatment in CrO_3-H_3PO_4-H_2O (0.2-0.5g CrO_3, 3.5-10 ml H_3PO_4, 100 ml H_2O) for 2-10 min at 80°C prior to Ti metallization. This etch removes surface oxide, leaving only an equilibrium final film of 25-30Å thickness, and it does not attack underlying Al metal. The CrO_3 concentration is particularly critical; too little CrO_3 results in Al attack by the H_3PO_4, whereas too much CrO_3 induces selective electrochemical corrosion of Al in certain areas of a device chip. Practical application was clearly demonstrated through the use of two split lots undergoing actual MOS device processing. Additionally, the etching treatment minimizes the requirement for surface Al-oxide monitoring during processing provided it is used just prior to Ti metallization.

A New Self-Aligned Contact Technology

Y. Tanigaki, S. Iwamatsu, and K. Hirobe

Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

ABSTRACT

A new self-aligned contact technology for high density MIS LSI is described in this paper. The technology does not need any alignment tolerances of contact regions which have been indispensable for the conventional Si gate technology. Therefore the technology makes a grate reduction in contact areas. An R-S flip-flop circuit was designed by the technology. The packing density has been increased about 20% compared with that of the conventional circuit structure.

A variety of technologies have been developed in order to increase the packing density of MIS LSI. These are the local oxidation of silicon (LOCOS) and the self-aligned Si-gate technology. The isolation area is reduced by the LOCOS technology because of forming channel stopper under the thick oxide region, and the gate area is reduced by the Si-gate technology forming the self-aligned gate structure. Even if these technologies are applied to the MIS fabrication steps, the contact region still occupies large area because sufficient tolerances are needed for a mask alignment. A new self-aligned contact technology is developed with high packing density of MIS LSI to solve the problem.

The steps involved in fabricating a Si-gate n-channel MIS LSI are as follows. The starting materials are 8-12 Ω-cm, (100) oriented, p-type silicon wafers. Active regions are formed by the LOCOS technology (Fig. 1a) first, and then the gate oxide is thermally grown in dry oxygen ambient for 105 min at 1000°C with an oxide thickness of 750Å. Then silicon nitride is deposited at 850°C by the reaction of silane (SiH_4) and ammonia (NH_4) gases. After the deposition, about 150Å of oxide is thermally grown on the silicon nitride film with steam ambient of 110 min at 1000°C, and polycrystalline Si (poly-Si) is deposited at 600°C (Fig. 1b). This is followed by the gate formation and the poly-Si layer is plasma-etched, and then phosphorus ions are implanted at an energy of 180 keV, a dose of 8×10^{15} cm^{-2} (Fig. 1c). The next processing step is the steam oxidation for 45 min at 1000°C. In this treatment, about 3000Å thick oxide film is formed only on the poly-Si gate because of using the silicon

Key words: MOS, integrated circuit, self-alignment.

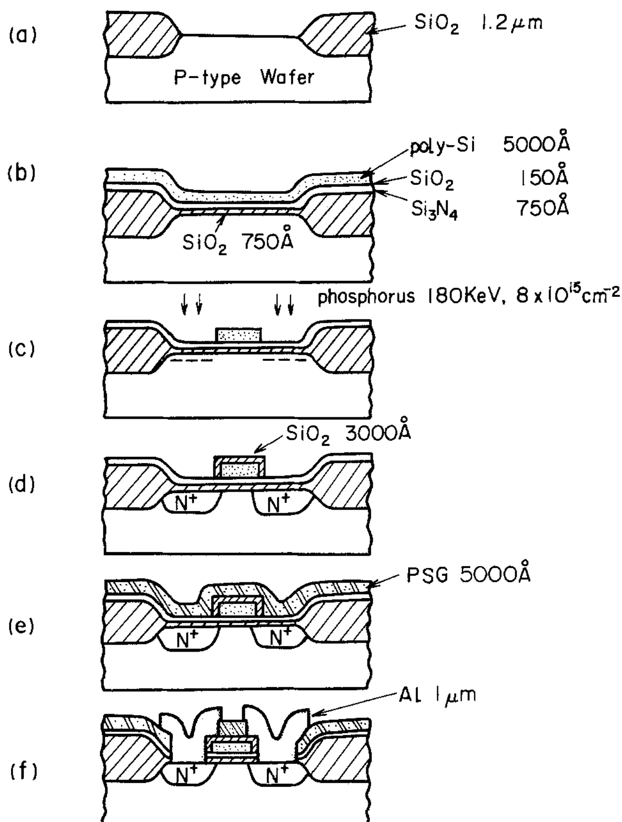

Fig. 1. Steps during fabrication of a Si gate n-channel MIS LSI by the self-aligned contact technology.

nitride film as a mask for oxidation, and the phosphorus drive-in diffusion is carried out simultaneously to form the diffused regions (Fig. 1d).

In the subsequent steps, PSG (phosphosilicate glass) is deposited, followed by annealing in N_2 ambient for 10 min at 1050°C and opening the contact windows. The contact windows on source or drain region and the contact windows on gate region must be opened separately because of the difference of oxide thickness on each region. Therefore we need 2 masks for opening contact windows. The process is completed by depositing aluminum (1 μm in thickness), defining the metal interconnect pattern, and annealing in H_2 ambient for 30 min at 400°C (Fig. 1f).

The new and conventional structures are compared in Fig. 2, where three kinds of alignment tolerances L_1, L_2, and L_3 are defined as follows: L_1, tolerance between the gate and the contact; L_2, tolerance between the isolation region and the contact; and L_3, tolerance between the isolation region and the contact, respectively. Overlapping of the contact to the gate can be tolerated on this technology since the oxide on the gate is thick enough to insulate the gate

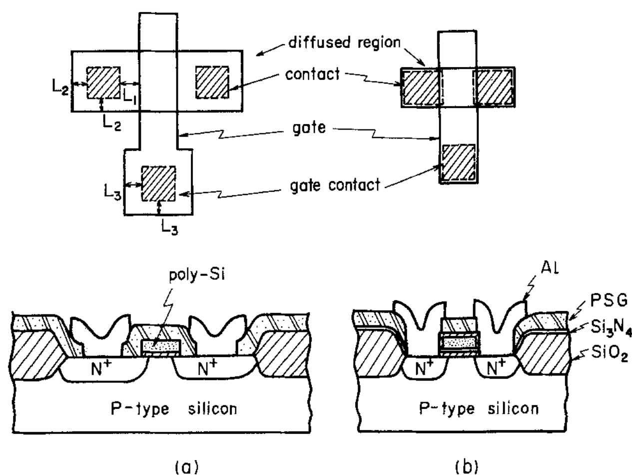

Fig. 2. Structures of Si gate MIS FET's fabricated by (a) conventional technology, and (b) self-aligned contact technology.

from the electrodes of source and drain after opening contact windows. When the contact windows on source and drain regions overlapped to the isolation regions, the silicon nitride layer under PSG (phosphosilicate-glass) prevents overetching of the thick oxide of the isolation region. Therefore, at the edge of the isolation region, thickness of the thick oxide is not reduced. No deterioration of p-n junction in electric characteristics was observed after annealing for aluminum metallization. Misalignment of gate contacts over the isolation region can be also tolerated since the silicon nitride film under PSG layer protects the thick oxide against reduction in thickness during overetching PSG film. There is no increase in step height at the edge of poly-Si on the isolation region, therefore opening does not occur in the aluminum metallization.

An n-channel Si-gate MIS FET was fabricated by the new technology. There was no reduction in electron mobility (μ_n = 600 cm^2/V-sec) and in breakdown voltage (80V) between the gate and source or drain. An R-S flip-flop circuit was designed and compared by the new and conventional technology. The packing density of the new circuits has been increased about 20% compared with that fabricated by the conventional technology. These results showed that the technology is very effective for achieving high packing density in MIS LSI.

Ohmic Contacts to GaAs Transferred Electron Devices

B. P. Johnson*

Electrical Engineering Department, University of Nevada, Reno, Nevada 89507

and C. I. Huang

Air Force Avionics Laboratory, WPAFB, Ohio 45433

ABSTRACT

The specific contact resistance of Au/Ge/Ni alloy contacts to GaAs for transferred electron devices has been measured. It is found that a shallow sulfur diffusion under the contact is effective in reducing the specific contact resistance by up to two orders of magnitude. This procedure is expected to improve the uniformity of threshold and bias voltages in integrated circuit configurations by making the contact resistance only 1-10% of the total device resistance.

Because of the low doping found in GaAs transferred electron devices (TED's) for microwave applications, the contact resistance to the device is the major part of the total device resistance. A survey of the literature indicates that for a given doping level, the contact resistance can vary up to two orders of magnitude as the processing parameters are varied (1-5). Significant variation can also occur across a wafer in a given run. This situation is allowable for discrete device configurations where postsorting is possible. In integrated circuit configurations, however, local variations are intolerable because threshold and bias voltages must be uniform from one device to the next in the same circuit. The purpose of this paper is to show that a shallow sulfur diffusion under the metallization pads can reduce the contact resistance to 1-10% of the total device resistance. The specific contact resistance is lowered by approximately two orders of magnitude over that measured on nondiffused samples.

The metallurgical and electrical properties of alloyed Au-Ge/Ni films on n-type GaAs are relatively well understood (1). Edwards, Hartman, and Torrens (2) have summarized specific contact resistance data of this and other contact alloys to GaAs through mid-1971. In general, their data show two order of magnitude variation in the specific contact resistance which ranges from a mean of 3×10^{-3} Ω-cm at a doping level of mid-10^{15}/cm^3 to 10^{-4} Ω-cm at 10^{17}/cm^3. Robinson (3) and Yu (4) have independently confirmed that by process optimization, the mean specific contact resistance can be lowered by up to one order of magnitude. For GaAs TED's doped from mid-10^{15}/cm^3 to mid-10^{16}/cm^3, the specific contact resistance values reported as well as those measured in our laboratories give a device contact resistance far greater than the intrinsic device resistance (typically 3000Ω). To lower the contact resistance to 1-10% of the total device resistance, a specific contact resistance of $\sim 10^{-5}$ Ω-cm is required. The exact value depends on the specific device configuration. This value is two orders of magnitude lower than that reported, and hence can only be achieved by the formation of a shallow n+ layer below the contact to give a doping level of mid-10^{17}/cm^3 to mid-10^{18}/cm^3.

The samples used in this experiment were semi-insulating GaAs substrates on which 25 μm vapor phase epitaxy layers were grown. The typical doping range was mid-10^{15}/cm^3 to mid-10^{16}/cm^3 n-type (Si). Ohmic contacts were formed by evaporation of a gold/12 weight percent (w/o) germanium alloy followed by nickel. The contacts were fused for 30 sec at 475°C in a hydrogen ambient. Figure 1 shows the experimental configuration used to measure the contact resistance. It was chosen to provide dimensions comparable to that of actual devices being constructed. The resistance between pads 1 and 2, 2 and 3, and 3 and 4 was measured, and the contact resistance R_c determined by elimination of the bulk GaAs and probe resistances. The specific contact resistance was then evaluated from (6)

$$r_c = \frac{(ZR_c)^2 \alpha}{\rho}$$

where Z and α are defined in Fig. 1 and ρ is the resistivity of the epitaxial material. This model assumes that the ohmic region is shallow in comparison to the total epitaxial layer thickness. Measurements were made on both as grown epitaxy layers, which were used as a control, and on epitaxy layers which had a shallow sulfur diffusion under the contact pads. Pattern definition was achieved by mesa isolation as indicated in the figure.

Donor diffusion into GaAs has been reported by several authors. Reeves and Donovan (5) have summarized the work through 1972, while Matino (7) presents more recent sulfur results. Germanium and

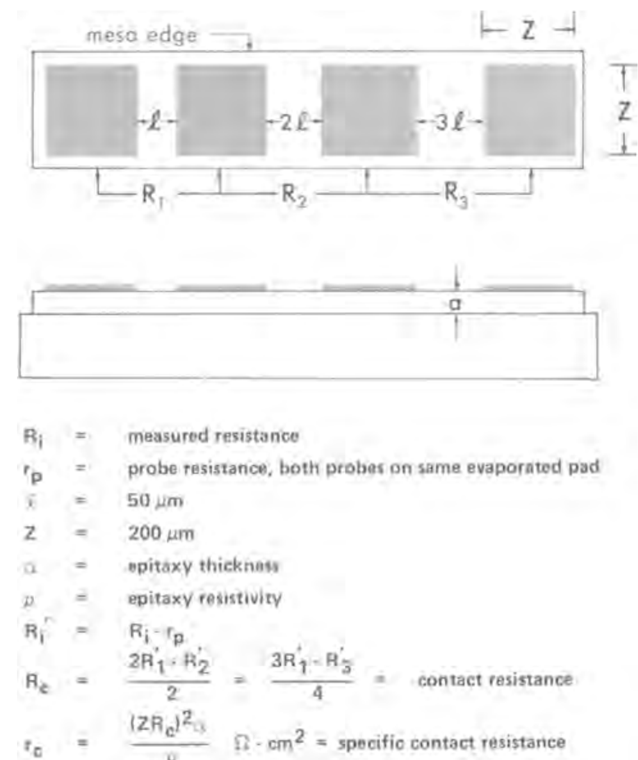

Fig. 1. Contact resistance measurement configuration

Key words: gallium arsenide, transferred electron devices, specific contact resistance, sulfur diffusion.

silicon were not considered for this work because of their amphoteric behavior. Sulfur was chosen over selenium and tellurium because of its higher diffusion coefficient and reported reproducible behavior (7). Diffusion calibration runs using Ga_2S_2 and As were carried out at 800° and 900°C in vacuum-sealed quartz capsules using a 5:1 by weight gallium sulfide to arsenic ratio. Uniform temperature was maintained over the entire length of the capsule ($\Delta T < 0.1°C$). Upon withdrawal from the furnace, the source end of the capsule was quenched to prevent deposition of the vapor on the sample surface during cooling. The results are compared to the data reported by Matino in Fig. 2. The curve gives a D_o of 1.34×10^5 cm^2/sec with an activation energy of 3.98 eV. The 5:1 ratio was chosen to minimize surface compound formation and yet maintain a high surface sulfur concentration. Surface compound formation was observed at 900°C using a 10:1 ratio.

Contact resistance samples were diffused at 800° and 900°C and processed along with nondiffused control samples to measure specific contact resistance. The diffusion depth was typically between 1 and 2 μm. The results are presented in Fig. 3. Each diffused sample data point represents the average value of measurements on 30 samples. The shaded area represents the two order of magnitude variation in specific contact resistance reported in the literature. The optimized values of Robinson (3) and Yu *et al.* (4) are indicated as well as the range of values measured in our laboratories on nondiffused samples.

Capacitance-voltage measurements on the diffused samples indicated a doping level (1×10^{18} cm^{-3} at 898°C and 4×10^{17} cm^{-3} at 789°C) corresponding to the solid solubility of sulfur in GaAs at these temperatures (8, 9). The mean specific contact resistance at these values is in good agreement with that actually measured on the diffused samples. The point at 898°C

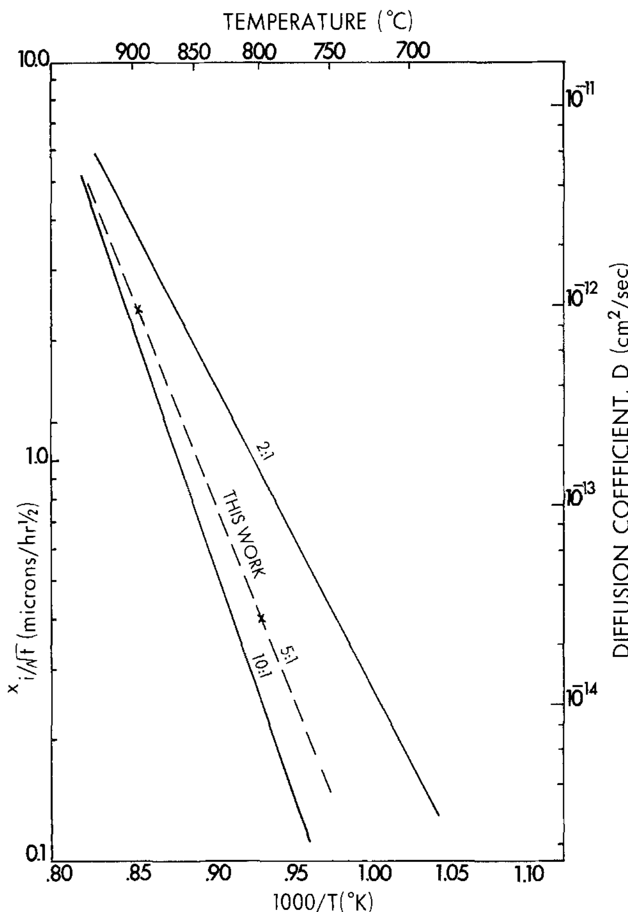

Fig. 2. Diffusion coefficient of sulfur into GaAs. 2:1 and 10:1 are from Matino (6).

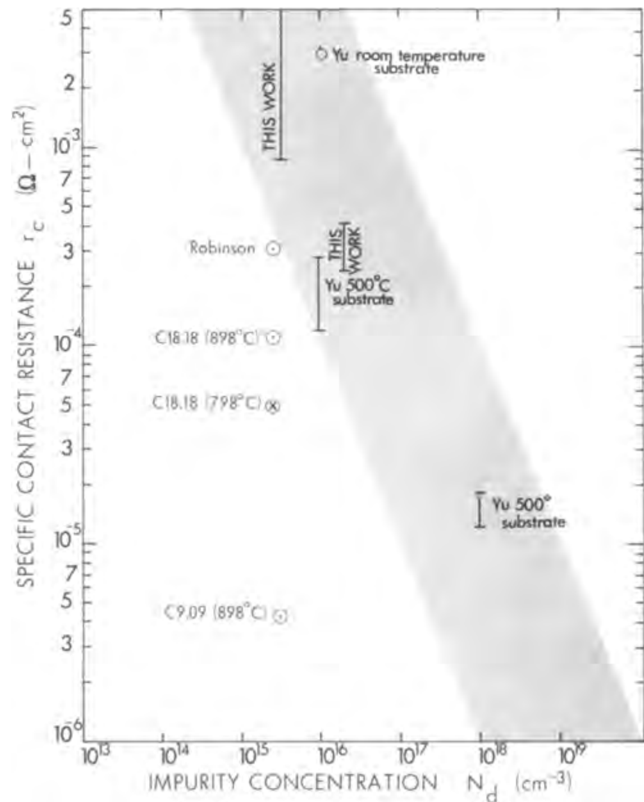

Fig. 3. Specific contact resistance measured on samples which were sulfur diffused at 898°C (⊙) and at 798°C (⊗). The shaded area represents the two order of magnitude variation in specific contact resistance reported in the literature. The optimized values of Robinson (3) and Yu *et al.* (4) are indicated as well as the range of values measured in our laboratories on nondiffused samples.

for sample no. C18.18 is included to illustrate the need for process monitoring. In this particular processing sequence, the problem was tracked down to a leak in the vacuum system during the run.

This work demonstrates that a shallow sulfur diffusion [as well as ion implantation (10)] should be successful in lowering the contact resistance of GaAs TED's from being the major part of the total device resistance, to a value that is 1-10% of the total device resistance. This is crucial for uniform device parameters and reduced power dissipation in integrated circuit applications of TED's.

ABSTRACT

The effects of destabilizing vertical thermal gradients on crystal growth and segregation in an inverted Bridgman configuration were investigated in Ga-doped Ge melts by monitoring the thermal characteristics of the melt and relating them through interface demarcation directly to growth and segregation. It was found, consistent with established thermohydrodynamic criteria, that as solidification progressed the melt exhibited successively turbulent convection, oscillatory thermal instabilities, and, finally, thermal stability. Growth under turbulent melt convection is characterized by pronounced and rapid fluctuations with the rate changing within 1 sec from negative to more than 30 μm/sec. A quantitative microsegregation analysis based on interface demarcation for the determination of dopant concentrations was performed. It showed that segregation under turbulent convection is in basic agreement with the BPS theory: Dopant incorporation is controlled by the microscopic rate of growth while convection-induced boundary layer perturbations constitute a second-order effect.

Time-dependent convective melt flow caused by unavoidable destabilizing thermal gradients has been identified as the primary cause of random compositional variations in semiconductor single crystals grown from the melt (1). The exact nature of such thermohydrodynamic instabilities in crystal growth systems (2) and their functional dependence on growth parameters have not as yet been established; more importantly, quantitative cause and effect relationships between convective flow and microsegregation are still not available.

Recently, the nature of convective instabilities associated with destabilizing thermal gradients was systematically studied for the growth of InSb (3). This study established the effects of convection in the melt on crystal growth characteristics and revealed some basic relationships between convection and dopant incorporation. The present investigation is concerned with the study of convective melt flow in a germanium growth system with destabilizing vertical thermal gradients and its effect on dopant (Ga) incorporation with primary emphasis on a quantitative analysis of segregation under turbulent convection.

Experimental Procedures

All growth experiments were carried out in an apparatus shown schematically in Fig. 1. The Ge charge and the Ga dopant (4×10^{19} atoms/cm^3 in the melt) were placed in a quartz tube of 1.3 cm ID, heated to slightly above the melting point with a cylindrical resistance heater, and brought into contact with an <111> Ge seed. The height of the molten zone at the start of the growth experiment was about 2.5 cm. Growth in the downward direction was achieved by controlled furnace power reduction. At a constant cooling rate of 0.43°C/min (obtained with a nominal

Vertical destabilizing thermal gradients: Ge = 27°C/cm at 2.5 cm melt height; InSb = 19°C/cm at 3.3 cm melt height; and 8°C/cm at 1.2 cm melt height.
* A and B refer to the simultaneously present modes of thermal instability (see text).

destabilizing vertical thermal gradient of 27°C/cm taken from the temperature difference between the growth interface and the bottom of the melt at the onset of the growth experiment) an average macroscopic growth rate of 2.8 μm/sec was established. Volume expansion during solidification was accommodated by a special graphite insert near the bottom of the quartz tube.

For the purpose of interface demarcation by current pulsing (4), electrical contacts were made with the seed crystal and the graphite pedestal. Current pulses (18A) of 50 msec duration were transmitted at intervals of 0.6 sec during growth under turbulent convection conditions; the interval between pulses was increased to 30 sec under oscillatory thermal instability and under thermal stability conditions.

Temperature measurements in the melt were obtained with a Chromel-Alumel thermocouple inserted through the graphite pedestal. During growth the location of the thermocouple junction was adjusted so that temperature measurements for various melt heights could be taken at a constant distance of approximately 5 mm from the growth interface. Since displacements of the thermocouple did not alter the growth and segregation behavior it is concluded that its presence did not noticeably affect the thermal behavior of the melt. Current pulsing was stopped prior to the termination of growth so that the last interface demarcation line could be identified and serve as a direct time reference between the temperature recording and the corresponding growth region [the current pulses were inductively registered by the thermocouple; see also Ref. (3)].

The growth and segregation analyses were performed on crystal segments cut along the growth axis; the segments were polished and etched (8 sec in 1HF + $1CH_3COOH$ + $1H_2O_2$) to reveal segregation effects and interface demarcation by interference contrast microscopy; for quantitative microsegregation analysis, dopant concentration profiles were determined by single-point probe spreading resistance measurements.

Experimental Results and Discussion

Thermohydrodynamics and growth behavior.—The nature of the thermohydrodynamic instabilities in the Ge melt under the present growth configuration and their effect on the growth characteristics were investigated through temperature measurements in the melt and through an analysis of the segregation inhomogeneities (striation patterns) in the grown crystal. The results indicated that the convective melt flow behavior depends strongly on the melt height and is in principle analogous to that encountered in an InSb growth system of similar configuration (3). Thus, with continuing growth in the downward direction (with decreasing melt height) the melt experienced successively turbulent, oscillatory, and laminar convection with correspondingly different growth and segregation behavior.

While the presently observed convective flow behavior is basically the same as that observed in InSb and consistent with established thermohydrodynamic criteria, it differs in detail as seen in Table I. At large Ge-melt heights (2.4-1.8 cm) a turbulent convective roll is established (Fig. 2) which rotates slowly about its vertical axis (3) (as indicated by large amplitude-low frequency variations). The temperature measurements and the characteristics of the corresponding segregation inhomogeneities in the grown crystal showed that the rotation of the convective roll about its vertical axis was arrested as the melt height decreased below 1.8 cm. Thus, the large amplitude-low frequency temperature variations in the melt ceased and concurrently the pronounced remelt striations in the growing crystal (which at larger melt heights overlap in the center of the crystal as a result of the

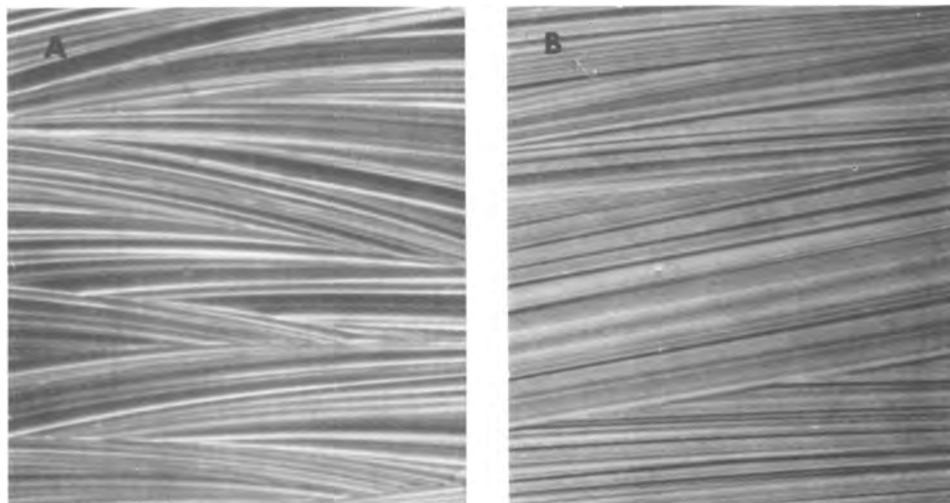

Fig. 2. Comparison of etched segments of Te-doped InSb (A) and Ga-doped Ge (B) crystals grown under turbulent convective melt flow. 20X.

vertical rotation of the convective roll) no longer form; the random non-remelt striations of higher frequency persist and assume an orientation normal to the growth direction (see below). It is of interest to note that coincident with this change in the convective flow pattern the average microscopic growth rate decreases from 24 to 2.8 μm/sec. The similarity of the convective melt flow behavior for Ge and InSb is evident in Fig. 2 which shows comparable crystal segments grown under turbulent convection.

The random temperature fluctuations changed to oscillatory instabilities as the melt height decreased to 1.7 cm. Temperature oscillations with a constant frequency of 0.4 Hz and an amplitude decreasing continuously from a value of ± 0.06°C were observed to a melt height of 1.2 cm. The oscillatory melt instability in germanium is different from that observed in InSb insofar as its frequency (although constant over significant time intervals) exhibits noticeable irregularities, particularly prior to transition to thermal stability at a melt height of 1.2 cm.

Dopant Segregation

Macrosegregation.—The macrosegregation behavior of the Ge-Ga system in the form of a compositional profile obtained by spreading resistance measurements (4) at spacings of 25 μm along the axis of the grown crystal is shown in Fig. 3. It can be seen that dopant segregation during growth under turbulent convection (left portion of the diagram) led to compositional variations in excess of about $\pm 10\%$. In contrast, segregation under both oscillatory instability (central portion) and thermal stability (right portion) exhibited compositional fluctuations of less than $\pm 2\%$. Figure 3 shows further that the Ga concentration in the Ge crystal increases steadily in the direction of growth (with the exception of one decrease which is followed by a rapid recovery). This finding is significant since the solidifying melt was subjected to abruptly changing convective flows which resulted in pronounced changes of the microscopic growth rate.

It would be desirable to make use of this compositional profile for a quantitative segregation analysis on the basis of the normal freezing equation (5). However, the average dopant concentration computed for the initial segment (turbulent convection) is not reliable since the measurements were taken at spacings of 25 μm and major compositional fluctuations associated with intermittent backmelting occur at comparative spacings (20-80 μm). Moreover, radial segregation cannot be ignored.

Microsegregation.—Segregation under turbulent convection (with extensive backmelting).—A quantitative analysis of the growth and segregation behavior on a microscale for a crystal segment grown at a melt height of 2.4 cm under turbulent convection is presented in Fig. 4. The growth rate analysis (curve B in Fig. 4), obtained from the spacing of successive interface demarcations,[1] shows that the average microscopic growth rate (24 μm/sec) is larger than the average macroscopic growth rate (2.8 μm/sec) by a factor of about 10 as a result of turbulent convection; the growth rate between the irregularly spaced periods of backmelting fluctuates significantly with maximum values in excess of 50 μm/sec; more importantly, the microscopic growth rate changes very rapidly, increasing after backmelting (negative rate) to more than 30 μm/sec within less than 1 sec.

In the context of the present microscopic growth rate analysis the inherent limitation of the interface demarcation technique for growth rate determination should be considered: The frequency of the interface demarcation (presently 1.7 Hz) was selected to yield optimum accuracy at the expected average growth rate; rapid growth rate excursions to very high and very low levels introduce, by necessity, uncertainties originating from limited growth rate resolution for high rates and spatial resolution for low growth rates. (in the present study the rate determination was optimized for the range of 10 to 30 μm/sec.)

The compositional profile obtained from spreading resistance measurements at 5 μm spacings is given by curve C of Fig. 4. The data indicate an average Ga concentration of $4.6 \times 10^{18}/\text{cm}^3$ with compositional fluctuations of $\pm 10\%$. A comparison of curves B and C in Fig. 4 shows that maxima and minima in dopant concentration are associated with corresponding maxima and minima in the microscopic growth rate. The observed coincidence of the growth rate and compositional maxima and minima shows that the major variations in dopant concentration originate from microscopic growth rate fluctuations; it also indicates that melt flow-induced fluctuations in the thickness of the diffusion boundary layer constitute a second-order effect under the present growth conditions.

BPS-segregation analysis.—In view of the preceding phenomenological considerations it is of interest to investigate the applicability of the Burton, Prim, and Slichter relationship (7) to segregation under turbulent convective melt flow; thus, the Ga concentration in the solid is given by

$$C_s = \frac{C_L k_o}{k_o + (1 - k_o) \exp(-V\delta/D)}$$

where C_s is the Ga concentration in the crystal C_L is the Ga concentration in the bulk of the melt, k_o is the

[1] The growth rate curve was obtained by fitting all spacings of interface demarcations to a computer-generated expression for the growth rate *vs.* growth distance employing a cubic (spline) interpolating polynomial (6).

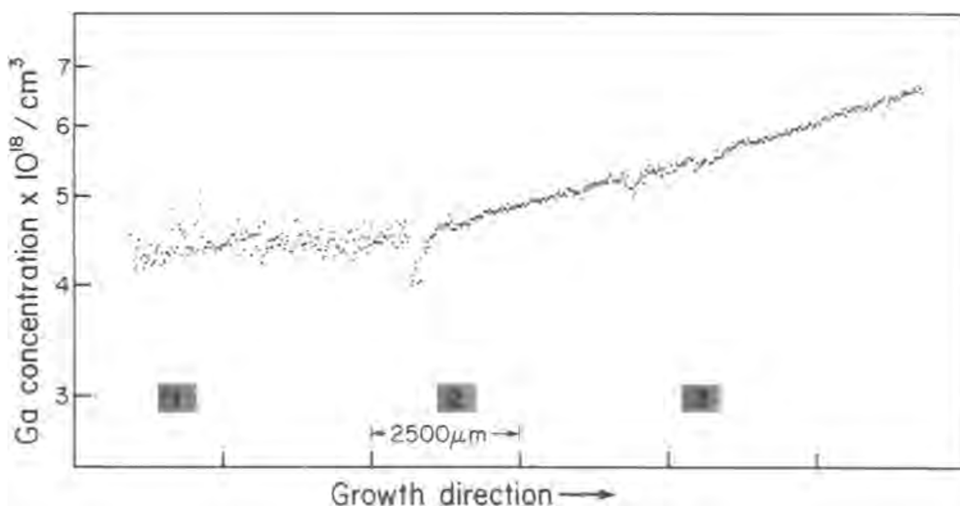

Fig. 3. Macroscopic longitudinal Ga-concentration obtained from single point spreading resistance measurements at spacings of 25 μm. Regions 1, 2, and 3, grown under turbulent convection, oscillatory instability, and laminar convection, respectively, were subjected to segregation analysis on a microscale (see Fig. 4, 6, and 7).

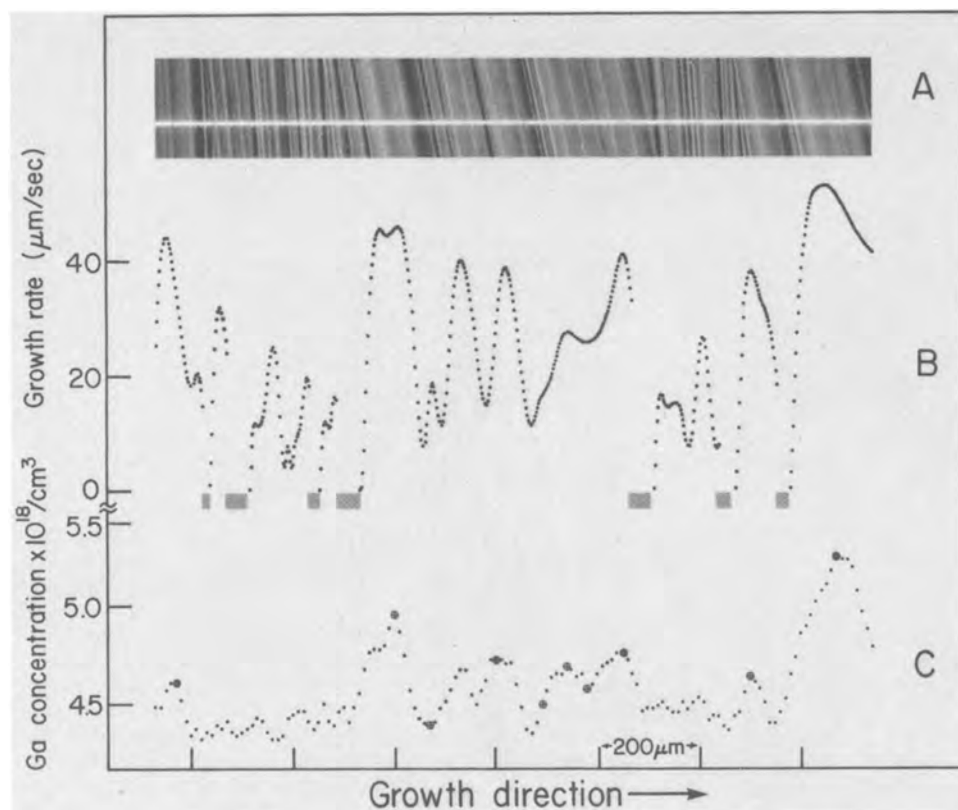

Fig. 4. Microsegregation analysis of Ge crystal grown under turbulent melt convection: (a) photomicrograph of etched crystal segment, (b) growth rate analysis, (c) compositional analysis. Ten randomly selected dopant concentrations on curve C (⊕) with the corresponding growth rates in curve B were subjected to a BPS analysis in Fig. 5. (Experimental points, indicated as ●, correspond to concentrations for which the growth rates are associated with potentially high measurement error because of limited rate resolution under turbulent growth conditions.)

equilibrium distribution coefficient, V is the microscopic growth rate, δ is the diffusion boundary layer thickness, and D is the diffusion coefficient of Ga in the melt. For the purpose of this analysis the Ga concentration in the melt is taken to be identical with the normal concentration in the original charge, since the grown region shown in Fig. 4 is located only 2 mm below the original regrowth interface. Considering the limited resolution of interface demarcation and the necessarily transient segregation behavior associated with pronounced growth rate accelerations and decelerations, the data points considered for analysis (indicated in curve C of Fig. 4) were randomly selected from regions of intermediate maxima and minima for which the reliability of the corresponding growth rates (12-42 μm/sec) is highest; some less reliable data involving growth rates in excess of 42 μm/sec are also included; excluded, for reasons to be discussed later, are data from regions immediately following remelting. The results are shown in Fig. 5; they are considered as indicative of basic compliance of the segregation behavior with the BPS theory; deviations from theoretical behavior at rates in excess of 42 μm/sec reflect in part the error associated with the determination of the growth rate due to limited resolution at the applied demarcation frequency (see above).

In view of the observed agreement between experiment and theory it is meaningful to analyze further

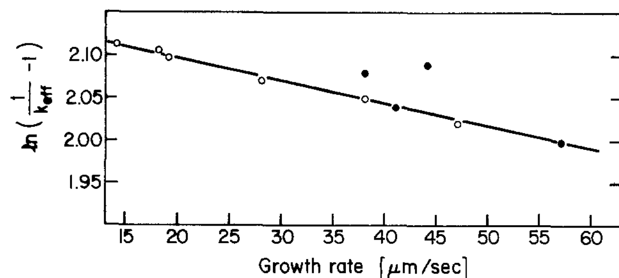

Fig. 5. BPS segregation analysis for growth under turbulent convection based on data in Fig. 4. (For points indicated as ●, see Fig. 4).

the results in Fig. 5. The slope of the BPS plot (δ/D) is found to be 26.3 sec/cm and the thickness of the convection-controlled diffusion boundary layer is computed to be 40 μm (taking $D = 1.5 \times 10^{-4}$ cm^2/sec). Extrapolating the Ga concentration in Fig. 5 to zero growth rate the equilibrium distribution coefficient, k_0, is found to be 0.108. This value is significantly higher than the one generally used (0.087) (8) but identical with that most recently obtained through extensive, as yet unpublished, segregation studies.

The applicability of the BPS theory to segregation under conditions of turbulent convection is surprising in view of the transient nature of the growth conditions; it can, however, be rationalized as a direct consequence of the prevailing high convective melt flow rates. Thus, the convection-controlled diffusion boundary layer thickness is rather small and diffusional adjustment of the segregated Ga to its steady-state value takes place within a short time interval. Taking $\delta^2/D = 0.106$ sec as the characteristic time constant for diffusional segregation readjustment following a growth rate perturbation (9), it must be concluded that the observed intermediate compositional maxima and minima are reasonably close to steady-state values. It is clear, on the other hand, that growth immediately following backmelting exhibits a segregation behavior to which the BPS theory cannot be applied; the dopant concentration profile adjacent to the growth interface is modified by the backmelt process and is most likely affected by a temporary reversal of concentration gradients (the backmelting solid is of lower Ga concentration than the bulk melt) leading to backdiffusion from the bulk melt into the diffusion boundary layer. Because of extensive backmelting the measured temperature fluctuations could not be qualitatively related to the microscopic growth rate and thus it was not possible to apply the Hurle, Jakeman, and Pike theory (10).

On the basis of the present analysis it is concluded that dopant segregation under conditions of turbulent convection (characterized by pronounced and rapid growth rate variations) is in good agreement with the BPS relationship; segregation variations due to con-

vection-induced boundary layer perturbations appear to be a second-order effect.

Segregation under turbulent convection (without extensive backmelting).—At a melt height of 1.8 cm both the growth and segregation behavior undergo a fundamental change. As discussed above the convection roll ceases to rotate about its vertical axis; however, high frequency temperature fluctuations characteristic for turbulent convection persist. Concurrent with the change in convective melt flow behavior, the pronounced remelt striations disappear (see Fig. 2). Since interface demarcation was applied intermittently only, a quantitative growth rate analysis at this transition region cannot be carried out. However, decreased spacing of impurity striations of the non-remelt type are taken as indicative of a pronounced decrease in the microscopic growth rate. This decrease could be quantitatively confirmed through interface demarcation applied again 2 mm below the transition region where growth took place without noticeable backmelting. At this region the average microscopic growth rate is found to be 2.8 μm/sec and thus virtually identical with the macroscopic rate of growth.

In the absence of detailed growth rate information it is of interest to consider phenomenologically the segregation behavior in the above transition region on the basis of the macrosegregation profile given in Fig. 3. It is seen that concurrent with the arrest of extensive backmelting, an abrupt drop of the dopant concentration to about $4.05 \times 10^{18}/cm^3$ takes place. This concentration change, although larger than expected, is consistent with a decrease of the microscopic growth rate from an average of 24 to 2.8 μm/sec expected for this region. (Experimental verification of this assumption could not presently be achieved.) The ensuing gradual dopant concentration increase, which takes place under a constant microscopic rate of growth, is clearly the result of a steady increase in the thickness of the diffusion boundary layer and thus reflects an abrupt decrease in the convective flow velocity. In the later stages of this transition region (location 2 in Fig. 3), a gradual attenuation of the compositional fluctuations from $\pm 10\%$ to about $\pm 2\%$ takes place as seen in Fig. 6.

Segregation under oscillatory thermal instability and under thermal stability (laminar convection).—The dopant segregation under oscillatory instability is characterized by virtual microscopic compositional homogeneities (fluctuations in Ga-concentration are less than $\pm 2\%$). This segregation behavior reflects both a constant microscopic growth rate (2.7-2.8 μm/sec) and relatively stable diffusion boundary layer characteristics.

A crystal segment grown during the transition from oscillatory thermal instability to thermal stability in the melt (location 3 in Fig. 3), together with the corresponding compositional profile, are shown in Fig. 7. It can be seen that in this transition region the microscopic growth rate remained constant while the dopant segregation increased gradually. It must therefore be concluded that the convective flow characteristics, in particular the flow velocity, contrary to the previously discussed transition region, did not change abruptly during the transition from oscillatory instability to thermal stability. The data must be taken as indirect evidence of the presence of laminar convective flow under conditions of thermal stability. No attempts, however, were made to confirm these conclusions through a calculation of the diffusion boundary layer thickness, for example (by applying the Burton, Prim, and Slichter relationship), since the required determination of the Ga concentration in the melt on the basis of the directional freezing equation was considered as unreliable for these late stages of growth.

Summary and Conclusions

The nature of thermohydrodynamic instabilities in Ga-doped Ge melts under destabilizing vertical thermal gradients was determined over a wide range of melt aspect ratios during crystal growth in an inverted Bridgman configuration. It was found that the nature of the convective instabilities (similar to those observed in InSb) changes with decreasing aspect ratio in agreement with theory. The effects of the various modes of convection in the melt on the growth characteristics were studied by high resolution etching analyses of the grown crystal. It was shown that the average microscopic growth rate for growth under time-independent convection melt flow and under oscillatory thermal instability was identical with the average macroscopic growth rate whereas that observed during growth under turbulent convection (because of extensive backmelting) was by about one order of magnitude higher.

Using high resolution spreading resistance measurements for compositional profiling on a microscale together with the microscopic growth rate data obtained through interface demarcation it was for the first time possible to perform a quantitative segregation analysis for crystal growth under turbulent melt convection. This analysis revealed that the dopant incorporation is primarily controlled by the microscopic rate of growth and segregation (with the exception of regions affected

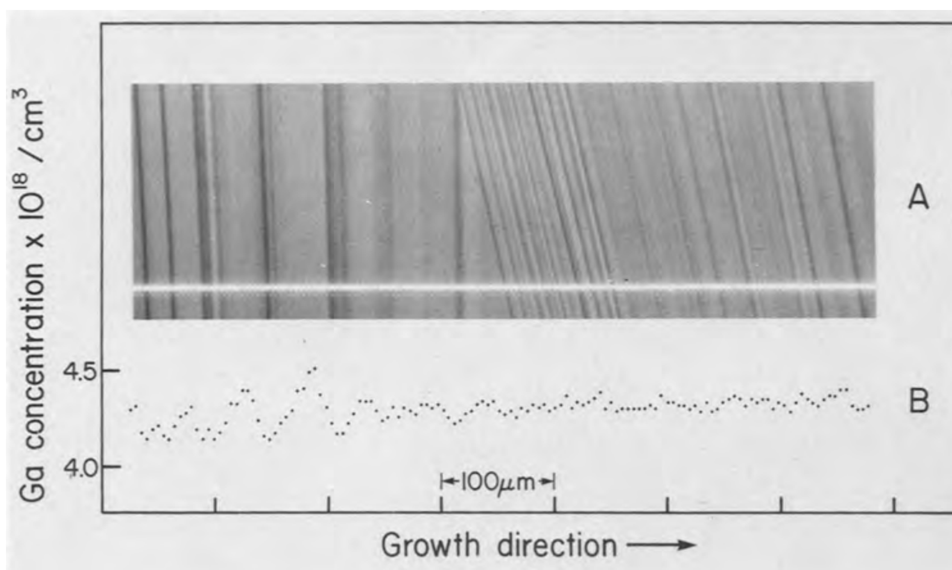

Fig. 6. Dopant incorporation in the transition region from turbulent convection to oscillatory instability (segment 2 in Fig. 2). Notice the attenuation of compositional fluctuations from $\pm 5\%$ to about $\pm 2\%$.

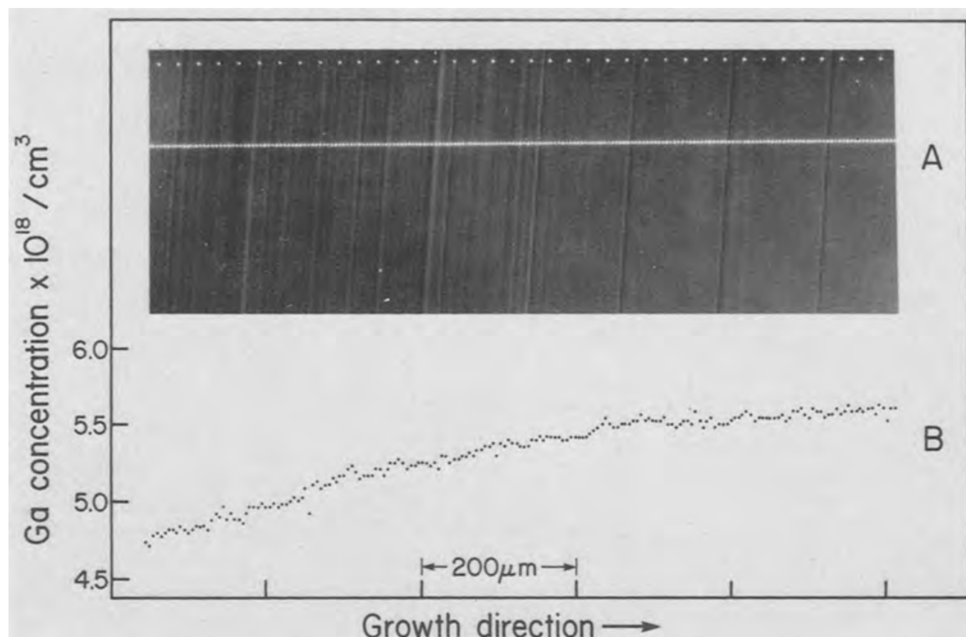

Fig. 7. Dopant incorporation in the transition region from oscillatory instability of time independent laminar convective flow (segment 3 in Fig. 2). See text.

by backmelting) is in basic compliance with the BPS theory. Convection-induced solute boundary layer perturbations were found to be a second-order effect. The applicability of the BPS theory to segregation under pronounced growth rate variations is attributed to the establishment of a small solute boundary layer thickness resulting from relatively high convective flow rates in the melt. Thus, growth rate controlled diffusional solute adjustment within the solute boundary layer is rapid and segregation can adjust without noticeable transient effects to randomly changing growth rates.

Plasma-Grown Oxide on GaAs

Semiquantitative Chemical Depth Profiles Obtained Using Auger Spectroscopy and Neutron Activation Analysis

C. C. Chang, R. P. H. Chang,* and S. P. Murarka*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Plasma oxidation of GaAs is a low temperature oxide growth technique with possible electronics device applications. Chemical depth profiles through 600-3000Å thick plasma-grown oxides were obtained using Auger spectroscopy combined with ion milling and were calibrated using neutron activation analysis. The "bulk" compositions of these oxides were uniform with depth and equivalent to those of mixtures of Ga_2O_3 and As_2O_3. Approximately the first 200Å of the oxide surfaces were always As-rich, but each oxide as a whole was As deficient and the Ga/As concentration ratio increased with oxide thickness from 1.1_8 at 600Å to 1.4_5 at 2780Å. The mechanism of As loss is the faster out-diffusion of As compared to Ga during oxidation and volatilization of surface As-containing species. A sheet of elemental As, amounting to about 10^{15} atoms/cm²/1000Å of oxide growth, was found at the oxide-GaAs interface. The interface widths were <30 and <70Å at oxide thicknesses of 600 and 2780Å, respectively.

Recent demonstration of the growth of native oxides on GaAs using a magnetically confined plasma medium suggested that the plasma oxidation technique may be of practical interest to electronics device technology (1). This technique has certain advantages over other methods, such as thermal oxidation or anodization. With thermal oxidation, the growth rate is too slow at low temperatures, and at temperatures sufficiently high for reasonably fast growth rates, there are the problems of As loss and recrystallization of Ga_2O_3 (2). Anodic oxides require various postgrowth anneals for stabilization and improvement of film properties, and the growth process is sensitive to the semiconducting properties of the GaAs. These oxides are also characterized by either a wide film thickness distribution or a diffuse oxide-GaAs interface that span a mean width of approximately 700Å for oxides 2500Å thick (3, 4). On the other hand, plasma oxide films were found to be uniform, homogeneous, dense, nearly stoichiometric, and amorphous in nature (1). Preliminary electrical measurements have shown that the GaAs MOS capacitors have relatively stable *C-V* characteristics as well as high breakdown voltages (1). The present paper reports on Auger spectroscopy studies of the plasma-grown oxide on GaAs in the thickness range between 600 and 3000Å. Knowledge of the oxide chemistry and depth profile should provide a better understanding of the chemical and physical processes involved in the oxide growth, as well as some idea of the "quality" of these oxides compared to other types of oxides.

Experimental

The plasma oxidation process was carried out in a linear plasma device described elsewhere (1, 5). An oxygen plasma (density $\cong 10^{10}$ particles/cm³, $T_e \cong$ 4 eV) was formed at a background pressure of 2×10^{-3} Torr and an ambient temperature of $\cong$40°C with a pair of rf aluminum electrodes which were driven in balance at the same d-c potential with a typical rf power of 300W at 20-30 MHz. The plasma thus formed (in the source region of the plasma device) was confined by an external magnetic field of 500G. The magnetic confinement also reduced the contamination from the chamber walls. The plasma column was 5 cm in diam and 50 cm long. The GaAs wafer, (100) orientation, Te doped, with a carrier concentration of 2×10^{17}/cm³, was first cleaned in dilute HCl and then mounted on a Monel substrate holder. The wafer surface was mounted normal to the magnetic field lines and at least 30 cm away from the electrodes to avoid sputtering contamination from the aluminum electrodes. The substrate was then biased at up to 90V positive with respect to the plasma for collecting electrons and negatively charged oxygen species.

Four samples were investigated for this report and they are listed in Table I together with the oxide thickness which ranged from about 600Å to almost 3000Å. The oxide thicknesses were determined using Rutherford backscattering. All the oxides were grown under essentially similar conditions except for No. 1782, which was grown at a slightly faster rate. Detailed descriptions of the growth conditions are outside the intended scope of this paper and will be presented in a forthcoming report.

Chemical analyses were performed by measuring the surface composition by Auger electron spectroscopy (6, 7), using a (Varian) cylindrical analyzer with an energy resolution of 0.25%. Typical operating conditions were 10 μA incident electron beam at 6 keV, 50μ beam diameter, and 2 eV a-c modulation; data were taken in the $d[EN(E)]/dE$ mode and multiplexed over only the relevant Auger peaks. Complete scans from 0 to 1800 eV were also taken from time to time to ensure that the multiplexed elements were the only species present in the oxide. Since hydrogen is not detectable by Auger electron spectroscopy, its possible presence was ignored in this work. Depth profiles were generated by measuring the surface composition while simultaneously milling the surface with a (Varian) Ar ion gun operated at 2 keV. The times required for ion milling the oxide from the surface to the oxide-GaAs interface are plotted against oxide thickness in Fig. 1 (filled points). As expected, the relationship is linear; the solid line drawn through the points represents a milling rate of 100 Å/min.

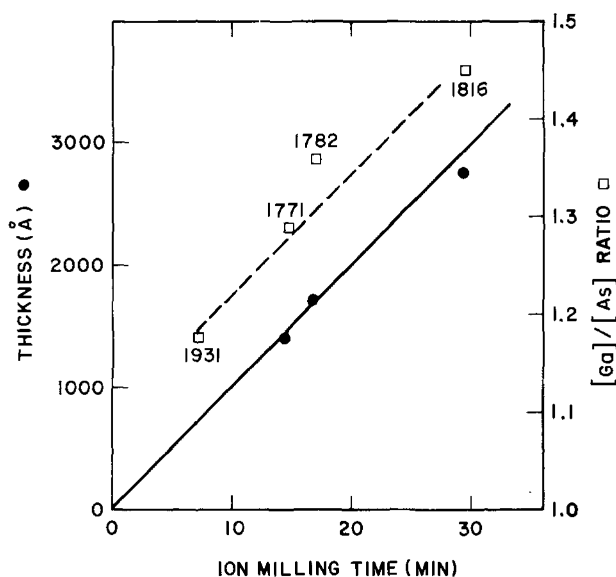

Fig. 1. The oxide thickness (filled points) and Ga/As concentration ratio (open squares) as functions of ion milling time. The over-all Ga/As concentration ratio increases with oxide thickness.

Neutron activation analysis was utilized to calibrate the concentration ratio of Ga and As in the oxide because this ratio was the only quantity for which a calibration could not be obtained from Auger data alone. Details are further described below.

Results

Calibration of the Auger data.—Quantitative Auger analysis (6, 7) can be accomplished by experimentally determining the coefficients for all of the known factors that affect the Auger signal intensity, so that the measured heights of peaks in the Auger spectra can be converted to composition in atom percent. This procedure of calibrating the Auger intensity is quite involved. Only an outline of the procedures followed in this work is presented here, with the appropriate references. We define quantitative analysis as one in which numerical results are calculated, together with some well-defined error limits. In the Discussion section, we describe some of the difficulties encountered in estimating meaningful error limits for the present work. Because of a lack of the statement of error limits, these analyses can only be considered semiquantitative.

Numerical evaluations of certain parameters and corrections for all experimental artifacts must be completed before quantitative depth profiles can be calculated. A description of these evaluations is now presented, organized into the five items discussed below. The first two items concern (*i*) the Auger sensitivity factors, and (*ii*) the correction factors for compositional changes induced by the ion beam used for ion milling and the electron beam used for Auger excitation. Three additional problems had to be considered. Item (*iii*): At the start of ion milling, the ion and electron beam interactions have not had time to establish steady-state conditions; in fact, at time t = 0 min, the surfaces are not perturbed at all, so that (*ii*) above does not apply at the oxide surface. Item (*iv*): At the oxide-GaAs interface, signals from the oxide and GaAs both contribute simultaneously to the Auger peak. Since the correction factors for GaAs and the oxide are different, these signals must first be separated before application of the correction factors. Item (*v*): We demonstrate below that some of the oxide-GaAs interfaces investigated here were only about 30Å wide; for such narrow interfaces, data normalization cannot be performed using peak heights measured at different times because of the rapid change of the Auger peak heights with time. Peaks

Table II. Parameters for quantitative Auger analysis

	Element		
	O	Ga	As
Auger electron energy (eV)	507	1067	1228
Inverse Auger sensitivity factors:			
Ion milled GaAs	—	1.0	1.6
Ion milled oxide	1.6	1.0	1.6
Ion, electron beam correction (oxide only)	1.0	1.0	2.0

Notes:
The inverse Auger sensitivity factors are applicable under the following conditions: 6 keV incident electron energy, 2V, a-c modulation, and analyzer resolution of 0.25%.
The inverse Auger sensitivity factors for Ga and As in the oxide and in GaAs were found to be the same in this work, in contrast to the different values found in Ref. (4). The new values are consequences of the higher energy resolution of the present apparatus. When the derivative-type spectra are used, the higher resolution results in (*a*) a reduced interference from the plasmon loss peak, and (*b*) a reduced interference among the closely spaced (<5 eV) multiplets which comprise each of the Ga and As peaks.

measured at the same instant must somehow be obtained. Each of the above five items will now be considered in greater detail.

Item (i): the Auger sensitivity factors.—The Auger sensitivity factors for Ga and As were determined (8) by an analysis of four reference GaAs surfaces: (*a*) cleaved in vacuum, (*b*) ion milled, (*c*) molecular-beam grown (Ga stabilized), and (*d*) molecular-beam grown (As stabilized). The sensitivity factor for O was taken from a previous calibration obtained by use of a single crystal of Ga_2O_3 (4). The resulting sensitivity factors are shown in Table II, together with the transition energies of the peaks selected for these analyses. The value of 1.6 for the O sensitivity factor was computed by multiplying the value of 0.64 [from Ref. (4), normalized to the Ga sensitivity factor of 1.0] by two transform factors, one for the difference in energy resolution and the other for the different incidence energy. These two transform factors were determined using the present apparatus by decreasing the energy resolution (increasing the a-c oscillation) and decreasing the incidence energy to 3 keV to simulate the operating conditions of Ref. (4).

Item (ii): ion and electron beam induced artifacts.—The ion and electron beam induced compositional changes were investigated by measuring the Ga and As concentration ratios for our plasma-grown oxides by neutron activation analysis. Although this correction factor had been previously obtained using an identical procedure applied to anodic oxides on GaAs (4), this factor might be different for the plasma-grown oxide because of the different physical and chemical properties of the two kinds of oxides. For the neutron activation analysis, one crystal of GaAs with about 1500Å of plasma-grown oxide was irradiated in a neutron flux, and then the oxide was etched off in a known volume of 1:1 solution of $HCl:H_2O$. A precise volume of this solution was then transferred to a 2 in. diam filter paper since the Li drifted Ge detector was calibrated for this geometry. Counting was performed as a function of time to determine the half-life of the detected radiation, and the concentrations of Ga and As were then calculated using known efficiencies. The amount of Ga was found to be constant with time but the amount of As decreased, as observed previously (4). We used the Ga and As concentrations extrapolated back to the time of dissolution as the value in the oxide. This procedure assumes no concentration change between the time of irradiation and the time of dissolution, no precipitation in the HCl solution, and no preferential adsorption at container walls. To minimize wall adsorption, micropipettes and beakers made from nonwetting polypropylene were used.

The desired correction factor for the Auger data was obtained by dividing the Ga/As concentration

ratio from neutron activation analysis, which was 1.2_9, by the apparent concentration ratio from Auger analysis. The latter was obtained as the ratio of areas under the curves for oxidized Ga and As in the depth profiles through sample No. 1771, with 1400Å oxide (possible errors caused by the 100Å difference between this sample and the one analyzed by neutron activation analysis are expected to be small and have been neglected).

The correction factors for the ion and electron beam induced compositional changes are listed in Table II. The value of 1.0 for the ion and electron beam correction of Table II for Ga was assumed to be that found for Ga_2O_3 (4). The value of 2.0 for the As correction factor, which derives from the neutron activation analysis measurement, is significantly different from the 1.6 determined earlier for anodic oxides (4). Although the reason for this difference is not known, there is no requirement, as stated earlier, that these values should be identical. The value of 1.0 for O is explained in Ref. (4).

To determine whether the ion or electron beam produced the larger effect, the result from electron bombardment alone was investigated and is shown in Fig. 2. It was found that under the present operating conditions, the decomposition of Ga oxide was negligibly slow, but the As oxide was rapidly decomposed and a new As peak, near the energy of As in GaAs, appeared in the spectra. Because of the relatively high energy resolution of the Auger apparatus, these chemically shifted (by about 7 eV) and unshifted peaks could be effectively resolved. The total As Auger signal could be measured as the sum of these two peaks. The open points in the figure indicate the change with time of the total Ga/As Auger signal ratio, which is seen to increase by a factor of two and level off in about 2 min. This increase suggests that some As is lost from the surface. The factor of two increase is equal to the correction factor of two found above using neutron activation analysis. Therefore, the major contribution to the correction factor comes from the electron bombardment and very little from the ion bombardment. This conclusion is consistent with the fact that the curves of Fig. 2 remain essentially the same when the data are taken with or without simultaneous ion milling. This last observation is somewhat unexpected because the ion milling should remove the decomposed As, and indicates that much more can be learned about the electron and ion beam interactions with these oxides by further Auger studies.

Item (iii): the nonsteady-state problem at start of ion milling.—The possible errors caused by the initial nonsteady-state conditions were reduced by varying the preferential sputtering correction linearly from 1.0 to 2.0 between 0 and 2 min during data acquisition. There should be nothing fundamental about the 2 min interval; this time was simply the interval to attain steady state as illustrated in Fig. 2 for the present operating conditions. Under different conditions (*e.g.*, electron beam intensity), this time interval is expected to be different.

Item (iv): separation of signals from the oxide and from the GaAs at the interface.—The Auger signals from the oxide and from GaAs could be distinguished in one of three ways. These are the use of: (*a*) the chemical shift, (*b*) the O Auger signal, and (*c*) the plasmon loss peak. We have tried all three methods and they gave essentially the same results within experimental error. Each method has its particular advantages and disadvantages and there was no one technique that was clearly more accurate than the other two. Typical results from the last two methods are compared in Fig. 3 for data from two samples with different interface widths. In the figure, the amount of GaAs was estimated using the oxygen peak by assuming that only Ga_2O_3, As_2O_3, and GaAs are present at the interface (open points), and by use of the Ga plasmon loss peak (filled points). From the close agreement of the two curves, it is concluded that the amount of interface material is too small to be detected using this type of analysis. For example, if large amounts of excess As or suboxides were present, the open points would lie to the left of the filled points in Fig. 3. Therefore, either method is equally useful for determining the amount of GaAs. Because use of the O peak was the simplest and the scatter in the data was least, this method was adopted for this work.

Item (v): obtaining simultaneous peak heights.—With the present apparatus, it was not possible to monitor several Auger peaks simultaneously. Therefore, one peak from each element was multiplexed and each element was recorded sequentially as a function of time. Then continuous curves were drawn, one through the maxima, and one through the minima, of the peaks from each element, defining an "envelope" describing the peak height variation of that element with time. The value of peak heights determined by the envelope for each element present at one given instant was then used for the computations. For sample No. 1931, several envelopes were obtained using data from different areas of the sample and superposed

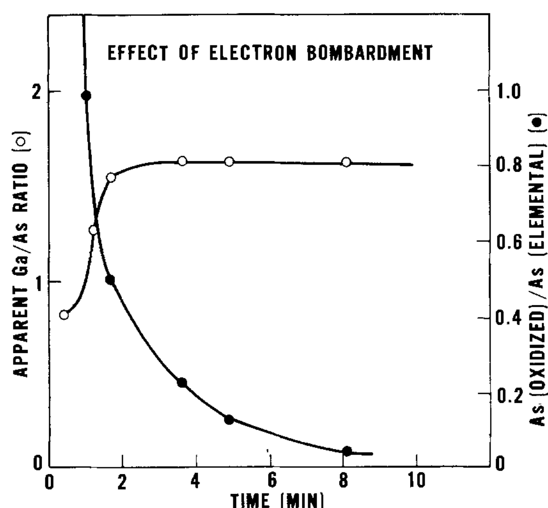

Fig. 2. Decomposition of As-oxide by electron bombardment. The decomposition is incomplete even after 4 min (filled points), but the method of peak height measurement adopted in this work (addition of the chemically shifted and unshifted peaks) gives the final steady-state value of the Ga/As ratio after only 2 min.

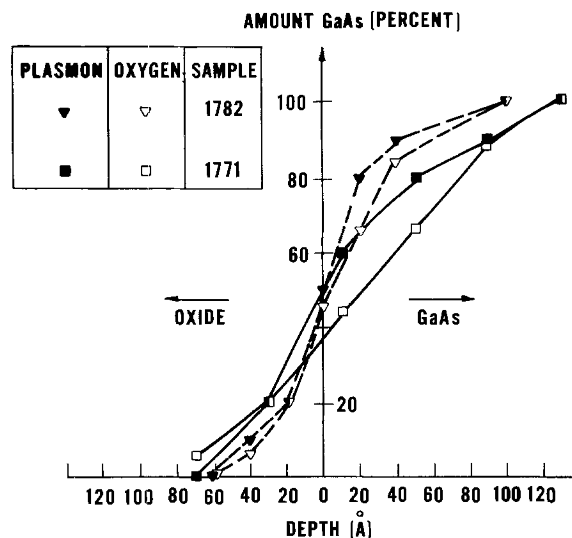

Fig. 3. Comparison of the use of the plasmon loss peak and the oxygen Auger signal for separating the Auger signals from oxidized and unoxidized Ga and As atoms at the oxide-GaAs interface.

(by matching the envelopes) to increase the density of data points and reduce the amount of envelope extrapolation between them.

Using the above correction factors and methodology, the chemical depth profiles of this work were obtained. The Auger intensities were measured as the peak-to-peak heights of the "derivative" spectra. Calculations were performed in the homogeneous approximation, *i.e.*, ignoring the oxide-GaAs layer sequence, since the details of the layer geometry were not sufficiently known. Compositions (in atom percent) were calculated as the normalized Auger signal (6, 7) A_i, for each element i, which includes the corrections for the Auger sensitivity factors of Table II. In addition, the Auger intensities were multiplied (4) by their proper preferential sputtering coefficients. The question of error limits is taken up in the Discussion.

The chemical depth profiles.—Chemical depth profiles from the four samples of Table I are displayed in Fig. 4-7. The interface regions are shown expanded in Fig. 5b-7b so that details of these abrupt interfaces can be seen. For the sample of Fig. 4, nonstandard ion milling conditions were used up to about 350Å, and that part of the data is not shown. All the depth profiles exhibit very similar general features, which are described in the following paragraphs.

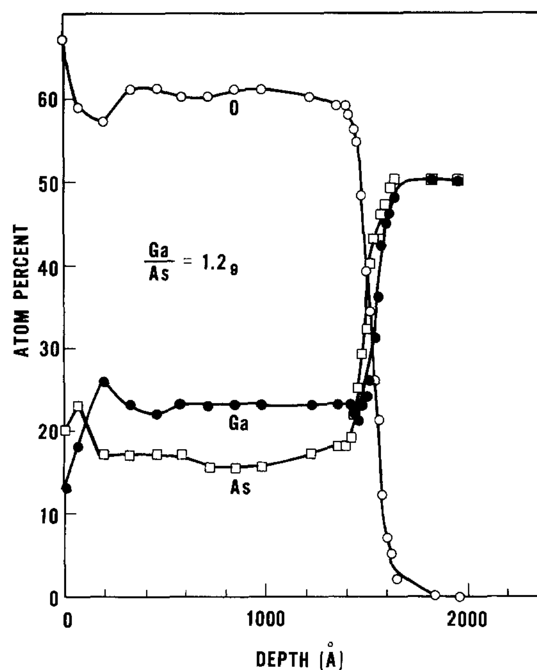
The "bulk" of the oxides contained about 60% O; therefore, the oxide compositions are consistent with those of mixtures of Ga_2O_3 and As_2O_3. The bulk of each oxide had a constant composition with depth, but with varying over-all Ga/As concentration ratios for each sample. The variation of this ratio with oxide thickness is illustrated in Fig. 1 (open squares). There appears to be a linear increase in this ratio with thickness, from 1.1_8 at 600Å to 1.4_5 at 2780Å; only sample No. 1782 deviates slightly from the linear relationship, presumably because it was grown under somewhat different conditions from the rest.

The oxide as a whole was always As deficient and, therefore, As must have been lost during growth. We describe below one possible mechanism for oxide growth which leads to a larger diffusion coefficient for As than for Ga. Since oxides of As are more volatile than oxides of Ga, the As deficiency is a reasonable consequence of the faster out-diffusion of As and the higher volatility of the As oxides.

The surfaces of the oxides always contained more As than Ga. Thus the faster out-diffusing species, not surprisingly, pile up at the surface. The significance of the apparent rise of the O concentration near the surface is presently not clear. It could arise from an error in our calibration scheme, or else it may be a real effect caused by the formation of As_2O_5. This compound has been identified from x-ray photoemission spectra on air-exposed GaAs surfaces (8). However, no distinct peak attributable to As_2O_5 could be discerned in the Auger spectra. Therefore, further interpretation of the apparent rise in the O concentration near the surface cannot be provided until Auger spectra from As_2O_5 are examined.

There is a region near the surface of approximately 200Å in which the As concentration decreases from about 20% to a value below the Ga concentration, in the direction away from the surface. This higher As concentration is opposite to that observed for anodic oxides, since the surface layer in the anodic oxide was As deficient (4). Therefore, it is most unlikely that both layers are experimental artifacts of the same method of analysis. This argument lends further credence to the validity of these depth profiles.

The interfaces between these oxides and GaAs are surprisingly abrupt. The interface width as a function of oxide thickness is plotted in Fig. 8. The convention used here to determine the interface width was to define the apparent width as two times the depth spanned in the profile between 85 and 50% of the



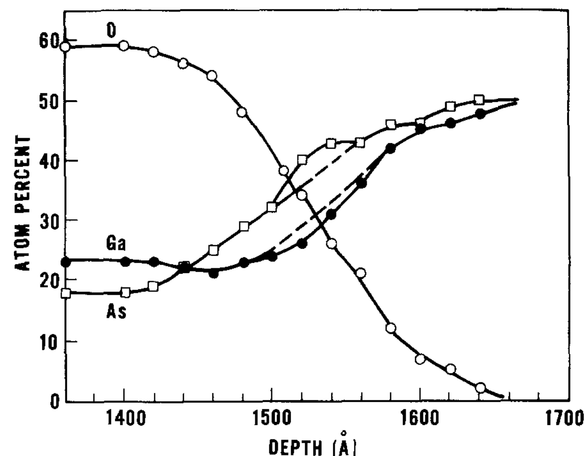


Fig. 5. (a, top) Chemical depth profile of sample No. 1771. (b, bottom) Expanded view of the oxide-GaAs interface region revealing details of the interface.

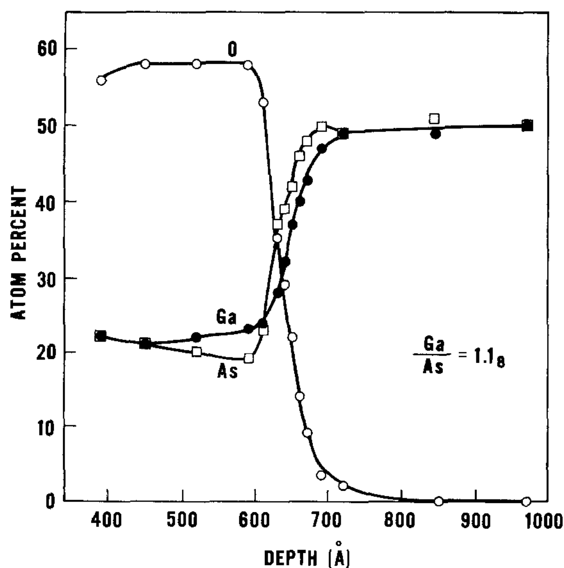

Fig. 4. Chemical depth profile of sample No. 1931. Note that the compositions for all three elements were computed for the same instant in time (see text).

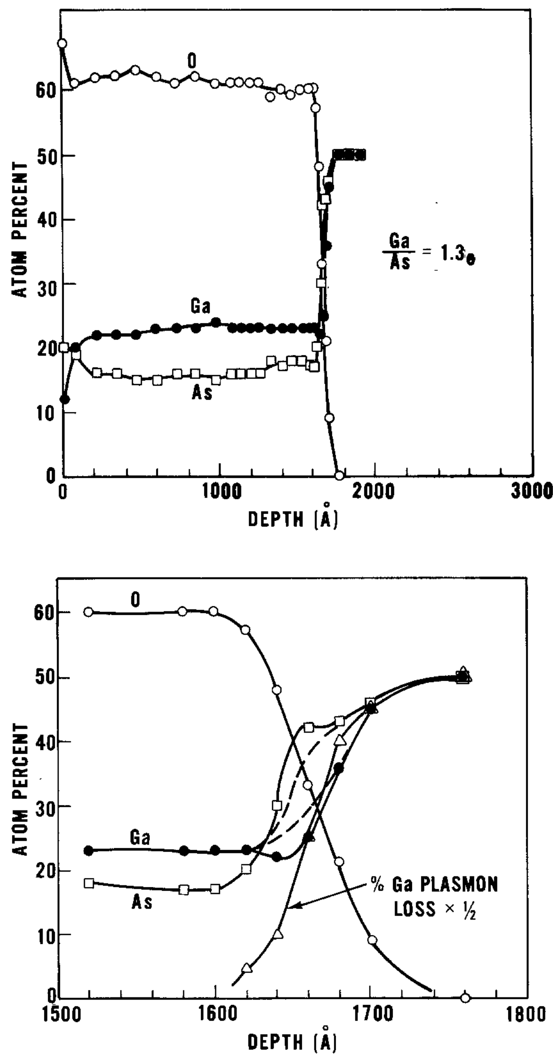

Fig. 6. (a, top), (b, bottom), Same as Fig. 5, sample No. 1782

"bulk" oxygen signal. The width thus defined is called the "symmetric mean width" [see Ref. (9) for the reasons for adoption of this convention, which provides the most reliable estimate of the width from the depth profiles and minimizes errors from ion milling artifacts, etc.]. This procedure does not take into account various broadening factors, the largest of which is due to the finite escape depth of Auger electrons. Data from SiO_2-Si interfaces (9) indicate that use of the apparent symmetric mean width of the oxygen profile leads to a broadening factor of at least 30Å. The estimated true interface width of Fig. 8 was therefore obtained by subtracting this 30Å from the measured apparent symmetric mean width. This procedure should be valid provided that the escape depth of 507 eV electrons in SiO_2 and in the present oxides are equal. The resultant widths ranged from <30 to <70Å. How much less will depend on how much worse the experimental broadening factors are for the GaAs systems studied here compared to the Si systems from which the 30Å broadening contribution was estimated. It is inconceivable that the broadening factors are less for the present systems, because these factors were minimally small for the Si systems (9).

The final topic we consider in detail is the As excess at the oxide-GaAs interface. "Excess As" is defined here simply as the amount of As in excess of the amount of Ga at a given depth. The interface regions are shown expanded in the b-figures (Fig. 5b-7b). Even for the thinnest oxide film, sample No. 1931, a clear As excess was detected (Fig. 4). For the next thicker film, a "bulge" appeared in the As profile near the depth at which the O signal is one-half of its bulk value. This suggests that the As responsible for the bulge is located at the interface because it has been shown (9) that the interface is within several angstroms of the point where the O signal is at half-maximum for the SiO_2-Si system.

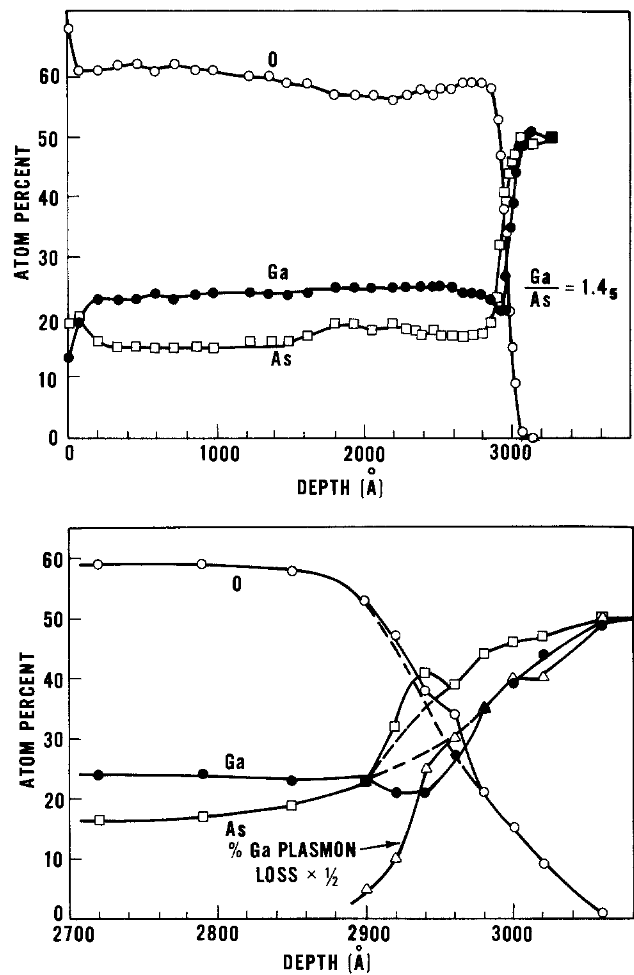

Fig. 7. (a, top), (b, bottom), Same as Fig. 5, sample No. 1816

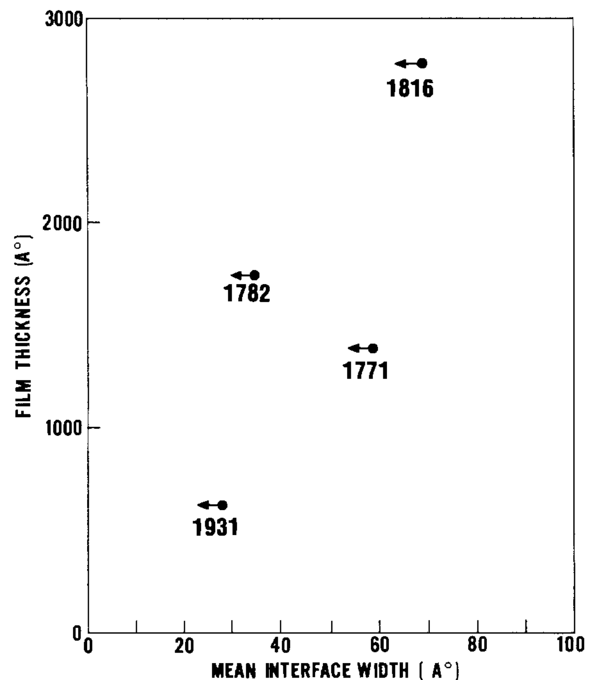

Fig. 8. Measured symmetric mean interface widths. The arrows indicate that the actual widths are expected to be smaller than the values indicated.

This bulge was visible in all of the profiles and was largest for the thickest film, No. 1816. Part of this apparent bulge may be an artifact due to an underestimate of the Ga peak height caused by mutual interference of the chemically shifted and unshifted Ga peaks in the oxide and GaAs, respectively. When the Ga peak is underestimated, the As (and O) peak heights become overestimated during the normalization process. Because the two Ga peaks were summed in the peak height measurement, we estimate that the megnitude of the bulge (amount of deviation from the dashed lines) is too large to be caused by spectral overlap alone. In addition, errors from spectral overlap should be the same for all the depth profiles, whereas the bulge increases with oxide thickness. Therefore, from the large magnitude of the bulge and its increase with oxide thickness, we conclude that the bulge is mostly real and must represent a thin layer of excess As at the exact location of the oxide-GaAs interface. The apparent mean width of this layer on the depth profile is only about 40Å and the true layer thickness is much less. The amount of excess As should be equal to the area between the As and Ga profiles at the interface. For the three thicker films, this amount was approximately 5Å or about two atom layers, if the bulge is ignored. For the thickest film, No. 1816, the bulge adds another monolayer of excess As. These amounts correspond to an As accumulation rate of approximately 10^{15} atoms/cm^2/1000Å of oxide growth. Because the plasmon loss peak associated with the excess As was prominent while the plasmon loss peak for Ga (and for As throughout the oxide) was much smaller, we conclude that the As is in elemental form, similarly to the case for the anodic oxide (4, 8).

Discussion

Some comments on the expected error limits of the present semiquantitative results are in order. All we can claim here is that we have incorporated into our analysis most of the known correction factors that could be numerically calculated. However, a meaningful estimate of the error limit is not possible for the present system because of insufficient experimental data. For depth profiles of SiO_2 on Si, an estimate of the error limits was attempted (9), but even for such a well-studied system, it was clear that the final answer was not unique because of several basic unknowns, such as the amount of suboxide at the interface. To illustrate some of the difficulties, we discuss here a few points of particular concern. (*i*) The accuracy of the neutron activation analysis for the Ga/As concentration ratio has not been tested. Since the depth profile and neutron activation data cannot obviously be obtained from the same sample, the sample-to-sample variations become important. The possible preferential loss of some chemical components during liquid transfer, are also not sufficiently known. (*ii*) An accurate determination of the Auger sensitivity factor for O in an oxide containing Ga and As has not yet been satisfactorily performed for lack of a good standard. We point out that the sensitivity factor of 1.6 used here should be compared to a value of approximately 0.6 in Ref. (10) (pp. 14-15; data were transformed to conform to the conventions, definitions, and operating conditions of this work). This is a disagreement of over a factor of 2 and represents one of the largest discrepancies of the Auger sensitivity factor in the literature. This disagreement results largely from the sensitivity of the O Auger peak shape to chemical environment [a different oxide was used in Ref. (10)]. This comparison illustrates the variability of the O Auger sensitivity factor depending on the chemical environment; however, there is presently insufficient experimental data to statistically establish the typical variations in the sensitivity factor with variations in properties of the Ga-As-oxide. (*iii*) Another source of uncertainty arises from the complexity of the interface structure. No provision was made in the above analyses for the presence of the As layer. Moreover, the formalism adopted effectively assumed that the proportion of oxidized Ga to oxidized As remained the same at the interface as in the bulk of the oxide. This assumption is probably not strictly valid because of the presence of the elemental As. Because of the various artifacts that cloud the As Auger data, all of the three methods for separating the Auger signals from the oxide and GaAs described in item (*ii*) above apply mostly to Ga. In fact, little is presently known about the precise distribution of the As atoms in the oxidized, elemental, and GaAs phases. In summary, we have clearly demonstrated that certain corrections must be applied to the Auger data for obtaining more quantitative depth profiles and that some of these corrections can be rather large; however, additional experimental work will be required before meaningful error limits can be estimated. Nevertheless, the reproducibility of the data was sufficiently high (about $\pm 5\%$) to justify those conclusions of this work based on what might appear, from these disclaimers, to be small differences between profiles from different samples.

The O concentrations in the oxide measured in this work are in agreement with those from studies of similar films using ion-induced x-ray analysis (11). However, there is significant disagreement for the Ga/As concentration ratio; the discrepancy is about 13% at oxide thickness of 1000Å but increases to about 30% near 3000Å. In the work of Ref. (11), no increase in the Ga/As ratio was found with oxide thickness. The reason for this discrepancy is presently being investigated. Although the possibility of an error in the absolute calibration of the present work cannot be ruled out, there is no known artifact which would cause the error to increase with oxide thickness.

The present understanding of the ion-mill depth profiling technique is insufficient to provide unequivocal proof that the excess As observed at the interface is real. However, a mounting quantity of evidence supporting the correctness of the depth profiles is accumulating, making it increasingly difficult to maintain a skeptical attitude. The existence of a sheet of As near the oxide-GaAs interface has already been hypothesized on the basis of anomalous ellipsometric results (12). The excess As seen in depth profiles of anodic oxides on GaAs has been directly examined after etch removal of the oxide to expose the As layer (4). Evidence for the elemental nature of this As was supplied both from x-ray photoemission data (8) and from the observation of prominent plasmon losses in Ref. (4) and in this work. Unless a phase separation had occurred, the different behavior of As from that of Ga cannot be explained. Finally, the presence of the sharp "bulge" described above and its increase with oxide thickness are difficult to explain away on the basis of an experimental artifact. The importance of the excess As idea cannot be overemphasized because if excess As does exist, it can provide the answers to many previously unanswered questions concerning oxides on GaAs. The As layer can (*i*) dominate important MOS properties of these oxides, (*ii*) control the surface potential of the semiconductor, and (*iii*) determine the semiconducting properties of the underlying GaAs by influencing the Ga vacancy concentration, etc.

The over-all As deficiency found in this work contrasts sharply with the nearly stoichiometric composition of the oxides obtained when an aluminum-oxide layer is used as a surface "filter" to confine the As within the growing oxide (13). Therefore, in addition to the ability to grow these oxides at low temperatures as demonstrated here, ways have also been found to control the relative amounts of Ga and As within the oxide.

Conclusions

The major conclusions of this investigation are:

1. The composition of the plasma-grown oxide is uniform with depth over 90% of its total thickness; the

oxide as a whole is As deficient and the Ga/As concentration ratio increased with oxide thickness from 1.1_8 at 600Å to 1.4_5 at 2780Å. There is a surface region almost 200Å thick which is As rich. The oxide composition is equivalent to that of a mixture of Ga_2O_3 and As_2O_3.

2. We propose that the mechanism for As loss derives from the faster out-diffusion of As compared to Ga during oxide growth (8) and the higher volatility of As oxides compared to Ga oxides. This conclusion means, of course, that there is a finite As out-diffusion during oxide growth.

3. A pile-up of elemental As was observed at the oxide-GaAs interface. The mechanism (4, 8) for the formation of the As layer is the preferential oxidation of Ga due to the higher heat of formation of Ga_2O_3 compared to As_2O_3. The As pile-up increased with oxide thickness, at the rate of approximately 10^{15} atoms/cm^2/1000Å of oxide growth.

4. The oxide-GaAs interface width was extremely narrow, ranging from <30Å at oxide thickness of 600Å to <70Å at 2780Å.

5. The electron beam produces a larger effect in decomposing the Ga-As-oxide than the ion beam and it is the As oxide that is rapidly decomposed; the decomposition of Ga oxide was not detected.

Experimental Investigation of the Gas Phase in a Chemical Vapor Deposition Reaction

Application to the Silane-Ammonia Reaction Leading to Silicon Nitride Deposits

G. Cochet, H. Mellottée, and R. Delbourgo

CNRS, Centre de Recherches sur la Chimie de la Combustion et des Hautes Températures, 45045 Orléans Cédex, France

ABSTRACT

The investigation of the gas phase composition of a CVD system was carried out applying a method derived from flame front structure research and implying a point-to-point analysis of concentrations and temperature profiles. A finely drawn nozzle-shaped probe is used to draw stable species samples out of the gas phase. They are subsequently compressed into a VPC analyzer. A fine silica-coated thermocouple is used to draw the temperature profiles. The method was applied to the co-pyrolysis of silane and ammonia forming silicon nitride on a vitreous sintered silica substrate heated at 950°, 1000°, and 1050°C at different values of the ratio of silane to ammonia. The results obtained localize the space, in the gas phase, and relatively to the substrate, where the solid phase starts condensing as the initial reactants are consumed. The method is reproducible and reliable. If properly developed it should lead to interesting applications in the interpretation of CVD aerothermochemistry and chemical kinetics.

One of the main problems raised by the interpretation of chemical vapor deposition mechanisms lies in the accurate space and time resolution of the reaction species and parameters. The question is not yet fully settled as to whether the reaction is localized in the gas phase or on the heated substrate or occurs simultaneously in the gas phase and on the substrate. Any attempt to interpret quantitatively CVD data should first aim at obtaining experimental evidence on the relative contribution of the gas phase and of the substrate reactions especially if the objective is one of obtaining theoretical models more satisfactory and general than those presently found in the literature (1, 2). The efforts made in this direction appear how-

Key words: chemical vapor deposition, silicon nitride, gas phase investigation.

ever to have been limited by experimental difficulties due to the necessity of controlling a high temperature reactive system under flow conditions.

This paper describes an attempt to apply to CVD systems a point-to-point probe and thermocouple analysis to determine concentrations and temperature profiles in a system leading to silicon nitride deposited on vitreous sintered silica by the co-pyrolysis reaction of silane and ammonia.

Experimental

The method used is an extension of the Fristrom and Westenberg (3) technique originally developed for flame front structure studies. Gas samples are withdrawn from the reaction zone at different points of the gas flow and a consistent profile can be drawn for each species by moving the probe from the unburned gas to the products and through the flame front. It has been shown that with adequate care and equipment (finely drawn quartz probes) minimum perturbation of the gas flow is achieved and that samples can be withdrawn from the reaction zone sufficiently rapidly to ensure quenching of the products. With minor modifications we have attempted to apply the same method to a CVD reactor.

Temperature profiles.—In order to establish temperature profiles one is led to introduce a fine thermocouple in the gas flow. If the diameter of the wires and junction are kept small (*ca.* 10-50 μm) no instability is added to the flow aerodynamics. Catalytic effects can be offset by coating the thermocouple with a fine silica coat. Radiative loss can be a source of error, the thermocouple behaving as a radiant heat sink. To account for this factor implies knowing the emissivity of the thermocouple and properties such as the thermal conductivity, specific gravity, viscosity, and flow rate of the gas phase. In a CVD system, at temperatures of the order of 1000°C, it appears that radiative loss can be neglected since the temperature drops very rapidly as one moves away from the substrate. Accounting for a proportionality of radiation loss with the fourth power of temperature, one obtains for a 20 μm probe, a gas phase in which hydrogen is the main carrier and a temperature of 1100°K, a correction of only 8°K value which is considered affecting only negligibly the temperature profiles drawn.

Pt/Pt-Rh 10% thermocouples were used throughout this work. The size of the thermocouple junction is less than 0.1 mm. A coat of SiO_2 obtained by dipping the thermocouple in silicone oil and flaming reduces catalytic effects.

Concentration profiles.—Sampling in the gas phase is obtained by a finely tapered quartz probe. Samples are drawn into the nozzle under reduced pressure (4-10 Torr), the orifice diameter is small (10-100 μm). The gases are drawn in rapidly and rapid flow rate quenches the species out of the reaction zone satisfying both representative and reproducible results.

Satisfactory quenching of samples is borne out by the application of this method to flame structure studies and the agreement obtained with mass spectrograph and EPR data (3). Also, the sample is essentially gaseous, no solid deposit being apparent in the probe except for traces similar to the Si_3N_4 deposited on the cold walls of the reactor (same color, ammonia smell, and Si-N bands found by infrared spectroscopy). There seems to be no reason to believe that these traces imply a variation in composition of the gas phase. As in the case of the thermocouple, the introduction of a fine probe in the gas flow does not affect the stability of the system. The emissivity of quartz is 2×10^{-2} (3) and, therefore, thermal effect can be considered negligible. Catalytic effects are also not significant and the only source of error seems to be the difference in diffusion rates of the various species present. In a CVD system in which a carrier gas is in most cases in excess the problem is limited to a binary system for which the diffusion coefficients can be calculated.

The samples are transferred to a gas chromatograph or to a mass spectrometer by any convenient means and the analyses of the gas phase can therefore be accomplished at least for all stable species.

Combining temperature profiles and concentration profiles, one can draw a point-to-point map of the gas phase and obtain important information on the evolution of the reactants from their inlet at the top of the CVD reactor down to the heated substrate where the condensed phase is deposited.

In applying these techniques to a CVD system heated by a high frequency device, one must be aware of the possible influence of the HF on the thermocouple. The relative dimension of the inductor and the susceptor (in this case the thermocouple) is such that the error appears to be small. The temperature recorded by the thermocouple has been compared to a reading obtained by infrared pyrometry. The maximum difference obtained, near the substrate, is less than 10°C. This does not affect significantly the profiles and gradients which were obtained.

CVD reactor.—The method described above was applied to the following system

$$3SiH_4 + 4NH_3 \rightarrow Si_3N_4 + 12H_2$$

depositing silicon nitride films on a vitreous sintered silica substrate.

The setup used is shown in Fig. 1. It consists of a panel comprising the different manometers, flowmeters, and needle valves. The reactants are mixed in a tube filled with glass beads. The reactor consists mainly of a graphite susceptor, protected by a coat of silicon nitride and heated by high frequency under 1 MHz. The substrate is a plane disk 1 mm thick, 28 mm diam made of sintered silica and adjusted on the susceptor.

The susceptor was designed to obtain a constant temperature (± 2°C) across a diameter. The temperature was measured by infrared pyrometry. The temperature of the graphite was kept constant by a regulating system connected to a thermocouple W 97%-Re 3%/W 75%-Re 25%. The top of the reactor is fitted with a mobile head designed to monitor the simultaneous lateral and vertical movement of the probe or thermocouple (Fig. 2). The positioning can be adjusted to 5×10^{-2} mm and readings can be taken every 0.1 mm along the vertical axis and radially every 1.0 mm. Samples were taken down to a distance equal to 0.5 mm from the substrate. Any attempt to probe at smaller distances from the substrate results in rapid clogging of the probe. The thermocouple wires were coated with SiO_2 by burning with a silicone oil.

The gas samples are drawn into a piston under a reduced pressure of the order of 10 Torr then compressed into a VPC analyzer fitted with a catharometer (4). The following gases were analyzed: SiH_4, H_2, N_2,

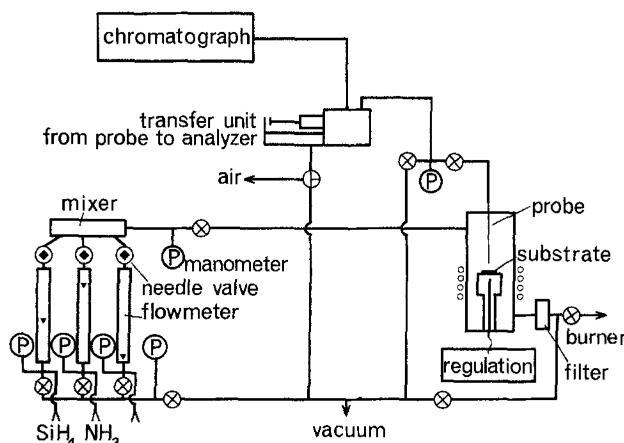

Fig. 1. Schematic layout of the apparatus

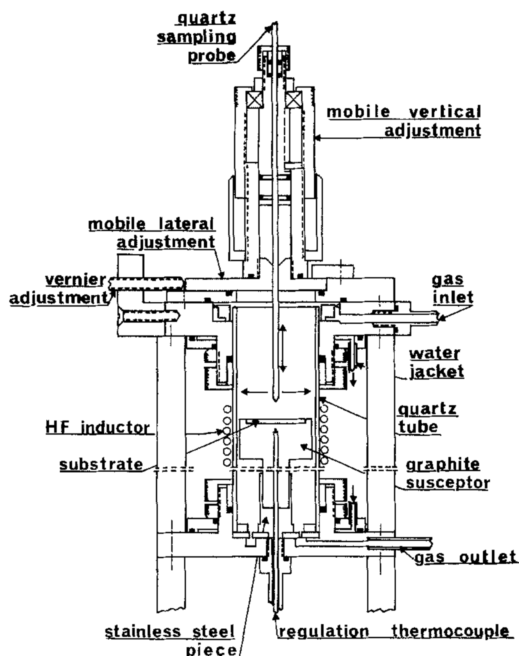

Fig. 2. Mobile probing head for thermocouple readings and gas samples.

NH_3, and Ar. Two columns were placed in series, one 2m long filled with Porapak T, heated at 110°C, the other, outside the chromatograph, 3m long fitted with 13*X*, molecular sieve, was kept at room temperature.

Down flow of the reactor, a metal grid filters the solid particles formed around the substrate. The flow gases are ultimately burned in a diffusion gas burner.

Reaction conditions.—The optimum conditions for obtaining Si_3N_4 from the co-pyrolysis of SiH_4 and NH_3 are given elsewhere (5). In the present case three temperatures of the substrate were systematically investigated: 950°, 1000°, and 1050°C.

We will recall that favorable conditions for Si_3N_4 require large values of the ratio of NH_3/SiH_4, at least of the order of 30 (6) and varying with the experimental conditions. In this investigation the mixtures studied were in the ratios 50/1, 100/1, 200/1, and no Si in excess nor any trace of Si-H bands as detected by infrared spectrometry were observed, as would be the case for lower values of the NH_3/SiH_4 ratio. The gas flow rates were set at 11, 22, and 44 liter/hr, corresponding to linear velocities of 0.25, 0.5, and 1.0 cm/sec.

Results

Temperature profiles.—The temperature profiles which were obtained are shown in Fig. 3. They refer to a mixture flow rate of 22 liters/hr with a ratio of NH_3/SiH_4 equal to 100/1 and a substrate temperature of 950°C. The y axis represents distances from the substrate along its axis and the walls of the reactor and the substrate are shown at the right and lower part of the figure. The profiles shown are isotherms drawn every 20°C.

The temperatures recorded are mean values and similar instabilities to the ones reported by Curtis and Dismukes (7) were observed. The frequency of these oscillations is of the order of 0.5 Hz with an amplitude depending on the carrier gas. It is of the order of 25°C for nitrogen or argon but is reduced to 4°-5°C in the case of hydrogen. Ammonia would lie in between hydrogen and nitrogen. These oscillations, like those observed by Curtis and Dismukes, could be interpreted in terms of perturbations due to convection and related to the number of Rayleigh ($R = Gr \cdot Pr$).

Two areas are clearly seen: At the center and approximately for 80% of the plate radial distance, the isotherms are nearly horizontal and the gradients small

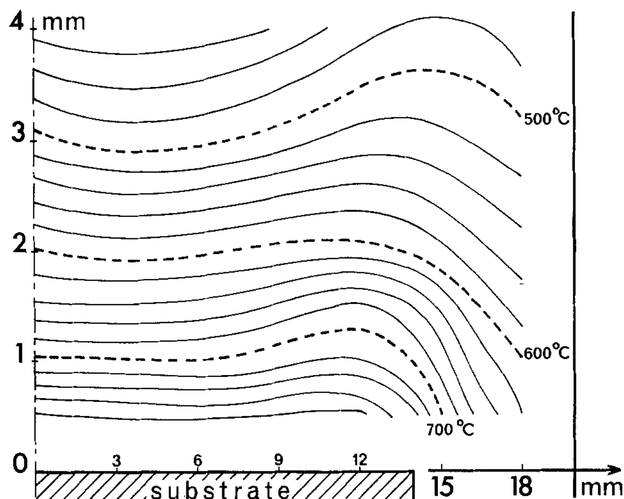

Fig. 3. Temperature profile map. NH_3/SiH_4 ratio = 100, total flow rate 22 liters/hr.

and practically negligible, near the walls the temperature is lower and the gradient steeper. In both situations the vertical gradient is also steep, especially near the heated substrate, as one would expect. Whereas little information can be drawn from the perturbated annulus near the walls, the study of the central radially isothermal core gives an estimate of the influence of the total flow rate and of the ratio of NH_3/SiH_4 or that of the inert gas eventually added.

Influence of the variation of the total flow rate.—The temperature gradients can be deduced from the temperature profiles along the axis of the reactor. The following figures present the variation of the temperature along the axis under a certain number of parameters. The substrate temperature is in all cases equal to 950°C.

Figure 4 shows the influence of the total flow rate in a case where the NH_3/SiH_4 ratio is equal to 100/1. The gradient appears to remain constant as close as 1 mm from the substrate. For smaller distances, between 0 and 1 mm, the gradient becomes steeper when the total flow rate increases. Analogous variations are obtained for other temperatures of the substrate and various NH_3/SiH_4 ratios.

Influence of the gas.—The temperature of the gas phase above the substrate is related to the nature of

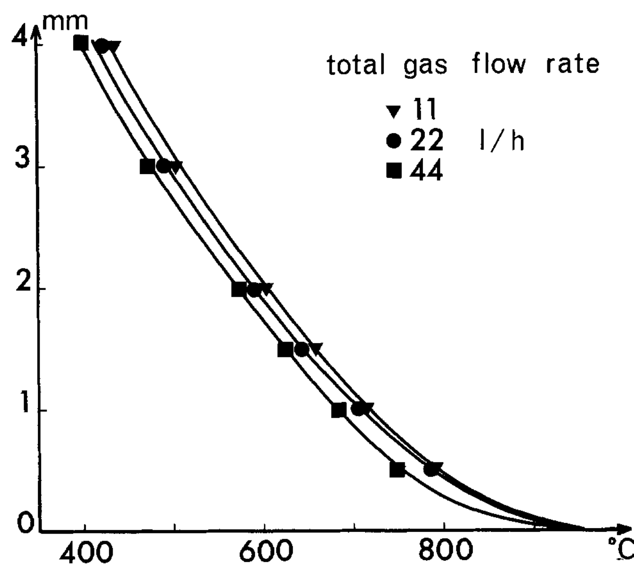

Fig. 4. Influence of the total flow rate on the gas temperature along the axis of the reactor. Substrate at 950°C, NH_3/SiH_4 = 100.

the gas mixture. This is especially important in the case of various carrier gases. This point is illustrated in Fig. 5 showing temperature profiles taken along the axis for a substrate temperature of 950°C and various gases flowing at 22 liters/hr. The temperature in the gas phase is a function of the thermal conductivity of the gas and is highest for gases exhibiting high conductivities. The ammonia curve which should normally lie between those of nitrogen and argon is shifted toward that of hydrogen. This is probably due to spatial thermal decomposition of NH_3 producing some hydrogen.

It follows that the knowledge of these profiles and gradients and the use of an appropriate gas or mixture of gases can be of help in optimizing the conditions for a satisfactory process of deposition.

Influence of the ammonia/silane ratio.—The influence of various ratios has been studied. Figure 6 shows the results obtained at 950°C and 44 liters/hr for three ratios of NH_3/SiH_4, 50/1, 100/1, and 200/1.

Two competitive parameters must be considered: the endothermicity of the reaction and the production of hydrogen. Immediately on the surface of the substrate, the temperatures are high enough to favor the syntheses of Si_3N_4. This also is favored by small values of NH_3/SiH_4. One notes also that vertical thermal gradients increase when this ratio decreases. In this area the influence resulting from the chemical reactions offsets the heat effect added to the gas phase by the hydrogen formed. On the other hand, above this hot zone, the vertical gradients increase along with NH_3/SiH_4 ratios. In this area the chemical reaction is reduced but the rapid diffusion of the hydrogen formed in the hot zone contributes to the heating of the gas phase.

Concentration profiles.—The following figures give the concentration profiles of the various species as a function of distance from the substrate and along the axis of the reactor. The substrate is heated to 950°C, total flow rate is 22 liters/hr, and the same three ratios 50/1, 100/1, and 200/1 were kept. The results are given for silane (Fig. 7), hydrogen (Fig. 8), and nitrogen (Fig. 9) without correction for diffusion coefficients. Correcting for diffusion would slightly shift the values along the x axis without significantly altering the trends shown. It follows from examining the curves that as one moves nearer to the substrate hy-

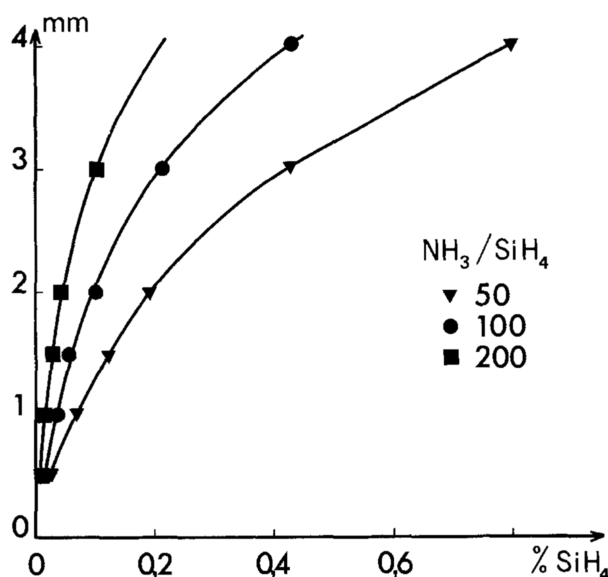

Fig. 7. Silane concentration in the mixture as a function of distance from substrate. Substrate at 950°C, total flow rate 22 liters/hr.

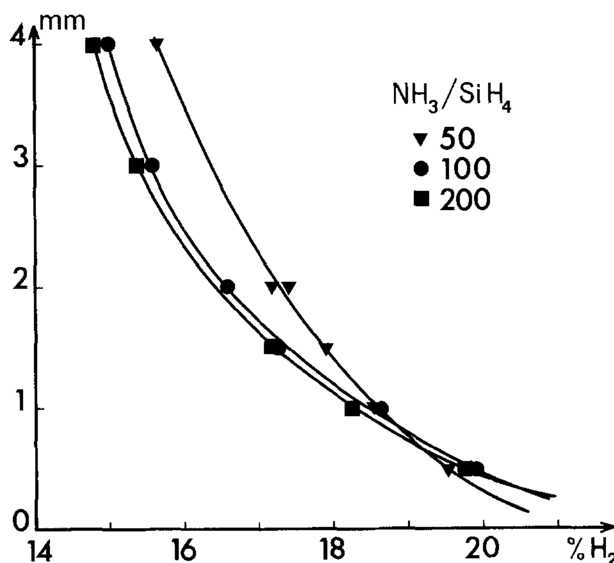

Fig. 8. Hydrogen concentration in the mixture as a function of distance from substrate. Substrate at 950°C, total flow rate 22 liters/hr.

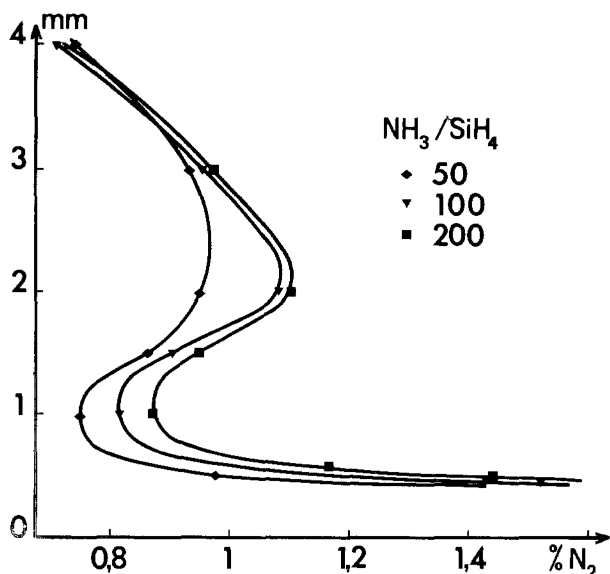

Fig. 9. Nitrogen concentration in the mixture as a function of distance from substrate. Substrate at 950°C, total flow rate 22 liters/hr.

drogen is steadily produced. Silane is practically totally dissociated at 0.5 mm from the substrate. Whatever the SiH_4/NH_3 ratio at this distance no more than 1% of SiH_4 is present.

The nitrogen curves offer some interesting features. They show the competition between the two main phenomena: first, the production of N_2 by the thermal decomposition of NH_3, slow at first but becoming very rapid as the temperature increases near the substrate; second, at 1-2 mm from the substrate, the depletion of the N_2 concentration which must be ascribed to its progressive combination with the products resulting from the decomposition of silane and mainly silicon to form at least some of the silicon nitride which will deposit on the substrate.

The results reported here are uncorrected for diffusion. Considering one in dealing with a large excess of one of the reactants, correction can be easily operated applying Hirshfelder, Bird, and Curtis (8) relations. This shows that close to the substrate the general mapping of the concentration curves is not significantly affected. Only their position relative to the substrate is slightly altered without any implication on the conclusions drawn.

Discussion

Silane is thermally unstable and decomposes rapidly as soon as temperatures of the order of 450°C are reached. At high temperatures the mechanism is partly homogeneous leading to compounds of the type Si_nH_{2n+2} and to their products of dehydrogenation. It is also heterogeneous leading to the formation of Si and H_2. This mechanism becomes predominant as temperature increases (9). Although the presence of hydrogen in large quantities tends to inhibit the decomposition, a cloud of fine particles of silicon or other condensed phases containing Si and H is clearly visible. When nitrogen, produced from the decomposition of ammonia, is present, they tend to react with it. It would be interesting to compare the amounts of free N_2 to the N_2 produced by the NH_3 decomposition and thus have an estimate of the nitrogen bonded. This is not easy because of the large excess of NH_3 and its moderate decomposition ratio resulting in an unsatisfactory accuracy in the analysis. Hydrogen however can be measured accurately and is produced by the silane decomposition. The fraction due to ammonia can be calculated and hence the nitrogen concentration. The difference between the nitrogen produced and the free nitrogen can be used to estimate the nitrogen bonded. These calculations, which are under the process of being carried out, require precise knowledge of the binary diffusion coefficients.

No direct evidence is available to support the contention that the nitrogen consumed is entirely converted to Si_3N_4 exclusively, other compounds are possible, such as $Si(NH)_2$, $Si_2(NH)_3$, and Si_2N_2.

However, equilibrium calculations on the system Si-N-H lead to limited information on the composition of compounds containing Si and N (except Si_3N_4) or containing Si, N, and H (10). The thermodynamic values for such compounds (in the condensed state) are not available and their theoretical formation cannot be estimated. On the other hand, although thermodynamic constants are known for SiN and Si_2N in the gas phase, these species are never present at equilibrium under CVD pressure, temperature, and concentration conditions. If compounds containing Si and N other than Si_3N_4 are formed, they are converted into Si_3N_4 on reaching the substrate as temperature increases, as witnessed by their absence in the deposit (11).

The most probable model would therefore be a consumption of nitrogen formed by the pyrolysis of ammonia at a distance approximately less than 2 mm from the substrate at temperatures reaching 600°C for which silane is already strongly decomposed. At this stage all that can be inferred is that the consumption of nitrogen can be due to its reaction with silane and with its degradation products without implying any specific stage in the kinetic mechanism.

Conclusion

The method described in the above study is now fully reproducible and reliable. It offers the possibility to localize in the gas phase above the substrate the point-to-point evolution of the gaseous reactants and their products of pyrolysis. In bringing evidence that the silane depletes steadily while flowing downward and is practically totally decomposed at 1 mm from the substrate, it seriously invalidates models in which the reaction is strictly localized on the substrate. It also allows the drawing of the temperature profiles in the gas phase and could be extended to establish an aerothermochemical model for CVD reactors combining kinetics data to heat and mass transport balances.

It should however not be underestimated that the system chosen to illustrate the method, $SiH_4 + NH_3$, lends itself to an analytical study which does not offer major difficulties. Other CVD systems may not be as easy to treat by this method, especially those leading to samples partially condensable as would be the case for systems for which one at least of the reactants is a liquid and is introduced under its own partial pressure. Its condensation in the probe or during compression before entering the VPC analyzer would lead to erratic values (*e.g.*, deposits using $SiCl_4$ or $TiCl_4$ as vectors for Si and Ti). However cases such as those which produce or consume hydrocarbons, boranes, hydrogen, hydrogen cyanide, hydrogen chloride, or fluoride should be able to be processed along very similar lines and cast some new light on the chemical vapor deposition mechanisms.

Crystallization in Copper-Containing Solder Glasses

R. G. Frieser,* J. L. Powell, and R. R. Tummala

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

A study of copper-containing lead glasses showed that heating such glass above 750°C produced significant amounts of Cu^+ ions, which, on subsequent thermal exposure, produced Cu_2O precipitation in the glass. This effect was found to be cumulative with respect to time and temperature. Bubbling oxygen through the glass melt below 1100°C reduced the Cu^+ ion concentration. Surface contamination both of the lead glass rods and of the substrate to which they were sealed enhanced the growth of Cu_2O. The mechanism of the Cu_2O precipitation is described.

High lead copper-containing glasses are frequently used to form seals between other glasses. During a study of such glasses, some crystallization was noted in the glass after the sealing step. Under a variety of sealing conditions, a reddish-brown precipitate was observed in these lead glasses. Precipitates were observed at the interface of the seal and the substrate glass, but primarily in the center of the bulk of the seal. The morphology of these crystals varied with the state of crystallization (Fig. 1). Their symmetry was found to be fourfold. The cited references provided a background for this study.

The CuO-Cu_2O Equilibrium

An examination of the literature revealed the following information. The decomposition temperature for CuO going to Cu_2O at a pressure of 1 atm is usually reported to be 1064°C. Though CuO is known to be triclinic, Cu_2O is face-centered cubic. However, the reported melting and transformation temperatures vary considerably (1). Thus, for CuO the decomposition temperature is given as 1064°C and the melting point as 1233°C, whereas a CuO/Cu_2O eutectic temperature is given as 1082°C. For Cu_2O, the reported melting points are 1210°, 1235°, and a range from 1084° to 1162°C. A 3.5% CuO/Cu_2O eutectic temperature is recorded at 1065°C. Furthermore, reported decomposition temperatures are higher for a 1:1 mixture of CuO and Cu_2O at the same oxygen pressures than for pure CuO (2).

A more recent critical review (3) of these equilibria (Cu/CuO and CuO/Cu_2O) lists a CuO/Cu_2O (68/32%) eutectic temperature at 1075°C. It points out that Cu_2O is unstable below 375°C and appears to break down into Cu and CuO. CuO, when heated to ~1110°C, melts at pressures less than 1 atm, with loss of oxygen and forming an oxygen-deficient liquid. The same article reports the dissociation pressure at the eutectic temperature to be ~0.5 atm. This implies that, when heated at oxygen pressures less than 0.5 atm, CuO will dissociate to Cu_2O in the solid state before melting. Melting will occur then, at the eutectic temperature at this pressure, with the formation of oxygen.

The data variations in the literature can be attributed to the variation of purity in the reported samples. Thus, the reported temperatures are only a guide. In view of the involved equilibria, it seemed pertinent to examine our starting materials at various temperatures. To ensure good thermal equilibrium we used powdered copper oxides. The oxides, CuO, Cu_2O, and a 1:1 mixture of each, were heated in a platinum crucible in air at 1110°, 800°, and 500°C for 1 hr and quenched (~500°C/min) in air to room temperature. We analyzed these materials by x-ray diffraction both before and after heating. The oxides were reagent grade chemicals used in the glass-making process. Table I summarizes the essential results of this investigation. The results of differential thermal analysis (DTA) of the original oxides are shown in Table II and Fig. 2.

Our preliminary experiments led to the following observations:

(*i*) The reagent grade Cu_2O contained some CuO and, possibly, even metallic Cu. (*ii*) The CuO material showed no contamination. (Contaminants less than

Table II. DTA endotherms of original oxides (±4°C)

Starting material	Major peak (°C) (CuO)	Minor peak (°C) (Cu_2O)	Area ratio of peaks [(CuO)/(Cu_2O)]
CuO	1068	1168	10:1
Cu_2O	1084	1158	4:1
CuO/Cu_2O (1:1)	1081	1154	2:1

~2% by weight do not show up on an x-ray diffractogram.)

(*ii*) Once copper oxide was heated to 1100°C in air, at least 90% was converted into Cu_2O, as indicated by x-ray data. Any metallic copper also present originally was eventually oxidized to Cu_2O (via CuO, with subsequent loss of oxygen).

(*iii*) Heating the same oxides to 800°C, however, oxidized the Cu_2O (and Cu) to CuO. At 500°C, apparently, the oxidation was not complete; thus, some Cu_2O remained.

(*iv*) The DTA traces (Fig. 2) supported the x-ray observations. The observed decomposition temperature for CuO was 1068°C, while, for the mixture, the expected eutectic melting temperature (1081°-1084°C) was observed. The precision of our DTA data is taken to be +3°-4°C. The minor peaks are apparently the Cu_2O melting point. The area enclosed by the curve is proportional to the amount of crystalline material present that melted at that temperature. The ratios (see Table II) of these areas indicate that the relative amount of Cu_2O was greater in the Cu_2O and mixed samples. The small peak attributed to Cu_2O in the DTA trace of the CuO samples was, presumably, not present originally, but can be attributed to the heating of the sample in the DTA system. From the x-ray work, we know that ~6% of the CuO samples was not reduced on heating above 1000°C.

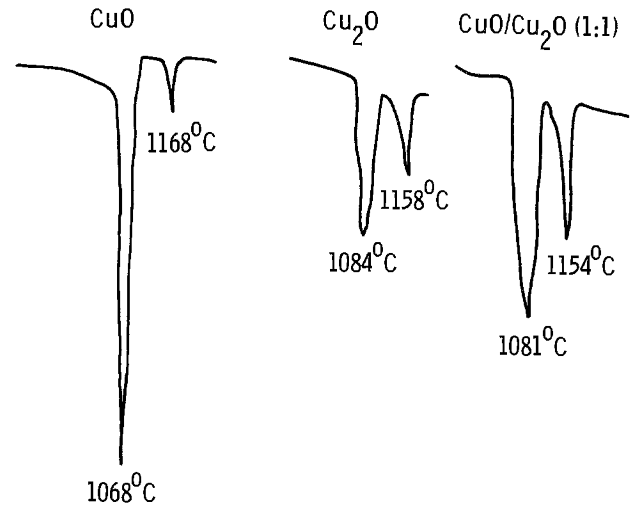

Fig. 2. Differential thermal analysis of copper oxides

Precipitation of Cu_2O in Copper Glass

Because the activity coefficients of the Cu^{++} and Cu^{+} ions in the glass are not known the exact equilibrium cannot be calculated but it is reasonable to

assume that, though the kinetics may differ, the equilibria in the glass are similar to those of the oxides. One might expect a slower rate of conversion (CuO to Cu_2O) in the glass. On the basis of these considerations, the primary species of copper ion to be expected in the glass should be Cu^+, regardless of the starting oxide, if the glass is heated above 1000°C during manufacture. Subsequent work, described later, indicates that conversion of CuO to Cu_2O starts at ~750°C at an undetermined, but very slow rate. To check this assumption, a modified glass was made by substituting Cu_2O for CuO on a weight basis in the standard glass. Table III gives the nominal weight composition (4). We used the standard manufacturing procedure, which was to mix all oxides, shown in Table III, completely in the dry state in a V-blender. Then the material was transferred to a Pt crucible (in 3 or 4 states) and heated slowly to 1080°C.

It should be mentioned at this point that initial heating of the standard glass above 750°C was carried out very slowly because of serious foaming once the charge reached 800°C. No foaming was noted, however, when Cu_2O was the copper source.

Glass Processing

Conventional fining time was ~2.5 hr at ~1080°C. The batch was cooled to ~500°-600°C, and sample rods were pulled for physical measurements. The glass was then remelted to 1080°C for 1 hr of fining. The charge was finally quenched in deionized water through which nitrogen gas was bubbled.

To make rods for subsequent seals, the cullet was reheated to 1080°C and then cooled to 500°-600°C, at which temperature the rods were pulled. Seals were made with such rods by heating the assembly (two rods between two pieces of soda lime glass) to 480°C for 15 min and cooling it to room temperature. The subsequent degree of crystallization in the seal is related to the thermal history of both the cullet and the rod. To assess the influence of both time and temperature on the precipitation in the seal, we conducted the following experiments: (*i*) In the conventional manner, rods were pulled from the cullet of both the standard glass and the modified glass. Seals were subsequently made from these rods at 480°C for 15 min. (*ii*) Other portions of the cullet were preheated at 500°C for 30 min and for 2 hr. Rods were not drawn from these preheated glasses, but seals were formed directly from the cullet.

From photomicrographs of these seals (Fig. 3 and 4), we drew the following summary observations: (*i*) All the crystals had fourfold symmetry and were reddish-brown under the microscope. (*ii*) Seals made from the rod had greater crystal density for each glass

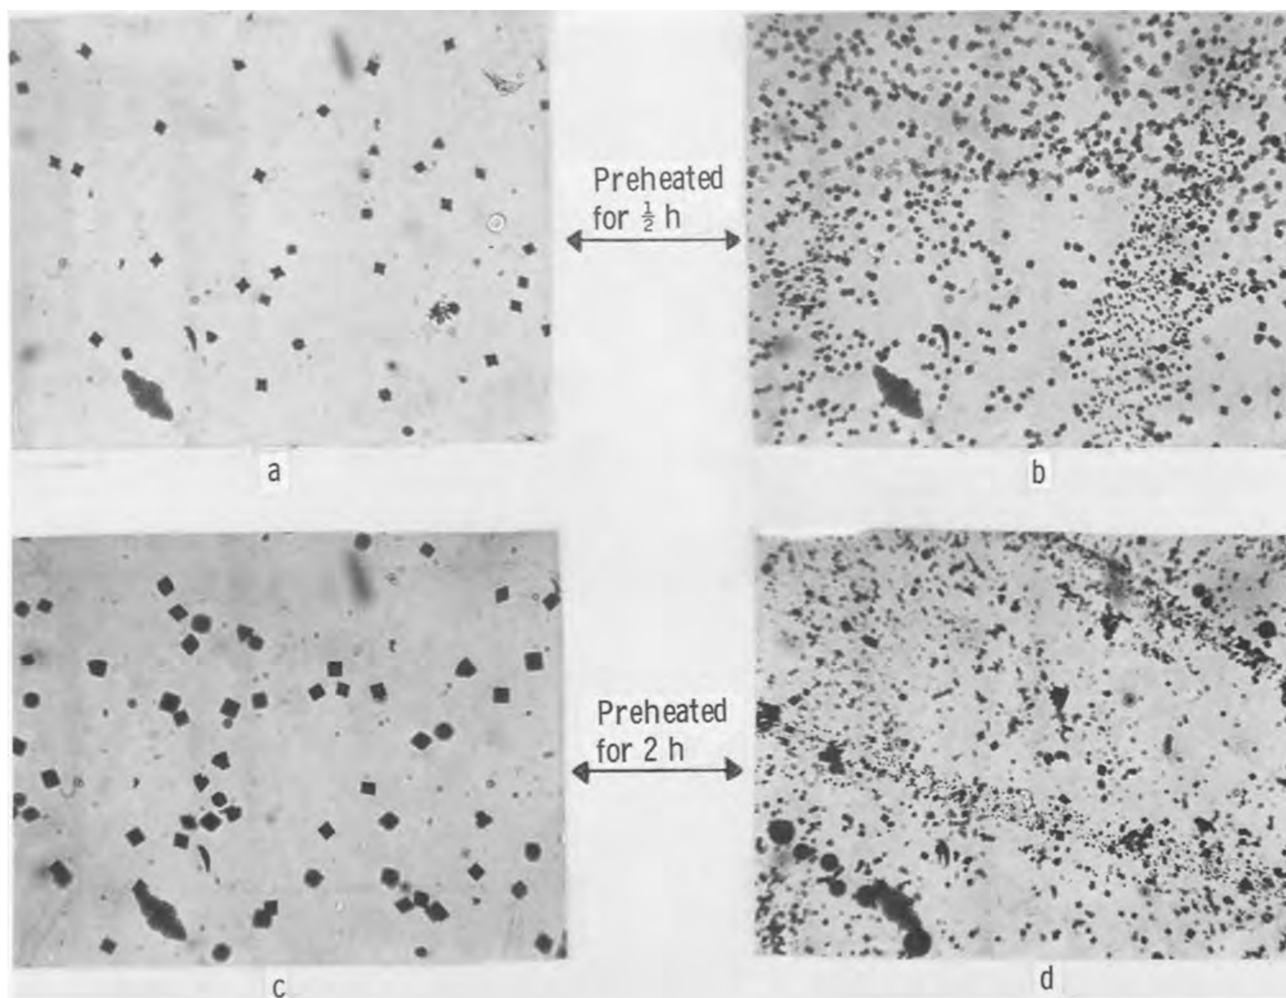

Fig. 4. Photomicrographs of standard-glass (a and c) and modified-glass (b and d) seals made after preheating for ½ or 2 hr (220X).

Table IV. Wet analysis of copper glass

Modified	CuO	4.30	14.0	1080	38.0	62.0

* O_2 bubbled through charge during fining.

than seals made from the cullet. (*iii*) Substituting Cu_2O for CuO in the original standard glass vastly increased the amount of brown precipitate in the seals made from modified glass. (*iv*) Preheating either glass before sealing decreased the number of crystals but increased their size. This effect was found to be proportional to the preheating time and was more pronounced in the modified glass than in the standard glass.

After carefully crushing the crystallized glass in alcohol and separating the brown precipitate from the matrix, we used x-ray analysis to show that the precipitate was Cu_2O.

We interpreted the preceding observations as follows: (*i*) The decomposition of CuO (*i.e.*, $2CuO \rightarrow Cu_2O + \frac{1}{2} O_2$) in glass is similar to that in the oxide. (*ii*) Nucleation of Cu_2O appears to depend on the length of fining time above 750°C in the glass (Fig. 4). (*iii*) The eventual size of the Cu_2O crystal, however, depends on the thermal treatment of the glass after fining.

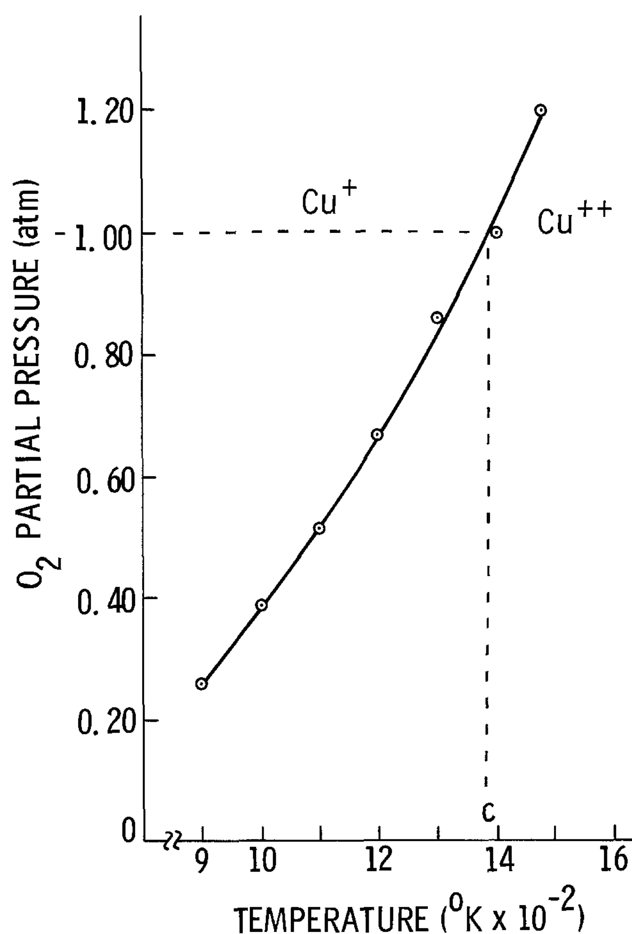

Fig. 5. Partial pressure of O_2 vs. temperature

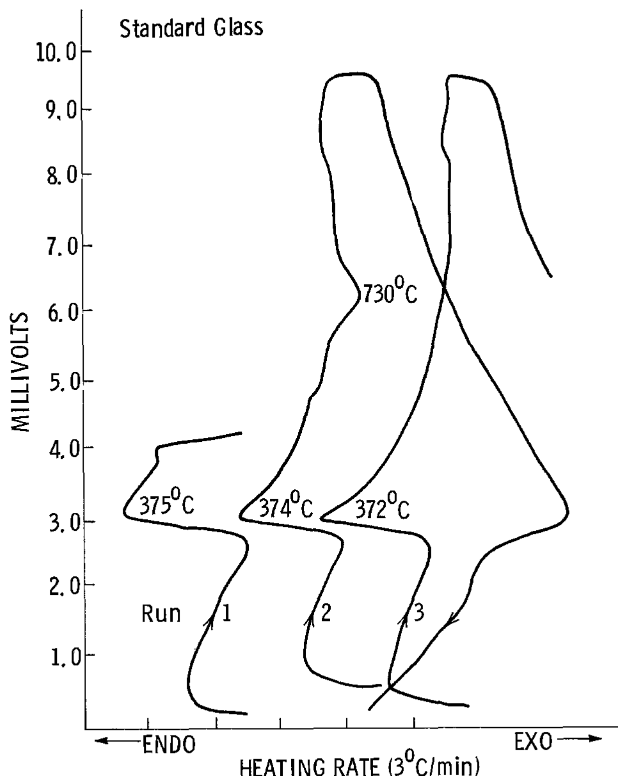

Fig. 6. Differential thermal analysis trace of standard glass

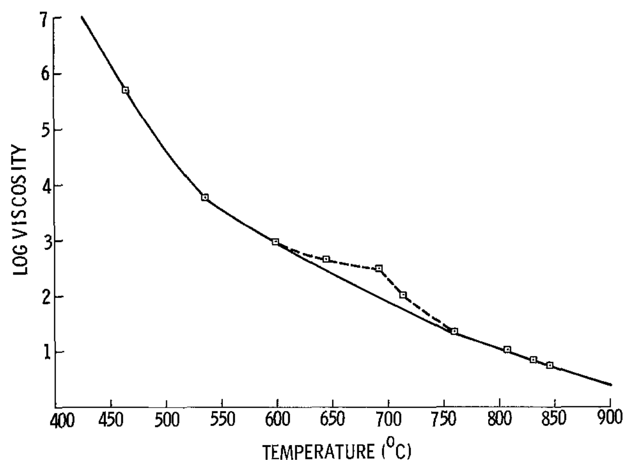

Fig. 7. Standard glass viscosity vs. temperature

Wet Analysis

The interpretations drawn from our experiments were supported by analytical work. A petrological technique was adapted to glass. Total copper (*i.e.*, Cu^+ and Cu^{++}) and Cu^{++} were determined separately, and Cu^+ was obtained by difference. Table IV summarizes pertinent data showing that a considerable portion of Cu^{++} was converted into Cu^+ when the glass was fired above 750°C. Reheating the glass for an extended period of time below 800°C, however, did not seem to change the Cu^+/Cu^{++} equilibrium in the glass. The data seem to indicate that bubbling oxygen through the molten glass at or below 1080°C shifted the equilibrium back to Cu^{++} ion in the glass. The maximum theoretical, rather than the reported value of Cu^{++}, was used to calculate Cu^+ when more than 100% theoretical was reported, because the precision of this technique is $\sim \pm 10\%$. Still the trend is apparent. Other oxygen-bubbling experiments showed a color shift from green to blue in the resulting glass. Such a shift at constant glass composition, especially in lead glasses, can be taken as an oxidative change

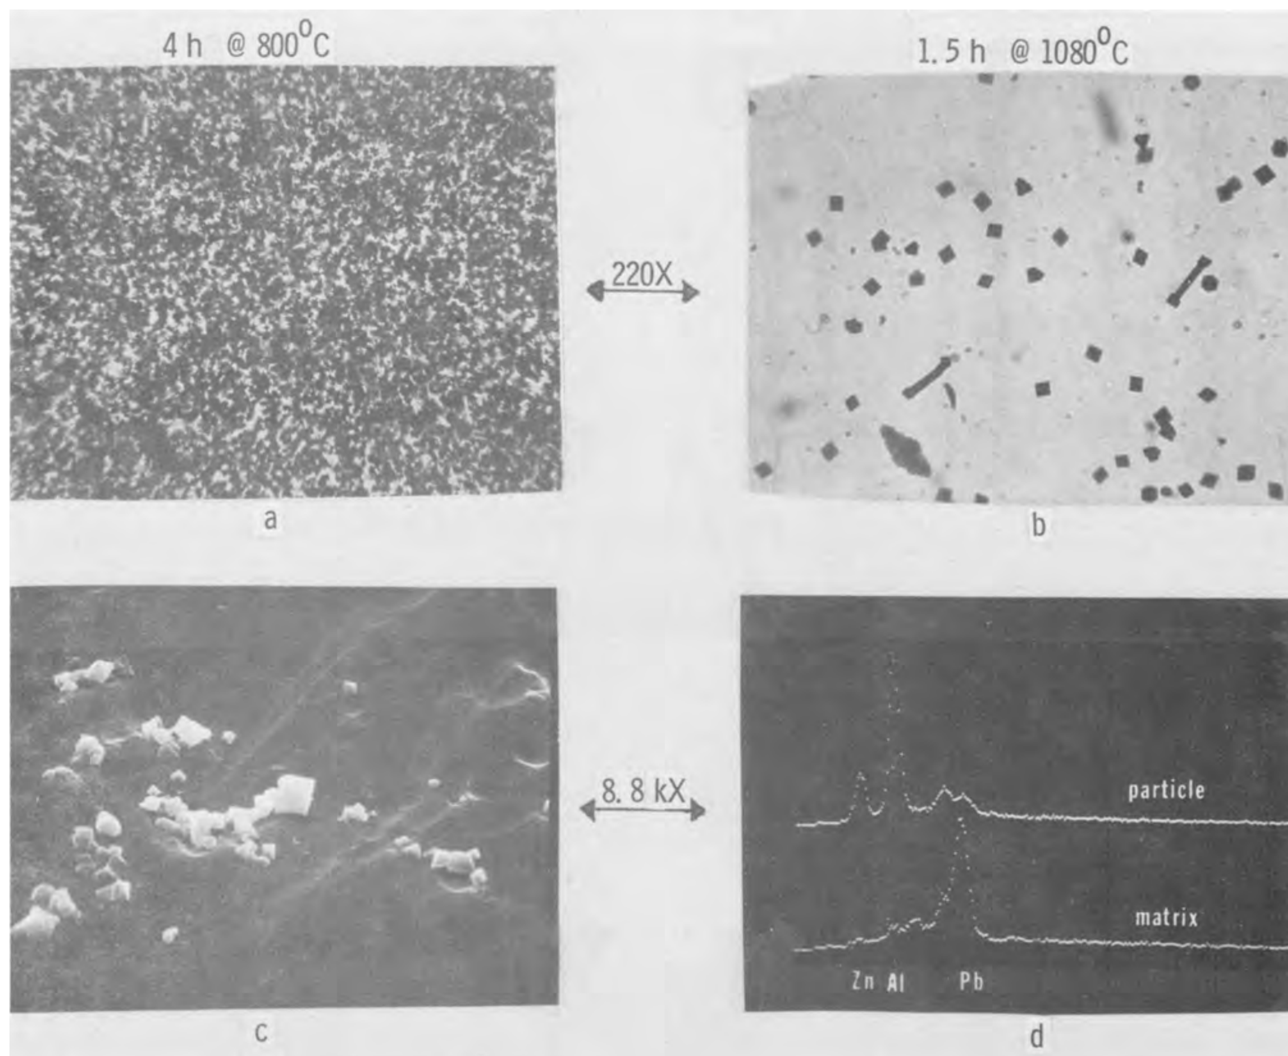

Fig. 8. Photomicrographs and SEM micrographs of standard glass, showing crystallization or phase separation.

from Cu^{+} to Cu^{++} (5). The O_2-bubbling experiments were based on the decomposition pressures of CuO (Fig. 5), which were calculated from the thermodynamic data of the Gibbs free energy (6). Figure 5 shows that maintaining both the partial pressure of oxygen above the glass melt at 1 atm and the melt temperature at 1100°C, causes the equilibrium to shift from Cu^{+} to Cu^{++}.

Thermogravimetric and Differential Thermal Analysis

Two samples of the standard glass were subjected to thermogravimetric (TG) analysis. The data did not correlate with any possible oxygen loss or gain as a result of the Cu^{++} to Cu^{+} shift. A reasonable conclusion was that whatever loss or gain of oxygen was experienced was overshadowed by losses of volatile constituents of the glass. From this experiment, we draw the inference that heating this glass above 750°C for prolonged times can change its composition and, possibly, the solubility of copper oxide in the remaining glass.

Phase Separation

Figure 6 shows a typical DTA trace of the standard glass. The first trace was taken to ~480°-500°C, and the glass was kept at this temperature for 30 min before being cooled to room temperature to simulate conventional sealing conditions. On the second and third traces the samples were taken to 1000°C. In addition to the transformation temperature at about 372°C, the second trace shows a broad exotherm at ~6.5 mV (730°C) which was either lost or reduced and shifted to a considerably higher temperature (8.5 mV or 910°C) on the third trace. This "bump" has been found to be characteristic of all standard glass DTA curves. A similar jog is noted on a viscosity curve supplied by Corning Glass Works on the standard glass billet in the temperature range 650°-750°C (Fig. 7).

The same temperature region is a potentially troublesome area for pulling rods. Our experience has shown that, once the glass is properly fined and cooled to room temperature, it should be brought back to ~1080°C before being cooled to 500°-600°C to get the proper viscosity to pull a 40 mil diameter rod. Unless the heat-treatment exceeded 1080°C, the rods turned out lumpy and rough and contained crystals. Under these conditions it was impossible to maintain a uniform and desired rod diameter. This phenomenon was called, for want of a better term, "phase separation." It was not clear, however, whether it was phase separated in the conventional sense, which would be two or more immiscible "liquids." Some crystalline matter was observed in this "phase." Figure 8a is an electron micrograph (220×) of a cullet sample of the standard glass, which was held at 800°C for 4 hr and examined. Reheating this sample to 1080°C for 1.5 hr, cooling it to 600°C, and pulling rods showed a large number of Cu_2O crystals in subsequent seals made from it (Fig. 8b). Scanning electron microscope (SEM) pictures of standard glass made at 800°C and subsequently heated to 500°C showed some indication of crystalline material. This was brought out by a dilute HNO_3 etch (Fig. 8c). Figure 8d is a mass spectrogram comparison of one of these crystals with that of the neighboring surface. It is clear (Fig. 8b) that these crystals were not

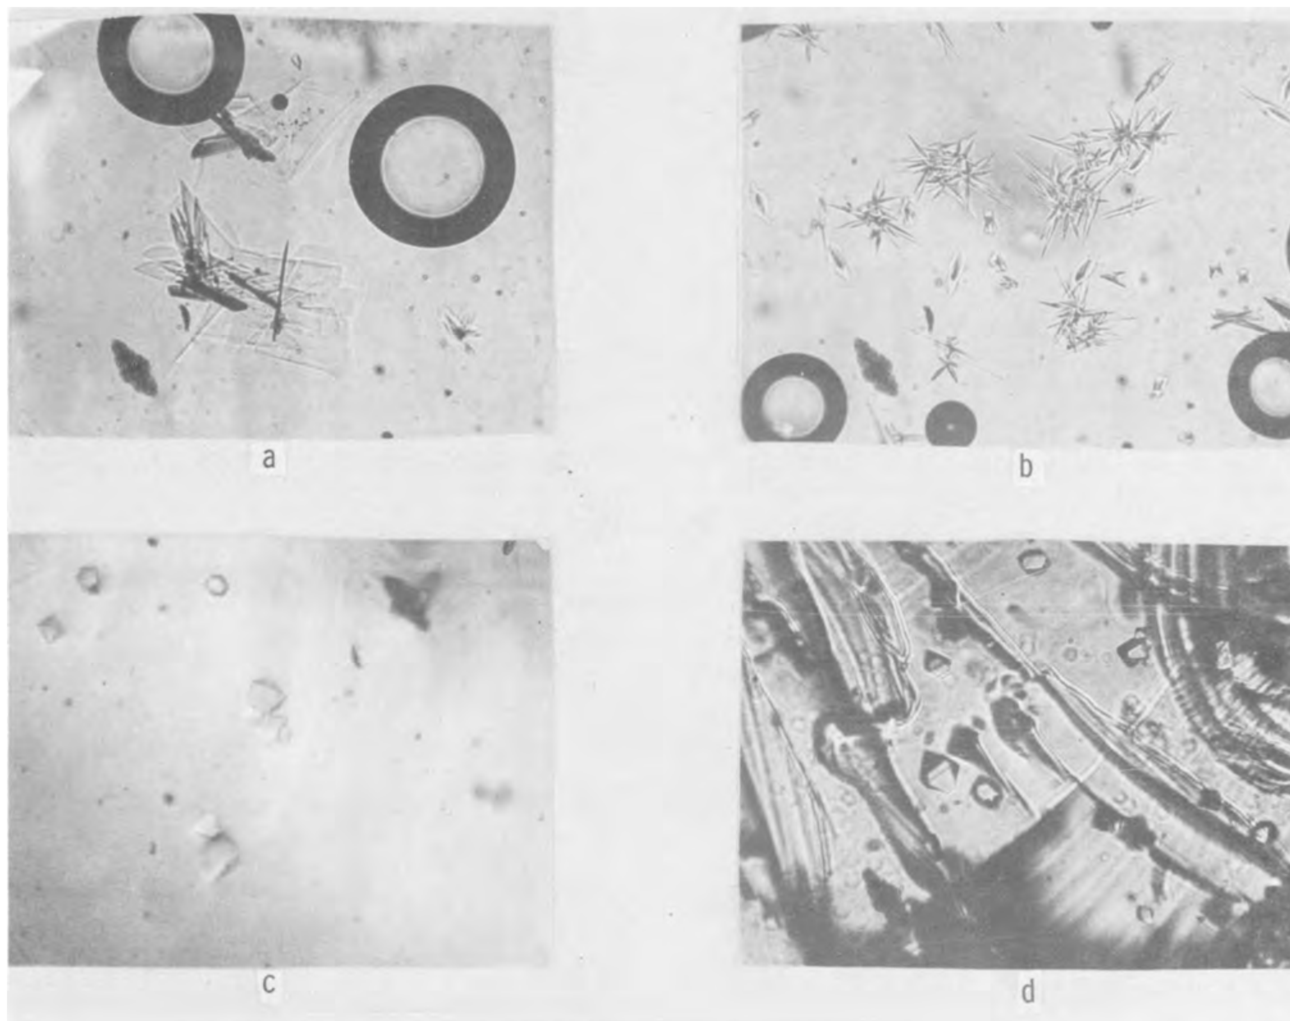

Fig. 9. Photomicrographs of noncopper-containing crystals in seal glass (220X).

Cu_2O but contained an increased amount of Al and Zn and were probably zinc aluminates.

During the course of these experiments, colorless, flat, circular crystals as well as octahedra crystals were occasionally noted in some of our experimental seals, which were made from cullets and rods. Powder x-ray and transmission electron microscopy (TEM) with an x-ray nondispersive analyzer disclosed the following crystalline materials: Al_2O_3 and $ZnAl_2O_4$ (octahedra), and $PbZnB_2O_6$ and $ZnPbO_3$ (plates and circular forms). Figure 9 shows representative samples of the variety of crystals observed. In a few cases, undissolved oxides of the original glass components (Table III) were observed as well.

Surface Effect

Figure 3c shows a definite surface influence on the crystallization pattern, if not on the nucleation, of the standard glass. Various acidic, basic, and organic surface treatments, both on the seal rods and on the substrates, did not seem to eliminate the brown precipitate, although some minimization was evident. It was apparent from observed patterns like those shown in Fig. 3c that surface contamination did enhance and orient the crystal growth of Cu_2O.

Conclusions

The following conclusions are drawn from the preceding study and apply only to the glass composition and techniques described herein:

1. Heating a copper-containing glass above 750°C produces a significant number of Cu^+ ions. The amount of Cu^+ formed appears to be directly proportional to the temperature and to the length of heating time at any temperature above 750°C. The higher the temperature, the faster the Cu^+ to Cu^{++} conversion. This reduction is irreversible, for practical purposes, and can lead eventually to the precipitation of brown Cu_2O.

2. The heat effect is cumulative. Prolonged and/or repeated exposure to subsequent temperatures, even as low as 480°C, can cause the Cu^+ ions present to grow into observable crystals, resulting in the brown Cu_2O precipitate.

3. Bubbling oxygen through the glass melt reduces Cu^+ concentration. A decrease in the Cu^+ concentration was noted when oxygen was bubbled through the glass melt in the temperature range of 600°-1080°C. However, some Cu^+ ions were still present; furthermore, the phase-separation problem appeared to be aggravated.

4. Surface contamination of the rod and substrate enhances the formation and growth of Cu_2O but apparently does not affect its autonucleation.

5. Surface treatment of the rod does not eliminate the Cu_2O crystallization in the final seal but does cause a small reduction in the Cu_2O content of the seal. We believe the reason that the Cu_2O crystallization was not eliminated was that the primary nucleation was a bulk nucleation.

Acknowledgments

The authors are indebted to numerous persons for data on this project. We should like to mention W. Fedrowitz and S. Teed for differential-thermal and thermogravimetric analyses, respectively, F. A. Toman and S. Lawhorne for x-ray analysis, R. M. Anderson for electron differential analysis, D. Cameron for

scanning electron microscopy, and R. T. Vineski for development of the analytical technique.

High Temperature Kinetics of Refractory Metal Gasification by Atomic Fluorine

Paul C. Nordine

Chemical Engineering Section, Department of Engineering and Applied Science, Yale University, New Haven, Connecticut 06520

ABSTRACT

Intrinsic kinetics for the F/Ir, Pt, Ta reactions were measured using microwave discharge, low pressure, transonic flow reactor techniques with filament gasification rates deduced from specimen resistance *vs.* time measurements. Data were obtained in the temperature ranges 1000°-1450°K for Ir, 600°-1430°K for Pt, and 1100°-3030°K for Ta, at F-atom partial pressures between 0.65-7.4 Pa. Also, transient filament resistance and temperature changes could be observed which lead to the conclusion that condensed fluoride films occur on the metals on exposure to atomic fluorine. These films do not inhibit the gasification reaction. The F/Pt data at $T > 800$°K and the F/Ir data agree within experimental error with kinetic models which assume a reactant pressure independent F-atom sticking coefficient and competitive first-order F-atom desorption, nth order (in the F-atom surface concentration) product molecule formation-desorption. The product species formation-desorption reactions are third order in the F/Ir system and are second order at higher temperatures and are fourth order at lower temperatures in the F/Pt system. Quasi-equilibrium preexponential rate law parameters based on the product species, IrF_3, PtF_2, and PtF_4, agree with those derived from the rate measurements. At lower temperature the F/Pt reaction is zero order in the incident F-atom flux. The F/Ta kinetics are qualitatively similar to the F/Ir, Pt kinetics but reaction persists to much higher temperature and nonintegral reaction order is obtained at the highest temperatures. A quantitative model of the F/Ta reaction kinetics is not proposed. Although this work confirms the condensed fluoride film model for the F_2/Ta reaction which was proposed by Machiels and Olander (8), the Ta gasification rates measured here exceed those predicted by their model. This disagreement suggests a change in the condensed fluoride stoichiometry between their experiments, at $p_{F_2} < 10^{-2}$ Pa and the present results obtained at $p_F > 0.6$ Pa. Instructive comparisons are made between the results obtained for these and the F/W, Mo, Ti systems (5, 14), and the implications of quantitative results from F/Ir, Pt models are discussed.

Fluorine is a mono-isotopic, highly electronegative element whose bond energy (157 kJ/mole) (1) is unusually low. However, it forms strong chemical bonds to other elements and will react with nearly every (nonfluoride) substance. Many polyvalent binary fluorides are volatile. These and other unusual properties of fluorine and fluorides lead to useful applications [*e.g.*, uranium isotope separation, chemical and excimer lasers, semiconductor etching reactions (2), and chemical rocket propellants (3)] but are also the source of difficult corrosion problems.

The chemical, physical, and thermodynamic properties of fluorine and fluorides and the kinetics of homogeneous fluorine reactions (4) have been studied in much detail. Heterogeneous reactions have received less attention, despite their importance to corrosion problems and the direct applications of fluorine gasification reactions, *e.g.*, to semiconductor etching (2). Heterogeneous reactions of atomic fluorine are of special interest because fluorine is easily dissociated and atoms usually undergo heterogeneous reaction more rapidly than do molecules (5, 6, 12).

Several recent papers have appeared on the intrinsic kinetics of fluorine gas/solid reactions. Studies of F_2 reactions include McKinley's investigation of the F_2/Ni reaction in a mass spectrometer (7), the modulated beam studies of F_2/Ta and F_2/UO_2 reactions by Machiels and Olander (8, 9), and a paper by Philippart *et al.* on the reactions of fluorine and metal fluorides with Ta, W, and Re (10). Sheer *et al.* studied the desorption of atomic fluorine from molybdenum at high temperature (11). Heterogeneous reactions of atomic fluorine were first investigated by Rosner *et al.*, who report kinetic measurements for the F, F_2/Mo, W

Key words: heterogeneous kinetics, iridium, platinum, tantalum, vaporization, kinetics, metals, refractory.

reactions (5) and the F, F_2 reactions with basal and edge planes of pyrolytic graphite (6). The F, F_2/BN reactions were studied near room temperature (12) and allow the gravimetric measurement of F-atom concentrations in flow systems. Also, F-atom heterogeneous recombination/reaction probabilities have been measured on several materials of construction near room temperature (13). Although this list is brief, the papers cited reveal a growing interest in heterogeneous fluorine reactions and document important new techniques by which these reactions may be studied. They provide some assistance in the selection of corrosion resistant materials of construction and begin to reveal the mechanisms by which fluorine gasifies solids.

This paper presents new kinetic data for the F-atom reactions with iridium, platinum, and tantalum. The principal conclusions include a verification of fluoride film formation (8) during the F/Ta reaction and the discovery of fluoride films during F/Ir and F/Pt reaction as well. The F/Ir, Pt gasification rates are accurately predicted by a kinetic model which contains derived kinetic parameters that agree with values predicted by the quasi-equilibrium model (33, 34). Comparison of the F/Ta data with the modulated beam results of Machiels and Olander (8) provides new insight regarding the surface kinetics. A comparison of Arrhenius diagrams for the F/Ir, Pt, Ta, W (5), Mo (5), Ti (14) reactions at equal reactant pressure demonstrates general trends common to all high temperature F/metal reactions which have been studied.

Experimental

The rate measurements reported here were obtained by use of the low pressure, transonic flow reactor illustrated in Fig. 1. The side-mounted probe was used in these experiments. In this flow reactor, metered Ar/F_2 mixtures pass through a 0.98 cm ID alumina tube where a 2450 MHz, ≈100W microwave discharge dissociates the fluorine molecules. The dissociated mixture then enters a Pyrex section and passes over an electrically heated metal filament mounted transverse to the gas flow. Average flow velocity at the discharge tube exhaust was 2.5×10^4 cm/sec at a total pressure of 133 Pa. Gaseous F, F_2 concentrations were computed from the measured Ar and F_2 flow rates, total pressure, and known (15, 16) microwave discharge dissociation efficiencies (*ca.* 90% for F_2).

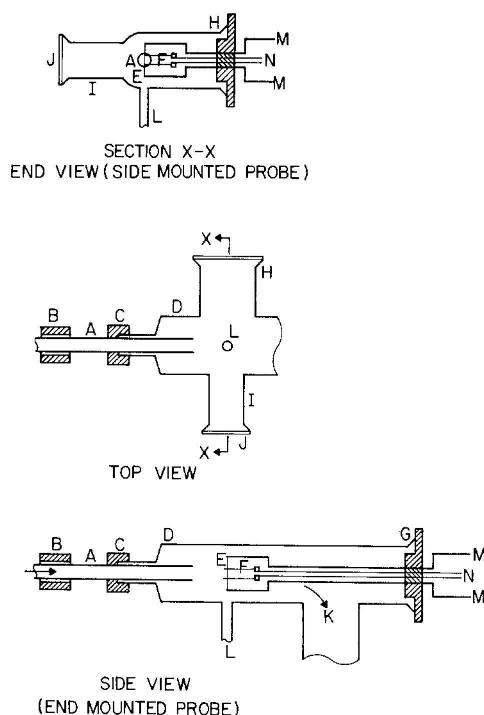

Fig. 1. Filament fluorination apparatus (schematic). A, Discharge tube (alumina); B, microwave cavity; C, O-ring coupling; D, test section (Pyrex); E, filament (specimen); F, voltage taps; G, O-ring joint (end mounted probe); H, O-ring joint (side mounted probe); I, pyrometer; J, optical flat; K, to fluorine trap, pump; L, pressure tap; M, to d-c power supply; N, to voltage-to-frequency converter.

Gasification rates were computed from the resistance-time curves for the central 0.3-0.4 cm of 0.038 cm diam filaments. In most experiments the filament temperature was allowed to increase by 200°-400°K during the experiment and rate *vs.* temperature was computed from resistance-time, temperature-time, and previously measured resistance *vs.* temperature data in the absence of reaction. These procedures are fully described elsewhere (17).

Specimen temperatures above 1000°K were measured with an optical pyrometer. Emittance corrections at $\lambda = 0.665\mu$ for Pt (18), Ir (19), and Ta (20) were obtained from the literature. The Pyrex windows were frequently changed to avoid temperature errors due to etching by fluorine and the window transmission corrections were checked by measuring specimen temperature with or without the window in the light path, using a second window to seal the system. Window corrections always agreed with an expected 5% reflection loss at each window surface.

The F/Pt reaction was also studied below 1000°K. In these lower temperature experiments the filament diameter was computed from measured room temperature resistance before and after reaction. Temperature at the beginning and end of reaction was determined from the high temperature to room temperature resistance ratio, using the known temperature coefficient of resistance. Temperature control was achieved by operating the power supply at constant voltage output with a resistance in series with the filament whose value was chosen to give approximately constant filament power dissipation per unit filament area. Inferred temperatures at the beginning and end of reaction usually agreed to ±10°K.

Most high temperature experiments were performed by setting the gas flow rates, discharge power, and reactant pressure and then heating the filament to the temperature of interest. However, for experiments below 1000°K it was necessary to adjust the filament temperature before its exposure to fluorine, and valves were provided to divert fluorine to the reactor exhaust or allow it to pass through the reactor. A few higher temperature experiments were also performed after these valves were installed. If the heating current was held constant, increases and then decreases in filament temperature (and resistivity) could be observed during a transient period at the start of reaction with fluorine. Following these initial temperature transients, a steady increase of resistance and temperature with time was observed, due to consumption of the filament by the gasification reactions.

Measurements of specimen resistivity provided a check on the temperature measurements. For platinum, the room temperature resistivity agreed to 0.7% with the literature value (21) and corrected pyrometer readings agreed to ±3°K with temperature deduced from resistance measurements. These measurements also show the platinum to be quite pure, for the room temperature resistivity of Pt is typically doubled by the addition of a few percent of an alloying element (22). For iridium, our room temperature resistivity measurement exceeded the literature value (23) by 13% and the temperature coefficient was about 6% low. These differences, which are probably caused by impurities, prevented a check on our iridium temperature measurements. However, no change in iridium specimen resistivity was observed after more than 30% material loss by F-atom gasification. After outgassing at 2500°K, temperatures of Ta filaments deduced from resistance or pyrometer mea-

surements agreed within 1%. However, during reaction with atomic fluorine, a small increase in resistivity and decrease in the temperature coefficient of resistivity were observed. Outgassing at 2500°K in Ar would reverse this effect. These resistivity changes are attributed to dissolution of oxygen and nitrogen impurities in the Ta filaments during reaction with fluorine. The high temperature kinetic studies of the O_2, O, N_2, N/Ta reactions reported by Rosner *et al.* (24, 25) and Feng (39) predict resistivity changes at the prevailing F_2 impurity levels which agree well with those observed here.

Polycrystalline platinum and iridium filaments were obtained from Engelhard Industries, Carteret, New Jersey, who stated the respective Pt and Ir purities to be 99.95 and 99.8%. A spectrographic analysis was supplied for Ir and showed (in parts per million): W, 1740; Re, 400; Pt, 240; Rh, 58; Al, 46; Ni, 32; Pd, 26; Cu, 23; Si, 21; and eleven other elements which added up to 28 ppm. The polycrystalline tantalum filaments (Thermionic Products Company, Plainfield, New Jersey) were stated to be at least 99.97% pure.

Fluorine (Matheson) was quoted to be 98% pure. After NaF trap removal of HF, we found total impurity content to be 1.8% (by volume) by the method of reaction with mercury (26). The argon (99.998% pure) was further purified by use of Oxisorb cartridges from MG Scientific Gases, which reduce O_2 content to *ca.* 1 ppm. The background impurity level in our flow system, due to leaks, outgassing, and argon impurity was checked by measuring the rate of Ta resistance change at *ca.* 2500°K in argon. Since the O_2/Ta gasification kinetics are known (25), we could demonstrate in this way that background O_2 pressures were about 5×10^{-3} Pa. After these experiments had been completed, a supply of 99.9+% pure fluorine was obtained from Argonne National Laboratory. We obtained a few data points for each metal with this high purity fluorine which gave the same reaction rates as did the commercial product.

Specimens were examined with a microscope before and after reaction. Molecular fluorine revealed a strong preference for attack at platinum grain boundaries but the surfaces of the grains showed a smooth recession. Atomic fluorine produced a uniform, smooth recession with Pt filaments with no perceptible preference for grain boundary attack. The rate of the F_2/Pt reaction was about 20 times less than that of the F/Pt reaction at 1100°K and equal reactant pressure, as determined by direct measurement of specimen diameters with the microscope. Reaction of F or F_2 with Ta at temperatures below 2100°K produced slight grain boundary etching and a streaked appearance on the surfaces of individual grains. At higher temperatures fluorine did not etch Ta grain boundaries but shallow undulations of irregular shape appeared on the filament surface. The tantalum grains were of irregular shape with typical dimensions between 0.02-0.08 mm. The streaked pattern on individual grains was often nearly parallel to a grain boundary over the entire grain with a streak spacing *ca.* 0.003 mm. The dimensions of the shallow undulations were typically 0.02 mm in a direction parallel to the filament axis and half that in the other direction. Observations on Ir filaments reacted with atomic fluorine between 1000° and 1400°K were similar to those reported for Ta below 2100°K, except grain boundary etching was not observed. Despite the somewhat nonuniform surface observed for Ta and Ir filaments and grain boundary etching of Ta, the specimen diameter change inferred from resistance measurements always agreed with that measured with a microscope.

Reactant and Product Fluxes

The method by which filament resistance and temperature *vs.* time data are reduced to yield product fluxes has been discussed (17). Necessary auxiliary data include the metal thermal expansion coefficients, which were obtained from Espe (22).

The incident flux, Z_i, of reactant species i, was calculated from the Hertz-Knudsen equation

$$Z_i = \overline{p_{i,w}}(2\pi m_i k \overline{T_{gw}})^{-1/2} \quad [1]$$

However, due to transport effects, the (perimeter mean) gas temperature at the filament, $\overline{T_{gw}}$, will differ from the ambient (T_∞) and filament (T_w) temperatures. Also, for sufficiently large reaction probabilities, the (perimeter mean) reactant pressure at the filament $\overline{p_{i,w}}$, will differ from the known ambient reactant pressure, $p_{i,\infty}$. It is necessary to consider the effects of energy, momentum, and mass transfer between the filament and gas stream to determine the values of $\overline{p_{i,w}}$ and $\overline{T_{g,w}}$ to be used in Eq. [1] and the resulting accuracy of calculated reactant fluxes.

Transport effects under the flow conditions chosen for these experiments are characterized by the dimensionless Mach, M, and Reynolds, Re, numbers. At the exit of the discharge tube these are Re = 224 (based on discharge tube diameter), M = 0.79. However, the centerline velocity in the jet issuing from the discharge tube should approach $3.22 \cdot 10^4$, *i.e.*, M = 1, and the Reynolds number at the filament, which samples the centerline velocity is thus Re ≅ 11.4 (based on filament diameter and free stream gas properties). Slip flow occurs at the filament, for the Knudsen number (ratio of ambient gas mean free path to filament diameter) is Kn ≅ 0.16. If, however, we neglect the effect of slip on gas phase convective energy transfer, the Nusselt number for convective energy transfer from the filament is (27) $\overline{Nu_h} = 2.1$ at Re = 11.4.

Energy transfer.—The perimeter mean convective energy flux from the filament (27), $\dot{q}''$, can be equated to the intrinsic heating of incident atoms (28)

$$\dot{q}'' = \overline{Nu_h} \cdot k_f \cdot (T_{g,w} - T_r)/d = \overline{N_{g,w}} \cdot \overline{c_{g,w}} \cdot R \cdot (T_w - \overline{T_{g,w}})\alpha/2 \quad [2]$$

where k_f is the gas thermal conductivity evaluated at the mean "film" thermal boundary layer temperature $[(\overline{T_{g,w}} + T_r)/2]$, $\overline{N_{g,w}}$, and $\overline{c_{g,w}}$ are the (perimeter mean) gas density and mean thermal speed at the filament (at $\overline{T_{g,w}}$) and α is the thermal accommodation coefficient. The gas dynamic recovery temperature, T_r, exceeds the ambient temperature (300°K) but, due to slip flow, should be less than the stagnation temperature of the free stream (≈380°K). The validity of Eq. [2] was checked by measuring the heat flux from a platinum filament in argon and in vacuum at $1260° < T_w < 1730°K$ from which we compute $0.41 \leq \alpha \leq 0.45$ if $300°K \leq T_r \leq 380°K$. The reported value (30) $\alpha(Ar/Pt) = 0.38$ at $1180° < T_w < 1590°K$ agrees well with these results as do the values obtained ($\alpha \approx 0.40$-0.45) by extrapolating lower temperature measurements (29) to the temperature range of interest here.

The accuracy of values for $T_{g,w}$ computed *via* Eq. [2] is limited by uncertainty in the appropriate gas dynamic recovery temperature and thermal accommodation coefficient. The maximum uncertainty in $T_{g,w}$ can, however, be evaluated from known limits on the values of these quantities. We assume $300°K < T_r < 380°K$ and $0.3 < \alpha < 1.0$. These limits on α represent the approximate lower limit of observed values for argon on bare metal surfaces and the maximum value, unity, which may obtain on gas or metal fluoride covered surfaces (28). Values of $T_{g,w}$ computed for the above limits on T_r and α were found to agree within ±25% with the convenient empirical equation

$$T_{g,w} = 24.1 \cdot T_w^{0.43} \quad [3]$$

which was used for subsequent data reduction. The uncertainty in reactant flux, computed from Eq. [1],

is about half the uncertainty in reactant temperature, *i.e.*, *ca.* ±12%.

Momentum transfer.—Since slip occurs in convective energy transfer it must also occur in momentum transfer, and the gas pressure at the stagnation line of the filament should be less than the stagnation pressure in the free stream. Heating of the gas by the hot filament would also tend to reduce the local stagnation pressure. Therefore, we measured the peripheral variation in recession rate of a Pt filament under conditions where the rate is first order in reactant pressure to deduce the peripheral variation in reactant arrival rate. It was found that the rate of diameter change was 1.33 ± 0.05 times greater for the diameter parallel to the direction of flow than for the diameter perpendicular to the flow. This rate difference equals that predicted by Pitot tube measurements at lower flow velocities ($\overline{M} \cong 0.41$ at discharge tube exit) where the ratio of local to ambient pressure was 1.41 at the leading edge, 0.98 at the trailing edge, and 0.90 at the sides of the Pitot tube and the peripheral average pressure exceeded the ambient pressure by *ca.* 2%. Thus, we conclude that momentum effects influence the pressure distribution around the filament but have a negligible effect on the average reactant pressure. This nonuniform pressure distribution allows an approximate measurement of reaction order. At higher temperatures the Pt filament diameter recession rate ratio is 1.90 ± 0.10, in agreement with that predicted for second-order kinetics.

Mass transfer.—If one neglects thermal diffusion, mass transfer due to irreversible surface reaction is described by an equation similar to that for energy transfer. The (perimeter mean) reactant consumption rate is

$$\dot{m}''_r = \overline{Nu}_m \cdot \overline{D\rho} \cdot (\omega_{r,\infty} - \omega_{r,w})/d = \omega_{r,w}\overline{\rho_{g,w}}\overline{c_{r,w}}\epsilon_r/4 \quad [4]$$

where ω_r is the reactant mass fraction in the free stream (∞) or at the filament (w), $\overline{c_{r,w}}$ and $\overline{\rho_{g,w}}$ are the reactant mean thermal speed and gas density at $\overline{T_{g,w}}$, and ϵ_r is the reaction probability. The product, $\overline{D\rho}$, of the binary reactant-argon diffusivity, D, and the gas density, ρ, is evaluated at the mean boundary layer (film) temperature, $\overline{T}$. Thus, if the apparent reaction probability, ϵ_a, is defined as the value which would be obtained when diffusion effects are neglected

$$\epsilon_a/\epsilon_r = \omega_{r,w}/\omega_{r,\infty} = [1 + (\overline{c_{r,w}}d/4D\overline{Nu}_m)(\overline{T}/T_{g,w})\epsilon_r]^{-1} \quad [5]$$

Estimated diffusion coefficients and the assumption $\overline{Nu}_m \approx \overline{Nu}_h = 2.1$ predict a correction due to mass transport effects equal to *ca.* 40% at $\epsilon_r = 1.0$ and about 8% at $\epsilon_r = 0.1$.

Although mass transport corrections to ϵ_a are clearly small, they are also uncertain due, for example, to errors in (*i*) estimated diffusion coefficients, (*ii*) gas temperatures from Eq. [3], and (*iii*) the effect of slip flow on $\overline{Nu}_m$. In fact, experiments performed at an F-atom reaction probability, $\epsilon_a(F) \approx 0.3$ show the corrections to be smaller than would be estimated from Eq. [5]. Figure 2 shows the rate of Pt gasification by atomic fluorine at 1100°K *vs.* total gas flow rate at constant reactant and total pressure. Diffusion limitations at low flow rates disappear as the flow rate increases and a flow rate independent rate of reaction is observed. Flow rate under normal operating conditions was 1300 cm³ (STP)/min. Above 1620 cm³(STP)/min flow from the discharge tube is choked (M = 1), leading to a local increase of pressure in the underexpanded gas jet at the filament and, thus, an increase in the rate of reaction. From these measurements we conclude that mass transport rates do not significantly influence reactant arrival rate

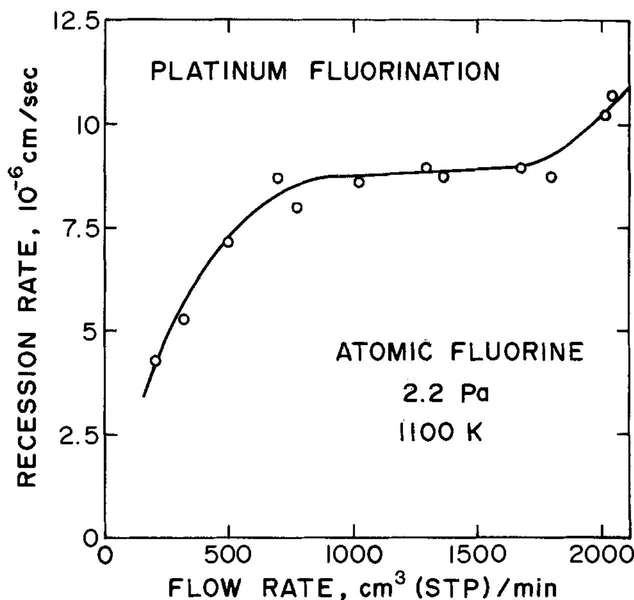

Fig. 2. Platinum gasification rate vs. gas flow rate at T = 1100°K, p_F = 2.2 Pa.

and neglect such corrections in the interpretation of rate measurements.

Results

Filament energy balance.—Transient effects on the filament energy balance are more precisely illustrated by the resistance-time curves (with measurements every 0.5 or 1.0 sec) than by the temperature-time curves which include fewer data points. The initial parts of resistance- and temperature-time curves for three F/Ta experiments using a constant current power supply are illustrated in Fig. 3. Each experiment shows a transient temperature increase followed by a temperature decrease prior to the continuous temperature and resistance increase with time associated with specimen diameter change. The initial temperature rise reflects the increased energy release which accompanies the exothermic gasification reaction. The subsequent temperature decrease reveals a less direct, reaction-induced increase of the specimen heat transfer coefficient, *i.e.*, an increase in its total emittance, ϵ_t, and/or thermal accommodation coefficient, α. If one assumes $\epsilon_t = 0.2$ and $\alpha = 0.3$ prior to F-atom exposure, the observed decrease in specimen temperature can then be explained by $\Delta\epsilon_t \cong 0.1$ or $\Delta\alpha \cong 0.5$. This reaction-induced increase in heat transfer coefficient was observed in all ex-

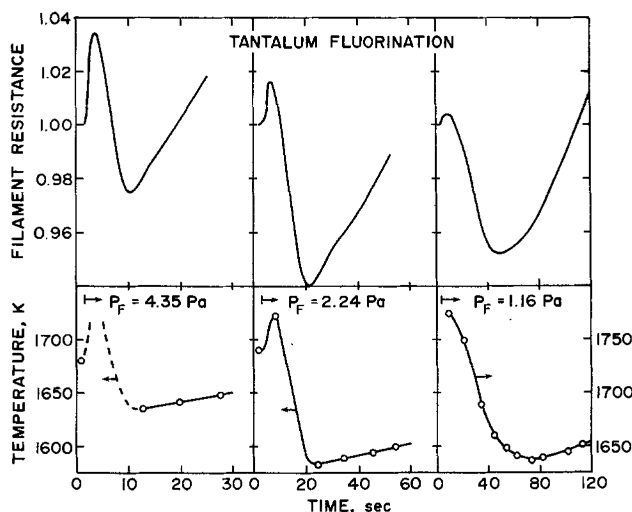

Fig. 3. Tantalum filament resistance and temperature transients on exposure to atomic fluorine with constant current heating.

periments with Ta filaments under conditions where the rate of Ta gasification increases with temperature but was absent in experiments at high temperature, where the rate of gasification decreases with temperature. Transient effects in the F/Pt and F/Ir experiments at 1000°-1200°K were similar to those illustrated in Fig. 3. At higher temperatures, the rates of F/Ir and F/Pt gasification decrease. The transient temperature increase due to the heat of reaction then becomes negligible but the increase in specimen heat transfer coefficient remains. Figure 4 illustrates resistance- and temperature-time effects for two higher temperature F/Ir experiments. These data show the transient effect to reverse in the absence of fluorine as illustrated by the temperature increase at the conclusion of each experiment. All rate data reported here were obtained from measurements subsequent to the initial transient effects. Experiments which employed a constant voltage power supply gave nearly constant temperature and rate data which agree with those obtained under constant current heating.

Gasification rate data.—It will be demonstrated that the order of F/Pt and F/Ir gasification reactions exceeds unity at high temperatures where the rate of reaction decreases rapidly with temperature. Under these conditions, more rapid gasification near the colder ends of the filament controls the duration of an experiment and eventually prevents further rate measurements. The order of reaction has been deduced from nth order Arrhenius diagrams, *i.e.*, plots of log $[\xi_{Me}/Z_F^n]$ *vs.* reciprocal temperature, where ξ_{Me} is the Pt or Ir gasification flux and Z_F is the incident flux of atomic fluorine. Such diagrams reveal nth order kinetics when data obtained at different pressures and temperatures merge into a single curve.

F/Ir kinetics.—The F/Ir data reveal first-order kinetics near 1000°-1100°K and a transition to third-order kinetics at higher temperature. The data, obtained at three different F-atom pressures are illustrated in Fig. 5, a third-order Arrhenius diagram. The lines drawn through the data were derived from the following empirical model of the reaction kinetics. It was assumed that:

1. A temperature and pressure independent fraction, $S_F(Ir)$, of the incident F-atoms stick on the surface and participate in the surface reactions.
2. The adsorbed F-atoms may (*i*) desorb or (*ii*) react with the substrate to produce IrF_3 product molecules.
3. The product molecule and F-atom desorption fluxes are given by the following Arrhenius-type rate laws

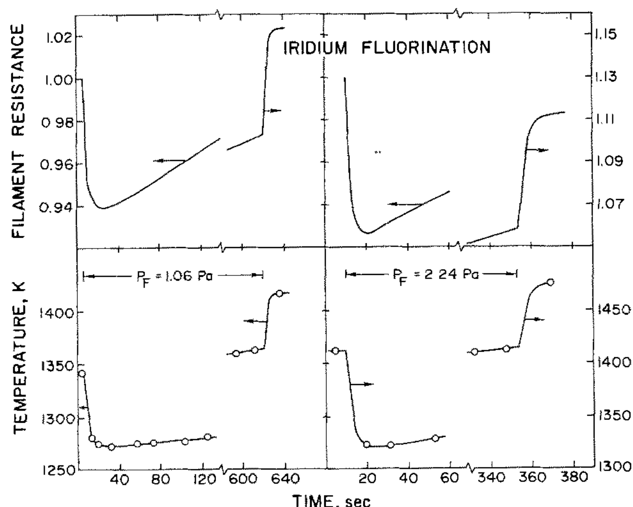

Fig. 4. Iridium filament resistance and temperature transients on exposure to atomic fluorine with constant current heating.

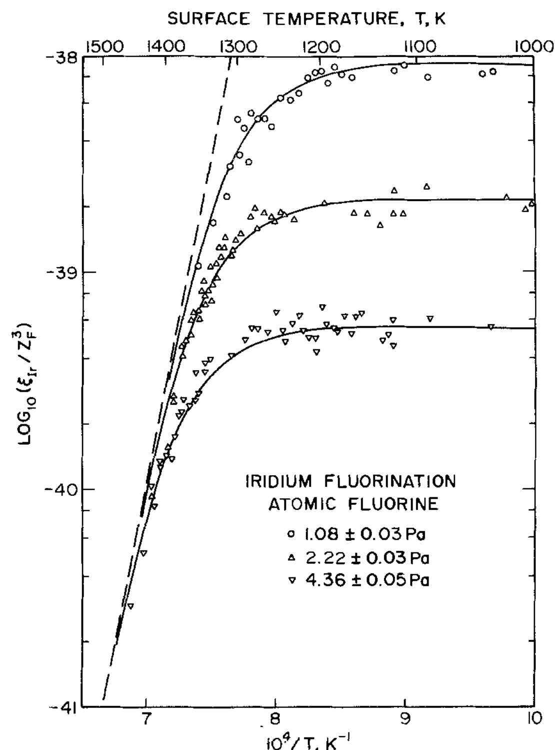

Fig. 5. Third-order Arrhenius diagram for F/Ir gasification reaction. Units for ξ_{Ir}, Z_F are atoms/cm^2 · sec.

$$\xi_F = A_F\theta_F \exp(-\Delta E^{\neq}_F/kT) \quad [6]$$

$$\xi_{IrF_3} = A_{IrF_3}\theta_{IrF_3} \exp(-\Delta E^{\neq}_{IrF_3}/kT) \quad [7]$$

where A, θ, and $\Delta E^{\neq}$ denote temperature independent pre-exponential constants, fractional surface coverage, and desorption activation energies, respectively.

4. The surface reaction by which adsorbed IrF_3 molecules are formed have the net effect that θ_{IrF_3} is proportional to θ_F^3 according to the following Arrhenius-type expression

$$\theta_{IrF_3}/\theta_F^3 = A_S \exp(-\Delta E^{\neq}_S/kT) \quad [8]$$

The constants, A_S, $\Delta E^{\neq}_S$ which appear in Eq. [8] are not elementary rate constants but, rather, reflect the net kinetic effect of several surface reactions or of a third-order surface equilibrium, as discussed below.

It is evident (see Discussion) that a fluoride film forms on the metal surface during reaction. However, the composition, porosity, and even the state (solid or liquid) of this film is unknown and the net surface reaction may occur *via* several different mechanisms. Langmuir-Hinshelwood type surface reactions can lead to Eq. [8], as could an equilibrium between adsorbed species and those dissolved in the fluoride film with a third-order reaction in the film. Also, the product species stoichiometry has not been established by independent measurements and no studies of the lower gaseous fluorides of iridium appear in the literature. However, if it is assumed that third-order kinetics derive from an equilibrium between adsorbed species, *i.e.*, that product desorption is the rate-limiting step, then the present results suggest that $IrF_3(g)$ is the product molecule.

To match the kinetic data, the constants in Eq. [6], [7], and [8] can be chosen so ξ_F is negligible at low temperature and all F-atoms which stick react to produce IrF_3 molecules. Therefore, at low temperature we take

$$S_F = 3\epsilon_{Ir} \text{ (low temperature)} \quad [9]$$

At higher temperatures, the surface F-atom mass balance, is

$$S_F Z_F = 3\xi_{Ir} + \xi_F \quad [10]$$

The sticking coefficient (from Eq. [9] and measured Ir gasification rates, yield the flux quotient

$$\xi_{IrF_3}/\xi_F^3 = \xi_{Ir}/(Z_F S_F - 3\xi_{Ir})^3 \quad [11]$$

which can be fit to

$$\xi_{IrF_3}/\xi_F^3 = A_{Ir} \exp(-\Delta E^{\neq}_{Ir}/kT) \quad [12]$$

Here, A_{Ir} and $\Delta E^{\neq}_{Ir}$ are the appropriate combinations of pre-exponentials and activation energies from Eq. [6]-[8]. The data were fit to Eq. [11] and [12] by (*i*) choosing a value of the sticking coefficient, (*ii*) calculating ξ_{IrF_3}/ξ_F^3 for all high temperature data for which $\epsilon_{Ir} < 0.037$ from Eq. [11], (*iii*) fitting these flux quotients to Eq. [12] by least squares, and (*iv*) repeating the calculation to find the value of S which minimized the variance for all data points. Numerical results are presented in Table I; the flux quotients computed from these results are shown by the solid lines drawn through the data in Fig. 5. The dashed line in Fig. 5 illustrates the limiting high temperature rate constant, $\xi_{Ir}/Z_F^3 = (\xi_{Ir}/\xi_F^3)S_F^3$, which may be used to calculate the Ir gasification rate from the F-atom flux when $\xi_{Ir} << Z_F$.

F/Pt kinetics.—The F/Pt data were obtained over a wider temperature range (600°-1430°K) than were the F/Ir data (1000°-1450°K) and show a greater variety of kinetic behavior. Included are zero-order kinetics at low temperature (600°-650°K), first-order kinetics between 800°-900°K, and second-order kinetics at high temperatures. A pressure and temperature dependent increase in reaction probability is observed between 900°-1300°K which suggests a change in product species. Also, at temperatures below 1000°K the rate of reaction depends on reactant purity as illustrated by experiments in which 35% O_2 was deliberately added to the fluorine.

The low temperature, zero-order kinetics are illustrated in Fig. 6, which plots the rate *vs.* temperature data in a zero-order Arrhenius diagram. Although the number of low temperature data points is small, they clearly merge into a single reactant pressure independent line in the 600°-650°K temperature range. It can be seen that addition of 35% O_2 to the reactant fluorine produces a pronounced decrease in the reaction rate below about 1000°K. However, data obtained with high purity (>99.9%) or commercial (≈98%) fluorine agree at all temperatures investigated. The line drawn through the low temperature F/Pt data is given by the equation

$$\xi_{Pt}(LT) = A \cdot \exp(-\Delta E^{\neq}/kT) \quad [13]$$

The coefficients in Eq. [13] were determined graphically and are reported (with estimated uncertainties) in Table I.

Table I. Fit of iridium and platinum gasification data

Metal	Quantity	Preexponential constant, $\log_{10}$ (A)	Activation energy $\Delta E^{\neq}$(kJ/mole)
Iridium	S_F	−0.616 ± 0.044	—
	ξ_{IrF_3}/ξ_F^3	−59.32 ± 0.87	−577 ± 25
	$(\xi_{Ir}/Z_F^3)_{HT}$	−61.19 ± 0.87	−577 ± 25
Platinum	$\xi_{Pt}(LT)$	30.8 ± 2.4	176 ± 29
	S_F	−0.178 ± 0.069	6.8 ± 1.1
	ξ_{PtF_2}/ξ_F^2	−28.88 ± 0.13	−238 ± 3

Figure 7 illustrates the first-order region between about 750°-900°K where the F/Pt reaction probability is independent of reactant pressure. A slow increase of ϵ_{Pt} with temperature is noted, which indicates a temperature dependent sticking coefficient, S_F(Pt). At about 900°K, depending on reactant pressure, the reaction probability exceeds that given by an extrapolation of the lower temperature first-order data. This effect is interpreted as a change in the product species, with fewer F-atoms required to gasify one Pt-atom rather than a nonlinear variation in log [S_F(Pt)] with reciprocal temperature. At even higher temperatures, a decrease in the rate of gasification is observed. The reaction is second order in this high temperature region, as illustrated in Fig. 8, a second-order Arrhenius diagram. In Fig. 6-8, the lines drawn through the data at temperatures above 750°K were derived from the following empirical model of the reaction kinetics. It was assumed that:

1. A temperature dependent, reactant pressure independent fraction, S_F(Pt), of the incident F-atoms stick on the surface and participate in the surface reactions. The sticking coefficient is given by the Arrhenius rate law

$$S_F(\text{Pt}) = A_F \exp(-\Delta E^{\neq}_F/kT) \quad [14]$$

2. The adsorbed F-atoms may (*i*) desorb or (*ii*) react with the substrate to produce PtF_2 or PtF_4 molecules.

3. The PtF_4, PtF_2, and F-atom desorption fluxes are given by Arrhenius-type rate laws similar to those written for the F/Ir reaction.

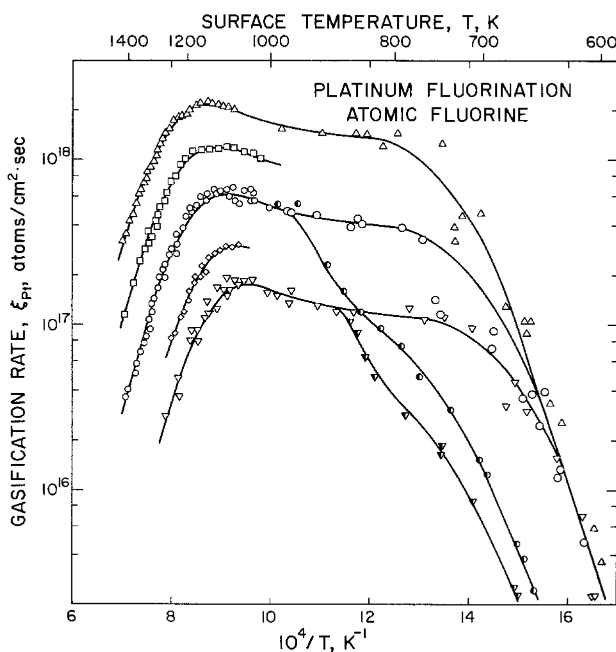

Fig. 6. Rate of platinum gasification by atomic fluorine vs. reciprocal temperature. △, p_F = 7.37 ± 0.03 Pa; □, p_F = 4.19 ± 0.15 Pa; ○, p_F = 2.20 ± 0.05 Pa; ◇, p_F = 1.08 ± 0.03 Pa; ▽, p_F = 0.65 ± 0.04 Pa. Half-filled symbols, 35% O_2 added to fluorine.

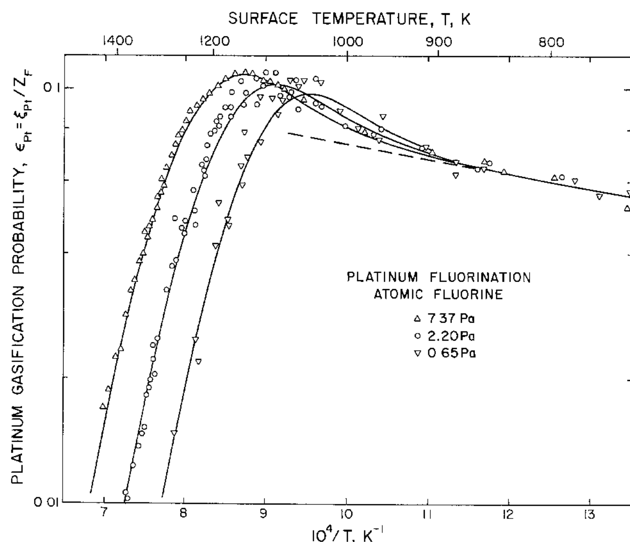

Fig. 7. F/Pt gasification probability vs. reciprocal temperature

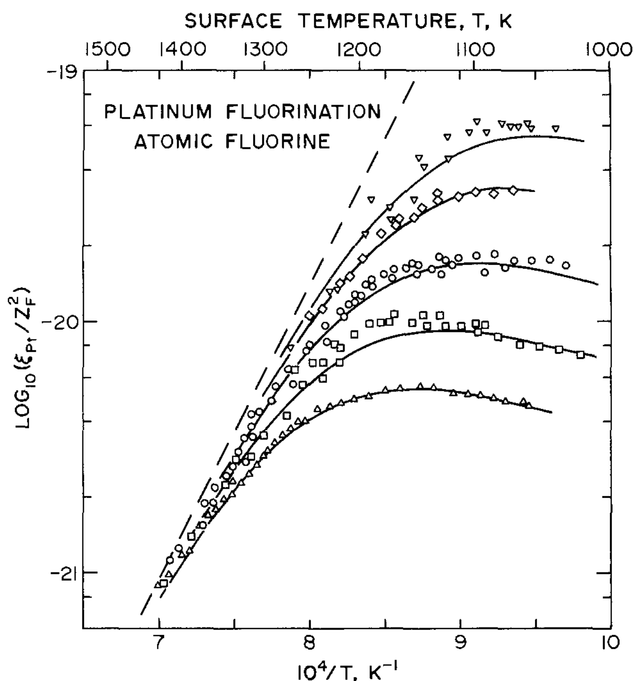

Fig. 8. Second-order Arrhenius diagram for F/Pt gasification reaction (symbols and units as in Fig. 6).

4. The surface reactions by which adsorbed PtF_4 and PtF_2 molecules are formed have the net effect that $\theta_{PtF_4} \propto \theta_F{}^4$ and $\theta_{PtF_2} \propto \theta_F{}^2$.

Proceeding as before, Arrhenius expressions can be written for flux quotients which do not involve the unknown surface concentrations.

The same comments in regard to product stoichiometry and the platinum fluoride film are appropriate here as were made earlier concerning the F/Ir reaction.

The F/Pt data were fit by least squares to the above model by the following method. At temperatures between 750°-900°K, almost all F-atoms which stick react to produce PtF_4, leading to

$$S_F(Pt) = 4\epsilon_{Pt} \quad [15]$$

Thus, A_F and $\Delta E^{\neq}{}_F$ were computed by a least squares fit of the first-order data to Eq. [14]. Above *ca.* 1200°K, ξ_{PtF_4} is negligible and

$$\xi_{PtF_2}/\xi_F{}^2 = \xi_{Pt}/(Z_F \cdot S_F - 2\xi_{Pt})^2$$

may be computed using extrapolated values of $S_F(Pt)$. The derived high temperature flux quotients were fit to the equation

$$\xi_{PtF_2}/\xi_F{}^2 = A_{2F} \exp(-\Delta E^{\neq}{}_{2F}/kT) \quad [16]$$

Finally, the complete F-atom mass balance

$$Z_F \cdot S_F = \xi_F + 2\xi_{PtF_2} + 4\xi_{PtF_4} \quad [17]$$

and Pt mass balance

$$\xi_{Pt} = \xi_{PtF_2} + \xi_{PtF_4} \quad [18]$$

can be solved in the intermediate temperature range, using values of $S_F(Pt)$ from Eq. [14] and $\xi_{PtF_2}/\xi_F{}^2$ from Eq. [16]. The resulting PtF_2 and PtF_4 fluxes were fit to

$$\xi_{PtF_4}/\xi_{PtF_2}{}^2 = A_{42} \exp(-\Delta E^{\neq}{}_{42}/kT) \quad [19]$$

The above calculation was iterated, with small corrections in the higher and lower temperature regions according to the results of the first calculation. Small changes in the computed preexponentials and activation energies were obtained but no further significant change occurred on repeated iterations. The numerical results are presented in Table I and illustrated by the lines drawn through the data in Fig. 6-8. It can be seen that the quantity $\xi_{PtF_4}/\xi_{PtF_2}{}^2$ is obtained with least accuracy. The calculation of this quantity was restricted to those data for which $0.2 < \xi_{PtF_2}/\xi_{PtF_4} < 5$; the fit of these data to Eq. [19] is illustrated in Fig. 9.

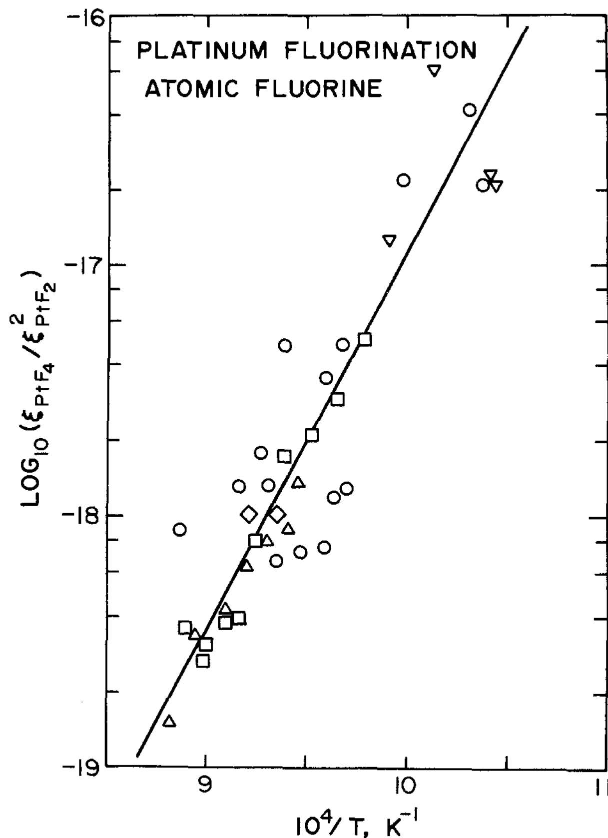

Fig. 9. Derived flux quotient $\xi_{PtF_4}/\xi^2{}_{PtF_2}$ vs. reciprocal temperature (symbols and units as in Fig. 6).

F, F_2/Ta kinetics.—Tantalum reacts with atomic fluorine over a greater range of temperatures than any other metal which has been studied. The exothermic gasification reaction quickly heats a Ta filament from 300°K to $T \cong 600$°K where $\xi_{Ta} = 6.6 \times 10^{16}$ cm^{-2} · sec^{-1} at $p_F = 2.26$ Pa, *i.e.*, $\epsilon_{Ta} \cong 9.4 \times 10^{-3}$. The F/Ta reaction also persists to very high temperature and was measured to $T = 3030$°K in these experiments. The F_2/Ta rate was not measurable at room temperature. Figure 10 illustrates the

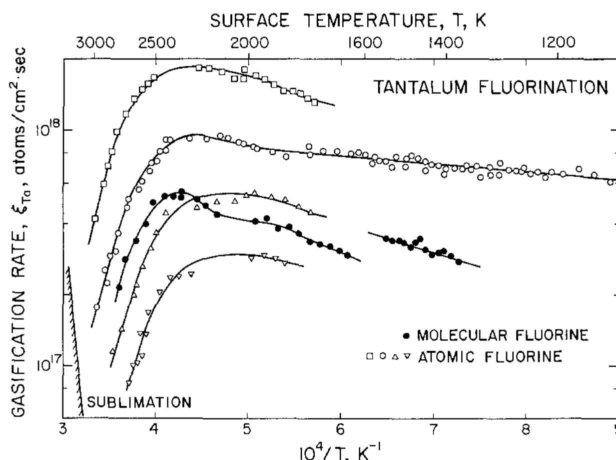

Fig. 10. Rate of tantalum gasification by atomic and molecular fluorine vs. reciprocal temperature. □, $p_F = 4.39 \pm 0.06$ Pa; ○, $p_F = 2.20 \pm 0.04$ Pa; △, $p_F = 1.167 \pm 0.004$ Pa; ▽, $p_F = 0.605 \pm 0.007$ Pa; ●, $p_{F_2} = 1.26 \pm 0.03$ Pa.

F/Ta rate data, obtained at four F-atom reactant pressures and F_2/Ta data at $p_F = 1.26$ Pa.

The lower temperature portion of the F/Ta Arrhenius diagram is easily explained by a temperature dependent, pressure independent sticking coefficient with reaction of all F-atoms which stick on the surface. If the product species is $TaF_5(g)$ one obtains $S_F(\text{Ta}) = 1.28 \exp(-1010/T)$. At 1850°K the reaction order is actually 0.84. Values less than unity are characteristic of a change in product species, as for the F/Pt reaction near 1000°K. At high temperatures the F/Ta reaction order is approximately 1.5 and the Arrhenius activation energy is $\Delta E^{\neq} \approx -290$ kJ/mole. The nonintegral reaction order cannot be explained by competitive desorption of atomic fluorine and a single tantalum fluoride. Further, it was noted that energy balance effects associated with the fluoride film disappear when the temperature coefficient of reaction rate becomes negative. Thus, a changing surface and the possible contribution of several gaseous species complicate the interpretation of high temperature F/Ta data, which was not carried further.

The F_2/Ta data seem to show a small influence of impurities in the fluorine on the rate of reaction. Fluorine purity for the data between 1370°-1540°K was 98% while the higher temperature data were obtained with 96% fluorine. However, no differences in F/Ta rate data were observed for fluorine of 96%, 98%, or 99.9% purity.

Errors in F/Ir and F/Pt kinetics.—The uncertainty in $S_F(\text{Ir})$ listed in Table I is an estimated value, ±10%. All other uncertainties were obtained from the data analysis. The largest contribution to error in the derived coefficients is the standard deviation of the mean values obtained in least squares calculations. However, each calculation gave two coefficients under the assumption that other derived constants in the model were equal to the values listed in Table I. Additional errors in the derived coefficients result from the uncertainty in all (6 for Pt, 3 for Ir) constants in the model; this effect has been included in computing the listed errors.

The rms deviation of the measured values of $\ln \xi_{Pt}$ or $\ln \xi_{Ir}$ from those given by the models is 0.080 for Pt, 0.117 for Ir, corresponding to deviations of 8% and 12% in the respective rates. The greater deviations obtained in the Ir data are mainly due to the larger slope of the high temperature region in the Arrhenius diagram. For example, if the only error were a temperature uncertainty of ±2°K, the consequent errors between measured and computed high temperature rates of reaction would be about ±3.4% for Pt, ±7.4% for Ir. Other sources of error have been discussed (17). It is concluded that the model fits the data within the precision of the measurements. This is not the case if one assumes the lower temperature F/Pt product is $PtF_3(g)$, formed by a third-order surface reaction. Then, the resulting coefficients of the model predict rate data to only 12.4%, largely due to a much poorer fit in the 950°-1250°K temperature range.

It may be remarked that the method of analysis nearly eliminates errors due to the uncertainty in the incident flux if the assumed product species are the actual product species. This is true because $Z_F \cdot S_F$ measures correctly the number of F-atoms which stick on the surface even though Z_F is uncertain by about 10%. The uncertainty in Z_F produces an additional error in S_F (which is not included in Table I) but not in the other coefficients.

Discussion

Fluoride film formation.—The mechanism by which the specimen heat transfer coefficient increases on exposure to fluorine must be consistent with the magnitude, rate, and reversibility of the induced specimen temperature decrease. Roughening of the metal surface is inconsistent with the reversibility and adsorption of an atomic fluorine monolayer would occur too quickly to explain the duration of the transient effect. The observed changes in heat transfer coefficient are thus attributed to formation of condensed metal fluoride films on the metal surfaces. The film presumably has a greater emissivity, thermal accommodation coefficient, and/or roughness than does the bare metal. Reaction under steady-state conditions then occurs *via* F-atom gasification of the fluoride film at a rate equal to that at which it is formed by F-atom diffusion to the underlying metal and/or metal atom diffusion to the surface.

The formation of fluoride films on tantalum has already been proposed by Machiels and Olander (8) for the F_2/Ta reaction on the basis of their modulated beam results at 690° and 930°K. This independent evidence for fluoride films confirms the present explanation of the transient temperature effects for tantalum and leads directly to the conclusion that fluoride films also form on Ir and Pt during reaction with atomic fluorine.

McIntyre and McTaggart (31) studied the kinetics of Cl, Br, I/Ag scale forming reactions by direct measurement of scale growth rates and report near unit reaction probabilities even at a scale thickness of several hundred nanometers. McTaggart (32) obtained similar results for the F/Ag reaction. Thus, the formation of fluoride films need not inhibit the rate of reaction as does oxide scale formation in many metal oxidation reactions. We note that the formation of fluoride films is not a necessary consequence of the present steady-state rate measurements. Indeed, the same mathematical analysis of rate data could be based on low coverage Langmuir-Hinshelwood type surface reactions on the bare metal surface. However, this hypothesis could not explain modulation experiments which more directly probe the surface kinetics, as Machiels and Olander have demonstrated for the F_2/Ta reaction (8).

Quasi-equilibrium F/Ir and F/Pt preexponential quotients.—The preexponential quotients listed in Table I agree well with values computed by a simple, quasi-equilibrium (QE) model (33, 34). If an adsorbed state equilibrium is assumed with unit metal activity and the surfaces are smooth, the measured desorption flux quotients will equal the adsorption flux quotients which obtain under gas/surface equilibrium conditions. For example, $\xi_{PtF_2}/\xi_F{}^2$ will be given by

$$\xi_{PtF_2}/\xi_F{}^2 = (Z_{PtF_2}/Z_F{}^2)_{EQ}(S_{PtF_2}/S_F{}^2) \qquad [20]$$

where $(Z_{PtF_2}/Z_F{}^2)_{EQ}$ is the quotient of equilibrium fluxes and S_{PtF_2} is the PtF_2 sticking coefficient. If, further, activation entropy effects are absent in PtF_2 or F-atom sticking (or cancel out of the following equation), thermodynamics and the Hertz-Knudsen equation yield

$$A_{2F} = (2\pi kT/m_{PtF_2})^{1/2}(m_F/1.013 \times 10^6)\exp(\Delta S°_{RX}/R) \qquad [21]$$

Here, m is the mass of a PtF_2 molecule or F-atom, the numerical factor provides appropriate conversion of units, and $\Delta S°_{RX}$ is the standard entropy of the reaction

$$Pt(s) + 2F(g) = PtF_2(g) \qquad [22]$$

Equation [21] and analogous expressions for the other gasification reactions yield the preexponential quotients reported in Table II. Entropies were obtained from Hultgren (35) for the metals, Janaf Tables (1) for atomic fluorine, and were computed for the iridium and platinum fluorides using the molecular parameters estimated for tungsten fluorides by Hildenbrand (36). In addition to the good agreement between experimental and QE preexponential quotients, thermodynamic property estimates for iridium fluorides by Wallace, Feber, and Hauth (40) also support the QE model. For example, they com-

Table II. Calculation of preexponential quotients

Flux quotient*	$\xi_{PtF_2}/\xi_F{}^2$	$\xi_{PtF_4}/\xi_{PtF_2}{}^2$	$\xi_{IrF_3}/\xi_F{}^3$
Mean temperature (°K)	1290	1040	1370

* Flux units are molecules/square centimeter · second or atoms/square centimeter · second.

pute equilibrium pressures of F and IrF_3 in equilibrium with solid iridium at 1500°K from which one obtains a value for $\xi(IrF_3)/\xi(F)^3$ within 50% of that given by the present results. There are, however, a sufficient number of unproved assumptions in the QE model (adsorbed state equilibrium, unit metal activity, absence of entropy effects in the molecular sticking coefficients) that its success should be viewed with caution, at least until the product species have been independently confirmed and their thermodynamic properties measured.

F, F_2/Ta kinetics.—The present F, F_2/Ta rate measurements can be compared with values predicted with the model and kinetic parameters derived by Machiels and Olander (8) from their modulated molecular beam study of the F_2/Ta reaction. At 690° and 930°K, respectively, they obtained second-order rate constants $k_R = 7.4 \times 10^{-14}$ and 7.9×10^{-14} cm²/sec and site densities $N_S = 5 \times 10^{14}$ and 8×10^{14} cm^{-2}. The rate of reaction to produce TaF_5 on the assumed TaF_3 film is then given by the second-order equation

$$\xi_{TaF_5} = k_R(N_S\theta)^2 \quad [23]$$

where θ is the fractional coverage of atomic fluorine. In the model the source (F or F_2) of the adsorbed fluorine does not influence the rate and all fluorine which is chemisorbed reacts to produce TaF_5(g). If we take $\theta \leq 1.0$ the above results predict $\xi_{TaF_5}(max) = 1.8 \times 10^{16}\ cm^{-2} \cdot sec^{-1}$ at 690°K and $5.1 \times 10^{16}\ cm^{-2} \cdot sec^{-1}$ at 930°K. These values are considerably smaller than the extrapolated higher temperature F/Ta or F_2/Ta rate data obtained here. Further, the one datum at $T \cong 600$°K gave $\xi_{Ta} = 6.6 \times 10^{16}\ cm^{-2}\ sec^{-1}$, also in excess of the predicted values.

The linear extrapolation of present F_2/Ta data over a large temperature range is a source of error which could produce the above discrepancy but no such error is present in the comparison of F/Ta data with the maximum predicted rates. The discrepancy in F/Ta rates may arise in the use of the Machiels and Olander mechanism at the much higher reactant fluxes of the present experiments. As the F-atom coverage of a TaF_3 film increases it is possible that the film stoichiometry changes, *e.g.*, to TaF_4, with a consequent influence on the mechanism and reaction rate. On the other hand, the film might already be TaF_4 (as suggested by Machiels and Olander) and a fit of their data to a TaF_4 film model might give better agreement with the present rate measurements. In either case, the qualitative features of the F_2/Ta and F/Ta reaction mechanism are the same in these two studies: Fluoride films form on the metal surface but these films do not produce a large reduction in the rate of reaction.

General features of metal fluorination reactions.—Kinetic data are now available for F-atom gasification of six metals: Pt, Ir, W (5), Mo (5), Ti (14), and Ta. The first-order Arrhenius diagrams for these reactions at an F-atom reactant pressure of *ca.* 2.2 Pa are illustrated in Fig. 11. The F/Mo and F/W curves are recalculated from the data reported by Rosner and Allendorf (5) using Eq. [1] and [3] to obtain the incident reactant fluxes. Except for Ir, each reaction shows the positive curvature in ln ϵ *vs.* reciprocal temperature characteristic of changes in product species. A change in product species with temperature is also suggested by the observation (5) of less than unit reaction order at 1350°, 1950°K for the F/W reaction, and at 1280°K for the F/Mo reaction.

The observed increase in Ti gasification rate at higher temperature contrasts with the decrease found with all other systems. This effect can be qualitatively understood by thermodynamic considerations. The over-all gasification reactions

$$Me(s) + nF(g) = MeF_n(g) \quad [24]$$

are endoentropic unless $n = 1$ in which case $\Delta S° \cong 0$. Therefore, if the reaction

$$Me(s) + F(g) = MeF(g) \quad [25]$$

is endothermic, the standard Gibbs free energies of all gasification reactions will become positive at sufficiently high temperature and a rate decrease will occur. The enthalpy of reaction [25] is positive if the vaporization enthalpy for the metal exceeds the monofluoride dissociation enthalpy. Known (1, 35-37) and estimated (38) thermodynamic data predict the observed high temperature behavior: at sufficiently high temperature, only titanium [$\Delta H°_v(Ti) = 439$ kJ/mole, $D°(TiF) \cong 630$ kJ/mole] can be gasified by atomic fluorine.

Summary

This paper presents new experimental results pertaining to reactant arrival rates in the low pressure, transonic flow reactor, the F/Ir, Pt, and Ta gasification kinetics, and the occurrence of fluoride films on Ir, Pt, and Ta metals during their reaction with fluorine. These results permit a more detailed interpretation of steady-state F/metal gasification kinetics than has been previously possible, chiefly through the quantitative agreement between F/Ir, Pt rate measurements and a model of the reaction kinetics. The principal results and conclusions are summarized below.

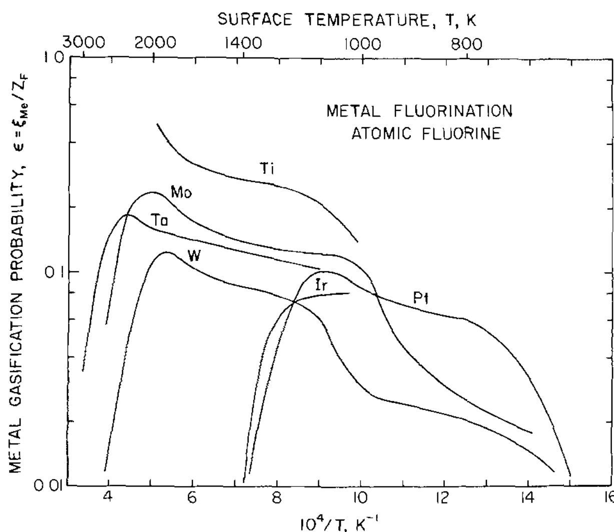

Fig. 11. Temperature dependence of reaction probabilities for the attack of iridium, platinum, tantalum, tungsten, molybdenum, and titanium by atomic fluorine, $p_F \approx 2.2$ Pa.

1. Gas phase mass transport does not significantly influence reactant arrival rate in the transonic flow reactor at near-sonic flow velocities, 130 Pa total pressure, and 0.038 cm filament diameters, even when the intrinsic gas/solid reaction probability approaches unity. However, the temperature of incident atoms exceeds the ambient temperature by an amount which depends on the filament thermal accommodation coefficient, α. Due to uncertainties in α, the gas temperature (given by Eq. [3]) is uncertain by 11-22% in the 1000°-3000°K temperature range which leads to a 6-11% uncertainty in incident reactant flux.

2. An increase in the Ir, Pt, and Ta filament heat transfer coefficient occurs on exposure to fluorine due to an increase in its total emissivity or thermal accommodation coefficient. The time required, magnitude, and reversibility of this effect imply that it is a result of the formation of a fluoride film on the metal surfaces. Adsorption of a single F-atom monolayer or roughening of the bare metal surface are inconsistent with the time required or the reversibility of the change in heat transfer coefficient.

3. The F/Ir reaction kinetics are first order in the incident F-atom flux below 1150°K, and third order at higher temperatures. The data fit, within experimental error, a model which assumes a temperature and reactant pressure independent sticking coefficient with competitive desorption of atomic fluorine and IrF_3 product molecules.

4. The F/Pt kinetics above 800°K are similar to the F/Ir kinetics except: (*i*) the sticking coefficient is slightly temperature dependent and (*ii*) PtF_2 and PtF_4 product molecules may be produced, each being the major product species in a different temperature range. At lower temperatures the F/Pt rate decreases and is zero order below 650°K. Oxygen (35%) added to the flourine reduces the rate of reaction below 1000°K but has no influence on higher temperature rate data. Further study of the corrosive properties of oxygen-fluorine mixtures would be of interest.

5. Quasi-equilibrium preexponential factors for the F/Pt and F/Ir rate laws agree with preexponential quotients derived from the data, and thus lend support to the assumption that second-, third-, fourth-order reactions imply PtF_2, IrF_3, and PtF_4 as the product species. However, independent verification of product species identity and other assumptions of the quasi-equilibrium model is not available and this agreement could be fortuitous.

6. The F/Ta data do not permit a simple quantitative interpretation as do the F/Ir, Pt data. Interpretation of the F/Ta results is complicated by the possible simultaneous occurrence of several gaseous species at the highest temperatures. Also, evidence from heat balance measurements indicates the fluoride film does not occur on tantalum at high temperature where the temperature coefficient of reaction rate is negative. The measured F/Ta rates do not agree with maximum values predicted by the F_2/Ta kinetic model of Machiels and Olander (8). This discrepancy may be due to a change in mechanism which results with reactant dissociation and a 100-200-fold increase of reactant pressure.

The successful fit of F/Ir, Pt data to kinetic models suggests these systems as promising candidates for further detailed study. Thermodynamic data for gaseous fluorides, molecular species sticking coefficients, and modulated beam studies of the surface kinetics would confirm or extend some of the present conclusions. Without such data, the mechanistic conclusions remain unconfirmed, but the simple mathematical models of F/Ir, Pt kinetics retain the significance that they faithfully reproduce the actual F-atom/metal gasification rates.

Acknowledgments

I thank Professor D. E. Rosner for the unpublished F/Ti data illustrated in Fig. 11 and also for valuable discussions of many aspects of this research. Argonne National Laboratory was most helpful in supplying the purified fluorine used in some of these experiments. The confidence and encouragement of Dr. H. M. Davis, Director of the Metallurgy and Ceramics Division of the U.S. Army Research Office, were essential to the success of this research program.

Manuscript submitted June 20, 1977; revised manuscript received Oct. 25, 1977. This was Paper 391 presented at the Atlanta, Georgia, Meeting of the Society, Oct. 9-14, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

The contact resistivity of metal-semiconductor contacts, a property of current interest (1-4), is usually obtained from measurements on samples with different contact areas (5) or by subtracting the bulk resistance (determined in a separate experiment) from the sample resistance (1). We describe in this note a method of pulse measurement which may be used to determine the contact resistance and the bulk resistance individually in one experiment. The method has been applied to determine the contact resistance for room temperature electroless nickel contacts and evaporated aluminum contacts to n- and p-type silicon samples having resistivities between 5 and 350 Ω-cm. Values of contact resistance, contact capacitance, and bulk resistivity obtained from the experiments are also presented.

The method is based on the equivalent circuit of a semiconductor sample with contacts as shown in Fig. 1(a). The bulk resistance is represented by R_B and the contact resistance and capacitances by R_{C1}, R_{C2} and C_{C1}, C_{C2}, respectively. A voltage pulse is applied to the sample through a resistance larger than the sample resistance and the resultant voltage across the sample is displayed on an oscilloscope. The voltage displayed on the oscilloscope near the initial end of the pulse (for the conditions stated below) is given by

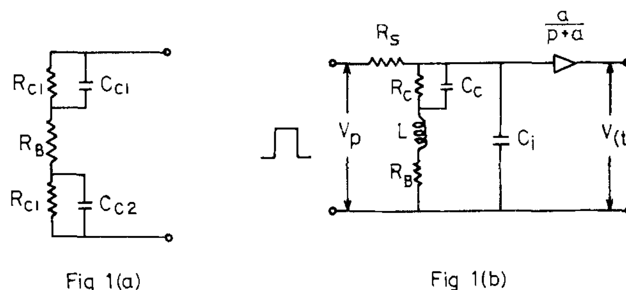
$$V(t) = [R_B + (aL - R_B)e^{-at} + R_C(1 - e^{-t/R_CC_C})] \frac{V_p}{(R_B + R_S)}$$

where V_p is the applied voltage, R_s is the resistance connected in series with the sample, L is the inductance of the lead connecting the sample to the ground plane, and $1/a$ is the oscilloscope amplifier time constant. C_C and R_C are, respectively, the lumped contact capacitance and resistance (see Fig. 1(b)). It has been assumed that $R_CC_C > 1/a$ and also that $1/ac_i >> R_B$, c_i being the input capacitance of the oscilloscope.

The voltage for large values of t is, on the other hand

$$V(t \to \infty) = V_p(R_B + R_C)/R_B + R_C + R_S)$$

The expected voltage wave shape is as shown in Fig. 1(c). We also find that the initial voltage is a step of height $V_pR_B/(R_B + R_S)$ if the length of the lead



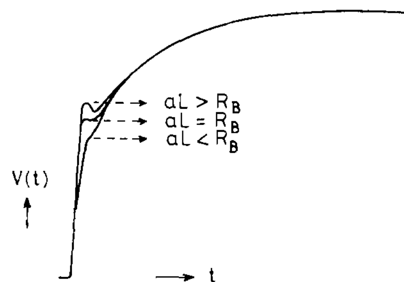


Fig. 1. (a) Equivalent circuit of a semiconductor sample with contacts; (b) actual circuit involved in the measurements; (c) expected wave shape of the voltage across the semiconductor.

is so chosen that the lead inductance satisfies the relation $aL = R_B$. (The length of the lead required for this adjustment in our experiment was between 1 and 7.5 cm.)

It is evident from the above relations that the contact resistance R_C and the sample resistance R_B may be obtained from separate measurements of the initial and the final voltage step. The value of C_c may also be estimated from the rise time of the initial exponential part.

This method has been applied to study the contact resistance of contacts made to silicon samples of both conductivity types (resistivity from 5 to 350 Ω-cm) prepared by the room temperature electroless nickel-plating technique (7) using the following procedure. Samples were first lapped with 800 mesh carborundum powder washed in deionized water, and degreased in boiling methanol. The degreased sample was cleaned in an ultrasonic cleaner and rewashed in methanol

Key words: interfaces, metal-semiconductor contact, electrical properties.

and deionized water. It was then dipped in 48% HF for 1 min and dropped in the nickel-plating bath. The deposition occurred in 8-10 min. Some vacuum-evaporated aluminum contacts were also studied for comparison.

Values of R_s, a, and C_l used in our experiment were, respectively, 100Ω, 2×10^8 sec^{-1}, and 10 pF. The sample dimensions were chosen so that R_B was in the range 5-20Ω. The voltage across the sample had the wave shape schematically presented in Fig. 1(c) and measurements were taken by adjusting the lead length to achieve the condition $aL = R_B$ in all the cases. The required values of L for satisfying this condition lie between 0.025 and 0.1 μH for the experimental values of $a = 2 \times 10^8$ sec^{-1} and R_B = (5-20Ω). This was realized by adjusting the length of the lead connecting the sample to the ground plane between 1 and 7.5 cm. Oscillograms showing the voltage wave shape under different conditions of adjustment are shown in Fig. 2. Our measured values of contact resistivity, bulk resistivity, and contact capacitance for samples of different nominal bulk resistivity are presented in Table I.

The contacts to all the n-type samples gave linear current-voltage characteristics, but for the p-type samples the relation was nonlinear. However, it is found from the pulse measurements that in all the cases significant contact resistance was present. Thus a linear current-voltage characteristic is not always an indication of a low resistance contact as is often assumed (8, 9).

The contact resistance for a freshly prepared contact made by the Ni-plating technique was found to be low for n-type samples, the contact being almost ohmic. The values of contact resistance for such contacts as obtained in our experiment are of the same order as reported by other workers (2, 10). It was observed, however, that the contact resistance of such contacts increased with aging or when a lead is attached to it by the usual process of soldering. Some results for aged contacts are also presented in Table I.

Results of Table I also show that the values of bulk resistivity obtained by the method for high resistivity and long-length low resistivity samples agree fairly well with the nominal values, which were obtained by the four-probe method for low resistivity samples and by the two-probe method (11) for the high resistivity samples. The resistivity of small length low resistivity samples obtained by the method does not, however, agree with the nominal values or vary with the length of the sample. It was found from studies on such samples of the same resistivity but of different lengths that the sample resistance corresponding to the same face area and excluding the contact resistance varied linearly with length, and the slope of the line correctly gave the bulk resistivity. These results indicated that there exists an additional contact resistance of about 0.2 Ω-cm^2 in series with the parallel combination of the contact resistance and capacitance contributed by the semiconductor surface layer. The value of this resistance, in contrast to that of the semiconductor surface layer, was always the same and was of such magnitude that it was negligible in comparison to the sample resistance for high resistivity and long-length low resistivity samples. It was important only in small-length low resistivity samples, but as it is reproducible, it could be eliminated by taking measurements on samples of different lengths as mentioned above. It should be noted in this connection that the other part of the contact resistance cannot be

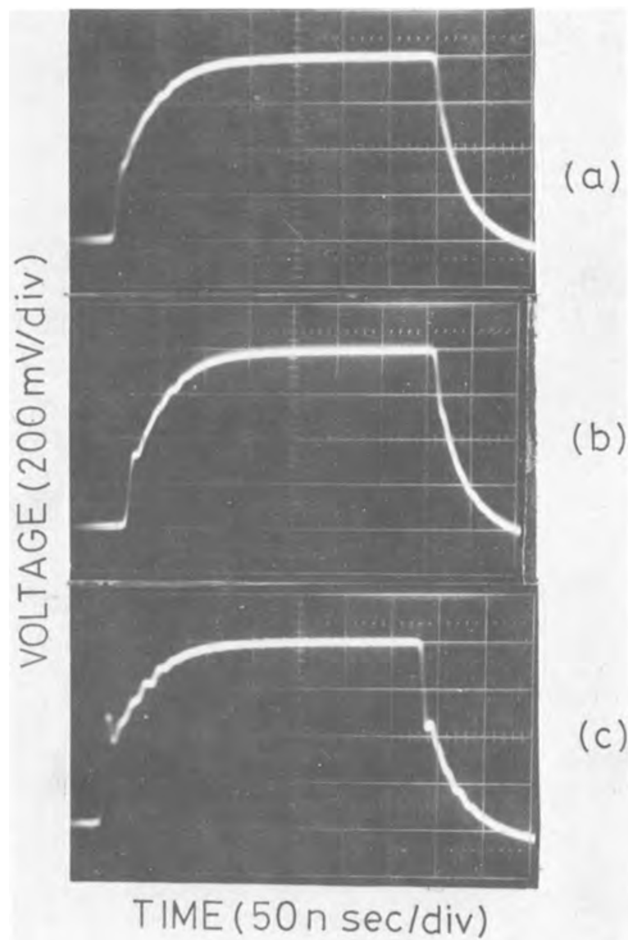

Fig. 2. Experimental wave shape of the voltage across the semiconductor sample (R_B =5.6 Ω); (a) Lead length = 0.5 cm; (b) lead length = 2.5 cm; (c) lead length = 3.5 cm.

Table I. Experimental results on contact and bulk resistance

Sample No.	Dimension of the sample: Length (cm)	Dimension of the sample: Area (cm^2)	Sample type	Nominal bulk resistivity (Ω-cm)	Experimental bulk resistivity (Ω-cm)	Contact resistivity (Ω-cm^2)	Contact capacitance (pF/cm^2)	Nature of contact
1	0.07	0.25	p	350	343	130	400	Electroless Ni

9	0.074	0.094	n	5	7.9	0.06	46,000	Electroless Ni (Freshly prepared; pressed leads)
10	0.074	0.117	n	5	8.2	4.0	—	Vapor-deposited Al
11	0.175	0.98	n	5	5.8	0.5	50,000	Electroless Ni (Aged sample; soldered leads)
12	0.293	0.092	n	5	5.4	1.3	37,000	Same as above
13	0.398	0.090	n	5	5.2	1.1	40,000	Same as above

easily determined by measurements on samples of different lengths as its value is sensitive to the conditions of contact processing and is not exactly reproducible.

The method described here thus directly gives us the values of contact resistance and capacitance due to the semiconductor surface layer as well as the correct values of bulk resistivity of high resistivity and long-length low resistivity samples. It may also be used to correctly obtain the resistivity of small-length low resistivity samples by taking measurements on samples of different lengths.

ABSTRACT

Li cells based on BiF_3 cathodes have been tested. In particular, the effect of cathode formulation and compacting pressure, nature of the solution, temperature, and current density have been evaluated. Through x-ray analysis, cyclic voltammetry, and coulometric analysis it was possible to ascertain that BiF_3 is reduced to Bi and then to Li_3Bi. During the first reduction process, ternary phases of the Li_xBiF_3 type are probably formed. Li/BiF_3 cells can give practical energy densities in excess of 200 W-hr/kg at the rate of 0.5 mA/cm^2.

The improvement brought about in the field of lithium primary batteries by the use of liquid or gaseous depolarizers, such as SO_2Cl_2 or $SOCl_2$ (1, 2), SO_2 (3), and O_2 (4), has not stopped the search for solid cathode materials for high energy, low rate cells. Indeed, for low rate applications the performances of the latter compare well with those of the former. On the other hand, problems such as safety, material corrosion, and chemical handling, often encountered with the first type of depolarizers, are almost irrelevant for cells based on solid cathodes.

Several new solid materials have been proposed for Li primary cells in the last few years. Two of them, namely, Ag_2CrO_4 (5) and fluorographite (6), are now used in commercial cells. In addition, several interesting compounds, especially chalcogenides, have been examined and some of them show promise of practical utilization (7).

Recently, in this laboratory, the behavior of Bi_2O_3 cathodes in Li button cells has been investigated (8). This oxide has a high specific capacity, *i.e.*, 0.345 A-hr/g for the reduction to Bi, and may be reduced down to Li_3Bi. Also its specific energy is of interest in spite of the relatively low load voltage (1.5V at 0.5 mA/cm^2 to 1.0V cutoff).

Following this line of research, BiF_3 has been subsequently examined. This fluoride has a specific capacity a little lower than that of Bi_2O_3, *i.e.*, 0.302 A-hr/g. On the other hand, Li/BiF_3 cells have higher mean discharge voltages (*ca.* 2.0V) and lower polarization losses at current densities above 1.0 mA/cm^2.

Experimental Aspects

Materials.—BiF_3 was prepared by dissolving Bi_2O_3 in excess hot HF solution. The fluoride tended to precipitate from the above solution, so that it was filtered out, washed to neutral *p*H, and dried at 150°C. During this preparation, BiOF is also reported to be formed (9) through a hydrolysis reaction. We checked with x-ray analysis (see Table I) that our compound was solely BiF_3. No lines attributable to BiOF or any other Bi compounds are present in the diffraction spectrum.

$LiAsF_6$ and $LiPF_6$ were special reagents used without any further purification. $LiClO_4$ was melted under vacuum at 250°C to eliminate residual water (10). $LiAlCl_4$ was prepared by melting at 200°C under N_2 atmosphere equimolecular amounts of predried LiCl and $AlCl_3$ (11).

All the solvents were purified by fractional distillation [propylene carbonate (PC) and butyrolactone (BL) under reduced pressure]. Methyl formate (MF) was distilled over Merck 4Å molecular sieve. The purification of tetrahydrofuran (THF) proved to be critical due to the possible formation of peroxides which could easily attack Li anodes (12). THF was kept several days on $LiAlH_4$, then poured into a still pot containing Li ribbon, and distilled under N_2 atmosphere. Even after this treatment, the Barnes test (13) revealed the presence of some peroxides. However, leaving the distillate in a dry box on lithium ribbon (in the dark) was effective in reducing the peroxide content below a detectable limit. The solvent so purified was stable toward Li.

Cathode preparation.—BiF_3 is a nonconducting material to which additives have to be added to ensure electronic conductivity. Graphite acetylene black, silver, and bismuth were used for this purpose. Some cathodes were prepared by adding binders such as Teflon and polyethylene. With the first binder, it was not necessary to heat the cathodic mixture before pressing the powder into a pellet, due to the cold flow property of Teflon. As for polyethylene, the mixture

Key words: Li batteries, BiF_3, nonaqueous solvents, cyclic voltammetry.

was heated at 120°C to allow flowing of the polymer prior to pressing. The cathode pellets (area, 1.26 cm^2) were supported on Ag powder pelletized at 500 kg/cm^2.

Cell assembly and discharge curves.—The cells (of the button type) were built by putting the lithium anode, three layers of a glass fiber separator (Whatman 934 AH) soaked with electrolyte, and the cathode pellet into a Teflon container with stainless steel terminals. Felt, cotton, and porous polypropylene separators were also tested, but unsatisfactory results were obtained. The cells, having capacities typically around 15 mA-hr, were kept in a dry box during the galvanostatic discharges.

Cell polarization curves.—Galvanostatic polarization curves were done on cells similar to those to be discharged by using an apparatus based on a function generator, a potentiostat, and a X-Y recorder. The decrease in cell voltage was recorded in various solutions as a function of the current, which was varied at the rate of 1.2 mA/min.

Cyclic voltammetry.—The working electrode was formed by pressing the test material (BiF_3 + C or Bi) on a tiny Ag net, so as to obtain a planar microelectrode. A Li rod hung to a Ag wire was used as a reference and was separated from the working electrode by a Luggin capillary. A Ag net counterelectrode completely surrounded the cathode material. Potentiostatic *I-V* curves were recorded at the sweep rate of 20 mV/sec.

Solubility.—BiF_3 was kept 10 days in various solutions to ascertain its solubility. After this time, the solutions were filtered and the amount of BiF_3 was titrated with the EDTA technique (14). Thiourea was used as an indicator at *p*H values 1.5-2.0. Blank experiments with known amounts of soluble Bi salts have allowed the accuracy of this technique in the presence of organic solvents to be ascertained.

Compatibility tests.—BiF_3 and organic solutions were put in large test tubes fitted with manometers in order to test the development of a pressure due to decomposition reactions. After a 5 day observation, neither discoloration nor gassing was observed in $LiClO_4$-PC and $LiClO_4$-THF solutions.

X-ray analysis.—The x-ray powder pattern was obtained on BiF_3 and on the discharged cathodes by using Mo Kα radiation filtered by Zr.

Experimental Results

The galvanostatic cell polarizations of Fig. 1 show that BiF_3 may sustain relatively high current densities. In this sense it is superior to Bi_2O_3 which could not be discharged without marked polarization at current densities over 1.0 mA/cm^2 (8). The shape of the curves is not the typical one, *i.e.*, a linear portion followed by a nonlinear drop. This would indicate that the reduction process is not single step, as is later confirmed by the analysis of the discharge curves.

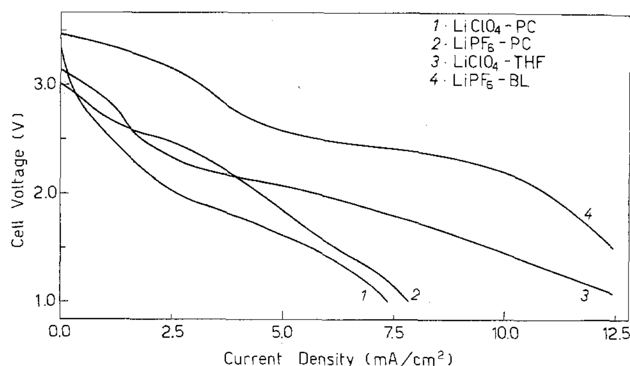

Fig. 1. Cell polarization curves in various electrolytes. Scanning rate. 1.2 mA/min.

Table II reports the effect of various electrolytes on the performance of the Li/BiF_3 cell. Four electrolytes, namely, $LiPF_6$-THF, $LiClO_4$-THF, $LiPF_6$-BL, and $LiClO_4$-PC, give satisfactory results both in terms of capacity and energy. However, the next screening test, *i.e.*, solubility, has allowed us to exclude the suitability of electrolytes containing F^- anions. Indeed, it was found that BiF_3 has no detectable solubility in $LiClO_4$-THF and $LiClO_4$-PC solutions, for the sensitive thiourea test did not show development of the typical yellow color. On the other hand, in $LiPF_6$-PC and in $LiAsF_6$-BL, the solubility of BiF_3 was $1.0 \cdot 10^{-3}$M and $2.2 \cdot 10^{-3}$M, respectively, due to the formation of soluble complexes of the BiF_4^- type. These values would not allow satisfactory shelf life. Therefore, the remainder of this investigation has been restricted to cells containing $LiClO_4$-PC or $LiClO_4$-THF.

The effect of the cathode formulation on cell performance is shown in Table III. Taking the specific energy as a reference parameter, cathodes containing polyethylene+graphite, Teflon+graphite, and more than 10% graphite are the most efficient ones. The specific capacities were only slightly affected by other formulations, but a decrease of potential was observed, this indicating *IR* losses (especially above 1.5V) due to unsatisfactory electronic conductivity. BiF_3, polyethylene+graphite hot pressed cathodes, and BiF_3+10% graphite cathodes were selected for further experiments on the effect of compacting pressure.

In Fig. 2 the variation of the specific capacity as a function of cathodic pressure is reported. In $LiClO_4$-THF solutions, BiF_3+C cathodes are almost insensitive to pressure variations in the range 2000-6000 kg/cm^2. On the other hand, in $LiClO_4$-PC solutions, the performances of BiF_3 cathodes, with or without polyethylene, are largely pressure dependent. These results confirm the importance of the cathode porosity (15) and also stress the interrelation between the porosity and the nature of the solution. This is hardly surprising

Table II. Effect of various electrolytes on the performances of of Li/BiF_3 cells. Current density, 0.5 mA/cm^2. 1.0V cutoff. Compacting pressure, 1500 kg/cm^2

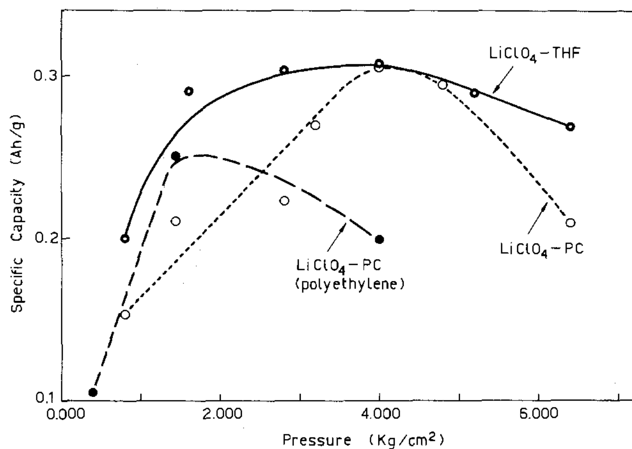

Fig. 2. Dependence of the specific capacity of BiF_3 cathodes on the compacting pressure. Current density, 1.0 mA/cm^2 in $LiClO_4$-THF and 0.5 mA/cm^2 in $LiClO_4$-PC. 1.0V cutoff.

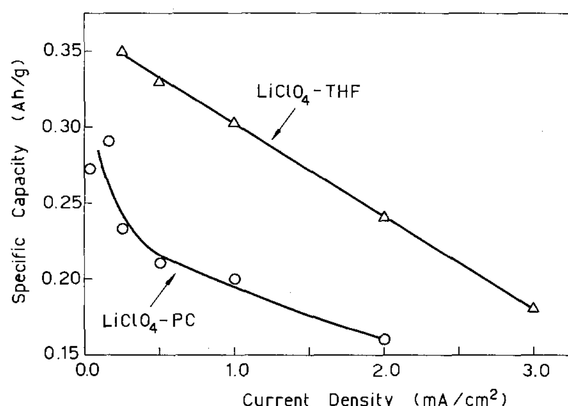

Fig. 3. Dependence of the specific capacity of BiF_3 cathodes on the discharge current density in $LiClO_4$-PC (compacting pressure, 1500 kg/cm^2) and in $LiClO_4$-THF (4000 kg/cm^2). 1.0V cutoff.

when considering that each cathode-electrolyte couple has its own interfacial structure.

Figure 3 shows the decrease of specific capacity as the current density is increased. As expected from the results of the polarization experiments, Li/BiF_3 cells containing $LiClO_4$ (1.3M)-THF solutions behave better in the current range examined. However, the gap between $LiClO_4$-PC and $LiClO_4$-THF is enhanced by the use of a more favorable compacting pressure for the cathodes used in the latter solution.

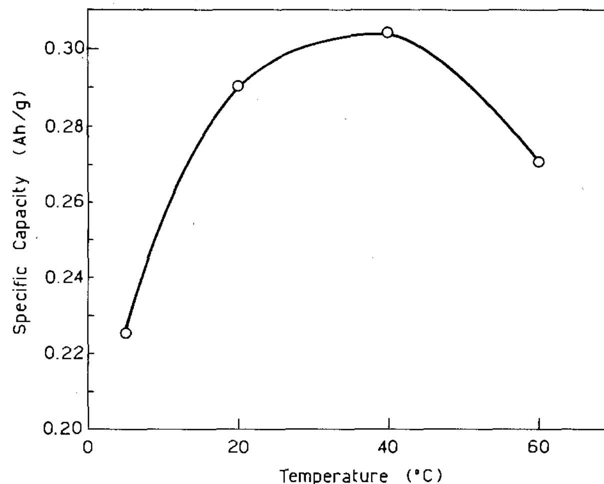

Fig. 4. Dependence of the specific capacity of BiF_3 cathodes on the temperature in $LiClO_4$-PC solutions. Current density, 0.5 mA/cm^2. 1.0V cutoff.

The behavior of Li/BiF_3 cells was also examined in the temperature range 20°-60°C (Fig. 4). Raising the temperature results in an increased capacity due to enhanced mass transfer. In particular, the theoretical value of specific capacity (0.302 A-hr/g) is reached at 40°C. The decrease observed above 40°C may be traced back to mechanical failure of the unoptimized positive electrode (BiF_3 + 10% graphite). Plastic-bonded electrodes should not present this shortcoming.

The effect of the volume of electrolyte was finally investigated in $LiClO_4$-PC solutions. As the electrolyte does not participate in the discharge process, the observed independence of the performances on the number of separator layers had to be expected.

Discussion

The reduction of Bi_2O_3 in organic solutions was found to be a two-step process giving rise to Bi and Li_3Bi, respectively (8). The reduction of BiF_3 leads to the same products. X-ray analysis on BiF_3 cathodes discharged down to 0.9V (Table IV) shows the formation of Bi and LiF through the over-all reaction

$$BiF_3 + 3Li \rightarrow 3LiF + Bi \quad \Delta G = -216 \text{ kcal/mole} \quad [1]$$

In the discharge curves of Fig. 5, an abrupt change in slope occurs around 1.0V, where the formation of Bi is supposed to end. A cell based on reaction [1] has the following characteristic values: E_o, 3.13V; specific

capacity (referred to BiF_3 only), 0.302 A-hr/g; specific energy (referred to Li + BiF_3), 0.876 W-hr/g.

If reaction [1] gave rise directly to LiF and Bi, these compounds would be in equilibrium with BiF_3, so that an OCV near 3.13V and independent of the state of discharge could be measured. Figure 6 shows that this is not the case for the present system, where the OCV's decrease as a function of discharge, finally reaching values far below 3.13V. X-ray analysis, done on a cathode discharged to 1.7V *vs.* Li/Li^+, confirms these results, showing that BiF_3 only is present as a crystalline phase. This may point to the formation of ternary phase (16) which, for BiF_3, may be written as Li_xBiF_3, where $0 < x < 3$. The final phase Li_3BiF_3 would decompose into Bi and LiF.

The crystalline structure of BiF_3 is not being retained during discharge (see Table IV). According to Whittingham (16), this would exclude reversibility of reaction [1], as was indeed ascertained by cyclic voltammetry experiments.

The shape of the discharge curves in THF-containing solutions is different from that of the curves obtained with all other electrolytes. Indeed, three distinct plateaus are visible in the range 2.5-0.9V, this being independent of the salt used.

The theoretical value of specific capacity is frequently reached in $LiClO_4$-THF solutions. As for $LiClO_4$-PC, the value is approached to optimum conditions, *i.e.*, low current density and medium-low cathode porosity. When working at current densities below 1.0 mA/cm^2 with BiF_3 cathodes pressed at 4000 kg/cm^2 in $LiClO_4$-THF, the theoretical capacity is somewhat exceeded (Fig. 3). The hypothesis of solvent decomposition at the cathode, sometimes observed for low potential values (17, 18), was made and checked by discharges and cyclic voltammetry experiments with graphite cathodes. The discharge curves have shown that above 1.0V decomposition of PC and THF on graphite is of relative importance. This was confirmed by cyclic voltammetry showing the typical spiked trend of solvent reduction only at high scan rates and below 1.0V *vs.* Li/Li^+. The explanation of this apparent discrepancy may reside in the consideration that the positive material formed by slow discharge is neither pure graphite nor the almost pure BiF_3 used in cyclic voltammetry. On the multicomponent cathode material, solvent decomposition may somehow be catalyzed above 1.0V.

The final part of the discharge curves of Fig. 7 is due to the reduction of Bi, according to the reaction

$$Bi + 3Li \rightleftharpoons Li_3Bi \quad \Delta G = -56 \text{ kcal/mole} \qquad [2]$$

This reaction was observed with Bi_2O_3, too, (8) and studied by Besenhard and Fritz (19), who were able to show its reversibility in the cell $Li/LiClO_4$-PC/Bi. Its features are the following: E_o, 0.81V; specific capacity (Bi only), 0.385 A-hr/g; specific energy (Li + Bi), 0.283 W-hr/g. Due to the potential of the Li/Bi couple, some solvent decomposition may also occur. However, we obtained evidence that the plateau below 1.0V in the discharge curve is mainly attributable to reaction [2]. In a first experiment, we discharged $Li/LiClO_4$-THF/Bi cells with and without graphite at the cathode, obtaining the same trend and nearly the same capacity. Cyclic voltammetry on a BiF_3+C electrode in $LiClO_4$-PC (Fig. 7) confirms the reduction of Bi. The peak starting at about 1.0V *vs.* Li/Li^+, to which an anodic peak at about 1.2V *vs.* Li/Li^+ corresponds, is equal to that observed during cyclic voltammetry experiments on a $Li/LiClO_4$-PC/Bi cell. Also with Bi cathode, an anodic peak at *ca.* 1.2V *vs.* Li/Li^+ was observed, thus confirming the results of Besenhard and Fritz (19).

The peak occurring at *ca.* 1.8V *vs.* Li/Li^+ corresponds to the reduction of Bi^{+3} to Bi. In $LiClO_4$-THF solutions, this peak tends to split, thus confirming the trend of the discharge curves.

Obviously, for practical cells only reaction [1] is important. We attempted to see which values of specific capacities and energies (based on the weight of anode, cathode, separators, and solution) could be attained at the end of this reaction. A $Li/LiClO_4$-PC/BiF_3, C cell partially optimized gave 100 A-hr/kg and 200 W-hr/kg at 0.5 mA/cm^2 (1.0V cutoff). These values are expected to increase through a more substantial optimization of the cathode, as may be inferred by Marincic's studies (15). Also the volumetric energies should have interesting values in view of the high density of BiF_3 [8.6 g/cm^3 (20)].

Conclusion

The investigation on BiF_3 as a cathode for lithium cells confirms that some Bi salts may be of interest in this field. BiF_3 has the same advantages shown by other fluorides with respect to the corresponding oxides, *i.e.*, higher voltages and lower polarization losses. Unlike the fluorides investigated heretofore, namely, CuF_2, AgF_2, and NiF_2, BiF_3 does not show an appreciable solubility in $LiClO_4$-containing electrolytes, thus allowing the prediction of a long shelf life for Li/BiF_3 cells. Lack of any interaction with the electrolytes substantiates this prevision.

The major disadvantage connected with the use of BiF_3 resides in its poor voltage regulation, which makes it unsuitable for powering watches or cardiac

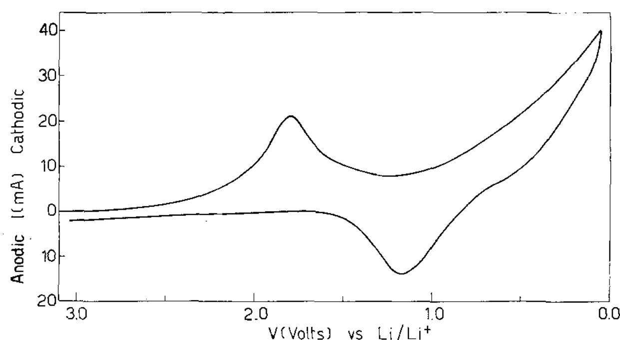

Fig. 7. Cyclic voltammetry of a BiF_3 electrode (with 2% graphite) in $LiClO_4$-PC. Sweep rate, 20 mV/sec.

pacemakers. On the other hand, in terms of energy density, rate capability, safety, and economy, this material seems to merit some attention for possible use in variable-resistance devices.

Analysis of Electrolyte Shunt Currents in Fuel Cell Power Plants

Murray Katz*

United Technologies Corporation, Power Systems Division, South Windsor, Connecticut 06074

ABSTRACT

A general mathematical model is presented for calculating the shunt currents and effective operating potentials of the materials in multicell stacks which have electrolyte interconnections between the individual fuel cells. The analysis takes into account the electrochemical polarizations that occur at the positive and negative ends of each shunt path. Numerical results are presented for an acid electrolyte fuel cell stack design.

Various types of fuel cell power plants use electrolyte or coolant paths interconnected to the individual cells of stacks. Electrolyte circulation is required in some types of fuel cells to distribute dissolved reactants or redox species or to remove reaction products and contaminants. In other fuel cell designs, the interconnected electrolyte is not a necessity, but is a design choice to perform such functions as heat removal, water removal, or to provide tolerance to electrolyte volume changes.

Proper design of these systems requires estimation of the magnitude of the inevitable nonuseful shunt currents through the various liquid paths. In addition, identification of the appropriate electrochemical reactions and effective corrosion potentials of the materials is required at the critical points of the shunt current circuits. This information is needed to assess the magnitude of the power loss, additional reactant consumption, material corrosion, and gas evolution rates, and to conduct tradeoff studies with other design requirements such as pumping power and uniformity of the distribution of fluids.

Previous analysis of such systems [Ref. (1-3)] considered only resistive effects and did not take into account the oxidation-reduction polarization processes that must occur at the positive and negative ends of each shunt path. Although useful for initial estimates of the shunt currents, the models in Ref. (1-3) could not be used to calculate the effective operating potentials of the wall materials since the polarization processes also affect the magnitude of the shunt currents. The purpose of this study was to extend the general mathematical model to include these polarization processes and to develop a general computer program for design purposes. A description of the model and its application to an acid fuel cell stack design is presented.

Theory

A fuel cell stack with interconnected anolyte is shown schematically in Fig. 1 at "open circuit" with respect to its useful load. However, the presence of the high potential across the common electrolyte path results in a set of ionic short circuits which are nonuseful electrical loads on the stack. The ionic current through each fluid port, hereafter called the "shunt current," is the direct result of an electrochemical charge transfer process for which the electrical energy is provided by the fuel cells. The shunt currents through the electrolyte cause a short or current drain on each cell in the stack since all the cells are elec-

* Electrochemical Society Active Member.

Key words: module design, fuel cell assembly, parasitic currents, manifold models, electrical analog.

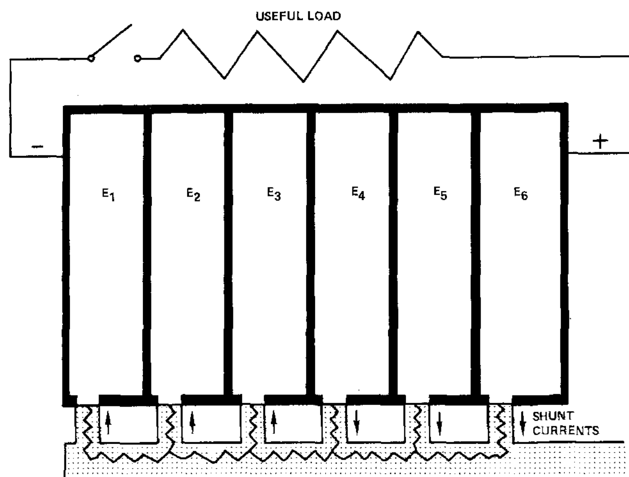

Fig. 1. Shunt paths through interconnected electrolyte

trically connected. The magnitude of the nonuseful current through each of the electrically connected cells is hereafter called the "current drain." The current drain on each cell is a measure of the nonuseful electrical load or additional reactant consumption imposed on each cell as a direct result of the ionic shunt currents through the fluid ports. The current drain on each cell varies with the cell position in the stack, and is a function of the cell voltage, the conductivity of the electrolyte, the ionic resistance of the ports and manifold, and the magnitude of the polarizations of the electrochemical processes involved at the positive and negative ends of each shunt current path. Each shunt current is somewhat dependent on the shunt currents emanating from adjacent cells since the effective ionic resistance of the manifold path is shared.

An electrical analog of the various electronic and ionic paths is shown in Fig. 2 to model the potential distribution of this system. Each cell is schematically represented as a battery with a terminal voltage E and a linear polarization characteristic denoted by a resistance R_c. This should be a good representation of the fuel cell performance with a small current drain. The external load is assumed to be disconnected. The ionic path resistances in the anolyte system are represented by R_p for the fluid distribution ports and R_m for the manifold. It is assumed that the surfaces of the manifold and ports are nonconducting. The conducting surfaces on which the ionic shunt currents exit or enter the cell are schematically represented by an imaginary Zener diode with a polarization characteristic $\phi(I)$ which is different in the forward and backward current direction. The diode simulates the different polarizations for the anodic reactions at the positive end of the cell stack and the cathodic polarizations at the negative end of the cell stack. For example, the polarization characteristic $\phi(I)$ for the decomposition of water is shown in Fig. 3. This fulfills the requirement of essentially zero current flow until the Nernst potential ϕ_o is exceeded (*e.g.*, 1.23V for water electrolysis).

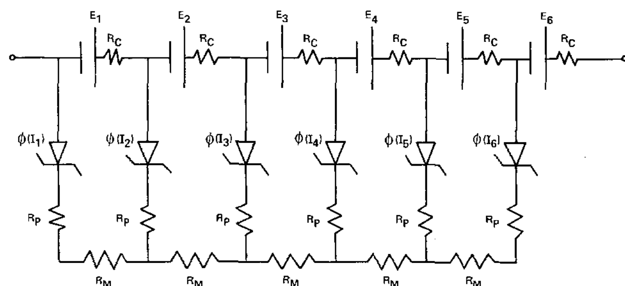

Fig. 2. Electrical analog of fuel cell stack

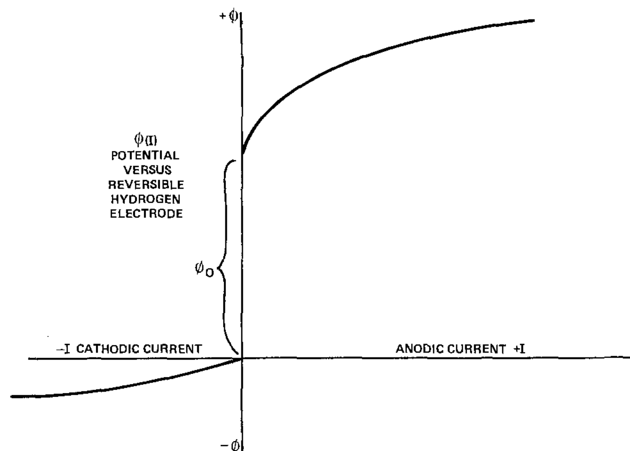

Fig. 3. Polarization function for decomposition of water

The mathematical solution of the individual shunt currents, I_j, depends on specifying the information for the polarization characteristic $\phi(I)$. This requires identification of the possible reactions at the reaction sites and prior experimental data or theoretical estimation of the polarization for the particular design being studied.

Typical anodic reactions at the positive end of the cell assembly are:

(*i*) Material corrosion
$M \rightarrow M^+ + e$
$C + 2H_2O \rightarrow CO_2 + 4H^+ + 4e$

(*ii*) Electrolysis of H_2O to O_2
$H_2O \rightarrow \frac{1}{2} O_2 + 2H^+ + 2e$

(*iii*) Oxidation of fuel
$H_2 \rightarrow 2H^+ + 2e$

(*iv*) Oxidation of ionic species
$M^z \rightarrow M^{z+n} + ne$

(*v*) Combinations of the above.

Some of the possible cathodic electrochemical reactions at the negative end of the cell assembly are:

(*i*) Electrolysis of H_2O to H_2
$2H^+ + 2e \rightarrow H_2$

(*ii*) Metal deposition
$M^+ + e \rightarrow M$

(*iii*) Reduction of O_2 (air)
$\frac{1}{2} O_2 + 2H^+ + 2e \rightarrow H_2O$

(*iv*) Reduction of ionic species
$M^{z+n} + ne \rightarrow M^z$

(*v*) Combinations of the above.

As an example of the application of this approach to an engineering design, let us consider the probable reactions and polarizations we might expect in a multicell assembly of acid electrolyte cells using carbon as a structural material and with an interconnected anolyte. A design of this type was considered for development by United Technologies Corporation early in the TARGET program but was dropped in favor of designs which preclude shunt currents. The polarization characteristic of a carbon surface exposed to a hydrogen-saturated anolyte, Fig. 4, shows schematically that three anodic electrochemical reactions occur as the potential difference between the carbon surface and the electrolyte varies from 0.0 to 2.0V. A small current due to hydrogen oxidation is possible in the potential range from 0 to 1.0V (*vs.* a reversible hydrogen electrode) because carbon is a poor hydrogen oxidation catalyst. Between 1.0 and 1.4V, a larger anodic current

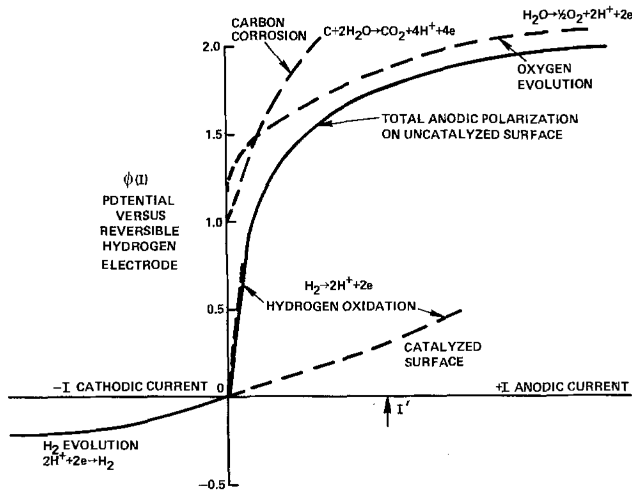

Fig. 4. Typical electrochemical reactions on a carbon surface with hydrogen present.

is possible from carbon oxidation whereas above 1.4V most of the current is due to oxygen evolution even though the carbon oxidation current continues to increase. Alternatively, if the carbon surface is catalyzed with platinum, the anodic current will be much higher at low potential since platinum is an excellent hydrogen oxidation catalyst.

Thus, it can be seen that the likelihood of carbon oxidation at the positive end of the stack assembly is dependent on the magnitude of the anodic shunt current and the nature of the surface. For example, a shunt current of magnitude I' will result in oxidation of uncatalyzed carbon surfaces, but no oxidation should occur with catalyzed carbon surfaces since the rate of hydrogen oxidation is sufficient to maintain the carbon in a safe potential region.

The likely cathodic electrochemical reaction associated with the shunt currents in the cells at the low potential end of the cell assembly is hydrogen evolution since no oxygen or air is present in the anolyte. Large cathodic currents are shown in Fig. 4 since carbon is a fairly good catalyst for hydrogen evolution. No carbon oxidation is expected at the negative ends of the shunt current circuits.

Mathematical Analysis

Application of Ohm's and Kirchoff's laws to the electrical network of an assembly of N fuels cells shown in Fig. 2 will yield N simultaneous equations with N unknown shunt currents. Consider the simple case of a four-cell stack shown in Fig. 5 where the ionic shunt currents $I_1, I_2, \ldots, I_N$ are defined as positive although it is quite evident that most of the shunt currents at the negative end will be in the reverse direction.

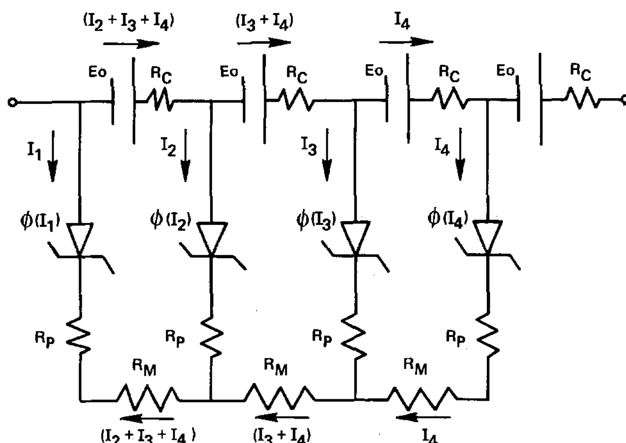

Fig. 5. Electrical analog of four-cell stack

Application of Kirchoff's law yields the first equation for $N = 4$

$$\sum_{j=1}^{j=4} I_j = 0 = I_1 + I_2 + I_3 + I_4$$

Three more equations may be written by applying Ohm's law to each loop starting at the zero voltage end of the network each time. For a four-cell stack, these equations are

$$E_o - \phi(I_2) + \phi(I_1) = -I_1R_p + I_2(R_p + R_c + R_m) + I_3(R_c + R_m) + I_4(R_c + R_m)$$

$$2E_o - \phi(I_3) + \phi(I_1) = -I_1R_p + I_2(R_c + R_m) + I_3(R_p + 2R_c + R_m) + I_4(2R_c + 2R_m)$$

$$3E_o - \phi(I_4) + \phi(I_1) = -I_1R_p + I_2(R_c + R_m) + I_3(2R_c + 2R_m) + I_4(R_p + 3R_c + 2R_m)$$

In order to use standard matrix techniques for solving N simultaneous equations, it is desirable to keep the equations linear. Thus, the polarization function $\phi(I)$, which is typically nonlinear, can be approximated by a series of straight lines.

$$\phi(I_j) = a_j + b_jI_j$$

where a_j and b_j represent the intercept and slope of the linear section containing I_j. Substituting the linear expression for the polarization and letting $R_m + R_c = R_{mc}$ produces the following set of four simultaneous equations for the four-cell stack of fuel cells

$$0 = I_1 + I_2 + I_3 + I_4$$

$$[1E_o - a_2 + a_1] = -I_1(R_p + b_1) + I_2(R_p + R_{mc} + b_2) + I_3R_{mc} + I_4(R_{mc})$$

$$[2E_o - a_3 + a_1] = -I_1(R_p + b_1) + I_2(R_{mc}) + I_3(R_p + 2R_{mc} + b_3) + I_4(2R_{mc})$$

$$[3E_o - a_4 + a_1] = -I_1(R_p + b_1) + I_2(R_{mc}) + I_3(2R_{mc}) + I_4(R_p + 3R_{mc} + b_4)$$

The general solution for N cells with $j = 1,2,\ldots,N$ shunt currents I_j can be written in terms of $i = 1,2,\ldots,N$ linear algebraic equations of the general form.

Equation $i = 1$

$$\sum_{j=1}^{j=N} I_j = 0$$

Equations $i = 2 \ldots\ldots N$

$$[(i-1)E_o - a_i + a_1] = [-(R_p + b_1)]I_1 + [R_p + (i-1)R_{mc} + b_i]I_i + \sum_{\substack{j=2 \\ i>2}}^{j=i-1} [(j-1)R_{mc}]I_j + \sum_{j=i+1}^{j=N} [(i-1)R_{mc}]I_j$$

A computer program was developed to solve for the unknown shunt current I_j in the above set of N simultaneous linear equations. The computer program employs a general usage computer subprogram which uses the Gauss-Jordan reduction scheme with the maximum pivot criterion to solve the equations. The computer program internally computes the matrix coefficients from the above general equations, thus requiring only E_o, N, R_m, R_c, and R_p and $\phi(I)$ as input items. The anodic and cathodic polarization data are input as a table and the slope and intercepts are

automatically calculated assuming a straight line between each pair of data points.

An iteration procedure is required in the computer solution because the polarization $\phi(I)$ is not known *a priori*. The calculation is initiated by computing the shunt currents with zero polarization by setting the polarization function constants a and b equal to zero. This establishes a first guess for the polarization function constants a and b to be used for each shunt current. A new array of coefficients is calculated and the shunt currents are recalculated until all the polarization constants remain unchanged from the last calculated value of the shunt currents. When the iteration is concluded, the polarization and shunt current at each cell are printed out.

The current drain in each fuel cell can be seen by inspection of Fig. 5 to be equal to the ionic current in the electrolyte manifold of the same cell. The current drain $(I_D)_n$ of the nth cell in a stack with N cells can be calculated from the shunt currents I_j from the following expression which holds for all cells except the (N)th or end cell which has no current drain

$$(I_D)_n = \sum_{j=n+1}^{j=N} I_j \text{ or } = \sum_{j=1}^{j=n} I_j$$

The average current drain per cell in a stack of N cells may be expressed as

$$\overline{I}_D = \sum_{n=1}^{n=N-1} (I_D)_n/N$$

The quantity $\overline{I}_D$, by Faraday's law, is proportional to the average quantity of reactants consumed by the fuel cells as a result of the shunt currents. The average power loss per cell, P_D, is then

$$\overline{P}_D = E_o \cdot \overline{I}_D - \overline{I}_D{}^2 R_c$$

The mathematical model can be used with or without the external load connected. When the external load is connected the appropriate values of cell voltage E and the effective over-all cell resistance R_c are required from the fuel cell performance curve. The model can also be applied to an interconnected catholyte system simply by reversing the sign of the fuel cell potential.

Application of the Mathematical Model

The mathematical model was used to predict the shunt currents and effective wall potentials of the carbon structural materials in an experimental 50 cell assembly of phosphoric acid cells with interconnected anolyte reservoirs which was being considered for development as a power plant component. The anode compartment side of the carbon plate which separates the cells of this stack is shown in Fig. 6. The electrolyte reservoir was located in the bottom section of the anode compartment of each cell in the space between the bottom ribs of the carbon plates and an uncatalyzed extension of the hydrogen electrode. The manifold and branch feed ports were designed to provide a high ionic resistance path and were coated with an electrically nonconducting resin to prevent electrochemical reaction. The electrolyte in each cell was connected through the manifold to a reservoir external to this stack. A mathematical analysis of this configuration was conducted to determine the current drain on the stack and to estimate the probability of carbon oxidation.

The contact bars in the pool region offer significant resistance to ion flow and this resistance is in series with the port resistance. It was assumed that the shunt currents originate primarily from the reservoir region near the feed port. An average ionic path length on each side of the port was estimated and this ionic

Fig. 6. Anode side of fuel cell separator plate

resistance, called the field resistance, was added to the actual port resistance to obtain the effective port resistance R_p. The following resistances were calculated for this design using a resistivity of 2.22 Ω-cm for 96% H_3PO_4 at 135° C: manifold resistance $R_m = 21.3\Omega$; port resistance, 113Ω; field resistance, 61Ω; effective port resistance, $R_p = 113 + 61 = 174\Omega$.

The effective cell resistance is obtained from the slope of the voltage-current characteristic which is typically nonlinear for hydrogen-air fuel cells. The effective cell resistance for this design varies from 0.002 to 0.02Ω depending on the external load and was considered to be negligible compared to the manifold and port resistances.

The polarization data for input to the computer program was obtained experimentally. A representative section of the hydrogen electrode was tested in a half-cell apparatus containing a hydrogen reference electrode. A strip ½ in. wide was immersed ½ in. into phosphoric acid electrolyte with hydrogen above the electrolyte to simulate the hydrogen saturated reservoir. Since the active width in the cell design being studied was ten times greater than the test sample, the current obtained at any given polarization was appropriately scaled.

The experimental anodic and cathodic polarization data used in the computer analysis are presented in Fig. 7. The anodic current data for the uncatalyzed carbon electrode show virtually no hydrogen oxidation in the potential range from zero to 1.0V, but carbon oxidation and oxygen evolution proceed rapidly at high overvoltage. A carbon strip catalyzed with trace quantities of platinum was also tested to compare with the uncatalyzed strip. The anodic current data shown in Fig. 7 for the catalyzed strip indicates significant hydrogen oxidation compared to the uncatalyzed carbon strip. The cathodic polarization data indicates that the rate of hydrogen evolution is much faster than the rate of hydrogen oxidation on carbon.

The polarization data shown in Fig. 7 and the calculated resistances presented above were used as input in the computer program. The calculated results of the current drain in each cell, ionic shunt currents

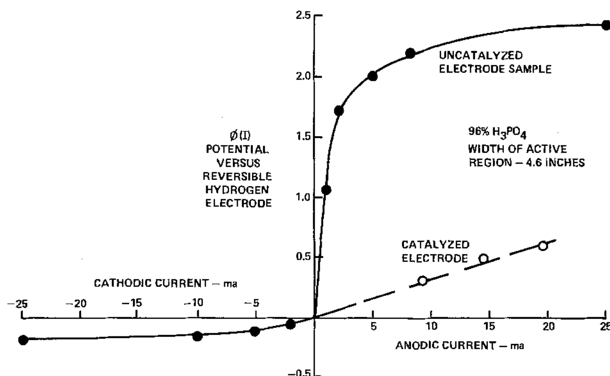

Fig. 7. Polarization data on carbon electrode in phosphoric acid

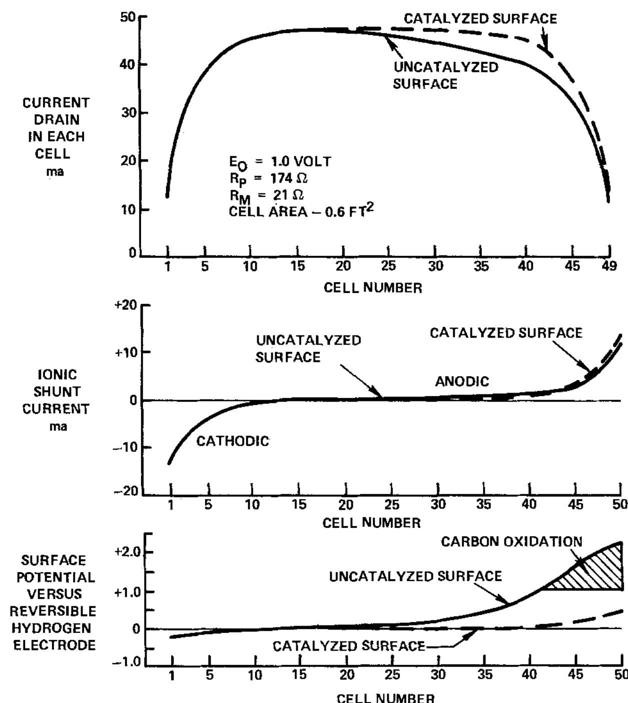

Fig. 8. Calculated results for a 50 cell stack

through the liquid ports, and the effective material potential as a function of cell position are shown in Fig. 8 for the 50 cell assembly of phosphoric acid cells. The calculated results are presented for the cases of uncatalyzed carbon and catalyzed carbon surfaces in the reservoir region to demonstrate the effect of the nature of the surface material on the polarization processes.

The calculated results indicate that the largest shunt currents occur through the electrolyte in the ports at the ends of the stack while the largest current drain occurs in the center cells of the stack. Thus, the rates of electrochemical reactions ocurring in the pool region are highest in the end cells whereas the reactant consumption is highest in the center cells of the stack. The shunt currents from the cells in the center portion of the stack are practically zero because of the balanced or low potential gradients between the surface and the electrolyte.

The calculated magnitude of the current drain on the 50 cell stack is very small and represents a negligible loss of power. For example, the maximum current drain which occurs on the center cell was calculated to be only 47 mA, which represents a current density of only 0.078 A/ft^2 based on the cell area of 0.6 ft^2. This value is calculated when the stack is at open external circuit and the cell voltage is the highest; approximately 1.0V per cell. When the external load is applied, the stack voltage is lower and the current drain will be proportionately lower.

The calculations predict that carbon oxidation should occur on the uncatalyzed carbon surfaces in the pool region of cells 41-50 since the effective surface potential in these cells falls in the range of 1.0-2.2 V *vs.* a reversible hydrogen electrode. The calculated results of the surface potential for catalyzed surfaces indicate that no carbon oxidation should occur since the rate of hydrogen oxidation is sufficient to maintain the carbon in a safe potential region. At the negative end of the stack hydrogen evolution is predicted in cells 1-10. A dielectric coating is required in the port and manifold region to prevent electrochemical reactions. It was calculated that a potential difference as high as 4.7V can exist across the coating in the manifold region of the cells at the positive end of the stack. Any slight dielectric breakdown of the coating in the most positive end cells is likely to result in simultaneous material oxidation and oxygen evolution which would further destroy the coating. Since any corrosion of structural components is inconsistent with the long life requirement for commercial fuel cell power plants, the interconnected anolyte design has not been considered for commercial development.

The mathematical model described above may be applied to many types of fuel cell power plants. Some examples are (*i*) circulating base electrolyte fuel cells (*ii*) circulating hydrazine or peroxide fuel cells, and (*iii*) circulating redox energy storage systems. In each case, the impact of the electrochemical processes occurring on the materials of construction at the critical points of the shunt current circuits can be evaluated with this mathematical model. In addition, the magnitude of the power loss due to the shunt currents through the electrolyte can be calculated for a specific design.

Conclusions

A general mathematical model has been developed for calculating the electrolyte shunt currents and effective operating potentials of the materials in multicell assemblies with interconnected electrolyte. The analysis takes into account the electrochemical polarizations at the positive and negative ends of each shunt current path. By linearizing the polarization function, the mathematical model is reduced to the solution of N simultaneous linear equations for an assembly of N cells.

In the application of this model to an aqueous acid electrolyte fuel cell power plant, some general observations can be made. The maximum electrolyte shunt currents usually occur in the end cells of the stack where the greatest potential gradient exists. This results in a current drain in all the cells, with the largest current drain occurring in the center cells of the stack. Material corrosion and oxygen evolution processes are likely to occur in the cells at the positive end of the stack unless another oxidation process is available to maintain the materials at a low potential level. Hydrogen evolution is the likely electrochemical process at the critical points of the shunt currents in the end cells at the negative end of the stack in the absence of other reducing agents. By proper design of the ionic resistance of the manifold and feed ports, the power loss due to electrolyte shunt currents can be maintained at very low levels.

Measurement of Battery Separator Resistances in Low Impedance Conductivity Cells by A-C Bridge Techniques

W. P. Kilroy* and C. T. Moynihan

Naval Surface Weapons Center, Electrochemistry Branch, White Oak, Silver Spring, Maryland 20910

ABSTRACT

Measurement of the resistance of battery separator membranes is frequently accomplished by taking the difference between the resistances of an electrolyte-filled conductivity cell with and without the separator inserted between the electrodes. For low resistance separators this may involve measurements of impedances of a few tenths of an ohm. It is shown via equivalent circuit analysis and experimental data on a low impedance cell filled with 45% aqueous KOH solution that a-c bridge measurements of separator resistances can be seriously in error if proper account is not taken of electrode impedance.

Efforts to improve battery performance are often centered on the development of a stable separator which contributes relatively little to the internal resistance. An approximate measure of the contribution of a separator material to the battery internal resistance is typically made (1) first by determining the resistance of the electrolyte solution, R_{sol}, between two plane parallel electrodes in a conductivity cell. After this the separator is inserted between the two electrodes and a new resistance, a combination of R_{sol} and the separator resistance, is measured. The contribution of the separator, R_{sep}, to the net resistance of the cell is then the difference between the two measurements. Plainly an accurate measurement of R_{sep} requires that R_{sep} contribute an accurately measurable increment to the sum of the resistances.

A case in point for the present paper is a separator for silver-zinc batteries using 30-45% KOH solution as electrolyte in which a good separator material may contribute as little as 0.01 Ω/in.^{2} to the internal resistance. An accurate measurement of R_{sep} thus requires that R_{sol} be of the order of 0.1 Ω/in.^{2} or smaller.

The usual method of carrying out resistance measurements of this type is by means of a conventional a-c Wheatstone bridge at audio frequencies. The cell impedance is balanced against a parallel resistance-capacitance combination (R_p, C_p). The balancing resistance R_p is usually identified with the cell resistance, R_{sol} or ($R_{sep} + R_{sol}$). As has been pointed out in the literature (2), the equivalent a-c circuit of the cell is not a parallel resistance-capacitance combination. This in turn can lead to large errors in the measurement of R_{sol} and ($R_{sep} + R_{sol}$), as shown below.

The simplest approximations (2) to the true equivalent circuits of a low impedance conductivity cell containing an electrolyte and an electrolyte plus separator are the series circuits shown, respectively, in Fig. 1a and 1b. R_L is the resistance of the leads between the bridge and conductivity cell, and C_{dl} represents the capacitance due to interfacial effects at the electrode surfaces (frequently referred to as "double layer capacitance").

If the circuit of Fig. 1a were measured on an a-c bridge, the equivalent parallel resistance would be (2)

$$R_p^{(a)} = \frac{1}{Re(1/Z^{(a)})} = \frac{(R_L + R_{sol})^2 + (1/\omega C_{dl})^2}{R_L + R_{sol}} \quad [1]$$

where $Re(1/Z^{(a)})$ is the real part of the complex impedance of circuit 1a. In the usual procedure for determination of the separator resistance using a conventional a-c bridge, the apparent resistance would be taken to be

$$R_{sep,\,app} = \frac{1}{Re(1/Z^{(b)})} - \frac{1}{Re(1/Z^{(a)})}$$

$$= R_{sep}\left[1 - \frac{1}{(R_L + R_{sol} + R_{sep})(R_L + R_{sol})(\omega C_{dl})^2}\right] \quad [2]$$

Equations [1] and [2] show that $R_p^{(a)} = R_L + R_{sol}$ and $R_{sep,\,app} = R_{sep}$ only in the limit of large values of ωC_{dl}. That is, neglect of a proper treatment of electrode impedances can lead to errors not only in the total resistance of the cell, but also to errors, in R_{sep} obtained

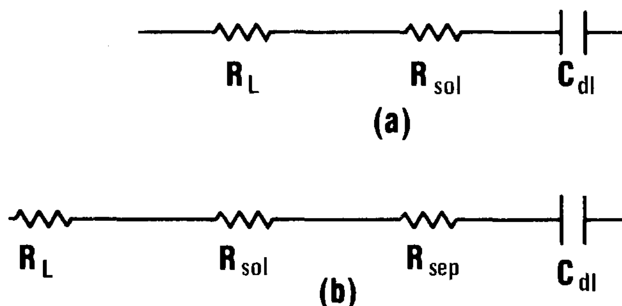

Fig. 1. Approximate equivalent circuits of a conductivity cell containing (a) electrolyte solution; (b) electrolyte solution plus separator.

* Electrochemical Society Active Member.

Key words: capacitance, resistivity, battery separator.

by difference. However, a correct determination of $(R_L + R_{sol})$ should guarantee a correct determination of R_{sep}. Consequently, in the present study we have carried out a series of resistance and capacitance measurements at various frequencies in order to determine what errors, if any, may arise in determinations of separator resistances for cells with 45% KOH electrolyte.

Experimental Section

The conductivity cell obtained from RAI Research Corporation consisted of two heavy gauge plane parallel square Pt electrodes, 2.54 cm on a side and 0.25 cm apart mounted in a Lucite holder. The cell also contained a provision for inserting film between the two electrodes. This feature was not used in the present study.

In order to assess the effect of electrode double layer capacitance, measurements were carried out for two electrode conditions; polished unplatinized platinum and heavily platinized electrodes.

The assembled cell was filled with Fisher Scientific 45 weight percent (w/o) aqueous KOH solution and allowed to stand overnight, refilled with fresh solution and the equivalent parallel resistance and capacitance, R_p and C_p, and measured at 25.0° ± 0.1°C over the frequency range 50-5000 Hz. Resistance measurements (accuracy 1%) were made using a General Radio 1650B impedance bridge with an external capacitance balancing decade box adjustable in steps of 10^{-4} μF and an external Hewlett Packard 200 CD audio oscillator.

A similar set of measurements of R_p and C_p were made at 25°C with the conductivity cell with platinized electrodes filled with 0.01M KCl aqueous solution in order to obtain the calibration constant for the cell. To obtain the resistance of the leads to the cell, R_L, the cell was filled with mercury to short circuit the two electrodes and the resistance measured; this gave a value of $R_L = 0.173\Omega$.

A calibrated capillary conductivity cell with platinized platinum electrodes was used to measure the conductivity of the 45% KOH solution. The equivalent parallel resistance of this cell filled with the KOH solution was 47.9Ω at 25.0°C and 1 kHz.

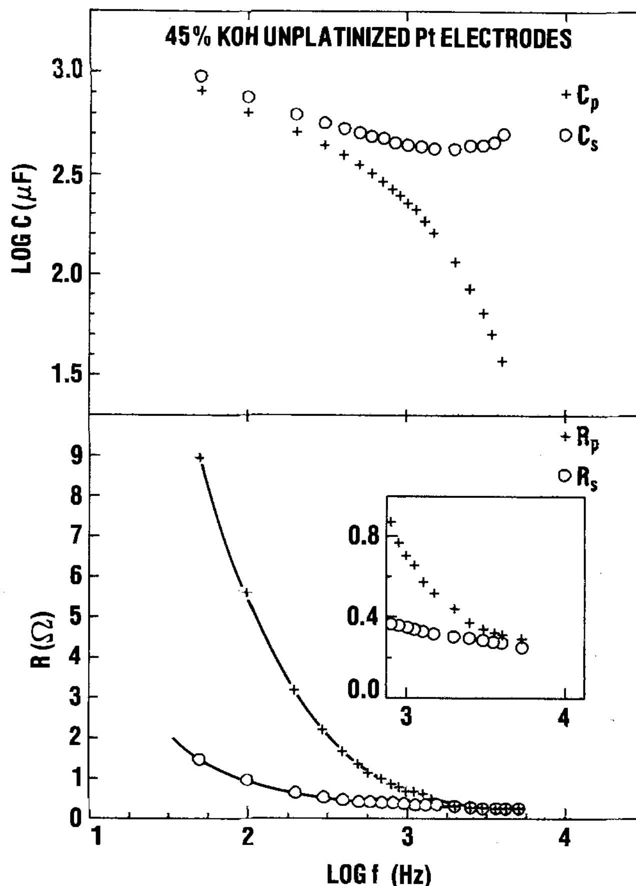

Fig. 2. Equivalent parallel and series resistances and capacitances vs. frequency of a conductivity cell filled with 45% KOH solution at 25.0°C using unplatinized Pt electrodes. Insert is an enlarged plot of the resistance data at high frequency.

Results and Discussion

The resistance, R_p, of the cell filled with 0.01M KCl solution was 27.5 ± 0.1Ω and independent of frequency over the entire frequency range. This indicates (*cf.* Eq. [1]) that contributions to R_p from frequency-dependent electrode impedance terms such as $(1/\omega C_{dl})$ are negligible, so that $(R_L + R_{sol})$ may be taken as the measured R_p value. Subtracting the measured value of R_L from this gives $R_{sol} = 27.3\Omega$. The cell constant, (L/A), obtained using the conductivity of 0.01M KCl solution (3), is 0.0386 cm^{-1}, which is in good agreement with the less precise (L/A) value of 0.039 cm^{-1} calculated from the electrode geometry.

$$R_s = R_L + R_{sol} + \frac{\{[R_F + R_W(\omega)]^2 + [1/\omega C_W(\omega)]^2\}[R_F + R_W(\omega)]}{[R_F + R_W(\omega)]^2 + \{\omega C_{dl}[(R_F + R_W(\omega))^2 + [1/\omega C_W(\omega)]^2] + (1/\omega C_W(\omega))\}^2} \quad [3]$$

Similarly the resistance R of the 45% KOH solution in the capillary conductivity cell is sufficiently large that it may be used directly to calculate the conductivity, 0.465 Ω^{-1} cm^{-1}, of the 45% KOH solution at 25°C.

In Fig. 2 and 3 the bridge measurements of R_p and C_p, respectively, are plotted *vs.* frequency for the 45% KOH solution in the conductivity cell with unplatinized and platinized electrodes. Also plotted are the equivalent series resistance R_s and capacitance C_s calculated from the complex admittance (2).

If the circuit of Fig. 1a were an accurate representation of the cell equivalent circuit, R_s and C_s would be frequency independent and equal, respectively, to $(R_L + R_{sol})$ and C_{dl}. R_s and C_s are frequency dependent, but are less so than R_p and C_p, so that the equivalent circuit of Fig. 1a is clearly a better approximation to the cell circuit than a parallel R_p, C_p combination.

A more realistic representation (2, 4, 5) of the equivalent cell circuit is shown in Fig. 4. $R_W(\omega) + C_W(\omega)$ are the resistive and capacitive components of the Warburg impedance, and R_F is the Faradaic impedance. In Fig. 4 we have neglected capacitance between the conductivity cell leads and the capacitance due to the dielectric constant of the electrolyte, since these contribute a negligible amount to the audio frequency impedance of the low impedance cell under consideration (2).

Equivalent circuit analysis of Fig. 4 gives for the equivalent series resistance [3].

Both $R_W(\omega)$ and $(1/\omega C_W(\omega))$ are frequency dependent with an $\omega^{-1/2}$ dependence (4), so that the high frequency limit of R_s is

$$\lim_{\omega \to \infty} R_s = R_L + R_{sol} \quad [4]$$

Equivalent circuit analysis of Fig. 4 shows that R_p approaches an identical high frequency limit, but at a slower rate (compare Eq. [1]).

The data of Fig. 2 and 3 exhibit this predicted behavior, that is: (*i*) both R_s and R_p approach the same limiting value at high frequencies, R_s more quickly than R_p; and (*ii*) the resistance values for both platinized and unplatinized electrodes approach the same frequency limit.

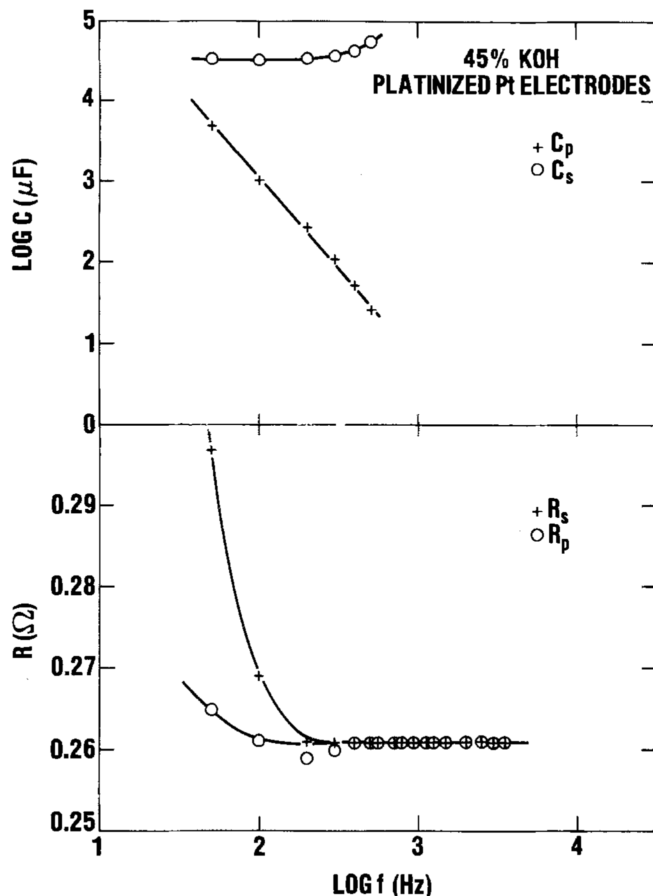

Fig. 3. Equivalent parallel and series resistances and capacitances vs. frequency of a conductivity cell filled with 45% KOH solution at 25.0°C using platinized Pt electrodes.

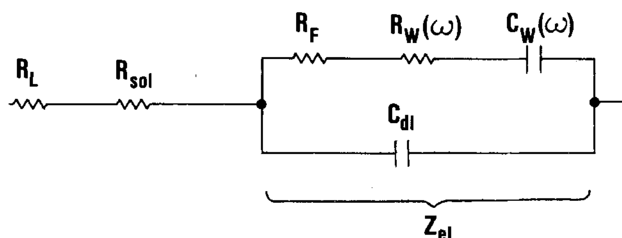

Fig. 4. Equivalent circuit of conductivity cell containing electrolyte

We may take the observed limiting high frequency value of $R_s = 0.261\Omega$ for the platinized electrodes and identify it with $(R_L + R_{sol})$. This agrees within experimental error with the value of $(R_L + R_{sol}) = 0.256\Omega$ calculated from the independently measured values of R_L, (L/A), and the conductivity of the 45% KOH solution.

Conclusions

One may obtain correct measurements of $(R_L + R_{sol})$ and of $(R_L + R_{sol} + R_{sep})$ and therefore of R_{sep} by audio frequency a-c bridge measurements on low impedance conductivity cells only if some precautions are observed. With platinized electrodes (cf. Fig. 3), R_p and R_s reach their limiting high frequency values only at the higher frequency end of the audio range, therefore, it is plainly not sufficient to make a measurement of R_p at a single frequency and assume it equal to $(R_L + R_{sol})$ or $(R_L + R_{sol} + R_{sep})$. Rather it is recommended that for low impedance cells, R_p and C_p measurements be made as a function of frequency, that R_s be calculated from R_p and C_p, and that the limiting high frequency value of R_s be identified with $(R_L + R_{sol})$ or $(R_L + R_{sol} + R_{sep})$. Platinized electrodes should be used, since their use leads to the approach of R_s to its limiting value within the observable frequency range (Fig. 3), while unplatinized electrodes may require extrapolation of R_s beyond the audio range in order to obtain the high frequency limit.

Electroless Gold Metallization for Polyvinylidene Fluoride Films

L. M. Schiavone

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

A method for metallizing polyvinylidene fluoride films with gold has been developed using an electroless plating process.

Metallized polyvinylidene fluoride (PDVF) has been found to be a good material for making piezoelectric devices once it has been poled. For this purpose, poled and aluminized PVDF is commercially available, but due to the rapid oxidation of the aluminum it is very difficult to make contact to it.

This paper describes a method of gold electroless plating used to metallize PVDF films. Since gold does not become oxidized it is an excellent choice for piezoelectric devices as well as for other uses such as flexible printed circuit boards.

Key words: PVDF films, electroless-plating process, piezoelectric devices.

Procedure and Experimental Data

Several important steps must be followed to achieve electroless plating: namely cleaning, sensitizing, activating, plating, and post cleaning.

Cleaning.—This is probably the most important step since a surface that is not free of grease and dirt will

not plate evenly and there may be areas where no metal will adhere.

Sensitizing.—This is achieved by immersing the PVDF film into a bath made of photosensitive salts such as $AgNO_3$, AgBr, $SnCl_2$, etc. The film is then exposed to light which reduces the salts to the metal in the bath.

Activating.—This process deposits a microthin layer of a catalyst needed to reduce the metal being plated. Palladium is an excellent catalyst for gold.

Plating.—Plating is done by immersing the film into an aqueous solution containing the desired metal. A layer will be deposited on the activated surface. Its thickness is determined by the amount of time the film is in the solution.

Post cleaning.—This is the final rinse and is used to remove any remaining solutions.

Gold-metallized PVDF was produced on 0.005 in. thick PVDF film using the following five steps:

(*i*) Cleaning in trichlorethylene for 4 min, acetone for 3 min, and n,n-dimethylformamide for 3 min and, finally, rinsing in distilled water.

(*ii*) Sensitizing by immersing the film in a 2.5*N* $SnCl_2$ solution and a 2.5*N* $AgNO_3$ solution for 10 min each. Both solutions were held at a temperature of 70°C. The sample was rinsed thoroughly in distilled water between solutions to avoid bath contamination. After the $AgNO_3$ bath the sample was again rinsed in distilled water, dried using nitrogen gas, and then exposed with a xenon lamp.

(*iii*) Activating in a $PdCl_2$, acetic acid bath (1) at 50°C for 30 min. Again the sample was rinsed in distilled water to be sure all of the solution was removed, leaving only a microthin film of palladium.

(*iv*) Plating by immersing the sample in a gold bath (2) at 85°C for 30 min. A magnetic stirrer was used to agitate the bath.

(*v*) Post cleaning by rinsing the film in distilled water several times following with two rinsings in warm methanol, and then thoroughly drying with nitrogen gas.

The result was a gold layer ~1 μm thick with a resistivity $\rho \approx 2.5 \times 10^{-6}\ \Omega$ cm which adhered to the PVDF and passed the "scotch-tape" test. It was possible to buff the layer using a Linde "C" impregnated felt pad with no adverse effects. A scanning electron microscope analysis showed the layer contained only gold. A second sample was made by the same procedure with a test pattern formed using Kodak-thin film resist (KTFR), see Fig. 1.

After initial cleaning, a thin layer of KTFR was spun on the sample and heated to 60°C for 15 min in a hot plate oven. The pattern was exposed using a xenon lamp and again heated to 60°C for 15 min. The KTFR was developed and rinsed in methanol.

Once the pattern was printed on the sample it was sensitized, activated, and gold plated. The KTFR was not affected by the different solutions and had to be removed with J-100 resist strip leaving a gold pattern on the PVDF. If the KTFR were removed after activating, the gold film would only plate on the remaining activated pattern, eliminating any gold waste.

Conclusions

The results of these tests show that PVDF can be metallized by using an electroless gold-plating process. Advantages of this method are that it is simple and economical because photoresist masking can be used with very little gold wasted, the need for expensive evaporating equipment is eliminated, and roll-to-roll processing is possible.

APPENDIX.

$PdCl_2$ Activator Solution (after Ref. 1)

Dissolve 0.3g $PdCl_2$ in 9 ml conc. HCl and dilute it with 9 ml H_2O. Add this mixture to 882 ml glacial acetic acid.

Au Plating Solution (after Ref. 2)

To make one liter of a 5× concentrate use: $KAu(CN)_2$, 4.3 g/l; KOH, 56.0 g/l; KCN, 32.5 g/l; KBH_4, 54.0 g/l. (*i*) Dissolve KOH in 500 ml of H_2O. Add KBH_4 and stir until dissolved; (*ii*) Dissolve KCN in 200 ml of H_2O. Add $KAu(CN)_2$ and stir until dissolved; (*iii*) Add solution No. 1 to solution No. 2 in a volumetric flask and make up to volume with distilled H_2O. Filter through Whatman filter paper No. 41. Store in a Teflon or polypropylene bottle. Do not tighten cap because hydrogen is liberated during storage.

Corrosion of Steel in Concentrated Sulfuric Acid

B. T. Ellison and W. R. Schmeal

Shell Development Company, Houston, Texas 77001

ABSTRACT

A model is presented for corrosion of carbon steel in 60-96% weight sulfuric acid with correlations and data to facilitate quantitative use of the model for mechanical and process design. Corrosion is limited by the rate of convective mass transfer of ferrous ion from a ferrous sulfate (corrosion product) film-liquid interface into bulk acid. This interface is saturated with ferrous ion. The model has been verified in both laboratory and plant acids with rotating cylinder and pipeline geometries and with a variety of carbon and low alloy steels. Ferrous ion is an inhibitor for corrosion, and sacrificial corrosion in certain equipment in plants in which acid is recirculated can protect other critical items in the system. Changing liquid levels in storage tanks, acid purges, addition of iron, and lining of vessels can affect corrosion rate in a plant system.

Sulfuric acid is an industrial catalyst for numerous organic chemical reactions, such as hydrations and alkylations, to produce many important commodities, such as alcohols, ethers, and gasoline. It is desirable to design plants so that carbon steel can be utilized in preference to more expensive materials as much as possible. Toward this end, quantitative corrosion models valid under chemical and fluid flow conditions anticipated for the plant are most useful. These conditions include presence of various chemical reactants in the acid as well as corrosion products which build up in the system because acid is continuously separated from desired chemical products and recirculated.

Much has been written about the corrosion of steel in concentrated sulfuric acid (1). An overview of the corrosion system can be gained by measuring the density of current supplied to a vertical rectangular specimen of AISI 1020 steel in stirred 70% weight acid in order to maintain the electrochemical potential of the specimen fixed (see Fig. 1). Two distinct regions appear in the anodic portion of this current potential curve. One is the "sulfation" range (−0.3 to +0.3V with respect to Ag/AgCl 1M Cl) where the current is independent of potential. Hines and Williamson found the film formed in this range to be duplex, the inside layer being a thin compact film and the outside layer a thick porous ferrous sulfate film (2). At 50 mV negative to the corrosion potential (here about −0.4V), the anodic rate measured by weight loss is identical to this rate in the sulfation region. The independence of anodic current density on potential near (both positive and negative) the corrosion potential implies that the anodic current, in the sulfation range, is also equal to the free corrosion rate. That is, the anodic process limits the corrosion rate.

The second distinct region appearing in the current potential diagram is the passive range, greater than +0.5V, where the steel is apparently covered by a ferric sulfate film over a passive oxide film (3, 4). The sharp peak at about +0.5V in Fig. 1 results from the change in oxidation states of the iron sulfate film already existing on the metal surface.

Donat (5) [see also Putilova (6)] and Poluboyartseva *et al.* (7) discovered that corrosion depends on flow rate and, for 94-96% sulfuric acid, probably on rate of mass transfer of iron sulfate, respectively. Wachter *et al.* (8) and Novakovskii (9) recognized a correspondence between the functionality of corrosion rate upon acid strength and ferrous sulfate solubility and concluded that corrosion rate depends directly on solubility. The objective of the present work is to develop, verify, and define a range of validity of a model to predict corrosion rates of carbon steel in concentrated sulfuric acid for geometries and conditions of industrial significance.

Key words: convective mass transfer, sacrificial corrosion, ferrous sulfate, corrosion inhibition.

Experimental Tools and Methods

Two well-defined turbulent flow fields were studied by means of a rotating cylinder and a pipeline apparatus. Corrosion rates were measured in the former apparatus by the two techniques involving measurement of loss of weight for a given time period and anodic dissolution rate. Corrosion rates were measured directly from weight loss for the pipeline apparatus. Tests could be carried out and environments changed rapidly with the rotating cylinder. Therefore, this device was used for investigating proposed models and the pipeline apparatus was employed for confirmation.

The rotating cylinder apparatus, except for the cylinder itself, was purchased from the Pine Instrument Company. Cylinder rotational speed of 400, 900, and 1600 rpm were obtained with a synchronous motor coupled to the cylinder through stepped pulleys. The rotational speeds were verified with a tachometer. The rotating cylinder was electrically insulated from its support. Electrical current was supplied to the cylinder through an external graphite brush for the anodic dissolution experiments.

The test solution was contained in a 15.24 cm diam Pyrex beaker. The temperature of the solution was adjusted with an electrical heating tape wrapped around the outside of the beaker. The heating tape was coupled to a Thermo Electric Model 400 pulse burst temperature control unit. This combination enabled test solution temperatures of 27°, 40°, and 60°C to be maintained to within ±1°C.

The cylinder shaft was fabricated from Monel alloy 400. The corrosion test specimens were sleeves slipped over this shaft. The specimens were 1.904 ± 0.001 cm

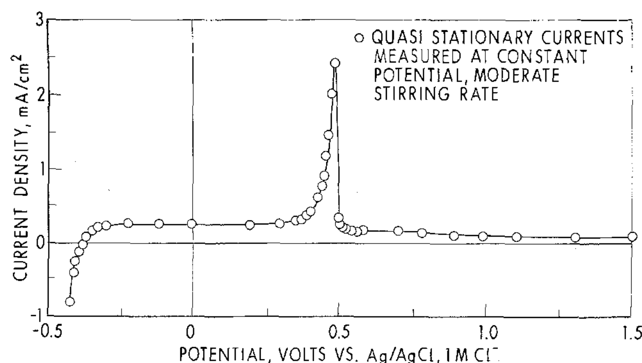

Fig. 1. Current potential curve of SAE 1020 carbon steel in 70% weight H_2SO_4 at 30°C.

in outside diameter by 2.54 ± 0.005 cm long. A 1.905 cm diam Teflon sleeve surrounded the shaft above the test specimen, and a 1.905 cm diam Teflon cap was threaded onto the shaft below the specimen, holding the specimen in place and isolating the shaft from the acid. The Teflon cap held the test specimen in place.

The weight loss experiments were 24 hr long. Cylinders were fabricated from AISI 1113 steel. Microstructure was equiaxed and consisted of lamellar pearlite and ferrite. Ferrovac E cylinders were also used; there was no difference in corrosion performance. The test specimens were sanded with 600 emery paper, degreased, and then weighed. After the experiment, the cylinders were removed, washed in distilled water, and then abraded lightly with a rubber eraser to remove any remaining $FeSO_4 \cdot H_2O$ film. The specimens were then reweighed.

For the anodic dissolution experiments, current-time curves were obtained while the specimens were maintained at a constant potential of 0.0V with respect to a Ag/AgCl 1M Cl^-, cracked glass seal reference electrode. A platinum gauze counterelectrode surrounded the rotating cylinder. Anodic dissolution currents were recorded on a strip chart recorder. The specimens were prepared as for the weight loss experiments; in addition, some specimens were electropolished in an acetic acid-perchlorate solution. Both of these methods of preparation led to the same experimental results.

The closed loop pipeline apparatus was constructed to permit measurement of corrosion rates of pipe walls under flow conditions typical of chemical plant environments. Corrosion test specimens were short pieces of 1 in. pipe fitted between upstream and downstream runs of 1 in. pipe, designed to assure that the velocity profile was fully developed at the test specimens. These entry and exit sections consisted of 1-in. Schedule 40 CPVC plastic pipe extending 183 cm upstream and 122 cm downstream from the test specimens. Steel transition pieces were screwed (with 1-7/16 NF threads and appropriate washers) to the plastic entry and exit lengths. The test specimens were bolted between these transition pieces (see Fig. 2). The transition pieces permitted development of the mass transfer characteristics of the flow before the acid contacted the test specimens. The test specimens and the transition pieces were machined with close internal diameter and concentricity tolerances which assured alignment between specimens to within 0.0025 cm. The specimens were fabricated from AISI 1015 steel tube and were 2.664 cm internal diameter by 7.62 cm long.

The basic components of the pipeline apparatus were the vessel, pump, flow metering and control equipment, and the test section (Fig. 3). The vessel was a 113.7 liter Pfaudler glass-lined steel autoclave. A Worthington 1CNG-32 Worthite pump took suction from the vessel through 2-in. CPVC pipe. A Hills-McCanna 1 in. Penton-lined control valve downstream from the pump maintained 0.03 liter/sec control over a 0.19-2.21 liter/sec range. Downstream of the valve, flows were sensed with either a 3.023 or 1.27 cm tantalum orifice and transmitted to a Foxboro controller (FRC) by a differential pressure cell. The flow recording and control system was calibrated with glycerol-water mixtures as well as with water alone. Downstream from the orifice, the acid entered the 1 in. Schedule 40 test section. The flow discharged from the test section back to the Pfaudler vessel. The temperature control system enabled an acid temperature of 60°C to be maintained to within ±2°C.

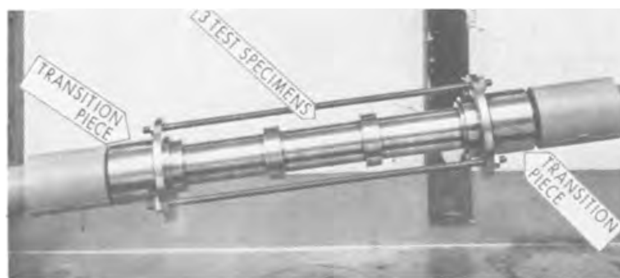

Fig. 2. Pipeline test specimens

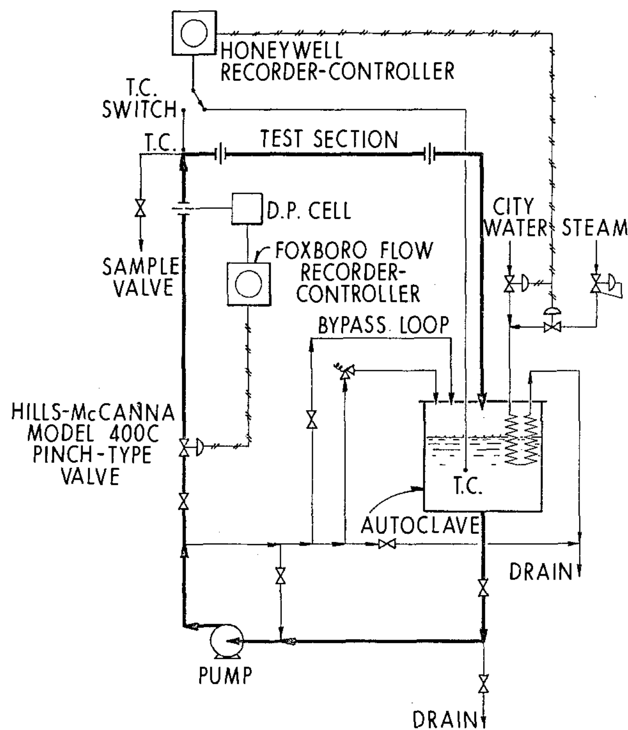

Fig. 3. Schematic diagram of pipeline corrosion test apparatus

Two Hastelloy B sheathed iron-constant thermocouples were available for temperature control. The first was located in the Pfaudler vessel, and the second was located at the entrance to the test section. The temperature difference between the two locations was always less than 1°C. Either of these thermocouples could be connected to a Honeywell temperature controller (TRC). This controller operated steam and water control valves which were on a line to the jacket side of the Pfaudler vessel. The temperature control system enabled an acid temperature of 60°C to be maintained to within ±2°C.

The day before an experiment the test specimens were degreased in acetone, cleaned by gentle abrasion (with a pencil eraser), weighed, and then the test section was assembled. The test section was tested for leaks with low pressure compressed air, then connected to the remainder of the pipeline apparatus.

Reagent grade H_2SO_4 (96% weight) was mixed with distilled water in the Pfaudler vessel to make 68% weight H_2SO_4. The acid strength was determined with a hydrometer. After mixing, the acid was cooled to 60° ± 2°C and the experiment begun. Periodically, acid samples were withdrawn for ferrous ion determination by titration with MnO_4^-. The test period was 24 hr.

At the end of the test, the specimens were cleaned and reweighed. The corrosion rate was calculated from the weight loss of the specimens. Three test specimens were used during each experiment.

Formulation of the Model

Anodic dissolution currents for AISI 1113 rotating cylinder, measured in 68% weight sulfuric acid at 27°, 40°, and 60°C at 400, 900, and 1600 rpm, were found to increase in proportion to velocity to the nth power where $0.6 < n < 0.8$, indicating that convective mass transfer is the likely rate-limiting step in corrosion (see Fig. 4). Next, experiments to identify the species whose mass transfer step is the slow step in the corrosion process in 68% weight H_2SO_4 demonstrated

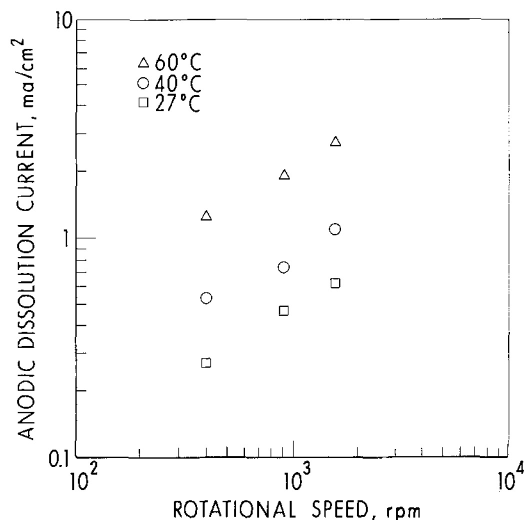

Fig. 4. Anodic dissolution currents vs. rotational speed for 1.905 cm diam cylinder in 68% weight H_2SO_4.

what Poluboyarteseva asserted for 94-96% weight H_2SO_4, that this species is ferrous ion.

The corrosion rate (C.R.) is proportional to the convective mass transfer rate of one of the species

$$\text{C.R.} = \pm Ah(C_f - C_{bulk}) \qquad [1]$$

where A is the conversion factor between moles per square centimeter-second and centimeter per year corrosion rate, h is the convective mass transfer coefficient, C_f is the concentration of the species at the corrosion product film-solution interface, and C_{bulk} is the concentration of the species in the bulk solution.

Anodic dissolution experiments were conducted with different concentrations of ferrous ion in the bulk and the anodic dissolution currents were observed to decrease linearly with the ferrous ion concentration (see Fig. 5). This indicates that the convective mass transfer of ferrous ions is indeed the slow step in the corrosion process.

Next, it was established that the appropriate value for C_f in Eq. [1] is the saturation concentration in acid of the salt, $FeSO_4$-H_2O, which is found on the metal wall. The mass transfer rate to a rotating cylinder is usually expressed as (10)

$$\text{Sh} = 7.91 \times 10^{-2}\text{Re}^{0.7}\text{Sc}^{0.356} \qquad [2]$$

Sh (Sherwood number) is a dimensionless mass transfer rate, Re is the Reynolds number, the dimensionless rotational velocity of the cylinder, and Sc is the Schmidt number, a fluid property characterizing the relative thicknesses of the momentum and mass transfer boundary layers (see List of Symbols for definitions). We determined the mass transfer characteristics of the rotating cylinder used in the present work by measuring the mass transfer limited current for oxygen dissolved in salt water and found that Eq. [2] fit these data to within 5%.

We computed C_f from Eq. [1] using measured values of the corrosion rate, C.R., and C_{bulk}, values of h calculated from Eq. [2], and a value of A of 2.24×10^8 (cm/yr) (moles/cm²-sec). Results given in Fig. 6 show that the computed C_f is independent of Reynolds number and strongly dependent on temperature, consistent with theory. Furthermore, the computed values of C_f are about equal to the saturation concentration of ferrous ion which was measured independently (see Fig. 7) by methods discussed in the Appendix.

A model of the corrosion process is formulated which is based on the corrosion rate of carbon steel in concentrated sulfuric acid being equal to the mass transfer rate of ferrous ions from a ferrous saturated fer-

rous sulfate film-sulfuric acid interface to the solution bulk, *i.e.*

$$C.R. = Ah(C_{sat} - C_{bulk}) \quad [3]$$

All of the information required to predict corrosion rates with this model are obtained from sources other than corrosion measurements. The mass transfer coefficient, h, can be obtained from standard engineering formulas in conjunction with diffusion coefficient and viscosity data. The saturation concentration of ferrous ions is obtained from thermodynamic measurements, and the bulk concentration of ferrous ion can be measured or calculated.

Confirmation and Use of the Model for 68% Sulfuric Acid

It is useful to express corrosion rates as dimensionless corrosion Sherwood numbers, Sh*

$$Sh^* = \frac{C.R.\, d}{A(C_{sat} - C_{bulk})D}$$

where C.R. is the measured corrosion rate (centimeter per year), d is the diameter of the rotating cylinder (or the diameter of the pipe), $(C_{sat} - C_{bulk})$ is the difference between the independently measured saturation concentration of ferrous ion and the measured bulk concentration of ferrous ion, A is the conversion factor previously defined, and D is the independently measured diffusion coefficient of ferrous ions in H_2SO_4 (see Appendix). Over the range of validity of the model, plots of Sh* *vs.* dimensionless parameters are the same as the corresponding plots using the mass transfer Sherwood number, Sh, found in the literature (see Fig. 8). For any geometry, plots such as Fig. 8 are universal relations of great utility, since one relation describes corrosion rate over a range of values of all parameters.

From Fig. 8, it can be seen that ±20% is about the limit on the accuracy of the predictions of the model. The cumulative errors in the measurement of diffusion coefficient, ferrous ions solubility, ferrous ion concentration in the bulk acid, and corrosion rate all influence the agreement between the measured corrosion rate and the predictions of the model. Ferrous solubility, in particular, is a difficult measurement so that the scatter in the data is understandable. (Data shown in Fig. 8 include tests with acid 40-70% weight saturated with ferrous ion.)

It is important that results obtained from anodic dissolution experiments be confirmed by weight loss measurements because it is possible that anodic dissolution currents are not equal to corrosion rates in this system. The reason that the anodic dissolution currents could be unrepresentative of free corrosion rates is that the film formed at the corrosion potential may differ from the film formed at 0.0V. For example, hydrogen gas evolution during free corrosion may affect the corrosion rate.

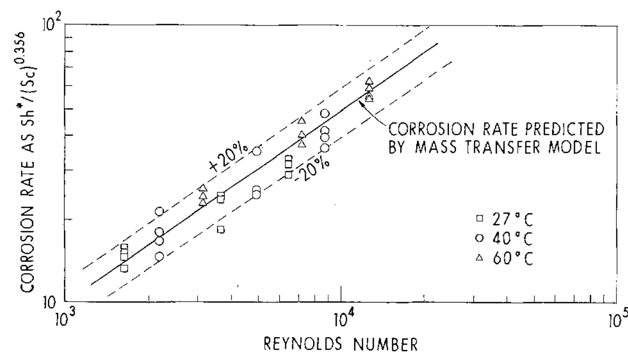

Fig. 8. Anodic dissolution rate (corrosion rate) of AISI 1113 cylinder in 68% weight H_2SO_4.

Twenty-four hour weight loss experiments were conducted with the AISI 1113 cylinder in lean 68% weight acid to verify the corrosion model in these conditions. The corrosion rate should be inversely proportional to the ferrous ion concentration in the acid and, therefore, should decrease as the corrosion product builds up in the acid. Ferrous ion concentrations in the acid were determined periodically so that a mean value with respect to time of the bulk ferrous ion concentration could be determined. This mean value was used as C_{bulk} to formulate the Sherwood number from the measured weight loss.

When the clean specimens (not covered with protective corrosion product film) were first immersed in the acid, they corroded vigorously. The corrosion model is only applicable after steady-state corrosion rates are obtained. The anodic dissolution experiments indicated that steady state is obtained within 30 min. The weight loss of a specimen after the first 30 min was subtracted from the total weight loss of a specimen to determine the Sherwood number. The weight loss during the first 30 min was determined from the ferrous ion concentration in the solution at that time. These weight losses usually accounted for about 5% of the total weight loss.

The results of the weight loss experiments are shown in Fig. 9. These corrosion rates are slightly higher than the predicted corrosion rates but the measurements agree with the predicted corrosion rates to within 20%. The rotating cylinder experiments were run over a range of temperatures from 27° to 60°C and a range of mass transfer coefficients equivalent to those in flows of from 91.5 to 336 cm/sec in a 10.16 cm ID pipe.

The model was confirmed in experiments in the pipeline apparatus. Twenty-four hour weight loss data were taken on the pipe specimens. These data were obtained with 68% weight acid at 60°C. Each reported weight loss is the mean of three weight losses under the same conditions. No weight loss deviated by more than 10% from the mean weight loss; typical deviations were 4%. The weight losses were formulated into a Sherwood number in the same way as the rotating cylinder weight losses were treated. The results are shown in Fig. 10 and are compared with mass transfer correlations proposed by several investigators. The data fit best the correlation of Harriott and Hamilton (11) for the conditions tested

$$Sh = 9.6 \times 10^{-3} Re^{0.913} Sc^{0.346}$$

The measured corrosion rates agree with the mass transfer correlation to within 5%.

The mass transfer model of the corrosion of carbon steel in 68% weight H_2SO_4, which was developed from rotating cylinder experiments, remains valid in pipe

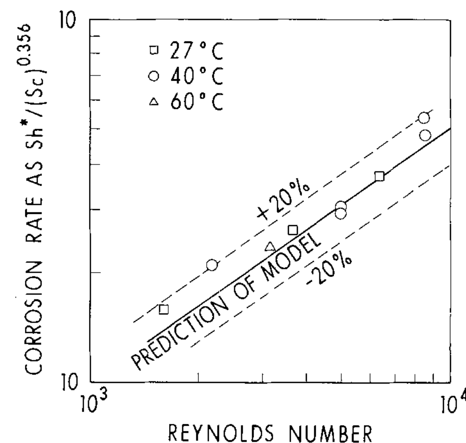

Fig. 9. Corrosion rates measured in 24 hr weight loss experiments of a 1.905 cm diam AISI 1113 cylinder rotating in 68% weight H_2SO_4.

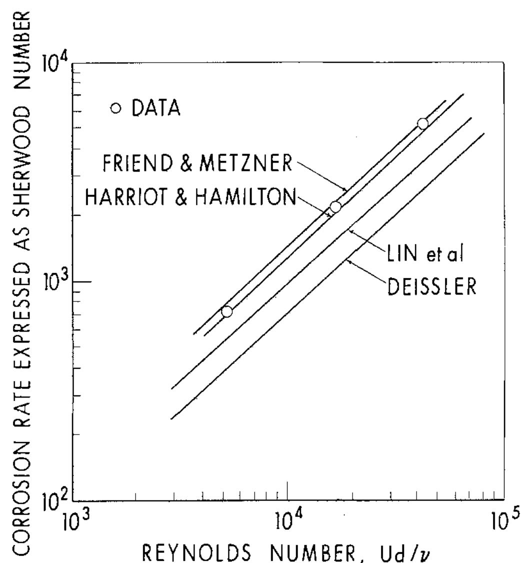

Fig. 10. Corrosion rate of carbon steel pipe walls in 68% weight H_2SO_4 at 60°C.

flow. The model can be expected to remain valid in other hydrodynamic situations.

Range of Validity

It is important to examine the validity of the model under a range of conditions of industrial significance. The model was formulated using 68% weight sulfuric acid. A few experiments were conducted with 78% weight H_2SO_4 to determine if the model is valid at this acid strength. The results of both weight loss and anodic dissolution experiments are shown in Fig. 11. It is seen that the predicted corrosion rates generally agree within 20% with the measured corrosion rates.

It had been believed previously (8) that the acid strength affected corrosion rate primarily by changing ferrous ion solubility (the higher the solubility the greater the corrosion rate). It is now apparent that the important parameters which are a function of acid strength are not only ferrous ion solubility, but also acid viscosity and ferrous ion diffusion coefficient. Even though the ferrous ion solubility in 78% weight acid is higher than in 68% weight acid, the corrosion rate is lower because the diffusion coefficient is lower and the viscosity is higher.

Literature data indicate that the mass transfer corrosion model should be valid over the acid strength range between 60 and 100%. The work of Poluboyartseva *et al.* (7) indicates that the model is valid for 96% weight H_2SO_4. Damon's data on the effects of carbon content and acid strength on the corrosion of carbon steel in sulfuric acid (12) indicate that the rate-controlling mechanism is the same for acid strengths between 60 and 100%.

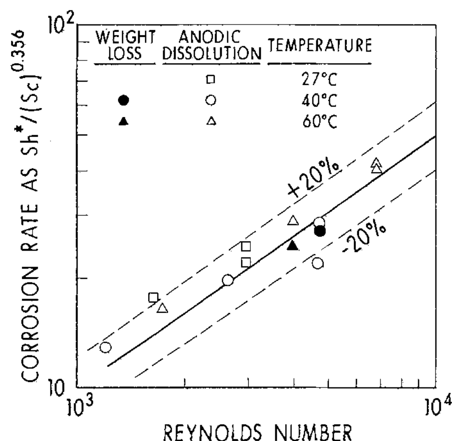

Fig. 11. Anodic dissolution currents and weight losses in 78% weight H_2SO_4.

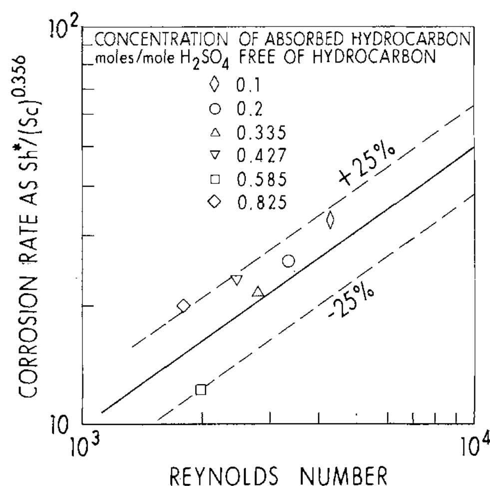

Fig. 12. Corrosion rates measured in 24 hr weight loss experiments in IPA fat 68% weight H_2SO_4 at 38°C, 900 rpm.

To determine the validity of the corrosion model in hydrocarbon fat acids,[1] a series of weight loss experiments was conducted in laboratory-fattened acid and plant acid. Weight loss experiments were conducted with the AISI 1113 cylinders over a range of isopropyl alcohol fatnesses[2] from 0 to 0.825. The weight loss tests were all conducted at 38°C, 900 rpm. The results are shown in Fig. 12. It is seen that the predictions of the model are not as accurate as for lean acids; however, ± 25% accuracy can be expected.

Some weight loss experiments were run with steels of varying composition to determine the effects of carbon content and copper content on corrosion steel in 68% weight H_2SO_4. The steels considered were AISI 1113, AISI 1018, AISI 1045, and U.S. Steel Corten (0.10 C maximum, 0.30 minimum Cu). All experiments were conducted at 900 rpm, 40°C with 68% weight H_2SO_4 free of organics. The results are shown in Table I. It is seen that the predicted corrosion rates agree with the measured corrosion rates to within 5%. These results indicate that steel composition is a minor variable in determining the corrosion resistance of carbon steel to concentrated sulfuric acid. The results are consistent with Damon's results (12). For acid strengths below

[1] Fat acids mean acids containing hydrocarbon and fatness means the concentration of absorbed hydrocarbon in moles per mole of H_2SO_4. Note that absorbed olefins react to form alcohols and other species. It is thus often possible to create desired equilibrium mixtures in the laboratory simply by adding alcohol to acid.

[2] Isopropyl alcohol is the primary equilibrium reaction product which exists when propylene is absorbed in sulfuric acid.

Table I. Effect of steel composition on corrosion rate of carbon steel in 68% weight H_2SO_4

Conditions: Tests were conducted at 900 rpm, temperature 40°C with 1.905 cm diam cylinders in 68% weight H_2SO_4.

Steel	Measured corrosion rate (cm/yr)	Predicted steady-state corrosion rate* (cm/yr)
AISI 1018	0.635	0.602
Corten	0.576	0.587
AISI 1045	0.691	0.673
AISI 1045	0.648	0.655
AISI 1113	0.640	0.653

* Changes in the predicted corrosion rate do not reflect a dependence of steady-state corrosion rate on steel composition but rather varying amounts of corrosion in the first half-hour. These variations produce differing amounts of dissolved ferrous ion in the acid when steady-state corrosion begins. Predictions are made with Eq. [4] using the mean concentration of ferrous ion in the solution during the experiment excluding corrosion in the first half-hour.

60%, steel composition is an important variable [see Ref. (12)].

Systems Aspects of Corrosion

The model for corrosion, Eq. [3], shows that the corrosion rate depends on physical properties of the local environment (temperature, acid strength, and concentration of absorbed species), geometry and flow conditions, and one parameter which reflects events at other times and places, the bulk ferrous ion concentration, C_{bulk}. In many commercial uses of sulfuric acid, the acid recirculates through a plant via absorbers, desorbers, reactors, exchangers, and intermediate storage vessels. Thus, events in some of these vessels which affect ferrous ion concentration in recirculating acid can have a dominant effect on the corrosion rate in other vessels and pipes.

A plant may be visualized as consisting of nodes representing vessels, exchangers, or pipes which are connected by lines representing flow of acid in a network or signal flow diagram. These nodes are connected to adjacent nodes consistent with the route of flow of acid. There will be a purge location represented by a node. For each node the concentration of ferrous ion in the exit stream (C^o_{bulk}) exceeds the concentration in the entering stream (C^i_{bulk}) by an amount proportional to the average corrosion rate ($\overline{C.R.}$) expressed as weight loss of iron per unit area and time

$$C^o_{bulk} - C^i_{bulk} = (\overline{C.R.})\alpha\theta \quad [6]$$

where α is the area per unit volume of the node and θ is the holding time of the node. If ($\overline{C.R.}$) is negative a precipitation rate is indicated. Notice also that the driving force for corrosion or precipitation is proportional to ($C_{bulk} - C_{sat}$) in the node.

The nodes and purge are sources and sinks for ferrous ion. They tend to pull the bulk ferrous concentration in the stream entering toward their saturation ferrous concentration as determined by local temperature and acid composition by corrosion or precipitation. The purge node has a saturation concentration of zero. The steady-state ferrous ion concentration will be determined by the most "influential" nodes, those with large residence times, large surface to volume areas, or large driving forces for corrosion or precipitation. Thus, ferrous ion concentration and, therefore, corrosion rates in pipes, vessels, and exchangers are determined by conditions in large storage tanks or very large heat exchangers.

If one node is dominant it is easy to predict the system bulk ferrous ion concentration by assuming it is the saturation condition in the dominant node. Conservative estimates of ferrous ion concentration which give an upper bound for corrosion rates can be made by assuming the bulk ferrous ion concentration is zero or, more realistically, equal to the saturation concentration in the "influential" node in which it is lowest.

From this it is apparent that lining or lowering the liquid level in an acid storage tank, raising the liquid level in a storage tank containing acid with absorbed hydrocarbon, or upgrading materials in an "influential" node can result in an increase in corrosion rate elsewhere in the system which is often thought to be mysterious. Inhibition of corrosion of downstream equipment has been effected by lowering steel chains into an acid storage tank in the same acid system to create a more "influential" node.

Conclusions

The corrosion rate of carbon steel or iron in 68-78% weight sulfuric acid is limited by the rate of convective mass transfer of ferrous ion from a ferrous sulfate film-liquid interface into bulk acid. The works of Damon (12) and Poluboyartseva *et al.* (7) indicate this model is probably valid for 60-96% weight sulfuric acid. The ferrous ion concentration at the interface is the saturation concentration of ferrous sulfate in the acid. The corrosion rate is, therefore, positively influenced by this saturation concentration, which increases with temperature, decreases with concentration of absorbed hydrocarbon in acid, and depends on acid strength in a complex way [see Ref. (8)]. The bulk concentration of ferrous ion is determined by events elsewhere in the acid system. Thus, inhibition of corrosion can be purposefully effected by sacrificial corrosion in large storage tanks, by addition of iron, or by lowering the liquid level in tanks containing supersaturated solutions to minimize ferrous sulfate precipitation. Inhibition has been accomplished successfully in a petrochemical plant by the intentional introduction of steel chains to a tank to increase the ferrous concentration in the acid. Accidental increases in corrosion of critical items can occur after increases in acid purge rate, lining of storage vessels, or lowering of liquid level in storage vessels. Corrosion rate is influenced by all variables which determine mass transfer coefficient, especially velocity, viscosity, and diffusivity of ferrous ion. The dependence of the latter two on acid strength is more significant than commonly appreciated. For example, the corrosion rate for 78% weight acid is generally lower than for 68% weight acid, despite the fact the ferrous solubility is higher, because the viscosity is higher and the diffusivity of ferrous ion is lower.

APPENDIX

It is appropriate to discuss briefly the prediction of physical properties required to use the model: ferrous ion solubility, viscosity, density, and ferrous ion diffusion coefficient in acid. Dependence of these on acid strength and concentration of absorbed hydrocarbon species is important.

Published values for the saturation concentration of ferrous ion in sulfuric acid are in considerable disagreement. For example, at 55°-65°C and 65-70% weight H_2SO_4, the following values for ferrous saturation concentration were found: 0.61% weight (13) and 0.17% weight (14). Solubility measurements were made in 68% weight lean acid at 23°, 38°, 48°, 65°, and 75°C. The results shown in Fig. 7 were obtained after allowing 8 days for equilibration from an initially supersaturated solution. To verify these results, 68% weight acid initially free of ferrous ion was equilibrated with solid $FeSO_4 \cdot H_2O$ at room temperature (about 25°C) for a month. The ferrous concentration was then measured as 5.8×10^{-3} moles/liter, which is in substantial agreement with the concentrations measured in the initially supersaturated solution. Solubilities measured in 78% weight acid as a function of temperature after 7 days equilibration are shown in Fig. 13. It is seen that these solubilities are about 1.5 times as high as those in 68% weight acid. Solubilities of ferrous ion were measured in acid containing isopropyl alcohol, the primary equilibrium reaction product when propylene is absorbed. About a month was required to obtain reasonably steady values of the saturation concentration. The solubility measurements for 38°C are shown in Fig. 14.

Viscosities for the lean acids were obtained from the literature (15, 16) for use in our calculations. Viscosities for the fat acids were determined at 25° and 60°C with a capillary viscometer according to ASTM D445. Viscosities at intermediate temperatures were obtained from Andrade's equation (17) where the constants were obtained from the 25° and 60°C data

$$\mu = Ee^{B/T}$$

For 67% weight acid, viscosities measured at 25° and 60°C are shown *vs.* concentration of absorbed propylene in Table II.

Densities may be found in the literature or measured directly with a hydrometer. In general densities de-

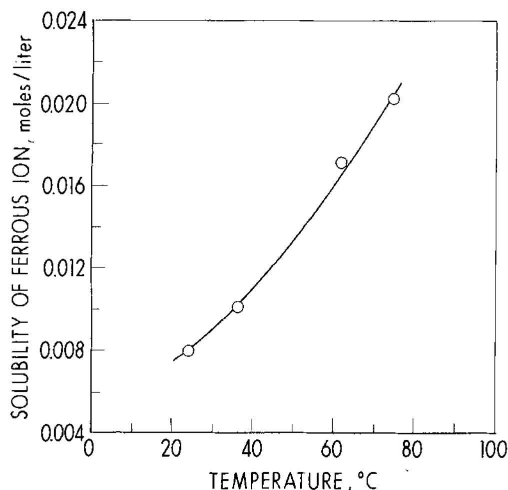

Fig. 13. Solubility of ferrous ion in 78% weight H_2SO_4 vs. temperature.

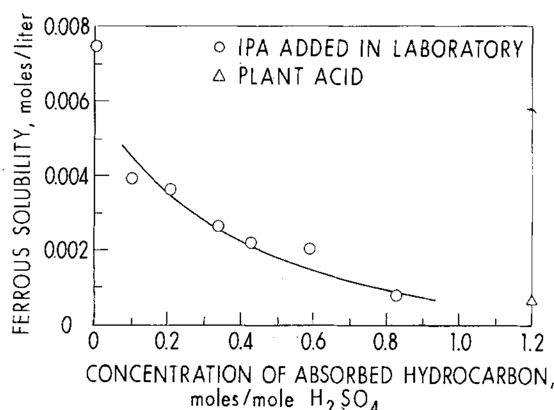

Fig. 14. Solubility of ferrous ion in 68% weight H_2SO_4 containing isopropyl alcohol.

crease with increasing concentration of hydrocarbons. For example, for propylene systems we used

$$\frac{d\rho}{df} = -0.12(\rho - 0.684 - 86/T)$$

where f is the moles of absorbed olefin per mole of H_2SO_4 and T is temperature in °K.

Diffusion coefficients for ferrous ion were measured with a rotating platinum disk electrode. The mass transfer limited current for the oxidation of ferrous ion to ferric ion was determined in an acid of known ferrous concentration. This current was then related to the diffusion coefficient for ferrous ion with Levich's equation (18).

The measured diffusion coefficient of ferrous ion in 68% and 78% weight lean acids are shown in Fig. 15. The diffusion coefficients measured at 24°C (68% weight H_2SO_4) and 30°C (78% weight H_2SO_4) were used with Wilke's formula (17)

$$D\alpha T/\mu$$

to compute the diffusion coefficient at other temperatures. The measured diffusion coefficient at 60°C (68% weight H_2SO_4) agrees within 8% of the value calculated from Wilke's formula.

Table II. Viscosities of 68% weight IPA fat sulfuric acid

Concentration of absorbed hydrocarbon	Viscosity (centistokes) 25°C	60°C
0	—	—
0.1	5.50	2.55
0.2	6.86	3.18
0.335	8.47	3.81
0.427	9.48	4.22
0.585	12.03	5.05
0.825	13.27	5.33

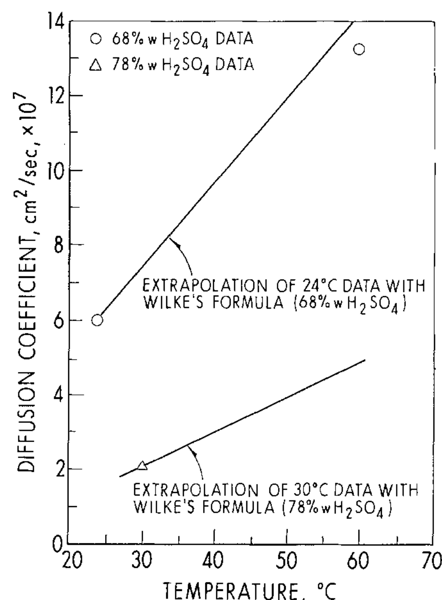

Fig. 15. Diffusion coefficient of ferrous ion in H_2SO_4 vs. temperature.

The diffusion coefficients of ferrous ion in the hydrocarbon fat acid were computed by extrapolating with Wilke's formula (19) the data obtained for 68% weight H_2SO_4. The extrapolation formula was

$$D = 1.68 \times 10^{-10}\, T/\mu$$

where T is in °K, μ in poise, and D in square centimeters per second. This equation can also be used to predict the ferrous ion diffusion coefficient in acids of differing strength. This equation overpredicts (about 30%) the measured diffusion coefficient in 78% weight acid. Although this extrapolation technique is not ideal, use of it did lead to results which were consistent with the other data taken in this research.

Preparative Electrolyses at Graphite Paste Anodes

Kevin D. Wolter and John T. Stock*

Department of Chemistry, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Two forms of thin-layer graphite-paste anodic preparative electrolysis systems have been developed. The rotating counterelectrode chamber of the simpler form provides the stirring action. In the other form, the surface of the paste is continuously reactivated. With this device, electrolysis of the highly anode-deactivating system tyramine in NaOH solution has been shown to yield a carbon-carbon "dimer."

Because graphite paste has been found to give very low anodic residual currents, this is a suitable electrode material for analytical-scale oxidation studies (1). A graphite paste preparative-scale anode has been described by Colaruotolo (2). He used a layer of paste that was spread on a platinum contact at the bottom of a beaker. Although simple, this design makes controlled spreading almost impossible, so that the resulting paste layer is uneven and usually quite thick.

Although electrolysis systems of quite high electrical resistance can be used successfully on the analytical scale, the resistance should be as low as possible when the large quantities of electricity needed for preparative work are involved. Conventional electrode materials have much lower specific resistances than has graphite paste. This suggests that a thin layer of paste should be spread on a low resistance substrate. The paste is made from graphite powder (G) and a nonconducting binder (B) such as Nujol. Accordingly, the B/G ratio (ml of binder per gram of graphite) should significantly affect the resistance of the paste. The paste must be coherent so that it will not break down under the motion of the cell solution or of the cell components. Adams (1) recommended a B/G ratio of 0.6:1 for voltammetric work.

Experimental

A single batch of Fisher Scientific Company grade No. 38 graphite powder was used throughout. Measurements of the electrical resistances of graphite-Nujol pastes gave poorly reproducible results. In general, the application of quite light pressure caused a considerable decrease in resistance. However, three facts become obvious (*i*) high B/G ratios give high resistance pastes, (*ii*) below a certain B/G ratio, the resistance of the past falls quite rapidly as this ratio is further diminished, (*iii*) when the B/G ratio is small, the resistance is comparatively low and is relatively insensitive to changes in this ratio. However, pastes of very low B/G ratio are friable. A B/G ratio of 1.2:1 was chosen as giving the best compromise of electrical and mechanical properties. The specific resistance of this paste was approximately 500 Ω cm.

In an attempt to quantify these conclusions, experiments were made with "frozen" pastes. These were made by mixing graphite powder with molten paraffin wax and allowing the mixtures to cool. After measuring resistances, several of the samples were thin sectioned for photomicrography. This showed that small graphite particles were much more numerous than large ones. Particle size analysis (Imanco Quantimet 720 Image Analyzer) of the stock of graphite powder confirmed this conclusion.

Two thin-layer graphite paste electrolysis systems were constructed. The graphite block cell (GBC) is shown schematically in Fig. 1. Block A is a 2.5 cm length of a 7.5 cm diam graphite rod. A circular groove was cut in the upper face to accept cell B, which is a 150 ml beaker with the bottom cut off. Graphite paste was spread to a uniform thickness of 1 mm or less on the graphite surface enclosed by the groove. The cell was then inserted and sealed into the groove with molten paraffin wax. Stirring was provided by a rotating chamber C, made from a Nafion® ion-exchange sheet (3). This chamber contained the counterelectrode and the catholyte, which was usually saturated KCl solution. All potentials were referred to a saturated calomel electrode through a thread-type salt bridge (4) and were controlled by a McKee-Pedersen Type MP-1026 potentiostat.

Figure 2 shows the essentials of the rotating drum cell (RDC). The reference electrode and counterelectrode compartment (3) are not included. The normal level of solution is indicated by the broken line. Horizontal graphite drum is 6.5 cm in diameter and 6.3 cm long. It has a Lucite axle that runs in U-shaped bearings mounted on the insides of opposing walls of the Lucite cell. This cell is 13 cm long, 12 cm wide, and 11 cm high. Electrical connection to the graphite drum

* Electrochemical Society Active Member.

Key words: electrooxidation, electrosynthesis, graphite paste electrode, electrode activation, tyramine.

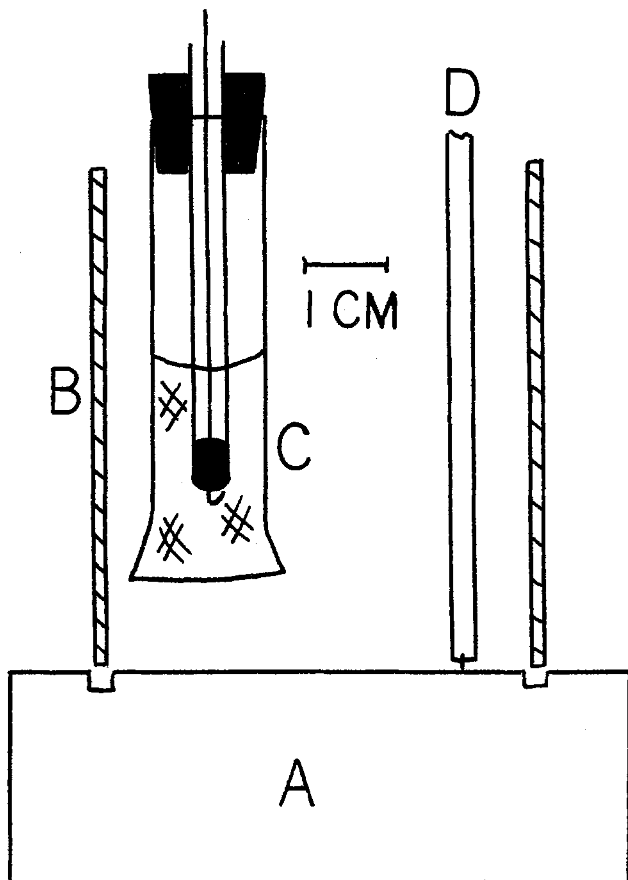

Fig. 1. Graphite block cell. A, graphite block; B, cut-down beaker; C, counterelectrode chamber; D, salt bridge.

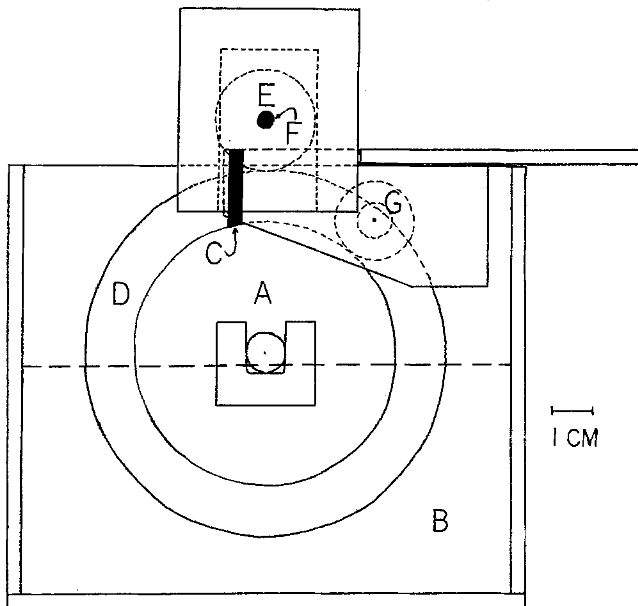

Fig. 2. Rotating drum cell. A, graphite drum; B, Lucite cell; C, carbon brush; D, knurled Lucite wheel; E, rubber drive wheel; F, steel drive shaft; G, reactivation roller.

is made through a small spring-loaded carbon brush that presses near the edge of the periphery of the drum. A knurled Lucite wheel attached to the drum is driven by small rubber wheel which is mounted on stainless-steel drive shaft. This is driven through an 8:1 reduction gear by a 1725 rpm motor. The drive shaft also carries a sprocket that allows reactivation roller to be chain driven. This Lucite roller, which is 1.9 cm in diameter and slightly shorter than the graphite drum, has two functions. First, it controls the thickness of the paste layer on the submerged portion of the drum. To this end, the reactivation roller is mounted on a movable inner housing so that the reactivation roller to graphite drum clearance can be changed. Normally, the clearance was 1 mm. In operation, the system sheds some paste, which falls to the bottom of the cell. Automatic paste feed was tried, but periodic manual application of paste to the drum works very well.

The second function of the reactivation roller is to restore the activity of the paste when an anode deactivator is to be electrolyzed. Some organic compounds form poorly conducting products that coat the anode and hence reduce or cut off the cell current (5). A preparative cell in which a rotating graphite drum reactivates a graphite cloth anode has been described (6). In the RDC, the approximate surface speeds of drum and roller are 1290 cm min^{-1} and 960 cm min^{-1}, respectively. The shear created by this difference in speeds resurfaces the paste before it reenters the solution.

Results and Discussion

Figure 3 shows the effect of the B/G ratio upon the electrical resistance of paraffin wax-graphite "frozen" paste. Resistance readings are relative only, and were obtained with a probe consisting of two 1 mm diam sharp-pointed steel pins fixed 3 mm apart. The pins were inserted in the "paste" to a depth of 5 mm. These results, in line with the general behavior noted for Nujol-bound pastes, were interpreted with the aid of the particle size analysis as follows. In region I, essentially all adjacent particles are in contact, so that the paste has a resistance that is both low and relatively insensitive to shifts in the B/G ratio. When, in region II, this ratio has become larger, the randomly distributed large particles are no longer in mutual contact but are bridged by the more numerous small particles. These provide conductive pathways that become less effective as the dispersion becomes more dilute. In region III the graphite particles fail to make effective contact and the resistance becomes very high.

Solutions of $K_4\,Fe(CN)_6$ in 0.1*M* KCl were used at a potential of +0.80V to check the capabilities of the electrolysis systems. With 0.25*M* $K_4Fe(CN)_6$ in the GBC, the highest current density, obtained with a very thin paste layer, was 68 mA cm^{-1} for a total paste area of 20 cm^2. Titration of residual $K_4Fe(CN)_6$ with standard $KMnO_4$ solution was used to estimate current efficiencies. Values were close to 100% with

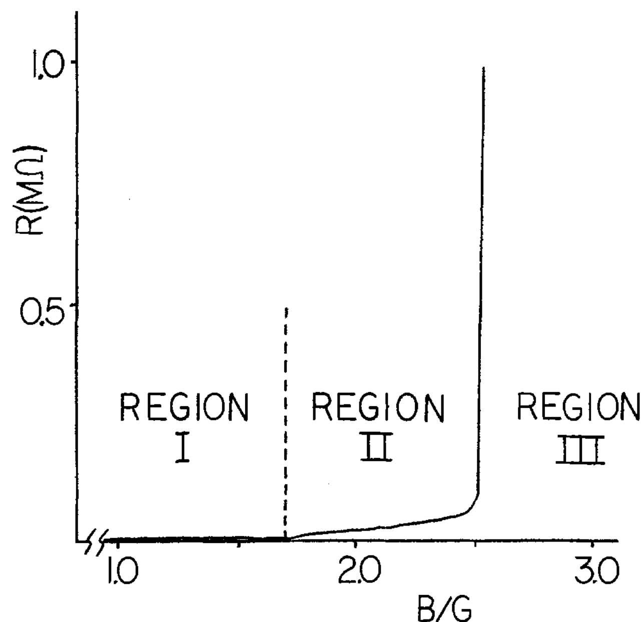

Fig. 3. Resistance as a function of B/G ratio for graphite-wax composites.

$K_4Fe(CN)_6$ concentrations up to approximately 8 m*M*, but became lower at higher concentrations.

Both systems have been used for the oxidative coupling of corypalline (7-hydroxy-6-methoxy-*N*-methyl-1,2,3,4-tetrahydroisoquinoline) and related compounds in aqueous media, with yields comparable to those obtained at graphite cloth or graphite felt electrodes (7). In particular, the simplicity of construction of the GBC and the ease with which its paste layer can be renewed make this system potentially useful for general oxidative syntheses. Experiments are now being made in which chiral and other liquids are used as binders in place of Nujol.

The GBC was used in an attempt to oxidize 1g of the hydrochloride of tyramine [*p*-(2-aminoethyl)-phenol] in 50 ml of 0.1*M* NaOH. At a potential of +0.80V, the current dropped from 80 mA to less that 1 mA within 2 sec. Several runs with the RDC under similar conditions showed that reasonable but somewhat fluctuating currents of 50-60 mA could be maintained for several hours, decreasing only when the substrate concentration was allowed to fall significantly.

In a preliminary report, Papouchado (8) concluded that 90-95% of the electrolytic oxidation products of tyramine were polymeric. On the basis of voltammetric and color-test data, these workers postulated that the nonpolymeric product was *p*-(2-aminoethyl)-*ortho*quinone. A run in the RDC with 3g of tyramine hydrochloride in 400 ml of 0.1*M* NaOH gave a current in the range 60-100 mA. The process was stopped when electricity equivalent to 2*e* per molecule of tyramine had been passed. The reaction mixture was rotary evaporated to dryness, using a hot water bath and reduced pressure (filter pump), and the residue was extracted with 50 ml of methanol. This solution was evaporated to a volume of approximately 5 ml, filtered, and the filtrate was transferred to four silica gel GF254 preparative TLC plates. Using 5% NH_4OH in methanol as developer, the presence of six products was inferred. The one preponderating was recovered in 0.4% over-all yield as a glass that softened at approximately 150°C. This material was identified by infrared and mass spectroscopy as a carbon-carbon "dimer" of tyramine, probably that shown at (a) in Fig. 4. (*IR*: peaks for aromatic C = C and O-H; ms: parent peak at m/e 272 and large peak at m/e 243). To support this identification, 7 mg of the product were acetylated and its mass spectrum was examined (parent peak at m/e 440, in line with formula (b) in Fig. 4; large peak at m/e 381.)

It appears that most of the tyramine is converted to dark-colored products that are probably polymers of the melanin type (9). The maintenance of the current by use of the RDC thus allowed an isolable quantity of a nonpolymeric product to be obtained in this extremely unfavorable case.

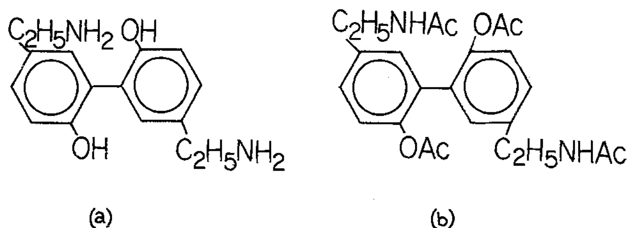

Fig. 4. (a) Carbon-carbon "dimer" of tyramine (b) acetylated "dimer."

Electrochemical Studies of Antitumor Antibiotics

III. Daunorubicin and Adriamycin

Gopalakrishna M. Rao,* J. William Lown, and James A. Plambeck*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

ABSTRACT

Daunorubicin and adriamycin, anthracycline antibiotics, have been investigated by polarography, cyclic voltammetry, and chronopotentiometry in aqueous media at 37.5°C, as have their aglycones daunomycinone and adriamycinone. A mechanism is proposed to explain the complex reduction behavior observed. The significance of the mechanism is discussed in relation to the antineoplastic and cardiotoxic activity of the clinically useful daunorubicin and adriamycin.

Daunorubicin, **1**, a fungal metabolite isolated from *streptomyces peucetius* (which also produces the related tetracyclines) is a member of the anthracycline class of antitumor antibiotics which includes adriamycin, cinerubin, rhodomycin, rutilantine, pyrromycin, nogalamycin, and carminomycin (1). These glycosidic antibiotics are among the most effective antineoplastic agents and show activity against a variety of experimental tumors and certain types of human cancer (1, 2). Daunorubicin was the first compound to show therapeutic effect in the treatment of acute leukemia in man (2). Biochemical evidence indicates that daunorubicin and adriamycin are metabolized in rat liver by an NADPH-mediated "daunorubicin reductase," an aldo-keto reductase, to daunorubicinol and adriamycinol, respectively (3, 4). Enzymatic reduction of the carbonyl group of daunorubicin occurs more readily than does that of adriamycin (5, 6). Daunorubicinol is the major excretion form of daunorubicin and is a major form of the drug in tissues (3); it has cytotoxic properties and is an important component in the action of the drug (3). Another important metabolic pathway leads to reductive cleavage of the glycosidic linkage to produce the 7-deoxyaglycones (6). The anthracyclines are currently considered to act by selective inhibition of both DNA-directed DNA synthesis and DNA-directed RNA synthesis in part by strong intercalative binding to duplex DNA in the cell nucleus; this binding prevents unwinding and strand separation during the semiconservative replication process (1).

There have been reports of chromosomal damage as a result of daunorubicin administration (7, 8). Similarly the marked immunosuppressive action of the anthracyclines appears to be related to the degradation of nucleic acids in blood lymphocytes (9-11). The chemical mechanism of this degradation of nucleic acids has not been investigated. However, there is a structural similarity between the quinone moiety of the anthracyclines and that of streptonigrin (12), mitomycins B and C (13), and certain 5:8-quinolinediones (14) which show antitumor properties and which we have shown cleave DNA after reduction by a common mechanism involving generation of superoxide radical anion and hydroxyl radicals (15-18). One therefore anticipated that a similar mechanism operates for the anthracyclines, which would have the added advantage of being firmly bound to the target DNA. We have recently confirmed that this process occurs between daunorubicin or adriamycin and supercoiled covalently closed circular DNA in the presence of a reducing agent (19).

Chemotherapeutic treatment of cancer employing daunorubicin and adriamycin is hampered by dose-related cardiotoxic effects (20-23) which have been shown to be associated with their inhibition of coenzyme Q_{10} mediated enzymes in mitochondria of the myocardium and with interference of electron transport processes and oxidative phosphorylation and which clearly involve the oxidative power of the anthracyclines (24-29).

For these three separate reasons a detailed study of the redox behavior of the anthracyclines is of interest. An earlier polarographic study of Calendi *et al.* shows a polarographic reduction wave with a formal potential of -0.6V for daunorubicin; however, depolarizer concentration and other polarographic parameters were not reported (30). Moreover, these authors argued that the disappearance of this polarographic wave when DNA was added to daunorubicin was evidence for the formation of a DNA-daunorubicin complex. It is well known that DNA adsorbs on mercury at this potential range (31), which makes this explanation unlikely. Therefore, we report the electrochemical reduction of daunorubicin (**1**), adriamycin (**1b**), and their aglycones *in vitro*, together with such related processes as are accessible to electroanalytical investigations. The structures of **1**, **1a**, and **2** (7-deoxydaunomycinone) are given in Fig. 1; the structure of adriamycin, **1b**, is identical to that of daunorubicin, **1**, except that the $—COCH_3$ ketone side-chain of daunorubicin is replaced by $—COCH_2OH$ in adriamycin.

Experimental

Daunorubicin hydrochloride (daunomycin), **1**, obtained from Calbiochem, was used without further purification. Experimental studies were carried out at three concentrations, 1.9×10^{-4}, 7.8×10^{-5}, and 1.9×10^{-5}M. The concentrations were determined spectrophotometrically on a Cary 118 spectrophotometer using the molar extinction coefficient of 11.4×10^3 at 485 nm (3). The solution was buffered at *p*H 7.1 with 0.1M phosphate buffer in 0.1M KCl in most of the experiments; however, the *p*H of the solution was varied from 6 to 8 in the *p*H-dependence study. The absorption spectrum includes a broad peak around 480 nm in the visible region which was used for analysis and three peaks at 290, 253, and 233 nm in the ultraviolet region.

The aglycone daunomycinone, **1a**, was prepared by acid hydrolysis of the antibiotic according to a literature procedure (32). The absorption spectrum of **1a** differs from that of **1**; the peak at 480 nm is broadened, the peaks at 233 and 290 nm are displaced to 228 and 310 nm, and the 253 nm peak is unchanged. The sample solution of **1a** was prepared as were the sample solutions of **1**. Its concentration was measured spectrophotometrically as 1×10^{-5}M, the maximum concentration which could be achieved due to the low solubility of this compound (33).

Key words: polarography, cyclic voltammetry, antibiotic, daunomycin, daunorubicin.

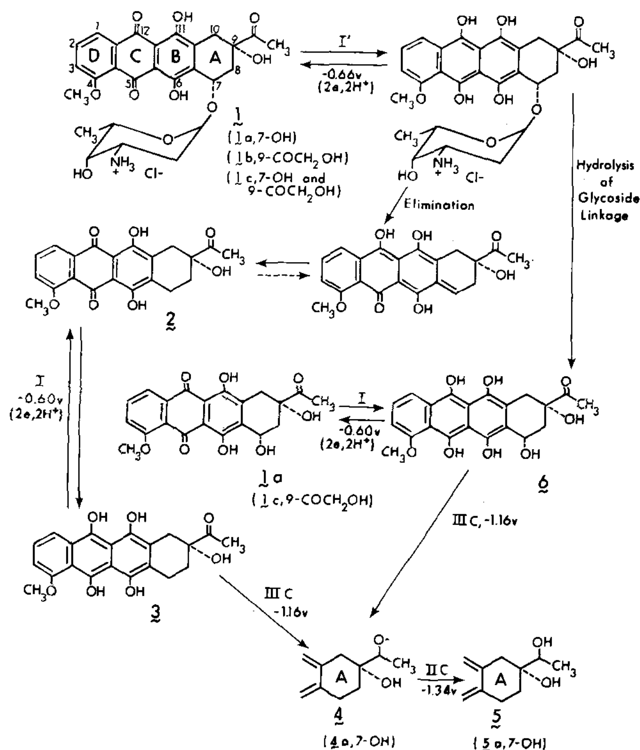

Fig. 1. Electrochemical reduction mechanism proposed. Only the part of the molecule involved in IIIC and IIC is shown for these steps. Potential of processes I and I′ are those for reversible behavior while potentials of IIC and IIIC are experimental peak potentials.

Solutions of the more soluble adriamycin, **1b**, (NCI sample) were 4.0×10^{-4}M and were otherwise prepared and used in the same manner as those of daunorubicin. The aglycone adriamycinone, **1c**, was prepared by acid hydrolysis (32) of adriamycin.

All other experimental conditions were as previously described (34); all potentials were measured and are given with respect to the aqueous saturated calomel electrode.

Results

Daunorubicin, **1**.—The classical d-c polarogram of 1.9×10^{-4}M daunorubicin at 5 sec drop time (0.0-−0.9V) showed two waves with a surface-complicated second wave plateau (Fig. 2) unlike the previously reported two-electron reversible single wave (30). The approximate half-wave potentials of these peaks are, for IC, −0.58V and, for I′C, −0.63V at *p*H 7.1; the average of these two values is close to the literature value of −0.6V (30).

Differential pulse polarography (0.0-−1.6V) gave four peaks depending upon both the drop time and the concentration (Fig. 3). The peak IC appeared at −0.59 ± 0.01V for all drop times 0.5-5 sec. Increasing the concentration had no effect on the peak potential at drop times 0.5-2 sec; at a drop time of 5 sec, however, a shoulder replaced peak IC as the concentration increased. The peak I′C appeared at −0.655 and −0.630V in the solution of 1.9×10^{-4} and 7.8×10^{-5}M, respectively. This peak was always a shoulder at 2 sec and almost undetectable at 0.5 sec even for the 1.9×10^{-4}M solution. Peak IIIC appeared at −1.14V at higher concentrations; the same process appeared as a wave in 1.9×10^{-5}M solution. The peak IIC appeared at −1.32V at all concentrations and drop times.

Chronopotentiometric studies confirmed the presence of all the processes mentioned above. The process that corresponds to the potential of wave IC influences the chronopotentiometric wave I′C. The combined wave has $E_{\tau/4} = -0.63 \pm 0.01$V; $E_{\tau/4}$ is the chronopotentiometric equivalent of the polarographic half-wave potential. The $i\tau^{-1/2}$ product for this wave increases with the increase in current; its chronopotentiometric constant $i\tau^{1/2}$ is proportional to $C^{0.67}$.

Figure 4 is a typical cyclic voltammogram of a *p*H 7.1 daunorubicin solution at 500 mV/sec. It shows three cathodic peaks (IC-IIIC) and one anodic peak (IA). A broad anodic peak also appears close to −0.2V. Multicycle runs showed, in addition to I′C, two more cathodic peaks at about −1.08 and −1.25V; the peak at −1.25V is better defined in alkaline solutions. These two additional cathodic peaks may appear during the first cycle at slow scan rates and, at higher scan rates, in alkaline solution. The cathodic peaks IIIC and IIC appeared at −1.16 ± 0.02V and −1.34 ± 0.02V at $\nu = 500$ mV/sec for solutions of *p*H 6-7.5; both these peaks were barely visible at *p*H > 7.5. No characterizable peaks appeared between −0.9V and the supporting electrolyte discharge in the

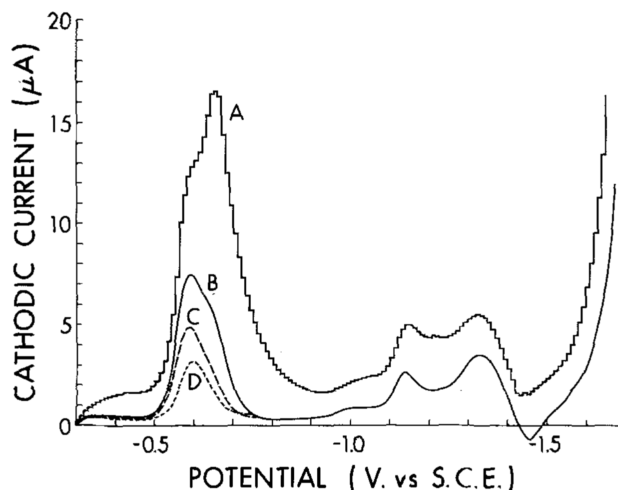

Fig. 3. Differential pulse polarogram of **1** (1.9×10^{-4}M), pH 7.1 in phosphate buffer, 37.5°C, ν = 2 mV/sec; drop times: A, 5 sec; B, 2 sec; C, 1 sec; D, 0.5 sec.

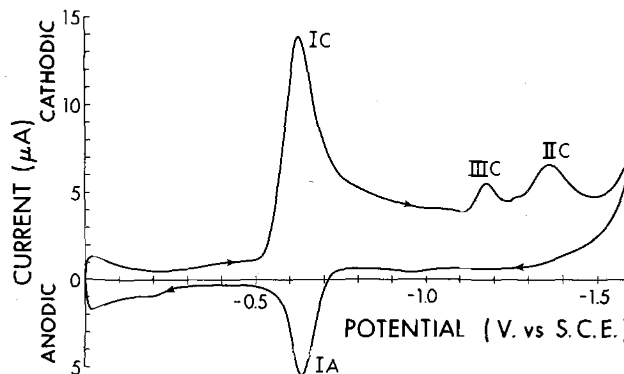

Fig. 4. Cyclic voltammogram of **1** (1.9×10^{-4}M), *p*H 7.1 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

vicinity of −1.2V when the *p*H of the solution was changed from 6.52 to 3.1. Restoring the *p*H of this solution to neutral caused these peaks to reappear. All these cathodic peaks appeared to shift anodic as the scan rate decreased; the relative shift for IIC was greater than IIIC. The appearance of these cathodic peaks and the absence of the corresponding anodic peaks indicates that these processes are not reversible.

Most of the cyclic voltammetric studies were restricted to the potential range of −0.3-−0.9V to avoid complications arising from the processes outside this potential range. With the range thus restricted, only IC, I′C, and IA were visible depending on the scan rate, concentration, and the *p*H of the solution.

The cathodic peak IC is prominent in 1.9×10^{-4}M solution of *p*H 7.1 at scan rates above 100 mV/sec. Below 100 mV/sec, the peak IC appeared either as a small peak or a shoulder (Fig. 5). The scan rate at which IC first appeared as a shoulder decreased as the concentration decreased and increased as the *p*H of the solution increased. The peak potential of IC is −0.62 ± 0.01V, independent of scan rate, up to 2 V/sec, and thereafter is shifted cathodic by 30-40 mV for each tenfold increase in scan rate. The $I_p\nu^{-1/2}$ product increased with the increase in scan rate; an approximate relationship of $I_p\nu^{-1/2}$ proportional to $C^{0.4}$ is obtained from the concentration dependence. Such a concentration dependence on current was observed for anthraquinones by Broadbent and Zollinger (35). According to these authors, the limiting current for the more positive wave was independent of concentration only above 10^{-4}M, the upper limit of the present study. A value of αn of approximately 1.4 can be calculated from the difference between the peak potential and the half-peak potential. This, and the *p*H dependence of peak potential of 58 mV/*p*H-unit for IC, suggests that the electrode process taking place at this peak potential may be an irreversible two-electron, two-proton process.

The potential of the anodic peak IA is −0.64 ± 0.01V, independent of scan rate, up to 500 mV/sec, and thereafter is shifted anodic by 30-40 mV for each tenfold increase in scan rate. The $I_p\nu^{-1/2}$ product increased with increase in scan rate. This peak potential has a *p*H dependence of 58 mV/*p*H unit. The peak IA appeared cathodic to IC at $\nu \leqq 2$ V/sec and anodic to IC at $\nu \geqq 2$ V/sec. The anodic peak sometimes became sharp, especially in 7.8×10^{-5}M solution (Fig. 6), in the vicinity of scan rate 100 mV/sec when I′C is approximately equal to IC, during the multicycle run at slower scan rates (Fig. 5), or upon excursion to very negative potential in a single cycle. The ratio of anodic to cathodic current of process I is constant at about 0.4 for $\nu \leqq 50$ mV/sec and then increases, reaching a value of 0.9 at 50 V/sec (except when IA is sharp or the solution is very acidic). This ratio passes through a maximum in the scan rate region where IA is sharp. In acidic solution, say *p*H = 3.1, the ratio I_p (IA)/I_p (IC) is almost unity at 100 mV/sec $< \nu <$ 50 V/sec, which is the scan rate limit at this *p*H. All these facts suggest that the process or processes giving rise to peak IA show the combined influence of the two cathodic processes of I and I′. The observed single anodic peak IA may arise from two separate but indistinguishable anodic processes, those of I and I′. In 1.9×10^{-4}M solution of *p*H 7.1, the height of the peak I′C is greater than that of the peak IC at $\nu <$ 100 mV/sec. The peak I′C began to become noticeable at slower scan rates as the concentration of the solution decreased and at higher scan rates as the solution *p*H increased. The peak I′C appeared as a shoulder to the peak IC in the solution of *p*H 6.5 at ν = 100 mV/sec; it disappeared upon acidification to *p*H 3.1 and reappeared when the solution *p*H was restored to neutral. The peak potential of I′C is −0.67 ± 0.01V independent of scan rate. The separation of peak potential between I′C and IA is about 30 ± 5 mV. This, and the *p*H dependence of 58 mV/*p*H unit for the peak I′C, suggests that the process occurring at the potential correspond-

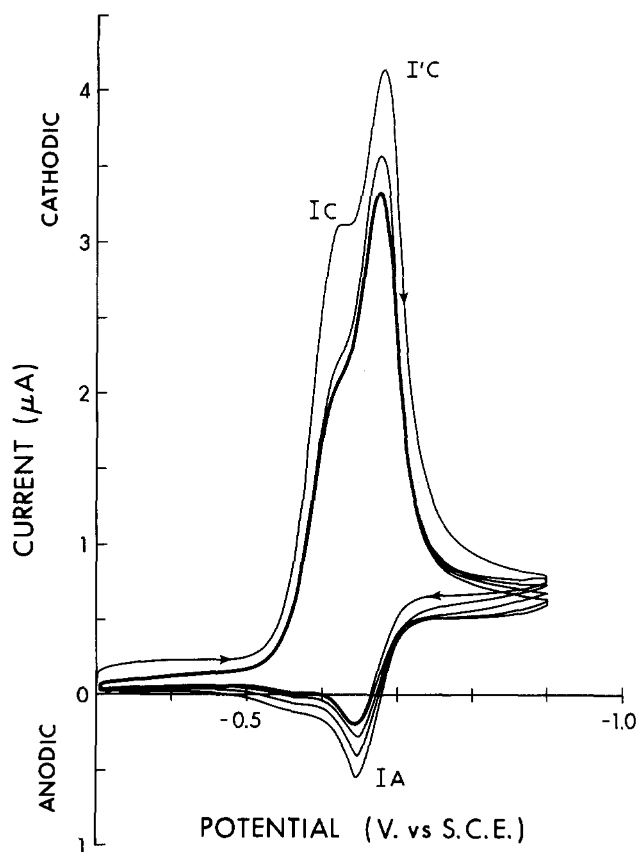

Fig. 5. Multicycle voltammogram of 1 (1.9×10^{-4}M), *p*H 7.1 in phosphate buffer, 37.5°C, ν = 50 mV/sec. Cathodic peaks decrease and peak IA increases with cycling.

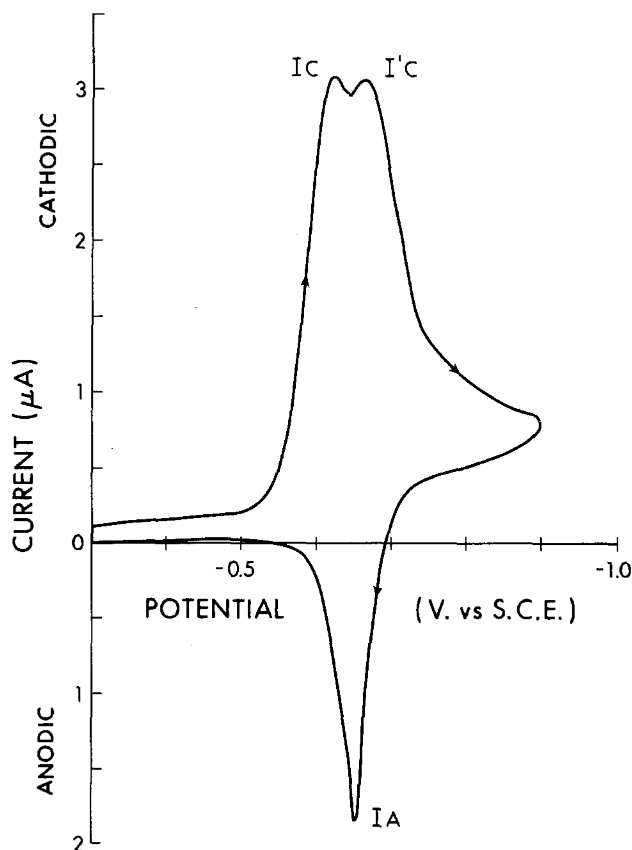

Fig. 6. Cyclic voltammogram of 1 (7.8×10^{-5}M), *p*H 7.1 in phosphate buffer, 37.5°C, ν = 100 mV/sec.

ing to the I′C is a two-electron, two-proton process. The $I_p\nu^{-1/2}$ product increased with the decrease in scan rate and the concentration dependence of $I_p\nu^{-1/2}$ is proportional to $C^{0.67}$, a similar relationship to that observed in the chronopotentiometric studies.

In multicycle runs, the peak IC observed on the first cycle disappeared in the second and subsequent cycles (Fig. 5 and 7). In the second cycle (at ν = 500 mV/sec for the solution of 1.9 × 10^{-4}M of pH 7.1), the height of the peak IA is increased, the height of the new peak I′C is greater than that observed for IC in the first cycle, and the peak separation between the peaks I′C and IA is 30 ± 5 mV. This value of 30 mV peak separation suggests a reversible two-electron process as explained above. Further cycling shows normal behavior, which is a slow decrease in peak height, with a slight or no change in peak potential, as the number of cycles increases. In ten times diluted solution, the height of the new peak I′C in the second cycle is, however, smaller than that of the peak IC in the first cycle (Fig. 7). Multicycle runs at slower scan rate showed similar behavior, but the peak IA grew sharper as the number of cycles increased (Fig. 5).

Daunomycinone, **1a**.—Solutions of daunomycinone at pH 6.86 gave three cathodic-anodic couples (Fig. 8), and two additional cathodic peaks.

Couple I has a cathodic peak IC (−0.60 ± 0.01V, independent of scan rate up to 20 V/sec) and an anodic peak IA (−0.604 ± 0.01V independent of scan rate up to 5 V/sec). At faster scan rates, the cathodic peak

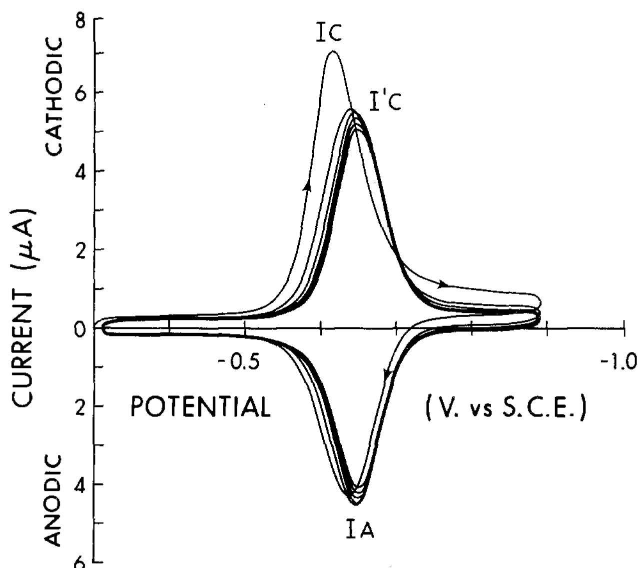

Fig. 7. Multicycle voltammogram of **1** (1.9 × 10^{-5}M), pH 7.1 in phosphate buffer, 37.5°C, ν = 500 mV/sec. First cycle indicated by arrows.

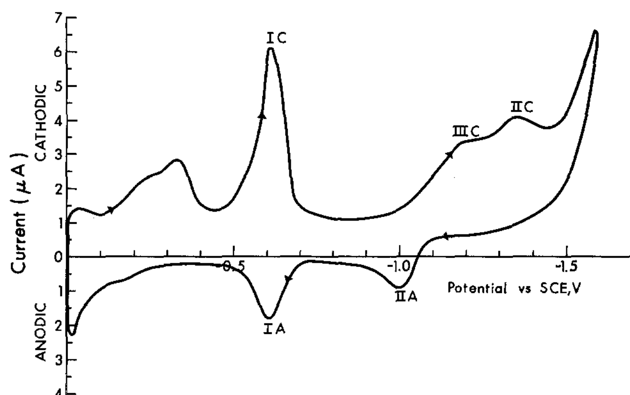

Fig. 8. Cyclic voltammogram of **1a** (approximately 1 × 10^{-5}M), pH 6.86 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

shifted more negative and the anodic peak shifted more positive with increase in scan rate. The ratio of the anodic current to the cathodic current is closer to unity above 500 mV/sec, but this ratio decreased with decrease in scan rate. When the potential range was restricted (−0.4-−0.8V) a current ratio of unity was obtained. The potential difference between the peak potential and the half-peak potential for the cathodic peak is approximately as expected for a two-electron process.

The cathodic peak IIC of couple II appeared at −1.35 ± 0.02V for ν = 500 mV/sec and shifted anodic as the scan rate decreased. The corresponding anodic peak IIA appeared at −1.00 ± 0.01V at ν < 1 V/sec.

A new couple not visible in daunomycin voltammograms, designated IV, was clearly present in those of **1a**, daunomycinone. This couple consisted of a broad cathodic peak IVC which at 50 mV/sec had a potential of −0.195V; a shoulder was present on the positive side. The peak potential became more negative and the peak became better defined as the scan rate was increased. The corresponding but smaller anodic peak IVA had a peak potential of −0.130V at ν = 50 mV/sec (shoulder on negative side). The peak potential became more positive with increasing scan rate and could no longer be distinguished from mercury dissolution at ν > 200 V/sec.

The cathodic peak IIIC was visible at scan rates below 1 V/sec, had a cathodic peak potential of −1.16 ± 0.01V and shifted slightly anodic as the scan rate decreased. Multicycle runs (0-−1.6V) did not show any additional peaks, but IC shifted cathodic with continued cycling until the peak potential of IC equaled that of I′C.

Adriamycin, **1b**.—The behavior of adriamycin was very similar to that of daunorubicin; the major peaks IC, IA, I′C, IIC, and IIIC, as well as the minor peaks, were observed. The slight differences in peak potential are summarized in Table I.

With adriamycin, repeated cyclic voltammetry to −1.6V gave rise to a new process (cathodic E_p −0.26V and anodic E_p −0.17V) which was barely observable on the curves. These are similar to the process IV which appear on the cyclic voltammetric curves of daunomycinone. Corresponding processes IV can barely be distinguished on a few of the curves for the most concentrated solutions of daunorubicin.

Adriamycinone, **1c**.—Solutions of adriamycinone at pH 7.04 gave cyclic voltammograms very similar to those of daunomycinone. Well-defined peaks were observed for IC, IA, IVC, and IVA (peak potentials −0.604, −0.600, −0.194, −0.123V at ν = 100 mV/sec). The cathodic processes IIC and IIIC, though present, were extremely ill defined; a peak IIA was distinguishable at −0.99V. Process I′ was clearly absent in both daunomycinone and adriamycinone.

Discussion

The mechanism proposed to account for the observed behavior of these compounds is shown in Fig. 1. The process I′ is ascribed to the reversible two-electron,

Table I. Peak potentials observed for antibiotics (against aqueous SCE)

Process	Peak potential		
	Daunomycinone (Volts)	Daunorubicin (Volts)	Adriamycin (Volts)
IC	−0.600 ± 0.01	−0.620 ± 0.01	−0.620 ± 0.01
IA	−0.604 ± 0.01	−0.640 ± 0.01	−0.625 ± 0.01
I′C	Absent	−0.670 ± 0.01	−0.660 ± 0.01
IIC	−1.35 ± 0.02	−1.34 ± 0.02*	−1.41 ± 0.02*
IIIC	−1.16 ± 0.01	−1.16 ± 0.02*	−1.18 ± 0.02*

* pH independent; all other processes at pH 7.0 ± 0.1. Scan rate in all cases 100 mV/sec.

two-proton reduction of the quinone group of daunorubicin, **1**, and adriamycin, **1b**, at a formal potential of -0.66 ± 0.02V against SCE. Precise measurement of this reversible process is prevented by two competing subsequent irreversible processes. First, rapid and irreversible elimination of the amino sugar moiety occurs, giving rise to 7-deoxydaunomycinone, **2**. This process parallels the principal pathway for human metabolism of the anthracyclines (36, 37). Like the parent antibiotic, **2** is capable of a reversible two-electron, two-proton reduction of the quinone group. Mild chemical reduction ($Na_2S_2O_4$) of **1** results in quantitative conversion to **2**, supporting this proposed process (38). Second, hydrolytic cleavage of the hydroquinone of **1** gives rise to the reduced form of the aglycone **1a**.

By either route, a system is formed (**2-3** or **1a-6**) which is a quinone-hydroquinone system capable of reversible two-electron, two-proton reduction. A further possible step would be dehydration at C_7 and C_9 of ring A to introduce aromaticity. In all of these three cases the structures are very similar, and the redox process I may involve contributions from them all. However, we believe that the elimination-tautomerism route through **2** is the most probable. The formal potential of I is -0.62 ± 0.02V, the potential being slightly less negative when the amino sugar is absent (**1a**, **1c**) than when it is present (**1**, **1b**), so that following reduction the hydroquinone forms will be present.

Once formed the hydroquinones such as **3** and **6** are capable of further reduction only at considerably more negative potentials where reduction of the side-chain carbonyl group on ring A can take place. This occurs in two irreversible one-electron steps designated IIIC (-1.16V) and IIC (-1.34V) to produce the final product alcohol. Such a mechanism is consistent with the experimental electrochemical data. The mechanism for adriamycin is identical to that for daunorubicin.

Quinone redox processes I and I'.—The two waves observed in the classical polarographic measurements correspond to the process I' and I, reduction of **1** and of **1a** or **2**, respectively, and represent kinetic rather than equilibrium reduction of the latter; the close similarity of half-wave potentials may explain why the separation was not observed by earlier workers (30) since differential pulse polarography is required to distinguish them clearly. The kinetic nature of I' is clearly evident from the effect of drop time shown for the two differential pulse polarograms of Fig. 3; the chemical steps take place within 3 sec, and the half-times of these heterogeneous steps (which are not directly comparable to similar homogeneous chemical kinetic steps) are 1 sec or less, since at such speeds their effect disappears.

The appearance of the combined waves IC and I'C in chronopotentiometry confirms the complication in separating the two processes. Moreover, the increase in $i\tau^{1/2}$ with increasing current is evidence for ECE mechanisms (39) such as are proposed here.

Cyclic voltammetry further characterizes the chemical step between the two charge-transfer steps for the reduction of **1** and **2**. The solubility of daunomycinone in water is low (32) as evident from the observation reported in this work such as low absorption in spectrophotometry and the smaller peak currents in cyclic voltammetry of **1a** compared to **1**. The charge transfer process I' appears to be an irreversible two-electron, two-proton process, but the irreversibility is due to the influence of the following chemical step. The facts to account for by the chemical step are: (*i*) the reversibility of process I for **1a** and **1c**, and the apparent reversibility of I at high scan rates for **1** and **1b**; (*ii*) the continued appearance of I'C and disappearance of IC in the subsequent cycles of a multicycle voltammogram of **1** (Fig. 7); and (*iii*) the influence of cathodic peaks IC and I'C on the anodic peak IA. In consideration of the last point, the anodic peak IA, at least at lower scan rates, behaves as the anodic counterpart of both. Under these conditions of slower speed, the charge-transfer process I' can have no anodic counterpart since the corresponding hydroquinone undergoes chemical reaction and is not available for reoxidation, and an anodic peak I'A should not be observed.

The rate of the irreversible chemical reaction that follows the initial reduction of **1**, breakage of the glycoside linkage, and tautomerization can be estimated from the cyclic voltammetry (34). Use of the anodic/cathodic peak current ratios of the voltammetric curves does not give a satisfactory value of k_f. However, the rate constant k_f can be estimated from the scan rate at which the peak I'C appears and the time required to scan between IC and I'C. The value is about 1 sec^{-1} and comparable with the half-time of 1 sec or less estimated from polarography.

Sidechain carbonyl reduction processes IIC and IIIC.—The nonreversible reduction processes IIC and IIIC are ascribed to the reduction of the side-chain carbonyl groups on the basis of their similarity to the reduction processes of acetophenone and 1'-acetonaphthone (40) and our observation that these peaks are absent when the side-chain carbonyl is protected by a ketal group. With the additional benzene ring in 1'-acetonaphthone, two separate peaks are observed (40). We attribute the peaks IIIC (-1.16V) and IIC (-1.34V) to the reduction of the side-chain carbonyl group on ring A as shown in Fig. 1.

The generally accepted reduction mechanism for the side-chain carbonyl compounds (aryl alkyl ketones) in neutral media (41) is:

$$ArCOR + e \rightarrow Ar\overset{\dot{-}}{C}OR$$

$$Ar\overset{\dot{-}}{C}OR + H^+ \rightarrow Ar\dot{C}(OH)R$$

$$AR\dot{C}(OH)R + e \rightarrow Ar\overset{-}{C}(OH)R$$

$$Ar\overset{-}{C}(OH)R + H^+ \rightarrow ArCH(OH)R$$

which is two one-electron processes each followed by a protonation step. Our data do not unambiguously show two one-electron steps each followed by protonation, and the mechanism shown in Fig. 1 therefore does not distinguish the protonation process.

Adriamycin gives peak IIC some 70 mV more cathodic than does daunorubicin, indicating that the reduction to the alcohol is considerably easier for daunorubicin than for adriamycin. This is consistent with the observed greater metabolic reduction to daunorubicinol (50-60%) than to the corresponding adriamycinol (15-20%) (3).

Other processes.—The surface complication on the diffusion-limited plateau apparent from the shape of the *i-t* profiles of the individual drops in the classical d-c polarography (Fig. 2) at potentials more negative than -0.7V may well be adsorption of **3** or **6** since the shape of the drops below this plateau is the normal rise expected for $t^{1/6}$ dependence. Sharp peaks observed in cyclic voltammetry at the slower scan rates or in the subsequent cycles of the multicycle run (Fig. 5 and 6) confirm the adsorption of **3** as these sharp peaks were attributed to two-dimensional phase transitions in the adsorbed layer or to lateral interactions between the adsorbed atoms (42).

The process IV occurring at potentials more positive than IC for **1a** and **1c** cannot be unambiguously defined, although it is discussed further in the following paper (40). This process was not found in the parent antibiotics at other than the trace level expected for very slight hydrolysis.

Conclusions

The proposed mechanism for the electrochemical reduction of daunorubicin is consistent with the view of Di Marco *et al.* (1). The metabolic transformation con-

sists of reductive modification of the chromophore associated with breakage of the glycosidic linkage with the formation of the 7-deoxydaunomycinone and similar species. Our experimental findings do not demonstrate the formation of daunorubicinol. Our observations, however, do not preclude the formation of daunorubicinol during enzymatic reduction (3), since the aldo-keto reductase involved in the side-chain reduction is unable to reduce the quinone functional group to its hydroquinone. Moreover, the quinone group hydrogen-bonded to adjacent hydroxyl groups, as in the present case of intramolecular hydrogen bonding between the C_5, C_{12} quinones and the C_6, C_{11} hydroquinones, is known to remain unaffected by some chemical reducing agents; for example, reduction of 1-hydroxyanthraquinone by zinc in the presence of acetic acid yields 1-hydroxyanthrone (43). The effect of hydrogen bonding upon the redox chemistry of these compounds is discussed further in the following paper (40).

The electrochemical results demonstrate that the quinone ring C of the anthracycline is more difficult to reduce than for example mitomycin C (32) (redox potentials of −0.600, −0.650, and −0.385, −0.468V respectively). The identical ring C redox potentials of daunorubicin and daunomycinone confirm that the more extensive degradation of DNA by the parent antibiotic than of the aglycone is due to the strong binding of the amino sugar moiety of the former to the DNA target (19).

In summary the present studies provide an electrochemical basis for interpreting the degradation of DNA that accompanies clinical administration of daunomycin, of the cardiotoxic side effects that depend directly on the oxidative capacity of the chromophore, and of its reductive enzymatic metabolism to 7-deoxydaunomycinone.

Acknowledgment

We are grateful to Dr. S. K. Sim of this Department for the preparation of **1a** and **1c** and to the National Research Council of Canada for support of this research through Operating Grants to J.W.L. and J.A.P. and to the National Cancer Institute of Canada for a research grant to J.W.L.

Manuscript submitted June 1, 1977; revised manuscript received Dec. 13, 1977. This was presented in part as Paper 273 at the Philadelphia, Pennsylvania, Meeting of the Society, May 8-13, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Electrochemical Studies of Antitumor Antibiotics

IV. Electrochemical Studies of Daunomycinone Analogues

Gopalakrishna M. Rao,* J. William Lown, and James A. Plambeck*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

ABSTRACT

Certain synthetic analogues of daunomycinone have been investigated by cyclic voltammetry in aqueous media at 37.5°C. The experimental results have been of significance in establishing the electrochemical reduction behavior of daunomycinone and the related compounds daunorubicin and adriamycin described in the preceding paper.

Daunorubicin[1] and adriamycin are members of the anthracycline class of antibiotics which are among the most promising for the alleviation of cancerous conditions in humans (1). A serious disadvantage of these drugs is their cardiotoxicity or congestive heart failure, which occurs in 20-30% of patients treated (2-6) and also their currently high price since the isolation yield from the fungus *streptomyces peucetius* is low. Consequently there is considerable current interest in developing viable synthetic approaches to these valuable drugs and the preparation of analogues having improved therapeutic indices.

To date research has concentrated on modifications of the anthracycline or aglycone portion of the molecule, since it has been shown that the amino sugar daunosamine is essential for anticancer activity. Substitution of other molecules for the amino sugar, such as a β-alanine ester of the 7-hydroxy group on the anthracycline, destroyed antitumor activity *in vivo* (7). Two independent total syntheses of the aglycone of daunorubicin and carminomycinone have been reported (8, 9) as well as the subsequent glycosidation with daunosamine (10). Adriamycin may also be prepared from the synthetic daunomycinone (7, 11) and some adriamycin analogues have been described (12).

Recent work has shown that microbial biomodification is useful in the preparation of analogues. Thus bacterial metabolism of daunorubicin by *streptomyces steffisburgensis* produced 7-deoxydaunomycinone and its carbonyl-reduced counterpart by NADPH mediated enzymatic side-chain reduction of the antibiotic (13). This work demonstrated that microbial metabolism of anthracyclines follows the same pathway previously demonstrated for mammalian metabolism.

In the preceding paper (14) we examined the redox behavior of daunorubicin by electroanalytical techniques as it pertains to three separate aspects of chemotherapy by the drug: (*i*) Metabolism by daunorubicin reductase which reduces the side-chain acetyl group and produces biologically active metabolites; (*ii*) cardiotoxicity which is associated with the interference with electron transport processes and oxidative phosphorylation; and (*iii*) chromosomal degradation which may result from single strand cleavage of nucleic acids by radicals produced by the drug *in vivo*.

To further characterize the effects of structural changes in the anthracycline moiety on these processes, we describe in the present paper the electroanalytical examination of a series of synthetic daunomycinone analogues which may prove useful in the prescreening of potential antitumor agents and assist in the molecular interpretation of the electrochemical behavior of daunomycin as reported in the preceding paper (14).

* Electrochemical Society Active Member.

Key words: cyclic voltammetry, antibiotic, daunomycin, quinone, antitumor, adriamycin.

[1] The parent antibiotic is currently called daunorubicin, but its aglycone is referred to as daunomycinone.

Experimental

Compounds **1**, **2**, and **3** were obtained from Dr. C. M. Wong, University of Manitoba, Canada, and were used as received. Reagent grade acetophenone (compound **5**) from Fisher Scientific Company was used without further purification. Technical grade 1'-acetonaphthone (compound **6**) from Eastman Kodak Chemicals was distilled under reduced pressure before use. Compound **4** was prepared by Dr. C. K. Majumdar of this department from **3** by refluxing 4 mg with a trace of *para*-toluenesulfonic acid in 3 ml toluene for 16 hr. Toluene was removed *in vacuo* and the residue was dissolved in 1 ml of chloroform, passed through a neutral alumina column (4 × 1 cm), and eluted with chloroform. Removal of the chloroform *in vacuo* gave about 3 mg of **4** as an orange solid. Its characteristics were: mp 197°-199°C, pmr δ ($CDCl_3$): 2.77 (s, 3H); 4.02 (s, 3H), 4.12 (s, 3H), 7.20-8.94 (m, 6H); infrared (KBr disk): 1680, 1670 cm^{-1} (=C=O); molecular ion (mass spectrum): 390.1108; calculated for $C_{23}H_{18}O_6$ 390.1116. The structures of these compounds are shown in Fig. 1. The solubility of these compounds in water is very low, and increases in the order $1 < 4 < 2 < 3 < 6 < 5$. Therefore, a known amount of the samples (400-700 μg

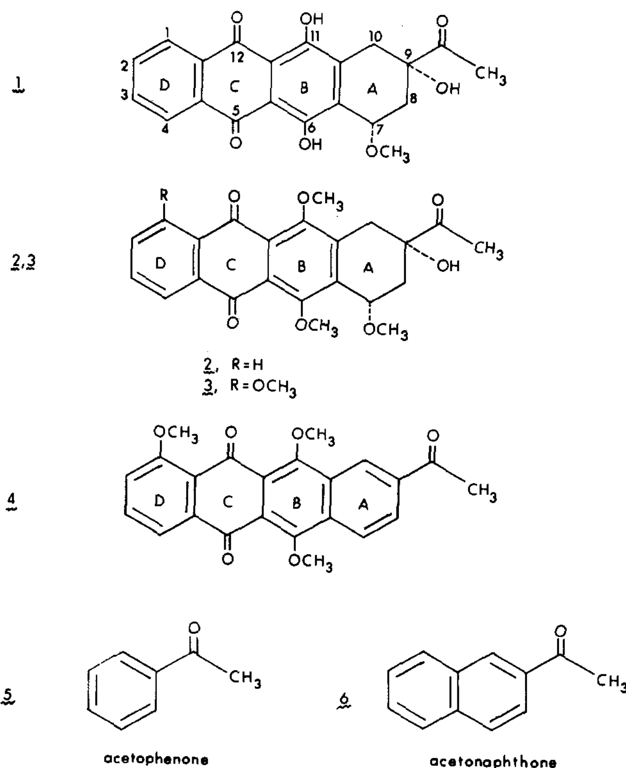

Fig. 1. Structures of compounds studied

for 1-4 and 1 mg for 5-6) were directly weighed into 5 ml of solution buffered at pH 7.04 ± 0.03 with 0.1M phosphate buffer in 0.1M KCl. However, not all of this material dissolved so that the actual concentrations correspond to saturated solutions of each of these compounds. These solutions were deaerated with nitrogen gas and stirred for 15 min prior to each experiment at 37.5° ± 0.02°C. Cyclic voltammetry, which was used in this study, and other procedures were described previously (15); all potentials were measured and are given with respect to the aqueous SCE.

Results

The peaks and processes described here follow the identification I, II, III, ... of the preceding paper (14).

Compound **1**.—At 500 mV/sec, compound **1** gives four cathodic peaks at −0.465V (I*C), −1.095V, −1.170V (IIIC), and −1.47V (IIC) and two anodic peaks at −0.438V (I*A) and −0.682V (IA) (Fig. 2). In the second cycle, two additional cathodic peaks appeared, one at about −0.2V and one at −0.687V (IC) (Fig. 3). In one of the experiments, about 2 mg of **1**, a relatively large amount compared to 430 μg in the above mentioned study was added to the 5 ml of buffer. A broad cathodic peak at a potential less negative than −0.2V, a cathodic peak at −1.27V, and one or two anodic peaks (or waves) at potentials more positive than −0.2V were observed, of which the first broad cathodic peak disappeared in the subsequent cycles. The peaks IC and IA appeared only when the cathodic-to-anodic scan reversal potential was more negative than −1.1V. The peak potentials of I*C and I*A shift, the cathodic peak shifting anodic and the anodic peak shifting cathodic, by 10 mV for each tenfold decrease in scan rate. The $I_p\nu^{-1/2}$ product for both I*C and IC decreases with decrease in scan rate. It is apparent from Fig. 3 that the ratio of anodic-to-cathodic peak currents for both processes I* and I are slightly greater than unity at ν = 500 mV/sec. Dependence of these ratios on scan rates, including 500 mV/sec, may not be of much value due to extreme difficulty in locating the base lines for IC and I*A.

Compound **2**.—The compound **2** gives two cathodic peaks (I*C, IIC) and two anodic peaks (I*A, IIA)

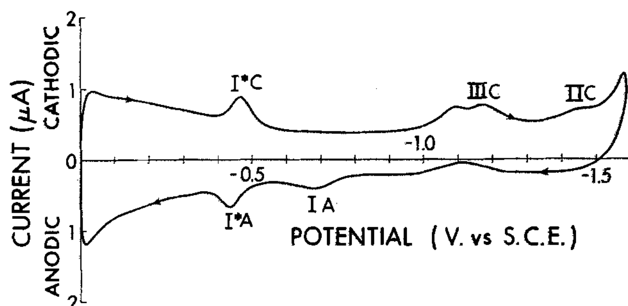

Fig. 2. Cyclic voltammogram of **1**, pH 7.04 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

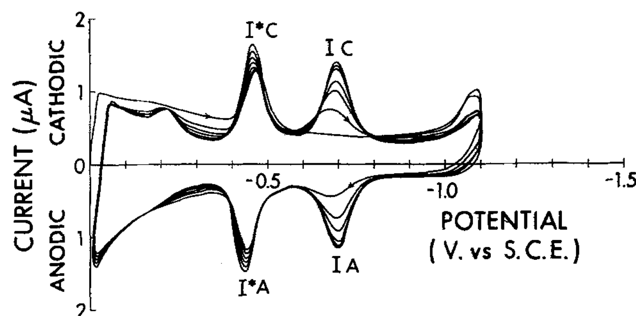

Fig. 3. Multicycle voltammogram of **1**, pH 7.04 in phosphate buffer, 37.5°C, ν = 500 mV/sec. The system I*C-I*A decreases, while IC-IA increases, with cycling.

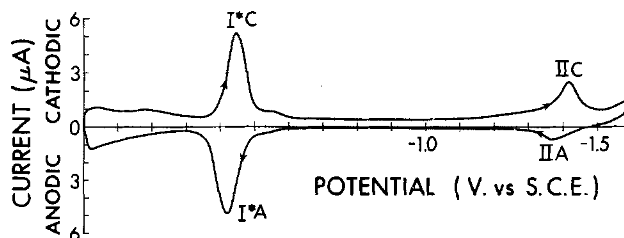

Fig. 4. Cyclic voltammogram of **2**, pH 7.06 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

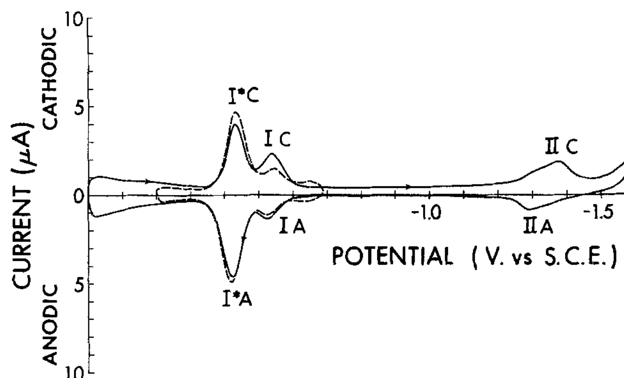

Fig. 5. Cyclic voltammogram of **2**, pH 7.06 in phosphate buffer, 37.5°C, ν = 500 mV/sec, solid line 0-—1.6V scan range, dotted line —0.3-—0.8V scan range. Solution of Fig. 4 after considerable cycling.

during the early part of the experiment at ν = 500 mV/sec (Fig. 4). In the later part of the experiment, *i.e.*, after making cyclic voltammetry measurements at slower scan rates up to 10 mV/sec, two additional peaks (IA and IC) appear as shown in Fig. 5. It is apparent from Fig. 4 and 5 that the presence of peak IC reduced the concentration of the material responsible for the peak I*C, *i.e.*, the peak height of I*C. The appearance of peaks I may be explained due to the formation of material responsible for peak I in the course of cyclic voltammetry at slow scan rates since our experimental solution was very dilute. Careful observation of Fig. 4 shows a very small peak at about −0.2V which disappeared in subsequent cycles of the multicycle runs. If the cell potential was held at −0.2V for different times between cycles, the height of I*C decreased exponentially with electrolysis time while that of IC simultaneously increased; the sum of the peak heights remained approximately constant. For example, electrolysis for 5 min decreased the height of I*C from 4.4 to 1.8 μA while the height of IC increased from 1.7 to 4.8 μA.

The peak potentials for I*C and IC are −0.442 ± 0.01V and −0.552 ± 0.01V, independent of scan rate up to ν = 1 V/sec; then shifted slightly cathodic with further increase in scan rate. The $I_p\nu^{-1/2}$ product decreases with decrease in scan rate for both peaks; however, this decrease is small for IC. On the other hand, the peak potential for I*A depends on the scan rate; for example, E_p = −0.425 ± 0.01V at ν = 500 mV/sec. As the scan rate is increased, the peak potential shifted to more anodic values by about 10-15 mV for each tenfold increase in scan rate up to 1 V/sec and then by a large extent. However, the peak potential of IA is −0.540 ± 0.01V, independent of scan rate up to 1 V/sec, and then shifted to anodic by a large extent with further increase in scan rate. It is apparent from Fig. 4 and 5 that the ratio of anodic to cathodic peak currents for both peaks I* and I are slightly greater than unity at ν = 500 mV/sec. The validity of these ratios is limited for the reasons mentioned above for compound **1**.

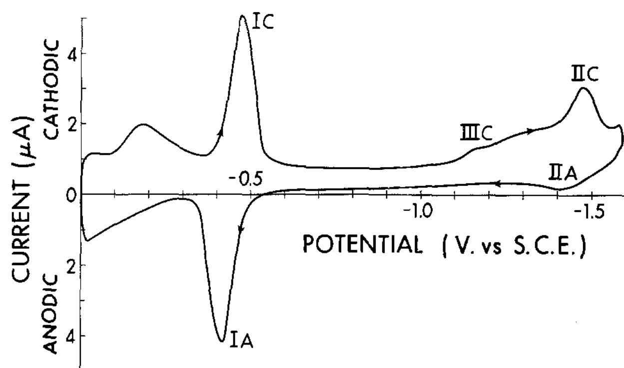

Fig. 6. Cyclic voltammogram of 3, pH 7.05 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

Small peaks IIC and IIA appear at most scan speeds and their peak potentials are −1.40 ± 0.02 and −1.34 ± 0.03V.

Compound **3**.—As shown in Fig. 6, compound **3** gives mainly two cathodic peaks (IC, IIC) and two anodic peaks (IA and IIA) at ν = 500 mV/sec. In addition, a broad cathodic peak at −0.184V (independent of scan rate) disappears in subsequent cycles of the multicycle runs. Very close observation of Fig. 6 indicates also the presence of two very small cathodic peaks (or waves) approximately at −1.17V (IIIC) and at −1.36V.

The cathodic peak (IC) at −0.472V for ν = 500 mV/sec shifts anodic by 15-20 mV for each tenfold decrease in scan rate. The corresponding anodic peak (IA) at −0.398V (when scanning range was restricted between 0 and −0.8V) for ν = 500 mV/sec shifts cathodic by 20-25 mV for each tenfold decrease in scan rate. The $I_p\nu^{-1/2}$ product for IC decreased with decrease in scan rate. The ratio of anodic to cathodic peak currents are approximately 1.2 at ν = 500 mV/sec and increased with decrease in scan rate.

Although the cathodic peak IIC appearing at −1.46 ± 0.01V is independent of scan rate, its anodic counterpart IIA, appearing at −1.42V and ν = 500 mV/sec, is less prominent at slower scan speeds.

Compound **4**.—Figure 7 is a typical cyclic voltammogram of compound **4** at 500 mV/sec. It shows three cathodic peaks (IC-IIIC) and three anodic peaks (IA, IIA, IIIA). Also, a broad cathodic peak, at −0.135V for ν = 500 mV/sec, shifts anodic by 30 mV for tenfold decrease in scan rate. This peak disappears in the second cycle of the multicycle runs as observed for the compounds discussed above. There are three more small cathodic peaks approximately at −0.360, −0.990, and −1.065V (Fig. 7).

Other than a cathodic peak at potentials more positive than −0.2V, only IC and IA are observed when the potential range is restricted to between 0 and −0.8V. Both IC and IA are independent of scan rate and appear at −0.506 ± 0.005V and −0.499 ± 0.005V. The $I_p\nu^{-1/2}$ product for IC decreases with decrease in scan rate. The ratio of anodic to cathodic peak currents and its scan dependence are similar to those for **3**.

The peak potential of IIIC is −1.16V at ν = 500 mV/sec and shifts anodic by about 30-40 mV for each tenfold decrease in scan rate. The anodic peak IIIA is better defined if the switching potential is more negative than −1.2V. The peak potential of IIIA is −0.40 ± 0.005V independent of scan rate. Small peaks IIC and IIA appear at most scan speeds; their peak potentials are −1.35 ± 0.01 and −1.30 ± 0.01V.

Compound **5**.—Acetophenone, **5**, gives only one cathodic peak (IIIC) at −1.53V for ν = 500 mV/sec and shifted anodic by 30-35 mV for each tenfold decrease in scan rate (Fig. 8). A very small anodic peak (IIIA) appears around −0.41V at 500 mV/sec; it is barely visible at lower scan speeds.

Compound **6**.—At ν = 500 mV/sec, 1′-acetonaphthone, **6**, gives two cathodic peaks (IIC, IIIC) and two anodic peaks (IIA, IIIA). A small anodic peak IIIA was visible around −0.39 ± 0.01V up to 100 mV/sec. The corresponding cathodic peak IIIC appears at −1.35 ± 0.01V, independent of scan rate. However, this peak becomes sharp and/or showed as a wavelike appearance on the anodic side of the peak. The cathodic peak IIC has a peak potential of −1.43V at 500 mV/sec and shifts anodic by 40-50 mV for each tenfold decrease in scan rate. The anodic peak IIA, better defined at slower scan speeds, has a peak potential of −1.26V at 500 mV/sec. This peak shifted cathodic by 30-40 mV for each tenfold decrease in scan rate.

Discussion

The quinone moiety (processes I, I)*.—The mechanism of the reduction of the daunomycinone analogues is similar to that for daunomycinone (14). The initial electrochemical two-electron, two-proton reversible electrochemical steps designated "I" are due to reduction of the respective quinones. An irreversible chemical reaction complicates the electrochemical step I. The absence of the cathodic peak I′C present in daunomycinone for **1-4** may arise because the analogues were less soluble than daunomycinone; peak I′C was observed only for an appreciable concentration of daunorubicin in solution (14).

The difference in the IC peak potentials of **3** and **4** is about 40 mV. Therefore, aromatization of the ring A shifts the formal potential of process I for **3** 40 mV more negative.

Wiles (16) has observed that methoxyanthraquinones are more readily reducible than the corresponding hydroxyanthraquinones. Comparison of the voltammograms of **1** and **2**, or of **3** and daunomycinone, shows an apparent anodic shift of I by substitution of methoxy for hydroxy in positions 6 and 11. The pres-

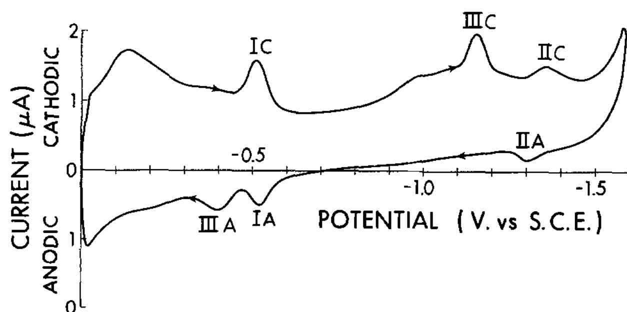

Fig. 7. Cyclic voltammogram of **4**, pH 7.03 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

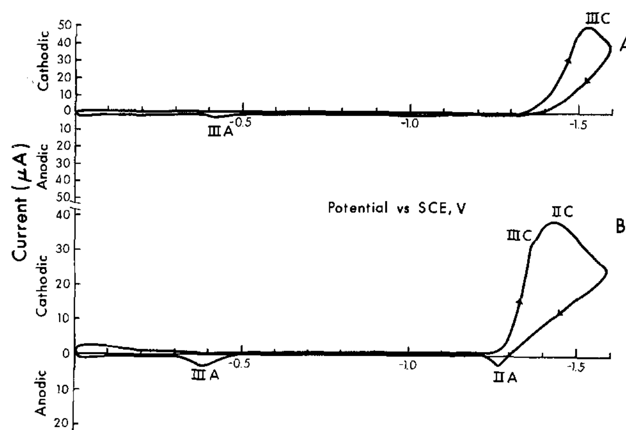

Fig. 8. Cyclic voltammograms of A, **5**, and B, **6**; pH 7.06 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

ence of either a hydroxyl group or sugar linkage at C_7 appears to have little direct influence upon the quinone reduction. Comparison of the IC peak potentials of compounds **1-4** indicates a positive ortho effect, probably due to the regular polar effect of the methoxy group. Contrarily, such an effect was not reported when a second methoxy was substituted affecting the same carbonyl group, in 1,8-dimethoxyanthraquinone (16).

The major phenomena exhibited in this study, however, are the peaks I* and the considerable shift in potential of I between the different analogues. Intramolecular hydrogen bonding in **1** and daunomycinone between the quinone oxygens at C_5, C_{12} and the hydroxyl hydrogens at C_6, C_8 is responsible for shifting the formal potential of these compounds about 150 $\pm$ 15 mV more negative than their respective methoxy derivatives. The difference in half-wave potential between 1,8-dimethoxyanthraquinone and 1,8-dihydroxyanthraquinone of 160 mV observed by Starka *et al.* (17) agrees well with our value of 150 $\pm$ 15 mV.

In compound **1**, an apparently reversible process designated I* appeared at a potential more positive than I. The process I* appeared to decrease with time, which indicates its nature is kinetic. This process I* was also observed for **2**, in which it was initially the only process present; the appearance of I, at lower height than I*, came only after continued cycling or upon reduction at -0.2V. With sufficient reduction at -0.2V, I* could be virtually removed. Process I* cannot be clearly distinguished for compounds **3** and **4** in which it may be hidden in the broad peaks. The difference in potential of peak I*C between **1** and **2** is only 23 mV, far less than the 135 mV difference for IC between **1** and **2** which we believe arises because the contribution of hydrogen bonding in **1** is appreciable while in **2** it is not. The distinction of the process I* from I as that of a more easily reducible tautomer is consistent with this behavior as the partial or complete loss of the 6,11 methoxy groups would reduce the difference for I*C between **1** and **2** if not eliminate it entirely. We then attribute process I* to the formation of more easily reducible tautomers such as the 6,12- or 5,11-dicarbonyl compounds. Such an explanation can be valid only if the methoxy groups can be removed to give access to the 6,11 positions. This removal is known to occur upon oxidation of *p*-methoxyphenol (20).

A process negative to all of the processes I-III, designated IV, was observed neither for daunorubicin nor for adriamycin (14), but was clearly present for both their aglycones, daunomycinone, and adriamycinone. This may be a redox process of the quinone structure which is inhibited by the presence of daunosamine in the parent antibiotics and hence appears only for the aglycones.

The daunosamine may influence the hydrogen bonding in the antibiotics so that the more easily reducible tautomers are not formed until it is removed. In this connection Yesair and McNitt (21) have commented upon the inhibition of reductive glycosidic cleavage by chelation of the dihydroquinone systems of anthracyclines and its relation to daunosamine.

The carbonyl side chain (processes II, III).—The reduction mechanism of the side-chain carbonyl group shown in Fig. 8 of (14), two irreversible one-electron processes (14), can be shown from behavior of compounds **4**, **5**, and **6**; separate protonation steps cannot be distinguished. We observe only one irreversible cathodic peak IIIC for acetophenone, which is consistent with the earlier work of Elving who observed one two-electron process due to the merging of the two one-electron reduction steps (19). However, we have observed two cathodic peaks, IIIC and IIC (both positive to the single cathodic peak for acetophenone, IIIC), and two anodic peaks (IIIA and IIA) for 1′-acetonaphthone and compound **4**.

The carbonyl group in acetophenone is more easily reduced than in acetone due to the strong inductive effect of the phenyl group (19). The increase in inductive effect as the number of benzene rings in a compound increases may explain the observed shift in the cathodic peaks (IIC and IIIC) toward more anodic potential as observed in componunds **4-6**.

Considering only ring A and its side-chain carbonyl group, the aromatic ring structure is equivalent to that of acetophenone while the alicyclic ring structure is equivalent to that of cyclohexanone. Acetophenone is more easily reduced than cyclohexane (18, 19). Thus our observation that reduction of the side chain carbonyl group in compounds **1**, **2**, and **3** occurs at more negative potentials than in compound **4** indicates that ring A of compounds **1**, **2**, and **3** has not achieved aromatic character (by dehydration and demethoxylation) prior to carbonyl reduction.

The Electrochemical Oxidation of Hydrogen Sulfide in the Tafel Region and under Mass Transport Control

M. Farooque and T. Z. Fahidy*

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

ABSTRACT

H_2S can be continuously oxidized about 1.21V (RHE) anode potential range at about 93% efficiency, according to the reaction scheme $H_2S \rightarrow S + 2H^+ + 2e^-$ which most probably involves the formation of an SH-chemisorbate on the (platinum) anode surface. At mass transfer-controlled conditions a limiting current is observed; rotating tripolar electrode cell experiments yield the value of 1.94×10^{-5} cm²/sec for the diffusion coefficient of H_2S in a 0.5 mole/dm³ aqueous H_2SO_4 solution, at 23°C.

In a previous publication (1) the oxidation of hydrogen sulfide at low potentials was described in a rotating tripolar wiper-blade electrode (RTE) system via continuous anode reactivation. At potentials less than about 0.5V (RHE) the most likely oxidation mechanism involves two first-order consecutive electrochemical reactions with the SH-chemisorbate as the intermediate product, responsible for the relatively rapid passivation (about 30 sec on an initially fresh anode surface); the RTE system was shown (1, 2) to be an efficient anode "reactivator" in the low potential range.

The extension of this study into the Tafel region and the mass transport-controlled region was stipulated by two major reasons. Firstly very little information about the nature of this reaction in these regions is available in the literature; the establishment of the most likely reaction mechanism is all the more intriguing as H_2S can be oxidized continuously past the range of passivation, characteristic of low potential oxidation. Secondly, oxidation at elevated potentials yields colloidal sulfur as the anode product, which is potentially useful for medicinal purposes, etc., apart from the obvious application in pollution control. Experiments in the mass transfer control regions may also be used to estimate the apparent diffusion coefficient pertaining to the electrochemical system. The present paper summarizes the results of such an investigation and is intended to offer a better understanding of the electrochemical oxidation of hydrogen sulfide over a relatively wide range of electrode potentials.

Basic Characteristics of the Oxidation Process

In the potential range of ~0.7-1.21V (RHE), where H_2S may continuously be oxidized on a platinum surface without noticeable passivation, the gaseous product evolved at the cathode is hydrogen (determined by a gas-chromatography analysis using a thermal conductivity detector and a 5A molecular sieve absorbent) and the anode product is powdery elemental sulfur: the latter is eventually suspended in the anolyte as a milky substance and coagulates after several hours of standing with sedimentation at the bottom. About 20 hr after oxidation, nearly 60% of the sulfur is insoluble in CS_2, the percentage of the CS_2-insoluble substance decreasing gradually with the aging of the product. It appears that the electrochemically produced sulfur is an unstable allotrope which is gradually transformed into a more stable form. Scanning electron microscope tests indicate that the average diameter of the sulfur particles in the milky substance is less than 10^{-4} cm. Chemical analysis of the electrolyte failed to detect any sulfate, sulfite, thiosulfate, or dissolved SO_2. Standard controlled-potential coulometry indicates that the oxidation reaction is a two-electron transfer process

$$H_2S \rightarrow S + 2H^+ + 2e^- \quad [1]$$

of about 93% current efficiency. In H_2SO_4 solutions the rest potential depends on the acid concentration and the partial pressure of H_2S as (3)

$$E \cong 165 - (59 \pm 2)pH - (40 \pm 15)P_{H_2S}\ \text{mV}$$

In cathodic polarization of a 0.5 mole/dm³ electrolyte with H_2 and H_2S bubbling, the Tafel slope is 0.12 ± 0.01V at potentials less than −100 mV on platinized Pt (<−150 mV at bright Pt) and the exchange current density is about 0.1 mA/cm² (bright Pt) and 0.4 mA/cm² (platinized Pt) (3, 4). In anodic polarization the Tafel slope is about 1.38V at ascending potentials and about 0.64V at descending potentials on bright Pt, whereas on platinized Pt, camel hump-like polarization is observed at ascending potentials and no reliable measure of the Tafel slope is obtained. The anodic peak has been ascribed (5) to delayed release of H atoms due to the porous structure of the electrode surface. The anodic exchange current density on bright Pt is about 0.2 μA/cm² from ascending potential *vs.* current curves, and about 0.068 μA/cm² from descending potential *vs.* current curves; the anodic polarization behavior of this system is not well understood.

The Mechanism of Oxidation

The preparation of the electrolyte and pretreatment of the platinum anode was the same as described earlier (1, 2). The electrolyte contained 0.00499 mole/dm³ H_2S dissolved in a 0.1 mole/dm³ H_2SO_4 solution. The potential of oxidation was varied from 1.15 to 1.21V (RHE) at a 22.5°C electrolyte temperature and the steady-state oxidation rate at each potential setting was measured, while the anode was rotated continuously at a speed of 2.0 rad/sec; the true anode area was measured (6) to be 210 cm². The experimentally observed steady-state oxidation rates are shown in Fig. 1. In Table I the results of a previously described (1, 2) likelihood-ratio analysis are presented for a number of plausible mechanisms, where the formulation of the intermediates was made on the basis that sulfur is known to form chain- and ring-molecules (in the following equations M denotes the surface of the platinum anode, and x and y denote the number of sulfur atoms associated with an active site on the platinum surface)

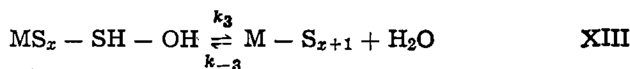
$$MS_x - SH + H_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} MS_x - SH - OH + H^+ + e^- \quad \text{XII}$$



$$MS_x - SH - OH \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} M - S_{x+1} + H_2O \quad \text{XIII}$$

The table does not contain those mechanism/rate-determining step combinations (models) whose residuals have been found much higher (*i.e.*, whose associated L_j values are much lower) than the five contenders shown. From a statistical point of view, Model 3-VII represents the most probable reaction mechanism, in spite of the fact that $\lambda_{32} \cong 4$ is less than 10 [which is the ordinarily accepted value to show "real difference in plausibility" (7)], since Model 2 carries four parameters in the associated rate expressions, and Model 3-VII carries only three parameters. Pertinent residual analysis shows no discernible trend, hence Model 3-VII is statistically adequate. The model equations are

$$I = a\theta_{MSH}^2 - b(1 - \theta_{MSH}) \quad [2]$$

$$\theta_{MSH} = 1/[1 + ce^{-VF/RT}] \quad [3]$$

where $a \equiv 2A_oFk_2$; $b \equiv 2A_oFk_{-2}C_{H_2S}$; and $c \equiv \frac{k_{-1}}{k_1} C_{H^+}C_{H_2S}^{-1}$. The numerical estimates of the three parameters, obtained by this regression analysis, are: $a = 38.846$ mA; $b = 0.91275$ mA; and $c = 1.3557 \times 10^{20}$. The model equations associated with the rest of the models have been given in detail elsewhere (2). The solid line in Fig. 1 represents the oxidation rate/oxidation potential relationship expressed by Eq. [2] and [3]. The apparent Tafel slope, computed via a linear regression analysis relating the experimental (V-E) *vs.* $\log_{10}I$ data is about 0.05V and the corresponding exchange current density, using the true electrode area of 210 cm^2, is estimated at the approximate value of 1.9×10^{-5} $\mu A/cm^2$ ($E \sim 0.3V$; residual sum of squares $\sim 2.067 \times 10^{-4}$; standard error of estimate $\sim 3.49 \times 10^{-3}$). The Tafel parameters are a function of the electrode rotation rate; comparison with Ijzermann's data (3) clearly shows the depolarization effect of rotation and surface renewal by wiping.

H_2S Oxidation in the Mass Transport-Control Region

The oxidation rate of H_2S was measured at different anode rotation rates in electrolytes containing 3.44, 11.2, and 12.5 mmole/dm^3 H_2S dissolved in a 0.5 mole/dm^3 H_2SO_4 solution, at an anode potential of 1.45V (RHE). Prior to each set of readings the apparatus was subjected to the following treatment: The cell was washed with deionized water, piperidine, and again with deionized water. The anode was subjected to a potential sweep from 40 mV to 1.6V at a sweep rate of 0.15 V/sec in a 0.5 mole/dm^3 H_2SO_4 solution. Finally the cell was washed with the experimental electrolyte and filled with it. Figures 2 and 3 show the effect of the anode rotation rate on the experimental limiting current density. According to a previous theoretical treatment of mass transport phenomena in a rotating multipolar cell equipped with wiper blades (8,9), the limiting current and the speed of rotation are related as

$$I_{L,avg} = A_o'zFDc_b \left[\frac{2}{\sqrt{\pi D t_s}} - \frac{4}{3\pi\sqrt{\pi \nu t_s}} \right] \quad [4]$$

A slightly improved relationship, developed recently (2, 10), yields

$$I_{L,avg} = \frac{2A_o'zFDc_b}{\sqrt{t_s}} \left[\frac{1}{\sqrt{\pi D}} + \frac{1}{\psi(\sqrt{\pi\nu})} \right] \quad [5]$$

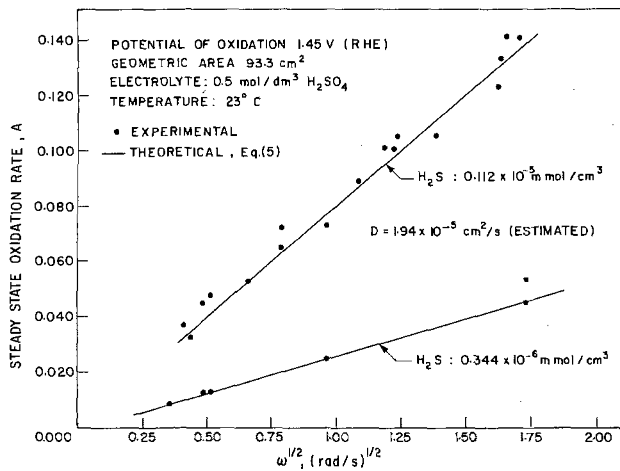


Fig. 2. Oxidation rate vs. rotation rate in the mass transport-controlled region.

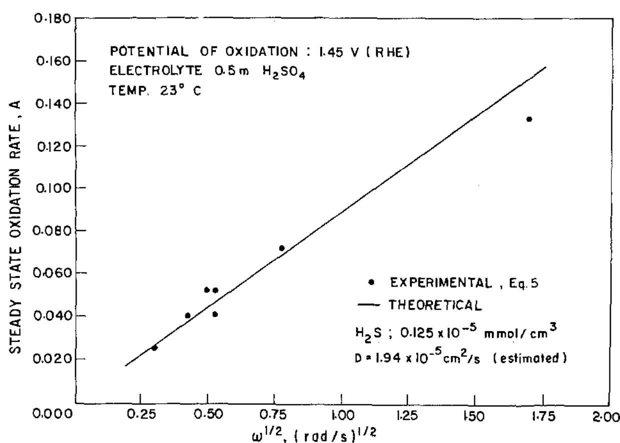

Fig. 3. Oxidation rate vs. rotation rate in the mass transport-controlled region.

where

$$\psi(\sqrt{\pi\nu}) \equiv \int_0^{\sqrt{\pi\nu}} \epsilon^{(y^3/6D\sqrt{\pi\nu} - y^2/4D)} dy$$

and t_s, the time required for the electrode surface to pass from one wiper blade to the next, is related to the rotation rate ω by the expression

$$t_s = \frac{2\pi r_1 - Wd}{\omega W r_1} \qquad [6]$$

Equation [5] was fitted to the experimentally observed rates, employing 30 experimental points and using Powell's least-squares algorithm (11). The regression lines, given by the solid curves in Fig. 2 and 3, possess an average absolute error of 7%, the residual analysis yielding again no discernible trend. Using the experimental values of $A_0' = 93.3$ cm² and $\nu = 1.0457$ mm²/sec, the diffusion coefficient of H_2S in H_2SO_4 is estimated to be 1.9425×10^{-5} cm²/sec with an associated variance of 1.25×10^{-10} cm²/sec.

Conclusions

The electrochemical oxidation of H_2S proceeds without passivation as a two-electron transfer process producing elemental hydrogen and a colloidal dispersion of sulfur at a current efficiency of about 93%.

The statistically most probable mechanism involves sulfohydrogen and sulfur-chemisorbates on the platinum anode with an M-SH → M-S recombination being the rate-controlling step. At high oxidation potential the reaction is mass transfer controlled and its rate is linearly proportional to the square root of the rotation speed of the anode in an RTE cell. The process appears to be a potentially useful means of H_2S pollution control.

The Effect of Slow Two-Electron Transfers and Disproportionation on Cyclic Voltammograms

Michael D. Ryan*

Marquette University, Department of Chemistry, Milwaukee, Wisconsin 53233

ABSTRACT

The EE mechanism (two-electron transfer) for cyclic voltammetry was investigated in considerable detail along with the effect of disproportionation. The theory was developed for either the first or second electron transfer being slow while the other one was reversible. It was possible to develop generalized working curves for the height and shape of the wave regardless of the difference in E°'s and the values of α and k_s. This theory was then applied to the analysis of the reduction of benzil in the presence of alkaline earth ions in dimethylformamide.

The theory for reversible and irreversible electron transfer has been examined in some detail previously for cyclic voltammetry (CV). The problem of multi-electron transfers in CV was studied first by Polcyn and Shain (1). The main quantitative emphasis was placed on the deconvolution of separated waves and only qualitative results were given for multi-electron waves. Myers and Shain (2) were able to quantitatively correlate the shape and peak current function of reversible voltammetric waves to their difference in $E^{o\prime}$s if the $E^{o\prime}$s were close together. It was found that the shape of the wave was independent of the relative values of the $E^{o\prime}$s only if the difference in $E^{o\prime}$s was greater than 180 mV. Otherwise, the wave will be broader than expected, even though it is still reversible. In addition, its shape and position are independent of scan rate. No correlations were made for quasi-reversible or irreversible electron transfers.

Multi-electron transfers can put a much more stringent demand on the rate of electron transfers if the wave is shifted significantly from its E^o because of the second electron transfer. Ruzic (3) has shown that, for polarography, the apparent heterogeneous electron transfer rate constant, k_s', for the over-all two-electron transfer is less than either of the individual rate constants, $k_{s,1}$ or $k_{s,2}$, if the second E^o, E_2, is more positive than the first E^o, E_1. In particular, the rate constant that is calculated using conventional theory is not the individual rate constant but an apparent one. Thus, the theory for quasireversible electron transfers in CV (4) yields the value of k_s'.

Competing with the multielectron transfer mechnism is the disproportionation mechanism. If the second electron transfer is so slow as to not be important and if E_2 is positive of E_1, the classical disproportionation mechanism can then occur. The theory for this mechanism has been developed and verified by Saveant (5). But very little work has been done in trying to assess the relative importance of the electron transfer mechanism (EE) as compared to the disproportionation (DISP) mechanism. For reversible electron transfers the cyclic voltammograms will not distinguish between these two mechanisms.

It is the purpose of this work to develop the cyclic voltammetric theory more generally for the EE mechanism, including the possibility of disproportionation, and to verify it experimentally. The emphasis will be placed on those cases where only one wave is observed, and either the first or second electron transfer is slow. Recent studies have shown several reductions that are now known to follow the EE mechanism (6). In this study, the electrochemical reduction of benzil in dimethylformamide (DMF) in the presence of alkaline earth salts, which is known to be a quasireversible two-electron transfer (6), is investigated in more detail in this work using the theory that is presented.

Key words: EE mechanism, cyclic voltammetry, disproportionation.

Experimental

Spectroquality N,N-dimethylformamide was obtained from Matheson, Coleman, and Bell. The solvents were dried as required using activated molecular sieves. Strontium and barium perchlorate were obtained from G. F. Smith Chemical Company and were vacuum dried at 250°C for 6 hr (7). Benzil was recrystallized from ethanol. The reference electrode is the same as was described in Ref. (6). Positive feedback resistance compensation was used in all of the fast scan rate experiments. A hanging mercury drop electrode was used as the working electrode. All solutions were deaerated with dry nitrogen. The diffusion equations were solved numerically using the technique of digital simulation (8). The flux equations for a two-electron transfer that were derived by Feldberg (9) were used to calculate the current.

Theory

The generalized EE mechanism that is discussed in this paper is given by reactions [1]-[3]

$$A + e \overset{E_1}{\rightleftharpoons} B \quad [1]$$

$$B + e \overset{E_2}{\rightleftharpoons} C \quad [2]$$

$$2B \overset{k_d}{\rightarrow} A + C \quad [3]$$

Each electron transfer has associated with it a $k_{s,i}$ and α_i value, where i = 1 or 2, for the first or second electron transfer, respectively. The analysis of the mechanism is divided into two major sections, depending upon whether the first or second electron transfer is rate limiting. In both cases, the mechanism is studied in the regions where only one wave is seen.

While each individual step has an α_i associated with it, the over-all electron transfer coefficient that is observed if one wave is seen has been derived by Mohilner (10). If the first electron transfer is limiting, then

$$\alpha n = \alpha_1 \quad [4]$$

If the second electron transfer step is limiting, the observed αn is

$$\alpha n = 1 + \alpha_2 \quad [5]$$

First-electron transfer limiting.— Reversible electron transfer.—Using the theory that was derived for polarography (3) and verified by digital simulation in this work for CV, the value of k_s' can be calculated as follows

$$k_s' = k_{s,1} \exp[-\alpha_1 \mathbf{F} \Delta E / 2RT] \quad [6]$$

where $\Delta E = E_2 - E_1$. As stated earlier, it is the k_s' value that is experimentally measured. Thus, α_1 and ΔE must be known in order to calculate $k_{s,1}$. In order to generalize the results, the dimensionless electron transfer rate parameter, ψ, will be used and is defined as follows

$$\psi = k_s/\sqrt{\pi a D_A} \quad [7]$$

and

$$a = n\mathbf{F}v/RT \quad [8]$$

where v is the scan rate and the other terms have either been defined or have their usual electrochemical significance. Combining Eq. [6] and [7], we obtain

$$\psi_1' = \psi_1 \exp\left[\frac{-\alpha_1 \mathbf{F}\Delta E}{2RT}\right] \quad [9]$$

The shape of the cyclic voltammogram depends on its reversibility (ψ_1') and on the difference in E^{o}'s (ΔE). These are two different parameters which must be evaluated separately. Cyclic voltammograms can be divided into three general classes depending on the value of ψ_1'. These classes are: (*i*) reversible, $\psi_1' > 7$, (*ii*) quasireversible, $0.1 < \psi_1' < 7$; and (*iii*) irreversible, $\psi_1' < 0.1$. Within these three classes, the shape of the wave is also dependent upon ΔE. In this paper, for each of the three classes, the effect of ΔE on these classes is examined. Several limiting cases have already been described. For the reversible and irreversible classes, Nicholson and Shain (11) have derived the shape and behavior of the wave if $\Delta E > 180$ mV. Myers and Shain (2) and Polcyn and Shain (1) have investigated the reversible case if $\Delta E < 180$ mV. These papers can be consulted to determine the shape of the wave and the value of ΔE. The irreversible case was also studied by Polcyn and Shain (1) for $\Delta E <$ 180 mV but quantitative analysis was possible only if two waves were seen.

The disproportionation reaction (reaction [3]) has no effect on the shape of the wave if the first electron transfer is the slow step. This is because B is rapidly reduced to C at the electrode surface. This is not to say that the disproportionation reaction does not occur but only that the reaction has no effect on the wave when it occurs in this situation. This was verified by digital simulation.

Quasireversible electron transfer.—For quasireversible electron transfers, the shape of the wave depends upon ψ_1' and ΔE, and is not very dependent upon α_1. If ΔE is larger than 180 mV, the value of k_s' can be calculated from the theory for quasireversible waves given by Nicholson (4). But even for $\Delta E > 180$ mV, noticeable deviations occur when the waves are simulated by the digital simulation technique (8, 9). The results are shown in Table I for ψ_1' less than 1. The deviations are due to the greater effect of α_1 on the peak potentials for the same value of ψ.

To calculate $k_{s,1}$, ΔE and α_1 must be known. The value of α_1 cannot be accurately determined unless scan rates large enough to make the wave irreversible are used. At these large scan rates, the theory presented in the next subsection on irreversible electron transfers can be used to calculate α_1. The value of ΔE can be calculated using the reversible theory if slow enough scan rates can be achieved or by using the irreversible theory that is described for fast scan rates. For ΔE values less than 180 mV, the working curve will depend upon ΔE in addition to ψ_1'. This effect is not large and can be corrected for in the same way as shown in Eq. [32] later in this paper.

Table I. Variation of ΔE_p values as a function of ψ_1' ($\alpha_1 = 0.5$)

ψ_1'	ΔE_p (mV) EE mechanism	Ref. (4)
1.0	45	42
0.5	61	53
0.2	107	79
0.1	156	106

Irreversible electron transfer.—In the case where single scan is used, the position, shape, and size of the reduction wave depends on the value of ψ_1', α_1, and ΔE. The wave does not occur at its thermodynamically defined E^o but at a more negative potential depending upon scan rate. In the theory as derived by Nicholson and Shain (11) for multielectron irreversible transfer, it was assumed that all the electron transfers except the slow one were fast, at least at the potentials where the reduction wave occurs. Polcyn and Shain (1) have shown that the wave will be affected if this assumption does not hold true but no quantitative theory was derived if one wave is observed. In order to provide a quantitative measure of the relative difference in reduction potentials, the parameter, ΔE_{AB}, is defined as

$$\Delta E_{AB} = \Delta E - \frac{59}{\alpha_1} \log \psi_1 \quad [10]$$

This equation is derived from the fact that an irreversible reduction is shifted to more negative potentials by a rate of $59/\alpha_1 \log \psi_1$. This parameter corrects ΔE for the fact that irreversible reductions do not occur at their thermodynamically defined potential but at some more negative potential depending upon α_1 and $k_{s,1}$. Similar to reversible electron transfer, only one wave is seen if ΔE_{AB} is positive and two waves are seen if ΔE_{AB} is negative enough. The exact values of these regions are shown later. By combining Eq. [9] and [10], ΔE_{AB} can be defined in terms of ψ_1', which is experimentally measured

$$\Delta E_{AB} = \Delta E/2 - \frac{59}{\alpha_1} \log \psi_1' \quad [11]$$

By using digital simulation (8), it was found that the theory for irreversible electron transfers derived by Nicholson and Shain (11) can be used if ΔE_{AB} is greater than $75/\alpha_1$ mV. In this case, the following diagnostic criteria for the cathodic peak potential, E_{pc}, the cathodic peak current, i_{pc}, and the peak $E_{pp/2}$ values can be calculated

$$i_{pc} = 0.992\, \mathbf{F} A C_A^* \sqrt{\alpha_1 D_A a_1} \quad [12]$$

$$E_{pp/2} = E_{pc} - E_{p/2} = 47.7/\alpha_1 \text{ mV} \quad [13]$$

$$dE_{pc}/d \log v = 30/\alpha_1 \text{ mV} \quad [14]$$

and

$$a_1 = \mathbf{F}v/RT \quad [15]$$

and where $E_{p/2}$ is the half-peak potential.

If ΔE_{AB} is less than $75/\alpha_1$ mV and only one wave is seen, the shape of the wave is changed from that predicted for an irreversible electron transfer and depends upon the scan rate. This is shown in Fig. 1 for three different values of ΔE_{AB}. As the scan rate is increased (ΔE_{AB} larger), the value of ΔE_{AB} will increase so as to make the wave approach the irreversible theory as given in Eq. [12]-[14]. The $E_{pp/2}$ value is most strongly dependent upon ΔE_{AB} for ΔE_{AB} values less than $75/\alpha_1$ mV. The variation of $E_{pp/2}$ values with ΔE_{AB} is shown in Fig. 2 for various values of α_1, where the $E_{pp/2}$ values have been normalized in the following manner

$$E^*_{pp/2} = \alpha_1 E_{pp/2} \quad [16]$$

For large negative values of ΔE_{AB} two waves are seen and each wave can be analyzed individually because A will reduce prior to the potential for the B wave. For intermediate values of ΔE_{AB}, the A reduction wave will overlap the B wave and hence a broaden wave will be seen. There is a maximum value for which ΔE can have and still see the behavior as described in Fig. 2. For the wave to begin to broaden, ΔE_{AB} must be less than $75/\alpha_1$ mV and ψ_1' must be less than 0.1. Thus, rearranging Eq. [11], we obtain

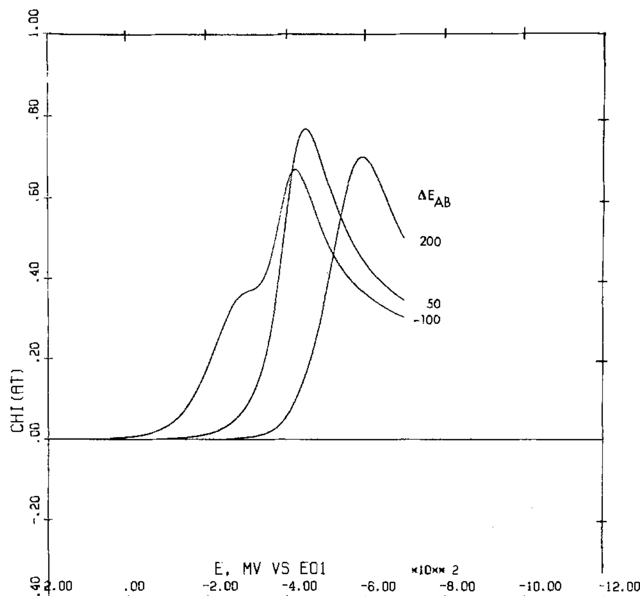

Fig. 1. The simulated cathodic scan for three different values of ΔE_{AB} (first-electron transfer irreversible).

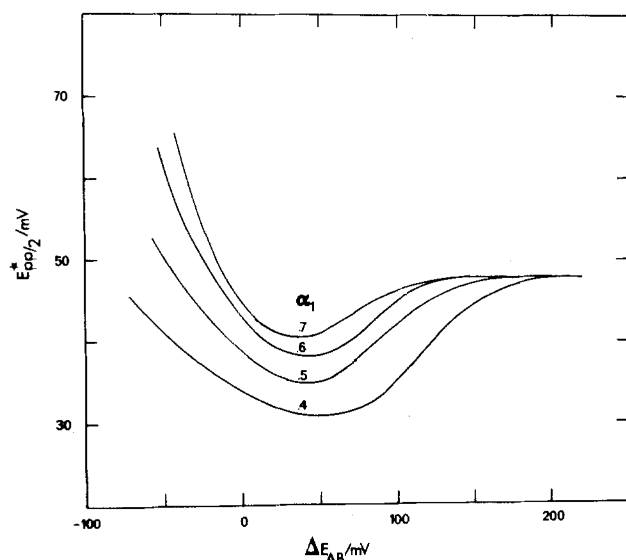

Fig. 2. The variation of $E_{pp/2}^*$ as a function of ΔE_{AB} for various values of α_1 in the case where the first electron transfer is irreversible.

$$\Delta E < \frac{32}{\alpha_1}\text{mV} \quad [17]$$

Otherwise, Eq. [12]-[14] will always hold when the wave is irreversible. In the limit of very slow scan rates, the $E_{pp/2}$ value is limited by the value derived by Myers and Shain (2). The peak current function goes through a maximum at the same point that the $E_{pp/2}$ values go through a minimum but the change in this parameter is not very large with the maximum change on the order of 20%, making this parameter less useful.

In the cyclic experiment, on the anodic scan, the reverse of reactions [1] and [2] occurs

$$\text{C} \overset{E_2}{\rightleftharpoons} \text{B} + e \quad [18]$$

$$\text{B} \overset{E_1}{\rightleftharpoons} \text{A} + e \quad [19]$$

For the return peak, reaction [19] is rate limiting, which is the second-electron transfer. A full discussion of this case is given in the next section and only a few pertinent details are given here. Either one or two waves can be seen on the return scan. The experimental conditions for the number of peaks that are seen are given in the next section.

With the information from the reverse scan, it is possible to determine all the parameters for the two-electron transfer. There are four unknowns which need to be evaluated from the experimental data. They are: E_1, E_2, $k_{s,1}$ and α_1. There are two other parameters that are related to these and are calculated during the analysis. They are

$$E_{1,2} = (E_1 + E_2)/2 \quad [20]$$

and ΔE. It is the aim of the rest of this section to develop the equations necessary to calculate these parameters from the data.

If two anodic peaks are seen, E_2 can be found directly from the most negative peak potential, $E_{pa(2)}$, because that wave will occur at its thermodynamically defined potential

$$E_2 = E_{pa(2)} - 0.0285 \quad [21]$$

The value of α_1 can be determined from several methods depending on the value of ΔE_{AB}. If Eq. [12]-[14] are obeyed, α_1 can be determined from the shift in E_{pc} or by the $E_{pp/2}$ value. If ΔE_{AB} is less than $75/\alpha_1$ mV (in other words, the shape depends upon scan rate), the value of α_1 can be determined from the more positive anodic peak potential, $E_{pa(1)}$. Thus

$$\frac{dE_{pa(1)}}{d\log v} = \frac{30}{1-\alpha_1}\text{mV} \quad [22]$$

The cathodic peak potential can be related to the $E_{1,2}$ value by the following equation (11) if $\Delta E_{AB} > 75/\alpha_1$ mV

$$E_{pc} = E_{1,2} - \frac{RT}{\alpha_1 \mathbf{F}}\left(0.339 - \log \psi_1' + \sqrt{\frac{\alpha_1}{2\pi}}\right) \quad [23]$$

and $E_{pa(1)}$ is

$$E_{pa} = E_{1,2} + \frac{RT}{(1-\alpha_1)\mathbf{F}}\left(0.339 - \log \psi_1' + \log\sqrt{\frac{1-\alpha_1}{\pi}}\right) \quad [24]$$

By taking the difference in the peak potentials, we obtain

$$\Delta E_p = \frac{0.059}{\alpha_1(1-\alpha_1)}(0.339 - \log\psi_1') + \frac{0.059}{1-\alpha_1}\log\sqrt{\frac{1-\alpha_1}{\pi}} + \frac{0.059}{\alpha_1}\log\sqrt{\frac{\alpha_1}{2\pi}} \quad [25]$$

Thus, since α_1 is known, ψ_1' can be calculated from the ΔE_p values. If ψ_1' is now substituted in Eq. [23], $E_{1,2}$ can be found. The value of E_2 is known from Eq. [21] so E_1 can be calculated by using Eq. [20].

If only one anodic peak is seen, α_1 can be found from the anodic or cathodic wave. If the anodic peak potential is used to calculate α_1, then as will be described in the next section, Eq. [26] must be used

$$\frac{dE_{pa}}{d\log v} = 30/(2-\alpha_1)\text{mV} \quad [26]$$

The value of ψ_1' can be found, as before, from the ΔE_p value but Eq. [28] must be used because E_{pa} is given by

$$E_{pa} = E_{1,2} + \frac{0.059}{2-\alpha_1}\left[0.339 + \log\psi_1' + \log\sqrt{\frac{1-\alpha_1}{2\pi}}\right] \quad [27]$$

Using Eq. [27], the variation of ΔE_p with ψ_1' is given by

$$\Delta E_p = \frac{0.118}{\alpha_1(2-\alpha_1)}(0.339 + \log \psi_1') + \frac{0.059}{2-\alpha_1}\log\sqrt{\frac{1-\alpha_1}{2\pi}} + \frac{0.059}{\alpha_1}\log\sqrt{\frac{\alpha_1}{2\pi}} \quad [28]$$

The value of $E_{1,2}$ can be found from Eq. [23]. The final problem is to find a method to determine E_1 and E_2 from $E_{1,2}$. To do this, either fast or slow scan rates must be used to separate either the anodic or cathodic peaks into two waves. It is theoretically possible to cause the cathodic peak to split apart if ΔE is less than -60 mV. If this is not possible, then scan rates fast enough to split the anodic peak apart must be used. If the cathodic peak begins to split apart, Fig. 2 can be used to calculate the value of ΔE_{AB} from the $E_{pp/2}$ values. From Eq. [11], it is possible to determine ΔE because α_1 and ψ_1' are known

$$\Delta E = 2\left(\Delta E_{AB} + \frac{59}{\alpha_1}\log \psi_1'\right) \quad [29]$$

Unless there is some change in the shape of either the anodic or cathodic wave it is impossible to determine E_1 and E_2.

Second-electron transfer limiting.—No disproportionation.—If the disproportionation reaction (reaction [3]) does not occur, the only way of producing C is by the direct reduction of B at the electrode surface. As with the previous case, an apparent electron transfer rate constant, k_s', is observed experimentally rather than the actual k_s value of the second step. The value of k_s' is given by

$$k_s' = k_{s,2}\exp\left(-(1-\alpha_2)\frac{F}{RT}\frac{\Delta E}{2}\right) \quad [30]$$

or

$$\psi_2' = \psi_2 \exp\left[-(1-\alpha_2)\frac{F}{RT}\frac{\Delta E}{2}\right] \quad [31]$$

As before, reversible behavior is observed if ψ_2' is greater than 7. If ψ_2' is less than 0.1, an irreversible wave is seen. For reversible waves, the shape of the wave (2) depends only on ΔE and is independent of ΔE if ΔE is greater than 180 mV.

Quasireversible electron transfer.—For quasireversible waves, the shape of the wave depends upon ψ_2' and ΔE and is not very dependent upon α_2. If ΔE is larger than 180 mV and ψ_2' greater than 0.5, the value of k_s' can be calculated from the theory for quasireversible waves given by Nicholson (4). The ΔE_p values as calculated by digital simulation for different α_2 values are given in Table II for several ψ_2' values less than 1.

If ΔE is less than 180 mV, the ΔE_p values are larger than predicted by Ref. (4). To a close approximation, the working curves for $\Delta E < 180$ mV can be obtained by adding the excess broadness, E_{exc}, as defined in Eq. [32] to the data in Table II

$$E_{exc} = \Delta E_{pr} - 29 \text{ mV} \quad [32]$$

where ΔE_{pr} is the ΔE_p value for a given ΔE (reversible case).

Irreversible case.—With a single scan, as defined earlier, the wave is irreversible if ψ_2' is less than 0.1.

Table II. Variation of ΔE_p values as a function of ψ_2'

ψ_2'	ΔE_p (mV) $\alpha_2 =$ 0.35	0.5	0.65	Ref. (4)
1.0	44	44	43	42
0.5	58	56	53	53
0.2	91	88	85	79
0.1	128	135	147	106

Irreversibility of the second electron transfer makes the second electron transfer occur at more negative potentials. In order to correct for this, we can define a parameter, ΔE_{BC}, which takes into account the effect of the slow electron transfer

$$\Delta E_{BC} = \Delta E/2 + \frac{59}{1+\alpha_2}\log \psi_2' \quad [33]$$

This parameter normalizes the combined effects of ΔE and ψ_2' on the relative positions of the two waves. From digital simulation, it was found that, if ΔE_{BC} is greater than 50 mV, the shape of the wave is given by the theory derived by Nicholson and Shain (11). Substituting $n = 2$ and $\alpha n = 1 + \alpha_2$, the following diagnostic parameters can be calculated

$$i_p = 0.992\,FA\sqrt{(1+\alpha_2)Da_1C_A^*} \quad [34]$$

$$E_{pp/2} = 47.7/(1+\alpha_2)\text{mV} \quad [35]$$

$$dE_p/d\log v = 30/(1+\alpha_2)\text{mV} \quad [36]$$

If ΔE_{BC} is less than 50 mV the wave will broaden and the peak current function will decrease. This effect can be seen in Fig. 3 for three different values of ΔE_{BC}. The variation in χ_p and $E_{pp/2}$ values can be calculated as a function of α_2 by the following normalizations

$$\chi_p^* = \chi_p/(1+\alpha_2)^{1/2} \quad [37]$$

$$E_{pp/2}^* = E_{pp/2}(1+\alpha_2) \quad [38]$$

The effect of ΔE_{BC} on χ_p^* and $E_{pp/2}^*$ is shown in Fig. 4 and 5. The variations in these parameters are qualitatively similar to the ECE and DISP mechanisms. It is only at fast scan rates that the χ_p and $E_{pp/2}$ values differ significantly from the ECE and DISP mechanism. But chronoamperometry will easily distinguish between these mechanisms because a two-electron diffusion-controlled wave can be obtained if a negative enough potential is used. In contrast, an ECE or DISP mechanism will show the slow kinetic step regardless of applied potential.

In a cyclic experiment, since the B to C reduction is limiting in this case, the C to B oxidation will be limiting on the reverse scan. Thus, the theory for the first-step limiting must be used to evaluate the oxidation peak.

As before, there are four parameters which must be determined: E_1, E_2, $k_{s,2}$, and α_2. Thus, four indepen-

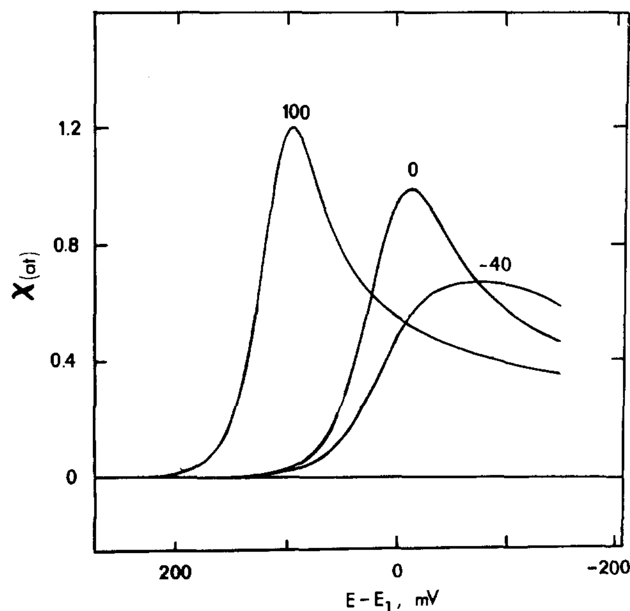

Fig. 3. The simulated cathodic scan for three different values of ΔE_{BC} (second-electron transfer irreversible).

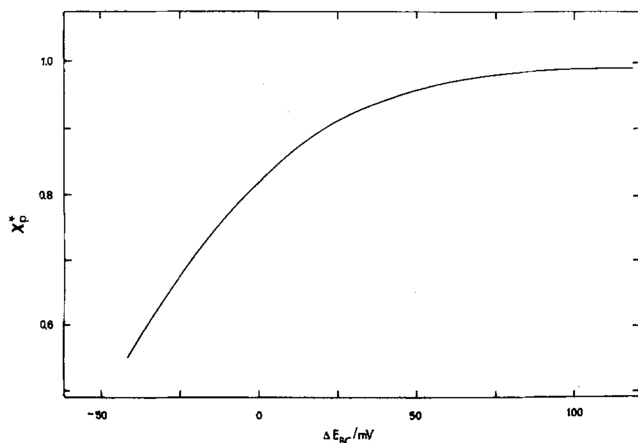

Fig. 4. The variation of χ_p^* as a function of ΔE_{BC} for the case where the second electron transfer is irreversible.

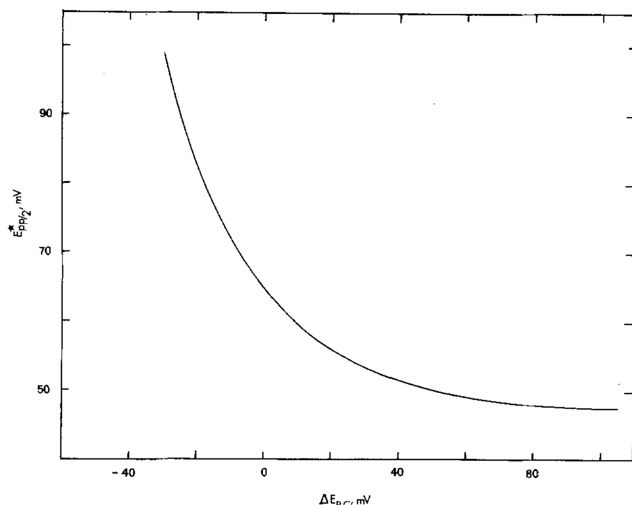

Fig. 5. The variation of $E_{pp/2}^*$ as a function of ΔE_{BC} for the case where the second electron transfer is irreversible.

dent equations must be derived. Only one anodic peak can be seen under practically any conditions where only one cathodic peak is seen as a consequence of Eq. [17]. This limits the existence of two peaks to ΔE values which are close to zero or negative. The value of α_2 can be calculated from Eq. [35] or [36]. The second equation that can be used to calculate these parameters is the cathodic peak potential (11), which is

$$E_{pc} = E_{1,2} - \frac{0.059}{1+\alpha_2}\left[0.339 - \log \psi_2' + \log\sqrt{\frac{\alpha_2}{2\pi}}\right] \quad [39]$$

In addition, E_{pa} is given by (11)

$$E_{pa} = E_{1,2} + \frac{0.059}{1-\alpha_2}\left[0.339 - \log \psi_2' + \log\sqrt{\frac{1-\alpha_2}{2\pi}}\right] \quad [40]$$

Combining Eq. [39] and [40], the ΔE_p values can be derived as a function of ψ_2'

$$\Delta E_p = \frac{0.118}{1-\alpha_2}(0.339 - \log \psi_2') + \frac{0.059}{1+\alpha_2}\log\sqrt{\frac{\alpha_2}{2\pi}} + \frac{0.059}{1-\alpha_2}\log\sqrt{\frac{1-\alpha_2}{2\pi}} \quad [41]$$

Once ψ_2' is calculated, $E_{1,2}$ can be calculated from Eq. [39]. The final determination of E_1 or E_2 requires that ΔE_{BC} be less than 50 mV so that the wave will begin to split apart. If ΔE_{BC} can be determined from the $E_{pp/2}$ or χ_p values, then

$$\Delta E = 2\left(\Delta E_{BC} - \frac{59}{1+\alpha_2}\log \psi_2'\right) \quad [42]$$

If ΔE is such that the wave does not begin to split apart, then a lower limit on ΔE can be established because ΔE_{BC} must be greater than 50 mV

$$\Delta E > 100 - \frac{118}{1+\alpha_2}\log \psi_2' \quad [43]$$

Thus, from Eq. [35] or [36], [39], and [41] and [42], we have four independent equations which allow one to calculate $k_{s,2}$, α_2, E_1 and E_2. The solution is simple because there is only one new unknown in each equation. It is important to obtain a good determination of α_2 since this is critical in all the equations. If the wave is beginning to split apart, it is probably more accurate to use the anodic peak potential to determine α_2 because that will not be affected. But fortunately, it turns out that unless the wave has broadened considerably, the calculation of α_2 from Eq. [36] is also not seriously affected even though Eq. [35] cannot be used.

Disproportionation.—For $\Delta E > 0$, the disproportionation reaction is favorable and can compete with the electron transfer if it is fast enough. In order to discuss this mechanism quantitatively, the rate constant, k_d, is normalized as follows

$$\lambda_d = k_d C_A^*/a \quad [44]$$

where λ_d is the disproportionation kinetic parameter. It is important to keep in mind that λ_d depends upon C_A^* while ψ_2 does not. Thus, it is possible to change λ_d without changing ψ_2 at the same time. In Fig. 6, the effect of the disproportionation reaction can be seen quite clearly. In this figure, the wave becomes dependent upon the disproportionation reaction and not on the second electron transfer. The same type of behavior is demonstrated in Fig. 7, where the electron transfer predominates if it is large enough in spite of a fairly significant rate for the disproportionation reaction. Qualitatively, the DISP mechanism is most important for negative values of ΔE_{BC}. If ΔE_{BC} is positive, the difference in the shape and height of the wave due to these two mechanisms is not large.

The effect of the disproportionation reaction on the EE mechanism was determined by the use of digital simulation (8). The results are shown in Fig. 8 and 9 for the χ_p and E_{pc} values for $\alpha_2 = 0.5$ as a function of ΔE_{BC}. It is assumed in this case that the wave is ir-

reversible ($\psi_2' < 0.1$). For quasireversible and reversible waves, the effect of the DISP mechanism is small. Using the criteria that the DISP mechanism predominates if χ_p is within 5% of the value for the wave when $\psi_2' = 0$, a range of ΔE_{BC} values can be calculated and the results are shown in Fig. 10. At the other extreme, the wave is defined by the EE mechanism if the E_{pc} value is within 2 mV of the value obtained when $\lambda_d = 0$. These values are also shown in Fig. 10. Between these two limits, the wave is controlled by both the EE and DISP mechanism and Fig. 8 and 9 can be used. These limits can be expressed as follows

DISP mechanism predominates if

$$\Delta E_{BC} < 25 \log \lambda_d - 70 \text{ mV} \quad [45]$$

EE mechanism predominates if

$$\Delta E_{BC} > 25 \log \lambda_d - 5 \text{ mV} \quad [46]$$

While these results were obtained for $\alpha_2 = 0.5$, the same conclusions were obtained for $\alpha_2 = 0.35$ and 0.65. The E_{pc} curve shown in Fig. 9 is almost independent of α_2. The χ_p curve (Fig. 8) does depend upon α_2 because the limiting value of χ_p when ΔE_{BC} is large does depend upon α_2. In general, this dependence is small and varies by only 10%, at most, for α_2 between 0.35 and 0.65. But the limits given by Eq. [45] do not depend upon α_2. This can be seen in Fig. 11 for $\alpha_2 = 0.35$, 0.5, and 0.65 and $\lambda_d = 10$.

Diagnostic Criteria and Data Analysis

The key to the analysis of cyclic voltammetric data for this case is a systematic approach. The analysis can

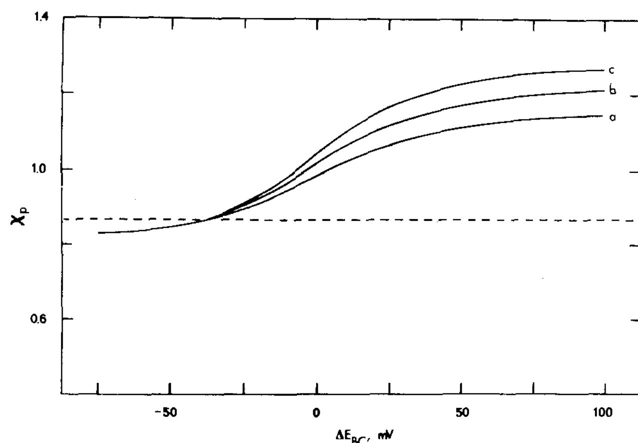

Fig. 11. Variation of χ_p as a function of ΔE_{BC} for $\lambda_d = 10$ and α_2 equal to (a) 0.35; (b) 0.50; and (c) 0.65. Dashed line indicates the value where χ_p has increased by 5%.

be segregated into the following steps:
1. determination that EE mechanism is occurring
2. determine if disproportionation is occurring
3. determination of the reversibility of electron transfer
4. identification of the slow step
5. calculation of electron transfer parameters

Step 1.—The determination that an EE mechanism is occurring is most easily done by double-potential step chronoamperometry. By comparison of the diffusion current with compounds of known electrochemical behavior, the n value can be calculated. Second, from the i_a/i_c ratio, the stability of the product can be verified and one can verify that no irreversible chemical reactions are occurring. Third, the $i_c\sqrt{t}/C_A{}^*$ value should be constant, indicating that no new electroactive products are formed. The value of the final potential must be negative enough so that the slow electron transfer step does not affect the $i_c\sqrt{t}/C_A{}^*$ value.

Step 2.—Since the value of λ_d depends upon $C_A{}^*$, the shape and position of the wave should be dependent upon $C_A{}^*$. Conversely, ψ' is independent of $C_A{}^*$, so one can determine if disproportionation is important under the conditions used.

Step 3.—If the shape or position of the wave is independent of scan rate, then the electron transfers are reversible. If the values of ΔE_p are between 30 and 150 mV, at least one of the electron transfers is slow and the wave is quasireversible. If the ΔE_p values are greater than 150 mV, the electron transfer is irreversible.

Step 4.—The identity of the slow step can be surmised from several ways depending upon the rate of the electron transfers. If the wave is quasireversible, it is difficult to determine the slow step because of the similarities in working curves. Only if scan rates large enough so that ψ' is < 0.1, (*i.e.*, the wave is irreversible) are used can one determine which step is slow.

If the electron transfer is irreversible, the identity of the slow step can be easily determined from the ratio of the peak currents, $i_{p,a}/i_{p,c}$, where $i_{p,a}$ is measured from a baseline calculated from the $t^{-1/2}$ decay of the cathodic current. If the first step is slow, then from Eq. [12] and [34]

$$i_{p,a}/i_{p,c} = \sqrt{(2-\alpha_1)/\alpha_1} \qquad [47]$$

Since $\alpha_1 < 1$

$$i_{p,a}/i_{p,c} > 1 \qquad [48]$$

for all values of α_1. Conversely, if the second electron transfer is slow

$$i_{p,a}/i_{p,c} = \sqrt{(1-\alpha_2)/(1+\alpha_2)} \qquad [49]$$

Once again, α_2 is less than one. Thus

$$i_{p,a}/i_{p,c} < 1 \qquad [50]$$

Substitution of typical values of α into Eq. [47] or [49] will show that there will be significant deviations from unity for the peak current ratio. In order to use this criterion with confidence, ψ' should be less than 0.1 ($\Delta E_p > 150$ mV) and reduced product must be stable.

Step 5.—The calculation of the parameters related to the electron transfer can now be determined once the previous steps have been completed. If the wave is reversible, only the $E_{1,2}$ value can be determined for sure. If ΔE is less than 180 mV, E_1 and E_2 can also be found. If the wave is quasireversible, then ψ' and $E_{1,2}$ can be calculated. Once again, if ΔE is less than 180 mV, E_1 and E_2 can also be found. If scan rates large enough to make the wave irreversible are used, α can be determined (and hence ψ if E_1 and E_2 are known). If the wave is irreversible, α can be calculated from the shape or shift in the wave and ψ' can be calculated from the ΔE_p values. Finally, $E_{1,2}$ can be found. If the values of ΔE_{AB} or ΔE_{BC} are appropriate, then E_1, E_2, and ψ can be found. In all this analysis, it is assumed that the other electron transfer remains reversible. This, in practice, limits the maximum scan rates which can be used to analyze the data by this method.

Results and Conclusions

The reduction of benzil (Bn) in 0.10F barium perchlorate with DMF as solvent is a two-electron quasireversible electron transfer. The cyclic voltammetric data for this solution is shown in Table III. Using the criteria discussed earlier, single and double step chronoamperometry verified that the reduction was a two-electron transfer for times at least as short as 1 msec and that the reduction product was stable. The second step in the analysis was to vary the concentration of benzil to determine if disproportionation was occurring. It was found that for C_{Bn} equal to 0.75 and 5.0 mM no change in the shape of the wave was observed (6). Thus, one could analyze the data in Table III without including the disproportionation reaction. The third step is to determine the reversibility of the electron transfer. Since ΔE_p is greater than 150 mV for all scan rates studied, the electron transfer is irreversible. Finally, because the $i_{p,a}/i_{p,c}$ ratios are much less than 1.0, the second electron transfer must be the slow step.

For the data below 1 V/sec, the experimental data fits quite well with the theory for an EE mechanism. From the ΔE_p values, it was possible to find α_2, which is equal to 0.66. Equation [39], [41] and [42] can then be expressed in the following manner

$$\log \psi_2' = -4.78(\Delta E_p + 0.021) \qquad [47]$$

$$E_{1,2} = E_{pc} + 0.0355\,(0.355 - \log \psi_2') \qquad [48]$$

$$\Delta E = 2(\Delta E_{BC} - 0.0355 \log \psi_2') \qquad [49]$$

The results obtained by these equations are shown in Table IV. Using these values as estimates, it was possible to generate theoretical voltammograms and compare them with the experimental data. This is shown in Fig. 12 for benzil at 100 mV/sec. The best values given in Table IV are obtained from the best fits of

the experimental data with the simulated voltammograms.

There occur significant deviations at scan rates above 1V/sec due to the slow rate of the first electron transfer. The values of $k_{s,1}$ and α_1 were determined by digital simulation, using the values already calculated for the second electron transfer. It was found that α_1 was equal to 0.7, and $k_{s,1}$ was equal to 6.5×10^{-3} cm/sec. The experimental data along with the theoretical curves are shown in Fig. 13 for the $E_{pp/2}$ values. An experimental voltammogram with the simulated wave is shown in Fig. 14 for benzil at 1.0 V/sec.

The rate of the first electron transfer appears to be unusually slow when compared to the rate of reduction with tetrabutylammonium perchlorate (TBAP) as a supporting electrolyte. But once again we are dealing with an apparent electron transfer rate constant, $k_{s,1}$*,

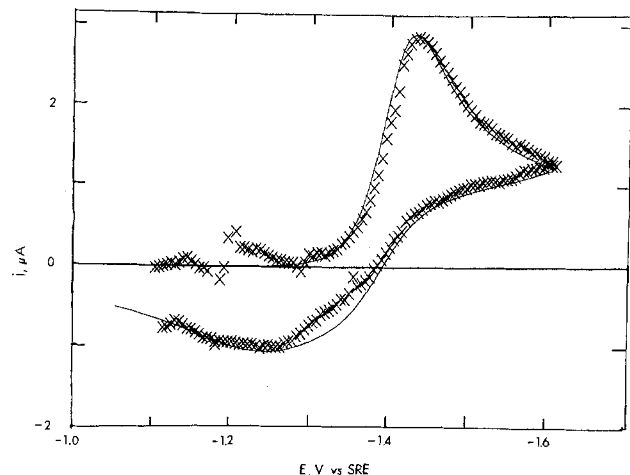

Fig. 12. Cyclic voltammogram for the reduction of 0.75 mM benzil in DMF with 0.10F $Ba(ClO_4)_2$. Scan rate = 100 mV/sec; solid line, theoretical; x, experimental points.

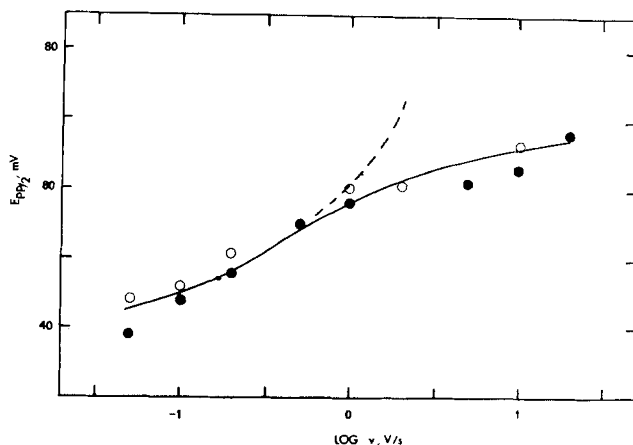

Fig. 13. The variation of $E_{pp/2}$ as a function of scan rate. Solid line, $k_{s,1}$ = 0.10 cm/sec, α_1 = 0.7, $k_{s,2} = 5.0 \times 10^{-4}$ cm/sec, α_2 = 0.66; dashed line, first-electron transfer reversible; closed circles, C_{Bn} = 0.75 mM; open circles, C_{Bn} = 5.0 mM.

instead of the true $k_{s,1}$. This is caused by the shift of the benzil

$$Bn + e \rightleftharpoons Bn^{\overline{\cdot}} \quad [50]$$

$$Bn^{\overline{\cdot}} + Ba^{2+} \overset{K}{\rightleftharpoons} BnBa^{\overset{+}{\cdot}} \quad [51]$$

reduction from its equilibrium position being due to the ion-pairing reaction. Since the wave occurs positive of the potential where benzil alone is reduced, the heterogeneous forward rate constant, k_{hf}, at the peak potential is less than $k_{s,1}$ due to the exponential relationship between k_{hf} and $k_{s,1}$

$$k_{hf} = k_{s,1} \exp \left[-\alpha_1 \frac{nF}{RT} (E - E^o) \right] \quad [52]$$

If one solves the boundary value problem for the above reaction, it turns out that $k_{s,1}$* is related to $k_{s,1}$ by the following equation

$$k_{s,1} = k_{s,1}^* (1 + KC_{Ba})^{\alpha_1} \quad [53]$$

where C_{Ba} is the concentration of the barium ion. For KC_{Ba} = 115 and α_1 = 0.7, $k_{s,1}$ is 0.18 cm/sec. This value of $k_{s,1}$ is within the range that has been observed for several quinones recently (12). This value is still smaller than the minimum value estimated in the presence of TBAP only. This difference cannot be due to ion pairing between the barium and perchlorate ions. While this will reduce [Ba^{2+}], it will at the same time increase the value of K because the K[Ba^{2+}] value was observed experimentally. In addition, estimations of the Ba-ClO_4 ion pair constant from Bjerrum's theory (13) and from data for Mg-ClO_4 in acetonitrile and acetone (14) indicate that ion pairing of the barium perchlorate electrolyte is insignificant in DMF. This lower rate constant could be due, though, to double layer changes caused by the presence of barium ions.

Using the information in Table IV, it is possible to estimate the maximum value for the disproportionation rate constant, k_d, using Eq. [45]. The maximum value of k_d depends upon scan rate, with the disproportionation reaction being more important at faster scan rates because ΔE_{BC} is decreasing. For C_{Bn} = 0.75 mM, it was found that k_d must be less than 700 M^{-1} sec^{-1}. This maximum value may be too small to see. A more practical value is probably 3×10^3 M^{-1} sec^{-1}. Since no disproportionation reaction is seen for the 5 mM solution, k_d must be less than 750 M^{-1} sec^{-1}. It is interesting to note that if ψ_2' were zero, a value of k_d = 750 M^{-1} sec^{-1} could be easily seen and calculated. Thus, for C_{Bn} = 5 mM and v = 50 mV/sec; λ_d

would be 2.7. But this reaction, if it occurs, is obscured by the second electron transfer.

The determination of $k_{s,2}$ for the reduction of benzil in the presence of strontium ion can be accomplished in the same way. The α_2 value was again found to be 0.65. Thus, Eq. [47]-[49] could be used. The results are shown in Table V. The calculated values for the benzil reduction with the strontium ion present agree well with the values determined by trial-and-error simulation. As was seen before (6), the second-electron transfer is somewhat slower with the strontium ion pair than with the barium ion pair. This difference, though, could be due to double layer effects.

The simplicity of this method of analysis is quite evident. Previously, it was necessary to perform a considerable number of trial and error simulations before the best fit could be obtained in order to determine the electron transfer parameters for the EE mechanism. But by use of the equations given in the paper, it was possible to directly calculate the parameters. A second advantage is that it is possible to identify significant deviations from the EE mechanism, as was shown in this case for scan rates in excess of 1 V/sec with barium ions present. If an EE mechanism is occurring with only one of the k_s values being slow, the shape of the wave should follow the criteria given previously. In particular, a good diagnostic criteria is the shift in the anodic and cathodic peak potentials with scan rates. Consistent α values should be obtained from these calculations. A factor complicating the analysis is the situation where both electron transfers may be slow. The diagnostic criteria will obey qualitatively the analysis given in this paper, but will fail seriously upon quantitative analysis. Work is in progress in this laboratory to present similar methods for the analysis of this case.

Transport Parameters for Potassium Hydroxide-Water Solution in a Cation Exchange Membrane

Manojit Sinha and Douglas N. Bennion*

Chemical, Nuclear, and Thermal Engineering Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The salt transport parameter L_e, the water transport parameter L_o, and the cation transference number $t_+{}^m$ have been measured for an RAI P2291 cation exchange membrane for aqueous KOH solutions. The transference number decreases with increase in concentration. For the concentration range 1.0-10.0M a straight line fit was obtained by linear regression. A correction to $t_+{}^m$ in the range of 0.453-0.846 has been used to compensate for the concentration gradient buildup in the porous electrodes due to the passage of current. The L parameters are not constant during the course of a dialysis experiment. An optimization procedure has been used to select the most accurate set of values of L_e ($=2.924 \times 10^{-5}$ cm/sec) and L_o ($=2.057 \times 10^{-4}$ cm/sec) for a single run.

An important application of ion-exchange membranes is in the field of batteries. Synthetic polymers were widely used as battery separators when attempts were being made to improve the performance and life of batteries. These were mostly commercially available films such as cellophane. In the past few years serious attempts have been made to make such films specifically for use as battery separators (1).

RAI-Permion 2291 membranes tested in this work are mainly for use in zinc-silver oxide batteries as an argentistatic spacer. The purpose of the argentistatic spacer is to inhibit the migration of $Ag(OH)_2^-$ in the alkaline solution. Cellophane was used in the early stages of practical zinc-silver oxide cells. Silver reacts with cellophane, thus deteriorating the film. There is an initial low rate of permeation of silver through the membrane (cellophane). After an appreciable period of time the rate of permeation increases. This is apparently caused because the membrane capacity for silver is reached. Permion membranes are more stable.

Permion membranes are made using a 1 mil thick low density polyethylene film made from a Bakelit DFD0602 resin (2). This resin has a narrow molecular weight distribution which is desirable since this gives the most efficient crosslinking per unit of energy used. The extruded film is crosslinked using high energy beta radiation to give a distance between crosslinked sites of 3000-5000 (that is the molecular weight between sites). Permion 2291 40/30 is then made from the crosslinked film by radiation grafting approximately 40% methacrylic acid onto the base film using a chain transfer agent to limit the chain length. (When a reactive monomer is present during irradiation, it may react with the free radicals giving a "grafted" side chain). This grafted film is finally converted to the potassium form by washing in 5% potassium hydroxide solution at 95°C for 3-4 min.

Permion 2291 is a weak cation exchange membrane meant to be used in alkaline electrolyte. It also appears to be useful in situations where high temperature, long wet stand, oxidation resistance, and high rate of charge/discharge are required.

The transference number of the K^+ ion and the L parameters are important in predicting shape change in the zinc electrode of zinc-silver oxide secondary electrodes (3). In this work the transference number of the K^+ ion has been experimentally determined through the RAI P2291 membrane in KOH solutions. The concentration range of measurement is 1.0-10.0M. The average diffusion coefficients of the electrolyte and solvent through the membrane have been measured in the range of concentration 4.95-7.63M. The specific conductivity and the fixed ion concentration of the ion-exchange membrane have also been measured.

Theory

Bennion and Rhee (4) define driving forces as a revised form of Stefan-Maxwell equation

$$d_i = \sum_j K_{ij}(v_j - v_i) \quad [1]$$

and, after a rigorous derivation arrive at flux equations written below

$$N_+ = c_+v_+ = z_-\mathcal{L}_e\nabla\mu_e + z_-\mathcal{L}_{eo}\nabla\mu_o + \frac{t_+i}{z_+\mathbf{F}} \quad [2]$$

$$N_- = c_-v_- = -z_+\mathcal{L}_e\nabla\mu_e - z_+\mathcal{L}_{eo}\nabla\mu_o + \frac{t_-i}{z_-\mathbf{F}} \quad [3]$$

$$N_o = c_ov_o = -\frac{z_+}{\nu}\mathcal{L}_{oe}\nabla\mu_e - \mathcal{L}_o\nabla\mu_o + \frac{t_oi}{\mathbf{F}} \quad [4]$$

Equations [2]-[4] define five independent parameters $\mathcal{L}_e$, $\mathcal{L}_o$, $\mathcal{L}_{eo}$, t_+, t_-. It must be kept in mind that $t_+ = (1 - t_-)$. Also, $\mathcal{L}_{eo} = \mathcal{L}_{oe}$. The sixth independent parameter is the electrical conductivity, κ, which appears in the current equation

$$i = -\kappa\nabla\Phi - \frac{\kappa}{n\mathbf{F}}\left(\frac{s_+t_-}{\nu_+} + \frac{s_-t_+}{\nu_-}\right)\nabla\mu_e - \frac{\kappa}{n\mathbf{F}}(nt_o + s_o)\nabla\mu_o \quad [5]$$

These flux equations need to be integrated across the membrane. It is easier to perform the integration if chemical potentials are replaced by concentration and pressure terms. At this point it should be mentioned that some investigators have used activity instead of concentration. Concentration is a quantity easy to understand and to measure, and hence it has been preferred to activity in this derivation.

Let us consider μ_e and μ_o to be functions of c_e and P, T being assumed constant. From first principles

$$\nabla\mu_e = \frac{\partial\mu_e}{\partial c_e}\nabla c_e + \frac{\partial\mu_e}{\partial P}\nabla P \quad [6]$$

$$\nabla\mu_o = \frac{\partial\mu_o}{\partial c_e}\nabla c_e + \frac{\partial\mu_o}{\partial P}\nabla P \quad [7]$$

* Electrochemical Society Active Member.
Key words: batteries, transference numbers, diffusion coefficients.

Also, the partial differentials may be written as

$$\frac{\partial \mu_e}{\partial c_e} = \frac{RT}{c_e}\left(1 + \frac{d \ln f_\pm}{d \ln c_e}\right) \nabla c_e \quad [8]$$

$$\frac{\partial \mu_o}{\partial \mu_e} = \frac{RT}{c_o}\left(1 + \frac{d \ln f_o}{d \ln c_o}\right) \frac{\partial c_o}{\partial c_e} \nabla c_e \quad [9]$$

And, using a simple, linearized equation of state $c_o = c_o^\circ - ac_e - b(P^\circ - P)$, we arrive at

$$\frac{\partial c_o}{\partial c_e} = -a \quad [10]$$

Substitution of Eq. [8]-[10] into Eq. [6] and [7] gives us

$$\nabla \mu_e = \frac{RT}{c_e}\left(1 + \frac{d \ln f_\pm}{d \ln c_e}\right) \nabla c_e + \overline{V}_e \nabla P \quad [11]$$

$$\nabla \mu_o = -\frac{RT}{c_o}\left(1 + \frac{d \ln f_o}{d \ln c_o}\right) a \nabla c_e + \overline{V}_o VP \quad [12]$$

If δ is the effective membrane thickness across which the integration is performed and when the electric current density is zero (the salt flux, N_e, can be defined as $N_e = N_+/\nu_+ = N_-/\nu_-$), the flux equations can be integrated to yield the following

$$N_e = -L_e \Delta c_e - L_{ep} \Delta P \quad [13]$$

$$N_o = L_o \Delta c_e + L_{op} \Delta P \quad [14]$$

The expressions for the L parameters are given below

$$L_e = -\frac{z_- RT}{\nu_+ \overline{c}_e}\left(1 + \frac{d \ln f_\pm}{d \ln c_e}\right)\frac{\mathcal{L}_e}{\delta} + \frac{z_- RT}{\nu_+ \overline{c}_o}\left(1 + \frac{d \ln f_o}{d \ln c_o}\right) a \frac{\mathcal{L}_{eo}}{\delta} \quad [15]$$

$$L_{ep} = -\left(\frac{z_- \overline{V}_e}{\nu_+}\frac{\mathcal{L}_e}{\delta} + \frac{z_- \overline{V}_o}{\nu_+}\frac{\mathcal{L}_{eo}}{\delta}\right) \quad [16]$$

$$L_o = -\frac{z_+}{\nu_-}\frac{RT}{\overline{c}_e}\left(1 + \frac{d \ln f_\pm}{d \ln c_e}\right)\frac{\mathcal{L}_{oe}}{\delta} + \frac{RT}{\overline{c}_o}\left(1 + \frac{d \ln f_o}{d \ln c_o}\right)\frac{a \mathcal{L}_o}{\delta} \quad [17]$$

$$L_{op} = -\left(\frac{z_+ \overline{V}_e}{\nu_-}\frac{\mathcal{L}_{oe}}{\delta} + \frac{\overline{V}_o \mathcal{L}_o}{\delta}\right) \quad [18]$$

Equations [15]-[18] are important because they show how the four transport parameters L_e, L_o, L_{ep}, and L_{op} are related to three independent transport parameters $\mathcal{L}_e$, $\mathcal{L}_o$, and $\mathcal{L}_{eo}$.

When the driving force ΔP is zero and the current density is not zero, the flux equations may be written in the following form

$$N_+ = -L_e \Delta c_e + \frac{t_+ i}{\mathbf{F}} \quad [19]$$

$$N_o = L_o \Delta c_e + \frac{t_o i}{\mathbf{F}} \quad [20]$$

In certain cases when concentrations inside the ion-exchange membrane are desired, an estimate can be made by using the Donnan exclusion principle. An ion-exchange membrane has fixed ions in the structure. Let us denote this fixed ion concentration by X. Then, the electroneutrality condition yields

$$c_+ = X + c_- \quad [21]$$

Treating both internal and external solutions as ideal, that is, neglecting activity coefficient correction, equality of potentials according to Gibbs-Donnan principle requires that at equilibrium

$$c_+ c_- = c^2 \quad [22]$$

where c = concentration of external solution. Combination of Eq. [21] and [22] yields

$$c_+ = \left[\left(\frac{X}{2}\right)^2 + c^2\right]^{1/2} + \frac{X}{2} \quad [23]$$

$$c_- = \left[\left(\frac{X}{2}\right)^2 + c^2\right]^{1/2} - \frac{X}{2} \quad [24]$$

where c_+ and c_- in this case denote concentrations of the respective ions inside the membrane.

The experimental cell is a dialysis-type cell fitted with capillary tubes to measure volume flows and electrodes to measure transference numbers and electrical conductivity, see Fig. 1.

The sign convention being used is: (*i*) Any flow into a compartment is positive; (*ii*) Any flow out of a compartment is negative.

Thus, a mass balance of compartment 2 is given by the equation

$$N_{e2} = \frac{V}{A}\frac{dc_{e2}}{dt} + \frac{c'_{e2}s}{A}\frac{dl_2}{dt} \quad [25]$$

where s = cross sectional area of capillaries; V = volume of compartment; A = area of cross section of membrane; and c'_{e2} = concentration in capillary if flow is into the compartment or, concentration in the compartment (c_{e2}) if flow is out of the compartment. Thus, when transport across the membrane is only by migration in an electric field

$$N_{e2} = \frac{V}{A}\frac{dc_{e2}}{dt} + \frac{c'_{e2}s}{A}\frac{dl_2}{dt} = \frac{t_+ i}{z_+ \mathbf{F}}$$

Since $dl_2/dt\ c'_{e2}s/A$ is very small it can be neglected. Hence

$$t_+ = \frac{V\mathbf{F}z_+}{iA}\frac{dc_{e2}}{dt} \quad [26]$$

When the solutions on both sides of the membrane have the same concentration (same electrolyte), from Eq. [10]

$$i = -\kappa \nabla \Phi \quad [27]$$

This is Ohm's law. The specific conductivity of the membrane, κ, is defined from Eq. [27] as

$$\kappa = \frac{i}{\nabla \Phi} = \left(\frac{I}{A}\right)\left(\frac{\delta}{\Delta \Phi}\right) \quad [28]$$

where $\Delta\Phi$ is the voltage drop across the membrane as measured by two Hg/HgO reference electrodes.

Equipment.—The major equipment used for the experiments are the cell (Fig. 2 and 3) and Hg/HgO reference electrodes which were made according to the procedure suggested by Bennion (5). Two cells were constructed. In the first one (referred to as the larger cell) each compartment had a volume of 50 cm³, and a cross-sectional area of 20 cm². The second cell (referred to as the smaller cell) had a compartment volume of 4 cm³ and a cross-sectional area of 3 cm². The basic design of both cells were the same.

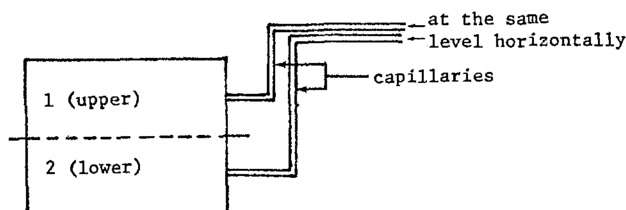

Fig. 1. Schematic diagram of cell assembly

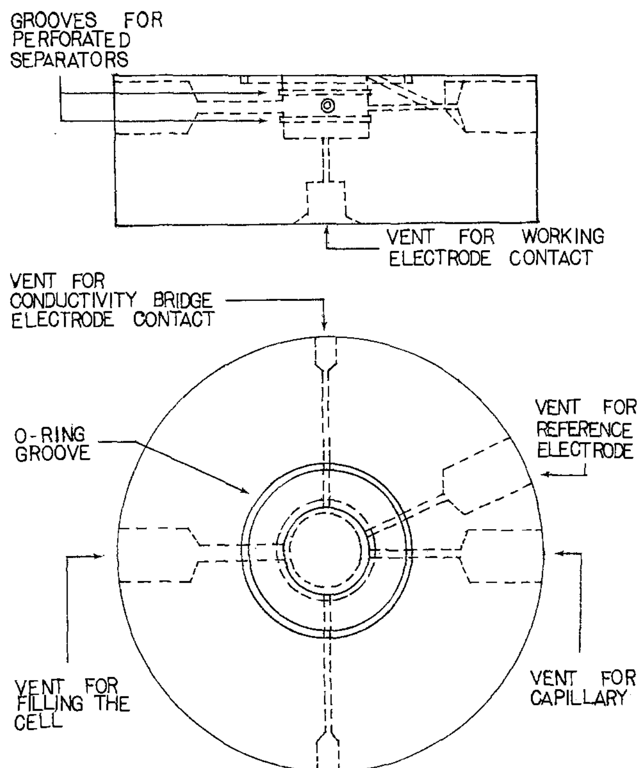

Fig. 2. Schematic diagram of a cell compartment

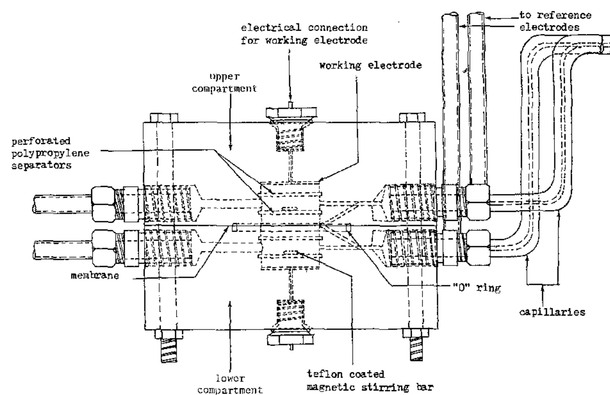

Fig. 3. Assembled cell

Experiments.—Two different experiments were conducted to find the diffusion coefficients, transference numbers, and specific conductivity of the membrane.

Hittorf experiment.—In this experiment both the cell compartments were filled with the same KOH solution. The working electrodes used were Ag/AgO porous electrodes or $Ni(OH)_2$/NiOOH porous electrodes (supplied by the Air Force Aero Propulsion Laboratory, Wright Patterson AFB). The cell compartments were separated by a Permion 2291 membrane (supplied by RAI Corporation). A precalculated current is passed for a predetermined time. This calculation is done assuming a transference number of 0.5, selecting a concentration that can be accurately measured, and determining current and time to give the change. During the course of the experiment the flow rates in the capillaries (horizontally placed tubes) were observed. At the end of the experiment the cell was taken apart and the solution concentrations in the two compartments were analyzed to give the change in concentration. The analysis of the solution was done by titrating with a standard HCl solution using as indicators a pH-meter and phenolphthalein.

At the start of the Hittorf experiment, the potential drop across the membrane was measured with Hg/HgO

a, b, c are separate runs with the same starting concentration.

reference electrodes, and thus the specific conductivity of the membrane was obtained.

Dialysis experiment.—This experiment is based upon a concentration difference imposed across the membrane and this difference decreasing due to diffusion across the membrane. The concentrations of KOH solution on either side of the membrane were known at the start of the experiment and were measured during the course of the experiment, as described later. Observation was also made of the flow in the capillary. It may be mentioned at this point that the concentration of the KOH solution in a compartment may be measured by an a-c conductivity bridge or by titrating samples. The latter method was used in this case.

Results

The results of the Hittorf experiments are summarized in Table I and Fig. 4. The mass transfer coefficients are calculated on the basis of observations

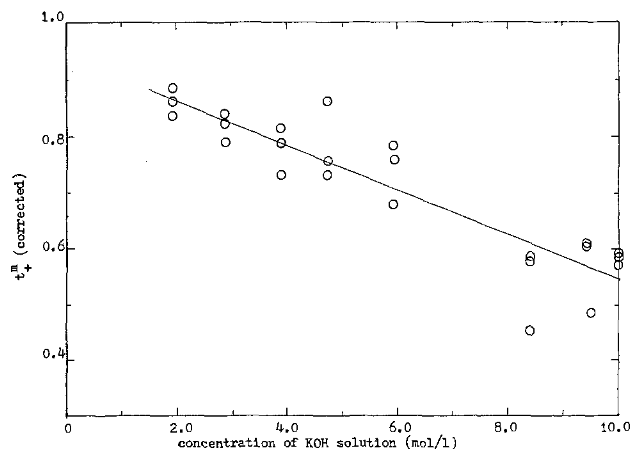

Fig. 4. Corrected transference numbers of K^+ ions through RAI P2291 membrane.

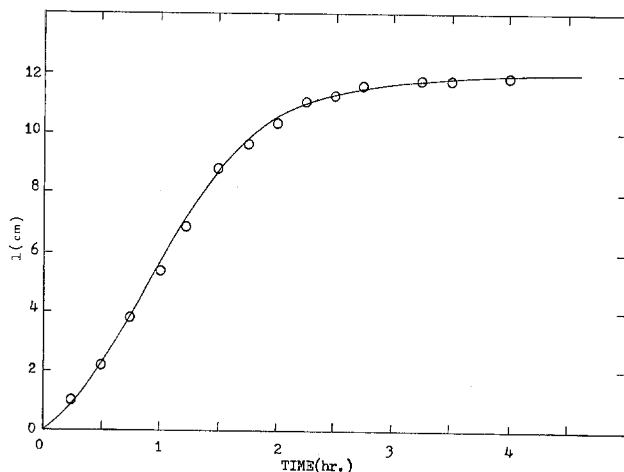

Fig. 6. Volumetric flow observed in the capillary corresponding to the upper compartment (solution flowing in) in dialysis experiment.

shown in Fig 5 and 6, and the procedure outlined in Appendix II. The results of the calculation are summarized in Table II. The specific conductivities are given in Table III.

From the data shown in Fig. 5 and 6 and the procedure outlined in Appendix II, the values of L parameters obtained are shown in Table II.

Discussion

Use of porous electrodes.—Porous electrodes were used instead of a plain metal sheet because their capacity is much higher. As a result, a much higher current can be passed without causing the electrode to "gas." Gassing is undesired because there is no outlet from the cell for the gas to escape and it builds up pressure forcing liquid out of the cell. There is one

Table II. Mass transfer coefficients

Starting concentration Upper compartment (mole/liter)	Lower compartment (mole/liter)	L_e (cm/sec)	L_o (cm/sec)	D_e (cm²/sec)	D_o (cm²/sec)
7.6295	4.9557	2.924×10^{-5}	2.057×10^{-4}	7.428×10^{-8}	5.225×10^{-7}

It should be noted that the L parameters are mass transfer coefficients, while the D's are diffusion coefficients. The conversion from one to the other is simple and is given below.

$$D_i = \delta L_i$$

where δ = thickness of the membrane = 2.54×10^{-3} cm.

Table III. Specific conductivity of membrane

Conc. of KOH on both sides of membrane (mole/liter)	Current (A)	Voltage drop (V)	Sp. conductivity (Ω cm)$^{-1}$
8.3993	0.250	0.01600	2.006×10^{-3}
9.4210	0.250	0.00965	3.326×10^{-3}
9.5080	0.200	0.00955	2.689×10^{-3}
9.9947	0.200	0.00975	2.634×10^{-3}

From the above table κ (av) = 2.664×10^{-3} (Ω cm)$^{-1}$.

disadvantage in using porous electrodes, however. As the electrodes are charged/discharged, a concentration gradient builds up within the thickness of the electrode. If the cell compartment is small, this difference, unaccounted for in the solution analysis, could be significant. Hence, simple corrections were made.

Preference of Ni electrodes over Ag electrodes.—$Ni(OH)_2/NiOOH$ electrodes were used in later experiments instead of Ag/AgO. When Ag/AgO electrodes were used, in a very short time the working area of the membrane (exposed to KOH solution) became colored dark brown. Two things may have happened which could cause the membrane to turn brown. It could have been attacked by KOH solution, which seemed unlikely. Another possibility was AgO going into solution and depositing in the membrane. This was verified by observing the membrane under a microscope. It looked as if some particles had deposited on the membrane and actually got enmeshed with it. The particles could be AgO or Ag, the silver being reduced by the membrane. A possible consequence of such a happening was membrane pores getting clogged or membrane molecules being oxidized and the properties of the membrane changing. So ($Ni(OH)_2/NiOOH$ porous electrodes were tried and they seemed to leave the membrane surface clear.

Comparison of L parameters with previous investigators.—Knowledge of the L parameters is necessary for the analysis of shape change in zinc secondary electrodes (3, 6). It is interesting to compare the values obtained in this work to the values estimated by Choi *et al.* in the above reference. In the analysis by Choi *et al.* there was one more species (Zn^{+2}) than in this analysis. Consequently, the flux equations for the K^+ and water were

$$N_{K,x}m = L_{kk}(c_K{}^n - c_K{}^p) + L_{kz}(c_{Zn}{}^n - c_{Zn}{}^p) + \frac{t_K m i}{\mathbf{F}}$$

$$N_{O,x}m = -L_{oz}(c_{Zn}{}^n - c_{Zn}{}^p) - L_{ok}(c_K{}^n - c_K{}^p) + \frac{t_o m i}{\mathbf{F}}$$

where L_{kk} = mass transfer coefficient of electrolyte and L_{ok} = mass transfer coefficient of water. These two equations may be compared with the Eq. [19] and [20].

Numerical values estimated by Choi *et al.* are given below for comparison with values in parentheses for this work.

$$L_{kk} = 1.0 \times 10^{-5} \text{ cm/sec } (L_e = 2.9 \times 10^{-5} \text{ cm/sec})$$

$$L_{ok} = 2.0 \times 10^{-5} \text{ cm/sec } (L_o = 2.0 \times 10^{-4} \text{ cm/sec})$$

It should be mentioned at this point that in the work by Choi *et al.* a lot of emphasis was laid on determining the cause of shape change. In the process not too much attention was focused on the exact values of the L parameters.

Comparison of electroosmotic flow with previous investigators.—The electroosmotic coefficient, t_o, played a very important role in the shape change in zinc secondary electrodes (3, 6). The values of electroosmotic flow observed in this work has been reported below for comparison with that observed by Choi *et al.*

The electroosmotic coefficient is defined as

$$N_o = t_o^m (i\,\mathbf{F}) \quad \text{for } \Delta P \text{ and } \Delta c_e \text{ zero}$$

where N_o = water flux (mole/cm^2/sec); i = current density = I/A (A/cm^2); I = current (A); and A = area of cross section (cm^2). Hence, we can also write

$$AN_o = t_o^m I/\mathbf{F} \quad \text{(mole/sec)}$$

Multiplication of both sides by partial molar volume of water gives the volume of water flowing (V_{fo}). Similarly, there is a volumetric salt flux (V_{fe}). These fluxes are given by the following equations

$$V_{fo} = AN_o\overline{V}_o = t_o^m I\overline{V}_o/\mathbf{F} \quad \text{(cm}^3\text{/sec)}$$

$$V_{fe} = AN_e\overline{V}_e = t_+^m I\overline{V}_e/\mathbf{F}n \quad \text{(cm}^3\text{/sec)}$$

Thus, the total flux (in the same direction due to electroosmosis) is

$$V_{ft} = V_{fo} + V_{fe} = \frac{I}{\mathbf{F}}\left(t_o^m\overline{V}_o + \frac{1}{n} t_+^m\overline{V}_e \right) \quad \text{(cm}^3\text{/sec)}$$

This is what Choi *et al.* have reported (6). From the above equation $V_{ft} \propto I$, provided everything else is constant, and V_{ft} is independent of A if I is constant. Taking the data for the case when initial solution concentration was 9.9947M, volume change observed (capillary flow) = 2.02167×10^{-5} cm^3/sec (volume flow inward for the anodic compartment). Change in volume due to the reaction at the electrode = $\Delta V_{el}/\Delta t$ = $(\frac{1}{2}\,\overline{V}_{Ag_2O} - \overline{V}_{Ag})\,(I/\mathbf{F}) = 1.232704 \times 10^{-5}$ cm^3/sec. (This has been calculated for the Ag electrode for a current of 200 mA. It should also be noted that the volume of the anode increases.)

Total volumetric flow (200 mA) = 3.254374×10^{-5} cm^3/sec

Total volumetric flow (1A) = 1.627187×10^{-4} cm^3/sec

The values reported by Choi *et al.* for 1A current were in the range of 1.5 to 2.0×10^{-4} cm^3/sec, and as we can see, the value observed in this work is comparable in magnitude.

APPENDIX I

Derivation of Concentration Profile in the Porous Electrode Due to Passage of Current and Correction for Transference Number

During the course of the Hittorf experiment a concentration gradient builds up in the porous electrodes. This necessitates a correction to Eq. [26]. As a result of this concentration gradient, the concentration in the compartment does not reflect the actual change produced due to the current alone.

The differential equation governing the concentration inside the electrode is

$$D_1 \frac{\partial^2 c}{\partial x^2} + (k_1 a)c = \frac{\partial c}{\partial t} \qquad \text{[A-1]}$$

Initial condition: at $t = 0$, $c = c^o$ for all x; boundary conditions: at $t > 0$, $c = c^o - At$ for $x = 0$; $\partial c/\partial x = 0$ for $x = L$; $D_1 = \mathfrak{D}(1 - d \ln c_o/d \ln c)$ = diffusion coefficient.

$k_1 a$ is an average reaction constant, which is calculated on the assumption that transference number of the positive ion (K^+) is ½, and the reaction is first order. The other assumptions made in this derivation are that the initial concentration is known and it is a steady-state process (current is constant throughout).

Using a change of variable as given below and following the procedure as given by Carslaw and Jaeger (7), a series solution is obtained

$$c/c^o = u \exp(k_1 at) \qquad \text{[A-2]}$$

$$\frac{c}{c^o} = \left(1 - \frac{At}{c^o}\right) + \frac{4}{\pi} e^{k_1 at} \sum_{n=1}^{\infty} \frac{1}{m} \sin\left(\frac{m\pi x}{2L}\right) + \frac{D_1 \pi}{L^2} \sum_{n=1}^{\infty} m \sin\left(\frac{m\pi x}{2L}\right) \left\{ \frac{(A/c^o)t}{D_1 m^2\pi^2/l^2 - k_1 a} \right.$$
$$\left. \frac{[1 - e^{(k_1 a - D_1 n^2\pi^2/l^2)t}]\left[\left(\frac{A}{c^o} - k_1 a\right) + (D_1 m^2\pi^2/4L^2)\right]}{(D_1 m^2\pi^2/l^2 - k_1 a)^2} \right\} \qquad \text{[A-3]}$$

This is the final solution for the concentration profile in the electrode. It should be noted that the solution is valid only for an open interval, and the solution is good for odd values of n only; thus, $m = 2n - 1$. Also, $L = \frac{1}{2}\, l$ = electrode thickness.

The actual transference number is

$$t_+^m(\text{corrected}) = \frac{V_t C^o - (V_c c^f + V_{el} C_{av})}{I(\Delta t)} \mathbf{F} \qquad \text{[A-4]}$$

APPENDIX II

Calculation of Average L Parameters from the Experimental Values

Since the concentration of KOH in a compartment varies during the course of a dialysis experiment, the values of L_e and L_o are not constant either. To find the average values of the L parameters with the least error, the procedure adopted is outlined below.

1. Choose values of L_e and L_o as estimated from experiment.
2. (*i*) Theoretically derive expressions for concentration profile with time as independent variable.
3. (*ii*) Compare this theoretical profile with the experimental profile.
4. Define an error function and calculate the error (E)

$$E = \sum \left[\frac{c_{em}(i) - c_{el}(i)}{c_{em}(i)} \right]^2$$

5. Vary L_e and L_o within the experimental limits and choose the set which gives the least error.

The derivation for concentration profile is given below: Subscript 1, 2 denote concentrations in the respective compartments. c_{eo} = total starting concentration = $c_{eo1} + c_{eo2}$; c_{eoi} = starting concentration in compartment i.

Assumptions used are as follows: (*i*) The total number of moles in the system is constant; (*ii*) The volumetric flow of solution in the capillaries is small enough to be neglected; thus, $dl_i/dt = 0$.

The electrolyte continuity equation can be easily integrated now, with the initial condition: at $t = 0$, $C_{e1} = C^o_{e1}$, yielding the result

$$C_{e1} = \frac{C^o_{e1} + C^o_{e2}}{2} - \frac{(C^o_{e2} - C^o_{e1})}{2} \exp\left(-2\frac{A}{V}L_e t\right) \quad [A\text{-}5]$$

A similar but more complicated expression can be derived if assumption (*ii*) is not valid (8).

An Electrochemical Study of Chromium in Molten $NaCl\text{-}AlCl_3$

C. L. Hussey,* L. A. King,* and J. K. Erbacher

The Frank J. Seiler Research Laboratory (AFSC), United States Air Force Academy, Colorado 80840

ABSTRACT

Chromium, introduced into NaCl-saturated $AlCl_3$ melt ($N_{AlCl_3} = 0.498$) as $CrCl_3$, underwent two reduction steps at a glassy carbon disk electrode. For the first reduction wave, $n = 1$ and $E_{1/2} = 1.09V$ *vs.* a reference electrode of aluminum in NaCl-saturated $AlCl_3$ at 175°C. The stationary electrode voltammetric response indicated that a reversible chemical step preceded electron transfer. A second reduction wave, $E_p{}^c$ *ca.* 0.1-0.2V, was attributed to the deposition of Cr(O). The chronoamperometric response for this wave was similar in form to that observed for nucleation rate-controlled depositions. Reoxidation of the Cr(O) deposit on the surface of a glassy carbon rotating disk electrode indicated that the oxidation product of this deposit, most likely a Cr(II) species, was adsorbed on the electrode surface. The adsorption of this species could be eliminated by employing either increased scan rates or higher temperatures. No chromium species other than Cr(III), Cr(II), and Cr(O) could be generated within the anodic limit of the NaCl-saturated $AlCl_3$ melt, *viz.*, 2.2V, in the temperature range of this study.

Chromium compounds are of considerable interest as cathodes for thermally activated molten salt reserve batteries, particularly batteries with LiCl-KCl eutectic electrolytes (1). Recent work in our laboratory has indicated that chromium compounds may also be used as cathodes for thermal batteries containing $NaCl\text{-}AlCl_3$ fused salt electrolytes (2). The discharge be-

Key words: cyclic voltammetry, rotating disk electrode voltammetry, chronoamperometry, chromium (III) chloride, molten salt.

havior of these battery systems is dependent in part on the electrode kinetic behavior of the cathode material. In order to realize the maximum efficiency of NaCl-$AlCl_3$ batteries which utilize chromium compounds as cathodes, knowledge of the electrode kinetic behavior of chromium compounds in the NaCl-$AlCl_3$ melt is required.

Previous electrochemical studies of chromium have been confined largely to the fused LiCl-KCl eutectic. Most of these examinations concerned the CrO_4^{-2} species. Unfortunately Cr(VI) compounds do not appear stable in alkali chloride-aluminum chloride melts (3, 4). Lower oxidation states of chromium have also been examined in the LiCl-KCl melt (5-7). In a recent cyclic voltammetric study, Levy and Reinhardt (7) determined the reduction mechanism of Cr(III) in LiCl-KCl to proceed via a two-step process to the metal. The intermediate species in this process, Cr(II), reacted with solvent chloride ions and precipitated as $CrCl_2$.

More limited electrochemical investigations of chromium compounds have been undertaken in alkali chloride-aluminum chloride fused salts (3, 8). Marshall and Yntema (3) found $CrCl_3$ to be insoluble in 14-20-66 mole percent (m/o) KCl-NaCl-$AlCl_3$ while $CrCl_2$ was soluble and could be decomposed to chromium metal at 0.16V *vs.* aluminum. Topol *et al.* (8) found similar behavior for $CrCl_3$ and $CrCl_2$ in 39-61 m/o NaCl-$AlCl_3$[1] and in addition obtained Cr(III) as an electrode surface film which could be reduced at 0.95V *vs.* aluminum.

This paper details an investigation of the electrode kinetic behavior of $CrCl_3$ in NaCl-saturated $AlCl_3$ melt, which was undertaken using stationary and rotating disk electrode cyclic voltammetry, chronoamperometry, and controlled potential coulometry.

Experimental

Apparatus.—Experiments were conducted in a nitrogen-filled glove box (Vacuum/Atmospheres Company, Model HE-53-6 DRI LAB). The moisture content was determined with a calibrated probe (Panametrics Company, Model 1000) and was maintained below 2 ppm.

For experiments with stationary and rotating disk electrode voltammetry, chronoamperometry, and controlled potential coulometry, a Princeton Applied Research Corporation Model 173 potentiostat/galvanostat, Model 179 digital coulometer, and Model 175 universal programmer were employed in combination. A Pine Instrument Company ASR-2 electrode rotator provided controlled electrode rotation. Data was recorded on a Houston Model 2077 X-Y recorder equipped with a time base.

The electrochemical cell used for stationary and rotating disk electrode voltammetry and chronoamperometry consisted of a Pyrex cup with a Teflon lid. Reference and counterelectrodes consisted of aluminum wire spirals (Alfa Ventron m5N purity) immersed in the same melt but isolated in tubes by fine porosity frits. The tubes were inserted into the melt through holes in the Teflon lid. A glassy carbon disk working electrode (9), geometrical area = 0.22 cm^2, was inserted into the melt in a similar fashion except that the hole in the Teflon lid was made large enough to allow free rotation of the electrode. For controlled potential coulometric determination of n values, a glassy carbon crucible was used as the working electrode. The resistance between the working and reference electrodes was determined to be 18-20Ω and was measured with a Beckman Instrument Company, Model RC-18A conductivity bridge.

Cell temperature was maintained to ±0.5°C with a platinum resistance element controlled furnace. The furnace consisted of an insulated aluminum block equipped with a cartridge heater. Regulated current to power the furnace was furnished by a Leeds and Northrup Electromax III controller.

Reagents.—Anhydrous $CrCl_3$ (Alfa-Ventron, 98% purity) was used as obtained. NaCl-saturated $AlCl_3$ was prepared by mixing $AlCl_3$ (Fluka, A.G., iron free) with excess NaCl (Baker, AR grade) and fusing at 175°C. The melt was purified utilizing a constant current electrolysis procedure (10). It was colorless after 14 days electrolysis with aluminum electrodes at 0.5 mA cm^{-2}. The composition of NaCl-saturated $AlCl_3$ melt was determined with the titration procedure of Boxall *et al.* (11) to be 49.75 m/o $AlCl_3$ (pCl = 1.03) at 175°C. This procedure was also used to change the $AlCl_3$ content of the melt as desired.

Results and Discussion

Chromium was introduced into NaCl-saturated $AlCl_3$ melt as $CrCl_3$. The material dissolved slowly to give a magenta solution and exhibited a solubility of 6.2 mmoles at 175°C. Adjustment of the chloride concentration of a melt 3.68 mmoles in Cr(III) from 89 mmoles (49.75 m/o $AlCl_3$) to 50 mmoles (49.86 m/o $AlCl_3$) induced precipitation of $CrCl_3$. This precluded detailed investigation of the electrochemical behavior of Cr(III) with changes in melt acidity. $CrCl_2$ was insoluble in the NaCl-saturated melt.

Figure 1 shows a stationary electrode cyclic voltammogram of Cr(III) in NaCl-saturated $AlCl_3$ melt. All potentials are referred to the Al(III)/Al couple in the same melt. Cathodic peaks are evident at 1.06V (A) and 0.19V (B) as are anodic peaks at 0.55V (C), 0.61V (D), 1.26V (E), and 1.15V (E'). Peak E' is obtained by reversing the scan immediately after the response at A is observed. Peaks C, D, and E are obtained by reversing the scan after the reduction process, B. Peaks *A* and *E'* were attributed to the apparently reversible Cr(III)/Cr(II) couple. The 0.10V anodic shift in the peak potential of E with respect to E' and the increased symmetry of E over E' indicates that the Cr(II) produced as a result of an A-B-C-D-E scan is absorbed on the electrode (12).

Peak B in Fig. 1 appears at a potential close to that observed by Marshall and Yntema (3) and Topol *et al.* (8) for the deposition of chromium metal. The B-C-D process is attributed to the deposition and stripping of Cr(O). A more detailed discussion of this electrode reaction is presented in a later section.

The cyclic volammograms shown in Fig. 2 were obtained with a rotating disk electrode. The reduction peak, A, in Fig. 1 appears as a rotation rate-dependent wave in Fig. 2a. The wave for B is not clearly defined due to the high background current but is approximately twice the height of the preceding wave for A.

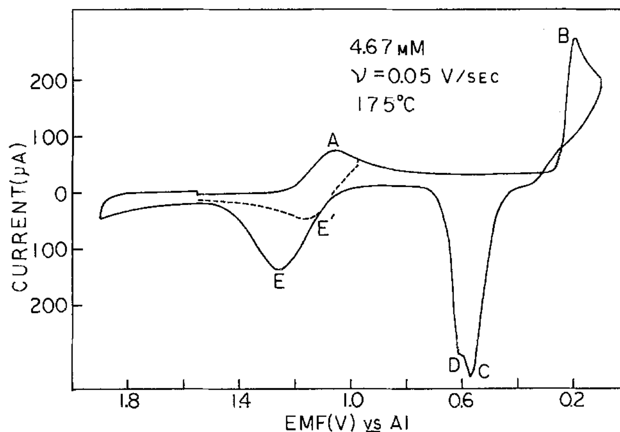

Fig. 1. Stationary electrode cyclic voltammogram of Cr(III). Dashed line shows response obtained by reversing scan after Cr(III) to Cr(II) reduction. Initial potential = 1.55V.

[1] Hereafter only the composition of the NaCl will be indicated. For example, 39 m/o NaCl-$AlCl_3$ will imply the presence of 61 m/o $AlCl_3$.

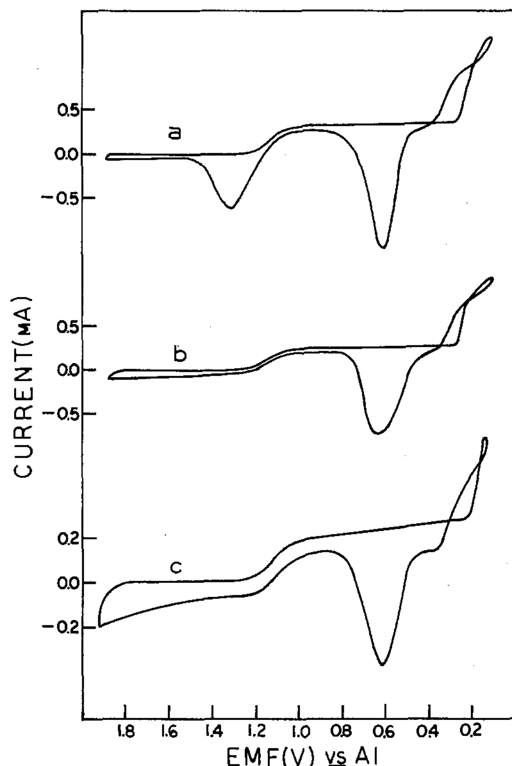

Fig. 2. Rotating disk electrode cyclic voltammograms of Cr(III) in 49.75 m/o $AlCl_3$. Initial potential = 1.55V. Rotation rate = 26.1 rad sec^{-1}. a, Cr(III) concentration = 4.67mmoles, ν = 0.05V sec^{-1}, 175°C; b, Cr(III) concentration = 2.73 mmoles, ν = 0.05V sec^{-1}, 225°C; c, Cr(III) concentration = 2.80 mmoles, ν = 0.20V sec^{-1}, 175°C.

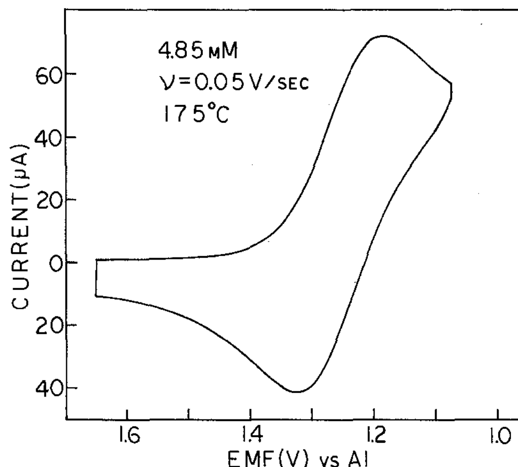

Fig. 3. Stationary electrode cyclic voltammogram of Cr(III) in NaCl saturated $AlCl_3$. Potential scan 1.700 to 1.075 to 1.700V.

The anodic process, E, in Fig. 1 also appears as a symmetrical peak in Fig. 2a. Peaklike responses obtained with rotating disk electrodes are due to reactions occurring on the electrode surface (13).

Transition of the surface response to a diffusional response can be brought about by simultaneously decreasing the Cr(III) concentration and increasing the temperature. The conversion becomes complete with 2.73 mmoles Cr(III) at 225°C as shown in Fig. 2b. Similar results can be induced at 175°C by increasing the sweep rate (Fig. 2c).

Characterization of the Cr(III) reduction.—A cyclic voltammogram represented by peaks A and E' in Fig. 1 is shown in more detail in Fig. 3. Using stationary electrode cyclic voltammetry, this couple was investigated as a function of sweep rate and concentration in NaCl-saturated $AlCl_3$ at 175°C. Data resulting from this investigation comprise Table I. Zero scan rate values of $i_p^c/\nu^{1/2}$ were obtained at 2.87 and 4.85 mmoles by constructing $i_p^c/\nu^{1/2}$ *vs.* $\nu^{1/2}$ plots from the data in Table I. The ratio of these intercepts was 1.66. In agreement with this, the ratio of Cr(III) concentrations for these two experiments was 1.69. The behavior of i_p^a/i_p^c [calculated using the empirical method of Nicholson (14)] with increasing scan rate indicates that a chemical step preceded the reduction wave (15). At slow scan rates E_p^a-E_p^c, E_p^c-$E_{1/2}$, and $E_{p/2}$-$E_{1/2}$ approach theoretical values of 0.089, −0.043, and 0.042V, respectively, expected for a one-electron reversible process at 175°C. A cathodic shift of E_p^c and an increase in the potential separations with increasing scan rate are also evident in Table I. A chemical reaction preceding Cr(III) reduction alone would be expected to cause an anodic shift in E_p^c with increasing scan rate (15). A cathodic shift resulting from *iR* effects would amount to only 5 mV maximum for the cell used in this study. Thus, the deviation of E_p^c from the expected behavior may indicate that either an additional reversible chemical step follows the reduction of Cr(III) or the Cr(III)/Cr(II) charge transfer process exhibits quasi-reversible behavior at fast scan rates.

Nicholson and Shain (15) showed the behavior of $i_p^c/\nu^{1/2}$ and i_p^a/i_p^c with increasing scan rate for reversible preceding and following chemical steps to be of an opposite nature. A reversible following chemical step with an equilibrium constant of sufficient magnitude to cause a 60 mV cathodic shift in E_p^c with a tenfold increase in scan rate as observed in this study certainly would be expected to cause the behavior of i_p^a/i_p^c to be more complex than observed. Thus, a reversible following chemical reaction seems unlikely.

A quasi-reversible charge transfer, which typically exhibits a cathodic potential shift, would account for the over-all cathodic shift in E_p^c with increasing scan rate (16). However, rate data for this process cannot be measured without some ambiguity since many of the effects observed with increasing scan rate, *e.g.*, the increase in potential separations also may be attributed to the preceding chemical step (15).

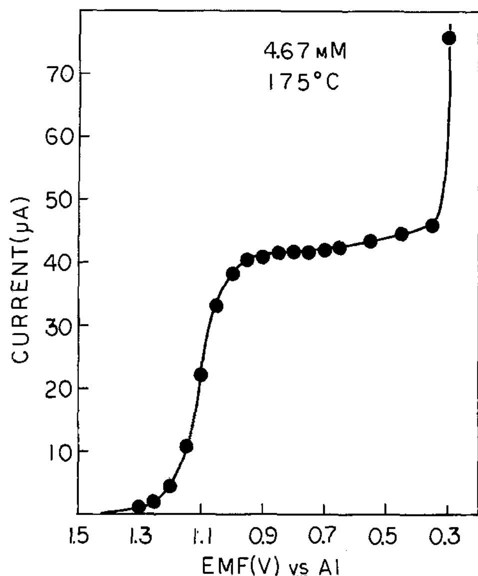

Fig. 4. Polarogram for the reduction of Cr(III) to Cr(II). Constructed from current-time data at 5 sec.

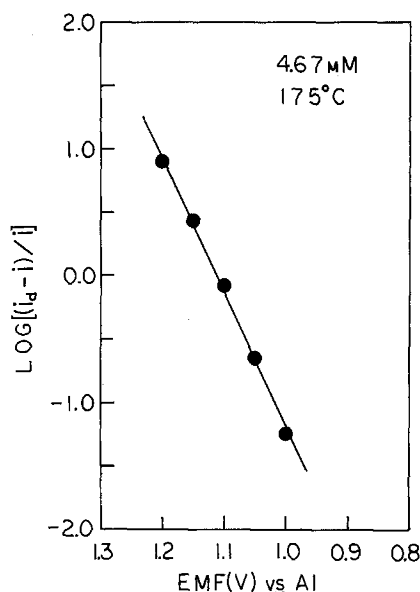

Fig. 5. Log $[i_d - i)/i]$ *vs.* potential for the polarogram in Fig. 4

A polarogram for the Cr(III)/Cr(II) reduction wave, constructed from current-time curves (17), is shown in Fig. 4. A plot of E *vs.* log $[(i_d - i)/i]$ for the polarographic wave (Fig. 5) was approximately linear over the region 0.11-0.95 i_d and exhibited a slope consistent with a one-electron reversible process. This information indicates that the Cr(III)/Cr(II) reduction process was nearly reversible for time intervals of 5 sec or longer. Table II summarizes polarographic data taken at different Cr(III) concentrations.

Cr(III) diffusion coefficient.—Provided that the Cr(III)/Cr(II) charge transfer process is sufficiently rapid at slow scan rates to be considered diffusion controlled, a diffusion coefficient for the Cr(III) species can be estimated by using techniques which allow extrapolation of the data to regimes in which diffusion control predominates over the preceding chemical step. Values of the voltammetric current function, $i_p^c/\nu^{1/2}$, approach the diffusion-controlled value at slow scan rates (15). Chronoamperometric currents approach diffusion-controlled values at sufficiently long times (18). Diffusion coefficients can be calculated from the zero current intercepts of $i_L/\omega^{1/2}$ *vs.* i_L plots which are constructed from limiting current data obtained at a rotating disk electrode (19).

At 175°C the Cr(III) diffusion coefficient was determined from the average values of the zero scan rate intercepts of $i_p^c/\nu^{1/2}$ *vs.* $\nu^{1/2}$ plots at different concentrations to be 2.2×10^{-6} cm² sec⁻¹, while the intercepts of chronoamperometric $it^{1/2}$ *vs.* $t^{1/2}$ plots yielded 2.4×10^{-6} cm^2 sec^{-1}. Viscosity values from Tørklep and Øye (20) density data from Fannin *et al.* (21) were used to calculate a value of 2.2×10^{-6} cm^2 sec^{-1} from the $i_L/\omega^{1/2}$ *vs.* i_L plot shown in Fig. 6.

The values obtained using the different methods are reasonably consistent. It is interesting to compare values obtained for other metal ions in NaCl-$AlCl_3$ melts. Boxall *et al.* (16) measured a value of 8.8×10^{-6} cm^2 sec^{-1} for Fe(III) in 50 m/o NaCl-$AlCl_3$ at 175°C. Gilbert *et al.* (22) determined a value of 7×10^{-6} cm^2 sec^{-1} for Zr(IV) in 48-49 m/o NaCl-$AlCl_3$ at 175°C. For Nb(V) in NaCl-saturated $AlCl_3$ at 180°C, Ting *et al.* (23) found a diffusion coefficient of $4.5\text{-}4.9 \times 10^{-6}$ cm^2 sec^{-1}. Recently, Phillips and Osteryoung (24) determined a value of 3.2×10^{-6} cm^2 sec^{-1} for Mo(V) in NaCl-saturated $AlCl_3$ at 175°C. The diffusion coefficient for Cr(III) appears considerably smaller than that measured for other metal ions in NaCl-$AlCl_3$ melts. Since it is not possible to assess how much the postulated quasi-reversibility of the charge transfer decreases this value, the average Cr(III) diffusion coefficient at 175°C, 2.3×10^{-6} cm^2 sec^{-1}, must be considered only approximate.

Characterization of the Cr(II) reduction.—Exhaustive coulometry of a melt 4.15 mmoles in Cr(III) at a potential of 0.10V resulted in a metallic deposit on the surface of the glassy carbon cell. A value of 2.1 was estimated for n for the Cr(II)/Cr(O) reduction after correction for the background current resulting from the proximity of aluminum deposition. The latter data were obtained in a melt containing no $CrCl_3$; the background current amounted to approximately 30% of the total current observed.

Table II. Polarographic data for Cr(III) reduction

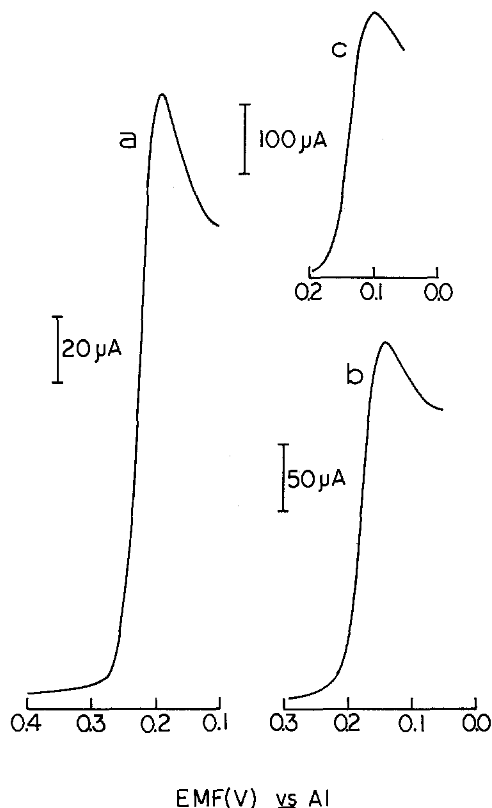

Fig. 7. Voltammetric peaks for the Cr(II) to Cr(O) reduction obtained during a cyclic voltammetric scan from 1.55 to 0.10 to 1.55V. Cr(III) concentration = 4.67 mmoles. a, ν = 0.05 V sec^{-1}, b, ν = 0.10 V sec^{-1}, c, ν = 0.20 V sec^{-1}.

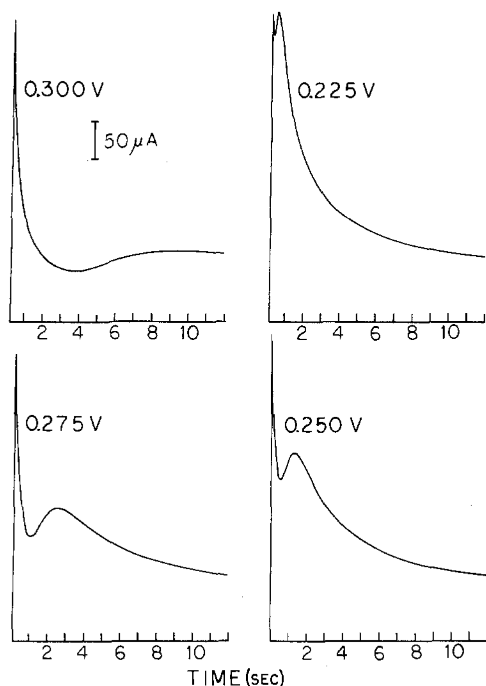

Fig. 8. Chronoamperometric response for the reduction of Cr(II) to Cr(O) at 175°C. Cr(III) concentration = 2.67 mmoles. Initial potential = 1.70V.

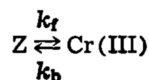
Voltammetric peaks for the Cr(II)/Cr(O) reduction are shown in Fig. 7. The cathodic shift in the voltammetric peak potential with increasing scan rate and the shape of chronoamperometric current-time curves (Fig. 8) indicate that reduction of Cr(II) is controlled by rate of nucleation in the initial phase of deposit formation (25). Similar behavior recently has been observed in NaCl-$AlCl_3$ melts for the deposition of insoluble $ZrCl_3$ and iron (22) and for the deposition of aluminum at a glassy carbon electrode (26).

When the deposit was reoxidized during stationary electrode voltammetry, it gave rise to two closely spaced peaks (Fig. 1) rather than the single stripping peak expected. Behavior closely resembling this was observed during reoxidation of iron deposited on a tungsten electrode in the 50 m/o NaCl-$AlCl_3$ melt (27) and was explained in that instance by considering that Fe(II) produced during anodization first depleted melt chloride in vicinity of the electrode and then diffused out into the bulk melt. This process may also be taking place during the oxidation of chromium in our study. Further, more detailed studies of this phenomena are needed to fully characterize the Cr(II)/Cr(O) deposition-stripping process.

Conclusion

The electrochemical reduction scheme of Cr(III) at a glassy carbon electrode at 175°C was shown to include the following reactions



$$\mathrm{Z} \underset{k_b}{\overset{k_f}{\rightleftarrows}} \mathrm{Cr(III)}$$

$$\mathrm{Cr(III)} + e^- \rightleftarrows \mathrm{Cr(II)}$$

$$\mathrm{Cr(III)} + e^- \rightleftarrows \mathrm{Cr(II)_{ADS}}$$

$$\mathrm{Cr(II)} + 2e^- \rightleftarrows \mathrm{Cr(O)}$$

$$\mathrm{Cr(II)_{ADS}} + 2e^- \rightleftarrows \mathrm{Cr(O)}$$

Determination of the nature of the electroinactive form of Cr(III), Z, was hampered by the insolubility of $CrCl_3$ in melts less than 50 mmoles in chloride ion. Thus, the identity of the preceding chemical reaction was not established. The Cr(III)/Cr(II) electron transfer exhibited quasi-reversible behavior at fast scan rates, and the Cr(II)/Cr(O) reduction exhibited behavior consistent with a nucleation rate-controlled reduction. The formation of Cr(II) electrode surface species was shown to depend on the following parameters: $CrCl_3$ concentration, temperature, and sweep rate. No oxidation states of chromium above Cr(III) could be obtained voltammetrically in NaCl-saturated $AlCl_3$ within the anodic limit of the melt.

Acknowledgment

We wish to express our appreciation to Professor Robert A. Osteryoung, Colorado State University, for many helpful discussions concerning this work.

Manuscript submitted May 23, 1977; revised manuscript received Nov. 18, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by the United States Air Force Academy.

Cathodic Deposition of CdTe from Aqueous Electrolytes

M. P. R. Panicker, M. Knaster,* and F. A. Kroger*

Department of Materials Science, University of Southern California, Los Angeles, California 90007

ABSTRACT

CdTe of well-defined composition has been deposited cathodically from an aqueous solution of $CdSO_4$ and TeO_2. Films with a rest potential of $< -0.3V$ *vs.* SCE are n-type, those with a rest potential $> -0.3V$ *vs.* SCE are p-type semiconductors. The rate of deposition increases with stirring rate; it is proportional to the TeO_2 concentration but independent of the $CdSO_4$ concentration. Films deposited at room temperature are amorphous, those deposited at higher temperatures are partly crystalline, the degree of crystallinity increasing with deposition temperature. Grain sizes are in the range 500-1000Å. Annealing at 350°C causes the crystallite size to increase to ≥ 0.5 μm.

Fabrication of large area solar cells on CdTe basis requires an economical process for the formation of thin films of n- and p-type CdTe on a conducting base. For front wall cells the base may be a metal; for back-wall cells the base must be transparent. Glass covered with semiconducting SnO_2:Sb or In_2O_3:Sn has been recommended.

So far, films of semiconducting II-VI compounds were usually made by deposition from the vapor phase. It seems attractive to investigate the possibility of using an electrochemical method. In principle both anodic and cathodic deposition can be used. CdS has been made by anodic deposition of sulfur from a solution containing S^{2-} ions on a cadmium anode (1) and a similar method should be possible for CdTe. On the other hand, both Cd and Te can be deposited cathodically; Cd from an aqueous solution of $CdSO_4$, Te from a solution of TeO_2 in H_2SO_4 and/or HF (2) or water (3). Therefore it may be possible to deposit CdTe cathodically.

The anodic method has the disadvantage that the stoichiometry of the deposit cannot be easily regulated. Therefore, we concentrate our efforts on cathodic deposition.

* Electrochemical Society Active Member.
Key words: overpotential, amorphous deposit, crystalline deposit, Pourbaix diagram.

Cathodic deposition can occur either by deposition of the individual components in the required ratio, or by deposition resulting from discharge and decomposition of a complex containing the two components. The former mechanism has been proposed for formation of CdSe and Ag_2Se (4), the latter mechanism was proposed for the cathodic deposition of Ni_3S_2 from a Ni thiosulfate solution, the proposed cathodic reaction being (5)

$$Ni_3(S_2O_3)_3 + 6e^- \rightarrow Ni_3S_2 + S_2O_3^{=} + 2SO_3^{=}$$

In the latter case the stoichiometry of the deposit can only be varied if individual deposition of Ni or S atoms also occurs.

A choice between the two different cathodic deposition mechanisms can be made by a study of the current efficiency of deposition and of the secondary products formed in the solution (6).

In this paper it will be shown that cathodic deposition of CdTe is possible, that it occurs by the deposition of the components individually, and that CdTe with a required deviation from stoichiometry can be deposited.

Theoretical; CdTe Deposition

Table I shows electrode reactions and the corresponding equilibrium electrode potentials for Cd or

Table I. Electrode reactions and the corresponding potentials vs. the normal hydrogen electrode according to Pourbaix (3)

Activity of ions refer to species in solution (moles per kg H_2O); activities of atoms refer to components of the deposited solid (equal to one for the pure component)

	Reactions	*E vs.* NHE (V)
a.	$Cd(s) = Cd^{2+} + 2e^-$	$E^\circ_{Cd} + \frac{RT}{2F}\ln(a_{Cd^{2+}}/a_{Cd}) = -0.403 + 0.0295\log(a_{Cd^{2+}}/a_{Cd})$

j.	$Ag(s) = Ag^+ + e^-$	$E^\circ_{Ag} + \frac{RT}{2F}\ln(a_{Ag^+}/a_{Ag}) = 0.799 + 0.0591\log(a_{Ag^+}/a_{Ag})$

Te according to Pourbaix (3). All potentials depend on the activities of ions in solution and on the activity of the component in the deposit. The potential of reaction d in addition depends on *p*H. For the formation of CdTe, in particular reactions a and d are important.

In a companion paper by one of us (8), cathodic deposition of compounds was classined under two classes, I and II, depending on whether the difference in equilibrium potentials of the pure components is larger or smaller than the shift in potentials due to variation of the component activity in the deposit resulting from compound formation. The activities of Cd and Te in CdTe depend on the stoichiometric composition of the compound, the two being related through the reaction

$$Cd(s) + Te(s) \rightleftarrows CdTe(s); G_{CdTe} \quad [1]$$

giving

$$\frac{a_{CdTe}}{a_{Cd}a_{Te}} = \exp(-G_{CdTe}/RT) \quad [2]$$

or for $a_{CdTe} = 1$

$$a_{Cd}a_{Te} = \exp(G_{CdTe}/RT) \quad [3]$$

At temperatures at which deposition is to take place, CdTe has an existence range stretching from CdTe in equilibrium with Cd to CdTe in equilibrium with Te. Thus the Cd activity varies from $a_{Cd} = 1$ at the CdTe/Cd boundary to $a_{Cd} = \exp(G_{CdTe}/RT)$ at the CdTe/Te boundary where $a_{Te} = 1$, with an opposite variation of a_{Te}. It is this variation of a_{Cd} and a_{Te} which causes the shift in the Cd and Te potentials.

For reactions a and d $\Delta E^\circ = E^\circ_{Te(d)} - E^\circ_{Cd} = 0.551 + 0.403 = 0.954V$. The free enthalpy of formation of CdTe from Cd and Te, $(G_{CdTe})_{298} = -24.5 - 2.4T = -25.5$ kcal/mole (9). Compound formation causes a shift of the Cd potential from the standard value (−0.403V) at the CdTe/Cd phase boundary to $-0.403 + (G_{CdTe})_{298}/2\mathbf{F} = -0.403 + 0.546 = 0.143V$ at the CdTe/Te phase boundary. The Te potential shifts similarly from 0.551V at the CdTe/Te phase boundary to $0.551 + (G_{CdTe})_{298}/4\mathbf{F} = 0.551 + 0.273 = 0.824V$ at the CdTe/Cd boundary (8).

It is seen that $\Delta E^\circ > (G_{CdTe})_{298}/2\mathbf{F}$. Therefore, CdTe has to be classified under class I, with Cd the potential-determining species under all conditions (8). The potentials at which CdTe can be deposited extend from $V_{dep} = -0.403 + 0.295 \log a_{Cd^{2+}} - \Delta V$ (the CdTe/Cd phase boundary) to $V_{dep} = 0.143 + 0.295 \log a_{Cd^{2+}} - \Delta V$ (the CdTe/Te phase boundary). Here ΔV is the overpotential; it is equal to

$$\Delta V = \eta + iR \quad [4]$$

where η is the discharge overpotential, i the current density, and R the resistance per square centimeter of electrode of the circuit between the cathode contact and the calomel electrode used to measure the cathode voltage. It contains contributions from the conducting layer of the cathode and from the deposited film. The former is appreciable for deposition on SnO_2:Sb or In_2O_3:Sn but would be negligible for deposition on a metallic cathode. The resistance of the deposit is expected to be proportional to the film thickness (d) and equal to ρd, ρ being the specific resistance of the deposit. Measurement of ΔV as $f(d)$ for deposition on a metallic cathode should make it possible to determine ρ.

In order to be able to deposit Cd and Te in almost equal quantities it is necessary to use an electrolyte with a high concentration of the less noble component, Cd, and a low concentration of the noble component, Te. During deposition the concentration of $HTeO_2^+$ in the electrolyte at the electrode-electrolyte interface is reduced to practically zero. The rate of Te deposition is therefore diffusion controlled. The larger $CdSO_4$ concentration, however, will not be appreciably changed during deposition. CdTe deposition occurs at a potential that is more positive than required for deposition of Cd as a separate phase, Cd required for CdTe formation only being deposited as a result of the free energy gain in forming CdTe and occurs only after Te has been deposited. Therefore, the rate of CdTe deposition should be limited by Te deposition and, since the latter is diffusion controlled, should increase with increased stirring and be proportional to the concentration of $HTeO_2^+$ in the electrolyte (10). It should be independent of the $CdSO_4$ concentration in the electrolyte.

It is to be expected that deposition at low current density (corresponding to a potential at the positive end of the deposition range) favors Te deposition and gives rise to Te-rich CdTe (a_{Te} is large); deposition at a large current density (corresponding to a potential

at the negative end of the deposition range) should give rise to Cd-rich CdTe (a_{Cd} large). For pure CdTe this should lead to formation of p-type CdTe at low current densities and to n-type CdTe at high current densities, with a gradual shift from one to the other with changing current density (11).

During deposition of CdTe, the concentrations of both Cd^{2+} and $HTeO_2^+$ in the solution tend to diminish. This is not a serious effect for Cd^{2+} which is present at a relatively large concentration. Periodic addition of Cd-salt to the solution may keep the concentration practically constant. On the other hand, both the low solubility of H_2TeO_3 and the need to limit the concentration of $HTeO_2^+$ in the electrolyte in order to be able to deposit Cd and Te in equal amounts restricts the $HTeO_2^+$ concentration to a relatively low value. This in turn makes it necessary to take special steps to keep this concentration constant. There are two ways in which this can be achieved. The first follows a proposal by Gobrecht *et al.* (4) to use two anodes. One of these is inert, consisting of platinum or graphite; the other one is active and consists of the noble component to be deposited, in our case, Te. Current passed through the Te anode injects $HTeO_2^+$ into the solution. By making $i_{Te}/(i_{Te} + i_{inert}) = 4/6$, the ratio of the numbers of electrons involved in the deposition of Te (4*e*) and CdTe (6*e*), or $i_{Te}/i_{inert} = 2$, just as much Te is injected into the solution as is deposited on the cathode, and the $HTeO_2^+$ concentration in the electrolyte remains constant.

In a second method the $HTeO_2^+$ concentration is kept constant by keeping the electrolyte saturated with TeO_2 by having TeO_2 present as a second phase. Either one or two anodes may be used: inert, the other (if used) consisting of Cd. Now maintenance of a ratio $i_{inert}/i_{Cd} = 2$ keeps the concentrations of both Cd and Te in the electrolyte constant.

Doped crystals can also be grown. For donor doping indium or gallium can be used. As seen in Table I, reactions e and f, the deposition potential of In is so close to that of Cd that addition of a small amount of indium salt to the solution should lead to codeposition of Cd and In in about the same ratio as they are in the electrolyte. As acceptors, Cu, Ag and Au or As and Sb can be used. Since these are relatively noble, the best results are to be expected with the addition of these elements in a small concentration to the electrolyte combined with the use of a Te-dopant alloy as active anode.

Experimental

Cathodic deposits were made from an aqueous solution of $CdSO_4$ (1 mole/liter) at a *p*H of 2.5-3. The $CdSO_4$ was analytical grade containing as impurities 100 ppm Cu and 50 ppm As. Two sets of experiments were done. In one the $CdSO_4$ solution was used without purification. In the other, the $CdSO_4$ solution was first purified by electrolysis with inert electrodes at a cathode potential of $-(0.6 + \Delta V)$V *vs.* SCE, just below the potential required for Cd deposition, which is $-(0.66 + \Delta V)$V *vs.* SCE. An initial current density of 0.1 mA/cm^2 decreased gradually, falling to a constant value of 0.02 mA/cm^2 after 12 hr. The current drop is due to removal of the impurities from the solution, the small rest current being due to evolution of H_2 and/or reduction of O_2.

TeO_2 was added to both the pure and nonpurified solution, either 10^{-5}-10^{-3} mole/liter to give an unsaturated solution, or excess amount to give a saturated solution. For deposition of CdTe from the unsaturated solution two anodes were used, one a rod of graphite (3 mm diam, 5 cm long), the other a rod of Te (5 mm diam, 5 cm long). As cathodes were used either nickel plates of $\approx$ 6 cm^2 submerged area, or glass plates covered with semiconducting SnO_2:Sb with a resistance of 10-20 Ω/□. The latter were put at our disposal by R. L. Rod and W. Penick of Monosolar Corporation, Santa Monica.

Currents through the two anodes with a ratio $i_{Te}/i_{inert} \approx 2$ were established by dividing a regulated current with the aid of a potentiometer. For deposition from a solution saturated with TeO_2 one inert anode was used. Experiments at constant cathode voltage were carried out with the aid of a potentiostat, Princeton Applied Research Model 173, using the potential difference between the cathode and a saturated calomel electrode as its input. Current-voltage and voltage-time curves were measured with the aid of a Moseley Autograf X-Y recorder, Model 7030A. The experiments were carried out from 25° to 100°C. The bath was stirred with a magnetic stirrer of variable rotation speed. The current efficiency of the deposition process was determined by comparing the weight of the deposit deposited in a certain time with the weight calculated from the number of coulombs passed through the circuitry, assuming a certain deposition mechanism and the corresponding number of electrons required per molecule of CdTe. With Cd requiring 2 and Te 4 electrons (reaction a and d of Table I), 6 electrons are required for CdTe.

The crystal structure of the deposition products was analyzed by x-ray diffraction and by low angle electron diffraction. The microstructure of the deposit was determined with the aid of the scanning electron microscope. The chemical composition was determined by the energy dispersive microanalytic unit of the scanning electron microscope. Conductivity type was determined by a hot probe thermoelectric power measurement, an initial positive voltage of the hot probe placed on the deposit indicating n-type, a negative voltage indicating p-type conductivity.

Results

Deposition conditions.—A plot of current density *vs.* cathode voltage (measured relative to a saturated calomel electrode, SCE) for deposition from a 1.2 mole purified $CdSO_4$ solution saturated with TeO_2 at 85°C, *p*H = 3.4 is shown in Fig. 1. The current increases rapidly at $-V_{dep} > 0.8$V. For various deposition voltages, the rest potential of the cathode covered with product was determined by measuring cathode voltage as a function of time after interruption of the current. Figure 2 shows the result for deposition under slightly different conditions (0.5 mole $CdSO_4$, unsaturated TeO_2 solution, *p*H = 1.45, *T* = 90°C). The potential drops instantaneously to a lower value (a → b) corresponding to $E_{rest} = V_{dep} + \Delta V$, then (in most of the cases) gradually drifts to a less negative value, E_{final}. E_{rest} is the rest potential of the product in equilibrium with the electrolyte of the composition which it has at the cathode/electrolyte interface during deposition, with $c_{HTeO_2^+} \approx 0$. E_{rest} shifts to more negative

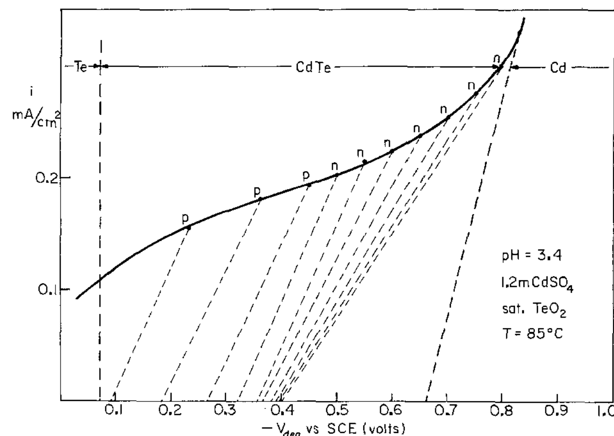

Fig. 1. Current density *vs.* cathode voltage for deposition at 85°C from a 1.2 moles $CdSO_4$ solution saturated with TeO_2; *p*H = 3.4, stirring rate 160 rpm.

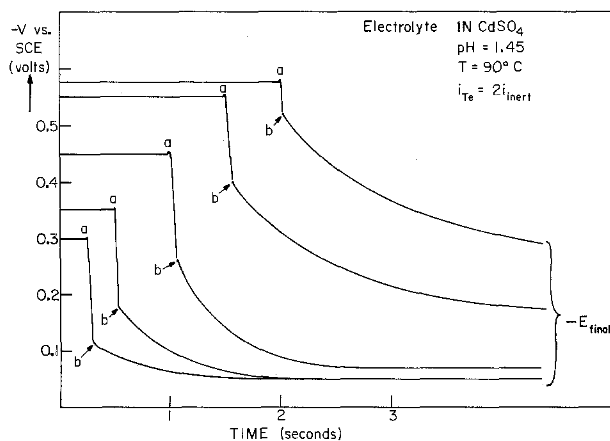

Fig. 2. Cathodic voltage *vs.* time during deposition from 0.5 mole $CdSO_4$, unsaturated TeO_2 solution, *p*H = 1.45, *T* = 90°C at different current densities (curves up to points a) and after interruption of the current.

values when the deposition voltage becomes more negative, *i.e.*, at larger current densities.

Figure 1 shows values of E_{rest} linked to the corresponding V_{dep} values by dashed lines. All except one are in the potential range expected for CdTe. The values of E_{final} are almost constant and correspond to the potential of the CdTe/Te phase boundary. E_{final} corresponds to the equilibrium potential of the deposit in equilibrium with electrolyte at its surface after this electrolyte has regained its normal bulk composition. Establishment of E_{final} involves electroless exchange of Cd from the product surface (ps) with Te from the electrolyte according to

$$2Cd_{ps} + 3H^+ + HTeO_2^+ = 2Cd^{2+} + Te_{ps} + 2H_2O$$

(a combination of reactions a and d of Table I). Since the bulk concentration of $HTeO_2^+$ in the electrolyte is far from zero, this leads to a surface consisting almost exclusively of Te, yet with sufficient Cd to have its potential determined by that species, thus establishing the potential of the CdTe/Te phase boundary.

For deposits made at $-V_{dep} > 0.8V$, E_{rest} remains for a long time constant at $E_{rest} = -0.66V$ *vs.* SCE, indicating that pure Cd has been deposited. Only when all the Cd has been transformed to CdTe by exchange of half of the Cd with Te does the potential shift to more positive values, reaching the same final value as found for the other deposits. These results suggest that the product layers having rest potentials $\geqq -0.66V$ *vs.* SCE consist of CdTe, layers deposited at more negative values consisting of Cd. For the prevailing conditions, formation of a Te product layer is expected at $V < (-0.66 + 0.546) \approx -0.11V$ *vs.* SCE, *i.e.*, at negative values of the current in Fig. 1. Deposition of pure Te is possible if the TeO_2 concentration in the electrolyte is increased to 10^{-3} which can be done if the *p*H is decreased to 2 (3). On the other hand, deposition on SnO_2:Sb of CdTe films with $E_{rest} < -0.5V$ *vs.* SCE requires that the *p*H is raised to 3 or 3.5. If this is not done, the SnO_2 layer dissolves, as would be expected from its electrochemical properties (3).

Figure 3 shows i-V_{dep} characteristics for different stirring rates, showing the increase in i with increasing stirring rate. Figure 4 shows i-V_{dep} characteristics for deposition from solutions with a fixed TeO_2 concentration of 7×10^{-3} and normal but different $CdSO_4$ concentrations. The current density and thus the deposition rate is independent of Cd^{2+} concentration, as expected.

Figure 5 shows the dependence of the current density on the TeO_2 concentration. The current density (and thus the deposition rate) is proportional to the TeO_2 concentration as expected for a process limited by Te diffusion. The shift in the V_{dep} of Cd to more

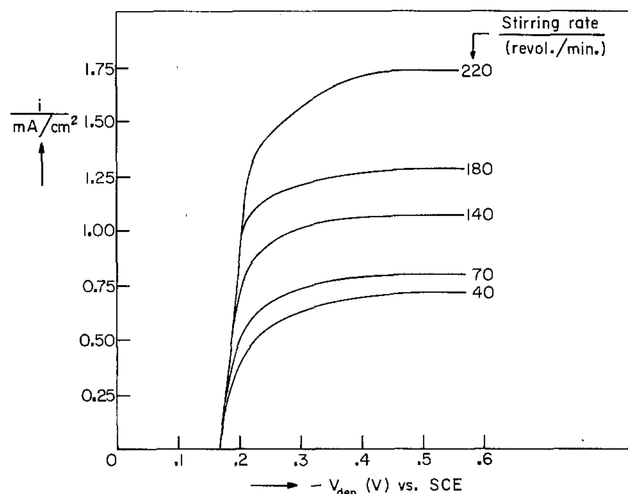

Fig. 3. Current density *vs.* cathode voltage for deposition at 75°C from an electrolyte 0.5 mole $CdSO_4$, low TeO_2 concentration, *p*H = 2.25 at different stirring rates (two anodes, $i_{Te} = 2i_{inert}$).

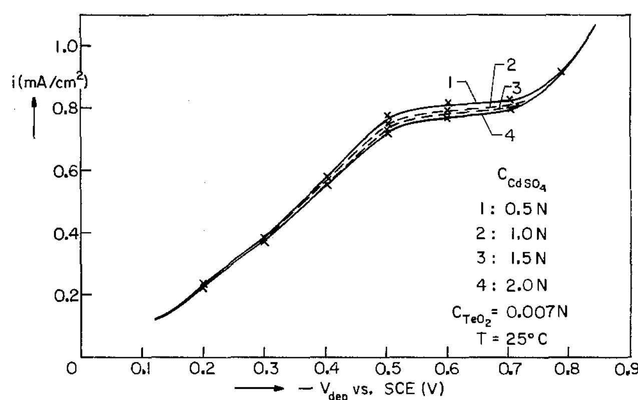

Fig. 4. Current density *vs.* cathode voltage for deposition at 25°C from an aqueous solution of 7×10^{-3} n-TeO_2 and different $CdSO_4$ concentrations varying from 0.5 to 2 normal.

negative values with increasing TeO_2 concentration is caused by the increase of ΔV resulting from a larger thickness of the product layer with increasing current density.

As mentioned earlier, $\Delta V = E_{rest} - V_{dep} = \eta + iR$. For deposition on a metallic cathode $R \approx \rho d$ and thus $\Delta V = \eta + i\rho d$. Figure 6 shows plots of ΔV *vs.* film thickness for deposition at different temperatures on

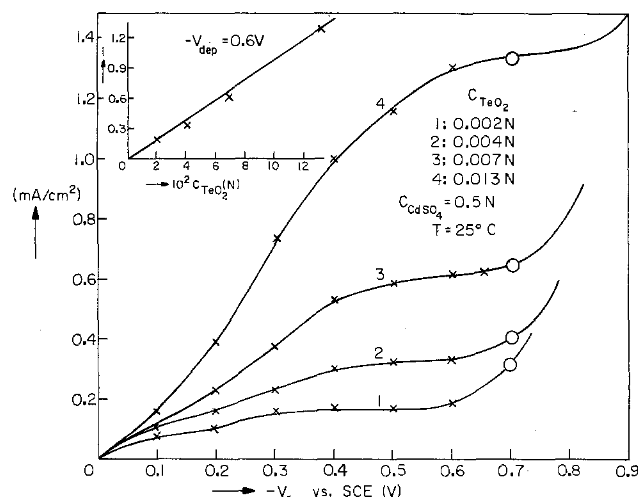

Fig. 5. Current density *vs.* cathode voltage for deposition at 25°C from an aqueous 0.5 n-$CdSO_4$ solution containing different amounts of TeO_2; *p*H = 0.5. Inset: *i* *vs.* c_{TeO_2} at $V_{dep} = -0.6V$ *vs.* SCE.

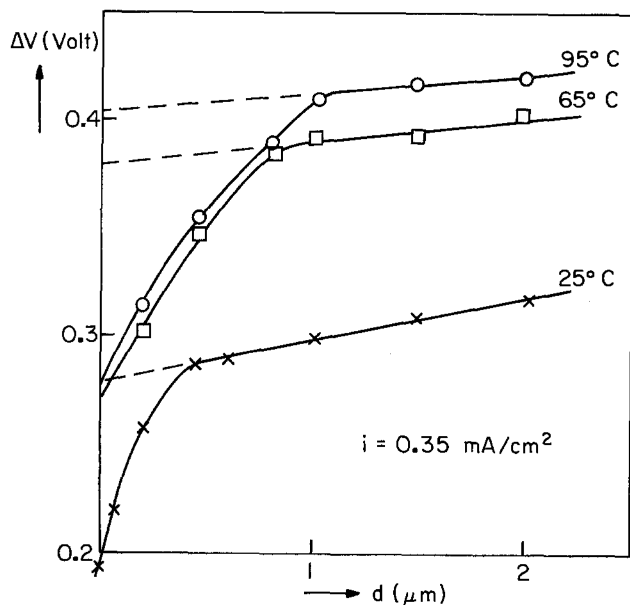

Fig. 6. $\Delta V = E_{rest} - V_{dep}$ as function of thickness of deposit, d, for deposits on nickel made at different temperatures from an aqueous solution of 1 mole $CdSO_4$/l saturated with TeO_2 at pH = 1.2, i = 0.35 mA/cm^2, different stirring rates.

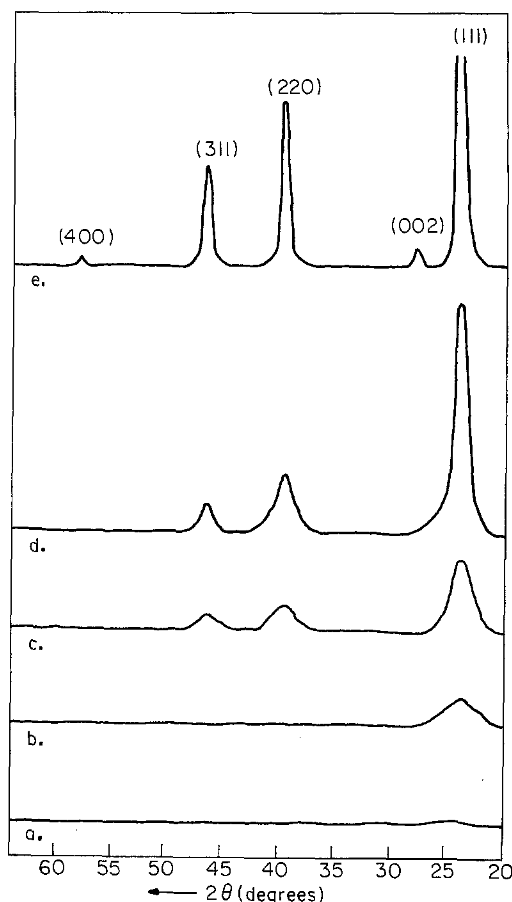

Fig. 7. X-ray diffraction patterns of films deposited on SnO_2-covered glass from a solution of 1 mole $CdSO_4$, saturated with TeO_2, pH ≈ 2.7, with current density 0.5 mA/cm^2 (E_{rest} = 0.18V) at 22°C (a), 35°C (b), 65°C (c), and 90°C (d), and the pattern (e) of film (a) after annealing for 3.5 hr at 350°C in an argon atmosphere.

a nickel cathode. The plots are nonlinear near the origin, indicating healing of the film, but are linear at thicknesses ≧ 1 μm. The slopes of the linear sections indicate resistivity values of 5.2 × 10^5 Ω cm for deposition at 25°C and of 2.9 × 10^5 Ω cm for deposition at 65° and 95°C. The discharge overvoltage η is 280 mV at 25°C, 380 mV at 65°C, and 404 mV at 95°C.

The deposition current efficiency calculated for formation of CdTe by deposition of Cd and Te individually, requiring 6 electrons per molecule CdTe, was found to be 87.5 ± 2.5% indicating that the assumed deposition mechanism is indeed operative. The small fraction of the current not used for CdTe formation must be due to evolution of H_2 or reduction of O_2.

Microstructure and composition determination.—The conclusions arrived at in the previous section are supported by results of determinations of chemical composition and crystal structure. Using the energy dispersive microanalyzer unit in the scanning electron microscope, layers with rest potentials between −0.6 and −0.2V *vs.* SCE were found to consist of 46.3 ± 4 atom percent (a/o) Cd and 53.3 ± 4 a/o Te. Layers with E_{rest} = −0.66V *vs.* SCE consist of Cd only.

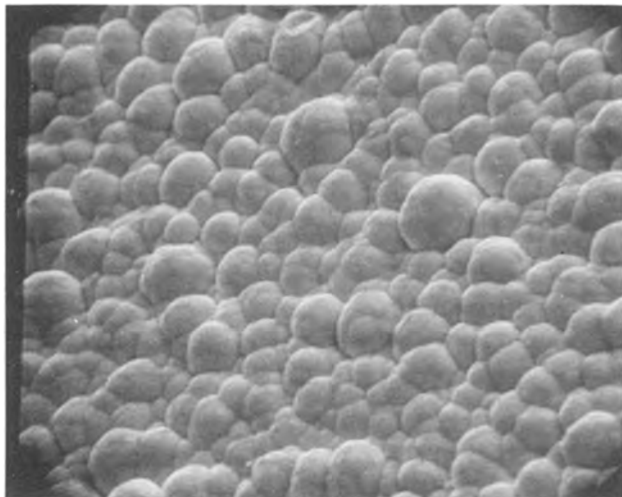
Figure 7 shows x-ray diffraction patterns for deposits with E_{rest} between −0.2 and −0.6V *vs.* SCE made at differnt temperatures. Deposits made at 25°C show only the weakest indication of one diffraction peak at 2θ = 25°; these deposits are largely amorphous. Deposits made at higher temperatures show diffraction lines of the blende structure with a lattice constant of 6.48Å as characteristic for CdTe. The diffraction lines increase in intensity with increasing deposition temperature. The width of the diffraction lines does not change appreciably with deposition temperatures between 35° and 90°C, indicating a constant crystallite size in the range 500 to 1000Å.

Annealing in an inert atmosphere for 3.5 hr at 350°C produces a film with the diffraction pattern shown in Fig. 7e; now the lines are sharp, indicating that the crystallite size has increased to ≧0.5 μm. The intensity ratio of different lines is not always the same in all CdTe patterns, indicating a certain amount of orientation in some of the films. Low angle electron diffraction of the films gives again the pattern of the blende structure with the lattice constant of CdTe.

Inspection of the films under the scanning electron microscope shows that films deposited at 25°C are amorphous. Figure 8a shows a top view, Fig. 8b shows a view of a fracture surface, and Fig. 9 shows a top view of a film deposited at 90°C. Films deposited under these conditions show a coarse structure, but it is difficult to determine the crystallite size with certainty.

Semiconductor properties.—Measurement of the voltage difference between a hot and a cold contact as a function of the time starting with the moment that the hot probe made contact with the film gave signals as depicted in Fig. 10. For one group of deposits the initial potential difference is negative, changing to positive after a few seconds. For another group the potential difference is positive at all times. It is believed that the former behavior indicates p-type, the latter n-type semiconductivity, the change in sign in the former group occurring as a result of a contribution of the n-type SnO_2:Sb base to the thermoelectric power. Attempts to make the method quantitative for carrier density determinations have failed. The type of semiconductivity determined in this manner for samples deposited at various voltages is indicated in Fig. 1. It is seen that films with $E_{rest} \leqq -0.3 \pm -0.05$V *vs.* SCE are n-type, those with $E_{rest} \geqq -0.3 \pm -0.05$V *vs.* SCE are p-type. Extrapolation to 85°C of de Nobel's data for the cadmium pressure at the p ⇄ n transition point of CdTe cooled after equilibrium at 700°-1000°C (11) gives $(a_{Cd})_{p,n} = 5.9 \times 10^{-14}$, corresponding to a potential $E_{rest} = -0.66 + 0.39 = -0.27$V *vs.* SCE, close to the observed value of 0.3 ± 0.05V.

The current density required to produce exactly stoichiometric CdTe with a rest potential equal to that of the p-n transition increases with increasing TeO_2 concentration in the electrolyte or, for deposition from a saturated TeO_2 solution, with decreasing pH (the



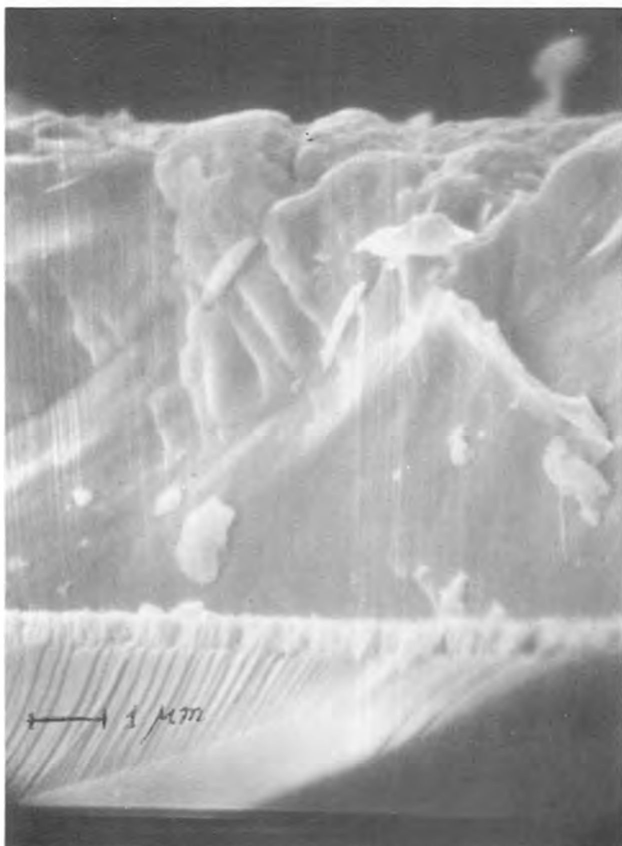


Fig. 8. Scanning electron microscope picture of a film deposited at 25°C on glass covered with SnO_2:Sb. (a, upper) Top view (magnification 5000×); (b, lower) fracture surface (magnification 10,000×) (the thin intermediate layer is the SnO_2).

TeO_2 solubility increases with decreasing *p*H at *p*H < 5); at given TeO_2 concentration, it increases with the rate of stirring. These effects result from the fact that the Te content of the deposit depends critically on the saturation current of the Te deposition which is proportional to TeO_2 concentration and the rate of stirring. The larger the saturation current, the more Te is deposited and the larger the current density has to be to deposit enough Cd to make the material stoichiometric.

N-type material was obtained at all deposition potentials by deposition from an electrolyte to which $10^{-2}\%$ $In_2(SO_4)_3$ had been added. P-type material was obtained at all deposition potentials by deposition from unpurified $CdSO_4$ solution (which contained Cu and

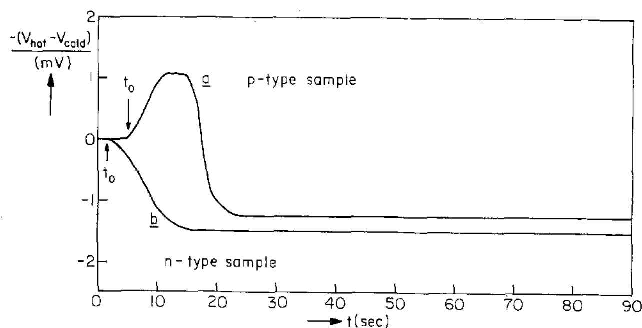

Fig. 10. ($V_{hot} - V_{cold}$) as *f*(time) for samples with different E_{rest} (prepared at different V_{dep}). a, n-type sample; b, p-type sample; t_0 = time at which hot point makes contact with the sample.

As) or from purified $CdSO_4$ solutions to which $10^{-2}\%$ $CuSO_4$ had been added.

The Pourbaix diagram of CdTe.—Recently Ohashi (12) constructed potential-*p*H diagrams for CdTe and ZnTe. The upper boundary of the CdTe field is in fair agreement with our results. However, the lower phase boundary (-1.1V *vs.* NHE at *p*H $= 0$) calculated from the reaction

$$2H^+ + 2e^- + CdTe = Cd + H_2Te$$

is much more negative than the potential at which in our experiments CdTe in equilibrium with Cd is formed: the equilibrium potential of Cd (-0.41V *vs.* NHE). The lower phase boundary is not determined by H_2Te formation, but by dissolution of cadmium present in excess over the stoichiometric ratio according to

$$Cd_{1+\delta}Te = \Delta Cd^{2+} + 2\Delta e^- + Cd_{1+\delta-\Delta}Te$$

with, at the phase boundary CdTe/Cd, $a_{Cd} = 1$. CdTe + Cd is not stable in a solution containing appreciable amounts of Te, Cd exchanging with Te with formation of CdTe. As long as free Cd is present and accessible, however, the potential remains determined and equal to the Cd potential. When all the Cd is used up or has become inaccessible by being covered with CdTe, Cd from the CdTe surface exchanges with Te with formation of a Te-rich surface, and the potential drifts to that of the CdTe/Te phase boundary. A corrected Pourbaix diagram for standard activities of the potential-determining species in the electrolyte is shown in Fig. 11. Formation of $HCdO_2^-$ will limit the CdTe field only at low concentrations and high pH.

Summary

Films made by cathodic deposition from an aqueous solution of $CdSO_4$ and TeO_2, having $0.2V < -E_{rest} < 0.6V$ *vs.* SCE, are identified as CdTe. The deposit is amorphous when deposited at room temperature, semicrystalline with grain size 500-1000Å when deposited in the range 35°-90°C. Annealing at 350°C in argon increases the crystalline size to ≥5000Å. The material is n-type when deposited to have $-E_{rest} > 0.3V$ *vs.* SCE p-type when having $-E_{rest} < 0.3V$ *vs.* SCE. Films doped with donors (In) or acceptors (Cu) grown from electrolytes containing these species are n- respectively p-type for all deposition conditions.

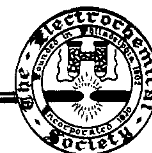
Technical Notes



The Standard Free Energy of Formation of Liquid Na_2SO_4 1160°-1220°K

Winston W. Liang*

Department of Materials Engineering, University of Illinois-Chicago Circle, Chicago, Illinois 60680

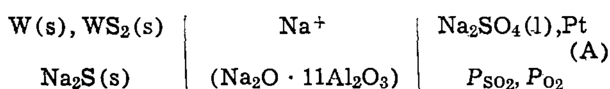
and John F. Elliott*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

With the use of the sodium reference electrode employing β-alumina as a solid electrolyte that has been described earlier (1-3), it has been possible to investigate the properties of liquid sodium sulfate in the temperature range 1160°-1220°K. This communication is a brief description of the results of the work. The

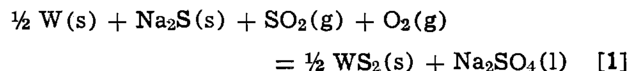
* Electrochemical Society Active Member.
Key words: sodium sulfate, emf measurements, free energy.

cell is the same as that employed earlier (2)



$$\begin{array}{c|c|c} W(s), WS_2(s) & Na^+ & Na_2SO_4(l), Pt \quad (A) \\ Na_2S(s) & (Na_2O \cdot 11Al_2O_3) & P_{SO_2}, P_{O_2} \end{array}$$

The over-all cell reaction is



$$\tfrac{1}{2} W(s) + Na_2S(s) + SO_2(g) + O_2(g) = \tfrac{1}{2} WS_2(s) + Na_2SO_4(l) \quad [1]$$

The cathode liquid consisted of reagent-grade anhydrous granular sodium sulfate which was purified further by drying it in a vacuum chamber at 600°-650°C for at least two days. The cell arrangement and the experimental procedure have been given in detail elsewhere (2). The gas compositions at the cathode employed in this study are given in Table I.

With equilibrium among the compounds in the anode chamber, and equilibrium between the gases and liquid Na_2SO_4 at the cathode

$$\Delta G^\circ_1 = -2\mathbf{F}E + RT \ln P_{SO_2} + RT \ln P_{O_2} \quad [1a]$$

The potential of the cell is E and $\mathbf{F}$ is Faraday's constant. Equation [1a] can be rewritten

$$-2\mathbf{F}E = \Delta G^\circ_f(Na_2SO_4) + \tfrac{1}{2} G^\circ_f(WS_2) - \Delta G^\circ(Na_2S) - \Delta G^\circ(SO_2) - RT \ln P_{SO_2} - RT \ln P_{O_2} \quad [2]$$

It is to be noted that the experimental cell potential must be corrected for the thermoelectric effect of the Pt-W junction to obtain the value of E for Eq. [1a] and [2]. The correction is 20-30 mV in the range of temperature of this work.

The cell (A) was used to measure the activity of sodium oxide in liquid sodium sulfate over a range of partial pressures of oxygen ($10^{-6} < P_{O_2}$, atm < 0.5) and sulfur dioxide ($10^{-6} < P_{SO_2}$, atm < 0.5) with a total pressure of 1 atm. With this cell it is possible to monitor the change in activity of sodium oxide in sodium sulfate arising from additions of Na_2O and SO_3 (SO_2 and O_2) to the sulfate. Sulfur trioxide, alumina/beta-alumina and platinum react to neutralize the sodium oxide added to the sodium sulfate melt depending on the selected experimental conditions. The neutralization of Na_2O by platinum is important when $a_{Na_2O} > 10^{-6}$; by alumina/beta alumina when $10^{-6} < a_{Na_2O} < 10^{-12}$ and by $SO_3(g)$ when the composition of the gas mixture employed has $P_{SO_3} > 10^{-5}$ atm.

The standard free energy of formation of liquid sodium sulfate by the reaction

$$2Na(l) + SO_2(g) + O_2(g) = Na_2SO_4(l) \quad [3]$$

can be obtained from the experimental results and data in Table II using Eq. [2] as follows

Table I. Composition of gas mixtures in volume percent

Gas mixture	Volume percent SO_2	O_2	N_2	Ar
A	50	50	—	—
B	50	10.5	bal.	—
C	50	2.5	—	bal.
E	0.45	50	bal.	—

Table II. Thermodynamic data

Compound	$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$ (J/mole)	Reference
$\tfrac{1}{2}WS_2(s)$	$-168,200 + 78.24T$	4
$Na_2S(s)$	$-435,550 + 124.3T$	5
$Na_2O(l)$	$-353,550 + 88.91T$	5
$SO_2(g)$	$-361,920 + 72.89T$	5
$Na_2SO_4(l)$	$-1,383,900 + 410.3T$	5

Standard states; W(s), $S_2(g)$, Na(l), $O_2(g)$, all at 1 atm pressure.

$$\Delta G^\circ_3 = -2\mathbf{F}E + RT \ln P_{SO_2} + RT \ln P_{O_2} - 267,400 + 46.06T, \text{(J)} \quad [3a]$$

Alternatively for the reaction

$$2Na(l) + \tfrac{1}{2} S_2(g) + 2\,O_2(g) = Na_2SO_4(l) \quad [4]$$

and

$$\Delta G^\circ_4 = -2\mathbf{F}E + RT \ln P_{SO_2} + RT \ln P_{O_2} - 629,300 + 118.95T, \text{(J)} \quad [4a]$$

Thus, with the cell it is possible to determine the standard free energy of formation of liquid sodium sulfate.

The experimental measurements are shown in Table III and the results in terms of ΔG°_1 are shown in Fig. 1. The full line through the data is the least-squares line for all points; its equation is

$$\Delta G^\circ_1 = -637,800 + 178.62T, \text{(J)} \quad [1b]$$

with uncertainties of approximately ±2500 J/mole in free energy, ±5000 J/mole in enthalpy, and ±4 J/mole °K in entropy. There appeared to be no systematic variation of the cell potential with the gas compositions. Inserting these results into Eq. [3a]

$$\Delta G^\circ_3 = -905,200 + 224.68T, \text{(J)} \quad [3b]$$

and into Eq. [4a] gives

$$\Delta G^\circ_f(Na_2SO_4) = -1,267,000 + 297.6T, \text{(J)} \quad [4b]$$

for the liquid with estimated uncertainties of ±15,000 J/mole in free energy, ±18,000 J/mole in enthalpy, and ±10 J/mole °K in entropy. It is to be recognized that the temperature interval over which the measurements were obtained is relatively small so that the un-

certainties in the enthalpy and entropy terms may be very large even though the precision of the value of the free energy may be relatively good. The experimental result (Eq. [4b]) at 1200°K is approximately 12,000J (3000 cal) below the value given in the JANAF tables (5). The data on sodium sulfate in those tables were calculated from measurements of the enthalpy of sodium sulfate by Coughlin (6). Considering the nature of the two sets of data the agreement in the values for the free energy is considered to be reasonably good. On the other hand, however, the thermodynamic properties of sodium sulfide which are used in obtaining Eq. [3a] and [4b] are somewhat uncertain (5).

Because of the large uncertainty in the slope of the experimental line in Fig. 1, it may be better to fit a line to the data based on the standard entropy of formation that has been obtained from thermal data, *i.e.*, −291.35 J/mole °C. Use of this slope with the experimental value of ΔG°_1 at 1200°K gives a value for ΔH°_1 of −773,000 J/mole as compared to −760,600 J/mole from the JANAF tables. With these data and with the data on Na_2S, SO_2, and WS_2 from Table II, the following is obtained for the standard free energy of formation of Na_2SO_4 [*e.g.*, (4)]

$$G^\circ_4 = -1{,}402{,}300 + 410.3T, \text{ (J)}$$

It is to be seen that this modified experimental result is in reasonable agreement with the published results (5), the enthalpy of formation of liquid sodium sulfate from Na(l), S_2(g), and O_2(g) being 12 kJ (3000 cal) more negative than the published value.

Transient Pitting during Film Growth on Aluminum at 1000 mV vs. SCE

J. Zahavi,[1] I. D. Ward, and M. Metzger*

Department of Metallurgy and Mining Engineering and Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

Electronmicroscopic evidence of transient pitting during growth of a porous anodic film on 99.999% Al in 2.4M H_2SO_4 even without Cl^- has been presented by Zahavi and Metzger (1). Anodizing was at 5 mA/cm² yielding a cell voltage ~7V with respect to a Pt cathode; some supplementary observations were made at 25 mA/cm² (~16V). It is of interest to know whether transient pitting phenomena also occur at lower potentials. A gravimetric study of film growth at +1000 mV_{SCE} in 2.4M H_2SO_4 without or with Cl^- additions had been made by Smaga and Metzger (2) with the material and specimen preparation (Electropolish A) employed previously (1). Electronmicroscopic examination of films grown under these conditions in acid without Cl^- is described in this note. Previously, the lowest potentials for which anodic film structure had been examined in any investigation were those of Ref. (1).

At 1000 mV_{SCE} it was found that after 2640 sec the film reached constant weight (2), as expected for a porous film when the pores have grown to a length at

Key words: film growth, pitting, aluminum.

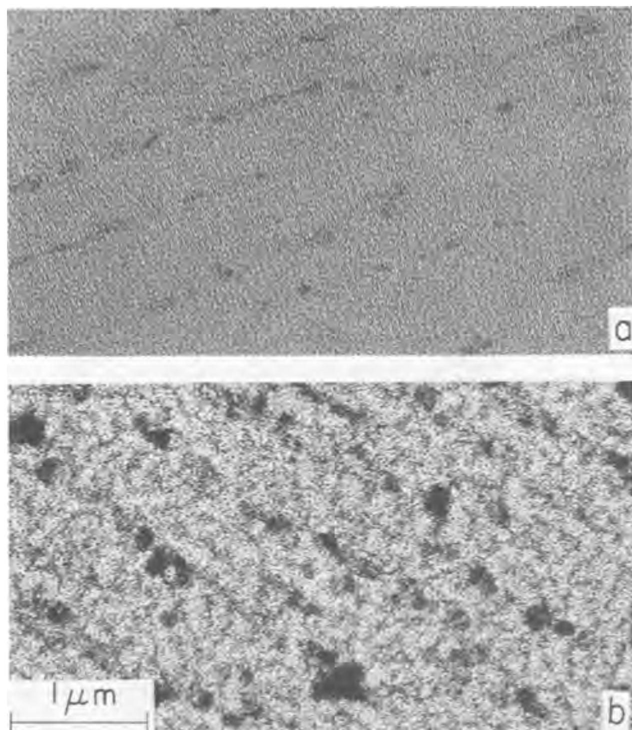

Fig. 1. Transmission electron micrographs of films detached after a) 1080 sec; b) 3000 sec anodizing at +1000 mV_{SCE}.

which the rate of chemical dissolution of their walls equals the rate of growth at the film base (3). From the tapered-pore model and limiting thickness was estimated as ~½ μm (2). Films for electronmicroscopic examination were formed for 600, 1080, and 3000 sec; over this period, the cell current, after its initial fall, was rising slowly from 0.6 to 0.8 mA/cm^2.

In transmission micrographs of detached films, Fig. 1a and b, the films were seen to be porous, and breakdown-pitting repair (BPR) "events" were visible as dark patches, usually elongated. The veining visible in the background of Fig. 1b originated in the surface topography produced by the $HClO_4$ electropolishing bath ("granular structure"), as discussed in Ref. (1). The appearance of the events was remarkably similar to that noted earlier (1) at a potential ~6V higher. The contrast at an event is the result of the extra mass thickness provided by the repair film beneath the main film and/or the local perturbation of the pore structure, as described previously (1).

Examination of films at much higher magnifications showed that pore diameters were small (<10 nm), but a precise determination could not be made. The pores apparently were far from being straight cylinders since they did not image as separated sharp round silhouettes of uniform size. The factors responsible for this would be (*i*) the pores were tapered by chemical dissolution of their walls; (*ii*) they were jogged or had sloping segments resulting from the BPR processes which had interrupted their growth (thus images of adjacent pores could overlap). Microscopic measurements of pore and cell diameters of anodic films are usually made on much coarser structures produced in various acids at "forming voltages" well over 10V and sometimes over 100V (3, 4, 5). If the figure for pore diameter of approximately 1.0 nm/V obtained in these studies (4, 5) is applied to the present case, and if the "forming voltage" in the present experiments is taken as the overpotential above the Al/Al_2O_3 reversible potential, the pore diameter predicted would be ~3 nm, which is not inconsistent with the observations.

Figure 2 shows an underside-replica micrograph of the 600 sec film. Evidence that this structure did not represent artifacts was (*i*) two sets of such replicas

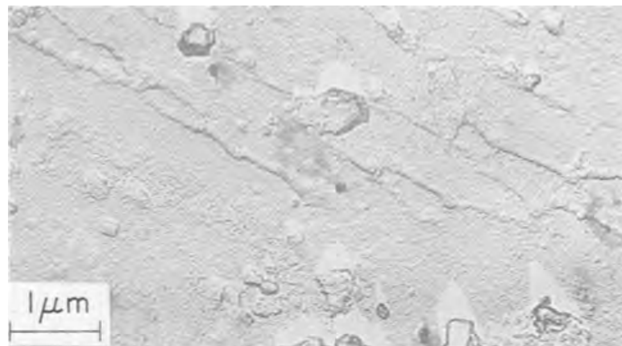

Fig. 2. Replica of underside of 600 sec film. Shadowed with Pt-C at $\tan^{-1}$ ¼.

from the 600 sec film and one from the 1080 sec film prepared with close attention to and some variation in details of procedure all gave consistent structures; (*ii*) the structures were basically similar to those obtained in an extended study of films formed at 5 mA/cm^2. Visible in Fig. 2 are irregular strings of very fine repaired pits and on them or elsewhere some larger repaired pits which are thought to have formed subsequently. The latter are the "events" visible in transmission as dark patches. It was deduced that the strings of fine pits gave by themselves little or no visible contrast in transmission and that the tendency toward elongation of the events seen in transmission was the result of the tendency for events to nucleate on the strings and sometimes a tendency for the events themselves to be elongated. The evolution of structures of this type and their relation to substrate orientation has been studied in some detail for anodizing $\lesssim$ 100 sec at 5 mA/cm^2 and is reported separately. Although anodizing times were much longer in the present work, the mass thicknesses of the films examined were in the same range, and the similarity of the transient-pitting structures in the two cases is taken to mean that the stages through which film structure passes depend more on mass-thickness than on potential in the range studied. This conclusion had been drawn earlier from observations on films formed at 5 mA/cm^2 at reduced cell voltages in acid containing Cl^- (1).

The significance of the transient pitting accompanying film growth for the understanding of several phenomena has recently been discussed elsewhere (6).

Thermal Oxidation Kinetics of Silicon in Pyrogenic H_2O and 5% HCl/H_2O Mixtures

Bruce E. Deal*

Fairchild Camera and Instrument Corporation, Research and Development Laboratory, Palo Alto, California 94304

ABSTRACT

The kinetics of the thermal oxidation of silicon in H_2O and in 5 volume percent (v/o) HCl in H_2O using a pyrogenic system have been investigated over the temperature range 900°-1100°C. Oxide thickness-oxidation time data, rate constants, and activation energies have been obtained for (111) and (100) oriented, 1×10^{15} cm^{-3}, n-type silicon. Results obtained for oxidation in H_2O are very similar to those reported previously for water bubbler systems. The addition of HCl to H_2O does not increase the silicon oxidation rate as with dry O_2, but the rate actually decreases apparently because of the reduced H_2O vapor pressure. The HCl also appears to reduce impurity contributions from the oxidation system.

Recent investigations concerning the oxidation kinetics of silicon in dry oxygen containing small additions of HCl or Cl_2 have been reported (1-4). These and other studies have indicated that such chlorine additions provide certain benefits to the resulting device structures, such as alkali ion passivation, higher and more uniform oxide dielectric strength, and improved junction properties due to lower leakage (5-8). Coincidentally increased oxidation rates have been observed with increasing chlorine concentration in the oxygen ambient (1-4). The reported improvements in device properties are probably due in part to actual incorporation of a chlorine species in the silicon oxide and reaction of this species with impurities (8, 9). It has been proposed that the increased oxidation rates are due either to the reaction products (such as H_2O and Cl_2 from O_2 plus HCl) or the effect of the chlorine species itself on the oxide growth mechanism, or both (1-4).

Less information is available concerning the oxidation of silicon in H_2O which contains small amounts of chlorine. There are indications, however, that chlorine is not incorporated in the oxide and that oxidation rates are not increased by the addition of HCl and other chlorine species to the water ambient (10).

Water or water-containing ambients have been used for the thermal oxidation of silicon since silicon dioxide was first employed for masking dopants during diffusion of silicon devices (11-13). Silicon oxidation kinetics in H_2O have been reported by several authors (14-16) for various process conditions. Most of these results were for wet O_2 (oxygen bubbled through H_2O) or steam (H_2O vapor boiled from a flask). More recently oxidation in a water ambient has been carried out by the pyrogenic reaction of H_2 and O_2 (17). This process is reported to be cleaner and easier to control in production environments.

The purpose of this investigation was to establish oxidation kinetics for the thermal oxidation of silicon in H_2O, to determine the effect of small HCl additions to the ambient on oxidation kinetics, and to compare the results of pyrogenic H_2O oxidation to those previously obtained with wet O_2 or steam introduced into the furnace from a quartz flask (hereafter referred to as a "bubbler" system). Data are reported for 1×10^{15} cm^{-3} n-type silicon with (111) and (100) orientations over the temperature range 900°-1100°C. A brief comparison with dry O_2 oxidation results is also included.

Experimental

Experimental conditions and procedures were the same as those reported previously (4). Silicon wafers used for this investigation were n-type 4-6 Ω-cm, with (111) and (100) orientations. Introduction of H_2O into the furnace was acomplished using a pyrogenic oxidation system involving water generation in the end of the furnace tube by the direct reaction of H_2 and O_2. The system, Model D-101, was manufactured by Corso-Gray Instruments, Sunnyvale, California. HCl of 99.99% purity was also introduced through this system. Concentrations of O_2, H_2, and HCl were controlled by calibrated flowmeters. Oxidations at selected ratios of H_2 to O_2 were carried out at temperatures of 900°, 950°, 1000°, 1050°, and 1100°C. Oxidation temperatures for the H_2O/HCl mixture were 900°, 1000°, and 1100°C. For the H_2O oxidations, wafers were pushed into the furnace with the water ambient flowing at 2 liters/min (44 cm/min). At the end of the oxidation time, the wafers were pulled rapidly from the furnace. For the addition of 5% HCl, the HCl flow was started after the wafers were in the furnace; at the end of the oxidation time, an N_2 flow was started, the HCl, H_2, and O_2 flows were stopped, and the system was purged with N_2 for 15 min before the wafers were pulled. Oxidation times in general ranged from 9 min to 8 hr.

Oxide thicknesses were measured using a Rudolph Model 436-200-E ellipsometer with a helium-neon source, with measurement reproducibility of ±3%. Mobile ion concentrations, Q_o/q, and fixed oxide charge, Q_{ss}/q, were determined by conventional capacitance-voltage techniques.

Oxidation kinetic data were analyzed in terms of the oxidation general relationship (15)

$$x_o^2 + Ax_o = Bt \quad [1]$$

where x_o is oxide thickness, t is oxidation time, and B and A are constants. [For H_2O oxidation, the constant

τ normally included in Eq. [1] has been found to be approximately zero (15).] The parabolic rate constants, B, and the linear rate constants, B/A, were calculated using the conventional procedure (15). These constants were then used to determine activation energies by means of Arrhenius-type plots.

Results

System calibration.—The first procedure in conjunction with this program was to calibrate the pyrogenic oxidation system. An attempt was made to generate 100% H_2O (760 Torr) by using exactly 2 parts H_2 to 1 part O_2. Oxidations were carried out at a particular temperature (1000°C) for specific times (15 and 60 min), and oxide thicknesses were compared with those reported previously for atmospheric steam (14-16). Unfortunately, some disagreement exists among the previous works because steam obtained from a boiling flask is difficult to control and reproduce. Even so, the results obtained in the pyrogenic system indicated lower thicknesses than most of those reported for the boiling flask method.[1] It was therefore decided to duplicate the oxidation rate obtained using O_2 bubbled through 95°C water (15). A series of oxidations with varying ratios of H_2 to O_2 indicated that 2.0 liters/min of H_2 plus 1.175 liters/min O_2 did duplicate reasonably well the O_2 through 95°C H_2O data over the temperature range investigated. This ratio was used for the H_2O oxidations reported here. In both cases, the ambient will contain a small excess of O_2 but its contribution to the over-all oxidation process is calculated to be less than 1%. It is also of interest to note that these results are identical to those reported in Ref. (17) for 1 atm H_2O oxidation of (111) silicon in a pyrogenic system.

H_2O oxidation data.—The data for the oxidation of (111) and (100) oriented silicon in pyrogenic H_2O over the temperature range 900°-1100°C are plotted in Fig. 1. The plots are in the form of log oxide thickness *vs.* log oxidation time. Also included are previous bubbler results for 1200°C (15), at which temperature differences between orientations are assumed to be negligible. The plots follow the general oxidation relationship (Eq. [1]) where at higher temperatures and for thicker oxides the reaction is generally parabolic (diffusion controlled) and at lower temperatures and for thinner oxides it is linear (surface controlled).

[1] Conversations with other investigators indicate the pyrogenic reaction of H_2 and O_2 is not 100% efficient.

Table I. Rate constants for the thermal oxidation of n-type, 4-6 Ω-cm, (111) and (100) oriented silicon in water

(2.0 liters/min H_2 + 1.175 liters/min O_2)

Oxidation temp. (°C)	Silicon orient.	A (μm)	B (μm²/hr)	B/A (μm/hr)	B/A ratios (111)/(100)
900	(100)	0.95	0.143	0.150	
	(111)	0.60	0.151	0.252	1.68
950	(100)	0.74	0.231	0.311	
	(111)	0.44	0.231	0.524	1.68
1000	(100)	0.48	0.314	0.664	
	(111)	0.27	0.314	1.163	1.75
1050	(100)	0.295	0.413	1.400	
	(111)	0.18	0.415	2.307	1.65
1100	(100)	0.175	0.521	2.977	
	(111)	0.105	0.517	4.926	1.65
					Avg. 1.68 ± 0.03

Rate constants were determined and are tabulated in Table I. Included in the table are the ratios of linear rate constant (B/A) values between (111) and (100) orientations. The ratios are quite consistent and the average is 1.68 ± 0.03 over the temperature range investigated.

Figure 2 is an Arrhenius-type plot of log B *vs.* $1/T$ from which an activation energy may be determined. The data are for both (111) and (100) orientations since B is not a function of orientation. Also included in the figure are previous data for dry O_2 oxidation (4, 15). The parabolic activation energy value of 0.78 eV for the pyrogenic system is similar to that previously reported (0.71 eV) for the bubbler process (15). It is not known if the falloff of B at 900°C is real or due to experimental error. A similar plot for the linear rate constant B/A is shown in Fig. 3. Here, the differences for the two silicon orientations are

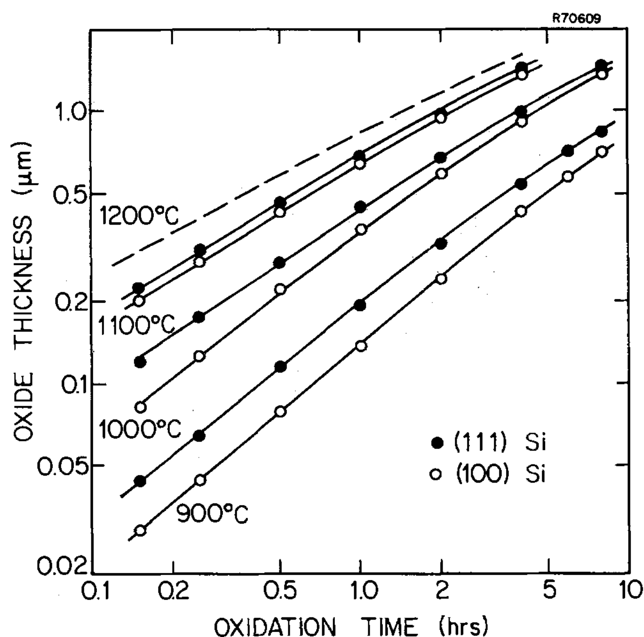

Fig. 1. Oxide thickness *vs.* oxidation time for silicon oxidation in H_2O (640 Torr).

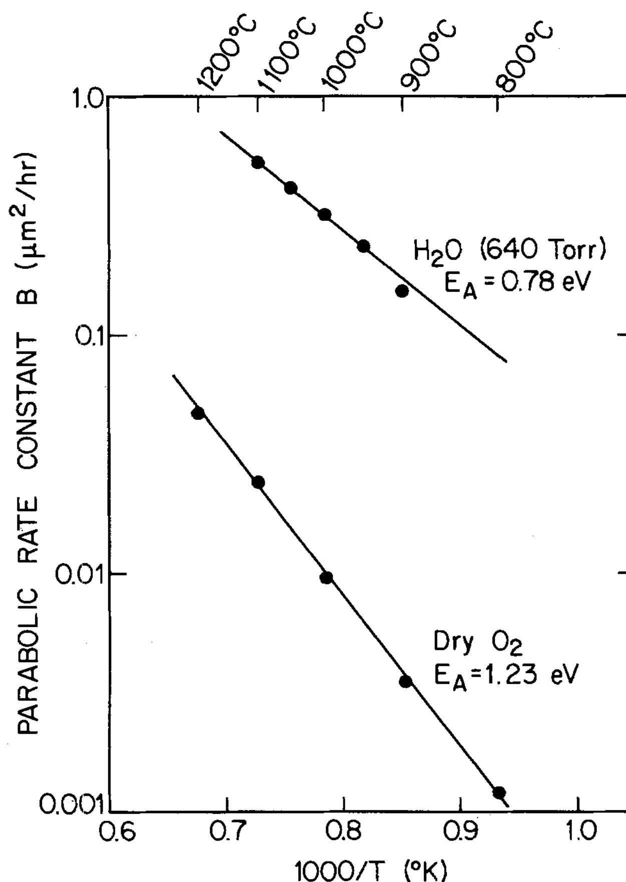

Fig. 2. Dependence of parabolic rate constant B on temperature for the thermal oxidation of silicon in pyrogenic H_2O (640 Torr) or dry O_2.

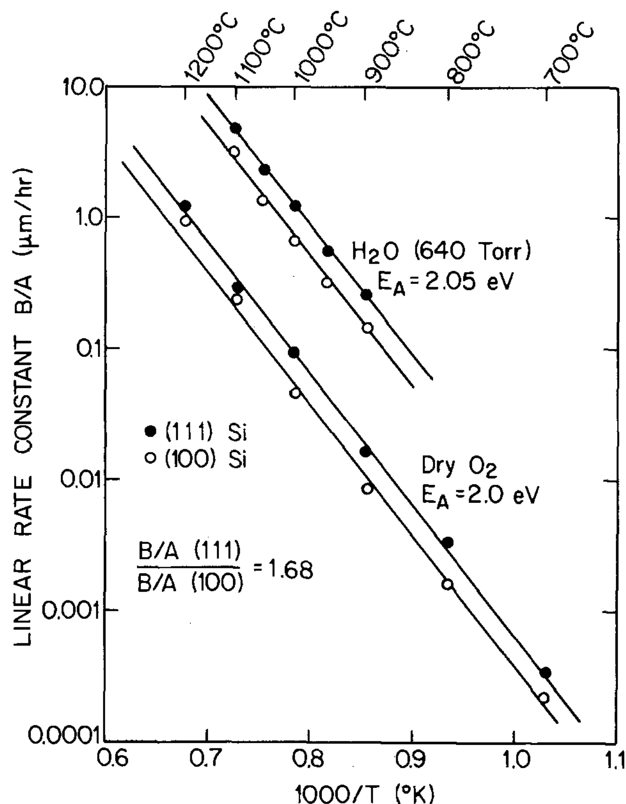

Fig. 3. Dependence of linear rate constant B/A on temperature for the thermal oxidation of silicon in pyrogenic H_2O (640 Torr) or dry O_2.

reflected by the two different but parallel plots. The activation energies for both are 2.05 eV, very similar to the previous bubbler results (15). Again, dry O_2 B/A values are included for comparison. However, in the latter case it is assumed that the activation energies for (111) and (100) silicon should be equal and the ratios of the B/A values should be the same as for H_2O. Thus, the line drawn through the (100) data points is drawn following this assumption. It can be noted that this constant ratio assumption for dry O_2 provides a reasonable fit for the (100) data, which was not possible previously because of its nonlinear nature (4).

If Arrhenius-type expressions of the form $B = C_1 e^{-E_1/RT}$ and $B/A = C_2 e^{-E_2/kT}$ are assumed, then values for the constants C_1 and C_2 may be calculated. These values, along with activation energies E_1 and E_2, are tabulated in Table II for both pyrogenic H_2O and dry O_2 silicon oxidation.

H_2O/HCl results.—Oxidations were carried out at 900°, 1000°, and 1100°C in a pyrogenic H_2O ambient with a 5% HCl addition. When oxide thickness-oxidation time data were compared with the H_2O results of Fig. 1, not only did the HCl addition provide no increase in oxidation rate, but an actual decrease was observed. Coincidentally, this decrease appeared to be about 5%; the amount of HCl added. Rate constants were determined and these are tabulated in Table III, along with B/A ratios for the two orientations. The latter average value of 1.72 was quite similar to the 1.68 value for H_2O.

If the values of B, the parabolic rate constant, for 5% HCl additions are compared with those for H_2O, an average ratio of 0.934 is obtained. This is reasonably close to 0.95 which would be expected for a straight dilution by the HCl. A similar reduction ratio between HCl and no HCl is obtained for the linear rate constant B/A, probably through the partial pressure reduction effect on B.

Special oxidations were carried out at 1000°C in which 5% N_2 was added to H_2O. Oxidation rates were approximately the same as those obtained with 5% HCl additions. This tends to confirm that the reduced oxidation rate for the HCl/H_2O mixture is due to a dilution of the H_2O by the HCl addition.

* Actual v/o HCl = 4.6%.

Oxide properties.—Some mention should be made concerning various physical and electrical properties of the oxides prepared in 5% HCl/H_2O ambients. First, the apparent thickness uniformity and appearance of these oxides were considerably better than corresponding H_2O oxides. Very few defects or color variations were observed. This is probably related to the fact that ionic contamination in the HCl/H_2O oxides was also low, as evidenced by Q_o/q values of less than 2×10^{10} cm^{-2} over the entire temperature range. These may be compared with Q_o/q values for the regular H_2O oxides of $<2 \times 10^{10}$ cm^{-2} at 900°C but ranging up to 3×10^{11} cm^{-2} at 1100°C. This trend of increasing contamination with oxidation temperature is believed to be due to increased reaction of the water with ionic impurities in the quartz tube at the higher temperatures. Apparently the HCl serves to complex these impurities in the apparatus.

Preliminary measurements of Q_{ss}/q indicated somewhat lower values at a given temperature than previously obtained for 95°C H_2O oxidations. This may be due to an effect of free hydrogen in the pyrogenic oxidation ambient.

Summary

Kinetic data for the oxidation of (111) and (100) oriented silicon in H_2O over the temperature range 900°-1100°C have been presented. The water was generated by the direct reaction of H_2 and O_2 in a pyrogenic system. Since it is apparently not possible to generate 100% water in this system, flow rates of the gases were selected to provide oxidation rates equal to those previously obtained for O_2 bubbled through 95°C H_2O, *i.e.*, ~0.85 partial pressure of H_2O.

Rate constants for the general oxidation relationship were determined, and values for (111) silicon agree quite well with those previously obtained for a 95°C H_2O bubbler system. As predicted by theory, the parabolic rate constants, B, exhibit no orientation de-

pendence. Linear rate constants, B/A, for (111) silicon are 1.68 times the (100) silicon values. Activation energies are 0.78 and 2.05 eV for the parabolic and linear rate constants, respectively. Again, these values correspond favorably with wet O_2 bubbler results. The 1.68 ratio between (111) and (100) linear rate constants was applied to the dry oxygen data recently obtained, and the line drawn for (100) silicon provides a reasonable fit for the Arrhenius-plot data points.

Oxidation kinetics were also determined for mixtures of 5 volume percent (v/o) HCl in H_2O using the pyrogenic system. Other process conditions were the same as indicated above for H_2O oxidations. It was found that the only change in the oxidation process due to the HCl addition is a decrease in rate constants approximately equal to the HCl concentration in the oxidation ambient. Apparently no chlorine species is incorporated in the oxide during H_2O/HCl oxidations (10). This fact plus the probability that HCl does not react with the H_2O would indicate that the HCl species itself does not enter into the reaction directly in either H_2O/HCl oxidations or in the O_2/HCl oxidations discussed previously (4, 18). If this is true, the previous proposal that the reaction products H_2O and Cl_2 are the primary species affecting O_2/HCl oxidation kinetics (18) is corroborated.

The results of this investigation also indicate that small HCl additions to H_2O oxidation ambients provide beneficial effects because of the gettering or complexing of alkali impurities in the quartz system. In addition, more uniform oxides with fewer defects are produced. The question of possible effects on the oxide charges due to free hydrogen in the pyrogenic system must yet be resolved.

Thermal Oxidation of GaAs in Arsenic Trioxide Vapor

Hiromitsu Takagi, Gota Kano, and Iwao Teramoto*

Matsushita Electronics Corporation, Research Laboratory, Takatsuki, Osaka, Japan

ABSTRACT

A new technique for thermal oxidation of GaAs is proposed. The native oxide films composed of As_2O_3 are plus β-Ga_2O_3 thermally grown under controlled vapor pressures of arsenic trioxide. The breakdown strength of the films is found to be as high as 5-7 $\times$ 10^6 V/cm, which is comparable with the highest value ever obtained for anodic oxide films. The leakage current is also on such a low level that it is of the order of 10^{-8} A/cm^2 per 1000Å at an applied voltage of 10V. The chemical properties evaluated in terms of etching rates for various etchants exhibit satisfactorily stable and favorable characteristics for GaAs planar processes.

Increasing interest is being shown in the growth of native oxide films on GaAs with the required properties for device applications. However, two previous procedures for the oxidation, thermal (1, 2) and anodic (3-8), have not proved consistently successful in obtaining chemically stable films with satisfactory physical properties.

It empirically appeared to be plausible that the poor electrical characteristics inherent in thermal oxide films, though much more stable than anodic oxide films, might be due to the chemical composition lacking arsenic trioxide (As_2O_3).

On the basis of these considerations we propose a new technique for thermal oxidation of GaAs in the As_2O_3 vapor phase. The native oxide films grown under controlled vapor pressure of As_2O_3 have shown excel-

Key words semiconductor, integrated circuits, etching, oxidation.

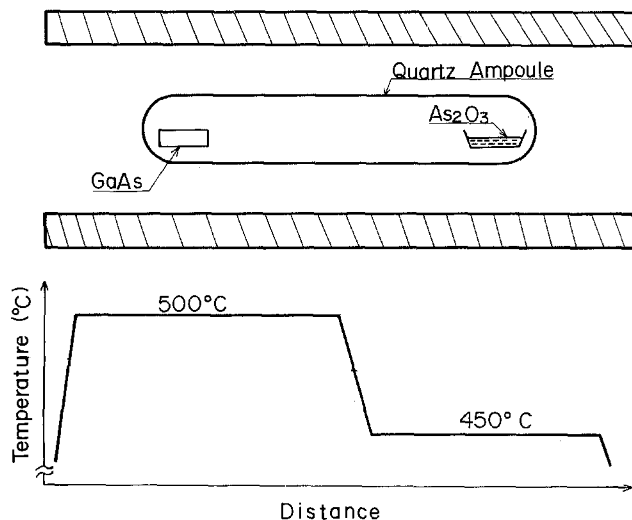

Fig. 1. Experimental setup for thermal oxidation in As_2O_3 vapor

lent properties in electrical characteristics as well as chemical stability.

Experimental Procedures

Figure 1 shows an experimental setup for the oxidation of GaAs crystals. A GaAs wafer to be oxidized is placed at one end of a quartz tube and high purity powder of As_2O_3 put into a platinum boat is placed at the other end. The quartz tube is then evacuated and placed into a double furnace which is regulated so that the GaAs wafer is maintained at an oxidation temperature (T_{OX}) while the As_2O_3 powder is at a lower temperature (T_{AO}) determining the vapor pressure in the system. The thermal equilibrium will be reached within 1 min. After the oxidation time the quartz ampul is quenched in water avoiding the As_2O_3 deposition on the oxide film. Wafers of Zn-doped p-type GaAs with a carrier concentration of 5 $\times$ 10^{16} cm^{-3} were used in the experiments. The (100) surfaces of the wafers to be oxidized were mechanochemically polished in an aqueous solution of NaOCl followed by chemical etching in a H_2SO_4:H_2O_2:H_2O (3:1:1) solution at 60°C for 10 min. The thermal oxidation was carried out at 500°C under an As_2O_3 vapor pressure of 700 mm Hg being in equilibrium with liquid As_2O_3 at 450°C.

Results and Discussions

In Fig. 2 an experimental result is shown of the relation between the oxide film thickness and the oxidation time. From the linearity observed up to about 1 μm thickness the oxidation rate is estimated to be

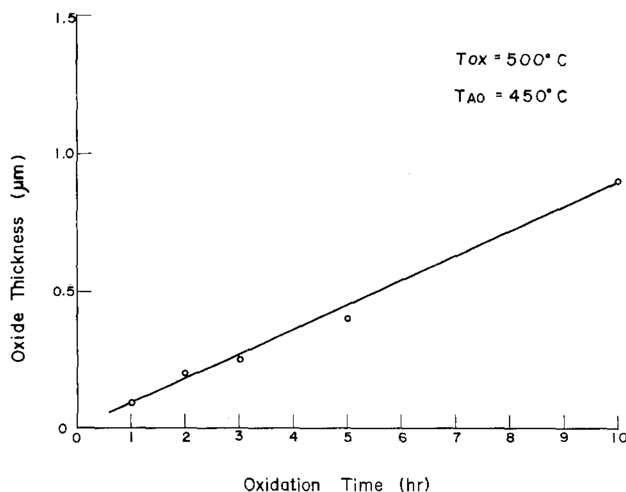

Fig. 2. Oxide film thickness vs. oxidation time

Fig. 3. Electron beam diffraction pattern of an oxide film. Film thickness is 3000Å.

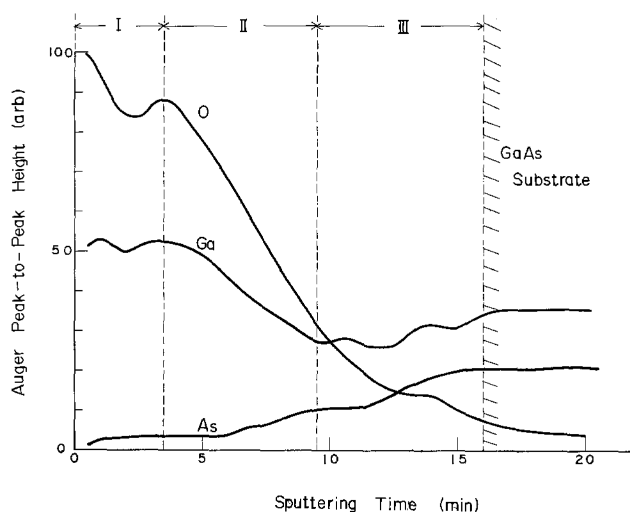

Fig. 4. Auger peak-to-peak height vs. sputtering time. Film thickness is 3000Å.

approximately 15 Å/min for T_{OX} = 500°C and T_{AO} = 450°C.

Figures 3 and 4 show an electron-beam diffraction pattern and a depth profile of the Auger peak-to-peak height, respectively, of an oxide film grown to a thickness of 3000Å. These figures apparently show that the dominant constituents of the film grown in the As_2O_3 vapor are represented by a quasibinary solid system As_2O_3-β-Ga_2O_3.

The composition profile along the film depth may be divided into three regions, I, II and III, as shown in Fig. 4. Within the top surface region I and the bottom interface region III, which are about 800 and 1200Å thick, respectively, the composition ratios of As_2O_3 to β-Ga_2O_3 can be regarded constant. The ratio in the intermediate region II which is about 1000Å thick, however, gradually decreases towards the substrate. This composition profile suggests that the oxidation process is diffusion limited in the solid oxide phase.

Electrical characteristics of the oxide films grown by the present technique were evaluated in terms of the breakdown strength and the leakage current. The aluminum evaporated dots with a 50 μm diameter were used for these measurements. In Fig. 5 the breakdown voltage and the breakdown strength are plotted as a function of the film thickness. The breakdown strength is as high as 5-7 $\times$ 10^6 V/cm, being comparable with the highest value ever obtained for the anodic oxide films. The leakage currents measured are of the order of 10^{-8} A/cm^2 per 1000Å thickness at an applied voltage of 10V.

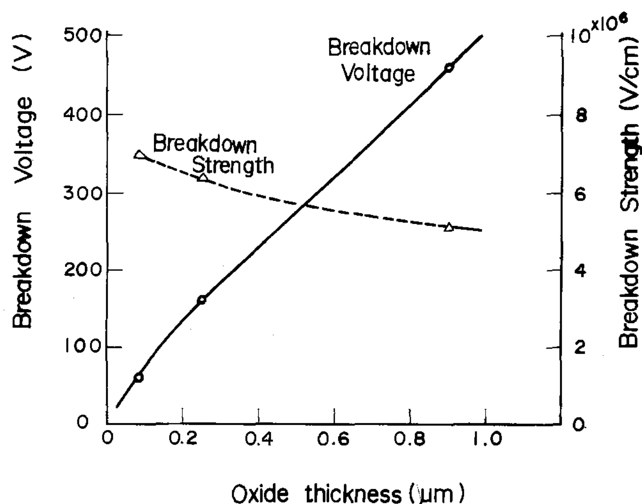

Fig. 5. Breakdown voltage and breakdown strength vs. oxide film thickness. Solid line and dashed line show breakdown voltage and breakdown strength, respectively.

The chemical properties of the films were also examined by measuring the etching rate for various etchants. In view of the results shown in Table I, it is expected that the conventional chemical technology for the silicon planar process is applicable to GaAs devices by using the present native oxide films.

Table I. Etching rates for various etchants (25°C)

Etchant	Etching rate (Å/min)
HCl (35%)	506
HCl (35%):H_2O = 1:1	227
HCl (35%):H_2O = 1:3	90
HF (46.5%)	179
HF (46.5%):H_2O = 1:1	108
HF (46.5%): H_2O = 1:5	52
H_3PO_4 (85%)	24

Summary

It has been shown that the GaAs native oxide films grown by the new thermal oxidation technique in the As_2O_3 vapor are composed of As_2O_3 and β-Ga_2O_3. Striking improvements in electrical and chemical characteristics of the films have been achieved. The present technology will be useful for the surface passivation and the planar integration of GaAs devices. Realization of GaAs MOSFET's is also expected.

Electroluminescence in an Epoxy Resin

R. Coïsson, C. Paracchini, and G. Schianchi

Istituto di Fisica dell'Università, Parma, Italy

ABSTRACT

Electroluminescence—which can be used as a probe for studying breakdown mechanisms—is studied in one type of epoxy resin at room temperature. The electroluminescence spectrum is compared with x-ray and ultraviolet radiation stimulated emissions. The behavior of luminescence bands with increasing applied voltage suggests that charge injection takes place and that the electroluminescence mechanism is that of impact ionization.

Several insulators with high dielectric strength exhibit a persistent electroluminescent emission at alternating fields some orders of magnitude lower than breakdown value. Such an effect has been observed both in crystalline (1) and amorphous materials (2). The emission appears localized near the metal-insulator interface, and it is probably caused by the same mechanisms that at higher fields trigger the breakdown (3). Under this point of view, electroluminescence can be used as a probe for studying the breakdown mechanisms and the effects intimately related to it.

In this work some results obtained from the study of the electroluminescence of one type of epoxy resin are reported. The interest in this kind of polymers in electrical applications has grown in the last years, mostly in view of their insulation properties (4). Nevertheless, it seems that the little knowledge of the phenomena leading to breakdown corresponds to the widespread electrical applications. Electroluminescence may give information on this subject (5).

The samples are thin foils (about 0.1 mm) of diglycidyl ether of bisphenol A (EPON 828, Shell), cured with triethylene tetramine (13 parts in weight every

100 parts of resin), prepared by a standard method in our laboratory. The measurements are performed at room temperature, under vacuum to avoid possible discharges in air. The electroluminescent effect appears with any alternating electric field of the order of 10^5 V/cm. Usually the samples are excited with square waves at a frequency of about 200 Hz. Electroluminescence spectra are recorded by measuring the signal, through a Hilger-Watts D.330 monochromator, with a trialkali photomultiplier (E.M.I. 9558 QA) and improving the signal-noise ratio by means of a Boxcar Integrator (PAR 160). The samples have on one side a contact indium or silver paint metal electrode, the other being insulated by means of a thin Teflon foil. In this way the possibilities of breakdown are greatly reduced without a great reduction of the applied field. For comparison, photoluminescence measurements at room temperature are also performed, exciting the emission either with soft x-rays (40 kV, 30 mA) or with u.v. radiation (60W deuterium lamp). The absorption spectrum of the resin is also recorded, by means of a Cary 15 spectrophotometer.

Figure 1 shows the luminescence spectra of the resin samples obtained with x-ray, electric, and u.v. stimulation (curves A, B, and C, respectively); the absorption spectrum (dotted curve) is also reported. The observed emission under x-ray excitation extends from ~500 to ~300 nm, with a maximum at about 325 nm; at shorter wavelengths, where the luminescence drops abruptly, the steep absorption edge is observed. If the luminescence is excited by electric field, the band extends approximately in the same spectral region, but its maximum is at about 340 nm. If the two spectra are normalized at 350 nm, the low energy sides of the two emissions nearly coincide. The same features are obtained with the spectrum of the luminescence excited by u.v. radiation; in this case the maximum intensity is at about 400 nm. The results reported in Fig. 1 suggest that the observed luminescence spectra are envelopes of several close bands, which are subsequently excited when the energy of the exciting source is increased. Moreover, it is also probable that the emission spectrum extends, at sufficient excitation energies, in the u.v. region beyond 300 nm, and that the self-absorption of the material is responsible for the drop on the short wavelength side.

Electroluminescence effects observed in high resistivity materials are usually attributed either to the alternate injection of carriers of opposite sign from the electrodes into the insulator (double injection) or to the impact excitation processes generated by one single type of carriers injected into the dielectric and accelerated by the high field region near the metal-insulator interface. If, in our case, different radiative recombinations are possible, each one excited at slightly different energy, one should expect, in the case of the impact excitation mechanism, a progressive shift of the spectrum toward the shorter wavelengths while the carrier energy, that is, the applied voltage, increases. On the contrary, it would be difficult to justify such a shift of the spectrum in the case of double injection mechanism, as an increase in the applied voltage would influence only the density of injected carriers, without affecting appreciably the recombination features.

On account of the low emitted light intensity, it would be difficult to notice this shift by directly comparing the spectra obtained under different voltage stimulation; it is easier to find the possible differences by comparing filtered emissions, as shown in Fig. 2. The light responses obtained simultaneously from two photomultipliers (say, A and B) are reported in arbitrary units, while the applied voltage is increased up to 2000V. In the case of curve 1 both photomultipliers receive the unfiltered emitted light: The straight line assures that their responses are proportional. In the case of curve 2 the light detected by the phototube B is filtered by a 400 nm cutoff filter: In this case the responses are no longer proportional, the signal of phototube B being progressively reduced with respect to the unfiltered situation. This result suggests that the electroluminescence emission is shifted toward shorter wavelengths when the applied voltage is increased and provides indirect evidence of an impact excitation mechanism. According to this model, Fig. 1 suggests that the energy of the accelerated injected carrier is intermediate between that of the u.v. and the X photons.

The above results suggest: (*i*) The luminescence of the resin is formed by several close bands extending from about 550 nm to the u.v. region; (*ii*) in the u.v. the emission is cut off due to self-absorption; (*iii*) by applying an electric field it is possible to inject carriers (presumably electrons) into the material; and (*iv*) the electric field generates impact excitation processes near the metal insulator interface, giving rise to luminescence.

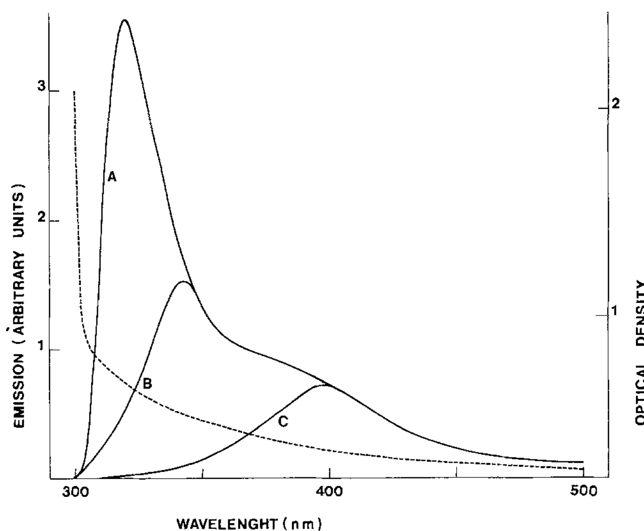

Fig. 1. Luminescence (full line) and absorption (dotted line) spectra at room temperature of a sample of diglycidyl ether of bisphenol A cured with triethylene tetramine. The three luminescence spectra indicated with A, B, and C refer to the light emissions obtained with x-rays, electric field, and u.v. stimulation, respectively.

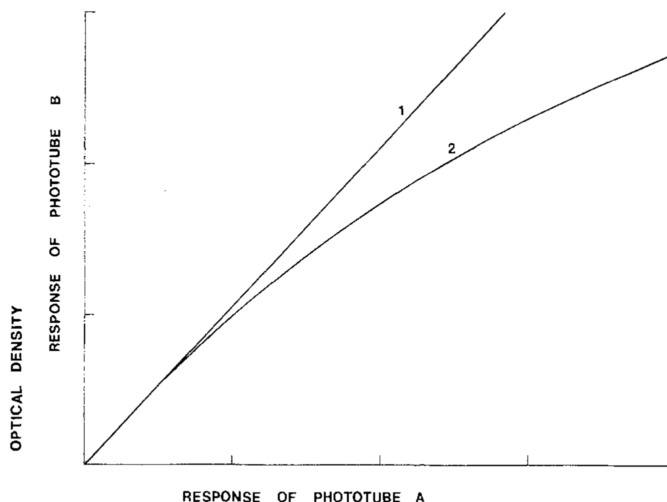

Fig. 2. The simultaneous responses of two phototubes (A and B) detecting luminescence are plotted one against the other. In the case of curve 1 both phototubes are unfiltered and their responses, when the applied voltage is increased, are proportional. In the case of curve 2 the light arriving at the phototube B is filtered through a filter cutting off at about 400 nm. On increasing the voltage, the signal of phototube B is progressively reduced with respect to that of A..

Studies of X-Ray Image Intensifier Output Screens

J. S. Prener* and R. K. Swank

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The performance of an x-ray image intensifier is governed by the properties of its four components: input phosphor screen, photocathode, electron optics, and output screen. P-20 output phosphor screens of various thicknesses were prepared by centrifugal settling and by electrophoretic deposition. In addition to the determination of screen density, we measured, as a function of accelerating voltage, screen brightness, MTF, and spatial noise due to screen graininess. Although there are claims in the literature regarding the superiority of electrophoretic screens, we found them to be no better than carefully deposited centrifugal screens.

An x-ray image intensifier (XRII) is a device for converting an incident x-ray pattern (as in medical radiology) to a visible light image. The brightness of the light image is considerably higher than that obtained with a simple fluoroscopic screen (1). The performance of an XRII is governed largely by the properties of its four major components (Fig. 1): the input phosphor screen, the photocathode, the electron optical system, and the output phosphor screen. For example, the resolution capability of an XRII is determined by the product of the modulation transfer functions (MTF's) of its components and the brightness of the visible image at a given x-ray flux, and operating voltage is determined by the conversion efficiencies of the input and output phosphor screens and the photocathode.

In XRII tubes the area of the light image is about one-hundredth that of the incident x-ray pattern in order that the image be transferred to a suitable receptor (eye, video pickup, cine film, etc) via optical lenses. Because of the reduced size of the optical image, the output screen must be capable of high resolution.

Various techniques have appeared in the literature for the preparation of output phosphor screens, each claiming to produce higher quality screens than those made by other methods.[1] In particular, claims have been made for the production of dense, fine-grained phosphor screens by electrophoresis having superior resolution, greater smoothness, and more uniform thickness and coverage when compared with screens made by the more common method of centrifugal or gravity settling of a phosphor (2-5). However, we could find in the same literature very little quantitative data relating screen density, MTF, and spatial noise (arising from screen graininess and thickness irregularities) to screen weight, electron accelerating potential, and methods of screen deposition. We describe in this paper our work on output phosphor screens in which we measured the density, MTF, and spatial noise of output screens of various weights per unit area, prepared by centrifugal settling and by electrophoresis as described by Varma and Ghosh (2).

Preparation of Screens

Centrifugal settling.—The screens were made using a fine-grained P-20 phosphor of 2.2μ median particle diameter.[2] A suitable weight of phosphor was suspended in 200 ml of a dilute aqueous solution of sodium bicarbonate and dispersed ultrasonically. It was then poured into a settling tank, shown in Fig. 2. During the settling, larger particles and agglomerates were

[2] Phosphor obtained from the General Electric Company, Chemical Products, Cleveland, Ohio.

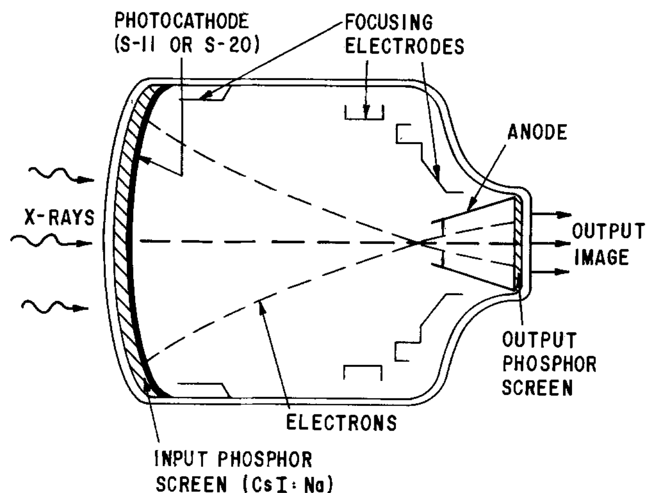

Fig. 1. X-ray image intensifier

Key words: spatial noise, resolution, modulation transfer, phosphors.

[1] For a description of the various methods, see Ref. (1).

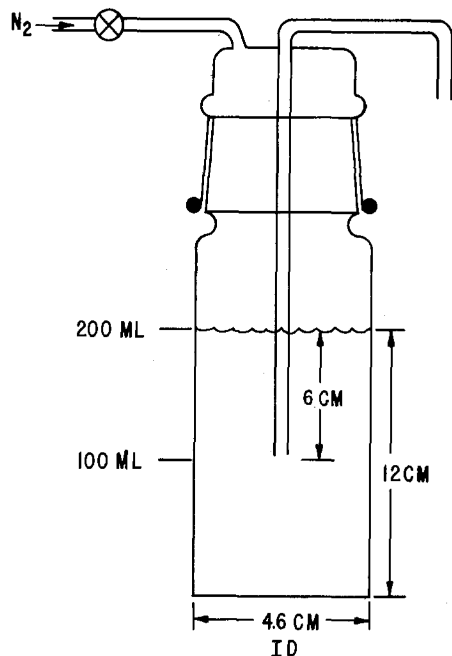

Fig. 2. Settling tank used in preparing phosphor suspensions for centrifugal deposition of screens.

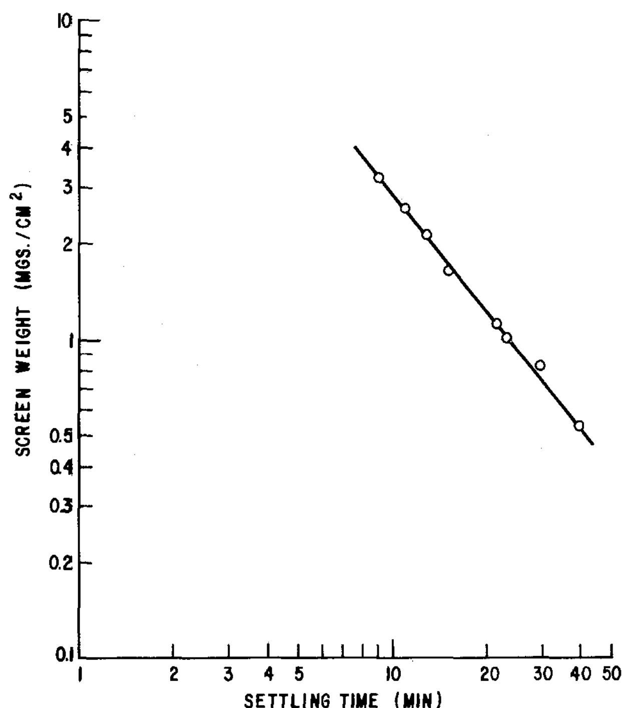

Fig. 3. Screen weight per unit area plotted as a function of settling time of phosphor suspension.

removed from the suspension. The final screen weight was determined by the settling time as indicated in Fig. 3. The top 100 ml were withdrawn after the required time, the potassium silicate binder added, and the suspension poured into two stainless steel cups containing the glass substrates. The phosphor was deposited by centrifuging for 15 min at 1000 rpm.

Electrophoretic deposition.—The method described by McGee *et al* (4) was used with the same P-20 phosphor. The system is shown in Fig. 4. The screen weight could be controlled by the time during which the potential was applied. Electrophoretic screens were found to be highly adherent, contrary to the statement made by Diakides (6). The good adherence is due to the increase in pH in the vicinity of the cathode and the consequent deposition of lanthanum and aluminum hydroxides at the cathode along with the

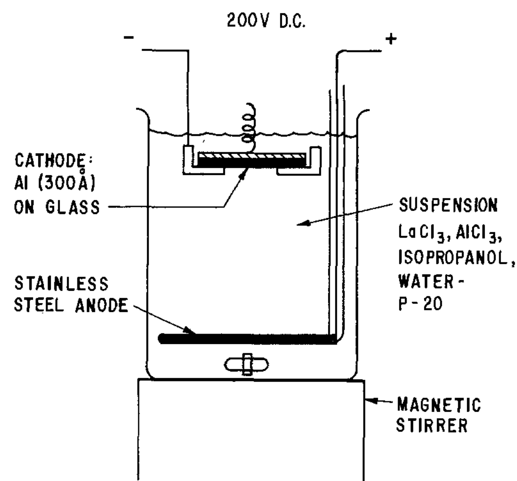

Fig. 4. Electrophoretic deposition system

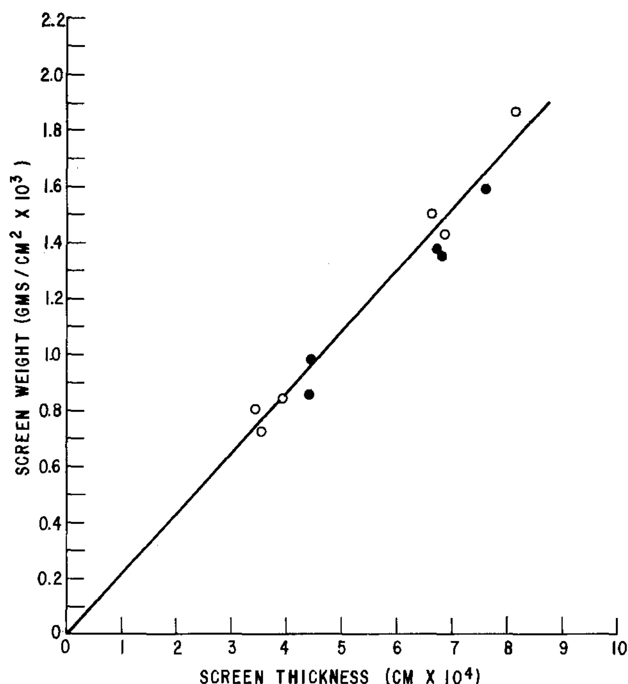

Fig. 5. Screen weight plotted against mean screen thickness. The slope of the line gives the screen density in g/cm^3. ○ Centrifugally deposited screens, ● electrophoretically deposited screens.

electrophoretically deposited phosphor. These hydroxides apparently act as cementing agents for the phosphor particle.[3] We did note, however, that there were pinholes in the phosphor screen which could be traced to pinholes in the evaporated aluminum layer.

Measurements and Results

Screen density.—The screen weight per unit area was determined by weighing. The screens were then covered with about 1000Å of Al and the mean thickness determined using a Sloan Dektak surface profilimeter. The thick Al coating prevented damage to the phosphor surface by the profilimeter probe. The results are given in Fig. 5. There appears to be no significant difference in density between our centrifugally deposited screens and those prepared by electrophoresis. The least squares fit to the data points yields a screen density of 2.17 g/cm^3, which is one-half the density of the P-20 phosphor crystals. This value of 50% in packing density is typical of phosphor screens.

Modulation transfer function.—Spatial resolution of imaging systems is usually described by the modulation transfer function. This function gives the relative

[3] See also Ref. (4) for a similar effect with magnesium salts.

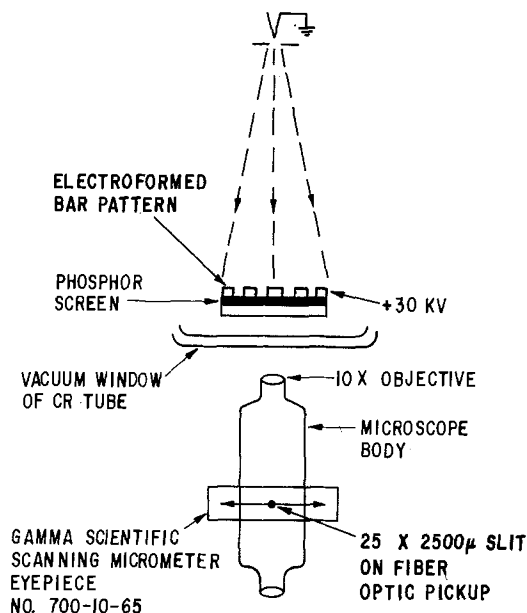

Fig. 6. Experimental arrangement used for measuring MTF

frequency response of the system to a sinusoidal spatially modulated input pattern. The limiting resolution of a system is commonly taken to occur at an MTF value of 0.05. The ideal output screen should have a high MTF value at a spatial frequency corresponding to the resolution of the XRII tube. Since this is typically near four line-pairs per millimeter at the input plane of the system, the 10-fold reduction in image diameter at the output phosphor required that we measure MTF at spatial frequencies to at least 40 line-pairs per millimeter (lp/mm).

The method used for the MTF measurements under cathode-ray excitation is illustrated in Fig. 6. An electroformed square wave nickel bar pattern was placed to within 25 μm of the phosphor surface.[4] The bar pattern consisted of seven line-pairs (*i.e.*, bar and space) each at spatial frequencies of 10, 20, and 40 lp/mm. In actual fact, what we label MTF in this paper is determined from the square wave response. The sine wave response would yield somewhat lower values but our data do not extend to high frequencies so as to permit the conversion. For purposes of comparison between screens the square wave response suffices. The emitted light from the phosphor was detected by scanning with a 25 μm wide slit on a fiber optic pickup located in the image plane of a 10-power objective.[5] A typical emitted light pattern as recorded on an X-Y recorder is shown in Fig. 7.[6] The MTF at any of the three frequencies was calculated from

$$\mathrm{MTF}_{(\text{output screen})} = \frac{1}{\mathrm{MTF}_{(\text{optical system})}} \times \frac{(S_{\max} - S_{\min})}{(S_{\max} + S_{\min})}$$

where $S_{\max}$ and $S_{\min}$ are the average of the five central maximum and minimum signals. The MTF of the optical system was determined by putting a piece of opal glass illuminated by a tungsten lamp in contact with the back side of the bar pattern. The microscope was then focused on the bar pattern and the square wave response recorded as above. The MTF of the optical system was found to be 0.899, 0.895, and 0.837 at

[4] To avoid charging under electron excitation the phosphors were coated in the standard manner with a thin nitrocellulose film and then with 800Å of Al. The organic film was then removed by baking in air at 350°C.

[5] The scanning microscope eyepiece was a Gamma Scientific Model No. 700-10-65 which has a 25 × 2500 μm slit. It was used with a Gamma Scientific Photometric Microscope System which consisted of a photomultiplier and photometer. The output signal was recorded on an X-Y recorder.

[6] The spacing variation particularly obvious at 10 lp/mm is not due to the bar pattern but arises from the nonlinearity of the scanning eyepiece output voltage with sweep distance. The variation is of no consequence as far as MTF measurements are concerned.

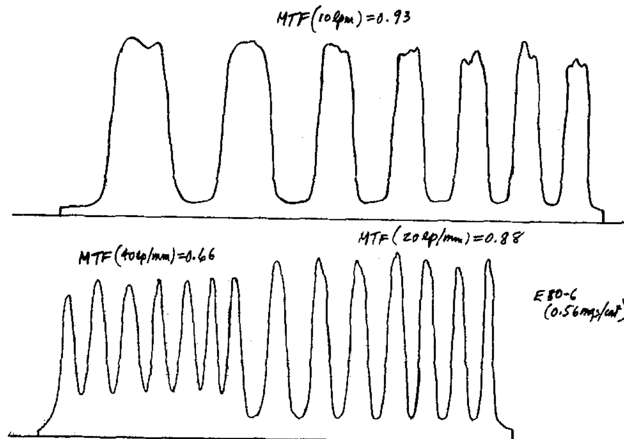

Fig. 7. Recorder trace of emitted light pattern in MTF measurement. Centrifugally deposited screen (0.56 mg/cm²); 30 kV.

the three frequencies. The results as obtained with a number of screens are shown in Fig. 8. For the range of screen weights investigated, the MTF decreases linearly with screen weight. Again we found no difference between the electrophoretic and settled screens.

The accelerating voltage dependence of the MTF is illustrated in Fig. 9. At lower voltages the MTF improves somewhat for thinner screens. The effect may be due to the decreasing range of the scattered electrons with decreasing electron energy. For the thick

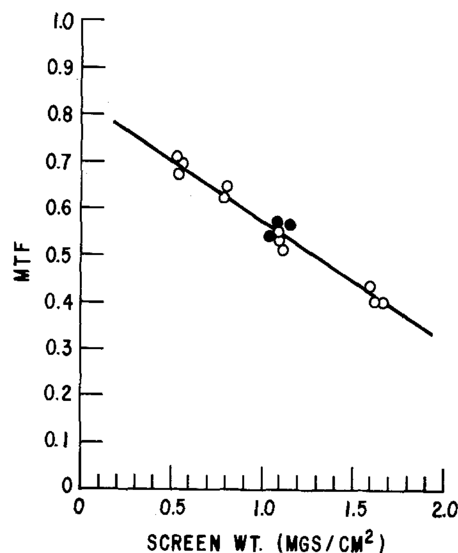

Fig. 8. MTF (at 40 lp/mm) plotted against screen weight. Accelerating potential 30 kV. ○ Centrifugally deposited screens, ● electrophoretically deposited screens.

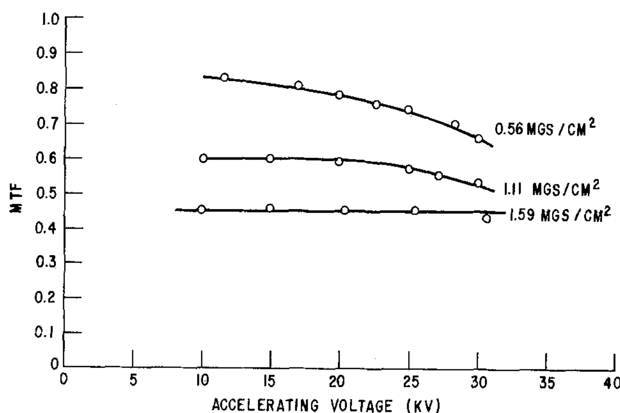

Fig. 9. Accelerating voltage dependence of MTF at 40 lp/mm. Centrifugally deposited screens.

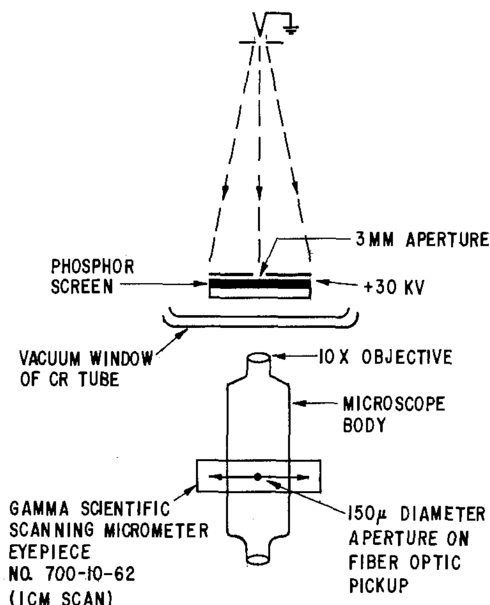

Fig. 10. Experimental arrangement for measuring spatial noise

screens no such dependence is seen since the low MTF value is determined primarily by light-scattering effects.

Spatial noise.—Spatial noise in the light image arises from the granular nature of the screen and from irregularities in thickness of screens so that electron penetration can take place at the thin spots. Presumably the "smoother" electrophoretic screens reported in the literature would have less spatial noise. The measurements were carried out as indicated in Fig. 10. The equipment was similar to that used in the MTF measurements. The bar pattern was replaced by a 3 mm aperture and the slit on the fiber optic pickup replaced by a 150μ diameter hole.[7] The Al-coated output screens were flooded by electrons and we scanned four separate 0.8 mm long sections of each screen. The 150μ aperture located at the image plane of a 10× objective corresponds to 67 lp/mm at the output screen. A typical trace of the emitted light is shown in Fig. 11. The ratio of the rms to the d-c value of the emitted light was taken as a measure of the spatial noise of a screen. The illumination of the screen by the electron beam was not perfectly uniform over the measured surface. As seen in Fig. 11 the light level is generally lower on the right than on the left and there is some bowing of the curves in the middle. It was, therefore, necessary to perform a Fourier analysis of the emitted waveforms in order to remove the very low spatial frequency components of the emitted light before determining the rms/d-c ratio.

Each trace as shown in Fig. 11 was sampled and digitized at 160 points. The result was attenuated by a half-sine wave over the initial and final 16 points so that the end points were brought smoothly to zero. This is necessary in order to reduce spurious high frequencies introduced when periodic boundary conditions are brought about by the discrete Fourier transform. The number of data points was increased to 256 by adding zeros, in order that a fast Fourier transform program could be utilized. After transformation, the spectrum was filtered by a sharp-cut filter to remove frequencies corresponding to less than about four full waves across the scans shown in Fig. 11. The spectrum was then retransformed, so that the filtered waveform could be compared to the original. When laid one over the other, the only difference visible to the eye was the removal of the base line tilt and curvature and the end attenuation referred to above. The rms noise value was

[7] Gamma Scientific scanning microscope eyepiece, Model No. 700-10-62. The output voltage of this eyepiece was linear with sweep distance.

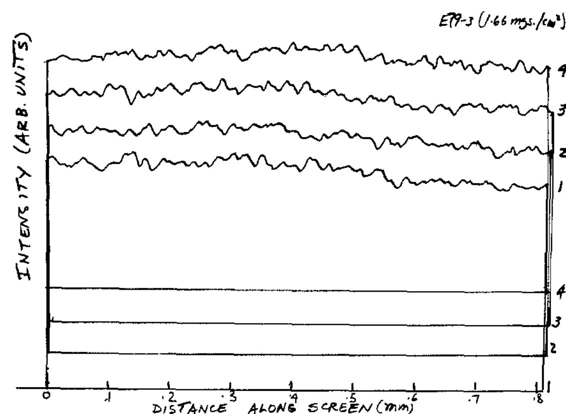

Fig. 11. Recorder trace of emitted light pattern in noise measurement. Centrifugally deposited screen (1.66 mg/cm^2); 30 kV.

computed from the area under a plot of the square of the filtered Fourier spectrum (Wiener spectrum). The results of four independent traces were measured and averaged for each observation point.

The results of our spatial noise measurements at 30 kV are given in Fig. 12. The spatial noise is seen to decrease linearly with increasing screen weight up to about 1.2 mg/cm^2. At 1.6 mg/cm^2 the spatial noise was not much lower. The reason for the knee in the curve is seen from the data on the dependence of emission intensity with accelerating voltage, as shown in Fig. 13. Screens with thicknesses of 1.6 mg/cm^2 were sufficiently thick so that electron penetration did not occur whereas thinner screens exhibited such penetration below 30 kV. Thus the noise in thin screens appears to arise primarily from electron penetration due to local variations in screen thickness. For thicker screens the spatial noise arises from light-scattering effects due to the granular structure of the screen. We also note that there is no significant difference between settled and electrophoretic screens. It appears that electrophoretic screens are not "smoother" than settled screens.

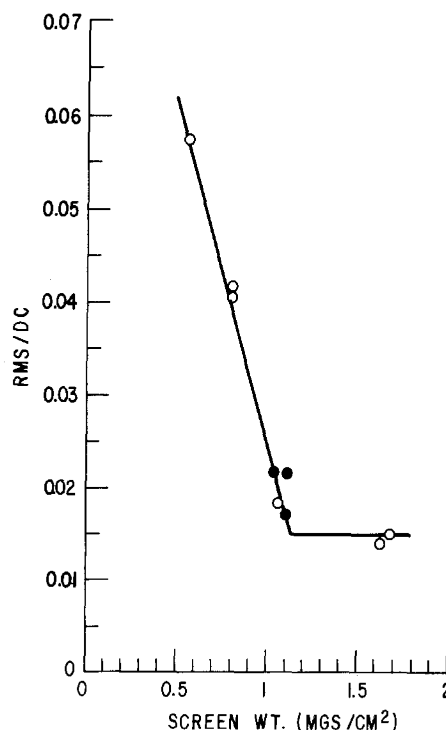

Fig. 12. RMS/D-C values of spatial noise plotted against screen weight. Accelerating potential 30 kV. ○ Centrifugally deposited screens, ● electrophoretically deposited screens.

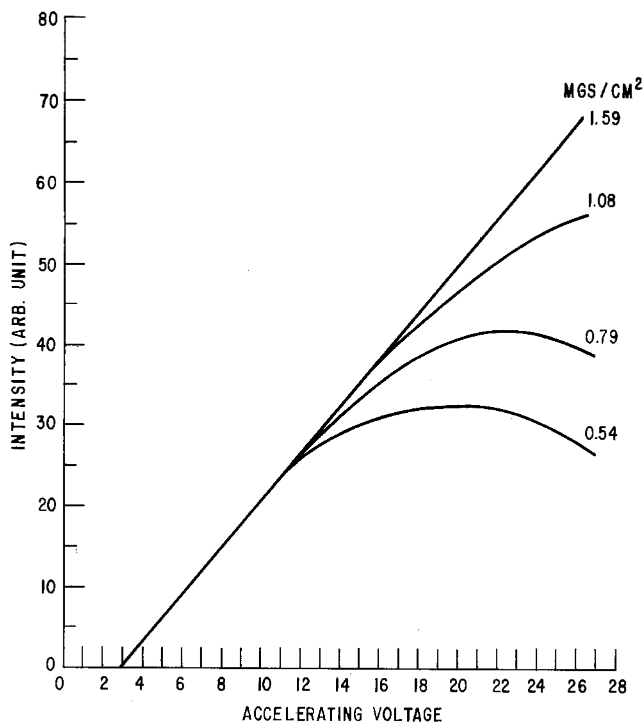

Fig. 13. Light emission plotted as a function of accelerating potential for various screen weights. Centrifugally deposited phosphors.

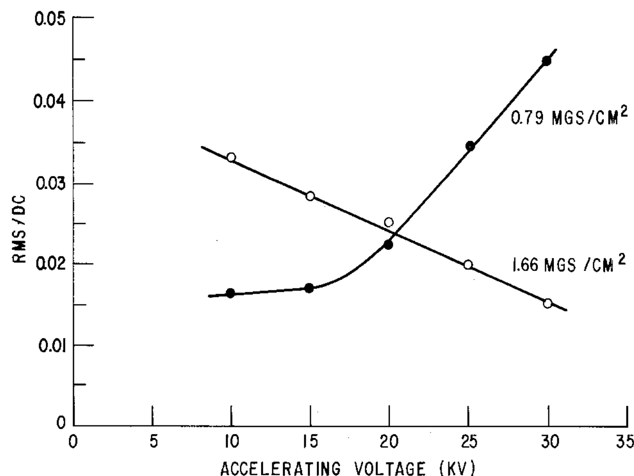

Fig. 14. Accelerating voltage dependence of spatial noise for two different centrifugally deposited screens.

The voltage dependence of spatial noise is shown in Fig. 14 for a thick and a thin screen. With decreasing electron energy the noise of the thin screen decreases since there are fewer thin regions available for electron penetration. At 10 kV the spatial noise of the thin screen is about as low as that of the thick screen at 30 kV. For the thick screen, however, we see that the noise increases with decreasing electron energy. We do not understand this result but it must be related to complex light-scattering effects arising from the fact that electron excitation occurs in thinner sections of the screen at low accelerating potentials.

Summary

Electrophoretically deposited screens appear to have the same density, MTF, and spatial noise as carefully prepared centrifugally deposited screens. Since electrophoretic deposition presents certain difficulties with regard to pinholes, there seems to be no advantage in this method of deposition.

P-20 screens of about 1.1 mg/cm² have high gain, low noise, and MTF values near 0.55 at 40 lp/mm. Higher MTF values can be achieved with thinner screens if the decreased brightness and increased spatial noise do not lead to objectionable image quality.

Ce^{3+} Luminescence in Hexagonal Aluminates Containing Large Divalent or Trivalent Cations

A. L. N. Stevels

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

By analogy with earlier studies on Eu^{2+} phosphors the luminescence of the Ce^{3+}-doped hexagonal aluminates, containing large divalent or trivalent cations, was also studied in relation to the crystal structure of the host lattices. The u.v. band ascribed to the luminescence of Ce^{3+} ions is found at a relatively short wavelength in the magnetoplumbites Ca-, Sr-, and CaMg aluminate: Ce and at a relatively long wavelength in the β-aluminas Ba- and BaMg aluminate. The distorted magnetoplumbites which include La- and LaMg aluminate and Ce- and CeMg aluminates themselves occupy an intermediate position in between the above-mentioned groups. The existence of various types of host lattices is also reflected in the shape and position of the excitation spectra of the Ce^{3+} luminescence. Differences in bond strength between Ce^{3+} ions and its surrounding oxygen ions, however, complicate the discussion of the position of the excited 5d levels of the Ce^{3+} ion. Apart from the u.v. band, a blue luminescence band was found in several Ce-activated aluminates. This band occurs in phosphors where oxygen ions are thought to have partially replaced the large cations of the host lattice and is ascribed to Ce-O associates. Next to direct excitation of these centers, the u.v.-emitting Ce^{3+} ions transfer part of their energy of the associates. If Mg^{2+} ions are present in the lattice, the oxygen ions at large cation sites seem to be "screened" and no blue luminescence is found. The quantum efficiency of most Ce-activated aluminate phosphors is 50-70%. Due to ineffective mutual energy transfer between u.v. emitting Ce^{3+} ions and between Ce-O associates no concentration quenching occurs in the systems considered. For the same reason the influence of the preparation method on the luminescence properties is generally less drastic than that of the corresponding Eu^{2+} phosphors.

The hexagonal aluminates can be divided into three groups with different, but closely related, crystal structures (1). The compounds $MeAl_{12}O_{19}$ (Me = Ca, Sr, Eu) have the magnetoplumbite-type structure (Fig. 1A). To this group also belong Mg-substituted Ca aluminates. Phases with the β-alumina structure (Fig. 1B) include $MeMgAl_{10}O_{17}$ (Me = Sr, Ba, Eu) types and also Ba aluminate itself.

$LaMgA_{11}O_{19}$ and $CeMgAl_{11}O_{19}$ belong to the group of distorted magnetoplumbites. The essential difference from magnetoplumbites is that in the distorted type part of the La(Ce) ions are thought to be replaced by oxygen ions (2). We designate such ions as O_{Me}. In β-aluminas the presence of O_{Me} has been established by an x-ray diffraction study on single crystals (1). Up to now we were not successful in obtaining single crystals from distorted magnetoplumbite-type materials. However, their nonstoichiometry and the occurrence of red Mn luminescence (2) strongly suggest the presence of O_{Me}. In La(Ce) aluminate itself 10-15% of the trivalent ions seems to be replaced by oxygen ions; in Mg-containing phases the percentage O_{Me} is between 5 and 10. As is shown in Fig. 1C the positioning of oxygen ions at La(Ce) sites would also involve a local rearrangement of Al^{3+} ions.

The Eu^{2+} luminescence in hexagonal aluminates containing large di- or trivalent cations has been studied extensively (1-7). Since the Ce^{3+} luminescence in these lattices has many aspects similar to the Eu^{2+} case, we give here a short survey of the properties of Eu^{2+} phosphors as far as these are relevant for the discussion of the Ce^{3+} luminescence.

In magnetoplumbite host lattices the Eu^{2+} luminescence is at a relatively short wavelength, that is in the blue and near u.v. In β-aluminas we find this band at a relatively long wavelength, namely in the blue or blue-green. The La(Mg) aluminates doped with Eu^{2+} take up an intermediate position in this respect. The existence of various types of host lattice is also reflected in the shape and the position of the excitation spectra of the Eu^{2+} luminescence (1). The quantum efficiency of the Eu^{2+} phosphors was found in most cases to be high. However, in magnetoplumbites the luminescence is quenched by substitution of small amounts of Mg^{2+} for Al^{3+} ions (6). Most probably oxygen vacancies are involved in the quenching processes. In distorted magnetoplumbites and β-aluminas the replacement of Al^{3+} by Mg^{2+} rather increases than decreases the efficiency of the phosphor (2, 7).

It was found that in β-aluminas the oxygen ions occurring at large cation sites can form associates with Eu ions, resulting in green-emitting centers. This green luminescence is strong in β-aluminas containing no Mg, that is in Ba aluminates (7). It can be argued that Mg^{2+} ions screen the Eu and O_{Me} ions from each other and thus prevent the formation of green-emitting centers.

Let us now consider the organization of the present paper on the Ce^{3+}-luminescence. First, the Ce^{3+} luminescence in the magnetoplumbites Ca-CaMg and Sr-aluminates is discussed. This group of phosphors shows features similar to the Eu^{2+} luminescence in these systems. To some extent this also holds for Ce^{3+} luminescence in β-aluminas. In the last named phases the solubility of Ce is only limited due to a preference of Ce^{3+} ions for magnetoplumbite surroundings. This hampers detailed studies, especially of the luminescence of Ce-O_{Me} complexes.

A further subject is the luminescence of the $(La,Ce)_{0.86}Al_{11.90}O_{19.14}$ series. These show a basic difference from the comparable La, Eu system since the u.v.-emitting Ce^{3+} ions can transfer effectively their excitation energy to the Ce-O_{Me} associates, whereas such a transfer from the "blue" Eu^{2+} ion to the "green" Eu-O_{Me} complex has only a low probability.

In the Ce aluminate/CeMg aluminate system it is demonstrated how the introduction of Mg^{2+} ions reduces the intensity of the blue band ascribed to the Ce-O_{Me} associates.

Key words: hexagonal aluminates, Ce^{3+} luminescence, energy transfer.

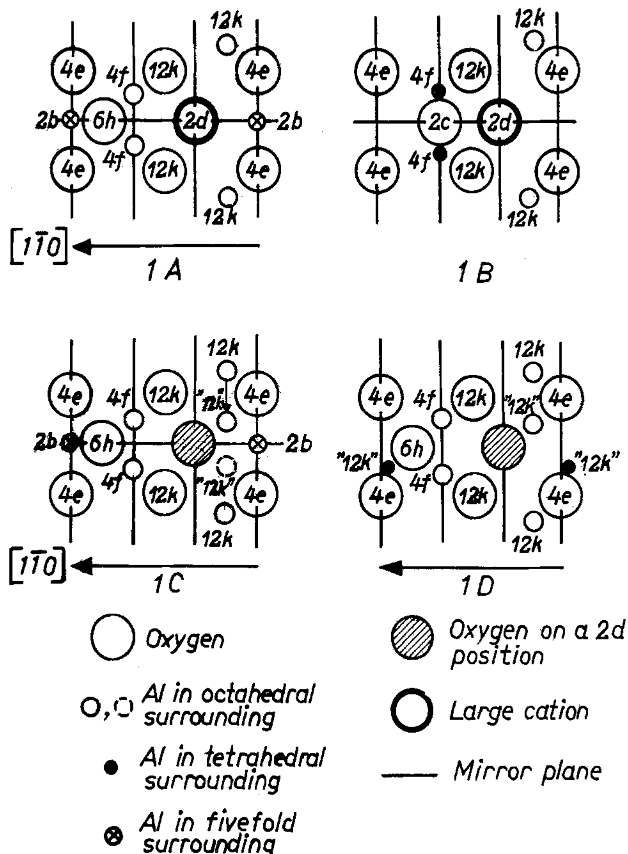

Fig. 1. Part of the unit cells of hexagonal aluminates. Only atoms in the [1$\bar{1}$0] plane have been drawn. A, the magnetoplumbite configuration; B, the β-alumina-type configuration; C, the configuration around oxygen ions replacing the large cation in the A type. The arrow indicates the shift of Al ions to one of the octahedral "12k" sites near the oxygen ion in the 2d position. The dashed "12k" site is available for excess Al^{3+} ions (see text); D, the configuration around oxygen ions replacing the large cation in magnetoplumbites (A type) containing small divalent cations (Mg^{2+}, Mn^{2+}). For the Al ions originating from the 2b site only half of octahedral "12k" sites near the oxygen ion are available. The divalent ions are located at tetrahedral "12k" sites.

The excitation spectra of the luminescence of Ce^{3+} ions are discussed in this paper. They show three (and sometimes more) bands between 220 and 320 nm. In contradistinction to the corresponding Eu^{2+} phosphors, the position of the center of gravity of the excited 5d levels is dependent on the host lattice. This can be correlated with the Stokes shift between the lowest excitation band and the emission band.

Our last subject is the discussion of the quantum efficiencies of Ce^{3+}-activated aluminates. Recent estimates (8) indicate that the energy transfer between Ce^{3+} ions is ineffective; the absence of concentration quenching in the systems considered confirms this opinion. The ineffective energy transfer in the Ce^{3+}-activated phosphors has the effect that in such materials the quenching of the luminescence by unintentionally introduced defects is generally less drastic than in the corresponding Eu^{2+} phosphors in which the Eu^{2+}-Eu^{2+} transfer efficiency was observed to be high.

Experimental

The samples were prepared by standard ceramic techniques (firing temperatures between 1200° and 1600°) from highly reactive γ-Al_2O_3, $MeCO_3$ (Me = Ca,Sr,Ba), or La_2O_3. The Ce ions were introduced in the form of CeO_2; by heating in N_2 containing a few percent H_2 these are reduced to their trivalent state. X-ray diffraction showed that only samples heated above 1400°-1450°C were free of $CeAlO_3$. The luminescence measurements were carried out as described in Ref. (9).

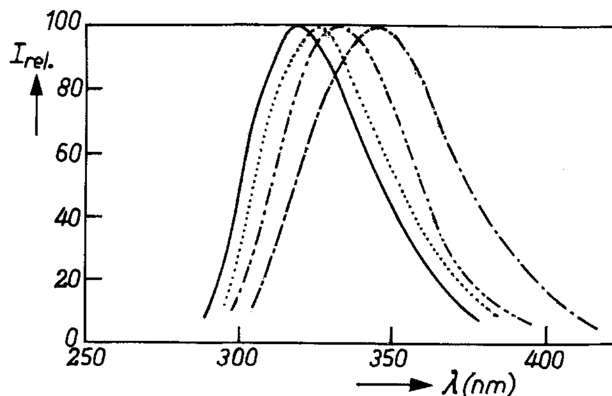

Fig. 2. Luminescence spectrum at 300°K (under 250-270 nm excitation) of the magnetoplumbites $SrAl_{12}O_{19}$: $0.14Ce^{3+}$ (———); $CaAl_{12}O_{19}$:$0.14Ce^{3+}$ (.....); $CaMgAl_{11.33}O_{19}$:$0.14Ce^{3+}$ (··—··—··—); and $La_{0.92}MgAl_{11.13}O_{19.08}$:$0.14 Ce^{3+}$ (—·—·—·).

Results and Discussion

Luminescence spectra.—Ce^{3+}-doped magnetoplumbites.—In Fig. 2 we show the luminescence spectra at 300°K of Ce^{3+}-doped magnetoplumbites and of the distorted magnetoplumbite $LaMgAl_{11}O_{19}$:Ce. The wavelengths of the maxima of the band are summarized in Table I where the maxima of the corresponding Eu^{2+} phosphors, see Ref. (1), have also been given. The curves in Fig. 2 and the data in Table I refer to samples containing 0.14 Ce. The well-known "two-band" character of the Ce band, due to the splitting of the ground state, is not clearly observed at these activator contents. In samples containing 0.02 Ce the two components of the luminescence band are better resolved.

On inspection of Table I it is seen that a striking analogy exists between Ce^{3+} and Eu^{2+}-activated aluminate phosphors. In the u.v.-emitting Ce^{3+} phosphors, $SrAl_{12}O_{19}$:Ce peaks at the shortest wavelength, 320 nm. Similarly $SrAl_{12}O_{19}$:Eu is the nearest u.v. one of the blue-emitting Eu^{2+} phosphors. Its maximum is at 395 nm. The order of peak wavelengths in the other Ce^{3+}-activated phosphors is the same as in the Eu^{2+}-activated materials. For sake of clarity, the spectrum of La aluminate has been omitted in Fig. 2. As is described later, this phosphor also has a strong luminescence band in the blue. However this band is not ascribed to the luminescence of "normal" Ce^{3+} ions but to the luminescence of Ce ion at a very short distance from oxygen ions. In $SrAl_{12}O_{19}$:Ce this blue band was observed to be present only in samples prepared with excess Al_2O_3 (see Fig. 3). If we consider, for instance, the phosphor $Sr_{0.85}Ce_{0.15}Al_{11.95}O_{19}$, O_{Sr} ions can be thought to be formed in the following

Table I. Maximum of the luminescence band, λ_{max} and quantum efficiency q.e. of aluminate:Ce^{3+} phosphors at 300°K. Within brackets the data are given for the corresponding phosphors activated with 2% Eu^{2+}

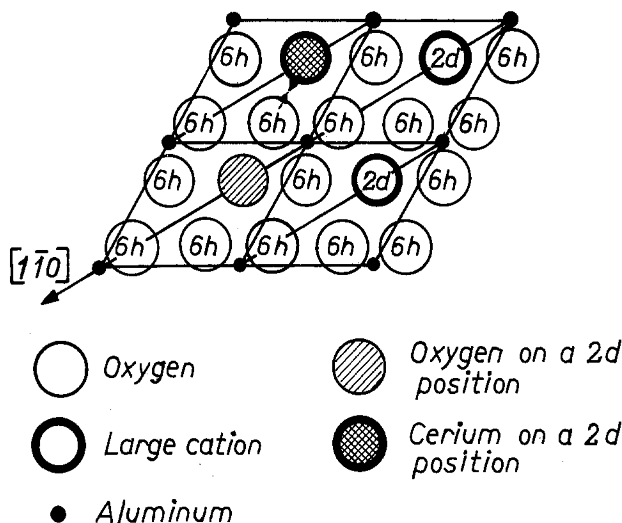

Fig. 4. xy plane at $z = \frac{1}{4}$ of the magnetoplumbite structure. Four unit cells are shown. In the lower left-hand cell an oxygen ion has replaced the large cation at the 2d site. The arrow indicates the interaction of an oxygen atom at a 6h site with an activator ion.

way

$$[Sr_{0.85}Ce_{0.15}]Al_{11.95}O_{19} + 8xAl_2O_3 \approx \left(1 + \frac{4x}{3}\right)$$

$$[Sr_{(0.85-6x/7)}Ce_{(0.15-x/7)}O_x]Al_{(11.95+4x/3)}O_{19} \quad [1]$$

(approximate formulas are given).

It was found that up to $x \approx 0.15$ the percentage of blue emission increases with x (that is the number of oxygen ions at Sr sites) so that it is most probable that the extra luminescence band is due to strong interaction of O_{Sr} with Ce ions.

As is seen in Fig. 4, this interaction is thought to proceed in an "indirect" way in the case of magnetoplumbites like Sr-aluminate. In fact, the presence of oxygen ions at 2d sites is supposed to induce a shift of one of its nearby oxygen (6h) ions toward a Ce^{3+} ion[1] in a neighboring unit cell, see also Fig. 1A.

Returning now to Eq. [1] and Fig. 3 we see that above $x \approx 0.15$ the relative intensity of the blue band decreases again, see Fig. 3, dash-dot line. In order to explain this observation, we note that in order to stabilize O-Ce complexes in "ideal" magnetoplumbites like $SrAl_{12}O_{19}$, Al ions at octahedral 12k sites in the crystal structure are supposed to shift to octahedral "12k" sites near O_{Sr}, see arrow in Fig. 1C and also Ref. (7). The Al^{3+} ions in excess of the "ideal" number of 12 per unit cell are most probably located at the 12k positions which are emptied by such a shift. With help of formula [1] it can be seen that above $x \approx 0.15$ the number of excess Al^{3+} ions ($=4x/3 - 0.05$) exceeds the number of shifted octahedral Al^{3+} ions ($=x$). This has the result that part of these excess ions will be located at "12k" sites as well, for instance, at the one indicated by the dashed circle in Fig. 1C. Apparently the presence of two Al^{3+} ions near O_{Me} screens the interaction with Ce ions so that a lower number of O-Ce associates results.

In Ce-activated Ca and CaMg aluminates no blue luminescence was observed in samples with excess Al_2O_3. This corroborates our earlier observation that in these compounds no O_{Ca} can be formed (2), or that the O_{Ca} formed are effectively screened from activator ions.

β-Alumina-type:Ce phosphors.—Figure 5 shows the luminescence spectra at 300°K of the Ce-doped β-aluminas $BaAl_{10\,2/3}O_{17}$, $BaMgAl_{11}O_{17}$, and $KAl_{11}O_{17}$. In all cases, very broad bands around 350 nm were found. The "two-band" character due to splitting of the Ce^{3+} ground state is clearly recognized. From Table I it is concluded that the maxima of the bands are situated at longer wavelengths than for magnetoplumbite:Ce phosphors. On comparing the emission maxima with those of Eu^{2+} phosphors we see, as in the magnetoplumbites, a parallel change of the peak positions on going from one host lattice to another.

The solubility of Ce^{3+} in β-aluminas was found to be only limited. Apparently Ce^{3+} ions prefer to enter magnetoplumbite surroundings rather than a β-alumina one. This is rather obvious in view of the fact that both Ce and CeMg aluminate have (distorted) magnetoplumbite crystal structures. The limited solubility especially refers to $SrMgAl_{10}O_{17}$-based phosphors, where we did not succeed in preparing single-phase samples. With x-ray diffraction it was established that $SrMgAl_{10}O_{17}$:Ce compositions decompose into a Ce-rich Sr aluminate and $SrMgAl_{10}O_{17}$. It could not be established whether the additional short-wavelength bands occurring in many Ba and BaMg aluminates were due to separation of a Ce-containing magnetoplumbite phase or to the existence of Ce-containing local Al_2O_3-rich deviations of the over-all composition in the β-alumina phase itself, see also Ref. (6).

We tried also in vain to prepare homogeneous Ba-aluminate:Ce phosphors with a blue luminescence band due to O-Ce complexes. In the compositions for which in the Eu-analog a strong green luminescence is found due to O-Eu associates (7), only a weak blue luminescence of O-Ce complexes was observed. The last named samples turned out to lie outside the homogeneity range of the β-alumina:Ce phase. In the x-ray diagram of such materials a number of lines were found which could not be identified as one of the forms of Al_2O_3, or as $CeAlO_3$. Attempts to prepare a homogeneous sample of the unknown phase, possibly a Al_2O_3-rich Ba-Ce aluminate, were not successful.

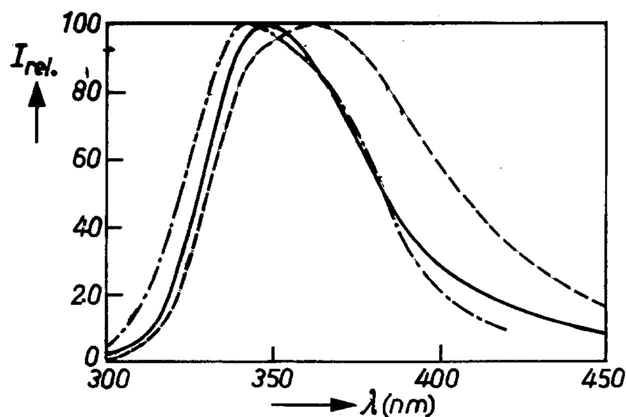

Fig. 5. Luminescence spectrum at 300°K (under 250-270 nm excitation) of $BaAl_{10\,2/3}O_{17}$:0.14Ce (———); $BaMgAl_{10}O_{17}$:0.14Ce (— — — —); and $KAl_{11}O_{17}$:0.14Ce (—·—·—).

[1] For simplicity reasons we call this "association;" the blue emitting centers are called O-Ce associates.

The La-aluminate/Ce-aluminate system.—It was reported before (1, 2) that the compounds La-aluminate and Ce-aluminate have a narrow homogeneity range. Homogeneous phases were obtained for the starting compositions $La_{0.86}Al_{11.90}O_{19.14}$ and $Ce_{0.86}Al_{11.90}O_{19.14}$ after firing at 1400°-1500°C. These formulas suggest that 14% of the large cation sites is occupied by oxygen ions. If these O_{Me} form associates with Ce ions, we expect to find two luminescence bands in $(La_{1-x}Ce_x)_{0.86}Al_{11.90}O_{19.14}$ phosphors, namely one due to the luminescence of single Ce^{3+} ions and one of the Ce-O associates.

In Fig. 6 a number of luminescence spectra at 300°K of phosphors of the (La,Ce)-aluminate series are shown (excitation 250-270 nm). Indeed two bands are observed, one having a maximum in the 330-350 nm region and the other with a maximum in the 410-430 nm region. With increasing Ce content x, the relative intensity of the longwave band increases. Since the quantum efficiency of the phosphors considered is 50-60% in the whole system, and the absorption of the 250-270 nm excitation energy is about 90% in all cases, it is concluded that the intensity of the blue band grows at the cost of the u.v. one. In Fig. 7 the percentage of quanta emitted in the blue has been plotted against the Ce content x. For x near 0 we see a percentage of the blue of about 16. If the O-Ce associates are formed in a random way, that is, if there is no preference of oxygen ions for association with La or Ce ions, the percentage of O-Ce associates is calculated, independent of the Ce content, to be equal to the figure observed in phosphors with low Ce content, namely $0.14/0.86 \times 100\% = 16\%$. In addition to the existence of a similar band in Al_2O_3-rich $SrAl_{12}O_{19}$: Ce, the agreement between the observed and the calculated amount of blue near $x = 0$ may be another piece of evidence for ascribing the blue luminescence band to the luminescence of O-Ce associates. Since the number of Al^{3+} ions per formula unit is lower than 12 it is concluded that as in $SrAl_{12}O_{19}$:Ce with $O_{Sr} < 0.15$ no Al^{3+} ions are present which would partially block Ce-O association.

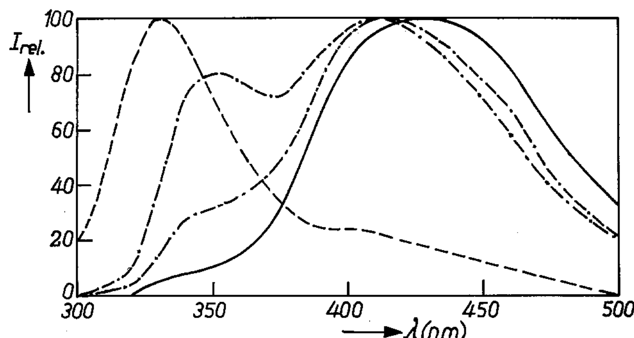

Fig. 6. Luminescence spectra at 300°K (under 250-270 nm excitation) in the $(La_{1-x}Ce_x)_{0.86}Al_{11.90}O_{19.14}$ system — — — —, $x = 0.02$; —·—·—, $x = 0.5$; — —·— —, $x = 0.14$; ———, $x = 1.0$.

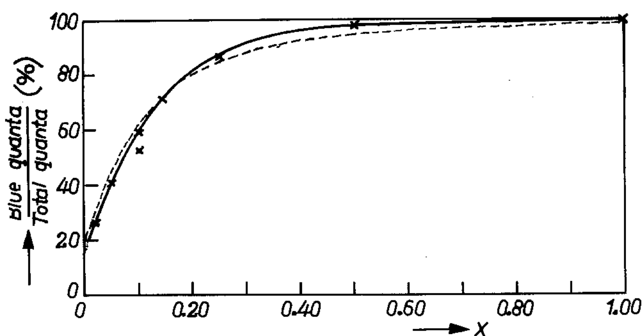

Fig. 7. Percentage of quanta emitted in the blue as a function of x in $(La_{1-x}Ce_x)_{0.86}Al_{11.90}O_{19.14}$ phosphors. The crosses represent measurements at 300°K, 250-270 nm excitation. The drawn line represents a calculated curve according to the Perrin model (12), $y_o = 0.13$, the dashed line that to the Förster model (13), $y_o = 0.20$, $R_c = 25Å$.

Let us now discuss why the relative intensity of the blue band increases strongly with the Ce content in $(La_{1-x}Ce_x)_{0.86}Al_{11.90}O_{19.14}$. Figure 8 shows that the excitation spectrum of the blue emission-drawn line, strongly overlaps the u.v. luminescence band, dashed line, of the "free" Ce^{3+} ions. The normalized overlap integral was estimated to be 0.6 eV^{-1}, which is considerably higher than for the overlap between excitation and emission spectra of free Ce^{3+} or Eu^{2+} ions (10).

If we assume that a dipole-dipole mechanism is operative we can write for the probability of energy transfer from free Ce^{3+} ions to Ce-O associates

$$P_{tr} = 3 \cdot 10^{12} \cdot \frac{P_{Ce}}{R^6 \tau_{Ce}} \cdot \frac{1}{E^4} \int f_{Ce}(E) \mathbf{F}_{Ce\text{-}O}(E) dE \quad [2]$$

where P_{Ce} = the oscillator strength of the $4f \rightarrow 5d$ transition in the Ce^{3+} ion; R = the distance between the free Ce^{3+} ion and the Ce-O associate (Å); τ_{Ce} = the decay time of the Ce^{3+} luminescence (sec); E = the energy transferred (eV); and $\int f_{Ce}(E)\mathbf{F}_{Ce\text{-}O}(E)dE$ = the normalized overlap integral. For $P_{Ce} = 0.01$ [a usual figure for this transition, (10)], $R = 5.6Å$ (the distance for nearest neighbors), 20 nsec for τ_{Ce} (11) and $E = 3.5$ eV, we find $P_{transfer}$ to be $2 \cdot 10^{11}$ sec^{-1} for nearest neighbors. This figure is about 4000 times higher than the radiative probability of the Ce ion $P_{rad,Ce}$ which is $\tau^{-1} = 5 \cdot 10^7$ sec^{-1}. We conclude that energy transfer between nearest neighbor Ce^{3+} and Ce-O associates will be very effective.

If the Ce^{3+} ions and the Ce-O associates are farther apart, the ratio $P_{transfer}$ drops with the sixth power of the distance R. It can be derived from Eq. [2] that at $R_c = 22Å$, $P_{transfer} \approx P_{rad}$. For comparison we note that for the effective Eu^{2+}-Eu^{2+} energy transfer in hexagonal aluminates R_c has a rather similar value, namely 18Å (1).

Now we will try to find a more quantitative description of the increase of the blue emission as a function of the Ce content x. Measurements of excitation spectra showed that the light output in the blue, on excitation at 330-380 nm, is essentially independent of the Ce content x, that is always about 45% of that on excitation in the 250-270 nm region. Since the efficiency is also independent of the energy transfer from Ce^{3+} ions to Ce-O associates—the quantum efficiency of the (u.v. + blue) luminescence is 50-60% in the whole system—we can apply models given by Perrin (12) and Förster (13) for sensitizer (the free Ce^{3+} ion)-activator (the Ce-O associates) systems where

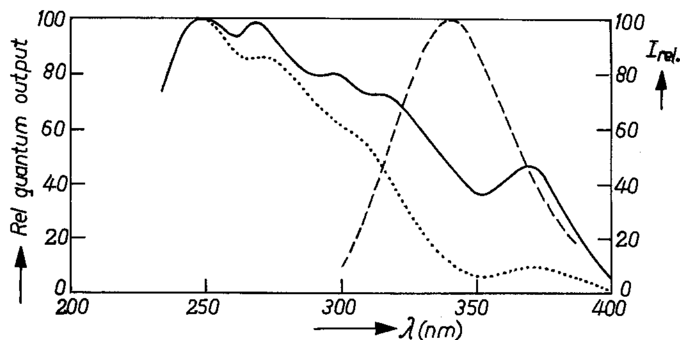

Fig. 8. Excitation spectra of the blue luminescence in $(La_{1-x}Ce_x)_{0.86}Al_{11.90}O_{19.14}$ phosphors (———); and of $Ce_{0.91}Mg_{0.25}Al_{11.65}O_{19.09}$ (. . . . . .). The dashed line represents the u.v. luminescence band in $(La_{0.98}Ce_{0.02})_{0.86}Al_{11.90}O_{19.14}$.

the sensitizer to sensitizer transfer is absent. As regards the last named point we note, see Ref. (8), that the probability of energy transfer between nearest neighbor Ce^{3+} ions in aluminate host lattices is very low, namely $\approx 4 \cdot 10^5$ sec^{-1}.

In the Perrin model (12) each sensitizer ion has an "active" sphere with radius R_o, in which energy transfer has an infinite rate and outside of which there is no energy transfer at all. Using the Perrin formula we can write for the percentage p of quanta emitted in the blue

$$p_{\text{blue}} = q + (100 - q)(1 - e^{-y/y_o}) \quad [3]$$

where q = the percentage of Ce ions associated with oxygen (= 16% in the La/Ce system); y = the effective Ce^{3+} content (in mole/m^3); y_o = the "critical" concentration. This parameter is related to R_o by $y_o = 3/(4\pi R_o^3)$. We note that R_o in the Perrin approach cannot be compared directly with critical distance R_c mentioned above.

The drawn curve in Fig. 7 has been calculated for $y_o = 0.13$. It is seen that with this value a very good agreement is found with the observed figures.

On using the same figure for y_o it is calculated that in Al_2O_3-rich $SrAl_{12}O_{19}$:Ce phosphors the maximum percentage of blue, found at a composition $Sr_{0.73}Ce_{0.13}Al_{12.15}$, would be 73%. A figure of 67% is observed (see Fig. 3), so that a satisfactory agreement exists between observed and calculated data.

The model of Förster (13) uses the fact that for dipole-dipole interaction P_{tr} is proportional to $1/R^6$. In our case his formula reads

$$p_{\text{blue}} = q + (100 - q)\left[\sqrt{\pi}\frac{y}{y_o}e^{(y/y_o)^2}(1 - \text{erf}\, y/y_o)\right] \quad [4]$$

where q and y are defined in the same way as in Eq. [3]. y_o is now related to the critical distance R_c by the (similar) expression $y_o = 3/(4\pi R_c^3)$. The dashed line in Fig. 7 shows that for a critical concentration y_o = 0.20 a reasonable agreement is obtained between observed and calculated figures of p_{blue}. The systematic discrepancies may indicate that y_o is slightly dependent on y. For $y > 0.20$, y_o would be <0.20 and vice versa. This is related to the fact that the Förster theory was derived for diluted and spherically symmetrical systems. In our case we deal with high activator contents which are concentrated in certain crystal planes. In view of these arguments a figure of 25Å for the critical distance R_c (estimated from y_o by formula 19 in Ref. (13), note that $y_o = 6\frac{1}{4}\,C_o$) is in reasonable agreement with the 22Å estimated for R_c with help of formula [3].

From the considerations given above we conclude that the simple Perrin model gives a good description of the observations. For the Förster approach several prerequisites are not fulfilled. However the agreement between calculated and observed figures is reasonably good. A better agreement is likely to be obtained if we calculate $P_{\text{tr to Ce-O}}/P_{\text{rad, Ce}}$ for discrete distances relevant in the aluminate lattice and apply the appropriate statistics.

The Ce-aluminate/CeMg-aluminate system.—In Eu^{2+}-activated β aluminas the oxygen ions at large cation sites were observed to be effectively screened from the activator by Mg^{2+} ions (2). In such a system no O-Eu associates were found to occur. In order to study such screening effects in Ce^{3+}-activated phosphors, the Ce-aluminate/CeMg-aluminate was chosen since it was found that the Ce-aluminate luminescence is almost completely blue, whereas CeMg aluminate shows a very strong u.v. emission band, see, for instance, Fig. 9. As is seen in Fig. 9, the compositions in between Ce- and CeMg aluminate, as those containing ½ Mg or ¼ Mg atom per formula unit, show both a blue and a u.v. luminescence band. Apart from changes

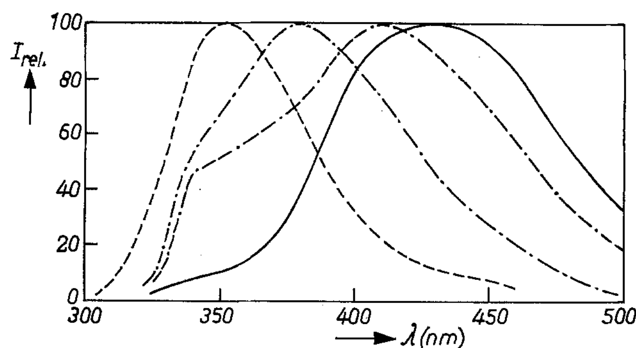

Fig. 9. Luminescence spectrum at 300°K (under 250-270 nm excitation) in the Ce/CeMg aluminate system. ———, $Ce_{0.86}Al_{11.90}O_{19.14}$; —·—·—, $Ce_{0.91}Mg_{0.25}Al_{11.65}O_{19.09}$; —·—·—, $Ce_{0.92}Mg_{0.5}Al_{11.47}O_{19.08}$; — — — —, $Ce_{0.92}MgAl_{11.13}O_{19.08}$.

in the position of the blue band we see that the amount of u.v. increases with increasing Mg content so that we conclude that O_{Ce} and Ce ions are screened from each other as in Eu^{2+}-phosphors.

Due to the fact that Mg^{2+} ions prefer to enter tetrahedral surroundings in the type of host lattice discussed here (15) it is assumed that the screening Mg^{2+} ions are located at tetrahedral "12k" positions as indicated in Fig. 1D. Three of such positions occur near one O_{Ce}; they can be considered to arise by shifting atoms in fivefold oxygen surrounding, position 2b in Fig. 1A, off the hexagonal axes which are indicated by drawn vertical lines

In order to discuss the screening effect of Mg^{2+} ions more quantitatively, we must first say a few words about the number of O_{Ce} as a function of the Mg content. The homogeneity of CeMg-aluminate was found experimentally to be narrow and to be around $Ce_{0.92}MgAl_{11.13}O_{19.08}$ in samples slowly cooled from 1500°C. For LaMg-aluminate a similar composition is found so that in both cases about 8.5% of the large cation sites is occupied by oxygen ions which is lower than in Ce- and La-aluminates where this percentage is 14%, see above. For the compositions in between Ce aluminate and for CeMg aluminate and corresponding La-compositions, the number of oxygen cations has not been established. However, it seems reasonable to assume that the number of $O_{Ce}(O_{La})$ decreases linearly with increasing Mg content, see drawn line in Fig. 10.

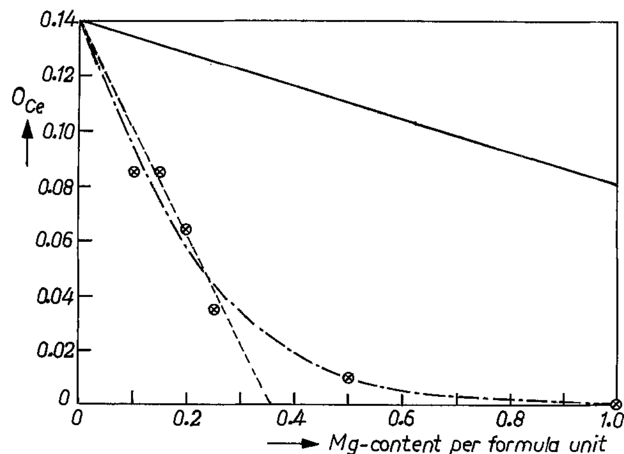

Fig. 10. Number of oxygen ions at Ce sites (O_{Ce}) in the CeMg-aluminate system. The drawn line represents the number of O_{Ce} assumed to be present. The crosses represent the number of O_{Ce} ions which are not screened by Mg^{2+} ions. This number was derived from luminescence spectra with the help of Eq. [3]. Through the crosses the dash-dot curve has been fitted. The dashed line represents the number of nonscreened atoms assuming that 3 Mg^{2+}-ions are needed to achieve complete screening of O_{Ce} from Ce.

If it is assumed that $3Mg^{2+}$ ions are needed completely to screen the O_{Ce} ions [see above and also Ref. (2)], the number of O ions which form complexes with Ce is represented by the dashed line in Fig. 10. The number of such ions derived with the help of formula [3] from the observed luminescence spectra, y_o, is taken to be 0.13, as given by the dash-dot line. It is seen that at very low Mg contents all Mg^{2+} ions seem indeed to be located near O_{Ce} in a ratio of 3:1. At higher Mg contents, Mg^{2+} ions also substitute on other sites of the lattice, giving rise to higher percentages of blue luminescence than expected from our considerations.

The number of ions involved in complex formation can also be estimated from excitation spectra in the 330-380 nm region. For the composition $Ce_{0.91}Mg_{0.25}Al_{11.65}O_{19.09}$ it is estimated that in this wavelength region the number of "active" O_{Ce} is about ¼ of that in $Ce_{0.86}Al_{11.90}O_{19.14}$, see dotted and drawn line in Fig. 8, so that q in formula [3] is equal to 4. Taking $y_o = 0.13$, it is then estimated that 85% of the emitted quanta would then be in the blue. The observed figure of 87% is in good agreement with the calculated one.

Excitation spectra.—In this section we restrict ourselves to the excitation spectra of the u.v. Ce luminescence in aluminates containing large di- or trivalent ions. The excitation spectra of the blue luminescence bands have essentially the same form and the same peak positions in the wavelength region below 300 nm, compare for instance Fig. 8 and 13, and are not discussed separately.

In Fig. 11-13 we show excitation spectra at 300°K of the maxima of the shortwave luminescence bands presented in Fig. 2, 5, 6, and 9. In all cases broad bands are seen which are rather superimposed. The D_{3h} local symmetry of the Ce^{3+} ions at the 2b sites, see Fig. 1A and 1B, leads us to expect that the excited 5d levels of Ce^{3+} are split into three (A′, E′, and E″) sublevels. Indeed three main bands can be recognized in the excitation spectra, although, especially in La-

and LaMg-aluminate: Ce and the β-aluminas: Ce, further splittings of these bands occur

In order to facilitate the discussion of the excitation spectra, a number of data are summarized in Table II. It is seen that in contradistinction to Eu^{2+}-doped aluminates (1), the center of gravity of the excited 5d levels of Ce^{3+} ions varies as a function of the aluminate host lattice between 36,800 and 41,300 cm^{-1}. Since the crystal field parameter Dq cannot be derived directly from energy level data; in the D_{3h} symmetry the energy difference between the highest and the lowest excited levels is used as a yardstick for the strength of the crystal field. It is seen in the second column of Table II that this field is the strongest in the β-aluminas, followed by the distorted magnetoplumbites containing Ce^{3+} or La^{3+} ions. Relatively weak fields are found in Ca, Sr, and CaMg-aluminate: Ce. In last-named phosphors a large Stokes shift between the lowest lying excitation band and the luminescence band is found. For CeMg aluminate and LaMg aluminate: Ce this shift is also large, whereas in β-aluminas and Ce aluminate or La aluminate: Ce much lower shifts are found.

In the corresponding Eu^{2+} phosphors the β-aluminas were also found to have a stronger crystal field and a lower Stokes shift than the magnetoplumbites (1). It was concluded that this is due to the fact that in the last-named lattice the bond strength [the rigidity of the lattice, see Ref. (16) and (17)] is higher and that the activator ion is very close to one of the surrounding oxygen ions. Since Ce^{3+} has a formal positive charge in aluminates containing large divalent ions a more detailed comparison with Eu^{2+} ions is hardly feasible. This also holds for the distorted magnetoplumbites where the Eu^{2+} ions have a formal negative charge.

As regards a qualitative explanation of the data in Table II the position of the center of gravity of the 5d levels seems to play a key role. It is seen that in Ce aluminate it is situated at the lowest energy, so that

Table II. Some data derived from the excitation spectra of aluminate:Ce^{3+} phosphors

	Center of gravity of excited 5d levels (10^3 cm^{-1})	Energy difference between highest and lowest excited 5d levels (10^3 cm^{-1})	Stokes shift (cm^{-1})
Magnetoplumbites			
$CaAl_{12}O_{19}$:0.14Ce	41.3	6.3	7400
$SrAl_{12}O_{19}$:0.14Ce	41.3	6.3	6700
$CaMgAl_{11.33}O_{19}$:0.14Ce	40.7	7.0	7000
β-aluminas			
$BaAl_{10\,2/3}O_{17}$:0.14Ce	39.1	11.6	4100
$BaMgAl_{10}O_{17}$:0.14Ce	39.0	11.6	5100
Distorted magnetoplumbites			
$Ce_{0.86}Al_{11.90}O_{19.14}$	36.8	9.3	3000
$La_{0.86}Al_{11.90}O_{19.14}$:0.14Ce	37.9	9.0	3200
$Ce_{0.92}MgAl_{11.13}O_{19.08}$	38.9	9.1	5900
$La_{0.92}MgAl_{11.13}O_{19.08}$:0.14Ce	39.9	8.9	6000

the contraction with respect to the free-ion level [at 51,000 cm^{-1}, see Ref. (17)] is very large. This contraction is ascribed to the reduction of interelectronic repulsion by a more covalent character of the bonds. If these bands are relatively strong the lattice can be considered to be "rigid." In that case, the Stokes shift between excitation and emission is relatively small due to the fact that the excited Ce^{3+} state cannot contract appreciably (16). In CeMg aluminate and LaMg aluminate: Ce the center of gravity of the 5d levels has shifted $\approx$2000 cm^{-1} toward higher energy. Apparently this lattice is "weaker," which results in a larger Stokes shift. A further increase of the Stokes shift is expected if we change from CeMg (or LaMg aluminate) to Ca, Sr, and CaMg aluminate: Ce phosphors. The observed shift is, however, much less than expected on the basis of the difference between Ce and CeMg aluminate or between the corresponding La-phosphors. We ascribe this to the formal positive charge on the Ce^{3+} ion when it replaces Ca or Sr. This charge causes a contraction of the ground state of the Ce^{3+} ion (17), resulting in a reduction of the crystal field and a moderation of the increase of the Stokes shift.

The formal charge on the Ce^{3+} ion also plays a role in considering the β-alumina: Ce^{3+} phosphors. Since, for instance, CeMg-aluminate has 5d levels centered at the same energy, we expect the β-alumina phosphors to have a weaker crystal field and a lower Stokes shift compared to this compound. The difference in crystal structure (see above) predicts, however, a stronger crystal field. This is indeed observed, so that we conclude that this difference is more decisive than the "charge effect."

Quantum efficiency of the luminescence.—In Table I, typical quantum efficiencies at 300°K of aluminate: Ce phosphors are given. The excitation used was at 250-270 nm. From the excitation spectra in Fig. 11-13 and from reflection spectra it is concluded that most of the phosphors listed are at about 90% from their maximum efficiency on excitation in this wavelength region. The only exception in this respect is LaMg aluminate: Ce where the maximum efficiency is about 80-85% against 60% at 250-270 nm excitation. The efficiencies of the phosphors containing 2% Eu^{2+} as activators are given within brackets (1). It is concluded that the Ce^{3+}-doped magnetoplumbites have slightly higher efficiencies than the Eu^{2+} ones; in the distorted magnetoplumbites the efficiencies are equal, whereas in β-aluminas the Eu^{2+}-doped phosphors are more efficient. The consideration of the "maximum" efficiencies does not change this picture substantially; except that for La-aluminate: Eu^{2+} the maximum efficiency is slightly higher than that of the Ce^{3+}-doped phosphor.

It was shown (8) that energy transfer between Ce^{3+} ions in aluminates has a low probability compared to radiative decay, so that concentration quenching phenomena are unlikely to occur. This is also evident from Table I since the quantum efficiency of the Ce- and CeMg-aluminate phosphors is only slightly lower than that of the La-diluted materials. A further illustration is that in aluminates containing large divalent cations the efficiencies of samples with high Ce content, for instance 0.14 per formula unit, see Table I, are higher than those with 0.02 Ce. This is in contradistinction, for instance, to the Eu^{2+}-doped Ca, Sr, and Ba aluminates (7). In the last-named phosphors energy transfer is very efficient compared to radiative decay.

The luminescence of magnetoplumbites doped with Eu^{2+} ions was reported (6) to be very susceptible to quenching by defects; energy transfer between the activator ions was found to play a crucial role in such quenching processes. Although the preparative conditions of the present materials were chosen in such a way that quenching by defects is avoided as much as possible, the susceptibility to quenching of the Eu^{2+} phosphors may be the reason why the efficiency of Ce^{3+}-doped magnetoplumbites is still slightly higher.

The lower efficiency of the Ce^{3+}-doped β-aluminas may be explained by the fact that in these phosphors a large number of large cation vacancies are present which quench the luminescence. In Eu^{2+}-activated β-aluminas these vacancies were found (2) to occur in concentrations up to 0.01 per formula unit. The efficiency of the Eu^{2+} luminescence was reported to decrease almost linearly below Eu^{2+} concentrations of 1%. We have not checked such relationships extensively in Ba-aluminate: Ce^{3+}, but in view of the fact that Ba aluminate 0.02 Ce ($q = 25\%$) already has a lower efficiency than of Ba aluminate: 0.14 Ce ($q = 50\%$) it is likely that in such phosphors even more Ba vacancies are formed than in the Eu^{2+} case. This may be related to the fact that, since Ce^{3+} is trivalent, not only may the "substitution reaction" of the type $Ba^{2+}{}_{Me} + Ce^{3+} \rightarrow Ce^{3+}{}_{Me} + Ba^{2+}$ occur, but also $3Ba^{2+}{}_{Me} + 2Ce^{3+} \rightarrow 2Ce^{3+}{}_{Me} + \square_{Me} + 3Ba$. Large cation vacancies may also be responsible for the low efficiency of Ca- and Sr-aluminates with low Ce content.

ABSTRACT

Metallurgical-grade silicon has been purified by the Czochralski pulling and floating-zone techniques. The purified material was used as substrates for the preparation of solar cells by diffusion and chemical vapor deposition techniques. The structure and electrical characteristics of purified metallurgical silicon and solar cells have been investigated.

Metallurgical grade silicon with a purity of about 98% is the most economical form of silicon available. It contains aluminum (up to about 0.75% by weight) and iron (up to about 0.5%) as the major impurities; other impurities include boron, chromium, copper, magnesium, manganese, nickel, titanium, and vanadium at concentrations up to several hundred parts per million. Because of its high impurity content, metallurgical silicon is unsuitable for device purposes. Since most metallic impurities have relatively low segregation coefficients (10^{-7}-10^{-3}) at the melting point of silicon, the zone refining of metallurgical silicon could provide silicon of sufficient purity for certain device applications where the purity requirements are not stringent.

In this work, silicon ingots were prepared from the metallurgical-grade material by the Czochralski pulling technique and were further purified by the floating-zone technique. Both Czochralski and float-zoned metallurgical silicon were used for the fabrication of solar cells. The electrical characteristics and conversion efficiencies of solar cells were measured. The experimental procedures and results are summarized below.

Experimental

Metallurgical silicon supplied by the Ferroalloy Division of Union Carbide Corporation was used as the starting material. A typical emission spectrographic analysis of metallurgical silicon is shown in Table I. Silicon ingots of about 2.7 cm diam were pulled from metallurgical silicon in a fused silica crucible by the Czochralski technique, and 60-70% of the charge was consumed. Because of the high concentration of impurities and particulate matter in the melt, the resulting ingots were polycrystalline and were further purified by floating-zone refining in a helium atmosphere for two passes at a rate of about 2.5 cm/hr. Both the Czochralski-pulled and zone-refined materials were sliced and used for the fabrications of solar cells. The structural defects in silicon slices were revealed by the Sirtl etch (2).

Silicon slices produced by both Czochralski and zone-refining techniques were all p-type with electrical resistivities in the range of 0.02-0.06 Ω-cm. They were used for the fabrication of solar cells by the diffusion and chemical vapor deposition techniques. The phosphorus diffusion was carried out at 950°C in the conventional manner using phosphorus oxytrichloride as the source material. The duration of diffusion was adjusted to yield a junction depth of 0.3-0.4 μm, and the sheet resistance of the diffused layer was in the range of 25-50 Ω/□. The grid contact to the diffused surface, 3 lines per centimeter, and the ohmic contact to the back surface were made by evaporating successively 1000Å of titanium and 2-3 μm of silver through metal masks, followed by annealing at 550°C in a hydrogen atmosphere.

In the chemical vapor deposition technique, the thermal reduction of trichlorosilane with hydrogen containing diborane or phosphine was used for the deposition of the active region on purified metallurgical silicon substrates (3). Typically, 5-20 μm of 0.05-1 Ω-cm p-type silicon and 0.4-0.6 μm of 0.003-0.006 Ω-cm n-type silicon were deposited successively on the substrate at 1150°-1200°C. The trichlorosilane content in the reactant mixture was adjusted to yield a deposition rate of about 1 μm/min for the p layer and of about 0.1 μm/min for the n^+ layer. The contacts to the epitaxial cells were also applied by evaporation as in the diffused cells. No antireflection coatings were applied.

The solar cells were characterized by measuring their current voltage characteristics in the dark and under illumination. The dark current-voltage characteristics of the p-n junction is directly related to the performance of the solar cell, and the data were fitted by the least squares method to the following two-exponential model (4)

$$I = I_{01}[\exp(qV/A_1kT) - 1] + I_{02}[\exp(qV/A_2kT) - 1] + \frac{V}{R_{sh}}$$

Where the first two terms represent the diffusion and the recombination currents, and the third term is the contribution from shunting. The illumination was carried out with an AMO solar simulator or a quartz-halogen lamp calibrated to AMO conditions, *i.e.*, the short-circuit current of a standard cell measured with the quartz-halogen lamp is the same as that measured with the solar simulator.

Results and Discussion

Czochralski ingot from metallurgical silicon.—Silicon ingots prepared from metallurgical silicon by the Czochralski technique were polycrystalline with large crystallites. Figure 1 shows the chemically etched surface of a slice cut perpendicular to the pulling direction; the center region is essentially single crystalline,

and the periphery area has many grain boundaries. The emission spectrographic analysis of the first section of a Czochralski ingot is shown in Table I. It is apparent that considerable purification of metallurgical silicon has been achieved because of the low segregation coefficients of metallic impurities in silicon.

Solar cells fabricated from Czochralski-pulled metallurgical silicon had poor characteristics. Figure 2 shows the current-voltage characteristics of a typical cell of about 5 cm^2 area under illumination with a quartz-halogen lamp equivalent to AMO conditions, and the solar cell parameters are summarized in Table II. Its low conversion efficiency, 2.4%, is due at least to two factors: carrier recombinations at grain boundaries and poor chemical perfection in the starting material. Attempts to fit the dark current-voltage characteristics of several cells into the two exponential model have produced no meaningful results due presumably to the large contributions of grain boundaries to the current flow.

Solar cells prepared on Czochralski-pulled metallurgical silicon by the thermal reduction of trichlorosilane showed better characteristics. The parameters of a solar cell of about 5 cm^2 area under AMO conditions are also summarized in Table II. Its conversion efficiency, 4%, is considerably higher than that of the diffused cell, indicating that the deposited silicon p-n junction structures are of considerably better chemical and structural perfection than the p-n junctions produced in metallurgical silicon by diffusion.

Table II. Properties of solar cells (5 cm^2 area without AR coatings) under AMO conditions

Starting material	Fabrication technique	V_{OC} (volts)	I_{SC} (mA/cm^2)	Fill factor (%)	Conversion effect (%)
Czochralski met. Si	Diffusion	0.5	15	32	2.4
Czochralski met. Si	CVD	0.57	15	63	4
Zone-refined met. Si	Diffusion	0.57	17	60	4.3
Zone-refined met. Si	CVD	0.58	17	70	5.1

Float-zone refined metallurgical silicon.—The concentration of metallic impurities in Czochralski ingots pulled from metallurgical silicon was further reduced by the float-zone process. After two-zone passes, emission spectrographic analysis has shown that in the upper one-third of the crystal, boron, aluminum, and iron at 1-10 ppm are the major impurities (Table I). The resulting ingot was essentially single crystalline, however, the density of defects (mainly dislocations) was relatively high, 10^5-10^6/cm^2.

The typical characteristics of solar cells fabricated from float-zoned metallurgical silicon by diffusion are shown in Fig. 3 and 4. Figure 3 shows the dark current-voltage characteristics of a solar cell of about 5 cm^2 area. Two distinct regions are apparent in the forward direction: carrier recombination dominates at low voltages, and normal injection occurs at higher voltages. The least squares fitting of this relation yielded the following data: $I_{01} = 1.5 \times 10^{-13}$ A/cm^2, $I_{02} = 1.9 \times 10^{-8}$ A/cm^2, and $A_2 = 1.79$. These characteristics are similar to the diode parameters reported in the literature (4). Figure 4 shows the current-voltage characteristics of this cell under illumination with a quartz-halogen lamp calibrated to AMO conditions, and the solar cell parameters are summarized in Table II. Its characteristics are considerably improved over those shown in Fig. 2, due to better structural perfection and higher purity in the zone-refined material.

The chemical vapor deposition technique was also used for the fabrication of solar cells on metallurgical silicon substrates purified by two floating-zone passes. Solar cells of both n^+/p/substrate and n^+/p^+/substrate configurations were prepared, and the latter showed somewhat better characteristics. The dark characteristics of a solar cell of about 5 cm^2 area prepared by depositing successively a 15 μm 0.1 Ω-cm p layer and a 0.4-0.5 μm 0.005 Ω-cm n layer on a substrate were analyzed on the basis of the two-exponential model. The I_{01}, I_{02}, and A_2 values at room tempera-

ture are 6.8×10^{-13} A/cm^2, 2.2×10^{-8} A/cm^2, and 1.76, respectively, again similar to the parameters reported in the literature. Figure 5 shows the characteristics of this cell under illumination equivalent to AMO conditions, and the cell parameters are summarized in Table II. These results again indicate that the deposited silicon p-n junction structures are of better chemical and structural perfection than those produced by diffusion.

Summary

Metallic impurities in metallurgical-grade silicon can be removed substantially by zone refining because of their low segregation coefficients in silicon. Solar cells prepared from the metallurgical silicon purified by two zone-pass refining, though somewhat inferior to those from semiconductor grade silicon, have reasonable conversion efficiencies.

Isothermal Silicon Liquid Phase Epitaxy from Supersaturated Tin

B. Jayant Baliga*

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

It is demonstrated that liquid phase epitaxial layers of silicon can be grown under isothermal conditions by using a supersaturated tin melt. This technique produces superior surface morphologies as compared to epitaxial growth using slow cooling of the melt. The epitaxial layer thickness has been found to vary linearly with supersaturation and as the square root of the growth time in agreement with the theory by Ghez and Giess.

Liquid phase epitaxial growth of III-V and other compound semiconductors has been extensively studied and used for many applications. In contrast, very little has been reported on the epitaxial growth of silicon from the liquid phase. D'Asora *et al.* (1) have reported on the growth of silicon layers by the undercooling of a tin melt with the objective of obtaining a low density of surface defects. Kim (2) has applied this technique to the growth of silicon contact pedestals. More recently, Girault *et al.* (3) have reported the growth of silicon layers by undercooling Ga-Al alloys. However, no attempts at isothermal silicon epitaxial growth have been reported in the literature. The use of isothermal conditions for the liquid phase epitaxial growth of gallium arsenide layers and magnetic garnet films has been reported to produce good results (4, 5). This growth process, consequently, merits investigation for the growth of silicon layers.

The kinetics of the epitaxial growth of silicon by the undercooling of a tin melt was examined in detail in an earlier paper (6). The surface morphology of such layers was also examined and has been reported (7). In these papers, it was demonstrated that at slow cooling rates, the growth is mass transport controlled and at fast cooling rates the growth becomes kinetically limited. Under fast cooling rates, terraced epitaxial layer surfaces were observed, and increasingly smoother surfaces were obtained by decreasing the cooling rate. In all these experiments no initial melt supersaturation was used. The above results indicate that growth under isothermal conditions should produce the smoothest surface morphologies. This growth can only be achieved of course, with initial melt supersaturation. This paper examines the kinetics and the morphology of silicon epitaxial layers grown under such isothermal conditions with melt supersaturations ranging up to 30°C. It is demonstrated that this growth technique can be used for the growth of thin epitaxial layers with ripple-free, specular surfaces.

Experimental Procedure

Apparatus.—All the epitaxial growth reported in this paper was performed using tin as the solvent. The experiments were conducted using the dipping technique with a vertical substrate geometry. The epitaxial reactor used in this study has been described in detail in Ref. (6), and only a brief description is given here. A 100-g tin melt was heated to the saturation temperature in a ¾ in. diam quartz crucible within a hydrogen ambient. The temperature of the melt was maintained to within ±0.5°C using a controller with a Pt/Pt-Rd thermocouple to control the power fed to the furnace elements. The temperature of the melt was monitored by using another Pt/Pt-Rd thermocouple placed outside the quartz tube and positioned at the center of the crucible. The emf of this external monitor thermocouple was calibrated to the melt temperature by inserting a Pt/Pt-Rd thermocouple (within a quartz tube) into the melt and maintaining the melt at various temperatures. In order to obtain uniform epitaxial growth over the substrate, the melt temperature was vertically profiled from the bottom of the crucible to the top, and the crucible position in the furnace was adjusted until this profile was uniform to within ±0.5°C.

Growth procedure.—The melt was saturated at the saturation temperature using 0.01 Ω cm, boron-doped silicon wafers. The saturation was conducted with stirring until no further loss in weight of the saturation wafer could be detected. Typical saturation times were 45 min long. After saturation, the melt temperature was lowered to the growth temperature. Throughout this study, the growth temperature was maintained at 949°C, and in order to obtain layers of uniform radial thickness no rotation of the substrate was performed during epitaxial growth (6).

The epitaxial layers were grown on (111) oriented (±1°), 25-35 Ω-cm, phosphorus-doped silicon substrates. The growths were conducted on the polished surface of the wafers as received from the vendor. The wafers were degreased, boiled in nitric acid, and given a dip in hydrofluoric acid just before loading into the reactor. The substrate temperature was brought up to the melt temperature by holding the wafer above the melt for 10 min. The wafer was then inserted into the melt for the growth duration. After the growth period, the substrate was quickly withdrawn from the melt and spun to minimize the adherence of tin droplets on the wafer. Some tin was usually found to be present at the bottom edge of the wafer and was removed by etching in aqua regia. The bottom and edges of the wafer have been excluded during the analysis of layer thickness and morphology.

The layers grown in this study were observed to be of p-type conductivity because the melt was saturated with boron-doped substrates. Since the growth was conducted on n-type substrates, the epitaxial layer could be defined by angle lapping and delineating the junction with copper sulfate solution. The epitaxial layer thickness was then measured using an interferometer to within ±0.2 μm. The epitaxial layer thickness was found to be independent of substrate size.

Experimental Results

Morphology.—Under isothermal growth conditions, a significant improvement in surface morphology, as compared to that achieved with slow cooling, was immediately apparent. The surfaces of layers grown with slow cooling have been previously demonstrated to exhibit surface ripples (7). Under isothermal growth these ripples were absent for all the layers grown under the range of supersaturation (up to 30°C) and

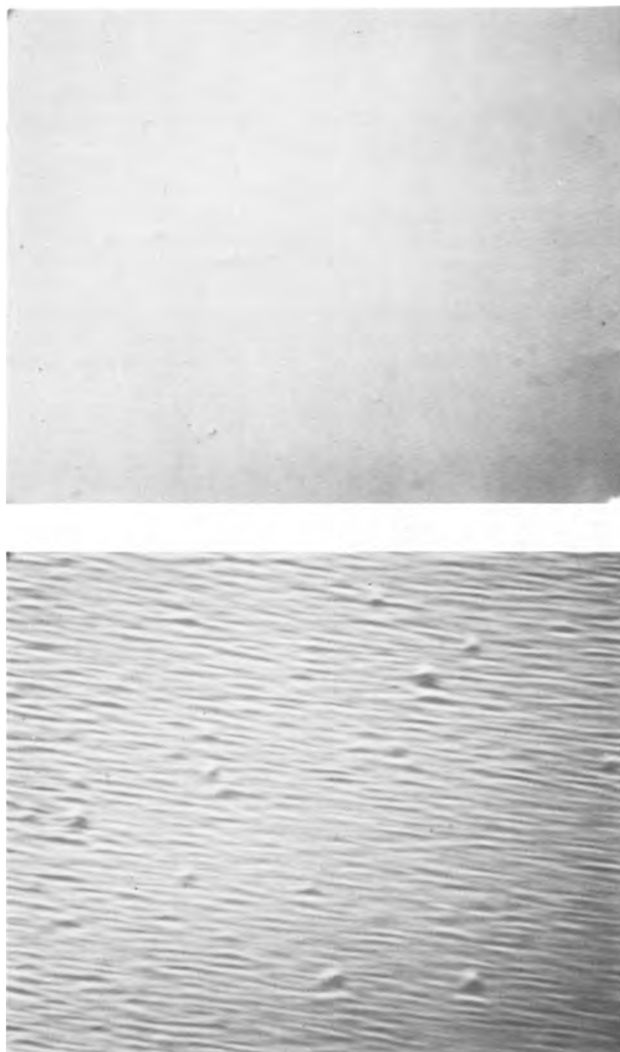

Fig. 1. Photomicrographs of wafers grown under (upper) isothermal growth conditions with a supersaturation of 21°C for 200 min (layer thickness of 4 μm), and (lower) a slow cooling rate of 0.2°C/min for 25 min (layer thickness of 5 μm). The shorter edge of each photograph represents 1 mm on the wafer surface.

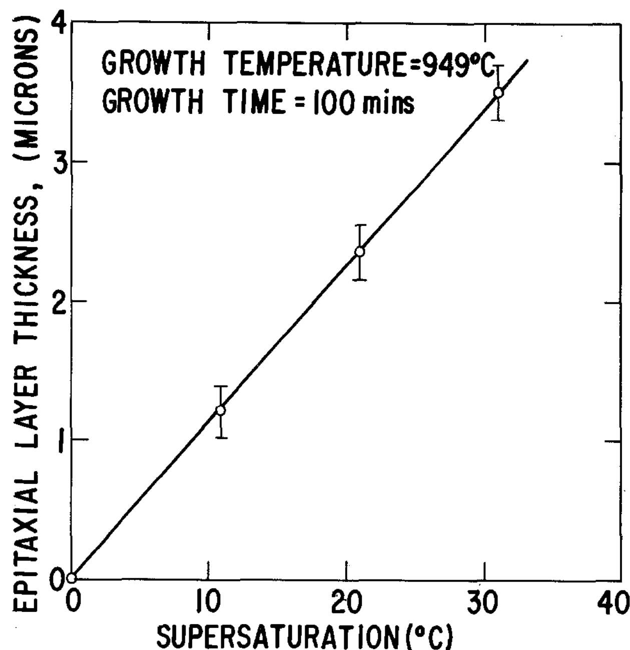

Fig. 2. Variation in epitaxial layer thickness with melt supersaturation.

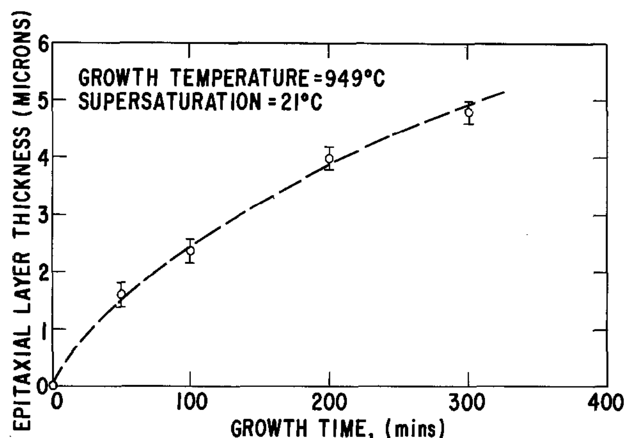

Fig. 3. Variation in epitaxial layer thickness with growth time at a fixed supersaturation.

epitaxial layer thickness (up to 10 μm) studied here. For purposes of comparison, Nomarski interference contrast photomicrographs of the surfaces of wafers grown under isothermal conditions and under slow cooling conditions are shown in Fig. 1. The significant improvement in surface morphology is apparent from these photographs.

Thickness.—The epitaxial layer thickness was measured as a function of both supersaturation and growth time. The variation in the layer thickness with supersaturation is shown in Fig. 2 for a growth time of 100 min. In this figure, the supersaturation has been given as the temperature difference between the melt saturation temperature and the growth temperature because the solubility of silicon in tin increases linearly in this small temperature range (8), and consequently the temperature difference directly represents the supersaturation. It is observed that the epitaxial layer thickness increases linearly with increasing supersaturation.

The change in epitaxial layer thickness as a function of growth time is shown in Fig. 3 for a supersaturation of 21°C. It is observed that the growth rate (slope of dashed line) is decreasing with increasing growth time. This type of behavior has also been observed during the epitaxial growth of GaAs under isothermal conditions (9). The nature of this increase in thickness with time, at a decreasing growth rate, is discussed in the next section.

Discussion

The kinetics of the epitaxial growth of thin films under isothermal growth conditions has been analyzed by Ghez and Giess (5). Although their paper discusses the growth of magnetic garnet films, the theoretical analysis can be applied to the data obtained in the growth of silicon layers in this study. The theory is based upon the assumption of a stagnant boundary layer through which growth units (silicon atoms here) can diffuse and the incorporation of these units into the epitaxial layer by a first-order reaction at the interface between the epitaxial layer and the melt. Further, a fixed concentration, C_L, is assumed beyond the boundary layer. Under these assumptions, the epitaxial layer thickness is predicted to increase linearly with the square root of the growth time and with supersaturation as long as the layer density is much larger than the solute concentration in the melt and as long as the growth rate is low (since the moving-phase boundary was neglected during the analysis). It can then be shown (5) that a plot of epitaxial layer thickness *vs.* square root of time will have a slope given by

$$\text{Slope} = \frac{2(C_L - C_e)}{\rho} \cdot \sqrt{\frac{D}{\pi}} \quad [1]$$

and a negative y-axis intercept given by

$$\text{Intercept} = -\frac{D(C_L - C_e)}{\rho k} \quad [2]$$

where C_e is the equilibrium concentration, ρ is the epitaxial layer density, D is the diffusion coefficient for the growth units in the melt, and k is the surface reaction constant.

It has been shown that the epitaxial growth of silicon in the present system is mass transport controlled at the lower cooling rates (6). Thus, under a zero cooling rate (isothermal growth) mass transport controlled growth by diffusion through a boundary layer can also be expected to occur. The other assumptions of the above theory are also satisfied here because the density of silicon (2.4 g/cm^3) is much larger than the silicon concentration in the melt (a maximum value of 0.045 g/cm^3 for a saturation temperature of 980°C), and the growth rates are extremely small (less than 0.05 μm per minute). This theory can, therefore, be used to analyze the data given in the previous section.

The data shown in Fig. 3 has been replotted in Fig. 4 in accordance with the above theory. It is observed that the layer thickness indeed increases linearly with the square root of time and has a negative intercept on the y-axis. By using this data and Eq. [1] and [2] for the slope and intercept, the diffusion coefficient (D) for silicon in tin at 949°C is calculated to be 6.4×10^{-5} cm/sec by using a supersaturation ($C_L - C_e$) of 0.37 atomic percent silicon in the tin (8). These values indicate that both reaction rate at the interface and the diffusion rate through the boundary layer play a role in controlling the growth rate.

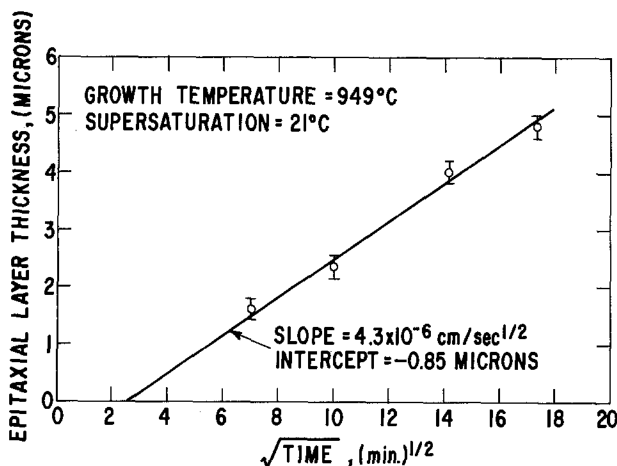

Fig. 4. Epitaxial layer thickness as a function of the square root of the growth duration under fixed supersaturation.

Conclusions

It has been demonstrated that the epitaxial growth of silicon can be achieved under isothermal growth conditions by using a supersaturated tin melt. It is observed that with this growth technique the epitaxial layer thickness increases linearly with supersaturation and as the square root of growth time. It is found that the epitaxial layers grown under isothermal conditions have superior surface morphologies as compared to those grown with slow cooling of the melt. However, the isothermal growth technique is primarily suitable for the growth of thin epitaxial layers. Since the silicon concentration in the melt depletes during growth, the growth rate decreases rapidly as film thickness increases. The application of the isothermal growth technique for thick epitaxial layers is, consequently, limited by the need for extremely large growth durations, as well as by the advent of bulk precipitation in the melt at high supersaturations.

Reactive Plasma Deposited Si-N Films for MOS-LSI Passivation

A. K. Sinha,* H. J. Levinstein, T. E. Smith, G. Quintana, and S. E. Haszko

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Amorphous Si-N films have been synthesized from SiH_4 and NH_3 by reactive plasma deposition at 275°C in an improved radial flow reactor. With appropriate control of machine and process variables, films have been made with Si/N ratio of 0.75-1.5, density of 2.8-2.2g cm^{-3}, refractive index of 1.9-2.3, stress of 2×10^9 dynes cm^{-2} compressive to 5×10^9 dynes cm^{-2} tensile, and electrical resistivity at 2×10^6 V/cm of 10^{20}-10^4 Ω-cm. The process is MOS compatible and it produces relatively thick (1 μm) crack-resistant Si-N films (at 450°-500°C) having excellent step coverage and good adhesion to both Au and Al metallization. This paper describes the deposition technique, effect of deposition parameters on various film properties, and the advantages these films offer in silicon integrated circuit technology.

In MOS-LSI technology, it is recognized that the effectiveness of the final passivation layer will, to a large extent, determine the ultimate reliability of the packaged device. The passivation layer is intended to protect sensitive areas of the device from outside contamination by, *e.g.*, Na^+ and moisture, and also to provide scratch protection for the Al metallization.

A potentially attractive material for this purpose is silicon nitride which provides an inert barrier (1, 2) to Na and H_2O as opposed to phosphosilicate glass (3) which acts as a "getter" for Na as well as moisture. However, the use of Si_3N_4 has been restricted because of the high temperatures ($\gtrsim$700°C) required for chemical vapor deposition of Si_3N_4 films (4) and because of high tensile stresses which limit the usable film thickness to ~2000Å (5).

Several investigations have been made concerning deposition of silicon nitride films at lower temperatures (<450°C) using an rf plasma to provide some of the activation energy needed for the reaction between SiH_4 and NH_3 or N_2 (6-10). The earlier systems utilized a quartz tube, an inductively coupled plasma, and gases flowing at a pressure of ~100 mTorr. These techniques generally lead to poor uniformity from wafer to wafer and inadequate step coverage. Reinberg (11) developed a radial flow reactor for Si-N deposition. He utilized a capacitively coupled rf discharge in a gas mixture consisting of SiH_4, NH_3, N_2, and Ar at relatively high pressures (0.5-1 Torr) and low powers (~50 W), in order to achieve good thickness uniformity and good step coverage. Rosler *et al.* (12) recently described a CVD process which also utilizes a radially symmetrical gas flow but in a direction opposite to that used by Reinberg; the capacitive discharge operates at a higher power (500W) and a relatively low frequency (50 kHz). Detailed data on the resulting $Si_xN_yH_z$ film composition ($0.8 \leq y/x \leq 1.0$), density (2.5-2.8 g cm^{-3}), resistivity (10^{15} Ω-cm), stress (1×10^9 dynes cm^{-2} compressive) etc., were reported by Kern and Rosler (13) for films deposited at 300°C.

We have devised certain improvements in the Reinberg radial flow reactor design which allows use of a wider range of deposition conditions and, consequently, a high degree of flexibility in tailoring the film properties (14). The main improvement consisted of a gas-flow discharge limiting shield which confines the plasma to a region above the substrates. It thereby enables use of higher rf powers without the adverse effects of a premature reaction between SiH_4 and NH_3 underneath the substrate table. This paper describes the deposition technique, effect of deposition parameters on various film properties, and the advantages these films offer in silicon integrated circuit technology.

Deposition Technique

Apparatus.—Figure 1 schematically shows the deposition apparatus consisting of a reactor, associated pumping systems, gas lines, and an rf power source.

The deposition reactor was a metal bell jar with a nominal diameter of 18 in. The cathode (16 in. diam) and the substrate table were made of Al and separated from each other by about 1 in. Heating was accomplished by means of quartz lamps mounted underneath the substrate table. A glow-discharge limiting shield was provided concentric with the heater and separated from it by ~¼ in. The gases were admitted underneath the heater, directed by the shield to flow radially inward over the surface of the substrate table and then exit to the pump through the center of the substrate table/heater assembly. Use of the gas flow discharge limiting shield eliminated premature decomposition of silane at higher rf powers since the gases were not exposed to the plasma until they were flowing over the substrates.

The pumping system was compatible with a high gas flow (>2 liters/min) at 1 Torr pressure. It consisted of a 150 cfm Leybold-Hereaus roots blower backed by two 17 cfm mechanical pumps running in parallel. The gas pressure was controlled by a throttle valve located in the roots blower line. The pressure was monitored

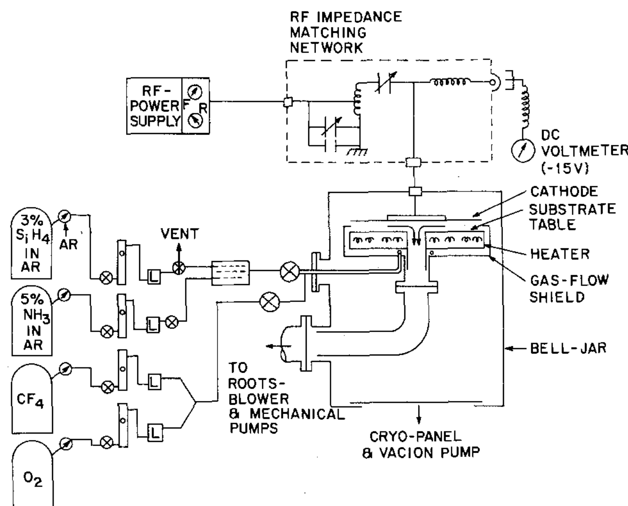

Fig. 1. Schematic of the apparatus used for deposition of RPD Si-N films.

* Electrochemical Society Active Member.

Key words: plasma-enhanced CVD, silicon nitride, thin films.

using a capacitance manometer (MKS Baratron) which provides measurements independent of the nature of the gas (and its conductivity). Facility was also provided to pump the system initially down to a base pressure of $\lesssim 10^{-6}$ mm with a cryopanel and a 400 liters/sec sputter-ion pump.

The reacting gases were 3% SiH_4 in Ar and 5% NH_3 in Ar. The delivery pressure was kept at 15 psig. The gases were led through rotameters to leak valves, L, and then on to a mixing chamber and finally to the deposition system. Special care was taken to keep these lines leak-tight. Similar but separate lines were provided for CF_4 and O_2 and an appropriate mixture of these two gases was used for plasma-etch cleaning of the station.

The rf power to the cathode was supplied by a Varian (13.56 MHz) power supply and an impedance-matching network of the conventional L-C type to which was added a fixed capacitor (Jennings, 220 pF) in parallel with the tunable load capacitor. This enabled satisfactory tuning with less than 10W reflected power at ~1 Torr pressure. The cathode d-c self-bias could be measured with a d-c voltmeter attached to the cathode power line via rf chokes.

Procedure.—The wafers (2 in. diam) were loaded in two concentric circles the bell jar was closed, and the system pumped down to $\sim 10^{-6}$ Torr using successively the mechanical pumps (to ~1 Torr), the roots blower (to ~3 mTorr), and the cryopanel and the sputter-ion pump (to $\sim 10^{-6}$ Torr). The final stage of the pumping added only 2-5 min to the total pumpdown time (~20 min). Next, the sputter-ion pump isolation valve was closed, the gases were admitted into the reactor, and the roots blower valve was opened again. A dynamic pressure (~600 mTorr) was established in the system with the gases flowing at the desired flow rates. Thereafter the roots blower valve was throttled to the desired pressure.

The rf plasma was excited to the desired power level. The plasma initiated and sustained the reaction between SiH_4 and NH_3 on the surface of the heated substrates. Typically, depositions were carried out for 1 hr to give Si-N films 1.1(±0.1)μm thick. The total turnaround time was <2 hr.

After every three runs, the system was cleaned *in situ* for 1-2 hr in a plasma (1000W) containing CF_4 + 8% O_2 at a flow of ~250 cm^3/min and a pressure of ~1000 mTorr with the substrate heater on. Subsequent to the cleaning operation a predeposition run (~15 min) was made with SiH_4 and NH_3 at the desired flows and pressure.

Film Evaluation Techniques

The film stress was deduced from change in curvature of the Si substrate due to the Si-N layer. For evaluation of 1 μm thick films, use was made of an optically levered laser beam to determine the substrate curvature (15). A more sensitive method was used for measurements on thinner films (~200Å); namely, the ABAC (automatic Bragg angle control) x-ray technique (16).

The refractive index was measured using an ellipsometer (5461Å). For film thickness and etch rate measurements, a step was etched in the film with 7:1 buffered HF (BHF) and the resulting step height was measured with the Talystep.

Rutherford backscattering analysis was used to determine the film composition and its density (17). Thinner films (~2000Å) on (111) Si were employed so as to get "clean" spectra and to reduce the background due to Si substrate by channeling along the [110] direction.

The density measured by Rutherford backscattering analysis was always within 10% and generally smaller than that determined from weight gain measurements on certain thicker films deposited under identical conditions (*e.g.*, conditions A and B of Table I).

The growth morphology of the film and its step coverage for various device topologies were determined using scanning electron microscopy on cleaved sections. The film structure was established using transmission electron microscopy in conjunction with selected area transmission electron diffraction.

The crack resistance of these films on various device structures was ascertained by heating them up to 450°-550°C (½ hr periods, air ambient), after which the films were examined in an optical microscope under interference contrast and/or polarized light. Usually when cracking occurred, it was gross and easily revealed. Further confirmation of the film integrity was provided by exposing the device structures to a metallization etch for 15 min followed by examination in the optical microscope.

Effect of Deposition Parameters

Five main process variables were investigated: (*i*) gas composition, (*ii*) total gas flow, (*iii*) pressure, (*iv*) substrate temperature, and (*v*) rf power to the plasma. Table I contains a summary of two "standard" processes (A and B) and the resulting film properties. Studies of variables (*i*) through (*iv*) were carried out in conjunction with process A, *i.e.*, at an rf power of 250W and with the remaining three parameters at the values given for process A.

Most of the data points, except those pertaining to "standard" processes A and B (Table I), represent averages of a limited number of measurements on 3-6 2 in. diam Si wafers located in the main outer row of the substrate table. In the worst cases, *i.e.*, at conditions farthest away from optimum, variations in some properties such as film thickness and etch rate could be as much as ±15%, but the uniformity improved to well within ±10% as the conditions approached optimum values.

Table I. Reactive plasma deposition conditions and resulting Si-N film properties for standard processes A and B

		Process A		Process B
A.	Reacting gases		$SiH_4/NH_3/Ar$	
B.	SiH_4 concentration (% flow)	1.70		1.78
	SiH_4/NH_3	0.71		0.79
C.	Total gas flow (sccm)		2320	
D.	Pressure (mTorr)		950	
E.	Substrate temperature (°C)		275	
F.	RF power (fwd/rev., W)	250/0		300/0
1.	Typical thickness (μm)		1.1 (±0.1)	
2.	Stress (10^9 dynes cm^{-2})	1-5, T		1, C
3.	BHF etch rate (Å/min)	100-200		75-150
4.	Refractive index	2.05 (±0.1)		1.95 (±0.1)
5.	Density (g cm^{-3})	2.55 (±0.05)		2.75 (±0.05)
6.	Composition (Si/N)	1.05 (±0.05)		0.8
7.	Cracking resistance (°C)	450		550
8.	Adhesion		Good	
9.	Step coverage		Excellent	
10.	Scratch resistance		Good	
11.	Dielectric constant	6.4		6.8
12.	Breakdown strength (10^6 V/cm)	3.9		5.0
13.	Resistivity at 2 × 10^6 V/cm (Ω-cm)	4 × 10^{13}		3 × 10^{15}

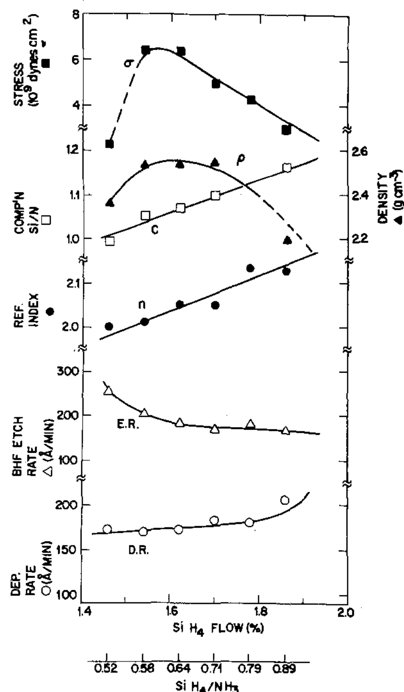

Fig. 2. Effect of SiH_4 concentration and SiH_4/NH_3 ratio on the properties of RPD Si-N films. (Other parameters kept constant at the values given for process A).

Gas composition.—Figure 2 shows the effect of increasing SiH_4 concentration ($1.4 \leq$ % $SiH_4 \leq 1.9$; $0.5 \leq SiH_4/NH_3 \leq 0.9$) on film properties for total flow of 2.3 std liters min^{-1}.

Increasing the SiH_4 concentration in the gas led to a corresponding linear increase in the Si/N ratio in the film (from ~1.0 to ~1.2) and a linear increase in the refractive index (from ~1.9 to ~2.2). With increasing SiH_4/NH_3 ratio, the film density ρ showed a broad peak ($\rho \approx 2.55$ g cm^{-3}) for $0.58 \leq SiH_4/NH_3 \leq 0.79$. The ρ decreased again at SiH_4/NH_3 ~0.9; however, this was not accompanied by a corresponding increase in the BHF etch rate, presumably because the films now had a much higher Si content (Si/N ~1.2). The film stress, σ, always tensile, showed a peak at SiH_4/NH_3 ~0.6, which is located at a slightly lower SiH_4 concentration than that for the peak in ρ. The choice of SiH_4/NH_3 ~0.7 for process A was selected on the basis of data on σ and ρ; one of the goals being to achieve a low σ in conjunction with high ρ (see section on Crack resistance, below).

Gas flow.—The total gas flow was varied in the range 1.0-2.5 liters min^{-1}, with the SiH_4/NH_3 ratio constant at 0.71 (Fig. 3) (% SiH_4 = 1.70). Under these conditions, the Si/N ratio in the film varied from 0.8 to 1.05; for this composition range, the film density seems to have a dominant effect on the BHF etch rate; a broad maximum in ρ corresponds to a broad minimum in the etch rate. The tensile stress decreases with increasing flow; this is probably the result of a higher film purity (with respect to possible N_2 contamination, see below) as the flow is increased.

Pressure.—The total pressure during deposition was varied from ~700 to 1000 (±25) mTorr. As shown in Fig. 4, increasing the pressure led to a higher deposition rate, whereas the density or the BHF etch rate did not change much. The refractive index decreased linearly. This generally (*i.e.*, for pressures $\gtrsim$ 750 mTorr) correlates with a decrease in the Si/N ratio in the film. The stress remains nearly constant in the range 700-950 mTorr.

Substrate temperature.—The range of substrate temperatures studied was $200 \leq T_S \leq 300°C$ (Fig. 5).

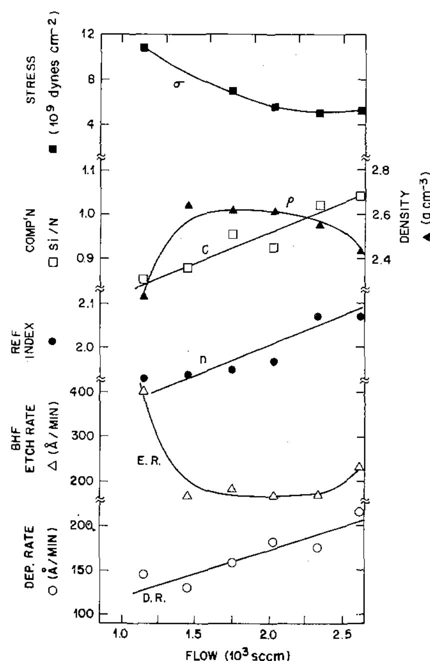

Fig. 3. Effect of gas flow on the properties of RPD Si-N films

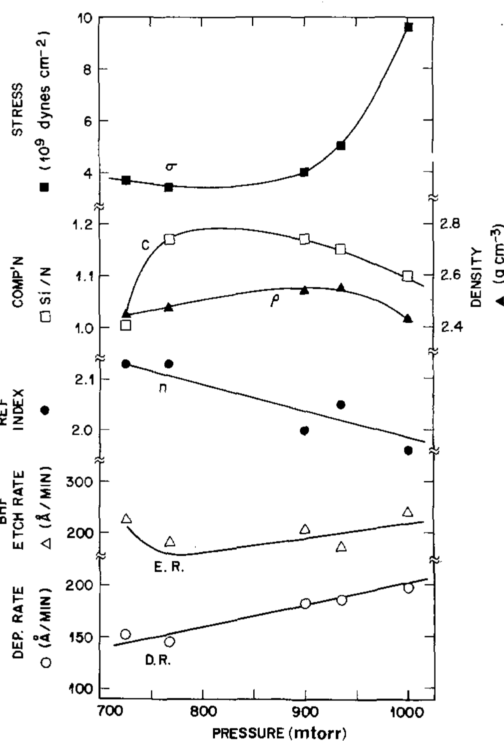

Fig. 4. Effect of gas pressure on the properties of RPD Si-N films

Higher temperatures were not investigated because the nitride films were intended for use on Ti/Pd/Au as well as Al metallization. As shown in Fig. 5, T_S has a pronounced effect on the BHF etch rate, which decreases almost exponentially with increasing T_S. The decrease in BHF etch rate is associated with a linear increase in the film density, ρ, and in the refractive index, n. Thus, for films deposited at 200°C, the BHF etch rate was 700 Å/min, the density was ~2.3 g cm^{-3}, and the refractive index was ~1.85. Interestingly, these films also had a rather large Si/N ratio (~1.2) and a high tensile stress (7×10^9 dynes cm^{-2}). With increasing T_S, both σ and Si/N ratio in the film displayed a shallow minimum at ~250°C; however, a higher T_S of 275°C was preferred because it led to films with yet larger density (2.55 g cm^{-3}) and somewhat lower etch rate without an excessive increase in σ.

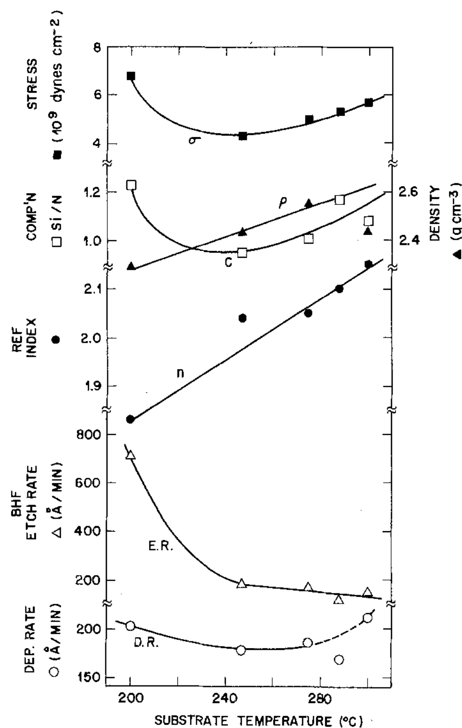

Fig. 5. Effect of substrate temperature on the properties of RPD Si-N films.

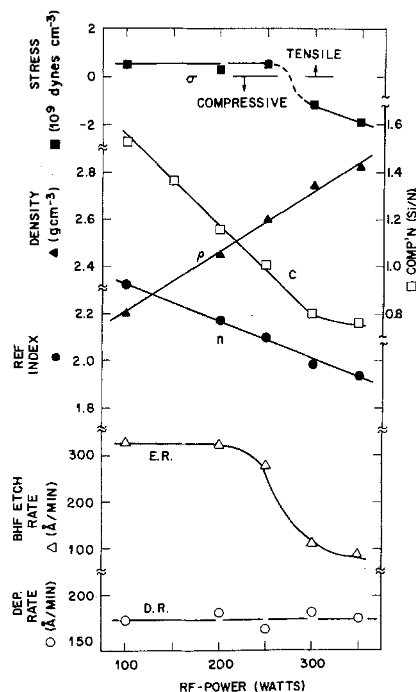

Fig. 6. Effect of rf power on the properties of RPD Si-N films. (Other parameters kept constant at values given for process B).

Rf power.—Tuned rf powers were investigated in the range 100-350W nominal, which were read off meters located at the power supply (Fig. 6). For this series of experiments, the SiH_4/NH_3 ratio was kept constant at 0.8 and % SiH_4 at 1.8. With increasing rf power, there is a rapid and linear increase in the film P (weight-gain measurements, using 1 μm thick films) from 2.2 g cm^{-3} at 100W to 2.8 g cm^{-3} at 350W. Films (1 μm) with Si/N >> 1 and lower density had a yellowish tinge when deposited on Al-metallized devices whereas those with Si/N $\lesssim$ 1 and densities $\gtrsim$ 2.4 g cm^{-3} appeared to be grayish and more transparent. Both the film σ and BHF etch rate showed a bimodal behavior at ~ 275W. Below this power level the stresses were very low tensile (~0.5 × 10^9 dynes cm^{-2}) and the etch rates were relatively high (275-325 Å/min). At rf powers $\gtrsim$ 300W, the stresses were compressive (1-2 × 10^9 dynes cm^{-2}) and the BHF etch rates were relatively low (~100 Å/min). Significantly, the refractive index decreased with increasing rf power, as did the Si/N ratio in the film. The latter, however, tended to level off at the stoichiometric value (Si/N ~ 0.75) for rf power > 300W.

The rf power readings quoted above are specific to the present system and its capacitive and inductive losses. It was found that the d-c (negative) voltage measured from cathode to ground was very small (1-10V). Peak-to-peak rf voltages were not measured, but since the cathode d-c voltages are small relative to gas ionization potentials [*e.g.*, 15.7 eV for Ar (18)], it is expected that the (positive) plasma potential with respect to ground must be quite high. This effect may be related to the system geometry, which consists of large electrodes (16 in. diam) in a relatively small volume (1 in. interelectrode spacing), and to the relatively large pressure (~ 1 Torr) of the discharge. These voltage characteristics may be contrasted with those present in typical rf sputtering systems (19), where the discharge operates at 5-10 mTorr pressure. The rf sputtering systems are associated with a very large cathode d-c self-bias of ~ 1 kV (19), which is nearly half the peak-to-peak or electron accelerating voltage. In such systems, the plasma is only slightly positive with respect to the ground.

Effect of N_2 and O_2 Additions to the Preferred Gas Mixture

Small amounts of air-leaks into the system, or substituting the NH_3 with N_2 as the source of N_2, were found to severely degrade the crack resistance. This was an unexpected observation since the literature contains examples of reactive plasma and reactive sputtering processes where preference is expressed for either N_2 (9) or NH_3 (6). Therefore, mixtures of NH_3 and N_2 were not suspect.

Figures 7 and 8 show the effect of N_2 addition on Si-N film properties. The control sample had a low tensile stress of 5 × 10^8 dynes cm^{-2}, an etch rate of 75 Å/min, and a refractive index of 1.92. Addition of small amounts of N_2 (up to 2%) caused a steep increase in tensile stress (up to 6 × 10^9 dynes cm^{-2}) as well as

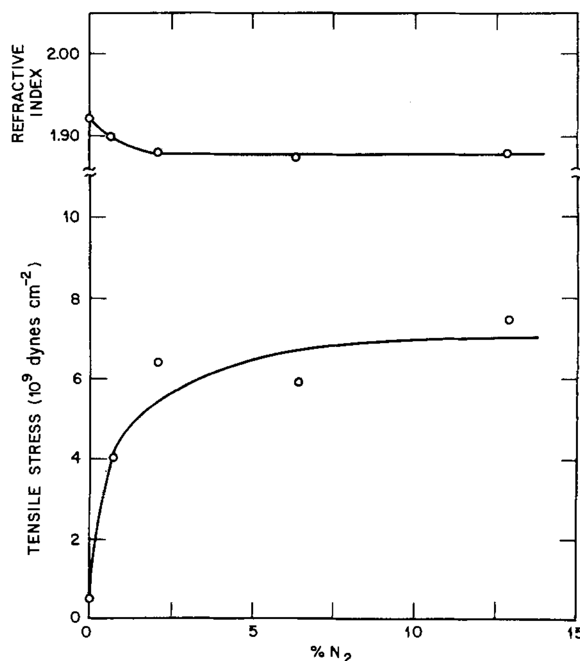

Fig. 7. Effect of N_2 additions to the reactant gas mixture (process A) on the tensile stress and refractive index of RPD Si-N films.

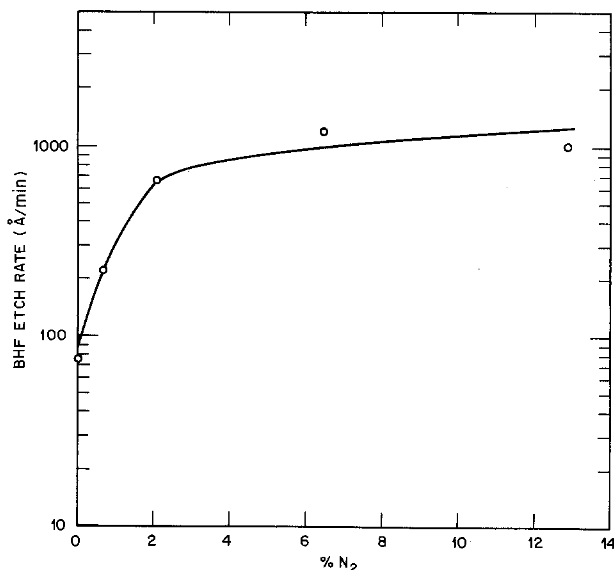

Fig. 8. Effect of N_2 addition to the reactant gas mixture on the etch rate in BHF of RPD Si-N films.

in the BHF etch rate (up to 700 Å/min) and a small decrease in the refractive index. At higher N_2 concentration in the gas stream, all of these film properties tend to level off. The high etch rate implies that these films have a lower density; the combination of low density and high tensile stress has been found to correlate with poor crack resistance of Si-N films at temperatures $\gtrsim$ 450°C (14, 15).

The addition of small amounts of O_2 to the reactant gas mixture had an even greater effect on BHF etch rate. As shown in Fig. 9, the etch rate continues to increase exponentially to ~3000 Å/min for 0.65% O_2, showing no sign of saturation. The effect on refractive index, n, is also quite severe (Fig. 10); n decreases from ~1.9 to ~1.6 for 0.65% O_2. The effect on film stress, σ, is relatively small. The σ initially increases to ~3×10^9 dynes cm^{-2} and then it decreases to almost zero for 0.65% O_2. It appears that some of the O_2 added to the gas stream gets incorporated into the film, leading to an oxynitride; hence the low n, very high etch rate, and the apparent stress-compensation effect (20).

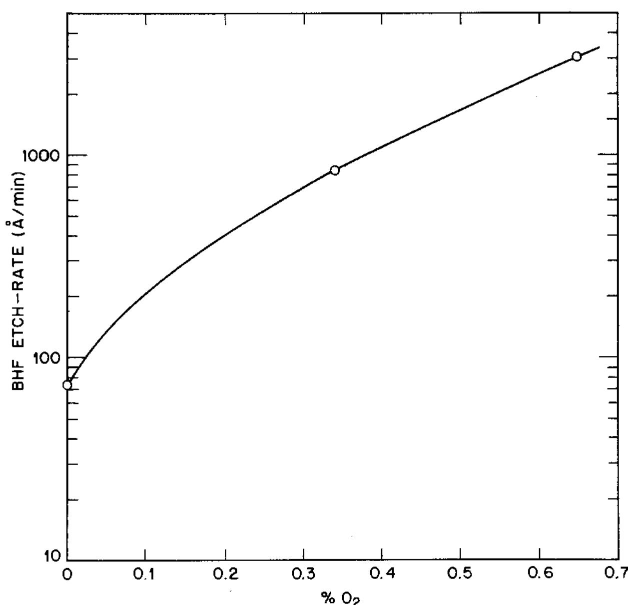

Fig. 9. Effect of O_2 addition to the reactant gas mixture on the BHF etch rate of RPD Si-N films.

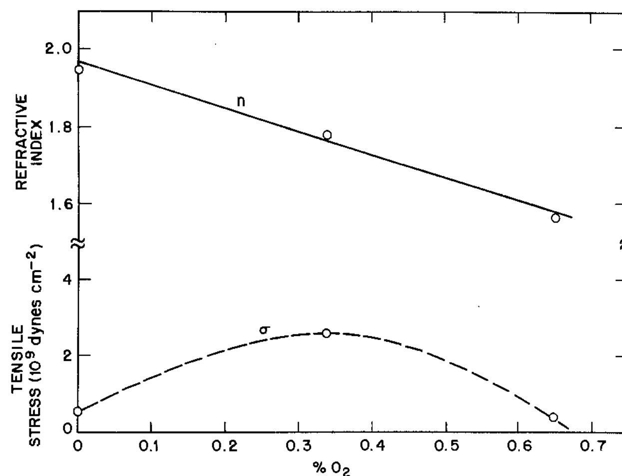

Fig. 10. Effect of O_2 addition to the reactant gas mixture on the tensile stress and refractive index of RPD Si-N films.

Discussion of Film Properties

Crack resistance.—Thick Si-N films (1 μm) on Al-metallized wafers cracked on heating to 450°C if the film stresses were too high ($\gtrsim 8 \times 10^9$ dynes cm^{-2}) or if the densities and deposition temperatures were too low ($\lesssim$2.2 g cm^{-3} and <<275°C, respectively). An example of extensive nitride cracking over both Al metallization and dielectric areas is shown in Fig. 11 for a Si-N film made at 250°C with a density of ~2.2 g cm^{-3} and a tensile stress of ~0.5×10^9 dynes cm^2. In contrast, films made using process A withstood 450°C, ½ hr treatments and those using process B did not show any cracking even at 550°C, ½ hr when the underlying Al was properly stabilized and it did not form large hillocks that punched through the Si-N film. Thermal stresses in Al, which form the driving force for hillock formation, have been shown to be a sensitive function of the film thickness and the initial microstructure (21). Most of our studies involved Al metallization (1-2 μm) evaporated at ~300°C and H_2 baked at 450°C prior to Si-N deposition.

It was recently proposed (14, 15) that the cracking resistance, CR, of a thick Si-N film at a given temperature T is functionally related to its density, ρ, intrinsic stress, σ_i, thermal mismatch, $\Delta\alpha$, with Si, and the deposition temperature, T_s, through the following equation (14)

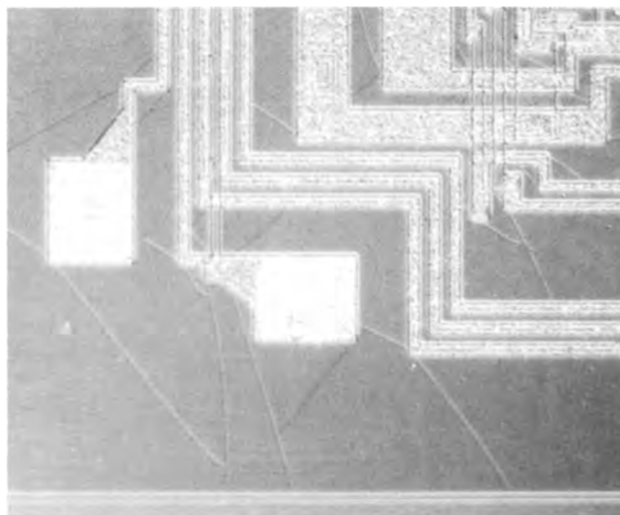

Fig. 11. Effect of a 450°C, ½ hr, air heat-treatment on the integrity of RPD Si-N film over Al-metallized Si wafer (film made at 250°C with a density of ~ 2.2 g cm^{-3} and a stress of ~ 0.5 $\times$ 10^9 dynes cm^{-2}).

$$\mathrm{CR} \approx \frac{\rho}{\rho_0} \cdot \sigma_u - \sigma_i - \frac{E'}{1-\nu'} \int_{T_s}^{T} \Delta\alpha \cdot dT$$

Where, σ_u is the ultimate tensile stress of a structurally "perfect" Si_3N_4 film with density ρ_0, and E' and ν' are the Young's modules and Poisson's ratio for the film. This equation correctly predicts that CR will be improved if ρ is increased, σ_i and $\Delta\alpha$ are made small, and T_s is made high relative to the test temperature. A quantitative application of the above equation, including thermal stress measurements, for various Si-N films is described in Ref. (15).

Thickness uniformity.—The radial symmetry of gas flow and of plasma electron density inherent in the reactor design provides a useful means of attaining good thickness uniformity on wafers arranged in concentric circles. There still remains the problem of uniformity as a function of radius of the circle in which the wafers are placed. Here, two opposing effects may be involved (11): (*i*) the reactant gas concentration, which gets depleted as the gases flow inward; high gas flow will prevent such depletion, which is also countered by increased velocity as the gases approach the center of the substrate table, and (*ii*) the electron density which depends on the rf power and increases on going toward the center of the substrate table. Therefore, in principle, uniformity can be optimized by adjusting the gas flow for a particular rf power or vice versa.

For the preferred processes (A and B of Table I), we employed both a relatively high throughput of the reactants (2.3 liters/min) and a high rf power (250 or 300W); conditions which are compatible with a fair degree of uniformity. The uniformity was better than $\pm 10\%$ from wafer-to-wafer (arranged in two circles containing 14 and 8, 2 in. diam wafers, respectively) and from one deposition run to the other. The best thickness uniformity was observed at the lowest powers investigated (100W at $T_s = 275°C$), but these films were unacceptable because of a tendency toward cracking at 400°C. At the higher rf powers ($\geq$ 350W), the thickness uniformity got much worse and $\pm 10\%$ uniformity could be achieved only over wafers in the outer circle.

Structure and growth morphology.—The amorphous nature of the present Si-N films was established by transmission electron microscopy. No contrast effects due to crystallites or voids could be seen in the bright- or dark-field mode, and electron diffraction patterns showed broad, diffuse halos characteristic of amorphous structure. Further insight into the nature of these films has been obtained by Lorentz-Lorenz correlation of the data on the film density, composition, and refractive index (17). The resulting magnitudes of electronic polarizabilities (α) suggest that the effective size of "Si" in plasma Si-N is quite high and probably corresponds to that of a Si-H complex. The α_{Si} increases with Si/N ratio indicating that Si-H complexes assume an increasing role in Si-rich Si-N films.

The growth morphology, as revealed by SEM examination, was always found to be smooth (layered) on the various surfaces investigated (Si, SiO_2, Al_2O_3, Si_3N_4, Al, Pd, Au) provided these surfaces were clean. However, in certain cases, we observed sporadic incidence of nodular growth, or hillocks; an extreme case is shown in Fig. 12(a). The device area in Fig. 12(b) shows nodules only in the dielectric areas, and with adequate cleaning, the situation corresponded to that of Fig. 12(c) where only a layered growth was observed.

We have correlated the occurrence of nodular growth with surface contamination (from baked-on residues of photoresist and intentionally introduced Sn and Pb at monolayer levels) and/or particulate matter. The presence of such contamination apparently triggers a vapor-liquid-solid growth (22) and/or gas

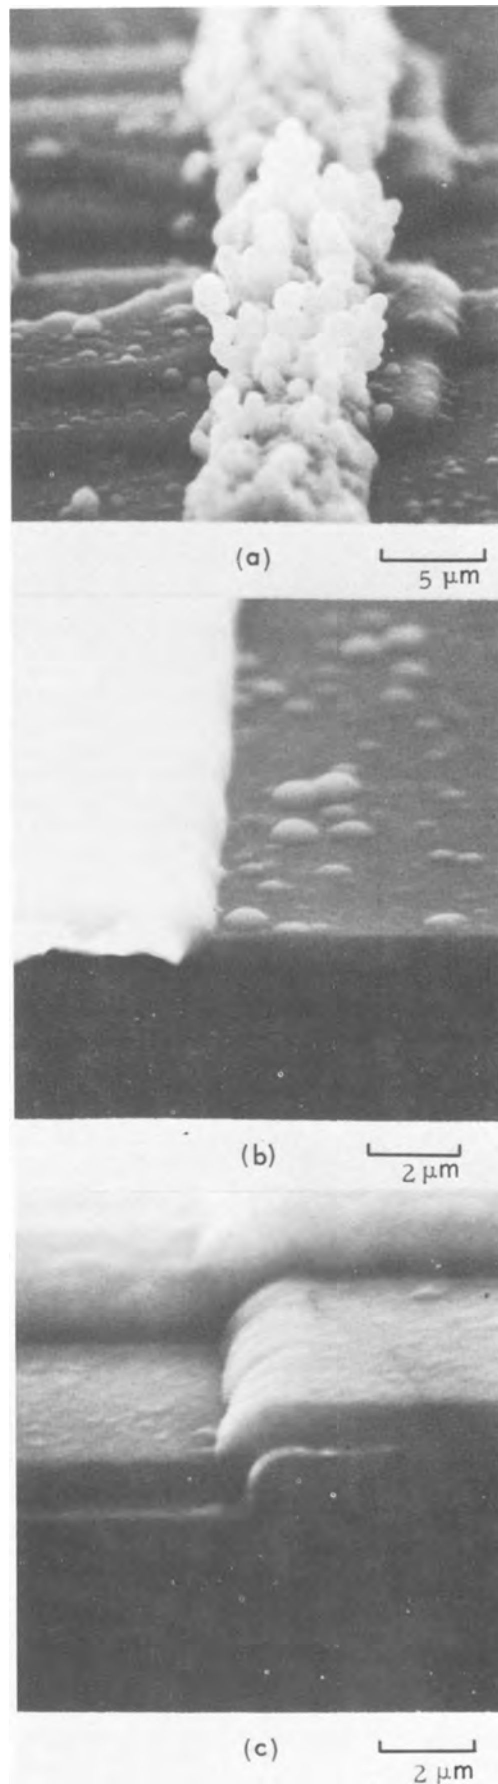

Fig. 12. Growth morphology of RPD Si-N films showing: (a) and (b) sporadic nodular growth (hillocks) on contaminated areas of device wafers, namely, Au lines and dielectric areas, respectively, and (c) layered growth on properly cleaned device wafers.

phase reaction (13) in the vicinity of the contaminated area. Such reactions in response to surface contamination were found to be more likely to occur under conditions of higher temperatures and larger flows, which also lead to "superior" crack-resistant films. Proper cleaning of the metallized wafers to remove any particulates and surface chemical contamination prior to H_2 bake was found to be desirable. One effective cleaning process involved scrubbing both sides of the wafer in Triton X (Rohm & Haas, Philadelphia, Pennsylvania) (1:20,000 dilution), followed by boiling in a mixture of 90% water and 10% H_2O_2 (high purity) for 10 min, followed by a cold deionized water rinse for $\geqq$ 15 min.

Step coverage.—Use of high pressures (relative to sputtering) during deposition and a surface-activated film growth process leads to excellent step coverage as illustrated in Fig. 13 and 14 for Ti/Pd/Au beam leads and Al metallization, respectively. As shown in Fig. 14(c), the Si-N layer conforms well to the underlying topology even where the walls are vertical or they have a slight negative slope. Particularly important is the absence of any reentrant angles at the bottom of the steps. Further evidence of excellent step coverage was obtained by immersing the coated device wafers for $\geqq$15 min in an appropriate metallization etch, such as hot H_3PO_4-CH_3COOH-H_2O for Al and KI-I_2 for Au, and then finding no attack on the underlying metal.

Si-gate MOS device compatibility.—MOS measurements were made on Si-gate MOS devices processed through second-level metallization and then subjected to the Si-N reactive plasma deposition, plasma etching of Si-N, and O_2 plasma stripping of the resist. The gate oxide capacitors showed no measurable increases in the oxide fixed charge or the surface-state density at midgap nor any radiation-induced bias-temperature instability. The absence of radiation-damage in above structures where the gate oxide is protected against soft radiation damage by the poly-Si appears to be due mainly to the use of relatively high pressures in the plasma and low levels of cathode d-c bias, as compared to rf or d-c sputtering processes.

Electrical properties of the present films were found to be a function of the film composition and its structures (23). The electrical resistivities (at 2×10^6 V/cm) for films with Si/N of 1.8, 1.0, and 0.75 were 4×10^4, 4×10^{13}, and 5×10^{19} Ω-cm, respectively. The dielectric strength similarly increased from $0.8 \rightarrow 3.9 \rightarrow 8.1$ MV/cm. The thermal activation energy for conduction was ~0.3 eV. The dielectric constant (1 MHz) ranged from 6 to 8.

The Si-N films have been successfully utilized to form structures containing Ti/Pt/Au beam leads on Al (Fig. 15); the device is effectively sealed by the combination of Au-beam leads and plasma SiN. Si-gate PMOS and CMOS logic devices have been fabricated with the above structure in plastic packages; the latter devices showed an extrapolated median time to failure of > 40,000 hr under bias-humidity-temperature (85°C/85% RH) aging with intentional ionic contamination present. No cases were encountered of any cathodic corrosion of Al after 10^6 device-hours of 85/85 aging.

Conclusions

Certain plasma deposited Si-N films may compare favorably with PSG passivation layers and even with CVD Si_3N_4. Thus, these Si-N films provide an inert barrier to Na and H_2O, unlike heavily doped, low temperature CVD (LTCVD) P-glass which is hygroscopic and can react with H_2O to form corrosive H_3PO_4 (24). Si-N films have excellent step coverage whereas LTCVD often leads to films with a dog-bone type of feature on top and reentrant angles on the bottom of the steps. Si-N films provide a suitable surface for subsequent deposiiton of Ti/Pt/Au films whereas the surfaces of undensified P-glass are such that it is difficult to deposit adherent films on it. The electrical resistivity and the density of plasma Si_3N_4 films are comparable with those of CVD Si_3N_4, but the former can have much lower and compressive stresses which allows a higher usable thickness of 1 µm.

In conclusion, plasma-enhanced CVD provides an attractive deposition technique for Si-N films for final passivation. Its advantages are: manufacturability, low temperature operation, good step coverage/uniformity, compatibility with Si-gate MOS devices, and great flexibility with regard to control of stresses, film composition, density, and cracking resistance. The dis-

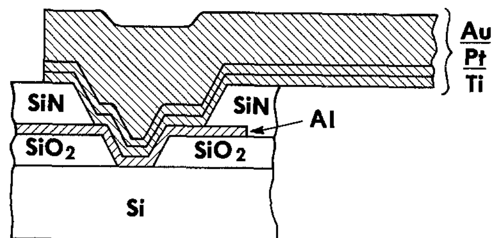

Fig. 15. Ti/Pt/Au beam leads to Al metallization passivated with RPD Si-N (Si/N = 1).

advantages are: a relatively complex reactor and process (many variables) and a sensitive growth morphology under certain conditions.

Boron Predeposition in Silicon Using BBr_3

P. Negrini, A. Ravaglia,[1] and S. Solmi

C.N.R.-LAMEL Laboratory Via Castagnoli, 1-40126 Bologna, Italy

ABSTRACT

The process of boron predeposition in silicon using a BBr_3 source is investigated for different times, temperatures, and doping gas compositions. The experimental conditions leading to the formation on the silicon surface of the boron-rich layer are determined. It is shown that the boron surface concentration in silicon, in equilibrium with the boron-rich layer, is higher than the solubility value and depends on doping gas composition. Different surface concentrations corresponding to different boron-rich layer compositions can explain the "anomalous" decrease of the amount of boron entering the silicon, which is observed in particular experimental conditions. In this evaluation both the strong concentration dependence of the boron diffusion coefficient and the translation of the BRL-Si interface have also been taken into account. Finally the rate-determining steps of the transfer of boron into silicon are discussed.

Boron is the p-type dopant most often used in silicon planar technology. The predeposition process, in spite of the many investigations carried out (1-12), still presents several important features not completely explained and interpreted.

It is well known (3-8) that in the usual working conditions a boron-rich layer (BRL), insoluble in HF, grows at the interface between boron silicate glass (BSG) and silicon. Notwithstanding the poor knowledge of the composition of the BRL, it has frequently been reported in the literature that the boron surface concentration in silicon, in the presence of this phase, is the solubility one (2-5, 12, 13).

Recently Armigliato *et al.* (14), by x-ray analysis performed on BRL specimens, clearly demonstrated the presence of SiB_6 as well as some additional interplanar spacings which may be attributed to B_4Si and B_6O. They conclude that the BRL consists of a mixture of phases and show that the boron surface concentration in silicon is markedly higher than the solubility value.

In this work we study the predeposition of boron in silicon for different times, temperatures, and doping gas partial pressures. The experimental conditions leading at the formation of the BRL are determined and the rate-determining steps of the doping process are discussed.

Experimental Procedure

Dislocation-free (111) oriented, phosphorus-doped, Czochralski-pulled silicon of nominally 1 Ω-cm has been used in our experiments. Slices were about 300 μm thick and mirror finished on one side.

Predepositions have been carried out at 900°, 1000°, 1050°, and 1100°C using a BBr_3 source kept at 24°C. High purity nitrogen was bubbled through the liquid boron tribromide source, and then, before entering the furnace, it was mixed with the main carrier gas which consisted of a mixture of variable amounts of nitrogen and oxygen. The apparatus and the procedures are described in a previous paper (15).

The predeposition cycle consisted of a 5 min preheating (N_2 plus O_2 flowing) followed by deposition for a given time, t_d, (BBr_3, N_2, and O_2 flowing), and by a final 3 min flush (N_2 plus O_2 flowing). A set of predepositions has been performed changing the partial pressure of oxygen, and another set changing that of the boron tribromide. In all cases the total gas flow was kept constant (2500 ml/min) by adjusting the main nitrogen flow.

The thicknesses of BSG and BRL formed during the predeposition cycles were accurately measured by a Talystep by making at least ten determinations for each specimen.

After predeposition, the BSG was etched with dilute HF, while the BRL was removed by boiling the slices in nitric acid or by anodic oxidation. The last technique makes possible a selective etching of the BRL to form the step necessary for the thickness measurement. The anodic oxidation was carried out at a constant current value and using as electrolyte a solution of 900 ml of ethylene glycol, 100 ml of H_2O, and 5g of KNO_3. Typical behavior of the experimental voltage *vs.* oxidation time relationship for samples with and without the BRL is shown in Fig. 1. When no BRL is present, the voltage drop across the growing SiO_2 layer is added to the voltage drop V_o due to the resistance of the electrolyte and of the silicon slice. In the presence of the BRL, this layer is first oxidized with formation of a compound soluble in the electrolyte, so that no increase of the voltage drop takes place during this time. The sudden growth of the voltage indicates the entire removal of the BRL and the beginning of the oxidation of the silicon below.

Sheet resistance, ρ_s, was measured by the four-point probe technique; five distinct determinations were made on each specimen.

Boron doping profiles were determined by successive anodic oxide stripping followed by Hall and resistivity measurements, using a Van der Pauw geometry. The total amount, Q, of boron entered into the

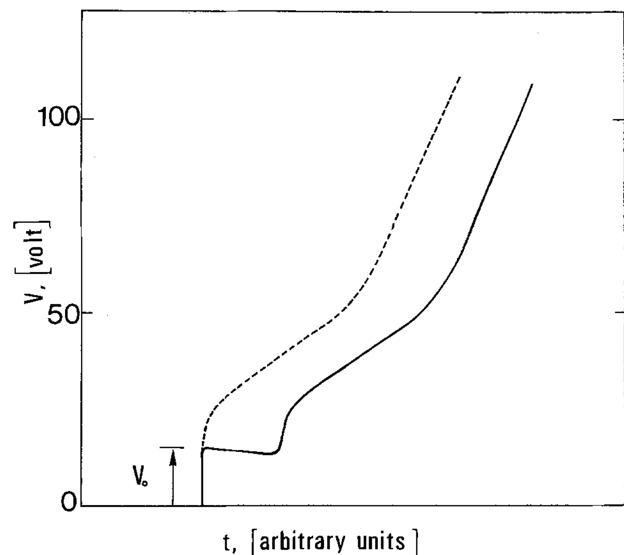

Fig. 1. Experimental voltage vs. time relationship during anodic oxidation. Continuous line refers to a sample with BRL.

[1] Present address: SGS-ATES, Agrate B. (Milano) Italy.

Key words: silicon, boron tribromide, boron predeposition, boron-rich layer.

silicon has been accurately determined in some cases by integration of the doping profiles. However, as this method is tedious and time consuming, a sufficiently accurate Q value can also be obtained more easily from the measured sheet resistance by the relationship

$$Q = \frac{1}{e \cdot \mu_{eff} \cdot \rho_s} \quad [1]$$

where e is the electronic charge and μ_{eff} the "effective mobility" of the boron-doped layer defined in Ref. (15). In all the measured predeposition profiles values of μ_{eff} very close together ($\mu_{eff} = 43.8 \pm 1.6$ cm^2/V·sec) have been ascertained. Therefore, a linear relationship between Q and $1/\rho_s$, with accuracy better than 4%, could be established for a broad range of values. A similar result has also been obtained by Allen (16).

Finally the predeposited specimens have been examined by transmission electron microscopy (TEM) in order to verify the eventual presence of boron precipitates.

Experimental Results and Discussion

Doping dependence on gas composition.—The amount of boron, Q, introduced into silicon during predepositions performed at 900°, 1000°, 1050°, and 1100°C is reported in Fig. 2 and 3 as a function of oxygen concentration. Boron tribromide partial pressure (0.04%) and predeposition cycle (5 + 20 + 3 min) were kept constant.

At 900°C, for the gas composition range considered, Q is quite insensitive to the oxygen percentage. At this temperature we have low oxidation rate and large deposition of B_2O_3, since its vapor pressure increases greatly with temperature (17). Thus the BSG consists largely of B_2O_3 and it is, in fact, partially dissolvable in H_2O. All the samples were covered with a thin BRL detectable by the hydrophilic behavior of the surface.

Conversely, Q is a sensitive function of the oxygen content at 1000°C; in particular, when the oxygen concentration is higher than about 8%, no BRL

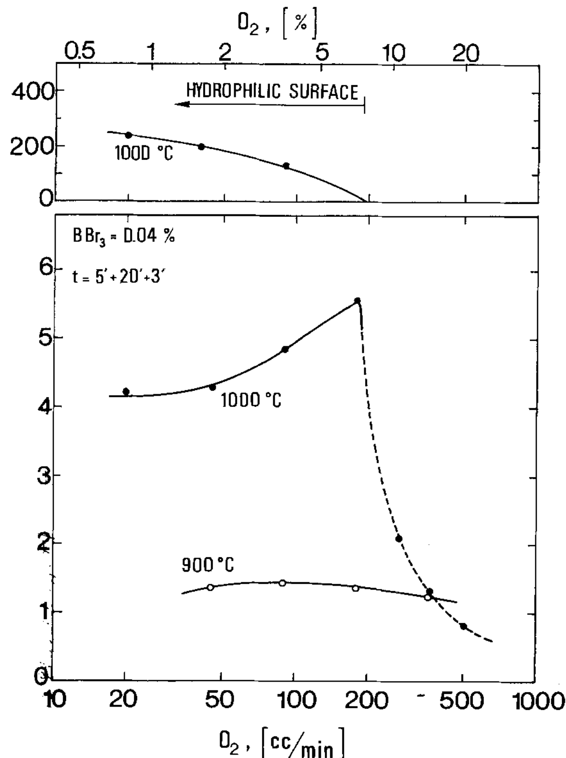

Fig. 2. Amount of boron, Q, and BRL thickness, X_{BRL}, vs. oxygen concentration for predepositions performed at 900° and 1000°C. BBr_3 concentration (0.04%) and deposition time (20 min) are kept constant. Dotted line means lack of BRL.

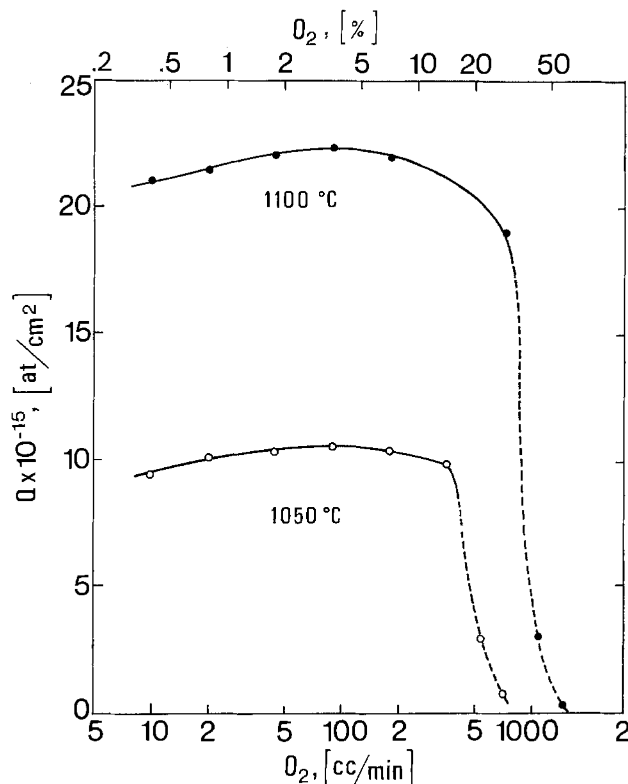

Fig. 3. Amount of boron, Q, vs. oxygen concentration for predepositions carried out at 1050° and 1100°C. BBr_3 concentration (0.04%) and deposition time (20 min) are kept constant. Dotted line means lack of BRL.

grows: In these conditions the doping, which is limited by B_2O_3 diffusion through the boron glass (5), considerably decreases when the oxygen concentration increases. For oxygen concentrations lower than about 8% we observe the formation of the BRL with thickness which increases as the oxygen concentration decreases. In spite of the presence of the BRL, Q is not a constant, but decreases with the increase of the BRL thickness.

The same qualitative behavior is obtained at temperatures of 1050° and 1100°C. For oxygen concentration higher than 14 and 29%, respectively, no BRL forms and Q greatly decreases when the O_2 percent increases. At lower oxygen partial pressures the BRL grows on the silicon surface reducing the dependence of Q on the gas composition. However we can again observe that Q is not kept constant by the presence of the BRL.

At temperature of 1000°C, where this phenomenon is more marked, the dependence of Q and of the BRL thickness, X_{BRL}, on boron tribromide concentration has also been studied. Figure 4 shows these results for predeposition carried out with a cycle of 5 + 20 + 3 min for two different oxygen concentrations (7.2 and 1.8%). With higher oxygen content Q increases with the BBr_3 concentration until the BRL starts to grow on the sample surface; then a further increase in the doping gas leads to an increase in X_{BRL} and to a decrease in Q. With lower oxygen concentration the BRL forms on all the specimens and its thickness greatly increases with BBr_3 percent while Q decreases.

Also in this case the presence on the silicon surface of the BRL does not provide a constant value of Q. A similar behavior has been reported in the literature (5, 12), but it has not been clearly explained.

Finally, as has been previously observed by other authors (3, 6), we have found that predepositions carried out in the conditions which give rise to the formation of the BRL, are more reproducible. From several experiments we have deduced that the fractional standard deviation

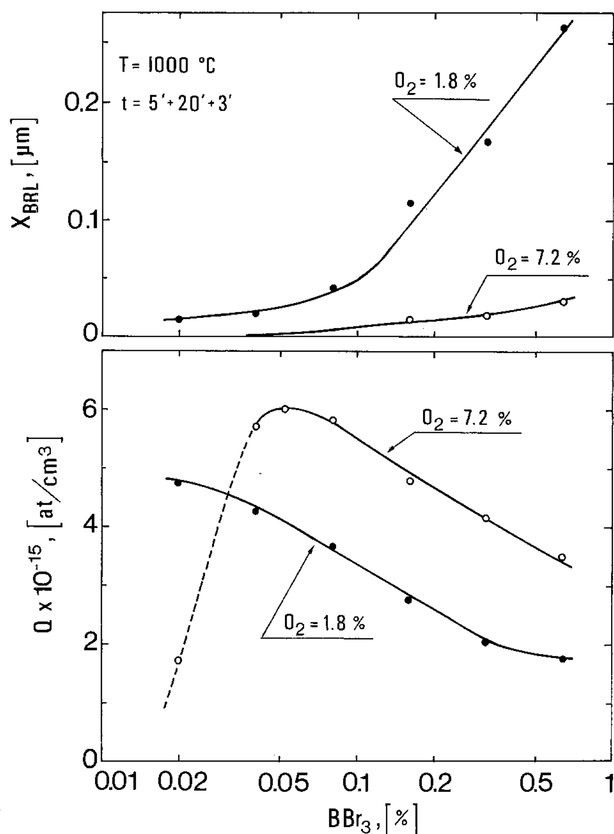

Fig. 4. Amount of boron, Q, and BRL thickness, X_{BRL}, vs. BBr_3 concentration for 20 min predepositions at 1000°C.

$$\sigma = \frac{1}{\overline{X}} \sqrt{\frac{\sum_{i\ j}^{n} (\overline{X} - X_j)^2}{n - 1}}$$

for different predepositions, carried out in the same conditions, was about 4% when the BRL grows and higher than 10% when the BRL is not present.

Doping dependence on predeposition time.—Figure 5 shows the value of Q as a function of predeposition time, t ($t = t_d + 3$ min; *i.e.*, deposition time plus 3 min flush time) for processes performed at

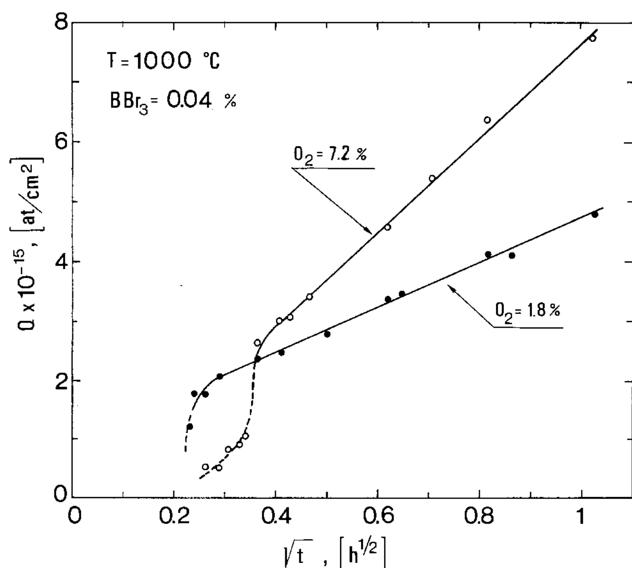

Fig. 5. Amount of boron, Q, vs. time (deposition time plus 3 min flush time) for predepositions carried out at 1000°C with 0.04% BBr_3. Dotted line means lack of BRL.

1000°C with 0.04% BBr_3 and two different oxygen concentrations, 1.8 and 7.2%, respectively. In both cases, after an initial transient, Q grows linearly with the square root of time.

A simple analysis of these data suggests that the surface concentration of boron in silicon, notwithstanding the presence of the BRL, is different for the two oxygen concentrations. In fact, the solution of the diffusion equation, considering the BRL as an infinite source, is (18)

$$Q = C_s \frac{2}{\sqrt{\pi}} \sqrt{Dt} \qquad [2]$$

where C_s is the surface concentration and D is the boron diffusion coefficient, both assumed to be constant.

Equation [2] gives a linear behavior of Q with $\sqrt{t}$, and the slope is proportional to the surface concentration.

The initial transient of Q is related to the presence of the BRL. In fact, if during the deposition time a layer of this phase forms on the slice surface, boron also keeps entering into the silicon during the 3 min flushing time. With an oxygen concentration of 1.8%, the BRL forms in a very short time (~0.5 min), while, with an oxygen concentration of 7.2%, the BRL formation is delayed (~3.5 min) by the silicon oxide grown during the preheating time and by the faster oxidation process occurring during predeposition.

Boron surface concentration.—Results presented in Fig. 2 and 4 show a decrease of Q when increasing X_{BRL} for predepositions carried out in the same conditions of time and temperature. Stach and Turley (9) ascribe this behavior to the displacement of the interface BRL-Si toward the bulk, as a consequence of the silicon consumption resulting from the formation of the surface phase. The contribution of this phenomenon, surely present, can be evaluated by solving the diffusion equation in a semi-infinite medium with a moving boundary. The solution in this case yields (19)

$$C(x) = (C_s/2) \left[\text{erfc} \left(\frac{x + \alpha \cdot X_{BRL}}{2\sqrt{Dt}} \right) + \exp \left(- \frac{\alpha \cdot X_{BRL} \cdot x}{Dt} \right) \cdot \text{erfc} \left(\frac{x - \alpha \cdot X_{BRL}}{2\sqrt{Dt}} \right) \right] \qquad [3]$$

where $\alpha \cdot X_{BRL}$ is the fraction of silicon consumed by the formation of a thickness X_{BRL} of the surface phase. By numerical integration of Eq. [3] the total amount of boron in silicon as a function of X_{BRL} is obtained. These results, together with the experimental behavior obtained from the data reported in Fig. 4, are shown in Fig. 6. The calculations have been performed with the hypothesis that the BRL consists of SiB_6 ($\alpha = 0.31$) and with the limiting case in which the consumed silicon is equal to the thickness of the BRL ($\alpha = 1$). From the plot it appears that this phenomenon aids in diminishing Q, but it cannot explain our experimental results.

Brown and Kennicott (12) observed the same phenomenon using a low temperature CVD deposited BSG as a source. They interpreted this behavior by assuming that a sudden lowering in the boron diffusivity takes place when the surface concentration reaches the solubility value. This effect was associated with a change of BSG properties which causes a reduction of the stress induced in the silicon crystal. This hypothesis, however, does not explain the results of Fig. 5 (Q *vs.* $\sqrt{t}$), where a different behavior for the samples processed at different O_2 partial pressures is also observed after the BRL formation.

We believe that in our case the phenomenon can be ascribed to the different value assumed bv the boron surface concentration in contact with a BRL of different composition.

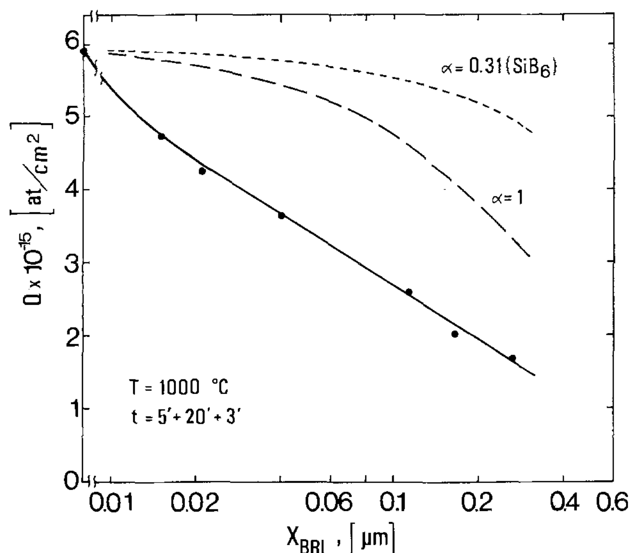

Fig. 6. Amount of boron, Q, vs. BRL thickness, X_{BRL}, for predepositions carried out at 1000°C for 20 min. The theoretical curves (dotted and broken line) are obtained by numerical integration of Eq. [3] with $\alpha = 0.31$ and $\alpha = 1$, respectively. Experimental data are obtainable from Fig. 4.

Accurate analysis of the chemical composition of the BRL carried out by Rutherford backscattering (20) and x-ray microanalysis (21) on samples processed at 1000°C with different doping gas compositions (the same conditions as Fig. 4) have clearly shown the presence of three elements: boron, silicon, and oxygen. The atomic percent of these elements is a function of the process conditions: In all the examined cases the percentage of boron is the prevailing one and is greater than 70 atom percent (a/o); this value increases up to about 80 a/o as the BBr_3 partial pressure increases. Oxygen and silicon range from 4 to 15 a/o and from 14 to 20 a/o, respectively. These analyses, together with the x-ray diffraction observations (14), lead to the conclusion that the BRL is formed by a mixture of several compounds and not by the conjugate phase of the Si-B system (B_4Si). Consequently, the boron concentration at the silicon surface is not the one corresponding to solid solubility and may change with the BRL composition.

In order to verify hypotheses, in Fig. 7 are reported the measured doping profiles of specimens processed at 1000°C for 20 min with different doping gas and, consequently, different BRL compositions. Profiles (a) and (c) refer to situations of high Q with thin BRL and low Q with thick BRL, respectively, while (b) represents an intermediate case. It appears from these results that there is an appreciable difference in the boron surface concentrations certainly higher than the uncertainty which affects the measurements ($C_s(a) = 2.7 \times 10^{20}$ cm^{-3}; $C_s(b) = 2.5 \times 10^{20}$ cm^{-3}, and $C_s(c) = 1.85 \times 10^{20}$ cm^{-3}).

We notice that in all cases the surface concentration is higher than solubility value [1.2×10^{20} atoms/cm^3 at this temperature (14)]. This is due to the presence of SiB_6 in the BRL; in fact the chemical potential of the solute associated with the second intermediate phase (SiB_6) must be higher than that corresponding to the equilibrium between the primary solid solution and its conjugate phase (B_4Si); therefore boron concentration in silicon is increased above the solubility value.

Studies on the kinetics of nucleation and precipitation of boron in silicon confirm that in the conditions of time, temperature, and oversaturation typical of a predeposition process, the nucleation of the conjugate phase B_4Si is hindered (14). Moreover, lack of precipitation has been confirmed by TEM observations on samples treated in the same experimental conditions as the one of Fig. 7.

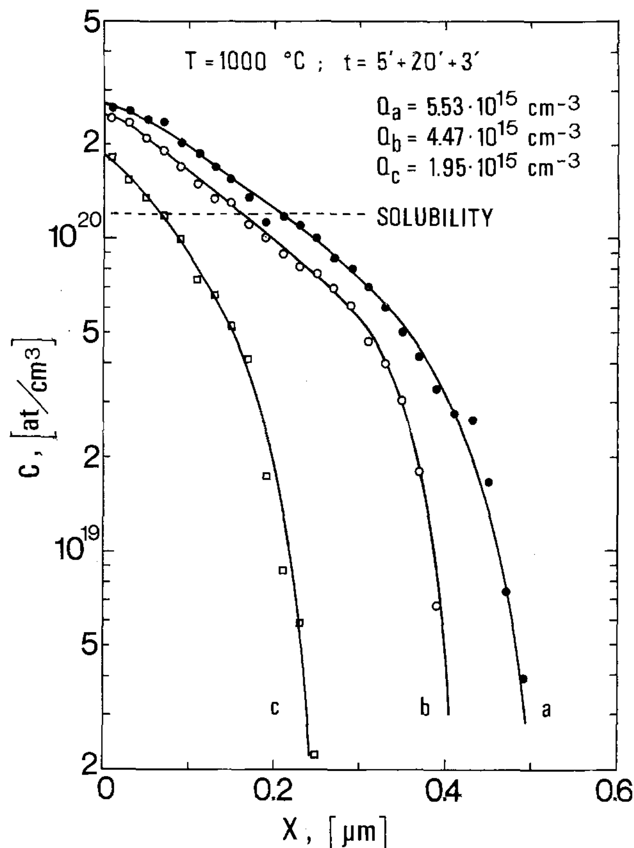

Fig. 7. Boron concentration profiles in silicon predeposited at 1000°C for 20 min. Gas composition: (a) 7.2% oxygen, 0.04% BBr_3, $X_{BRL} \leq 50$Å; (b) 1.8% oxygen, 0.04% BBr_3, $X_{BRL} = 210$Å; (c) 1.8% oxygen, 0.32% BBr_3, $X_{BRL} = 1600$Å. Solubility value is also reported in Ref. (14).

The observed differences in the surface concentration can explain the different values of Q provided that the dependence of boron diffusion coefficient on concentration is taken into account.

With reference to profiles (a) and (c), and assuming a linear dependence of D on concentration, as proposed by Fair (22), it can be shown that

$$\frac{Q(c)}{Q(a)} = \left[\frac{C_s(c)}{C_s(a)}\right]^{3/2} = 0.57 \quad [4]$$

If one assumes the concentration dependence of D proposed by Thai (23) and subsequently modified by Jain and Overstraeten (24), a ratio $Q(c)/Q(a) \simeq 0.47$ is obtained. Adding to this effect the further decrease of Q due to the displacement of the BRL-Si interface we can explain the experimental ratio $Q(c)/Q(a) = 0.36$, resulting from the profiles reported in Fig. 7.

Finally we point out that changes of boron surface concentration in presence of BRL are very small with respect to the ones observed when the surface phase is not present: In fact, in order to have a reduction of 30% in C_s it has been necessary to increase by an order of magnitude the BBr_3 concentration.

Summary and Conclusions

This work presents the results of an experimental investigation of the boron predeposition in silicon carried out for different times, temperatures, and gas composition.

The formation of the BRL on silicon samples is favored by the decrease of the oxygen and/or the increase of the BBr_3 partial pressure.

The rate-determining step of the boron predeposition process may be summarized as follows:

(*i*) *BRL not present.*—The amount of boron available at the BSG-Si interface completely penetrates

into the silicon and the rate-determining step is the diffusion of B_2O_3 through the boron glass (5). Reproducibility and uniformity of the process depend largely on the oxygen and boron tribromide concentrations in the furnace.

(*ii*) *BRL present.*—Q is limited by the diffusivity of boron in silicon and by its surface concentration. This concentration, which is not the solubility one, changes with the composition of the BRL. However the process is repeatable since the changes of C_s with doping gas composition are small.

The different values of Q obtained by predeposition carried out with the same time and temperature can be quantitatively explained by the change in C_s, if the large concentration dependence of the boron diffusion coefficient and the translation of the BRL-Si interface are considered.

On the Electrical Properties of Cuprous Iodide

T. Jow* and J. Bruce Wagner, Jr.*,[1]

Materials Research Center and Department of Materials Science and Engineering, Northwestern Universtiy, Evanston, Illinois 60201

ABSTRACT

The electrical properties of single and polycrystalline CuI have been studied using the a-c method for CuI equilibrated with copper and C. Wagner's d-c polarization cell. Values for the total conductivity, electron hole conductivity, transference number for Cu^+ and electron holes, the diffusivity of electron holes, and double layer capacitance at the CuI-graphite interface were obtained.

The electrical conductivity of cuprous iodide has been measured by various authors (1-6). Cuprous iodide is a predominantly ionic conductor at temperatures above 300°C (2). Its conductivity greatly depends on the small deviation from the ideal metal-to-nonmetal ratio (2, 5). The excess conductivity is due to hole conduction induced by the excess iodine (1, 4-5).

Hebb (7) first pointed out that it is possible to suppress either the ionic or the electronic transport in galvanic cells by an appropriate choice of the electrodes and to deduce the partial conductivity of the migrating particles from the quotient of the current density and the potential gradient. C. Wagner (8) established the d-c asymmetric cell (or d-c polarization cell) measurement for the determination of the partial electronic conductivity in a predominantly ionic conductor by evaluating the steady-state current-voltage relation. This method has been utilized on cuprous halides (9, 10), silver halides (11-13), lead halides (14-16), calcia stabilized zirconia (17), etc.

In addition to steady-state polarization cell measurements, unsteady-state or transient polarization cell measurements have been used to study the kinetic properties of the electrode (18-20), the electrolyte (10, 21), and the interfacial phenomena (21, 22) between the electrolyte and the electrode. In the present study, an ion-blocking electrode (graphite) was used as the electrode. Because of virtually no solubility of copper in the graphite electrode, the kinetics of copper ion diffusion into the graphite electrode are not considered.

Raleigh (22, 23) first used the potentiostatic technique on a polarization cell to study the double layer

* Electrochemical Society Active Member.
[1] Present address: Center for Solid State Science, Arizona State University, Tempe, Arizona 85281.
Key words: electrical conductivity, transference number, double layer capacitance, electron hole diffusivity.

capacitance of AgBr against the blocking electrode. Weiss (21) measured the voltage relaxation in a polarization cell to obtain the diffusivity of the electrons in AgBr. Joshi and Wagner (10) combined the d-c steady-state and the aforementioned unsteady-state measurement methods of the polarization cell to obtain the partial conductivity, mobility, and concentration of electron holes in cuprous chloride.

The purpose of the present study on cuprous iodide is to use d-c steady-state measurements to obtain the partial electronic conductivity of cuprous iodide and transient measurements to obtain the diffusivity of the electronic carriers in cuprous iodide, and the double layer capacitance at the interface between the cuprous iodide and the blocking electrode.

Theory

Steady-state polarization cell measurements.—Wagner's polarization cell (8) of the following configuration

$$(-)\ \mathrm{Cu}\ |\ \mathrm{CuI}\ |\ \mathrm{graphite}\ (+) \qquad \text{(I)}$$
$$x=0 \quad x=L$$

was used to measure the electronic conductivity of the mixed conductor, CuI.

The steady-state current passed through cell (I) with a positive d-c potential, E, which is smaller than the decomposition potential of CuI, applied on the graphite electrode consists of only electronic current. The equation for this current as a function of the applied potential has been derived by C. Wagner (8). When $\sigma_\oplus >> \sigma_\ominus$ and $EF/RT >> 1$, Wagner's equation may be expressed by (9, 10)

$$I_e = I_\oplus = (ART/L\mathbf{F})\ \sigma_\oplus{}^\circ \exp\left(\frac{E\mathbf{F}}{RT}\right) \qquad [1]$$

where I_e = electronic current at steady state; $I_\oplus$ = electronic current due to electron holes; A = cross-sectional area of the electrolyte (assumed constant and the same as the interface area of the electrodes); $\sigma_\oplus{}^\circ$ = electronic conductivity due to electron holes in CuX equilibrated with Cu; and the other terms have their usual significance. $\sigma_\oplus{}^\circ$ can thus be determined from a plot of log I_e *vs.* the polarization potential E. Equation [1] was derived under several assumptions which are discussed in Ref. (8). In the derivation of Eq. [1], the band bending and any interfacial effects are neglected.

Unsteady-state or transient polarization cell measurements.—When a potential E_1 is applied to the polarization cell (I) with the positive potential on the graphite electrode, the activity of copper partial pressure of iodine at the blocking electrode ($x = L$) are fixed electrochemically by the potential. They are given by

$$a_{\mathrm{Cu}} = \exp(-E_1\mathbf{F}/RT) \qquad [2]$$

$$P_{\mathrm{I_2}} = \exp[-2(E_d - E_1)\mathbf{F}/RT] \qquad [3]$$

where E_d is the decomposition potential of CuX. Since copper halides are p-type conductors (9, 24), the electron hole concentration at the blocking electrode ($x = L$) can be expressed as follows (8)

$$c_\oplus{}^1 = c_\oplus{}^\circ \exp(E_1\mathbf{F}/RT) \qquad [4]$$

where the superscript 1 denotes "under potential E_1," and $c_\oplus{}^\circ$ is the electron hole concentration in cuprous iodide coexisting with copper. The steady-state electron hole distribution at E_1 can be expressed as

$$c_\oplus(x) = c_\oplus{}^\circ + (c_\oplus{}^1 - c_\oplus{}^\circ)x/L, \quad 0 \leq x \leq L \qquad [5]$$

A transient response or the unsteady state of the polarization cell is achieved either by the "potentiostatic method" (22, 23), *i.e.*, the applied voltage is changed abruptly from E_1 to E_2 where E_2 is a new value of the applied potential and observing the change of current with time, or by the "voltage relaxation method" (21) in which the polarized potential E_1 is switched off suddenly and the change of the open-circuit potential of the cell with time is observed.

The phenomena of these two methods have been discussed rather extensively in Ref. (10). The main results are mentioned in the following sections.

Potentiostatic method.—When there is an abrupt change in applied potential on cell (I) from E_1 to E_2, a transient current flows corresponding to kinetic processes which are required to repolarize the cell at the newly fixed potential. The reasons (10, 25-27) for the occurrence of this unsteady-state current may consist of: the solid electrolyte-solid electrode interfacial double layer capacitance existing at CuX and graphite interface; redistribution of electrons and electron holes inside the electrolyte; or copper diffusion into the graphite electrode.

A typical transient current-time profile for a potential step from E_1 to E_2 is shown schematically as in Fig. 1 $I_\oplus(E_1)$ and $I_\oplus(E_2)$ are the initial and final currents at steady states under potentials E_1 and E_2, respectively. I_0 is the initial peak current. (In the present study, the current due to copper diffusion into the graphite electrode is too small to be considered.)

For a pure capacitance, the decay of the charging current should obey

$$I(t) = I_0 e^{-t/RC} \qquad [6]$$

where I_0 is the initial peak current, R is the total resistance, and C is the capacitance. Raleigh (22, 23, 28) has studied double layer capacitance in silver halide polarization cells rather extensively. He attributed double layer capacitance as an intrinsic property existing between solid ionic and solid electronic conductors. He found that the decay of the double layer capacitance charging current generally does not show one single decay constant (29).

The current-time relation due to redistribution of electron holes for a potential step changing from E_1 to E_2 can be obtained by solving Fick's second law

$$\frac{\partial c_\oplus}{\partial t} = \tilde{D}_\oplus \frac{\partial^2 c_\oplus}{\partial x^2} \qquad [7]$$

with the following initial and boundary conditions

$$c_\oplus(x) = c_\oplus{}^\circ + (c_\oplus{}^1 - c_\oplus{}^\circ)x/L \quad t = 0, \quad 0 \leq x \leq L \qquad [8]$$

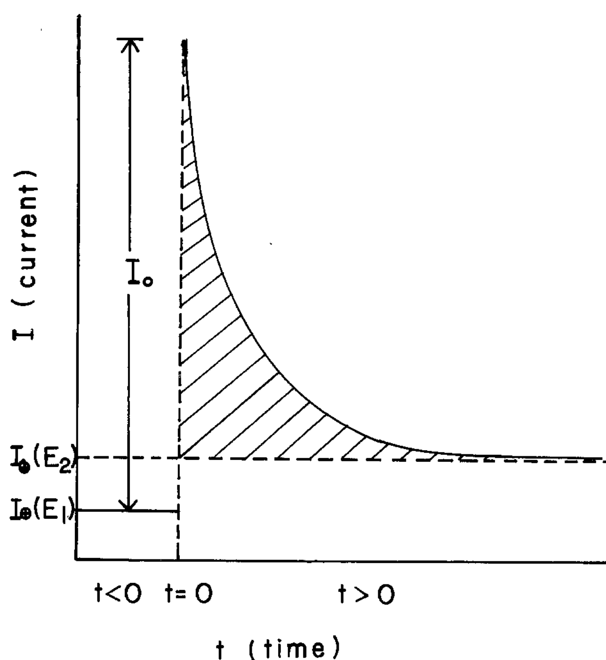

Fig. 1. Schematic current-time profile for a potential step from E_1 to E_2 in a (—)Cu|CuI|Graphite(+) polarization cell.

$$c_{\oplus} = c_{\oplus}^{\circ} \quad \text{at} \quad x = 0, \quad t \geq 0 \qquad [9]$$

$$c_{\oplus} = c_{\oplus}^{2} \quad \text{at} \quad x = L, \quad t \geq 0 \qquad [10]$$

where $c_{\oplus}^1$ and $c_{\oplus}^2$ can be obtained by using Eq. [4] and the superscripts 1 and 2 refer to the concentrations of electron holes in CuI at the blocking electrode under E_1 and E_2, respectively.

The current due to electron holes at $x = L$ for the semi-infinite rod, or the short-time solution (30) has the following form

$$I(t)|_{x=L} = \frac{A}{\sqrt{\pi \tilde{D}_{\oplus}}} (RT/\mathbf{F}) \sigma_{\oplus}^{\circ} t^{-1/2} (e^{E_2\mathbf{F}/RT} - e^{E_1\mathbf{F}/RT}) + I_{\oplus}(E_2) \qquad [11]$$

where $\sigma_{\oplus}^{\circ} = \mu_{\oplus} e c_{\oplus}^{\circ}$ and $\tilde{D}_{\oplus} = \mu_{\oplus} RT/\mathbf{F}$ were used.

But the current for the finite length L (31) can be expressed as follows for $x = L$

$$I(t)|_{x=L} = I_{\oplus}(E_2) + 2[I_{\oplus}(E_2) - I_{\oplus}(E_1)] \sum_{1}^{\infty} e^{-\tilde{D}_{\oplus} n^2 \pi^2 t/L^2} \qquad [12]$$

and the current at $x = 0$ is

$$I(t)|_{x=0} = I_{\oplus}(E_2) + 2[I_{\oplus}(E_2) - I_{\oplus}(E_1)] \sum_{1}^{\infty} (-1)^n e^{-\tilde{D}_{\oplus} n^2 \pi^2 t/L^2} \qquad [13]$$

From the semi-infinite rod solution Eq. [11], the slope of $I(t)$ *vs.* t plot is independent of the thickness of the electrolyte but depends on the initial and final potentials, E_1 and E_2.

Equations [12] and [13] can be approximated by retaining the first term of the infinite series if $t > L^2/\tilde{D}_{\oplus}\pi^2$. Thus

$$I(t)|_{x=L} \cong I_{\oplus}(E_2) + 2[I_{\oplus}(E_2) - I_{\oplus}(E_1)] e^{-\tilde{D}_{\oplus} \pi^2 t/L^2} \qquad [14]$$

$$I(t)|_{x=0} \cong I_{\oplus}(E_2) - 2[I_{\oplus}(E_2) - I_{\oplus}(E_1)] e^{-\tilde{D}_{\oplus} \pi^2 t/L^2} \qquad [15]$$

Accordingly, the unsteady current due to redistribution of electron holes at $x = L$ changes from a value higher than steady state to that at steady state. At $x = 0$, it changes from a value lower than steady state to that of the steady state.

Voltage relaxation method (10, 21, 30).—Consider the polarization cell (I) under a potential E_1 at steady state. When the potential is removed from the cell, the open-circuit potential $\Delta V(t)$ of the cell will change with time according to the equation

$$\Delta V(t) = \frac{RT}{\mathbf{F}} \ln \left[\frac{c_{\oplus}(t)}{c_{\oplus}^{\circ}} \right] \qquad [16]$$

where $c_{\oplus}(t)$ is the concentration of holes at the CuI|graphite interface which decreases with time because of the diffusion process inside the electrolyte (the double layer capacitance existing at the CuI|graphite interface is assumed negligible).

By substituting $c_{\oplus}(t)$ which can be obtained by solving Fick's second law with proper boundary conditions into Eq. [16], a relation of $\Delta V(t)$ with t is obtained as follows (30)

$$\tilde{D}_{\oplus} t = -\frac{4L^2}{\pi^2} \ln \left\{ \frac{\pi^2}{4} \frac{\exp\left(\frac{\Delta V(t)\mathbf{F}}{RT}\right) - 1}{\exp\left(\frac{E\mathbf{F}}{RT}\right) - 1} \right\} \qquad [17]$$

Therefore, if $t > 4L^2/\pi^2\tilde{D}_{\oplus}$ a plot of log [exp $(\Delta V(t)\mathbf{F}/RT) - 1$] *vs.* t should yield a straight line. This method can be used to test the significance of any interference from the double layer capacitance at the CuI|graphite interface by using electrolytes with different thicknesses since the rate of the voltage relaxation is inversely proportional to the square of the thickness of the electrolyte.

Experimental

A single crystal pellet of CuI was obtained from Professor C. Schwab of the Universite de Strasbourg. It was sectioned, polished, and washed successively in acetone, dilute HCl, and acetone. The Cu|CuI|graphite cell was then assembled in a spring-compressed mounting.

The two different length pellets (0.17 and 0.53 cm) used in voltage relaxation measurements were prepared by pressing the CuI powder at 75,000 psi in a 5/16 in. steel die. Alfa ultrapure anhydrous CuI powder (99.998%) was used without further purification. The freshly pressed pellets were then mounted in a double polarization cell (25, 30). The double cell was then heated at 440°C for one day under 1 atm of purified flowing argon. Table I shows the spark source mass spectrometric analysis of the crystal and of the powder samples.

The density of the pressed pellets was about 95% of theoretical as determined by measuring the dimensions and weighing. Copper (99.999%) rod from American Smelting and Refining Company was used as the reversible electrode. Pyrolytic graphite from Union Carbide was used as the blocking electrode. A resistance furnace was used in a horizontal position, the cell temperature was controlled by a Research Incorporated Model TC 5192 thermac controller and AMBAC Brute II d.c. power supply. A Chromel-Alumel thermocouple which was calibrated by the phase transitions of CuI was used to monitor the cell temperature. The principle of the circuit for applying the voltage steps to the cells is the same as that of Joshi and Wagner (10).

[a] No determination was made for hydrogen. Determinations of tantalum and gold were not made since tantalum slits are used in the mass spectrometer and the samples were sparked against high purity gold counterelectrodes. Residuals in the mass spectrometer interfere with the determinations of O, Te, and Hg. Background lines interfere with the detection of N. Other impurities not listed were undetected and have concentrations less than 0.1 ppm atomic except for zinc. Because of interfering background lines, the detection limit for zinc is 2 ppm by weight.

[b] Determined for 3×10^{-7}C exposure.

[c] May be due to residuals in the mass spectrometer.

N.D., not detected.

The d-c input potentials were supplied by Keithley 260 Nanovolt Source. The cell current in response to a voltage step was monitored across various standard resistors using a Tektronic Model 564B storage oscilloscope with a Type 2A63 differential amplifier and Type 3B3 time base for short time periods of 10 sec or less, and an analog-to-digital converter in Data General's Nova 1220 computer for longer time periods. The computer data taking time interval can be 10 msec or integer multiples of it. The applied polarization potential and steady-state cell current were measured by a Doric Model DS-100 digital voltmeter.

The total conductivity of the single and polycrystalline CuI pellets was measured by an impedance bridge (General Radio 1650A) at 1000 Hz on a Cu|CuI|Cu cell. For the voltage relaxation measurements, the open-circuit potentials of the cell were recorded by an X-Y recorder (Ominographic 2000).

Results and Discussion

Steady-state polarization measurements.—The total conductivity σ_{tot} and partial electronic hole conductivity $\sigma_{\oplus}^{o}$ of CuI are shown in Fig. 2. The Arrhenius plot of the total conductivity in γ-phase cannot be fitted into a straight line. This curvature has been discussed by Matsui and J. B. Wagner (32). The electron hole conductivity obtained from C. Wagner's polarization method gradually approaches the total conductivity below 250°C. These samples of CuI exhibited predominantly electronic conduction below 220°C The total conductivity agrees very well with the data of Biermann and Oel (6) and of J. B. Wagner and C. Wagner (9). The activation energies in the three phases inferred from the Arrhenius plot of the logarithms of the total conductivities *vs.* $1/T$ are shown in Table II. The activation energy in γ-phase is calculated from the temperature range of 330°-360°C. The dependence of electronic hole conductivity on temperature of cuprous iodide in the γ-phase can be expressed as

Table II. Activation energies for total conduction in cuprous iodide

Phase	Transition temp. (°C)	Temperature range (°C)	Activation energy (eV)
α	TM 605	402-440	0.09
β	Tr. 405	372-400	0.90
γ	Tr. 369	330-369	2.03

$$\sigma_{\oplus}^{o}(\gamma\text{-CuI}) = 16 \exp\left(\frac{0.44\text{ eV}}{kT}\right) \quad [18]$$

The transference number t_j of a mixed conductor is defined as the ratio of the partial conductivity σ_j to the total conductivity σ_{tot} where j denotes an ionic or an electronic carrier. The transference numbers of cuprous iodide of this study are compared with Tubandt's results (2) in Fig. 3. The larger electronic transference numbers obtained by Tubandt at low temperatures may possibly result from electrolyte surface leakage effects and impurities in his samples.

Plots of log $I_{\oplus}$ *vs.* the applied polarization potential E of cell (I) used to obtain the electronic conductivity, are shown in Fig. 4 and 5. These plots yield a theoretical slope of $\mathbf{F}/2.303\,RT$ in accord with the Wagner's

equation below a certain potential E_o. These slopes deviate from the theoretical values when $E > E_o$. The linear region which exhibits the theoretical slope becomes narrower as temperature decreases for the γ-phase.

Joshi and Liang (16) have proposed a critical potential E_c, where the Wagner equation is only valid when $E < E_e$. They defined E_c by following equation

$$E_c \equiv -\frac{2.303\,RT}{\mathbf{F}}\log\left[\frac{\sigma_\oplus{}^o}{\sigma_{ion}}\right] \qquad [19]$$

The above equation is obtained by equating the electronic hole conductivity at the blocking electrode $\sigma_\oplus{}^o \exp(E\mathbf{F}/RT)$ to the ionic conductivity of the electrolyte σ_{ion}, that is to say that Wagner's equation is valid when $\sigma_\oplus{}^o \exp(E\mathbf{F}/RT) << \sigma_{ion}$. For PbF_2, which was studied by Joshi and Liang (16), the applied polarization potentials that satisfy the Wagner's equation range from 30 to 80% of the critical potential E_c calculated from Eq. [19]. For CuI, the experimentally determined potential E_o (E_o is the highest potential that still satisfies Wagner's equation, *i.e.*, where the slope of log $I_\oplus$ *vs.* E amounts to $\mathbf{F}/2.303\,RT$) is smaller or approximately equal to the critical potential E_c in α- and β-phases. However, in γ-phase, when $E > E_c$, a plot of log $I_\oplus$ *vs.* E still exhibits Wagner's theoretical slope. The comparisons of E_o with E_c for CuI are shown in Table III. These results indicate that Joshi and Liang's criterion is too restrictive for CuI.

The reason for the changed slope of log $I_\oplus$ *vs.* E when $E > E_o$ may be explained as follows. The increasing applied potential on the polarization cell increases the hole concentration at the CuI-graphite interface exponentially with the applied potential (see Eq. [4]). In the derivation of Eq. [4]. Boltzmann statistics (or ideal solution law) is used for the electron holes. But when the hole concentration starts to become comparable to the density of states at the bandedge, Fermi-Dirac statistics instead of Boltzmann statistics should be used. Therefore, the hole concentration no longer increases exponentially with voltage at the previous rate.

Using the value of the hole concentration of CuI equilibrated with copper obtained in this study (see Eq. [11]), the hole concentration at the CuI-graphite interface can be calculated. For example, at 384°C, $c_\oplus{}^o = 5 \times 10^{16}$ cm^{-3}, when $E = 0.38$V, the hole concentration $c_\oplus$ at the CuI-graphite interface is 4×10^{19} cm^{-3}, at $T = 352$°C, $c_\oplus{}^o = 1.2 \times 10^{17}$, when $E = 0.24$V, $c_\oplus$ at the CuI-graphite interface is 1×10^{19} cm^{-3}. However, if we assume that the effective mass of holes in CuI is the mass of electron, the density states of holes can be estimated (33) to be about 8.1×10^{19} cm^{-3} at 384°C; 7.5×10^{19} cm^{-1} at 352°C. Since the calculated hole concentrations at the CuI-graphite interface and the estimated density of states at the bandedge are of the same order of magnitude, we conclude that the failure of the Boltzmann statistics is responsible for the change of the slope at the higher potentials.

The reason that Joshi and Liang's criterion is too restrictive for CuI is because there is a regime in which the hole concentration at the CuI-graphite interface is not large enough to invalidate Boltzmann statistics but large enough such that σ_{ion} is not very much larger than $\sigma_\oplus{}^o \exp(E\mathbf{F}/RT)$.

Table III. Comparisons of E_o with E_c for cuprous iodide

T°C	σ_{tot} $(\Omega\text{-cm})^{-1}$	$\sigma_\oplus{}^o$ $(\Omega\text{-cm})^{-1}$	E_c (V)	E_o (V)	E_o/E_c

Unsteady-state polarization cell measurements.—Current-time relation during the transient state.—A schematic current-time profile for a potential step from E_1 to E_2 was shown in Fig. 1. The peak current I_o represents the total current of the electrolyte. The corresponding initial resistance, R_o, from the potential step $\Delta E = E_2 - E_1$ is the total resistance of the electrolyte. Since the d-c electronic resistance, R_e, is much greater than ionic resistance, R_i, in a predominantly ionic conductor R_o is approximated by R_i. A linear relation is obtained by plotting I_o *vs.* potential step $\Delta E = E_2 - E_1$ with $E_2 > E_1$ and the value of E_1 fixed.

The transient current-time relation plotted as log $[I(t) - I_{\oplus}(E_2)]$ *vs.* t and $[I(t) - I_{\oplus}(E_2)]$ *vs.* $t^{-1/2}$ at $T = 375°C$ are shown in Fig. 6 and 7, respectively. From Fig. 6 one sees that the current decay exhibits multiple relaxation processes rather than one single decay constant. The residual decay current even lasts for a few minutes. The charge transfer contributed by this residual current decay consists of about 50% of the total. This has also been observed by Raleigh (22,

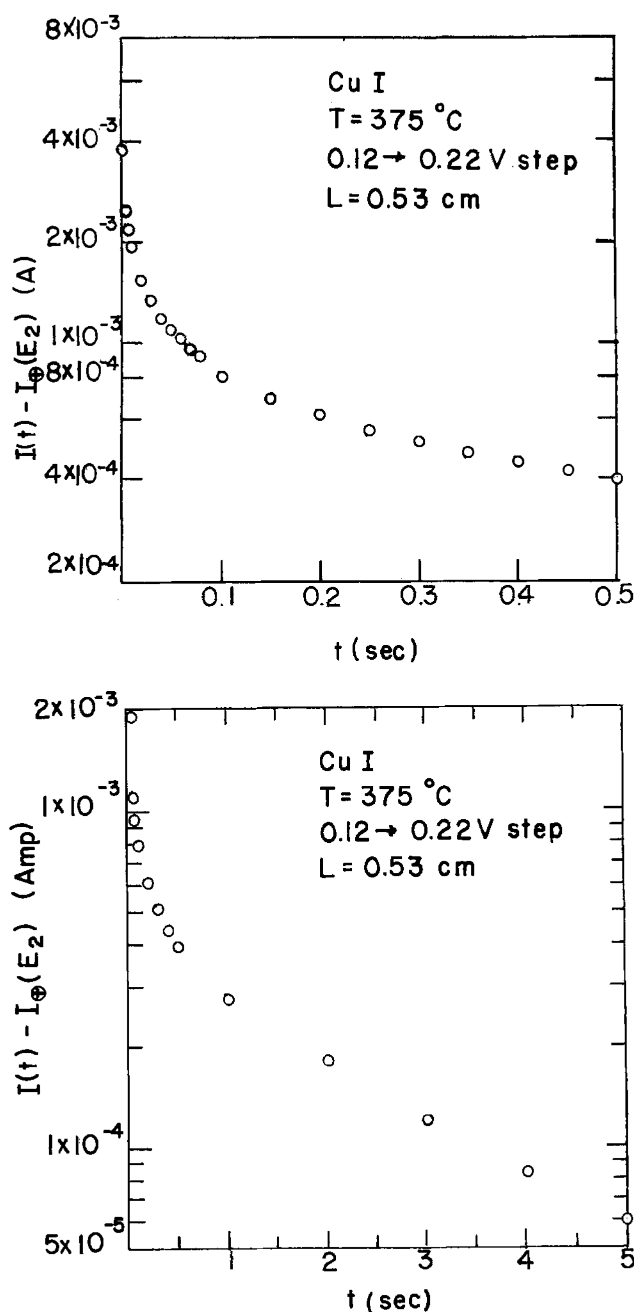

Fig. 6. Plots of log $[I(t) - I_{\oplus}(E_2)]$ vs. t for a potential step from 0.12 to 0.22V for polycrystalline CuI of $L = 0.53$ cm at 375°C.

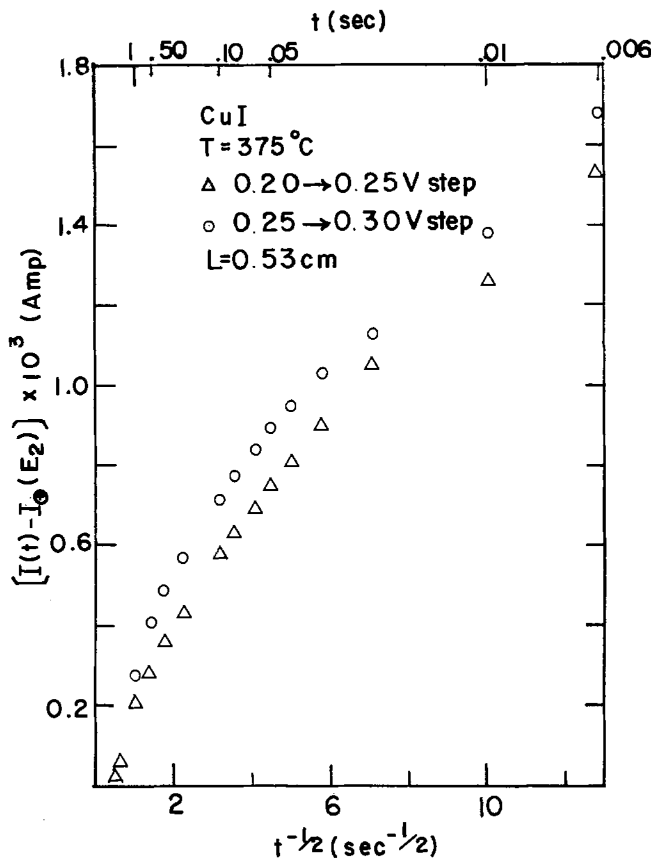

Fig. 7. Plots of $[I(t) - I_{\oplus}(E_2)]$ vs. $t^{-1/2}$ for polycrystalline CuI

23) on the double layer capacitance studies on AgBr polarization cells.

According to Eq. [11], the slope of a plot of the transient current due to redistribution of electron holes *vs.* $t^{-1/2}$ is proportional to $[\exp(E_2\mathbf{F}/RT) - \exp(E_1\mathbf{F}/RT)]$. However, from Fig. 7, the slopes at 0.20-0.25V and 0.25-0.30V voltage steps do not show the relation indicated, since at $T = 375°C$ the slope ratio should be $[\exp(0.30\ \mathbf{F}/RT) - \exp(0.25\ \mathbf{F}/RT)]/[\exp(0.25\ \mathbf{F}/RT) - \exp(0.20\ \mathbf{F}/RT)] \cong 127/52 = 2.4$ according to Eq. [11]. The nonapplicability of the semi-infinite rod solution may be a result from an inevitable interference of the double layer charging current in the short time range and/or the predominant ionic conduction assumption for the solution is no longer satisfied within this voltage range.

In the γ-phase, the electronic conductivity which contributes to the total conductivity is appreciable (see Fig. 2). When the applied potential jumps to a higher value but lower than the decomposition potential E_d, the current-time profile is different from that shown in Fig. 1. This is shown schematically in Fig. 8. The current decays first and then goes up.

The physical situation can be understood as follows. When the d-c potential on a γ-CuI cell is stepped upwards, $E_2 - E_1$ appears across the resistance part of the cell where the cuprous iodide is of the initial stoichiometry which is fixed by E_1. The step current (peak current I_o) corresponds to this voltage step. But because of the capacitive charging effect which is a short-time process, the current will decay as $I_o e^{-t/RC}$. Simultaneously, the current due to the redistribution of electron holes occurs. At short times, the graphite electrode will inject holes into CuI at a rate according to Eq. [11] or [12]. That is also a decaying current. The current at the copper-cuprous iodide interface during transient increases from the initial steady state to the final steady state (see Eq. [13] or [15]). When $\sigma_{\oplus}°$ is appreciable and E is high, the conduction at the cuprous iodide-graphite interface is predominantly electronic. Therefore, the slower upgoing transient

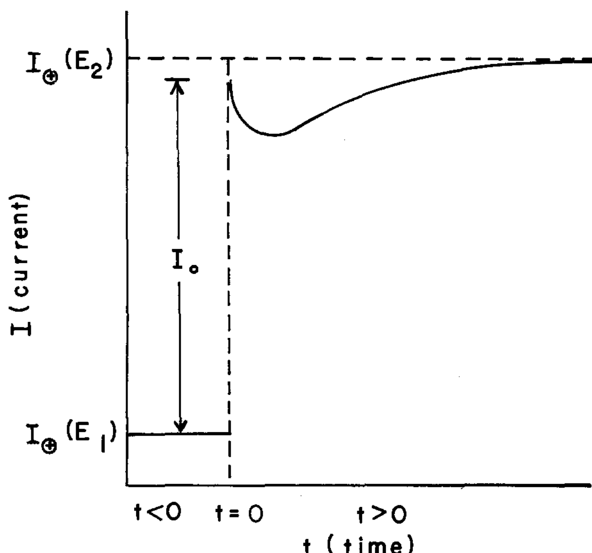

Fig. 8. Schematic current-time profile for a potential step from E_1 to E_2 when E_2 is high for polycrystalline CuI in the γ-phase.

response at the copper-cuprous iodide interface is shown.

Voltage relaxation measurements.—The voltage relaxation $\Delta V(t)$ was recorded after the polarized voltage, 0.2V, was switched off from the cell. Figure 9 shows log [exp $(V(t)\mathbf{F}/RT) - 1$] *vs.* t for the β-phase of CuI. The effective diffusivities of holes, $\tilde{D}_\oplus$'s, were obtained from the slope using Eq. [17]. By the same method, $\tilde{D}_\oplus$'s in a temperature range of 324°-362°C were also obtained. These values are plotted against $10^3/T$°K in Fig. 10.

According to Eq. [17], the ratio of the slopes of log [exp $(\Delta V(t)\mathbf{F}/RT) - 1$] *vs.* t of a long specimen to that of a short specimen is $L^2(\text{short})/L^2(\text{long})$. The slope ratio of samples at 403°C with lengths of 0.53 cm to those of 0.17 cm was calculated as 1/9.2 from Fig. 9 (straight line portion of the curves). The inverse ratio of the square of the thickness of these two specimens is 1/9.7. The agreement between these two ratios is very good. This indicates that the voltage relaxation is a diffusion-controlled process and the interference from the double layer capacitance is negligible.

By using the Einstein relation, $\mu_\oplus = D_\oplus/kT$ and $\sigma_\oplus{}^o = e\mu_\oplus c_\oplus{}^o$, the hole concentration in CuI equilibrated with copper is calculated and is shown in Fig. 11.

Double layer capacitance.—The double layer capacitance was measured at 347°C by applying a voltage step in a very low voltage range (from 10 to 50 mV) to the thin single crystalline sample (0.12 cm). The transient current due to redistribution of holes is minimized and double layer capacitance becomes dominant. The charge was obtained by graphically integrating the current with respect to time from oscillographic pictures. The capacitance was obtained from the slope of the charge transfer Q *vs.* E plot (see Fig. 12). The value was found to be 357 μF/cm^2.

Conclusions

From the steady-state measurements cuprous iodide was shown to be a predominantly ionic conductor in the α- and β-phases and it gradually becomes a predominantly electronic conductor as the temperature decreases in the γ-phase. The log $I_\oplus$ *vs.* E plots satisfied the Wagner theoretical slope for low values of applied potentials. This indicated that the electronic conductivity of cuprous iodide is proportional to the square root of the partial pressure of iodine. At higher applied voltages, the log $I_\oplus$ *vs.* E plots deviate from the Wagner theoretical slope because of the nonideality of the electron holes at high concentrations large applied potential).

The unsteady current-time relation was too complicated to be analyzed by the pure capacitance model and the current due to redistribution of electron holes. Comparing the voltage relaxations of different cuprous iodide sample lengths, the voltage relaxation method has good applicability, and the diffusivities of electron holes at various temperatures were calculated by this method. The double layer capacitance was obtained by measuring the charge transfer in the low voltage range. Its value is about 357 μF/cm² at 346°C.

The Detection of Structural Defects in GaAs by Electrochemical Etching

M. M. Faktor and J. L. Stevenson

Post Office Research Centre, Martlesham Heath, Ipswich, Suffolk, IP5 7RE England

ABSTRACT

Two methods of anodically etching n-GaAs have been investigated. Subsequently they have been used to detect crystallographic defects present in bulk-grown, single crystal material. The first method provides topographical featuring of the semiconductor anode. The selective discrimination of defects achieved via this controlled electrochemical technique is superior to that obtainable from standard chemical etchants. The second dissolution regime, in which an interfacial oxide layer is continuously present, permits smooth, featureless removal of material. Thus a simple two-stage anodization procedure has allowed the damage characteristic of the Beilby layer to be probed. Thereafter, a total, smooth removal of this damaged surface layer permits identification of bulk crystallographic defects—dislocation structures well known in GaAs require the dissolution of only 0.5 μm. Analysis of the semiconductor electrode condition in the electrolytes used for etching has yielded model results. Such analyses have enabled the relationship between the electrical properties of the defected GaAs and the individual topography of the defects as etched to be explored.

The electrochemical characteristics of gallium arsenide and other III-V semiconductors have recently attracted increasing interest. As well as providing a route for an automated electrical assessment of both epitaxial and substrate quality material (1, 2), anodic oxide films have been intensively studied (3, 4), mostly in connection with MOS device applications utilizing GaAs.

The studies reported here have some relation to both of these topics, but are differently aimed overall. It has become increasingly clear in the production of liquid-phase epitaxial GaAs and $Ga_xAl_{1-x}As$ for optoelectronic devices that routine evaluation of the material should center on the crystallographic defect content of the epilayers (5). Some defects act as nonradiative, enhanced recombination centers, which reduce the efficiency of photoabsorptive devices (solar cells) and which degrade and may terminate the efficiency of photoemissive units (lasers) (6). Chemical etching would appear to provide the technically easiest means of defect identification once the etchant has been calibrated (7). However, the current state of the art is inadequate for the purpose indicated. Optical resolution of etch pits in single $Ga_xAl_{1-x}As$ layers has recently been reported by Komiya *et al.* (8) as possible only after the dissolution of 4 μm in a H_2O_2/HF solution. For $GaAs/Ga_xAl_{1-x}As$ double heterostructure material, where all five epilayers together occupy about this very thickness (9), a ten-fold improvement in the resolution achieved per unit depth probed would be the minimum desired. Although defect detection in heterostructures has been displayed (5) via the use of the AB etchant (10) in a modified form, an extra thickness of epitaxial growth was necessitated in order to accommodate the lack of etch discrimination.

Both Ambridge *et al.* (1) and Niehaus and Schwartz (3) were able to report in the work already cited that electrolytic etching of GaAs produced features at the electrode surface. These were presumed related to the defects in the sample. Kuhn-Kuhnenfeld (11) used a chemical etchant of standard composition for GaAs under conditions where the photovoltaic properties of the semiconductor provided effective electrolytic control. Although the procedure was not subjected to a critical calibration, various features became well resolved after 2 μm of etching. Several appeared "dislocation like." Later Saitoh *et al.* (12) used the same scheme of photoassistance together with the AB etch composition and were able to gain a good delineation of defects with the removal of less than 1 μm of material.

We report here on the development of two complementary techniques of anodic dissolution of n-GaAs; one to yield a topographically featured surface, and the second to allow continuous, smooth etching. The electrode polarization studies which preceded the design of each technique are detailed in an Appendix. Correlation of the morphological detail displayed via the first etching mode has been carried out with the use of double crystal x-ray reflection topographs. The selective resolution of defects such as dislocations by our electrochemical technique is shown to be superior to that obtained from other currently advocated etching techniques (7). Minimal dissolution is required (0.5 μm or less) close to the target set.

In this instance, our attention is given to bulk-grown n-GaAs alone. Therefore we are describing the trial of these methods on substrate quality material. However, as a specific example of the resolution capability and to illustrate how the procedures can be used to profile the defect content of a GaAs slice in depth with high accuracy the differentiation of surface damage and bulk defects close to the surface of a substrate are described.

Experimental

Much of the apparatus used in this work has been described previously by Ambridge *et al.* (1, 2). A major difference here, however, concerned the cell construction, where an all-glass unit was designed. This was basically a small spectrophotometer cell with a PVC sample mounting ring (2) mounted directly onto one face which had been predrilled as appropriate. There were, as before, inlet/outlet ports for electrolyte flow and limbs for the insertion of a saturated calomel reference electrode and a carbon cathode. A platinum wire electrode for capacitance measurements was inserted directly through the side of the PVC ring. Both the sealing of the GaAs sample onto the ring and the provision of electrical contact to it were achieved via sprung probes of tin-coated gold wire (2).

By mounting the cell directly onto a microscope stage plate and using an inverted metallurgical microscope, observation of the whole exposed GaAs electrode surface (~7 mm^2) was possible at a magnifica-

Key words: gallium arsenide, electroetching, oxide films, dislocations, striations.

tion of 30× (at the eyepiece). Examination of fine topographical details developed during anodization such as etch pits, areas of nondissolution, and surface film nucleation sites was very straightforward. Illumination of the electrode was direct via the microscope optics and since all of the polarization behavior reported here involves illumination, a continuous visual observation of the electrode was possible. The optical source was a 250W high pressure mercury arc lamp set to provide Koehler irradiance of the sample.

Measurement of electrode potential was obtained through a high impedance digital voltmeter (Solartron LM 1604). An autobalance capacitance bridge (Wayne Kerr B641), operating at 1.592 kHz, was used for measurement of interfacial capacity. Polarization of the illuminated electrode was attained by use of the potentiostat designed by Bremner *et al.* (13). Cell current was monitored using an electrometer (Keithley Model 602) with its output facility linked to a digital integrator (Time Electronics TS100A). Two electrolytes new to GaAs electrochemistry were used throughout this work. They were: as stock solutions, 0.5M Tiron (1,2 dihydroxybenzene-3,5 disulfonic acid disodium salt) which had a pH = 3.45; and 0.3M sodium dihydrogen orthophosphate pH = 4.32. The GaAs used had been boat grown and cut into slices in a {100} orientation (Mining and Chemical Products Limited and Monsanto Chemicals Limited). All were silicon doped.

Electrochemical Characteristics and Technique

Electrode capacitance.—Reproducible Mott-Schottky characteristics were obtained from unilluminated n-GaAs ($N_d = 2.0 \times 10^{17}$ cm^{-3}) electrodes (14) using both of the electrolytes chosen for use here. The flatband and open-circuit potentials are plotted in Fig. 1 together with previously published data.

Electrode polarization.—Illumination of the same electrode samples yielded sizable photopotentials (~ −450 mV) and, in the usual manner, allowed stable anodic polarization (reverse-biasing of the Mott-Schottky barrier) curves to be obtained (Fig. 2). Current/voltage behavior was also examined using various solutions formed by mixing the two basic electrolytes.

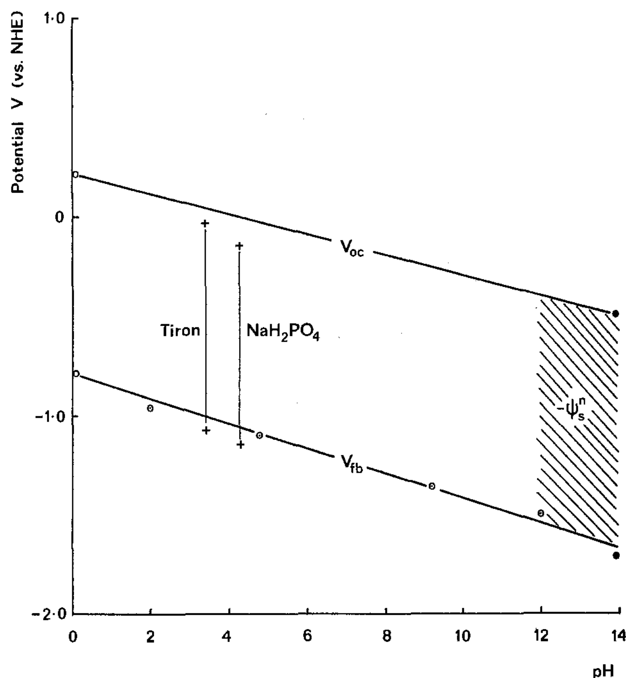

Fig. 1. Collation of data concerning the variation in band bending at the unilluminated n-GaAs electrode with electrolyte pH. Values for the flatband potential (V_{FB}) and the open-circuit (rest) potential (V_{oc}) are taken as follows: ○ Benard and Handler (29); ⊙ LaFlere *et al.* (41); ● Ambridge and Faktor (14).

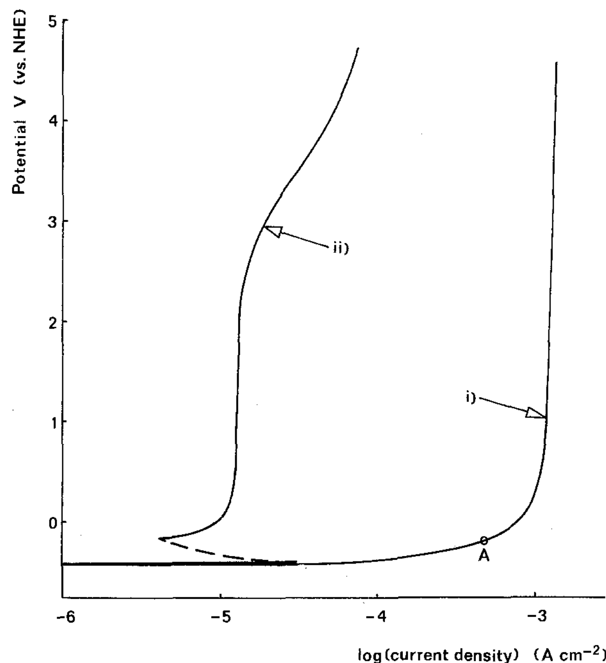

Fig. 2. Current-voltage behavior of an illuminated n-GaAs electrode (same sample as Fig. 1) in: i. 0.5M Tiron; and ii. 0.3M NaH_2PO_4. The point A marks the experimental condition for step 2, Fig. 5.

For example, it was found that only small proportions of Tiron (10% v/v) were required in the electrolyte to yield current characteristics identical to Fig. 2i. In this case, the reverse-bias breakdown behavior of a lower doped n-GaAs electrode was examined—again with illumination—and found to be as plotted in Fig. 3.

Electrode morphology.—Since all of the curves such as shown in Fig. 2 and 3 were gained with an experimental arrangement which allowed direct visual inspection of the electrode, the surface morphology developed was very easily relatable to particular polarization conditions. The photographs in Fig. 4 are representative of etching under steady-state conditions at the points marked A in Fig. 2i and B in Fig. 3.

The result of the single etching experiment shown as Fig. 4i bears no similarity to morphologies found either by Kuhn-Kuhnenfeld (11) or Saitoh *et al.* (12)

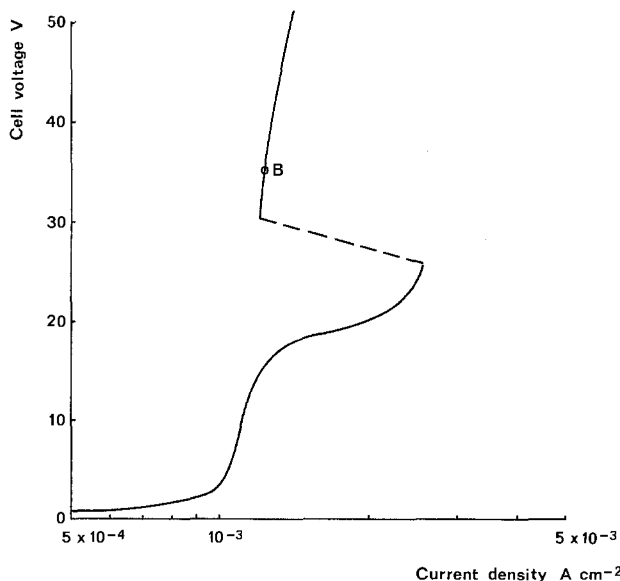

Fig. 3. Extended current-voltage plot for an illuminated n-GaAs electrode (2.6 × 10^{16} donors per cm^3) in a mixed electrolyte (10% 0.5M Tiron/90% 0.3M NaH_2PO_4). The point B marks the experimental condition for step 1, Fig. 5.

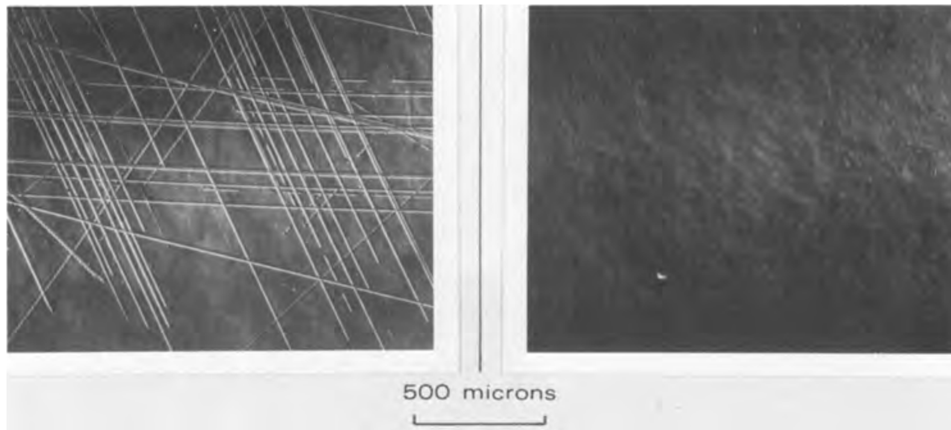

Fig. 4. Photomicrographs (Nomarski interferometry) showing surface morphologies developed after electrochemical etching of two separate samples: i. at point A in Fig. 2i, 0.2 μm removed; and ii. at point B in Fig. 3, 5.2 μm removed.

in those studies of the photoassisted chemical dissolution of n-GaAs which we judge to be closest to our fully controlled electrochemical conditions. In our case, the sample used had been mechanochemically polished using a standard bromine/methanol routine immediately prior to anodization. It appeared, therefore, that the low overpotential etching in Tiron solution had revealed features representing imperfections introduced during the sample preparation. This supposition was confirmed by subjecting similarly finished slices to a sequential etching experiment as indicated in Fig. 5. Step 1 was accomplished by use of the defect-independent etching conditions (point B in Fig. 3) leaving a surface typically as that shown in Fig. 4ii. Then after a simple replacement of electrolyte, step 2 was initiated and the surface topography monitored through its duration using the microscope. Both d_1 and d_2—the successive etch depths— were easily calculable via the integrated current density (for details, see the Appendix). As an example, the two etched surfaces pictured in Fig. 6i and 6iv were obtained with material removals of $d_1 = 2.0$ μm and $d_2 = 0.57$ μm. The minimum value of d_1 found necessary in order to avoid the appearance of etch features caused by polishing damage was 0.5 μm for the mechanochemically polished slices.

Crystallographic Defect Studies

We shall begin here with comments concerning the polishing damage encountered during the single etch experiments. Clearly no information concerning the bulk defect structure of n-GaAs substrate wafers can be obtained definitively without the removal of the damaged surface layer.

In fact, the appearance of prepolished surfaces after a single step 2 etch changed quite sharply with prior alteration of the polishing rate (this made principally by varying the bromine content of the polishing solution). Where low rates had been used, the surface took on a continuously disturbed form, with all of the linear features as per Fig. 4i in close coalescence. Thus a form of Beilby layer (15) was present. Its characteristic depth was, however, no different from that exhibited by the discretely scratched surface. The damage itself might arise from particles of abrasive material or even GaAs which have remained attached to the slice after any mechanical treatment, or, more probably, have become trapped on the polishing pad at any time since its manufacture. We note that in spite of warnings to the contrary (7), mechanochemically prepared GaAs slices are still taken to be damage free (16). Our ability here to reveal minor work damage, such as that caused by mechanochemical polishing, and to profile its region of confinement near the surface at submicron levels, illustrates nicely the fine resolution of defective material attainable with the electrochemical etching methods.

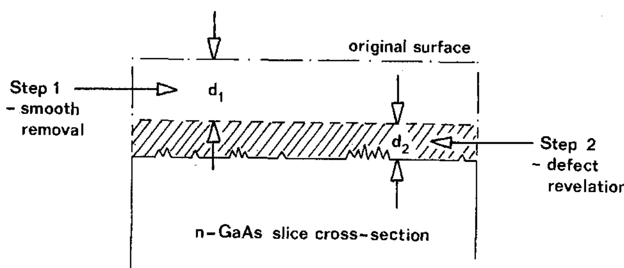

Fig. 5. Schematic representation of the sequential electrochemical etching experiment. The cross-hatched region marks the "layer" probed for defect content.

With regard to the crystallographic imperfections of the bulk, the etched slice photographed in Fig. 6i is only one of a number which have been subjected to a cross correlation with structural defect analysis by x-ray methods. Double crystal x-ray reflection topography was chosen—it has the advantage of probing a near surface layer alone (17, 18). More generally the two techniques used over-all then have independent origins, particularly so, as we shall show later, with the etching performed electrolytically. The x-ray topography was used first to map as fully as possible the defect content of the sample. Since not all possible dislocation Burgers' vectors will yield contrast at a single reflection, only a superposition of two x-ray topographs will provide a complete map of the dislocation distribution. Figures 6ii and 6iii are micrographs of the photographic plates on which the two x-ray exposures covering the same area were recorded, but the superposition is made difficult because the topographs are unavoidably distorted geometrically with their foreshortened axes perpendicular. Attempts at reaching a graphical correspondence between all three topographs, that is including the detail available after the sequential etching of the same sample area (Fig. 6i), are further hindered by a significant disparity in the depth resolution of the techniques. The morphology of Fig. 6i resulted from a dissolution in the topographical etching mode (d_2) of 0.57 μm, while the surface layer thickness imaged by the x-ray technique was ~18 μm (17, 18). Hence there is involved here a sampling discrepancy factor of more than thirty.

In view of these problems, the over-all correlation is judged fairly satisfactory. Note first that the pronounced linear feature present at the left-hand edge of all three topographs is the result of a deliberate scratch mark made as a geographical reference point. Thereafter, particular correspondences can be seen between the linear array of features extending along the line of the arrow marked A in Fig. 6i and 6ii, and also between a group of features at B in both Fig. 6i and 6iii. The line of detail labeled A in Fig. 6ii contains several linear images (one is arrowed at a) which do not appear in the complementary x-ray topograph. Analysis

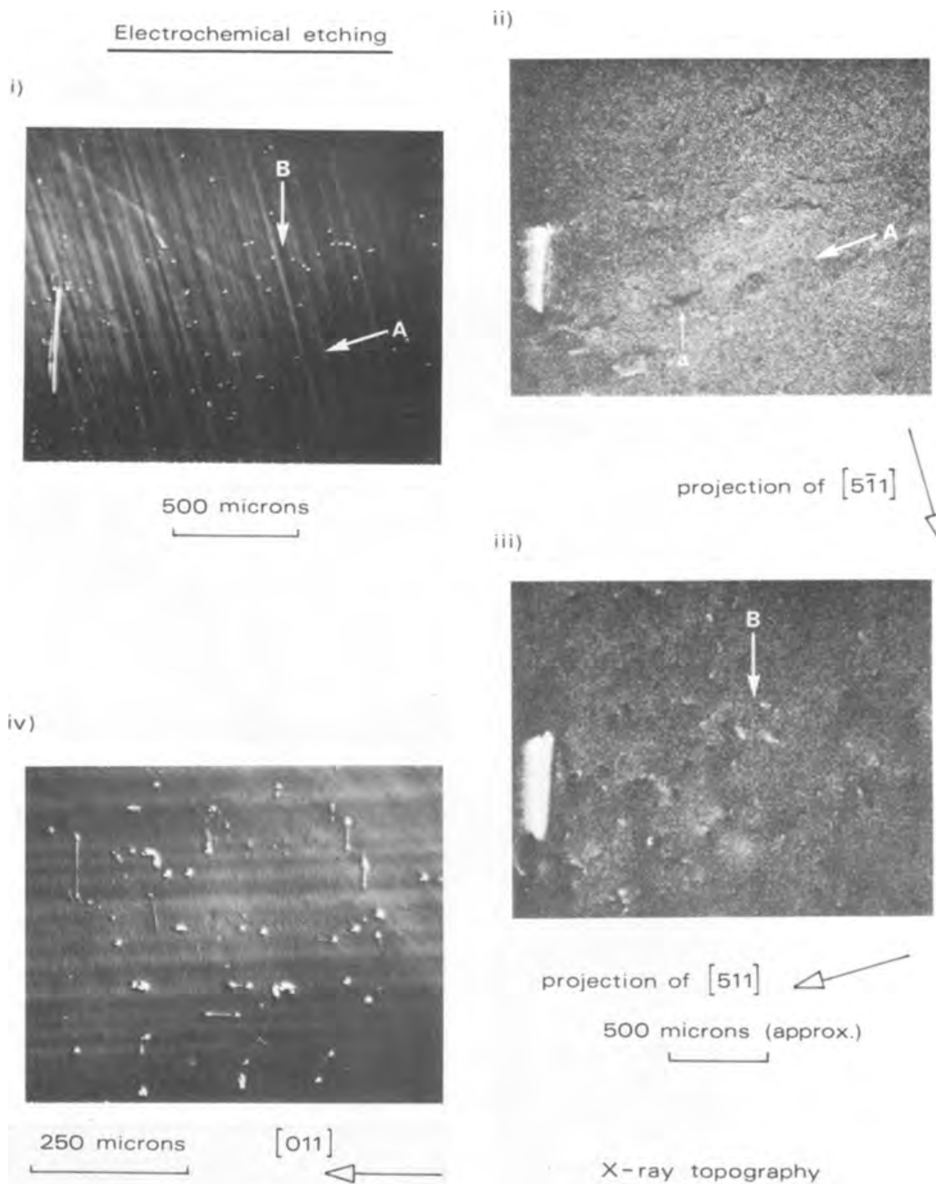

Fig. 6. Results of the etching calibration. i. Sample surface-morphology after electrochemical etching as indicated in Fig. 5, with d_2 0.57 μm; ii. and iii. double crystal x-ray reflection topographs recorded for the sample prior to etching, using the 5$\bar{1}$1 and 511 reflections from GaAs, respectively; and iv. features resulting from sequential electrochemical etching at an adjacent area to that shown as i. (n-GaAs sample, Si-doped, 8.6 $\times$ 10^{17} donors per cm^{-3}).

of the diffraction conditions show this to be a dislocation with a high (probably complete) edge component. Clearly it lies in a [011] direction. The absence of a comparable linear feature from the etched surface is probably attributable to the difference in depths probed, as described already. On a neighboring area of the same sample (which was not clearly imaged by the x-ray method due to slice curvature) the electrochemical etching did produce linear features arrayed along both the [011] and the [0$\bar{1}$1] directions (see Fig. 6iv, which has an increase in magnification and a sample rotation relative to Fig. 6i). Thus an ability to reveal both dislocation outcrops (for dislocations inclined to the surface plane) and dislocation lines (lying in the surface plane) is indicated. In this connection, note that the linear features present in Fig. 6iv are all terminated by a roundel, similar to those which, individually, represent dislocation outcrops. This indicates a segmentation of the dislocation into, presumably, the <110> directions and therefore at these points it either enters the bulk or was originally attached to the slice surface. Electron microscopy of bulk-grown GaAs has indicated previously that this dislocation type is often dominant (19).

The type and scale of defect discrimination demonstrated here is simply not attainable with many of the chemical etchants reported in the literature as suitable for defect analysis in GaAs (7), though the best characterized of these, the AB etch (10), may, under conditions of dilution (5, 20) and together with photoassistance (12), yield a comparable detection.

Some significant information concerning the mechanism by which defects are revealed in the step 2 electrolytic etching case can be gained by consideration of the data contained in Fig. 1 and 2i. (Note that an account of the characteristics contained in Fig. 1-3, together with their relation to previous work on the electrochemistry of GaAs, is given in the Appendix.) First, by using the surface barrier potential ($\psi_s{}^n$) shown for Tiron in Fig. 1, a band diagram for the appropriate semiconductor/electrolyte contact (at open-circuit, and unilluminated) can be constructed. This is shown as Fig. 7i. With subsequent illumination, the electron hole pairs photogenerated within the electrode produce a decrease in the barrier height while any anodic overpotential applied thereafter acts in the reverse-bias sense, assisting the diffusion of holes toward the interface. Under these circumstances, the photocurrent shown as Fig. 2i is produced. The diagram ii in Fig. 7 is a schematic representation of the electrode condition at point A on the polarization curve 2i where the anodic overpotential is +250 mV. If applied potentials in excess of 250 mV are used, a photocurrent saturation is attained and the electrode subjected to normal reverse-bias conditions, the depletion width increasing with voltage. Finally, on any further increase in potential, breakdown conditions will be approached.

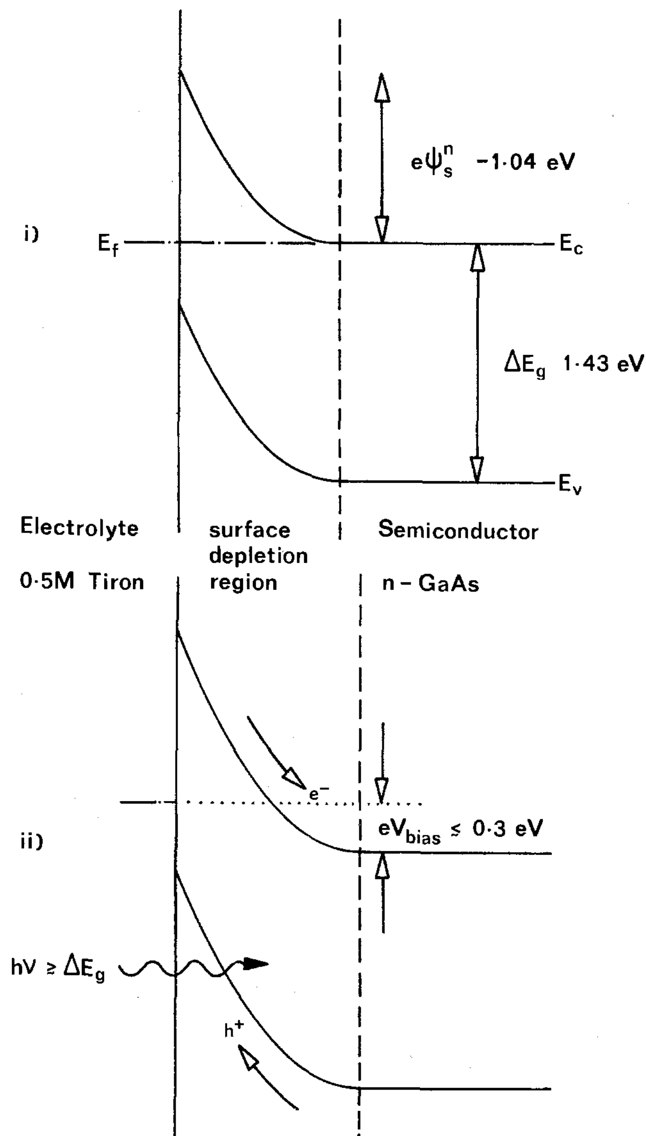

Fig. 7. Band diagrams representing: i. quantitatively, the n-GaAs electrode (unilluminated, and at the open-circuit condition) in contact with 0.5M Tiron electrolyte; and ii. schematically, the n-GaAs/0.5M Tiron half-cell under conditions represented by point A in Fig. 2i.

Any interband state acting as an electron-hole recombination center within the depletion width marked in Fig. 7ii will then introduce two localized perturbations to the over-all polarization behavior near the rest condition. First, there is a reduction in the open-circuit photopotential, and second, a stifling of the hole current which supplies the anodic dissolution reaction. Clearly the operation of the latter will produce points of low etching rate at the sites where nonradiative recombination processes are facile. It has long been well-known that dislocations can act as efficient nonradiative centers in most of the III-V compound semiconductors (21).

We have found that all of the discrete features etched on samples such as shown in Fig. 6i (where all of the defects are supposed characteristic of the bulk material) and Fig. 4i (where the defects arise from polishing operations) are indeed elevated in profile. This was ascertained by use of a Talysurf instrument on some heavily etched samples. The surface features produced on n-GaAs samples in both of the photoassisted chemical etching studies already referred to (11, 12) exhibited a similar cross-sectional geometry. Although Kuhn-Kuhnenfeld (11) recorded negative photopotentials—as happened here—and attempted an explanation of the etching action via his data, no ascription of a mechanism for defect delineation can be realistically made on the basis of such singular observations. This is because the overpotential available for the dissolution remains largely chemical in origin. Only by the addition of a full electrochemical control, as that obtained by our fixing of the electrode potential of the semiconductor sample, can the over-all mechanism depicted semiquantitatively in Fig. 7ii be justifiably proposed.

This contention is open to experimental test. Although at low overpotentials the localized recombination processes are responsible for impeding the dissolution, an increase in applied bias should lead to a reduction in defect resolution. This follows because the increased field strength imposed in the depletion region during the traversal of the photosaturation is responsible for a decrease in the probability of minority carrier trapping at the imperfection (22). There is an intrinsic mechanism involved (that is a field effect on the capture cross section of the trap) and probably also a contribution resulting from the increased energy imparted to the carrier (23). Thus the experiment consists of comparing the resolution of defects at different anodic potentials. The photomicrographs of Fig. 8 display the results obtained from such a study.

Two separate Si-doped samples were involved, labeled D and S, and clearly have very different defect morphologies. Each was examined at three adjacent areas. The micrographs Di and Si show the surface morphology obtained after "standard" sequential electrochemical etching, as per Fig. 5, with a step 2 overpotential of ≤ 300 mV and with $d_2 = 0.57$ μm and 0.40 μm, respectively. There is a significant discrepancy between the resolution attained for Di and that yielded by the sample shown in Fig. 6i and 6iv, even though the etching conditions were the same in each case. Their dissimilar behavior might be taken to indicate that a different degree or type of dislocation decoration was specific to each. The wafers had almost identical carrier concentrations, but originated from different manufacturers. This marked discrepancy in etch behavior was observed consistently through a whole range of samples obtained from these two suppliers. The topography shown by the sample S has, in the equivalent case (Si) two basic elements. The striations present in the left-hand portion of the micrograph were originally supposed to derive from a known facet effect often incurred during the bulk solidification of GaAs (24). Clearly some extensive microfaceting would be required to produce the features as observed. However, the same defected area gave a strongly imaged, banded contrast on an x-ray topograph. This is probably inconsistent with simple variations in dopant concentration alone (7). The common severity with which these features were resolved by both techniques leads us to suspect that they have a basic crystallographic origin, possibly linked to lamellar twinning (7). (Note that there are also striations present in Fig. 6i, but they are very much weaker than those of Si. Also the accompanying x-ray topographs there (6ii and 6iii) have no image matching the striae. Our conclusion is that these etch features do correlate with simple variations in dopant concentration, and hence carrier mobility, and that the periodic distribution arose there from thermal cycling occurring during solidification.) Also present for Si, and covering the whole area of the micrograph, is an array of small nodular features at a density of $\sim 2 \times 10^6$ cm^{-2}. Their origin is as yet uncertain. However, considering the carrier concentration of the sample ($N_d = 2.4 \times 10^{18}$ cm^{-3}), dopant precipitation would appear to be a strong possibility. Some attempts were made to check the comparative behavior of this wafer on use of the AB chemical etchant (10), both in a standard form and also with dilution and photoassistance together (12). Only in the latter case was a clear resolution of the same nodular topography attained. The concentrated etchant produced only a marginal featuring of the

surface, certainly not as clear a morphology as that observed for GaAs doped with Se and Te at the same concentration levels (25). For these materials, Stirland (25) has observed good correlation between etch pit features (at localized densities of between 10^6 and 10^8 cm^{-2}) and small defects allied to dopant precipitates. The evidence for the presence of similar imperfections in silicon-doped material is certainly much less clear and our result can only be advanced as an additional preliminary indication of similar precipitation effects.

The changes in the etch morphologies developed at different electrode potentials are shown in sections ii and iii of Fig. 8. The central pair of micrographs (Dii and Sii) illustrate the results gained after using an overpotential of 1.25V. (This is sufficient to double the possible voltage drop across the depletion region and therefore to increase the field strength relative to that of the first etching experiment by a factor of $\sqrt{2}$.) Interestingly, the resolution of each defect type is affected differently. The striated features (in Sii), the origin of which we have been unable to identify with complete confidence, remain as well resolved as in the initial case Si. In Dii, only those dislocations resolved most severely in the first instance have now produced a local perturbation of the anodic current, while the distinctive nodular features present in Si are no longer revealed at all in the second case. The material removal was held constant for each sample ($d_2 = 0.57$ and 0.40 μm were the average removals for D and S, respectively). At this stage we can conclude that the qualitative model dealing with the selective resolution of imperfections has been amply verified by the experi-

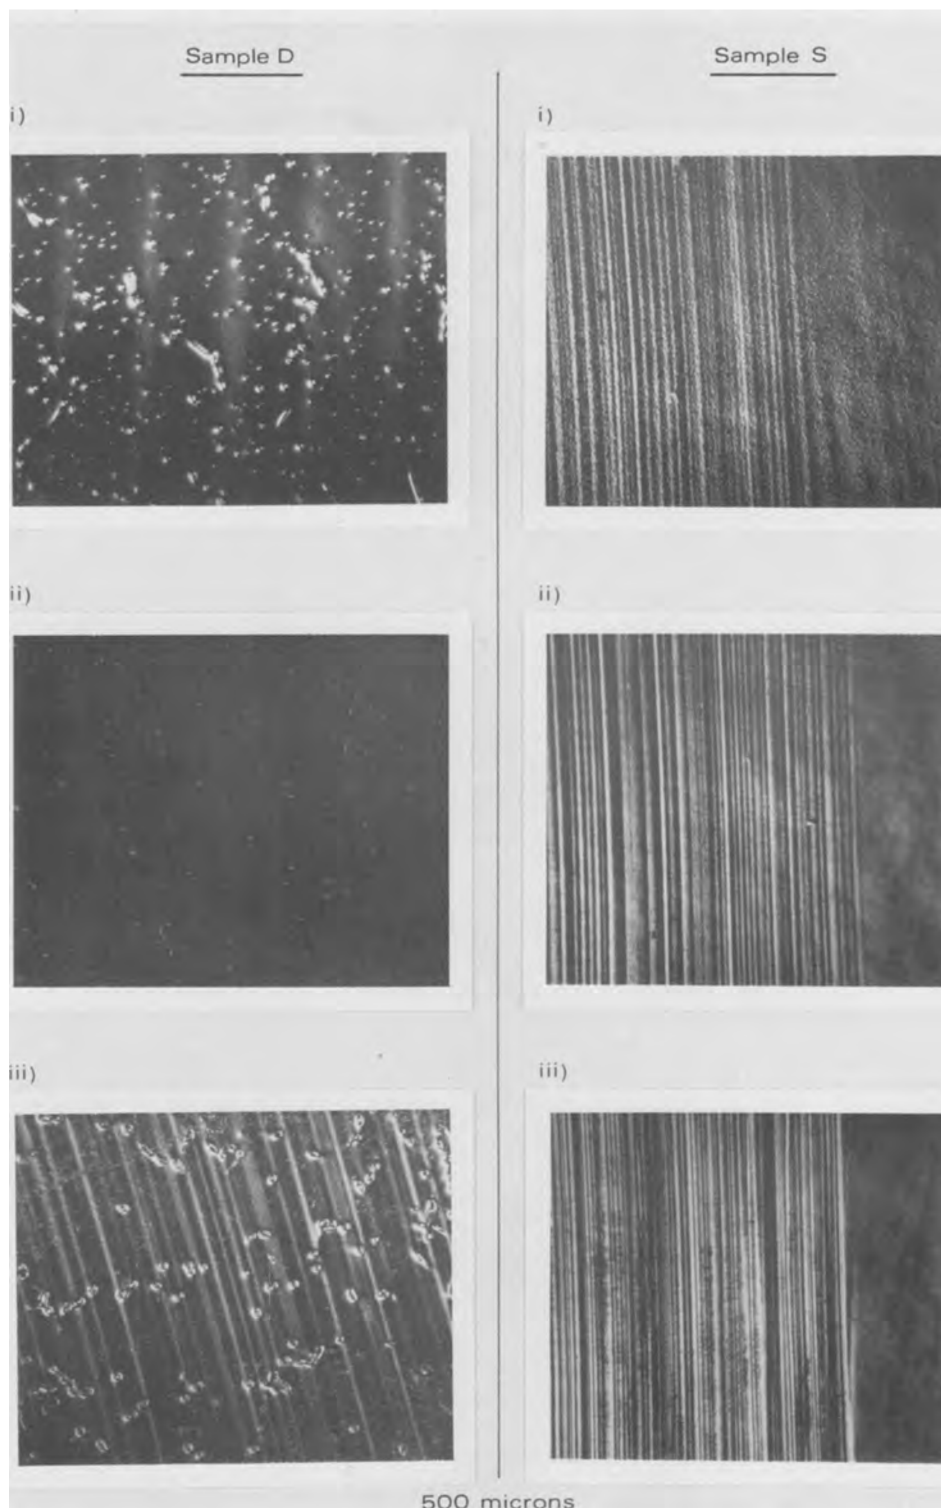

Fig. 8. Nomarski interference micrographs showing the etch morphologies developed during the defect revelation procedure at different anodic electrode potentials; i. overpotential ~250 mV; ii. overpotential 1.25V; iii. overpotential ≥ 1.75V. (n-GaAs samples: D, Si-doped, 7.8 × 10^{17} donors per cm^3; S, Si-doped, 2.4 × 10^{18} donors per cm^3).

mental results. Additionally, there appears to be available some semiquantitative information concerning the minority carrier lifetime at different defect centers.

In connection with this last statement, the results gained at current densities exceeding the photosaturation are of interest (Diii and Siii). The defects which were acting primarily as recombination centers in the low overpotential etching, should, under the necessarily higher overpotential conditions now required, participate as localized breakdown sites. The use of this etching regime is known from previous experiments to result in a discretely pitted surface (26, 27). Thus an inversion of the etch morphology is possible on traversing the whole anodic potential range. This is shown separately here in Fig. 9 by the comparative display of Talysurf traces for the two sample areas photographed as Di and Diii in Fig. 8. Because the electrochemical etching was confined to a well-defined circular area, the boundary etch step could be used for calibration of the vertical axis. These steps are positioned in line on the left-hand side of Fig. 9. The etch profile is then clearly resolved in both cases, consisting of elevated (ridged) features for Di and depressed (pitted) features for Diii. The edge step was also used to calibrate optical microinterferometers of the standard Michelson type and also a Nomarski differential interference contrast objective and use of these techniques confirmed that an inversion of etch topography was indeed gained on increasing the anodic potential. Finally, sample S was also subjected to etching at current densities > 1.5 mA cm^{-2}. In this case, (Siii), the dissolution is largely confined to the heavily striated material and the imperfections responsible for the nodular features in Si do not contribute individually to the reverse-bias breakdown of the sample area probed. The generation/recombination characteristics of each type of defect are clearly quite different.

Summary and Discussion

Our aim in this work was to procure a technically simple method for the resolution of crystallographic defects in GaAs, preferably with a resolution such that reproducible results could be gained with the removal of ≤ 0.5 μm of material. Of necessity, two previously untried methods of anodic dissolution have been investigated. The technique thus developed consists of:

(*i*) A defect-insensitive etch (step 1 in Fig. 5) which can be used for the removal of damaged material from as-polished surfaces, or to accurately section the slice to any predetermined depth. The anodic dissolution here is carried out continuously with an oxide film present at the interface to preserve the initial topography.

(*ii*) A defect-revealing etch for n-GaAs which has a high sensitivity related directly to the electronic characteristics of the imperfection (step 2 in Fig. 5).

Used in sequence, these two dissolution regimes allow: (*i*) the depth characteristic of polishing damage to be gauged quantitatively for any method of slice preparation; and (*ii*) the defect content of the bulk material (n-GaAs substrate) to be determined with a resolution not attainable with any of the standard chemical etchants used previously for GaAs.

One distinctive element of the technique described here has cardinal importance. The adoption of fully electrochemical etching conditions, in which chemical reaction between the etchant and semiconductor has been deliberately excluded, leaves the dissolution totally dominated by the optoelectronic properties of the sample. That is, etching only occurs at locations on the surface where the anodic current is either uninhibited or, alternatively, enhanced. Therefore the correlation of morphological features produced against defects identified by an independent crystallographic technique (as per Fig. 6) comprises a relation between the structural origin of the imperfection and its electronic consequence. Thus our experimental method corresponds quite closely to those adopted for detailed studies of structural defects and their nonradiative recombination characteristics in n-GaP (23, 28), except that in this case the etching and the optoelectronic probe are done neatly in combination.

Furthermore, the manner in which the semiconductor properties of GaAs dominate its electrode behavior indicates an easy extension of the method into analyses of epitaxial GaAs and probably also other III-V compounds. Working, for example, with the epitaxial structure of most interest at this time [the five-layer GaAs/$Ga_xAl_{1-x}As$ sequence grown for injection laser fabrication (9)], we have been able to probe the n-GaAs buffer material and its homoepitaxial interface with the substrate, and also, separately, the succeeding n-$Ga_{0.65}Al_{0.35}As$ layer. Results from this and other areas of similar material assessment will be described in a subsequent publication.

Note

During the period while this paper was under review, a publication on the same topic (42) has appeared in the literature. We have carried out anodic etching experiments on n^+-GaAs exactly as described by

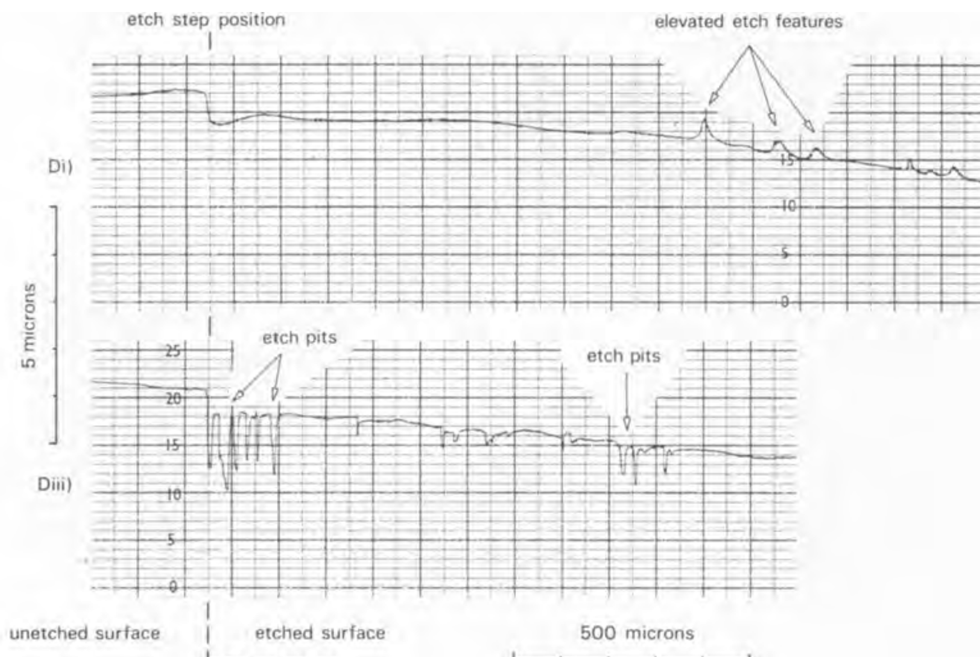

Fig. 9. "Talysurf" profiles of the etched surfaces photographed as Di and Diii in Fig. 8.

Greene in an attempt to classify the defect revealing conditions according to our Fig. 8. The most important distinction is that no deliberate illumination is included in Greene's experimentation. Thus, automatically, the rather "heavy-weight" conditions imposed (maximum current density 2 mA cm^{-2} and cell voltage 10V) lead to a defect resolution of types ii and iii in Fig. 8, depending somewhat on the level of ambient illumination. These are not the most sensitive conditions. For example, only the prephotosaturation current density etching of sample S in Fig. 8 (Si) resolves the high density of nodular features which we suspect are related to impurity precipitation defects in Si-doped n^+-GaAs.

Acknowledgments

We are grateful to Mrs. M. A. G. Halliwell for pursuing the x-ray topographic study referred to in this paper, and for many useful discussions concerning this aspect of the work. Further experimental design and assistance was given by R. M. Redstall, M. C. Case, and J. C. Regnault. We are also indebted to Dr. T. Ambridge and Dr. R. Heckingbottom for their interest and advice.

This paper is published by permission of the Director of Research of the British Post Office.

Manuscript submitted March 21, 1977; revised manuscript received Oct. 31, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1978 JOURNAL. All discussions for the December 1978 Discussion Section should be submitted by Aug. 1, 1978.

Publication costs of this article were assisted by the Post Office Research Centre.

APPENDIX

Use has been made in these studies of the anodic capacitance and polarization characteristics of n-GaAs.

Electrode capacitance.—The only systematic examination of the depletion characteristics of GaAs/electrolyte contacts is that due to Benard and Handler (29), who determined specifically the semiconductor surface potentials but used only strongly acidic media. The collection of data assembled in Fig. 1 includes that measured for the electrolytes used here, and confirms that the n-type semiconductor surface is in substantial depletion under open-circuit conditions. One noteworthy aspect is that the band-bending ($|\psi_s^n|$) for the electrolytic contact appears to exceed almost everywhere in the pH range the values measured for n-GaAs/metal junctions ($-0.80V \geqq \psi_s^n \geqq -0.95V$) by Mead (30). There is also present a systematic variation of ψ_s^n with pH, and this produces a differential resolution of the crystallographic defects in step 2 etching conditions, just as that obtained by variation of the bias voltage and pictured in Fig. 8. The highest etch discrimination is procured therefore with acidic media, where the field strength in the depletion layer is lower. Note that Fig. 1 will not apply to electrolytes containing strong oxidizing agents (31).

Electrode dissolution and passivation.—It is well known that the anodic dissolution of the wide bandgap semiconductors requires the participation of holes. Pleskov (32) first confirmed that this was the case for GaAs, having investigated the anodic currents gained using both acidic and alkaline electrolytes. The curve shown as Fig. 2i here, where use has been made of the complexant electrolyte Tiron, is of the same classical form (33, 34) and yields, over-all, two important advantages in the topographical etching studies. First, the anodic reaction has a strict six-electron equivalence (35), which allows the integrated current density to be converted automatically to the average dissolution depth. Second, it allows the electroetching to occur without interference from insoluble products at the electrode surface, in contrast to, say, sulfuric acid solutions which leave precipitated arsenious oxide (26). Importantly also, the electrolyte is acidic (see a, above).

Conversely, the anodic polarization curve obtained using the phosphate electrolyte (Fig. 2ii) shows passivation characteristics similar to those observed for various GaAs electrodes by Harvey (36, 37). Since curves 2i and 2ii were recorded under identical illumination conditions, it is clear that the straightforward photosaturation limitation present in the first instance has been replaced in 2ii by a kinetic restraint due to product insolubility.

From Fig. 3 it is apparent that a mixture of the two electrolytes allows both of these individual characteristics to appear in succession. Specifically, the addition of the complexant (Tiron) to the barrier oxide forming electrolyte (NaH_2PO_4) has led to a large increase in the steady-state current density achievable in the presence of a uniform anodic oxide film (compare point B in Fig. 3 with the original passivation curve 2ii). As yet we have been unable to clearly resolve the individual roles of photoinjection and Schottky barrier breakdown in the supply of holes for the over-all dissolution reaction. A six-electron equivalence is maintained however, with a 1 mA cm^{-2} current density corresponding to a continuous removal rate of 1.7 μm per hour. Some experimental observations concerned with the effect of aqueous electrolyte composition on the outcome of GaAs anodization have been published by Schwartz *et al.* (38). In comparison, the specific complexant action of Tiron, as set out above for the mixed electrolyte, is rather better defined than the anion-type dependencies noted by Schwartz *et al.* Also, the use of an electrochemical regime where oxide dissolution is uniformly enhanced for the machining of GaAs (see step 1 in Fig. 5) was not dealt with. In fact, one particularly important application (the precise thickness trimming of epitaxial layers) has generally been subjected to a noncontinuous method, where, in separate steps, the oxide is first grown and then removed under open-circuit dissolution conditions (3, 39, 40). Clearly this multiple-stage processing may lead to some cumulative inaccuracy in assessing the over-all material removal.

On the Nature of Fixed Oxide Charge

S. I. Raider[*,1] **and A. Berman**

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

An oxidation-induced fixed oxide charge Q_{ss} is known to be generated in the SiO_2-Si interfacial region. In the light of recent determinations of the composition and width of this interfacial transition region, a reexamination of the nature of this charge is undertaken. A model, consistent with known transition region composition, is proposed in which a positively charged silicon-oxygen complex is formed as an intermediate reaction product of the oxidation process. This intermediate may be trapped within the transition region when the oxidation reaction is terminated by quenching in the oxidizing ambient. The concentration of this complex is proportional both to the excess oxygen concentration and to the nonoxidized Si-Si bond density in the transition region. The model is also consistent with the dependence of Q_{ss} on such factors as oxidant pressure, oxidation temperature, inert-gas annealing, and substrate orientation.

Electrically active sites such as fixed oxide charge, Q_{ss} form in the oxide film at or near the SiO_2-Si interface (1) during the oxidation reaction. Their formation occurs within the same region in which Si is incompletely oxidized and within which the oxidation process takes place (2, 3). The number of nonoxidized Si atoms present within this transition region cannot be identified with Q_{ss}. The density of these charge sites after oxidation (10^{12} cm^{-2}) (1, 4) is significantly lower than the nonoxidized Si-Si bond density (10^{15} cm^{-2}) within the transition region. Q_{ss} is reduced further (to 10^{10}-10^{11} cm^{-2}) by postoxidation annealing treatments (1, 4). The magnitude of Q_{ss} depends intimately upon the thermal oxidation process (1). Despite numerous studies, the relationship between thermal oxidation and Q_{ss}, as well as the chemical nature of Q_{ss} is not well understood. Control of fixed oxide charge densities, which are of technological importance, remains largely empirical.

Recently, the composition and width of the SiO_2-Si interface, formed by thermal oxidation of <100> and <111> oriented Si surfaces were characterized by analysis of x-ray photoelectron spectroscopy (XPS) data (5-8). Changes in Si chemical bonding at this interfacial region were derived from XPS spectra (5, 8). Although the detection limit of x-ray photoelectron spectroscopy is approximately 10^{13} cm^{-2} and does not provide a means for direct observation of the sites responsible for Q_{ss}, the XPS findings do provide a new picture of the transition region within which these electrical instabilities must be understood. We have therefore reconsidered the thermal oxidation process and the related chemistry that occurs at an SiO_2-Si transition region and that may influence the oxide charge densities.

Fixed Oxide Charge

The properties of fixed oxide charge have been summarized in several papers (1, 4) and review articles (9-12) and are only briefly described here. These charges form a positive space charge in the oxide film during the thermal oxidation process and induce a negative image charge in the Si substrate. Fixed oxide charges are stable under moderate temperature-bias conditions and are unaffected by changes in surface potential. Densities are dependent upon substrate orientation with Q_{ss}<111> > Q_{ss}<100>. Chemical etching (1) and internal photoemission experiments (13, 14), as well as the dependence of Q_{ss} upon substrate orientation, indicate that Q_{ss} is near to the substrate. For example, results of internal photoemission experiments suggest that most of the charge is located at less than 20Å from the substrate and is spatially distributed within the SiO_2-Si transition region.

Factors that influence Q_{ss} include oxidation and annealing ambients and the oxidation temperature. Charge densities reflect the final oxidation or annealing conditions. The formation or reduction of Q_{ss} is reversible provided that steady-state conditions are achieved. In a reactive dry oxygen ambient, Q_{ss} increases with decrease in oxidation temperature. An example taken from the earlier literature (1) shows that Q_{ss} is about 4.2×10^{11} cm^{-2} after 2000Å thick films have been annealed to minimize Q_{ss} and subsequently oxidized at 550°C. After oxidation of Si at 1200°C, Q_{ss} is 2×10^{10} cm^{-2}. Varying the rate at which a sample is pulled from a hot zone in an oxidation furnace is equivalent to adjusting the final effective oxidation temperature at which the oxidation reaction is quenched, thereby altering Q_{ss}. High temperature an-

nealing in an inert ambient, such as Ar gas, minimizes Q_{ss}. N_2 gas, which is often used as an annealing ambient to reduce charge densities, is not chemically inert. Under certain conditions, annealing in N_2 will result in an interaction between N_2 and Si and will increase the density of electrically active sites (15-18).

The relationships between oxidation temperature, inert gas annealing, and Q_{ss} are summarized in Fig. 1 by the well-known Deal oxidation triangle (1, 11). The cross sections in Fig. 1 show a clear relationship between Q_{ss} and the concentration of excess oxygen, C_i, at the transition region. For instance, at high temperatures (cross section a), C_i is low because the oxidation rate is high compared with the rate of supply of in-diffusing oxygen. At low temperatures (cross section b), C_i is high because the diffusion rate is large compared with the greatly reduced oxidation rate. Finally, an inert-gas anneal (cross section c) will both consume and out-diffuse the excess oxygen.

When an annealed SiO_2-Si structure with low Q_{ss} is subjected to further oxidation, the rate at which the new value of Q_{ss} is reached is proportional to the oxide film thickness (4). This rate is associated with the rate of oxygen transport through the oxide film and thus with the attainment of the steady-state value of C_i. Pautrak and Pfister (19) obtained a direct relationship between Q_{ss} and oxygen pressure by annealing 2500Å thick films, grown at 1240°C, in oxygen at various oxygen pressures, p, and anneal temperatures. Q_{ss} increased linearly with $p^{1/2}$ to some saturation pressure (determined by the given anneal temperature) once a steady-state concentration of oxygen oxidant at the transition region had been reached.

Other workers have observed that Q_{ss} is a monotonic function of the excess oxygen within the transition region, C_i (4, 20, 21). As early as 1967, Kubo and Ichinohe (21) suggested that electrical instabilities, such as Q_{ss}, caused flatband voltage shifts in capacitance-

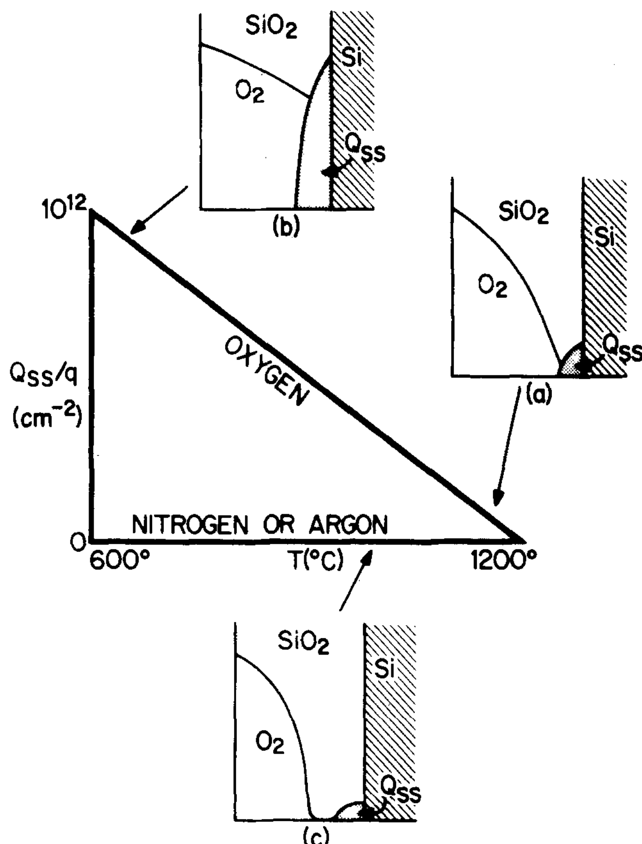

Fig. 1. The dependence of Q_{ss} on final oxidation temperature and ambient as represented by Deal's Q_{ss}-oxygen triangle. The sketches of the thermal oxide cross sections indicate the proposed relationship between Q_{ss} and the oxidation conditions.

voltage curves and were related to dissolved oxygen in SiO_2 near the interface. The solubility of oxygen in 10Å transition region layers should range from 6×10^9 to 2×10^{11} cm^{-2} based on oxygen solubilities in SiO_2 (3) and in crystalline Si (22, 23). These appear somewhat low to account for maximum Q_{ss} values of about 2×10^{12} cm^{-2}.

In addition to the relationship between Q_{ss} and C_i, Q_{ss} is also associated with the fast surface-state density, N_{ss}. For example, Arnold *et al.* (20) have observed that Q_{ss} and fast surface-state density, N_{ss}, are initially proportional to each other after Si oxidation in O_2 and that their densities exhibit the same dependence upon orientation. Although both are formed during oxidation, the fact that these instabilities have different annealing properties demonstrates that they are not manifestations of a single chemical entity. The chemical processes that affect N_{ss} and the ability of these states to act either as donors or as acceptors are consistent with the model in which a surface state corresponds to a chemically unsaturated silicon atom, $\equiv$Si· (24). No single microscopic model is accepted that accounts for the reported variations in Q_{ss} with changes in processing.

SiO_2-Si Transition Region (6, 7, 9)

Several compositional changes occur at an SiO_2-Si interface. The total Si atom concentration per unit volume decreases by a factor of 2.2 when Si is oxidized to form SiO_2. Crystalline Si surfaces with <100> and <111> orientations possess 6.78×10^{14} and 7.85×10^{14} Si atoms cm^{-2}, respectively. As a consequence of the directionality of the bonds in the Si substrate, the number of Si-Si bonds accessible to an oxidant at a <111> oriented surface is 11.76×10^{14} cm^{-2}; on a <100> oriented surface, the corresponding number of bonds is 6.78×10^{14} cm^{-2} (25). Based upon the XPS detectability limit, the number of nonoxidized Si-Si bonds in thermally grown, amorphous SiO_2 was found to be less than 10^{13} cm^{-2} (6).

A nonstoichiometric interfacial transition region, 7-10Å thick, is formed between single crystal Si substrates and thermally grown SiO_2 films. It is graded in composition and increases in chemically bonded oxygen content with distance from the substrate. This gradation is nonlinear. The Si is more than 50% oxidized in the first 2.5Å beyond the substrate. For example, the average composition of the first 2.5Å of oxide film is $SiO_{1.4}$ on a <100> oriented substrate and is $SiO_{1.2}$ on a <111> oriented substrate (6b). Both Si-Si bonds and Si-O-Si groups are present within the transition region, but not as a mixture of Si and SiO_2. Instead, x-ray photoelectron spectroscopy data indicate that Si tetrahedra, Si-$(O)_x(Si)_{4-x}$, are formed, in which x varies from 0 to 4 in going from the substrate to the stoichiometric SiO_2 film. Within the sensitivity limits of x-ray photoelectron spectroscopy, no evidence of the formation of an intermediate, such as Si^+, whose binding energy should be greater than that of Si 2p in SiO_2, is detected. The width and composition of this region remain invariant with change in oxidation temperature (25°-1050°C), in oxidant [O_2, O_2/N_2, H_2O, HNO_3, H_2O_2(30%)], or in oxide film thickness (20-1000Å). Postoxidation annealing at 1000°C in N_2 for 30 min does not alter the transition region.

The composition and width of the transition region are altered only with change in substrate orientation (7, 9). Oxides formed on <111> oriented substrates have transition regions that are 10Å thick and that possess 1.4×10^{15} nonoxidized Si-Si bonds cm^{-2}, whereas transition regions on <100> oriented substrates are 7.5Å thick and possess 0.8×10^{15} Si-Si bonds cm^{-2} (6b). The nonoxidized Si bonds within the transition regions are proportional to the accessible Si-Si bonds (25) at a substrate surface.

Transition region nonstoichiometry, which is often suggested as the origin of Q_{ss} (1), does not contribute

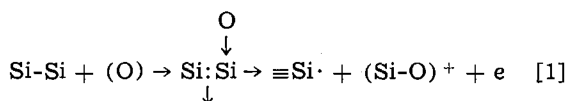
directly to the density of electrically active sites. As previously indicated, transition region composition is unaffected by several of those factors or processes that alter Q_{ss}. Changes in Q_{ss} are directly related only to changes in transition region composition associated with a change in substrate orientation. However, the number of nonoxidized Si-Si bonds within these transition regions is significantly greater than the change in the density of electrically active sites.

Thermal Oxidation of Si

During the thermal oxidation process, crystalline Si substrate surfaces are converted into amorphous SiO_2 films. This conversion involves an interfacial chemical reaction in which the oxidant is first transported through an oxide film and is absorbed in the transition region. Oxidant transported to this region is assumed to be neutral (26) and composed either of O_2 molecules, which subsequently dissociate, or of (O) atoms. The nature of the oxygen adsorption and dissociation processes within the transition region is not known although several models for the initial oxidation steps have been proposed (27-30). When an oxidation reaction does occur, considerable strain should arise at an SiO_2-Si interface as a result of direct insertion of oxygen atoms between Si-Si bonds. A transition region between a single-crystal Si surface and an amorphous, stoichiometric SiO_2 film presumably forms in order that oxygen atoms be accommodated by the substrate with a minimum of internal strain. The formation of different transition regions on <111> and on <100> Si substrates is then associated with differences in the internal strains that would otherwise accompany oxidation of these oriented surface layers. Bond distances change from 2.3Å for a Si-Si bond in the substrate, to 3.0Å, for a Si-O-Si group in an oxide film. Incorporation of oxygen into the Si substrate lattice to form an oxide film while still retaining a predominantly 3 dimensional structure requires displacement of Si atoms from their original lattice sites. These displacements are consistent with the decrease in Si atom concentration of more than 50% when crystalline Si is oxidized to form SiO_2 within the transition region. The tetrahedral bonding of the nonoxidized Si surface atoms to the substrate acts as a constraint upon this oxidation process. Changes at the substrate surface are facilitated if the oxidation reaction occurs via a multistep process. The consequences of a multistep oxidation process are considered below.

Model

The oxidation reaction occurs at accessible nonoxidized Si atoms within the transition region. However, fixed oxide charges, which are associated with the oxidation process, form at only a small subset of these reaction sites. This can be rationalized when considering the observed correlations between the excess oxidant concentration and Q_{ss} and by assuming that electrically active sites are intermediates formed during an oxidation reaction. A two-step oxidation reaction is proposed that involves Si-Si bond breaking and siloxane (Si-O-Si) group formation. The Si-Si bonds within the transition region are under tension. Oxygen molecules or atoms, both of which contain unpaired electrons, interact with accessible nonoxidized Si-Si bonds. This initial oxidation reaction in which Si-Si bonds are broken is only weakly thermally activated with an activation energy, E_a, near zero. For a given substrate orientation, the extent of this interaction is determined by C_i. Oxygen solubility is presumably enhanced by complex formation with nonoxidized Si. A reaction occurs with formation of two different electrically active intermediates such as are shown in Eq. [1]



$$\text{Si-Si} + (\text{O}) \rightarrow \text{Si:Si} \rightarrow \equiv\text{Si}\cdot + (\text{Si-O})^+ + e \quad [1]$$

The dangling bond, $\equiv Si\cdot$, corresponds to fast surface states, and the positive Si-oxygen complex, $(Si\text{-}O)^+$, corresponds to fixed oxide charge. This positive complex represents a possible configuration for Q_{ss} consistent with the known composition of the transition region and with the properties of Q_{ss} (31). Little is known of positive Si-oxygen complexes, although Brosious (32) has recently proposed that an ESR signal from oxygen dissolved in crystalline Si can be associated with a positively charged vacancy-oxygen defect.

Reaction [1] implies that the fixed oxide charge density and the fast state density are equal and consistent with the proportionality observed by Arnold (20). Differences detected between the magnitudes of the oxide charge and the fast state densities can indicate that additional chemical reactions are occurring. Alternatively, they may signify that the stabilities of the two intermediates formed in reaction [1] at elevated temperatures during an oxidation reaction are significantly different when brought to room temperature, perhaps because of different effective quench temperatures.

Reaction [1] involves neutral reactants. An electron must be transferred to the substrate to obtain a positive charge within the transition region. This positive oxide charge is localized within the transition region by formation of the oxygen complex, whereas the transferred electron is delocalized in the substrate. A double layer exists as a consequence of this first step in the oxidation reaction at the SiO_2-Si interface. This double layer, rather than the transport of charged oxygen species through the oxide film to the transition region, may account for changes in oxidation kinetics observed by Jorgenson (2) when a bias is applied across an oxide film during the thermal oxidation reaction (33).

Formation of intermediates at a transition region during a Si oxidation reaction presumably occurs with other oxidants, such as H_2O, HCl, and Cl_2. In contrast to reaction with O_2, these reactants form nonbridging, or terminally bonded, intermediates during the Si-Si bond breaking reaction as is shown below

$$\text{Si-Si} + H_2O \rightarrow \text{Si-H} + \text{Si-OH} \quad [2]$$

$$\text{Si-Si} + \text{HCl} \rightarrow \text{Si-H} + \text{Si-Cl} \quad [3]$$

$$\text{Si-Si} + Cl_2 \rightarrow 2\text{Si-Cl} \quad [4]$$

The parabolic and linear rate constants both increase when Si is oxidized with these oxidants which form terminally bonded groups (1, 34-36). A higher steady-state broken-bond density is obtained both within the oxide film and within the transition region. Oxidant diffusion rates are increased. Oxidation kinetics are also enhanced at the SiO_2-Si interface (37). Intermediates such as Si-Cl, which have bond energies only 0.7 eV less than Si-O (4.7 eV), are detected within the first 200Å of the oxide film (38).

The second oxidation reaction step involving oxygen as oxidant is the thermally activated reaction in which siloxane groups are formed as is shown in [5]

$$\equiv\text{Si}\cdot + (\text{Si-O})^+ + e \rightarrow \text{Si-O-Si} \quad [5]$$

In reaction [5], $(Si\text{-}O)^+$ complexes react at typical oxidation temperatures with incompletely oxidized Si atoms such as $\equiv Si\cdot$, as shown above, or with Si-Si bonds. Reaction [5] therefore decreases both Q_{ss} and N_{ss}. This reaction is exothermic and leads to a stable siloxane structure. The reactants are covalently bonded to the 3 dimensional transition region structure and therefore require local reorientation for reaction [5] to occur. Restructuring, or the displacement of Si atoms from their original lattice sites during this thermal oxidation reaction, can occur at three levels: at the substrate surface, within the transition region, and within the oxide film where bond angles are modified to accommodate newly formed oxide film (38). This restructuring is presumably a thermally activated

process that, in part, determines the rate of oxide film formation.

Electrically active intermediates are formed in reaction [1] and are consumed in reaction [5]. The temperature dependence of the O_2 oxidation reaction on Q_{ss} formation is readily understood by considering these reactions. As oxidation temperatures decrease, reaction [1], with $E_a = 0$, dominates and is limited only by the availability of oxidant at the transition region. The concentration of intermediates in the transition region increases during the Si-Si bond-breaking reaction. This results in a maximum Q_{ss} at low oxidation temperatures. As oxidation temperatures are increased, reaction [5] competes with reaction [1]. Intermediates formed in the Si-Si bond breaking reaction at the higher oxidation temperatures react during the siloxane formation reaction yielding a low steady-state concentration of these intermediates. This results in a low fixed oxide charge density.

Annealing in an inert ambient involves only reaction [5]. Intermediates formed in reaction [1] react to form siloxane groups by annealing in inert ambients at elevated temperatures. As the transition region is depleted of excess oxygen, the density of $(Si\text{-}O)^+$ complexes is reduced. This proceeds until the $(Si\text{-}O)^+$ density is minimized and results in a minimum Q_{ss}.

Other chemical reactions can occur during high temperature annealing that yields electrically active intermediates. For example, minimization of oxidant at the transition region by annealing at elevated temperatures in vacuum or in inert gases free of oxidant can cause SiO to form. Decomposition of the unstable SiO species will presumably generate electrically active sites. Vacuum annealing SiO_2(1000Å)-Si structures at greater than 1000°C for about 2 hr has been reported to increase N_{ss} and cause oxide shorts (4, 40). Oxide films, 150Å thick, have been evaporated from Si surfaces while annealing in high purity Ar at 1100°C for about 16 hr (41). At present, it is not known whether this formation of SiO occurs uniformly at an SiO_2-Si interface or at local defect sites (42). An additional reaction, the interaction of N_2 gas with Si at elevated temperatures, mentioned above, also generates electrically active instabilities in the absence of oxidant.

The concentration of nonoxidized Si-Si bonds in the transition region, as well as C_i, determine the concentration of complexes formed during the oxidation reaction and, therefore, the fixed charge density. Differences in densities of fixed oxide charge associated with substrate orientation can be associated with different Si-Si bond concentrations at the oriented substrate interface. More Si-Si bonds are present at <111> interfaces. More complexes are formed in the <111> transition region during the oxidation process. The capability of minimizing Q_{ss} and N_{ss} in transition regions on <111> and <100> oriented substrates is determined by the ability to drive the oxidation reaction to completion at these interfacial regions.

The stability of Q_{ss} is determined by the stability of the Si-oxygen complex formed within the transition region as an intermediate during the thermal oxidation process. This positively charged complex is localized, or fixed, as a result of complex formation with oxygen. Charge densities are minimized under conditions at which an oxidation reaction is driven to completion and siloxane groups are formed. Positive charge may also be introduced into the oxide film by other means. These include biasing at electric field strengths of about 1 MV/cm and at temperatures > 300°C (1) and ionizing radiation. However, it is not expected that these positive charges are chemically equivalent to fixed oxide charge formed during an oxidation reaction or that they will possess similar stabilities.

Summary

It has been conjectured in the past that fixed oxide charge is a reflection of excess unoxidized Si bonds, or sometimes of an oxygen deficiency, in the oxide. Recent studies show that the density of excess Si bonds in the SiO_2-Si transition region is of the order of the surface density of atoms in Si, *i.e.*, far greater than observed values of Q_{ss}/q. Furthermore, the stoichiometry and width of the transition region are unaffected by those parameters that can drastically influence the magnitude of Q_{ss}.

The chemical origin of oxidation-induced fixed charge and fast surface states is proposed to be the intermediate complexes generated during the formation of the SiO_2-Si transition region. These electrical instabilities are formed during the oxidation reaction

$$\text{Si-Si} + (\text{O}) \rightarrow \equiv\text{Si}\cdot + (\text{Si-O})^+ \rightarrow \text{Si-O-Si}$$

where the dangling bonds, $\equiv Si\cdot$, are identified with fast states and the $(Si\text{-}O)^+$ complexes are identified with fixed charge. This transition region has a steady-state gross stoichiometry and width, but is being continuously reformed at a rate that is necessarily that of the oxidation reactions. The density of the intermediates depends upon the concentration of nonoxidized Si bonds (orientation-dependent) as well as the concentration of excess (probably dissolved) oxygen. The values of Q_{ss} and N_{ss} will reflect this density at the time the reaction is quenched.

The electrically active intermediate sites are attached to the 3 dimensional solid structure. Elimination of these sites requires completion of the above oxidation reaction. This is accomplished as a consequence of postoxidation inert-gas annealing. The model proposed here is consistent with the known properties of oxide charge and fast surface-state generation and anneal as well as with the properties of the SiO_2-Si transition region.

Diffusion Layers Formed in Si Substrates during the Epitaxial Growth of BP and Application to Devices

Takao Takenaka, Mitsuharu Takigawa, and Katsufusa Shohno*

Faculty of Science and Technology, Sophia University, Kioicho 7, Chiyoda-ku, Tokyo 102, Japan

ABSTRACT

Either n-type (phosphorus) or p-type (boron) diffused layers are formed on Si substrates during the epitaxial growth of n- or p-type boron monophosphide (BP) on Si substrates by using a B_2H_6-PH_3-H_2 system. At an early growth stage of BP on Si substrates a very small amount of boron and phosphorus covers the substrate surface, which will be a diffusion source. The properties of the diffused layers thus formed are dependent on substrate temperatures and reactant gas flow rates. BP layers then grown on the substrate do not act as a diffusion source. So we can realize many types of BP-Si heterojunctions. Of these combinations, a wide gap window solar cell (η = 8.3%) and a wide gap emitter transistor (β = 16) are fabricated and their characteristics are investigated.

Since Chu *et al.* (1) succeeded in epitaxial growth of boron monophosphide (BP) on a SiC substrate in 1971, several attempts have been made to grow BP epitaxially on Si substrates (2-4). We found that p-type (boron) or n-type (phosphorus) diffused layers are formed on Si substrates during the epitaxial growth of n- or p-type BP on Si substrates by using a B_2H_6-PH_3-H_2 system. In this paper, properties of p-type (boron) or n-type (phosphorus) diffused layers thus formed on Si substrates are studied. Conduction types of a grown BP film and a diffused layer can be controlled easily, so it is possible to fabricate many combinations of BP-Si heterostructures. Here a window solar cell and a wide gap emitter transistor are fabricated and their characteristics are investigated.

Epitaxial Growth of BP on Si

The apparatus for the epitaxial growth of BP on Si substrates using a B_2H_6-PH_3-H_2 system was described previously (3, 4). The upper part of a quartz reaction chamber having inner dimensions of 25 × 40 × 400 mm^3 was water-cooled. Mirror-finished Si substrates had a plane 2° off-oriented from the (100) face in the direction of a (110) plane. They were placed on a SiC-coated graphite susceptor and heated externally by an rf generator (5). The substrate temperature was measured with an optical pyrometer calibrated by a platinum-platinum-rhodium thermocouple beforehand.

* Electrochemical Society Active Member.

Key words: diffusion, BP, epitaxy, solar cell, transistor.

Reactant gases were diborane (B_2H_6) and phosphine (PH_3) diluted to 1 and 5% in hydrogen, respectively. The carrier gas was high purity hydrogen and the flow rate was 2500 cm^3/min. The diluted B_2H_6 gas of 20 cm^3/min and the diluted PH_3 gas from 50 ~ 1000 cm^3/min were mixed with the main carrier gas. Particular attention was paid to the control of the amount and time of introduction of reactant gases. The flow rate of B_2H_6-H_2 gas is extremely important to obtain BP layers of high crystal perfection. On the other hand the flow rate of the PH_3-H_2 gas does not change the perfection of a grown crystal.

The substrate temperature was 950°C for growing n-type BP and 1050°C for p-type BP, independent of the flow rate of PH_3-H_2 gas. The results are shown in Fig. 1. The main impurity in grown BP layers was autodoped Si ($\simeq 10^{19}$ cm^{-3}) which is known as an amphoteric impurity. That is, both types of BP are grown without any additional doping gas.

Diffusion Layers Formed in Si Substrates

We found that the diffusion of P and/or B onto a Si substrate takes place during the growth of BP. Diffusion layers thus formed on Si substrates of n-type with 3 ~ 5 Ω-cm and of p-type with 10 Ω-cm were investigated.

BP layers were removed electrolytically from the substrates and a thin SiO_2 layer on the Si surface was etched with HF-NH_4F solution. The conduction type of a diffused layer was determined from its thermoelectric

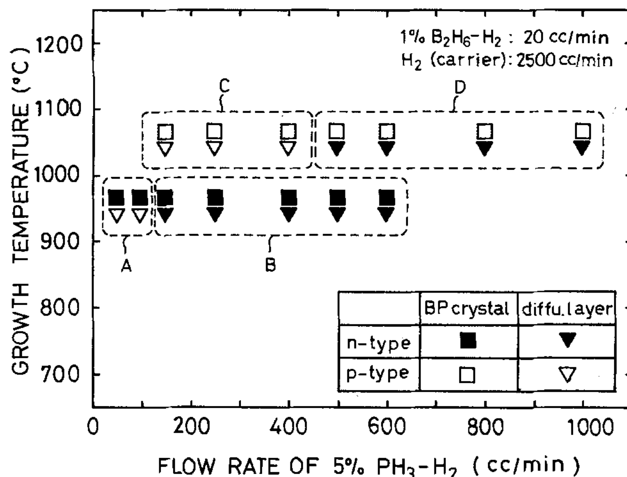

Fig. 1. Conduction type of BP and diffusion layer depending on flow rate of 5% PH_3 and substrate temperature.

power. The surface resistance was measured by the conventional four-point probe method and the diffusion depth by spherical drilling (6) and staining. The surface concentration of diffused impurities was determined by assuming an error function as the impurity profile.

It is possible to realize easily both conduction types of the diffused layers on Si substrates as well as of the BP layers by varying the flow rate of the PH_3-H_2 gas or the substrate temperature. The results are summarized in Fig. 1 for the flow rate of the 5% PH_3-H_2 gas. The conduction type of diffused layers on Si substrates is determined mainly by the flow rate of the PH_3-H_2 gas when the substrate is kept at a constant temperature: n-type (phosphorus) diffused layers are obtained for a flow rate larger than 150 cm^3/min at 950°C and 450 cm^3/min at 1050°C while p-type diffused layers are formed for a flow rate smaller than 100 cm^3/min at 950°C and 400 cm^3/min at 1050°C.

The surface concentration of n-type diffused layers increases with increasing flow rate of the PH_3-H_2 gas at 950°C as shown in Fig. 2. The growth time was 20 min and the B_2H_6-H_2 flow rate was strictly kept at 20 cm^3/min. On the other hand the surface concentration of p-type diffused layers decreases by increasing the flow rate of the PH_3-H_2 gas at 1050°C. The flow rate of the B_2H_6-H_2 gas has to be controlled very carefully because it determines the growth of BP and influences its crystal perfection: BP films of best quality are obtained when the growth rate is 700 Å/min. If the crystal perfection is so poor as to have twins, planar defects, and so on, the surface concentration of the diffused layers cannot be reproduced. The surface concentration and the diffusion depths of n-type diffused layers are given as a function of their growth time in Fig. 3. The surface concentration decreases inversely proportional to the square root of the growth time but the diffusion depth increases. This suggests that a very thin diffusion source, which does not crystallize to BP, is formed at an early growth stage. The amount of diffused phosphorus is calculated from the figure to be $Q = 5 \times 10^{13}$ cm^{-2}. Similar results were obtained for BP samples which were grown epitaxially and then heat-treated.

Next, diffusion experiments were performed by using B_2H_6-H_2 gas (20 cm^3/min) and PH_3-H_2 gas (250 cm^3/min) independently. The surface concentration of boron and phosphorus is shown in Fig. 4 as a function of diffusion temperature. The values for boron at temperatures higher than 1100°C are almost the same as the value of its solid solubility in Si (7), but the values for phosphorus are far less than that for boron. The curves for boron and phosphorus cross at

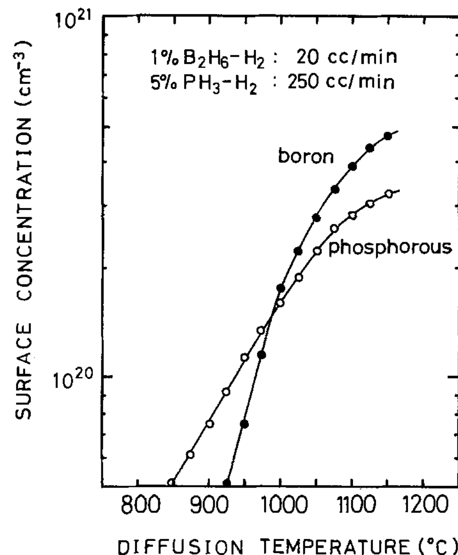

Fig. 4. Phosphorus and boron surface concentration as a function of diffusion temperature using individual reactant gas of 5% PH_3 and 1% B_2H_6.

about 1000°C. This indicates that n-type diffused layers will be formed at 950°C and p-type diffused layers at 1050°C. It is expected from the surface concentration of phosphorus, $N = 1.2 \times 10^{20}$ cm^{-3}, calculated from Fig. 4 and the total amount of diffused-in phosphorus $Q = 5 \times 10^{13}$ cm^{-2}, that the diffusion source should be formed within 5 sec in the very early growth stage of the BP. That is, only a small amount of boron or phosphorus covers the Si surface first and the BP layer then grown protects this diffusion source and the grown BP crystal does not act as a diffusion source.

Figure 4 also indicates that the compensation of boron and phosphorus occurs on the substrate under BP layers: Thus the concentration of boron or phosphorus determined experimentally is only a net value estimated from concentration in Fig. 2.

Application to Devices

By combining the conduction types of grown layer BP, diffused layer, and Si substrate, eight different junctions are realized as shown in Table I. The combination in groups A and B includes a wide gap window solar cell (8) and a wide gap emitter transistor (9, 10).

Wide gap window solar cell.—BP is a semiconductor with an indirect forbidden energy gap of 2.0 eV, low resistivity ($10^{-3} \sim 10^{-4}$ Ω-cm) (11-14), low reflectivity (10% in visible light) (11), and large hardness (4700 kg/mm²) (15). So the thin BP layer is useful for a window of Si solar cells and is also effective in reducing the radiation degradation. Furthermore it reduces the series resistance and reflection loss.

The nBP-pSi heterostructures were obtained in the growth region A on a p-type Si substrate of 0.1 Ω-cm. The acceptor concentration is larger than the p-type (boron) diffused layer of 4×10^{17} cm^{-3}. The grown n-type BP layer has a thickness of 0.75 μm and a carrier concentration of about 10^{19} cm^{-3}. The BP layer was removed from the Si substrate selectively by the usual photolithographic process and comb-shaped Al electrodes were evaporated. The size of the cell thus fabricated was 2×2 mm². The current-voltage characteristic suggests the existence of interface states in the BP-Si heterojunction: The forward current has a region proportional to exp (eV/nkT) with $n = 6 \pm 2$. The backward current is large and does not saturate.

Spectral photocurrents excited with monochromatic light (Shimadzu Spectronic 20) were measured at room temperature. The results are shown in Fig. 5. Apparently the spectrum broadens towards the short wavelength region compared with the spectrum of a Si cell. This is attributed to BP having the wider forbidden energy gap than Si. The conversion efficiency of the cell is fairly low. There would be many recombination states in the BP-Si interface due to the differences in lattice constants ($a_{Si} = 5.43$Å, $a_{BP} = 4.53$Å) and thermal expansion coefficients ($\alpha_{Si} = 2.6 \times 10^{-6}$ deg^{-1}, $\alpha_{BP} = 4.8 \times 10^{-6}$ deg^{-1}).

Table I. Eight junctions realized by combining conduction type of BP, diffusion layer, and Si substrate

REGION	BP CRYSTAL	DIFFU. LAYER	Si SUB.	ENERGY BAND STRUCTURE (BP / Si)	DEVICE

D	p	n	n		DIODE
			p		TRANSISTOR

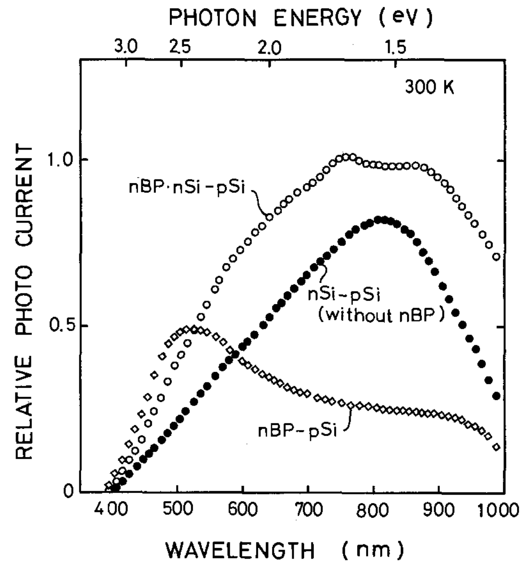

Fig. 5. Spectral photocurrent of wide gap window solar cells with nBP-pSi and nBP·nSi-pSi structure. That of nSi-pSi cell after removing nBP layer from nBP·nSi-pSi cell is shown for comparison.

The nBP · nSi-pSi cell was fabricated by growing BP epitaxial layer on a p-type (100) Si substrate (5-8 Ω-cm) in the region B of Fig. 1. The carrier concentration of the n-type BP layer was about 10^{19} cm^{-3} and the thickness was about 0.75 μm. The surface concentration of the n-type diffused layer was 8×10^{18} cm^{-3} and the diffusion depth was 0.3 μm. The forward current has two regions proportional to exp (eV/nkT) with $n = 1.9$ and 1.5. The dark current-voltage characteristics are almost the same as those of a Si p-n junction cell.

The spectral photocurrents of nSi-pSi cells, made by removing the nBP layer electrolytically from the nBP · nSi-pSi cell are shown in Fig. 5 for comparison. The short-circuit current with an nBP layer is apparently larger than that without an nBP layer, due to a difference in reflectivity of BP and Si. The conversion efficiency of the solar cell with an nBP layer and without an nBP layer is $\eta = 8.3\%$ and $\eta = 6.5\%$, respectively. These values are estimated roughly by using a commercially available solar cell of p-n Si structure with antireflection coating of SiO and a conversion efficiency of 12% as a standard.

Wide gap emitter transistor.—The electrical properties of the BP-Si interface will be evaluated by the injection efficiency at an emitter junction. Two types of wide gap emitter transitors were prepared: One is nBP-pSi-nSi and the other is nBP · nSi-pSi-nSi structure having a cascade junction nBP · nSi-pSi emitter, whose electronic band structures are shown in Fig. 6.

The fabrication process is shown in Fig. 7. After the p-type base was diffused for n-type Si, nBP was epitaxially grown. At the same time, the n-type diffused layer for cascade junction was formed. Fabrication processes are as follows: Remove the nBP layer selectively mesa-etch by masking the nBP emitter then evaporate Al and delineate contact areas, and again mesa-etch the collector junction. A photograph of a chip is shown in Fig. 8.

The forward current of the emitter heterojunction for the nBP-pSi-nSi transistor has a region proportional to exp (eV/nkT) with $n = 6.0$. The backward current is large and does not saturate. The common emitter current gains of these transistors are $0.6 \sim 0.8$. These characteristics are strongly affected by recombination states located at the interface between BP and Si.

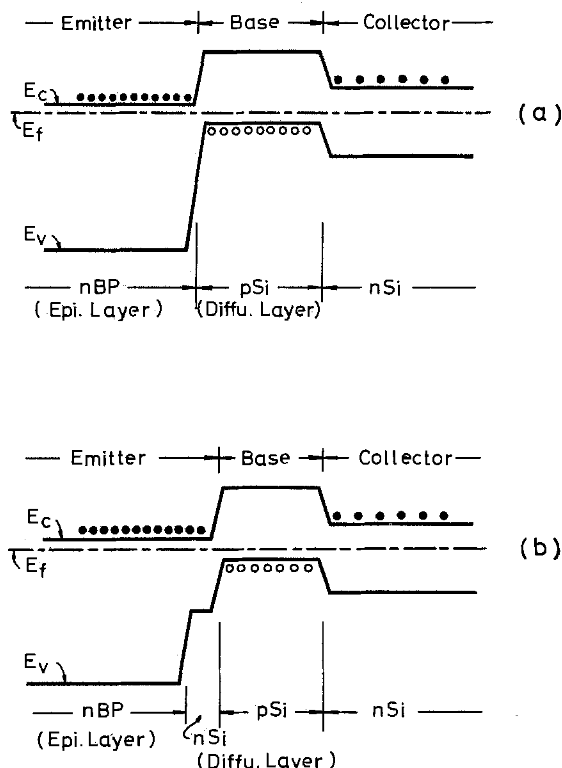

Fig. 6. Energy band diagram of wide gap emitter transistors with nBP-pSi-nSi (a) and nBP·nSi-pSi-nSi (b) structure.

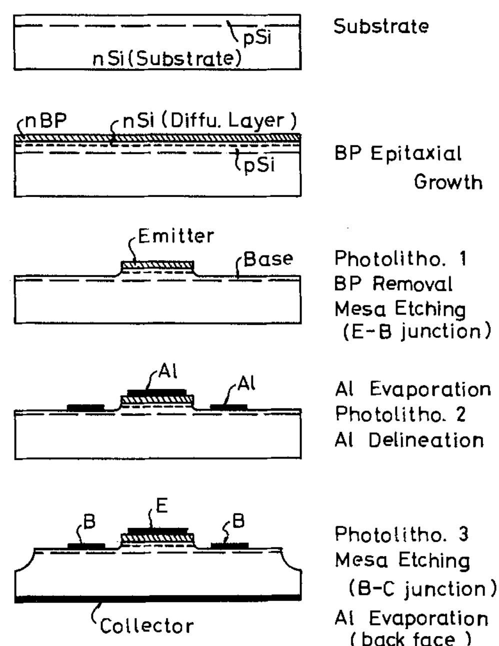

Fig. 7. Fabrication process of wide gap emitter transistor with nBP·nSi-pSi-nSi structure.

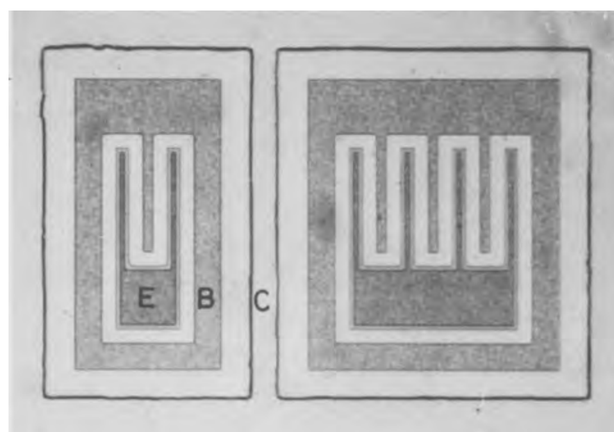

Fig. 8. Photograph of wide gap emitter transistor with nBP·nSi-pSi-nSi structure (E, emitter; B, base; C, collector).

Typical current-voltage characteristics for the nBP nSi-pSi-nSi transistor are shown in Fig. 9. The common emitter current gain β is about 16 and the injection efficiency of the emitter heterojunction is about 0.94 if the other gain factors are assumed to be unity. The forward current of the emitter junction has two regions proportional to exp (eV/nkT) with $n = 2.6$ and 1.6. The backward current of the junction does not saturate, similar to that of a Si p-n junction. The breakdown voltage of the collector junction was about 250V.

Conclusions

The epitaxy of BP on Si substrates using a B_2H_6-PH_3-H_2 system can be controlled to form either n-type (phosphorus) or p-type (boron) diffusion layer on the Si substrates. At an early growth stage within the first few seconds, a small amount of boron and phosphorus was supplied as a diffusion source, and BP layers grown subsequently do not act as diffusion sources. Several types of BP-Si junctions were realized out of possible combinations of BP layer, diffused layer, and Si substrate. A wide gap window solar cell ($\eta = 8.3\%$) of nBP · nSi-pSi structure and a wide gap emitter transistor ($\beta = 16$) of nBP · nSi-pSi-nSi structure demonstrated applicability to devices.

Kinetics of Silicon Growth under Low Hydrogen Pressure

M. Jean-Pascal Duchemin, M. Michel Bonnet, M. François Koelsch

Thomson CSF, Département Microélectronique Hyperfréquence, Domaine de Corbeville, 91401 Orsay, France

ABSTRACT

The kinetics of silicon deposition have been studied in a reactor working under reduced hydrogen pressure between 10 Torr and atmospheric pressure (760 Torr) for the following silicon sources: SiH_4, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$. In every case, the kinetics are controlled by the surface at low hydrogen pressure whereas at higher pressure the mass transfer becomes slower. When the kinetics are controlled by the surface, the deposition rate is inversely proportional to the square root of the hydrogen pressure and is activated. In the opposite case the deposition rate is inversely proportional to the hydrogen pressure and does not depend on the temperature. This result, and the fact that the depositions are monocrystalline even at low temperature when the pressure is lower than 70 Torr, show that the hydrogen is strongly adsorbed on the silicon surface. The deposition made at low pressure and low temperature have abrupt impurity profiles which allow us to realize good quality microwave components.

Over the past few years there has been a demand for submicron monocrystalline silicon layers. These structures are grown, for instance, in order to make IMPATT diodes working over 50 GHz (such a structure for use at 90 GHz has 3 layers whose total thickness is 7000Å) microwave Schottky diodes (for X and Ku bands) or rapid integrated circuits.

In every case these layers must be grown upon very heavily doped substrates ($\rho \leq 0.001\ \Omega \cdot cm$) or upon substrates containing buried layers having this resistivity. It is essential for the active layer to be clearly defined and the substrate-layer or layer-layer transitions to be as steep as possible (some hundred angstroms). Further, it is necessary to reduce solid-state diffusion of impurities of the substrates toward the active layer to minimize the autodoping of the active layer by the impurities of the substrate, and finally, to eliminate the transient mechanisms which take place at the beginning and end of growth. One can act on diffusion by lowering the growth temperature. For that reason silicon sources with a fast kinetics of decomposition such as SiH_4, SiH_2Cl_2, or even $SiHCl_3$ are used. Typical growth temperatures are 1000°C.

Some years ago, Chiang (1, 2) reported that with a helium carrier gas it is possible to grow defect-free silicon at temperatures lower than 900°C. However the absence of the reducing effect limits the possibility of using this process. More recently, Townsend (3) has shown that one can reduce the quantity of hydrogen adsorbed on the silicon surface and grow excellent quality layers at a lower temperature by using a low hydrogen pressure. This technique has the added advantage of reducing autodoping because the impurities which escape from the substrate diffuse faster through the stagnant layer. In addition, purging and the transient mechanisms at the beginning and end of the epitaxial process are accelerated at reduced pressure. For all these reasons, this technique is expected to be a significant development. However, little is known up to now about the kinetics of epitaxial growth at a low hydrogen pressure. The purpose of this work is to study some features of the growth kinetics as a function of pressure and to compare low pressure and atmospheric pressure growth mechanisms.

Key words: silicon growth, reduced pressure, autodoping.

Experimental Procedure

For this study we used a horizontal reactor heated by induction at low frequency (50 kHz) and with air-cooled walls.

The control gas panel is classical and is like the panels which are on conventional systems working at atmospheric pressure. It is equipped with four source lines of silicon ($SiCl_4$, $SiHCl_3$, SiH_2Cl_2, SiH_4) and four doping lines (one line N, another P, another N^+, and finally a line P^+); the N doping is obtained with arsine and the P doping with diborane.

Pressure control is carried out by means of a mechanical gauge, and temperatures are measured by an optical pyrometer using Allen's corrections so as to take into account the emissivity peculiar to silicon. It should be noted here that there is a great difference in temperature between the substrate and the susceptor when working at low pressure; this difference is as much as 140°C at 10 Torr. The reason for this is the re-

duction of the thermal conductivity of the gas layer between the substrate and the susceptor.

A rotary pump of 100 m^3/hr is used to maintain the pressure of the gases which flow in the reactor at a level lower than atmospheric pressure.

A molecular sieve serves to prevent the back diffusion of oil toward the reactor; a liquid nitrogen trap is used during hermiticity trials but this is ineffective when working at several Torr because the mean free path is then much lower than the trap dimensions. An adjusting valve is used to control the internal pressure of the reactor independently from the rate of reactant gas flow, this being done by limiting the pumping rate.

The graphite susceptor, coated by a thin layer of silicon carbide (SiC) can contain three substrates, 40 mm in diameter. In all the experiments described below, the hydrogen flow is kept constant at the rate of 18 liters/min, measured under standard conditions of pressure and temperature. A rough diagram of this equipment is given in Fig. 1.

Results

The kinetics of growth of the silicon have been studied as a function of the following parameters: nature and partial pressure of the silicon source, hydrogen pressure, and temperature. Let us start by defining these parameters:

p_{source} and p_{H_2}—partial pressures of the source species and of the hydrogen inside the reactor and

x_{source}—molar fraction of the source in the hydrogen

$$x_{source} = \frac{\text{number of source molecules}}{\text{number of source molecules} + \text{number of hydrogen molecules}}$$

In the case where the number of molecules of the source species is far lower than that of hydrogen (100 times smaller), $p_{total} \simeq p_{H_2}$

$$p_{source} = x_{source} \times p_{H_2}$$

It is to be noted that the partial pressure of the source can be changed in two different ways: (*i*) either by maintaining the molar fraction constant and modifying the total pressure; or (*ii*) by maintaining the total pressure constant and varying the molar fraction of the source

Order related to the source molar fraction.—For the 10-500 Torr pressure range, we have observed that the growth rate is linearly proportional to the source molar fraction when the source is silane, as can be seen in Fig. 2a and 2b. In the case of the chlorosilanes, the growth rate is not strictly a linear function of the source molar fraction as can be seen for trichlorosilane in Fig. 2c.

Order related to the hydrogen pressure.—Experiments made with a constant source molar fraction.—The variation of the growth rate as a function of the hydrogen pressure in the reactor was studied by maintaining constant the following parameters: the hydrogen flow measured at atmospheric pressure; the source molar fraction; and the surface temperature. Under these conditions, three growth rate variation ranges can be observed for silane: (*i*) for low hydrogen pressures, the growth rate increases proportionally to the square root of hydrogen pressure; (*ii*) within a second pressure range, the growth rate becomes almost independent of the pressure; and (*iii*) at higher H_2 pressures, the growth rate decreases following a function which is more abrupt than a linear function. These results are given in Fig. 3a. Figures 3b-d show similar data for the other sources SiH_2Cl_2 $SiHCl_3$, and $SiCl_4$. The same three variation ranges are again observed. However, the growth rate at low H_2 pressures is strictly proportional to the square root of the hydrogen pressure only in the case of silane.

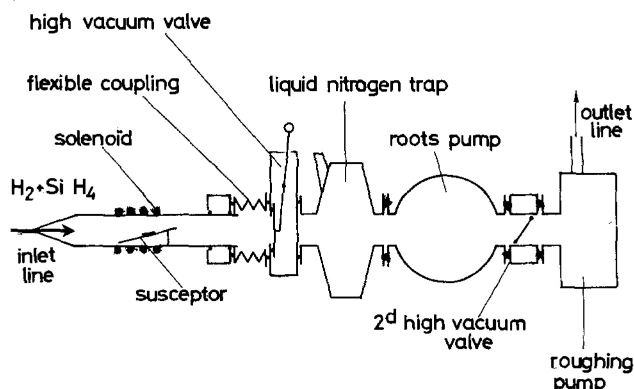

Fig. 1. Diagram illustrating the principle of the system used to study growth process at low pressure.

Expression of these results for a constant partial pressure of the source.—In order to understand the growth mechanisms it is easier to use as a fixed parameter the partial pressure of the source at various total pressures in the reactor. It is, however, difficult to do this experimentally. It would require one to vary at one and the same time the hydrogen pressure and the source molar fraction so as to keep product $x_{source} \cdot p_{H_2}$ constant. On the other hand, one can readily recalculate the growth rates as a function of the hydrogen pressure for a fixed partial pressure of the silane. This can be done using the preceding results (Fig. 2b) in the case of silane by employing the linear relation between the growth rate and the source molar fraction for a fixed hydrogen pressure. Thus, the new value of the growth rate for a partial pressure of silane (P silane) different from the experimental partial pressure is

$$\left(\frac{dx}{dt}\right)_{calculated} = \left(\frac{dx}{dt}\right)_{\substack{experimental \\ at\ p_{source}\ (experimental)}} \times \left[\frac{p_{source}}{p_{source}}\right]_{experimental}^{selected}$$

Thus in the case of silane, three variation ranges are observed in the calculated diagrams: (*i*) The growth rate varies proportionally to $(p_{H_2})^{-1/2}$ within a first range; (*ii*) the growth rate is proportional to $(p_{H_2})^{-1}$ within a second range; and (*iii*) the growth rate decreases more rapidly than $(p_{H_2})^{-1}$ beyond a certain value of the pressure. These results can be seen in Fig. 4a. Figures 4b-d give the results for the compounds SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$. The same variation ranges are observed for the chlorosilanes although strictly speaking the transformation is not exact since the growth rate is not completely proportional to the partial pressure for these compounds.

Influence of the temperature.—The temperature has a very different action on the two variation ranges of the growth rate. It can thus be seen in Fig. 5a, which corresponds to experiments made in function of the pressure for a constant initial molar fraction of silane, that a rise in temperature increases the growth rate in the first (low pressure) range while the temperature is without effect on the same growth rate beyond a certain value of the hydrogen pressure. This same effect can also be seen in Fig. 5b which gives the same experimental results calculated for a constant partial pressure of the silane source.

The results of a more complete study of temperature as a variable parameter are given in Fig. 6a-c in the

Fig. 2. (a) Growth rate as a function of SiH_4 molar fraction, the pressure is 20 Torr, and temperature 900°C; (b) Growth rate as a function of SiH_4 molar fraction for different hydrogen pressures; temperature 930°C; (c) Growth rate as a function of $SiHCl_3$ molar fraction for different hydrogen pressures; temperature 990°C.

case of silane for an initial molar fraction of this source of 2.1×10^{-3} and different hydrogen pressures: 10, 70, and 500 Torr. Figure 6d gives these same results recalculated to a partial pressure of silane of 2.1×10^{-2} in all cases.

Influence of hydrogen pressure on crystalline perfection.—We have observed that the temperature limit at which the deposited layer becomes polycrystalline is lowered when working under reduced pressure. This result has been mentioned by Townsend (3). We studied this phenomenon by keeping constant the hydrogen flow at 18 liters/min and the silane molar fraction at 10^{-3} in all cases. The results obtained are given in Table I and correspond to an averaged estimation made over a large number of depositions.

Thus for example, at 910°C for a hydrogen pressure of 10 Torr and a growth rate of 0.18 μm/min, the surface finish remains perfectly polished and only a few stacking faults are to be seen on the edge of the substrate in the case where this latter has been cleaned in the reactor by an HCl etching for a few moments at atmospheric pressure before putting the system under vacuum.

Under our experimental conditions, the surface finishes obtained with the different chlorosilanes are satisfactory when the pressure is greater than 250 Torr. At a lower pressure the surface finish is rough. However, the layers are monocrystalline. This can be explained by the effects of the silicon transport by HCl between the susceptor which is very hot and the substrate which is much colder. (This difference in temperature is due to the difficulty of substrate heating by contact in a system under vacuum.) This silicon transport is made easier under low pressure by the fact that the diffusion coefficients of all the compounds contained in the gas phase are higher at low pressure than at atmospheric pressure.

Kinetics of doping.—We studied the epitaxial layer doping with arsenic using arsine as a doping source. The experiments were made at 930°C for a silane molar fraction of 2.1×10^{-3}. In Fig. 7 we can see the variation of the level of the free carriers as a function of the hydrogen pressure when the arsine molar fraction is kept constant. When the hydrogen pressure varies, the level of the free carriers follows the same variation function as the growth rate. At the lowest pressures, the dopant carrier concentration is proportional to $(p_{H_2})^{+1/2}$. Beyond a certain higher value of the hydrogen pressure it becomes insensible to the pressure.

In the same way as before for the growth rate, the evolution of the level of the free carriers can be cal-

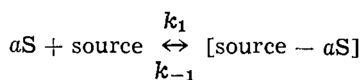
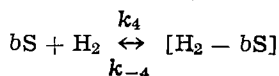
Fig. 3. Growth rate as a function of H_2 pressure for a given source molar fraction: (a) in the case of SiH_4; (b) in the case of SiH_2Cl_2; (c) in the case of $SiHCl_3$; and (d) in the case of $SiCl_4$.

culated for a constant value of the partial pressure of arsine. These results are given in Fig. 7 curve II. Two ranges can be seen: At low pressure, the level of free carriers is proportional to $[p_{H_2}]^{-1/2}$; and beyond a certain value of the pressure the level of free carriers is proportional to $[p_{H_2}]^{-1}$.

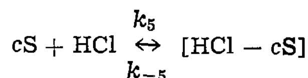
Discussion.—All the experimental results which have been described can be easily explained by using a model of heterogeneous catalysis recently used by Seto (4) in the case of polycrystalline silicon deposition under nitrogen atmosphere at atmospheric pressure. In this model, Seto makes the following assumptions: (*i*) growth rate is proportional to the number of adsorbed species; (*ii*) the absorption of all species takes place on crystalline sites of the silicon surface which are of the same type. Under these conditions, the different heteroequilibrium are functions of the values of the partial pressures and equilibrium coefficients. These equilibriums can be represented by the following chemical equations



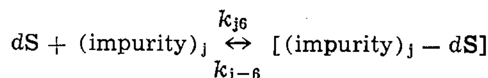
$$aS + \text{source} \underset{k_{-1}}{\overset{k_1}{\leftrightarrow}} [\text{source} - aS]$$



$$bS + H_2 \underset{k_{-4}}{\overset{k_4}{\leftrightarrow}} [H_2 - bS]$$



$$cS + HCl \underset{k_{-5}}{\overset{k_5}{\leftrightarrow}} [HCl - cS]$$



$$dS + (\text{impurity})_j \underset{k_{j-6}}{\overset{k_{j6}}{\leftrightarrow}} [(\text{impurity})_j - dS]$$

Where: a is the number of sites fixing a molecule of the source; b is the number of sites fixing a molecule of H_2; c is the number of sites fixing a molecule of HCl; d_j is the number of sites fixing a molecule of impurity j; S represents one silicon surface site; and k_1, k_4, k_5, k_6 and k_{-1}, k_{-4}, k_{-5}, k_{-6}, are, respectively, the adsorption and desorption coefficients. In the case of the hydrogen, $b = 2$ can mean that the adsorption of a H_2 molecule takes place on two crystalline sites or that two hydrogen atoms are adsorbed on two adjoining sites.

Let us introduce the covering ratio of the silicon surface, called θ, defined as the ratio of the number of crystalline sites of the surface occupied by a particular type of adsorbed atoms, to the total number of sites. These covering ratios are thus θ_{source}, θ_{H_2}, θ_{HCl}, θ_{impurity}. The covering ratio of the surface by an impurity can be calculated if we assume that the surface remains in equilibrium with the gas phase; that is to say that the adsorption and desorption rates are high

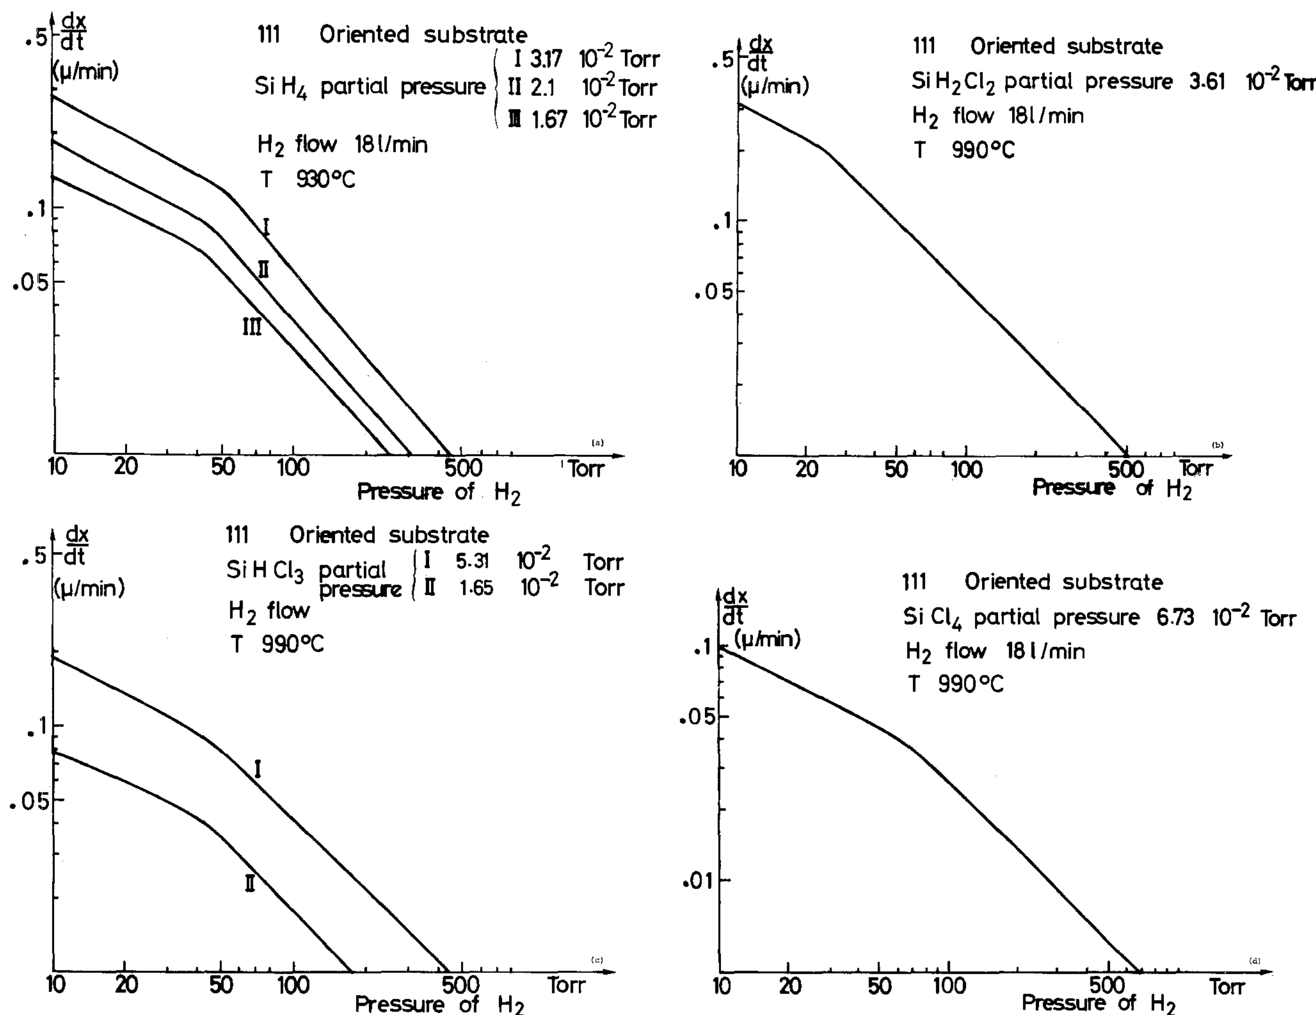


Fig. 4. Growth rate recalculated from the data of Fig. 3 for a given source partial pressure: (a) in the case of SiH_4; (b) in the case of SiH_3Cl_2; (c) in the case of $SiHCl_3$; and (d) in the case of $SiCl_4$.

in comparison with the decomposition rate of the silane. In this case, we can just say that the adsorption rate is equal to the desorption rate. The adsorption rate of a specie is proportional to its partial pressure, to the number of sites available to fix one molecule, and to the adsorption constant

$$v = p_{SiH_4} k_1 [1 - \theta_{SiH_4} - \theta_{H_2} - \theta_{impuritiesj}]^a$$

The desorption rate is proportional to the quantity of sites occupied by the concerned species

$$v = k_{-1} [\theta_{SiH_4}]^a$$

If we suppose that the growth rate is proportional to the number of sites occupied by a source molecule (of silane, for example)

$$\frac{dx}{dt} N = \frac{m_{Si} k_2}{d_{Si}} \times \frac{[K_1 \, p_{source}]^{1/a}}{1 + [K_1 \, p_{source}]^{1/a} + [K_4 \, p_{H_2}]^{1/b} + \ldots}$$

K_1, K_4, K_5, and K_6 represent in this equation the different coefficients of equilibrium

$$K_1 = \frac{k_1}{k-1} \quad K_4 = \frac{k_4}{k-4}$$

The other parameters being defined as: dx/dt is the growth rate; N is the number of silicon atoms per cm^3; m_{Si} is the mass of a silicon atom; and k_2 is the true coefficient of the chemical reaction on the surface.

The molar fraction of the HCl source compounds is small in comparison to H_2, typically $\leq 10^{-3}$. That of the doping impurities is about 10^{-5}-10^{-9} in most cases. There are therefore good reasons to think that

$$[k_4 \, p_{H_2}]^{1/b} >> [K_1 \, p_{source}]^{1/a} + [K_5 \, p_{HCl}]^{1/C} + \ldots$$

We can therefore pose the problem of whether the adsorption of hydrogen is strong or not, that is to say whether it plays a physical role or not. These two hypotheses are given by the inequalities

$$K_4 \, p_{H_2} >> 1 \quad \text{or} \quad K_4 \, p_{H_2} << 1$$

In the first case the hydrogen pressure is an active parameter on the growth rate; in the second case, this pressure is without effect. However the experimental results have shown that the growth rate was influenced by this parameter, it is therefore necessary to admit that $K_4 \, p_{H_2} >> 1$. The growth rate can therefore be represented by the relation

$$\frac{dx}{dt} = \frac{m_{Si} \, k_2 [K_1 \, p_{source}]^{1/a}}{N \, d_{Si} [K_4 \, p_{H_2}]^{1/b}}$$

Thus the apparent coefficient of the decomposition rate is in fact a function of the true coefficient of the reaction rate k_2 and of the equilibrium coefficients K_1 and K_4.

The constant k_2 can be studied while working under a low pressure of a pure silicon source, silane for example, or in an atmosphere of a rare gas which is very little adsorbed on the surface. Thus Joyce and Bradley (5) have shown the results observed while working with pure silane under low pressure; Seto has recently published results obtained with silane in argon, while Richman and Chiang (6) had published the same results in a helium atmosphere.

The experiments undertaken during this study were made under different pressures with the view to explaining the role of this gas on the surface of the silicon during growth. Thus when the pressure is fairly

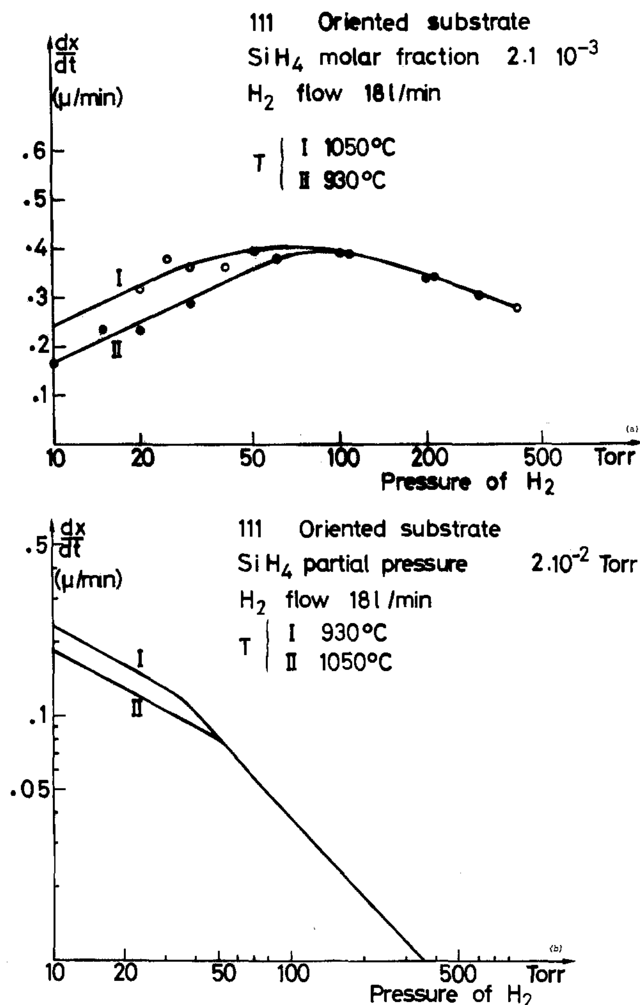

Fig. 5. (a) Growth rate as a function of H_2 pressure for a given SiH_4 molar fraction and two different temperatures; (b) Growth rate as a function of H_2 pressure for a given SiH_4 partial pressure and two different temperatures.

low, the gas diffusion coefficients and the mass transfer coefficients are higher than at atmospheric pressure, the concentrations of the different species are therefore the same on the surface of the layer and in the gas phase. Moreover, the efficiency of the reactor is so weak ($\eta \simeq 5\%$) that it can be considered that the concentration of the source is at any point in the reactor very close to that of the gases that have been introduced. All the experimental results can be explained simply with the model thus defined.

In the first variation range, represented for example in Fig. 5b or 4a, in the case of silane for pressures lower than 40 Torr, the mass transfer is fast and the film growth rate can be considered to be controlled by the rate of surface reaction. Seto's model shows that if the rate is proportional to $[p_{H_2}]^{-1/2}$ the adsorption of the hydrogen molecule is on two silicon sites, while a direct proportion between growth rate and the partial pressure of the silane would indicate an adsorption of silane on a single silicon site. We should note that Seto came to this conclusion as far as the adsorption of the silane on silicon is concerned. In contrast, Joyce and Bradley thought that they had shown the adsorption of the silane molecule on two silicon sites. However it is possible that their system was not well defined or there were, perhaps, important depositions on the sides of the reactor. Chabert and Peyrelavigne also concluded that silane is adsorbed on two silicon sites in the preparation of SiO_2.

In the first pressure range, for which the growth rate is controlled by the pressure, the reaction is controlled by the rate of the surface reaction. An activation energy of 15 [kcal][mole]$^{-1}$ can be deduced from the curve of Fig. 6a where the logarithm of the growth rate is plotted as a function of the inverse of the absolute temperature.

The second variation range of the growth rate, observed at pressures greater than 40-50 Torr corresponds to a limitation of the rate by gaseous diffusion. The growth rate is proportional to the diffusion rate of the source. It is therefore inversely proportional to the total pressure and relatively independent of temperature.

At very low pressure, 10 Torr for example, we are in a region controlled by the surface. At higher pressure, that is 70 Torr, the growth rate can be either controlled by the surface or by the mass transfer according to the temperature; under $T = 850°C$ the reaction is activated. Finally above 500 Torr, the mass transfer is low compared to the surface reaction and growth rate is insensitive to temperature.

Seto's model of heterogeneous catalysis can also explain the influence of the total pressure on the incorporation process of arsenic. Silane, the usual source, is not the only specie in competition with hydrogen on the surface, all the species present in the gas phase share the silicon surface. It is therefore the same for the molecules of the impurities which are also in competition with the hydrogen. In this way

$$N_d = \frac{\text{Constant}[K_{j6}\, p_{(\text{impurity})j}]^{1/d}}{K_4\, p_{H_2}{}^{1/2}}$$

The model thus defined therefore explains the fact that the doping level is proportional to $[p_{H_2}]^{-1/2}$ for low hydrogen pressures, when the partial arsine pressure is constant. The doping level then becomes proportional to $[p_{H_2}]^{-1}$ for higher pressures when the mass transfer has become sufficiently small.

The results given here concerning the quality of the crystal should be compared with those of Bloem (8). This author observed, at atmospheric pressure, that the limit of growth rate for which the layer becomes polycrystalline increases when the growth rate increases. Bloem showed that when we plot the curve which represents this growth rate as a function of the inverse of the absolute temperature, we obtain a straight line whose slope allows the calculation of an activation enery of 115 kcal/mole. Bloem then suggests that this energy is similar to that of silicon diffusion in silicon. He indicates that the slow stage in the monocrystalline growth of silicon is therefore the diffusion of free silicon which is looking for a crystalline site on the surface. The coefficient of self-diffusion of silicon in silicon has an activation energy of 110 kcal.

There is no real disagreement between our results and those of Bloem. However, there is matter for discussion since he does not take into account the role of hydrogen on the growth surface, an effect which becomes clear when the hydrogen pressure decreases. We must then admit, as shown by Townsend, that the adsorbed hydrogen molecules on the surface as well as all the species present there, hinder the crystalline arrangement of the growth.

Application of epitaxial growths obtained at low pressure.—P-n junctions.—Very abrupt junctions have been obtained by growing boron doped p^+ layers at low pressure under the following conditions: temperature, 930°C; pressure, 10 Torr; $dx/dt = 0.2$ μm/min; and hydrogen flow, 18 liters/min, measured at 760 Torr. Levels of free carriers of $7 \cdot 10^{19}$ acceptors per cm^3 were obtained. When the p^+ layer is grown immediately after a type n layer of a level close to 10^{17} carriers per cm^3, in a same growth process, the transition between the n layer and the p^+ layer is less than 300Å.

Impurity profile between the substrate and the epilayer.—The autodoping of epitaxial layers grown at atmospheric pressure is great when the substrates are heavily doped with phosphorus ($\rho \lesssim 10^{-3}$ Ω·cm). We

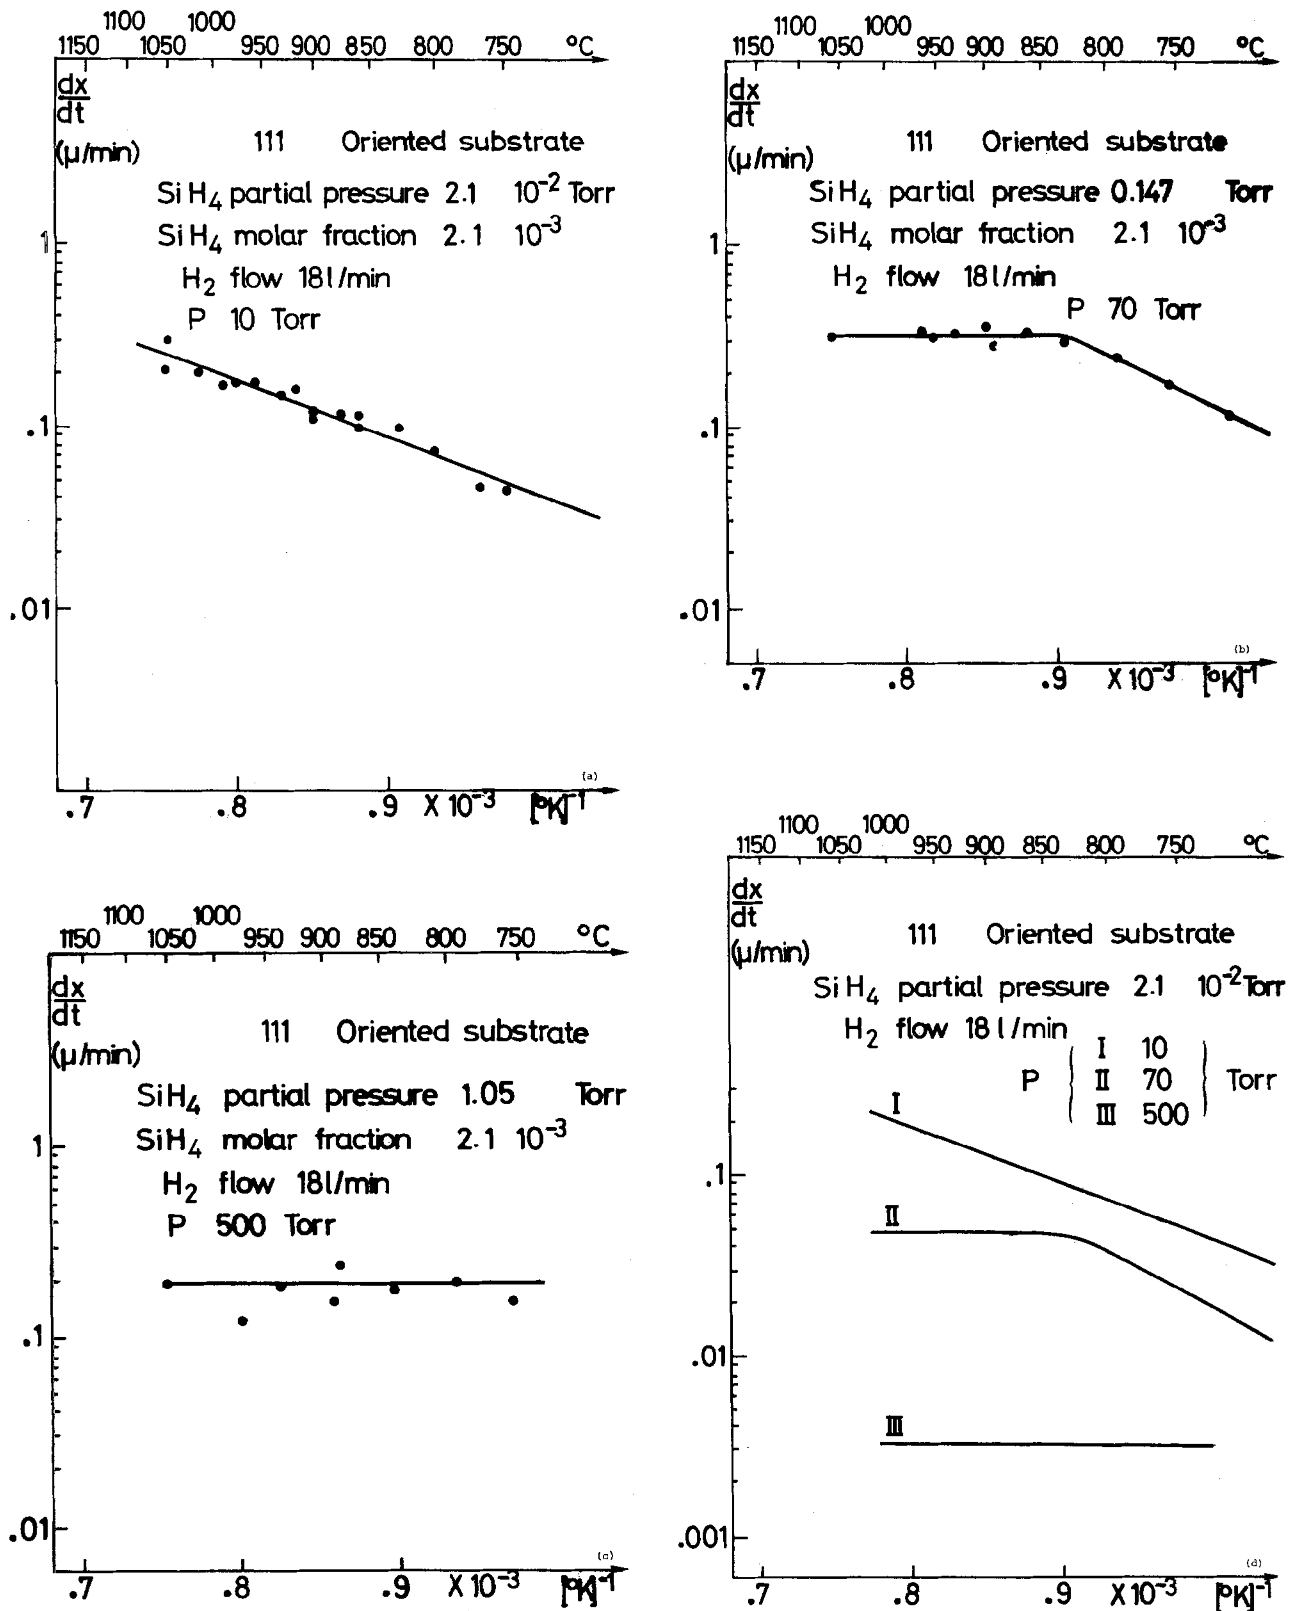

Fig. 6. Growth rate as a function of temperature in the case of silane for a given SiH_4 molar fraction: (a) H_2 pressure is 10 Torr; (b) H_2 pressure is 70 Torr; (c) H_2 pressure is 500 Torr; and (d) the same results recalculated for a given SiH_4 partial pressure.

have made similar layers on such substrates when operating at a hydrogen pressure of 10 Torr. As can be seen in Fig. 8, the effect due to autodoping is suppressed and the transitions are very abrupt. The exact profile of the impurities is more abrupt than the profile measured by the capacity-voltage method because of the Debye length. The actual profiles are then in agreement with Fick's laws. The abrupt transitions and the rapid purges obtained at low pressure allow the growth of layers of several thousand angstroms with a precision of ± 300Å. The reduction in autodoping due to the contamination by impurities which have escaped from the back side of the substrate can also be explained by Seto's model. For this, let us suppose that the evaporation rate of the impurities from the the back side of the substrate is constant. The partial pressure of the residual impurities in the reactor is

$$p_{\text{impurities}} = x_{\text{impurities}} \times p_{H_2}$$

which gives for the residual level of free carriers

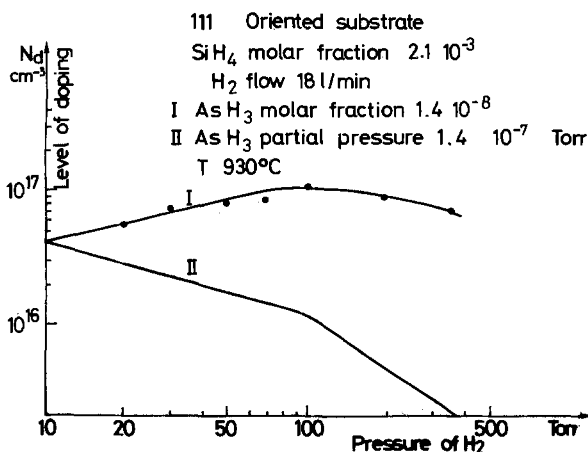

Fig. 7. Level of doping as a function of H_2 pressure: I, for a given AsH_3 molar fraction; II, for a given AsH_3 partial pressure.

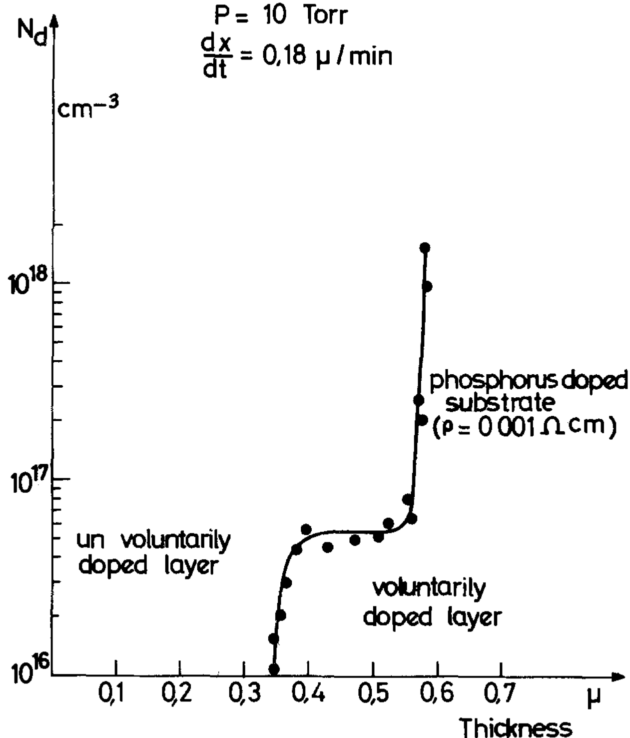

Fig. 8. Impurity profile obtained between a very heavily doped substrate and an epilayer by using a low temperature process.

$$N_{d_{\text{residual}}} = \frac{\text{constant } K_6 \, x_{\text{impurities}} [p_{H_2}]^{1/2}}{[K_4]^{1/2}}$$

The observations made of this phenomenon are in agreement with the preceding expression. Thus when the working pressure is 10 Torr, the residual level due to the escaped impurities of the substrate is reduced by a factor between 5 and 10.

Realization of microwave devices.—Schottky diodes working at 10 GHz have been made by using epitaxial structures grown under low pressure. The characteristics of the layer, the growth conditions, and the electrical performances of these diodes are summarized below.

For the epitaxial layer we used 111 oriented substrates, doped with phosphorus, of 10^{-3} Ω·cm resistivity. The metallurgical thickness of the layer was 0.17 μm, the electrical thickness 0.14 μm, the level of free carriers $1 \cdot 10^{17}$ atoms/cm³.

The layers were deposited at an actual temperature of the substrate of 930°C and a pressure of 10 Torr. The growth rate was 0.2 μm/min.

The geometrical characteristics of the diodes are the following: contact, Cr-Au; diameter of the diodes, 8 μm. The electrical characteristics of the diodes were then: 0V junction capacity, $C_{jo} = 0.12$ pF; breakdown voltage, 3V; noise factor, 4.7 dB when the input power of the local oscillator was 2 mW.

Conclusions

The experiments of silicon crystal growth carried out at a low hydrogen pressure have underlined the important role of hydrogen on the silicon surface during growth. By growing between 10 and 100 Torr for a constant partial pressure of each of the compounds SiH_4, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$, the growth rate presents following variation rate ranges: (*i*) At low pressure, the rate of film growth is proportional to $[p_{H_2}]^{-1/2}$ and is activated by temperature. Growth is controlled by surface hydrogen in competition with different source species (or doping species) on the surface. Layers are defect free even for temperatures lower than 900°C; (*ii*) At higher pressure, growth rate is proportional to $[p_{H_2}]^{-1}$. It is not a function of temperature; it is mass transfer limited.

Growth at low temperature and at low pressure allows us to obtain very steep impurity profiles between a very heavily doped substrate and the epilayer because both solid-state diffusion of impurities and autodoping are reduced. Less autodoping is obtained because the rate of gaseous diffusion of impurities which escape from the substrate is accelerated further, transitions between layers differently doped are more abrupt because purges are accelerated, and transient mechanisms are suppressed. For all these reasons the low pressure growth process is a great improvement in the fabrication of microwave devices.

An Experimental Study of Various Cross Sheet Resistor Test Structures

Martin G. Buehler* and W. Robert Thurber

National Bureau of Standards, Electronic Technology Division, Washington, D.C. 20234

ABSTRACT

Newly designed cross sheet resistors are shown to give the same (within 0.5%) measured sheet resistance as conventional van der Pauw structures. Diffused boron and phosphorus layers with sheet resistances near 200 Ω/□ were studied with the sampled areas varying from a square 6.4 μm (0.25 mil) on a side to a circle 762 μm (30.0 mils) in diameter. An increase in measured sheet resistance values was observed due to surface leakage currents, and an equivalent circuit model was developed to explain the results. The effect of joule heating on measured sheet resistance values was observed in both large and small cross structures.

In the microelectronics industry the sheet resistance of conducting layers is frequently measured with a four-terminal resistor in the shape of a bridge (1) or a van der Pauw (2) test structure. More recently, it was shown mathematically that the sheet resistance can be determined from the van der Pauw formula if the resistor has the shape of a Greek cross provided the arm length of the cross is greater than the arm width (3). Since the cross sheet resistor can be made as small as allowed by lithographic processes, the structure permits the study of electrical conduction effects in inhomogeneous materials where the nonuniform regions are of the order of the dimensions of the heart of the cross. Such effects have been observed in silicon on sapphire by Ham (4) and are anticipated in deposited layers such as aluminum and polycrystalline silicon. In this study the previous theoretical work is verified experimentally by comparing measurements on the new Greek-cross structures with conventional van der Pauw structures where the region of interest is contacted by four contacts which approximate points. Effects such as surface leakage currents and joule heating are discussed in terms of their influence on sheet resistance values. It was found that leakage currents due to surface channels can cause an apparent increase in the measured sheet resistance.

Equivalent Circuit Model

Experimental studies of various sheet resistor test structures were undertaken to verify that the sheet resistance can be properly calculated from the van der Pauw formula when interferences are negligible. In these studies, the six different test structures shown in Fig. 1 were fabricated by a planar silicon technology where the diffusions were made through oxide openings and contacted by evaporated metal layers. These structures appear on test pattern NBS-4 which includes many structures previously studied on test pattern NBS-3 (5). The structures are listed in Table I where various critical dimensions are cited. Structure 4.11 is a circular gated van der Pauw sheet resistor with a field plate extending from the periphery of the diffused layer to a channel stop diffusion which is the same conductivity type as the substrate. The offset quadrate cross, represented by structure 4.26, was studied experimentally by Perloff and co-workers (6) and found to be a viable test structure.

An equivalent circuit model for these junction-defined sheet resistors is shown in Fig. 2 where the sheet resistor terminals are labeled A, B, C, and D. In the model, the four resistors labeled R_1 represent the resistance of the region of interest, R_2 is the arm resistance, and R_3 is the surface shunt resistance between contact pads. In one test structure, the peripheral surface resistance R_3 can be controlled by a gate labeled G. The surface resistance between one of the contact pads and a nearby diffused area labeled

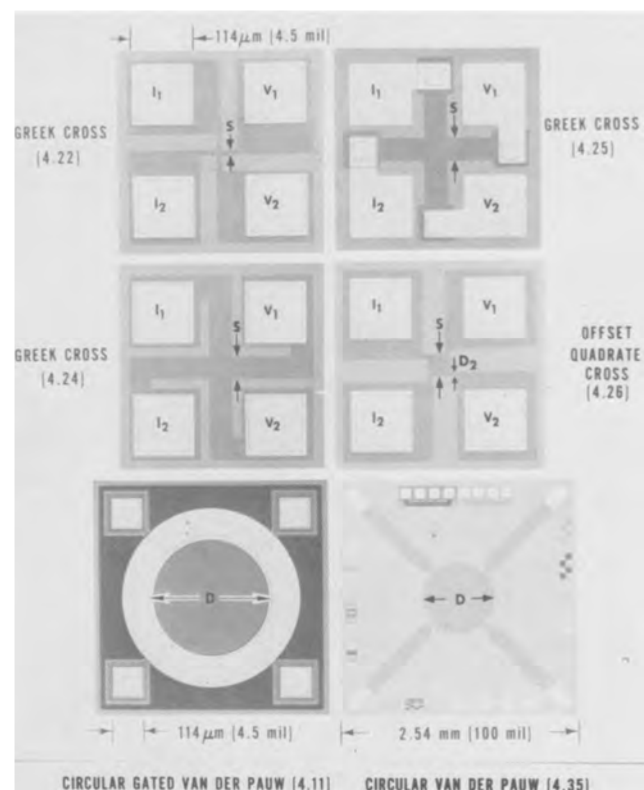

Fig. 1. Sheet resistor test structures. See Table I for explanation of symbols. The structures at the periphery of the square containing structure 4.35 are not a part of this structure.

E is shown as R_3^*. The entire structure is isolated by a junction from the substrate which is contacted at S. The model assumes that contact resistance at the probe pads is negligible and that pinhole shorting from the probe pads to the substrate is absent. In addition, current in the oxide is assumed to be negligible, and the substrate is assumed to have negligible resistance.

The computation of the sheet resistance and other factors follows from the measurement of resistance. The notation used for these resistances follows from the observation that the contact pads A, B, C, and D are arranged in a square as shown in Fig. 2. Two measurement positions are designated as the zero- and ninety-degree positions. In the zero position forward current $I_{AB}(+I)$ is passed into A and out of B and the voltage $V_{DC}(+I)$ is measured at D with respect to C. For reverse current, the current $I_{AB}(-I)$ is passed into B and out of A and the voltage is measured at D with respect to C. Both $I_{AB}(-I)$ and $V_{DC}(-I)$ are negative quantities. The static resistances, determined for the zero-degree position for both forward $(+I)$ and reverse $(-I)$ currents, are

$$R_0(+I) = V_{DC}(+I)/I_{AB}(+I) \quad [1a]$$

$$R_0(-I) = V_{DC}(-I)/I_{AB}(-I) \quad [1b]$$

In the ninety-degree position the current terminals are D and A and the voltage terminals are B and C. The static resistances are

$$R_{90}(+I) = V_{CB}(+I)/I_{DA}(+I) \quad [2a]$$

$$R_{90}(-I) = V_{CB}(-I)/I_{DA}(-I) \quad [2b]$$

The incremental resistance for both forward $(+I)$ and reverse $(-I)$ currents determined from measurements at the zero-degree position is

$$R'_0(\pm I) = \frac{[V_{DC}(+I) - V_{DC}(-I)]}{[I_{AB}(+I) - I_{AB}(-I)]} \quad [3]$$

and at the ninety-degree position is

$$R'_{90}(\pm I) = \frac{[V_{CB}(+I) - V_{CB}(-I)]}{[I_{DA}(+I) - I_{DA}(-I)]} \quad [4]$$

Note that $V_{DC}(-I)$, $I_{AB}(-I)$, $V_{CB}(-I)$, and $I_{DA}(-I)$ are all negative quantities. The average resistance determined from measurements at the zero- and ninety-degree positions for currents $\pm I$ is

$$R(\pm I) = [R'_0(\pm I) + R'_{90}(\pm I)]/2 \quad [5]$$

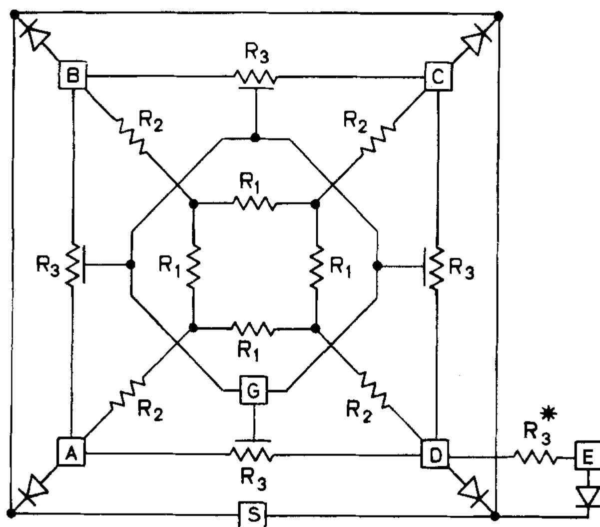

Fig. 2. Seven-terminal equivalent circuit model used to explain the effect of surface leakage currents on sheet resistance values. This circuit models a symmetrical, peripherally gated, junction-defined sheet resistor with a substrate and isolated junction contacts.

The sheet resistance is determined from the van der Pauw formula (2)

$$R_s = f[\pi R(\pm I)/\ln 2] \quad [6]$$

where f is a correction factor related to the geometrical asymmetry of the sheet resistor; see the Appendix. The value of f is related to the asymmetry factor, F_A, which is given by

$$F_A = [R'_0(\pm I) - R'_{90}(\pm I)]/R(\pm I) \quad [7]$$

As indicated in the Appendix, f is within 0.1% of unity for $F_A \leq 10.74\%$. The value of F_A is used in the experimental studies to quantify the degree of asymmetry encountered in the various sheet resistors. Since the sheet resistors in this study have a high degree of symmetry ($F_A \leq 3\%$), f was taken as unity in the computation of the sheet resistance.

The measurement of the sheet resistance assumes that offset voltages encountered in the measurement system can be eliminated by taking the difference in voltages at both forward and reverse currents. The zero offset factor, F_0, is calculated from

$$F_0 = \frac{(|R_0(+I) - R_0(-I)| + |R_{90}(+I) - R_{90}(-I)|)}{2R(\pm I)} \quad [8]$$

where taking the absolute value of the quantities leads to a worse case estimate. Small values of F_0 indicate that the measurement system is adequate.

In the measurement of the sheet resistance, it is assumed that the conduction mechanism is ohmic. To quantify the linearity of the current voltage characteristics, a linearity factor, F_L, is calculated by determining the average resistance at two different current levels. For currents at $\pm I$ and $\pm nI$, F_L is given by

$$F_L = [R(\pm nI) - R(\pm I)]/R(\pm I) \quad [9]$$

One might be tempted to try to quantify the linearity of a layer by measuring additional resistance values at the 180- and 270-degree positions. For layers with linear resistivity, the reciprocity theorem indicates that such resistances determined at 180 and 270 degrees are equivalent to resistances determined from the zero- and ninety-degree position, respectively (2). If the resistivity of the layer is linear, reciprocity holds. However, the converse—that if reciprocity is obeyed, the resistivity is linear—may not be true. Layers with nonlinear resistivity are better identified by the linearity factor, F_L.

Test Structure Intercomparison

The test structures listed in Table I were fabricated in both n- and p-type silicon wafers. Sheet resistance variations across typical wafers are shown in Fig. 3 and 4. The values shown in Fig. 3 were obtained from a p-type layer formed by a boron nitride diffusion at 965°C for 45 min with a junction depth of 1.6 μm in a (111)-oriented, phosphorus-doped 59 Ω·cm silicon wafer. The sheet resistance values in Fig. 4 were obtained from an n-type layer formed by a solid silicon pyrophosphate diffusion at 950°C for 20 min with a junction depth of 1.1 μm in a (111)-oriented, boron-doped 3 Ω·cm silicon wafer. On test pattern NBS-4 all the sheet resistors are in close proximity except for structure 4.35. The sheet resistance values shown for this structure are an average of two values measured at sites on either side of the one where the other structures are clustered. This procedure reduces the effect of sheet resistance gradients on the comparison of sheet resistance values from structure 4.35 with those from the other structures.

In these studies measurements were made in the dark. The current from a constant current source was either determined from the voltage drop across a standard resistor or assumed to be within the stated accuracy. Current reversal was achieved by switching the current through a mechanical switch or relay rather than reversing the current source. For the

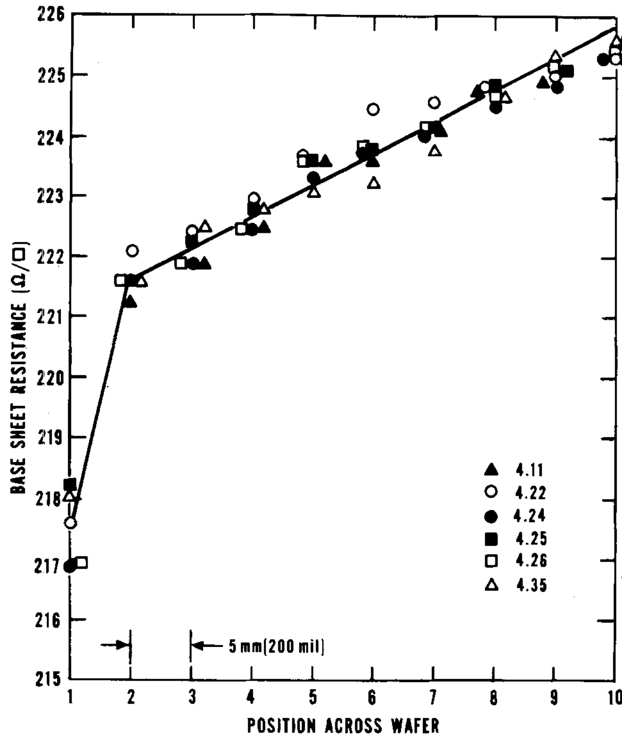

Fig. 3. The p-type sheet resistance variation as measured by various test structures across an n-type 59 Ω·cm wafer (B59Ph-1).

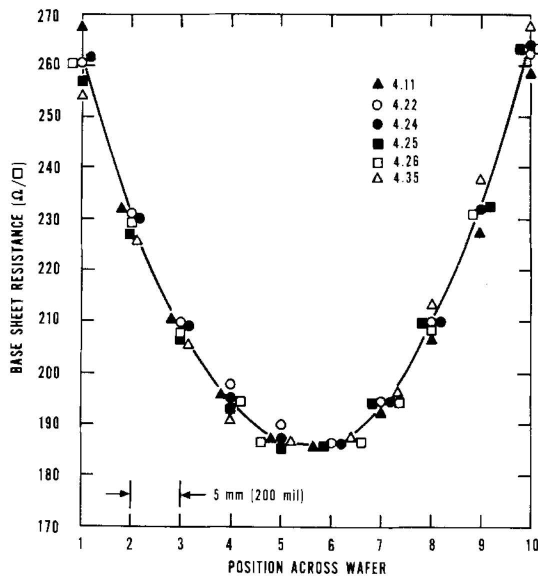

Fig. 4. The n-type sheet resistance variation as measured by various test structures across a p-type 3 Ω·cm wafer (B3.0B-3).

resistive structures studied here this procedure ensures that the magnitude of the reverse current equals that of the forward current. Voltages were measured with a digital voltmeter with a resolution of 1 μV. The measurement current was chosen so that the measured voltage was between 0.5 and 10 mV. The sheet resistance was calculated from Eq. [6] where the currents used in the computation were approximately 100 μA. The substrate was allowed to float electrically during these measurements.

Figure 3 reveals that the measured sheet resistance values for the various test structures are typically within 0.5% of each other in spite of the fact that the region being sampled is as small as a square 6.4 μm on a side (structure 4.22) or as large as a circle 762 μm in diameter (structure 4.35). This is a ratio of over 10^4 in area. The excellent agreement of these values confirms experimentally the conclusion drawn from a theoretical analysis (3) that the Greek crosses in Fig. 1 are valid van der Pauw sheet resistors. The ratio of arm length to arm width varies from 2.2 for structure 4.25 to 5.0 for structure 4.22. It is anticipated that structures with ratios as low as unity would also give results consistent with theory.

Interferences

In the measurement of the sheet resistance various interferences can lead to erroneous values. Some of these are listed in Table II and are discussed in this section.

The effect of surface leakage currents on sheet resistance values measured on wafer B92B-2 is dramatically shown in Fig. 5. This wafer was fabricated along with the wafer shown in Fig. 4 except that near the end of the process the oxide was removed and a new thin wet oxide (120 nm thick) was regrown at 925°C for 50 min. As shown in Fig. 5, sheet resistance values vary by as much as a factor of 4 from the corrected value obtained on the gated van der Pauw structure, 4.11. To quickly verify that surface leakage currents were excessive, the two-terminal resistance between two adjacent junction-isolated sheet resistors was measured on each of the wafers used in this study. These resistances are shown in Table III as R_3* values. The surface leakage current problem is clearly indicated by the fact that R_3* for wafer B92B-2 is at least 500 times lower than other values.

The equivalent circuit model, shown in Fig. 2, was used to explain the effect of surface leakage currents on the sheet resistance values shown in Fig. 5. (In the following development the diodes, R_3*, and the gate shown in Fig. 2 were ignored.) When measuring the sheet resistance, the current, I, is passed between adjacent terminals (*e.g.*, A, B) and the voltage difference, V, is measured between the other two terminals (*e.g.*, C, D). The desired situation is one in which the value of R_3 is infinite and the value of R_2 is zero. In this case, $R = V/I = R_1/4$. By setting R_1 equal to the sheet resistance, R_s, then $R = R_s/4$. For this simple model, $R = R_s/4$ is a sufficient approximation to the van der Pauw expression, $R = R_s(\ln 2/\pi) = R_s/4.53$.

The network shown in Fig. 2 was solved for $R = V/I$ with the use of the indefinite admittance matrix ap-

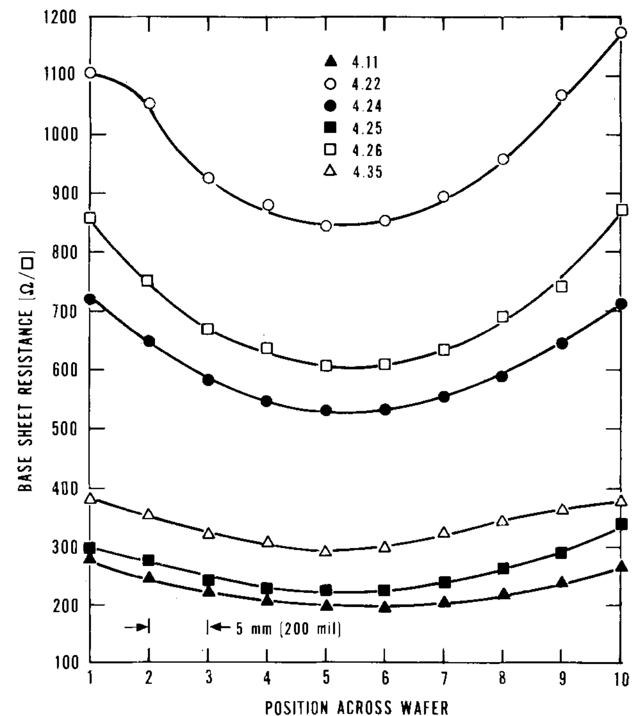

Fig. 5. The n-type sheet resistance variation as measured by various test structures across a p-type 92 Ω·cm wafer (B92B-2). This data shows that surface leakage currents can dramatically affect measured sheet resistance values.

Table II. Effect of interferences on various quantities determined from junction-defined, cross sheet resistors

Effect	Interference	Possible cause
Asymmetry factor large	Nonuniform sheet resistance across structure	Nonuniform lateral doping and/or junction depth variations
	Nonuniform structure boundaries	Poor photomasks and/or poor wafer fabrication
	Bulk leakage current	Low junction breakdown voltage
Zero offset factor large	Photovoltaic effect	Too much light
	Thermoelectric effect	Thermal voltages at relays and/or probe contacts
	DVM zero offset	Instrumentation problem
Linearity factor large	Joule heating	Excessive current. Poor design (structure too narrow)
	Nonlinear resistivity	Grain boundaries and/or junctions
	Oxide-silicon interface currents	Oxide charge causes channels
Sheet resistance value incorrect	Part of structure missing	Poor fabrication and/or structure near edge of wafer
	High contact resistance	Poor fabrication
	Metal-to-substrate shorts	Pinholes in oxide
	Surface currents across oxide	Incomplete metal removal
	Oxide-silicon interface currents through inversion layer	Excessive oxide charge and/or interface states
	Poor junction isolation	Low breakdown voltage or too much light

Table III. Parameters for wafers used in this study

Wafer number	Type	Resistivity ($\Omega \cdot$ cm)	R_3* (Ω)	BV (V) at 10 μA
B92B-2	p	92	3000	6

proach (7). The solution requires the reduction of both 7 by 7 and 5 by 5 matrices. The result is

$$R = \frac{V}{I} = (8G_1^3G_2G_3 + 16G_1^3G_3^2 + G_1^2G_2^3 + 8G_1^2G_2^2G_3 + 20G_1^2G_2G_3^2 + 2G_1G_2^3G_3 + 8G_1G_2^2G_3^2 + G_2^3G_3^2) \div (4G_1^3G_2^3 + 32G_1^3G_2^2G_3 + 80G_1^3G_2G_3^2 + 64G_1^3G_3^3 + 12G_1^2G_2^3G_3 + 64G_1^2G_2^2G_3^2 + 80G_1^2G_2G_3^3 + 12G_1G_2^3G_3^2 + 32G_1G_2^2G_3^3 + 4G_2^3G_3^3) \quad [10]$$

where $G_1 = R_1^{-1}$, $G_2 = R_2^{-1}$, and $G_3 = R_3^{-1}$.

An evaluation of this expression normalized by $R_1/4$ is shown in Fig. 6. It shows that, when the surface leakage currents are negligible ($R_3 >> R_1$), the region of interest is measured ($4R/R_1$ approaches 1) provided that the resistance, R_2, in the arms is not too large. It also shows that, when surface leakage currents are large ($R_3 \lesssim R_1$), surface conduction completely dominates the measured R value and R is smaller than the desired $R_1/4$ value. Finally, when surface leakage currents are modest ($R_3 > R_1$), the curves show that the surface conduction causes R to be much larger than the desired $R_1/4$ value when the arm resistance is large ($R_2 > R_1$).

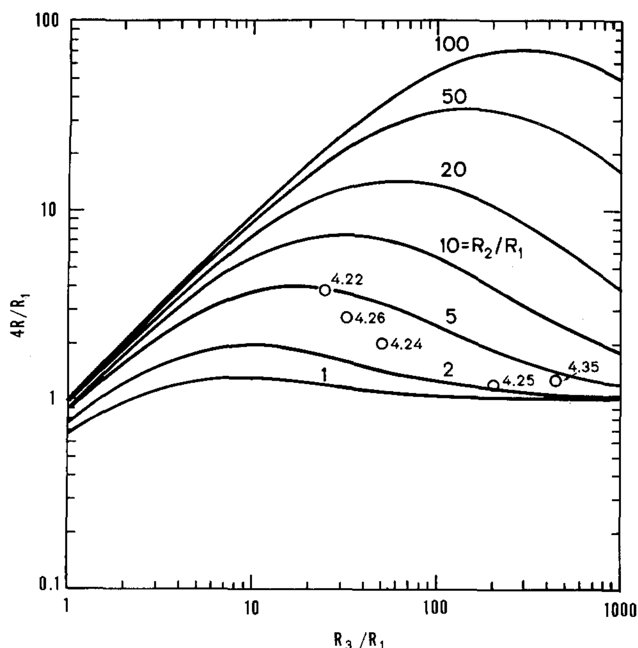

Fig. 6. An evaluation of the equivalent circuit model shown in Fig. 1. The data points are values from wafer B92B-2; see Table IV.

For each structure used to obtain the results shown in Fig. 5, R_1, R_2, and R_3 values were determined. In this analysis the sheet resistance of the phosphorus layer was taken as 200 $\Omega/\square$. Thus, R_1 is 200Ω and R_2 is 200Ω times a geometry factor for the arm. From circular MOSFET measurements [structure 4.15 which is identical to structure 3.15 (5)] the surface channel sheet resistance on wafer B92B-2 was found to be 20,000 $\Omega/\square$ at zero gate voltage. Thus, R_3 is 20,000Ω times a geometry factor representing surface conduction between adjacent arms. From the R_2/R_1 and R_3/R_1 ratios, the $4R/R_1$ values were determined from Fig. 6; the results are listed in Table IV. Also listed in Table IV are the sheet resistance values from Fig. 5 taken at position 5 and normalized to $R_{so} = 199\ \Omega/\square$. As seen in Table IV, the correlation between the R_s/R_{so} ratio taken from Fig. 5 is close to the $4R/R_1$ ratio calculated from the equivalent circuit model. This confirms the effect of surface leakage current on sheet resistance values.

Geometrical asymmetry of test structures is reflected in the asymmetry factor F_A. For the structures studied, F_A was always small (less than 3%) so that in evaluating the sheet resistance from Eq. [6], little error is introduced in assuming $f = 1$. The F_A values are interpreted in the following way. For the n-type wafers the results in Table V indicate that the cross structures 4.22, 4.24, and 4.25 have a higher degree of symmetry than the other structures in that their mean F_A values are low. The higher mean F_A values for structures 4.11, 4.26, and 4.35 are attributed to human errors introduced in the hand preparation of the 100× photomask artwork. The F_A values measured from the p-type wafer do not have a trend identical to the n-type wafers, and this is thought to be due to small surface channel currents. The exact interpretation of F_A values is still under study, but

geometrical asymmetry introduced by photomask fabrication, photolithography and etch processes, and nonuniform conductivity must be contributing factors. The asymmetry factor, F_A, is also expected to be useful in detecting structural boundary anomalies and in identifying those structures which have a high degree of symmetry.

To ensure that zero offset and nonlinearities have a minimal effect on the sheet resistance values, the factors F_0 and F_L were evaluated using Eq. [8] and [9] with $I = 100$ μA and $n = 2$. Results determined from measurements on at least 10 sheet resistors on two wafers are listed in Table V. The offset factors, F_0, are generally below 0.2% which means that photovoltaic, thermoelectric, and DVM zero offset effects can be neglected. The linearity factors, F_L, are generally much less than 0.2% which means that the conducting layers are being measured in the ohmic range.

Bulk leakage current problems can be identified by monitoring the breakdown voltage from the structure to the substrate. Breakdown voltage values for the wafers used in this study are listed in Table III. The breakdown voltage current of 10 μA was chosen to be one-tenth of the current used to measure the sheet resistance. As seen in Table III, wafer B92B-2 has a breakdown voltage of only 6V. However, this breakdown voltage is large enough to allow the sheet resistance to be determined since the compliance voltage at the current source did not exceed 1V at 100 μA.

The effect of joule heating on sheet resistance values is shown in Fig. 7 for structures 4.22 and 4.24 found on wafers B59Ph-1 and B3.0B-3. These measurements were taken at a fixed time after the current was switched to the next higher value. As seen in the figure, the structure with the larger arms (4.24) can carry more current before overheating. The ratio of arm widths for the two structures is six to one. This

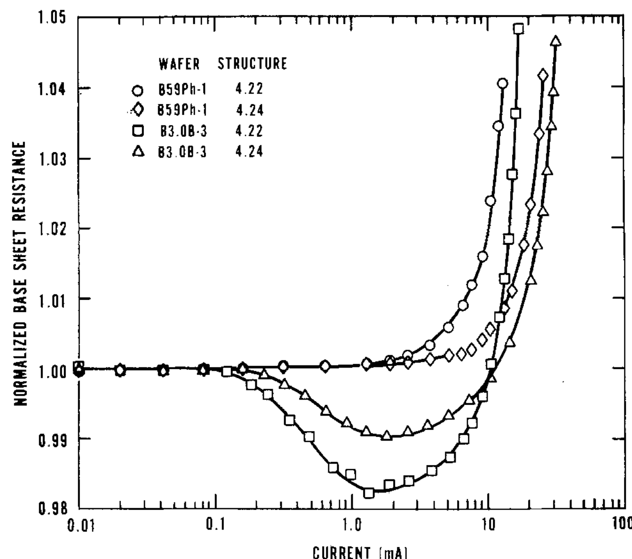

Fig. 7. The effect of joule heating on the sheet resistance of p-type and n-type layers fabricated with the use of a small cross (4.22) 6.4 μm wide and a large cross (4.24) 38.1 μm wide.

leads to an expected current ratio of $\sqrt{6} = 2.45$ for equal power dissipation. As seen in the figure, the observed current ratio of about two is slightly less than anticipated. The dip in the curves of Fig. 7 for wafer B3.0B-3 is attributed to the saturation of a small surface channel current. The increase in the resistance at high currents is consistent with the positive temperature coefficient of resistivity for moderately doped silicon layers. The heating effect was confirmed by an increase in the temperature of the wafer chuck as monitored by a thermocouple imbedded in the chuck. Junction breakdown effects can be ruled out since the compliance voltage at the current source was always less than the junction breakdown voltage.

Design Considerations

It is important that interference-free test structures be designed so that a minimum of tests is needed to ensure correct sheet resistance values. With proper design and proper measurement procedures most of the above interferences can be minimized and those that remain can be detected and faulty data identified. To minimize the effect of surface leakage current the curves in Fig. 6 indicate that the cross arms should be as short as possible. This is confirmed in Fig. 5 where structure 4.25 is clearly superior to structure 4.22. However, the arm length should not be less than the arm width or a correction factor must be used in evaluating the sheet resistance (3). In addition the surface resistance should be as large as possible. One way to accomplish this is by making the current path between contact points as long as possible. This is difficult if large diffused probe pad areas are needed for probing the layer prior to metallization, but if a channel stop diffusion is used, the surface resistance can be made large. The ultimate in control is achieved with a channel stop and a peripheral gate biased so as to shut off surface currents. If channel stops or gates are not feasible, then surface currents can be detected by measuring the resistance to a nearby diffused region which is physically separated from the sheet resistor but is the same type of diffusion.

A minimum of six probe pads is needed to ensure that a junction-defined sheet resistor is fully testable and that interferences are identifiable. The six pads should include the four sheet resistor contacts, a substrate contact, and either a gate or a separately diffused region. The substrate contact allows the effect of bulk junction leakage currents to be evaluated. Excessive bulk leakage can be expected when the junction has a soft reverse breakdown. Of course, no measurement is possible when the compliance voltage at the current source exceeds the junction breakdown voltage. When the sixth contact is a separately diffused region, surface leakage current problems can be identified but accurate sheet resistance values may not be obtainable. When the sixth contact is a gate and if a channel stop is used (such as in structure 4.11), problems due to surface leakage currents can be eliminated as interferences on the sheet resistance values.

The cross and van der Pauw test structures present a measurement problem because the measured voltages are much lower than those measured on bridge-type

structures. In some cases large currents must be forced through the cross structure in order to obtain a detectable voltage. This is particularly true for low sheet resistance layers formed by emitter diffusion or metal deposition. If a voltmeter with limited sensitivity is used, then the arm width of the cross structure should be as large as possible to allow measurements at high currents with minimum joule heating. If a voltmeter with adequate resolution is used, then a minimum line width cross can be measured with currents small enough to avoid joule heating.

Conclusion

Experimentally it was demonstrated that sheet resistance values derived from cross sheet resistors can be correctly calculated from the van der Pauw formula. Conventional van der Pauw sheet resistors as large as 762 μm (30.0 mils) in diameter agree within 0.5% with cross structures as small as 6.4 μm (0.25 mil) in width. The geometrical asymmetry of all structures studied was no worse than 3% so that the sheet resistance can be evaluated from the van der Pauw equation with $f = 1$. The effect of interferences such as surface leakage current and joule heating on sheet resistance values was observed experimentally and design suggestions are given to minimize these effects.

12	0.1249	1.128
14	0.1700	1.151

APPENDIX

The van der Pauw factor f shown in Eq. [6] is related to the resistances measured at the zero- and ninety-degree positions through (2)

$$\cosh\left(\frac{r-1}{r+1}\frac{\ln 2}{f}\right) = \frac{1}{2}\exp\left(\frac{\ln 2}{f}\right)$$

where

$$r = R'_0(\pm I)/R'_{90}(\pm I)$$

The asymmetry factor, F_A, given in Eq. [7] and expressed in terms of r, is

$$F_A = 2(r-1)/(r+1).$$

Values for r, F_A, and $1 - f$ are listed in Table VI. They indicate that F_A values can be quite large before f is significant. Calculations from the above equations reveal that for $F_A \leq 10.74\%$, $1 - f$ is less than 0.1%.

Bridge and van der Pauw Sheet Resistors for Characterizing the Line Width of Conducting Layers

M. G. Buehler,* S. D. Grant, and W. R. Thurber

National Bureau of Standards, Electronic Technology Division, Washington, D.C. 20234

ABSTRACT

It is shown that the line width of conducting layers can be computed from simple d-c electrical measurements made on bridge and van der Pauw shaped test structures. A compact six-contact, cross-bridge sheet resistor test structure was developed to make this measurement directly. Line widths measured on boron nitride diffused layers indicate that the method is sensitive to width variations of the order of ±0.1 μm (±4 μin.)

The measurement of line widths in the microelectronic industry is needed for the process control and design of integrated circuit components. For process control, line-width measurements are useful in monitoring the many etching processes which define the width of oxide windows and conducting layers. In circuit design, the value of diffused or implanted resistors is determined in part by the line width of the conducting layer.

Conventional methods for measuring the line width include both optical (1) and electrical techniques.

* Electrochemical Society Active Member.
Key words: cross-bridge structure, diffused layer, line width, process control, sheet resistance.

The electrical techniques commonly employ the double-bridge method (2) which requires the fabrication of two bridge structures of different width. Since this measurement technique is a differential-type method, it suffers from errors in taking the difference of large numbers.

An alternative to these methods is the determination of line widths using a bridge structure (3) in combination with a van der Pauw test structure (4). The width of the bridge structure is calculated from measurements of its resistance along with knowledge of the length between the voltage taps and the sheet resistance value obtained from the van der Pauw structure. The advantage of these vehicles is that they can be combined into one compact structure with the same line width, which means that the conductivity of the composite is more uniform than would generally be true for separate structures. In addition, the computation of the line width does not depend on the difference of large numbers; however, the analysis of the van der Pauw structure requires the measurement of low voltages, usually in the range from 1 to 10 mV. This is not a problem for laboratory-based instrumentation but precludes the use of those integrated circuit testers which do not measure these low voltages.

Test Structure Design and Fabrication

Line drawings of the test structures used in this study are shown in Fig. 1-4. Metallized contact to diffused regions is shown by the crosshatched areas. Structures 3.22 and 3.28 were fabricated as a part of test pattern NBS-3 (5) and the structures 7.18 and 7.23 were fabricated as a part of test pattern NBS-7 (6). The dimensions for these structures are listed in Table I.

The bridge test structure shown in Fig. 1 was designed in accordance with the ASTM standard (3) which requires that $W_m \geqq 3D_m$ and $B_m \geqq 2W_m$. In addition the lateral diffusion and overetch effects were minimized by requiring that $A_m \geqq 5X_j$ and $C_m \geqq 5X_j$, where X_j is the junction depth. The subscript m indicates a parameter referred to photomask dimensions.

The offset quadrate-cross test structure shown in Fig. 2 was designed to eliminate the contact shorting

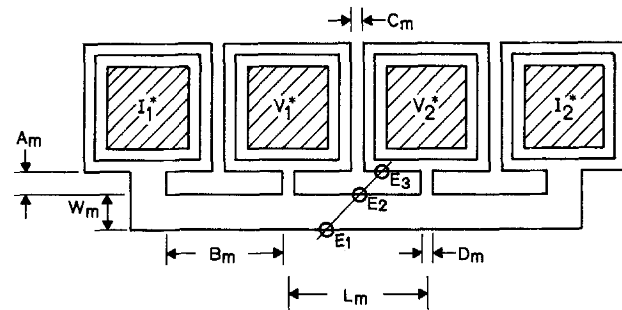

Fig. 1. Bridge sheet resistor test structure (3.28). The edges E_1, E_2, and E_3 are used to determine the width from optical photomicroscopic measurements.

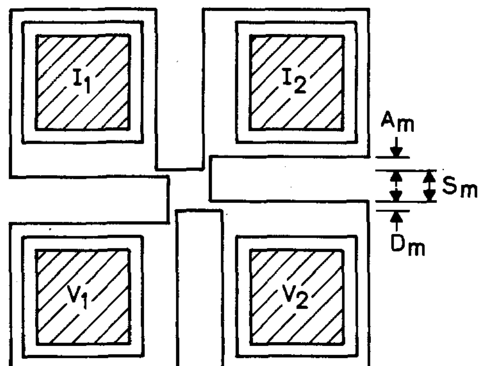

Fig. 2. Offset quadrate-cross test structure (3.22)

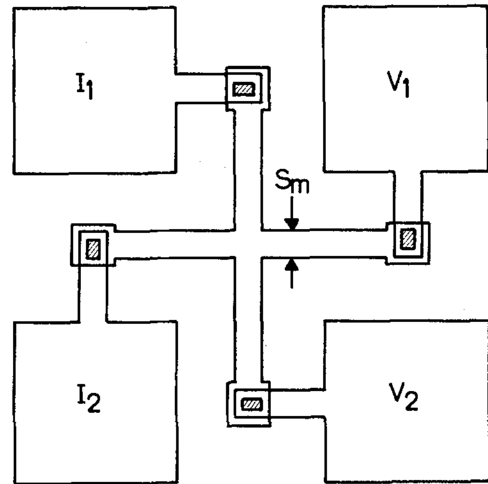

Fig. 3. Greek-cross sheet resistor test structure (7.18)

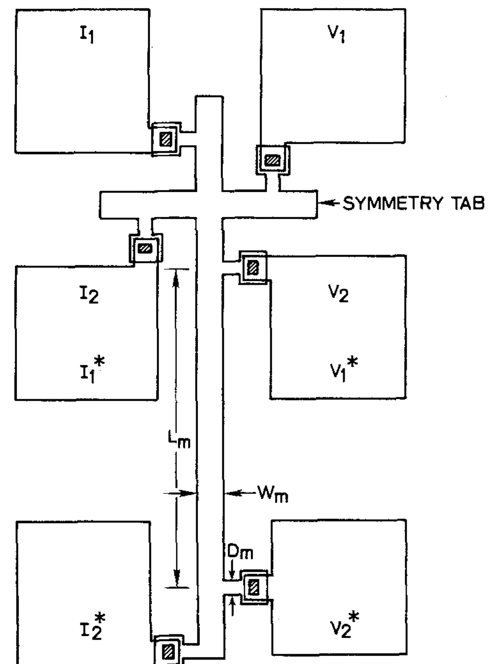

Fig. 4. Cross-bridge sheet resistor test structure (7.23)

correction factor (7) associated with the van der Pauw equation. For this structure where $A/S = 0.33$ and $D/S = 0.17$, the correction factor is much less than 0.1% and may be neglected. Likewise, the Greek-cross test structure shown in Fig. 3 was designed so that the arm length is greater than the arm width which means that the contact shorting correction factor associated with this structure also can be neglected (7).

The cross-bridge structure shown in Fig. 4 is a combination of the bridge structure shown in Fig. 1 and

Table I. Test structures

Number	Figure	Type	Photomask dimensions μm (mil)
3.28	1	Bridge	A_m = 25.4 (1.00) B_m = 127.0 (5.00) C_m = 12.7 (0.50) D_m = 12.7 (0.50) L_m = 139.7 (5.50) W_m = 38.1 (1.50)
3.22	2	Offset quadrate cross	A_m = 25.4 (1.00) D_m = 6.4 (0.25) S_m = 38.1 (1.50)
7.18	3	Greek cross	S_m = 14.0 (0.55)
7.22	4	Cross bridge	D_m = 8.0 (0.31) L_m = 200.0 (7.87) W_m = 16.0 (0.63)

the Greek-cross structure shown in Fig. 3. The bridge part was designed in accordance with the ASTM standard (3) except that $W_m = 2D_m$. The cross part was designed to eliminate the contact shorting correction factor (7). In order to preserve the symmetry of the cross, symmetry tabs were introduced at the ends of the arms denoted I_1, I_2, and V_1. These tabs are intended to compensate for the extension of the structure along the arm denoted V_2.

The test structures shown in Fig. 1-4 were fabricated by photolithographic processes using contact printing and an n-p-n transistor process. Both emitter and base sheet resistors were fabricated. The base sheet resistors, which were used to obtain the results reported in this study, were fabricated on n-type, (111)-oriented silicon substrates on which a 300 nm thick oxide was grown in steam at 1100°C. Diffusion windows were etched in the oxide. The boron nitride predeposition diffusion was at 965°C in dry nitrogen for about 30 min. After a deglaze in 10% hydrofluoric acid solution, the base was diffused at 1100°C for 18 min in wet oxygen, followed by 40 min in dry oxygen, followed by 15 min in dry nitrogen. This creates over the base regions a 350 nm thick oxide that masks the subsequent emitter diffusion. The final high temperature steps occurred at 1025°C for 20 min and at 925°C for 45 min. The structures were complete after opening the contact windows and patterning the aluminum metallization. The base sheet resistance was nominally 200 Ω/□. Test structures 3.22 and 3.28 were fabricated in wafers numbered 28, 29, and 30; the junction depth was 2.1 μm. Structures 7.18 and 7.23 were fabricated in a 9 Ω-cm wafer, D8.8 Ph-1; the junction depth was 1.6 μm.

Electrical Measurements

The electrical measurements utilized the d-c four-probe method where current was forced between two contacts to the resistor and the voltage was measured between two additional contacts. The current from a constant current source was determined either from the voltage drop across a standard resistor or was assumed to be within the stated accuracy. Current reversal was achieved by switching the current through a mechanical switch or relay to ensure that the magnitude of the reverse current equals that of the forward current. The magnitude of the current was chosen so that the measured voltage was between 0.5 and 10 mV. The substrate was allowed to float electrically during these measurements.

The line width is determined from measurements on the bridge structure in combination with measurements on the van der Pauw structure. The sheet resistance is determined from the van der Pauw structure by utilizing probe pads labeled I_1, I_2, V_1, and V_2 shown in Fig. 2, 3, or 4 and is calculated from the van der Pauw formula (4)

$$R_s = \pi R(\pm I)/\ln 2 \quad [1]$$

where $R(\pm I)$ is the incremental resistance determined from the current and voltage measurements for both directions of current and both contact orientations; see preceding paper (8). The parameter f which appears in the complete form of the van der Pauw formula is assumed to be unity in this study since the asymmetry factor, F_A, was much less than 10% (8).

The line (or window) width is determined by utilizing probe pads labeled I_1^*, I_2^*, V_1^*, and V_2^* shown in Fig. 1 and 4. The effective width, W_e, of the current-carrying channel is calculated from

$$W_e = R_s L_m / R^*(\pm I) \quad [2]$$

where R_s is determined from Eq [1] and L_m is the distance between voltage taps as determined from the photomask. The incremental resistance determined from measurement for both forward $(+I)$ and reverse $(-I)$ currents is given by

$$R^*(\pm I) = [V^*(+I) - V^*(-I)]/[I^*(+I) - I^*(-I)] \quad [3]$$

For measurements made in the forward current mode, the current $I^*(+I)$ is passed into I_1^* and out of I_2^* where both $I^*(+I)$ and $V^*(+I) = V_1^*(+I) - V_2^*(+I)$ are positive quantities. For measurements made in the reverse current mode, both $I^*(-I)$ and $V^*(-I)$ are negative quantities. The above expressions assume that the voltage taps do not significantly perturb the current flow in the current-carrying channel.

If the test structure is a diffused layer then the effective width is

$$W_e = W_m + \alpha X_j + W_{oe} \quad [4]$$

where W_m is the width determined from the photomask, W_{oe} is the incremental change in the width due to photolithographic effects and overetching, and αX_j is the effective incremental change in the width due to lateral diffusion where X_j is the junction depth and α is the lateral diffusion factor (9). Since the lateral diffusion cannot be observed from the top surface of the structure, the optically observable line width is

$$W = W_e - \alpha X_j = W_m + W_{oe} \quad [5]$$

These quantities are shown in detail in Fig. 5.[1]

Line-Width Measurements

Line widths for the bridge structure shown in Fig. 1 were measured as a function of position across a wafer by both electrical and optical techniques. In order to compare the two techniques, the factor αX_j, with α assumed to have the value 0.3 (9) and $X_j = 2.1$ μm for wafers 28, 29, and 30, was subtracted from the effective line width, W_e, which was evaluated from the electrical measurements with the use of Eq. [2]. In Fig. 6 the sensitivity of the method to etch time is illustrated by an experiment where the base diffusion

[1] If the test structure is a deposited layer, the effective width, which is the same as the optically observable width, W, is $W_e = W_m - W_{oe}$.

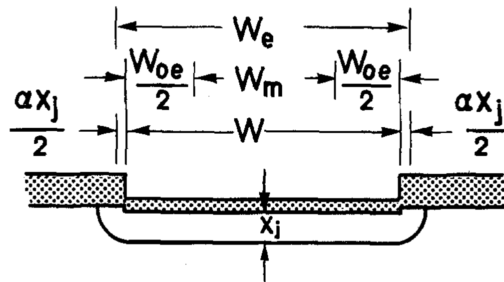

Fig. 5. Cross-sectional view of a diffused region showing various dimensions. To account for lateral diffusion effects, the width of the conducting channel is increased by an amount αX_j where the conductivity in this region is the same as in the main channel.

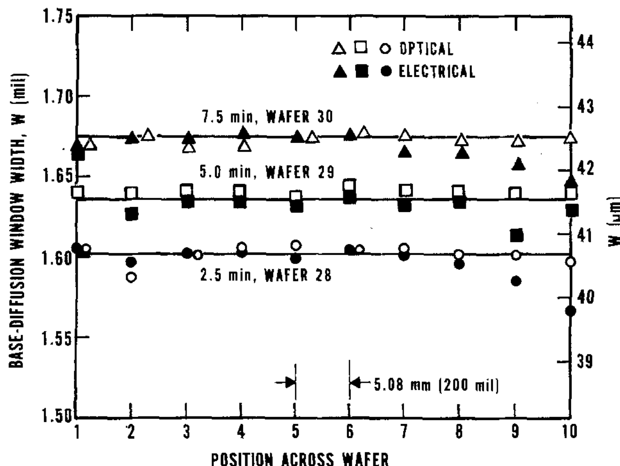

Fig. 6. Width of the base diffusion window as measured electrically and from photomicrographs along the diameter of wafers etched for different times.

window was etched for a different time on each of three wafers. The measurements demonstrate the effect of increased etch time on the window width.

The optical measurements were made directly on photomicrographs of various bridge test structures. An optical microscope with a 40× objective was operated in the dark field mode to obtain photomicrographs. The magnification as measured on the photomicrograph was 585×. The method used to determine the line width is illustrated by the points labeled E_1, E_2, and E_3 shown in Fig. 1. The distance between edges E_1 and E_3 is assumed to be unaffected by the photolithographic processes or the etch times. This distance was taken from the nominal photomask dimension and for structure 3.28 is 63.5 ± 1.3 μm (2.50 ± 0.05 mils). The distance between edges E_1 and E_2 corresponds to the optically observable width. In measuring this width a scale was placed on the photomicrograph at a convenient angle such that the distance between E_1 and E_3 was a convenient multiple of the actual dimension. The distance between edges E_1 was read directly from the scale. The estimated repeatability of both the electrical and optical line-width measurements was ±0.05 μm (±2 μin.).

The results obtained from the photomicrographs and shown in Fig. 6 compare favorably with the values obtained from the electrical measurements and in all cases the values are larger than the measured photomask width, $W_m = 39.2 \pm 0.3$ μm (1.545 ± 0.01 mils). Sheet resistance values are typically more uniform in the center of a wafer than at the periphery. The fact that the bridge and van der Pauw resistors are located about 50 mils apart on the test pattern would affect the agreement between the electrical and optical measurements more at the edge of the wafer. The results from the center of the wafer illustrate that the electrical width measurements are sensitive to width changes of the order of ±0.1 μm (±4 μin.).

Line widths were also measured with the use of the cross-bridge test structure shown in Fig. 4. Before computing the line width it is necessary to verify that the sheet resistance is correctly determined from the cross-bridge structure. This demonstration is shown in Fig. 7 where the sheet resistance from adjacent Greek-cross (7.18) and cross-bridge structures are compared. The results shown in Fig. 7 were analyzed by the least squares method where the slope of the line is 0.98 and the intercept is 2.9 Ω/□. The standard deviation for these measurements is 0.7% which means that sheet

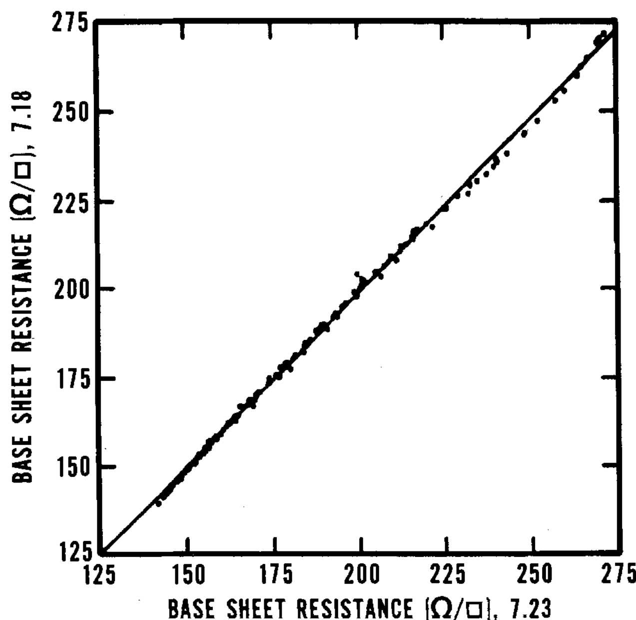

Fig. 7. Comparison of sheet resistance results from the Greek-cross (7.18) and cross-bridge (7.23) test structures.

resistance values can be adequately determined from the cross-bridge test structure.

Other comparisons between the Greek-cross (7.18) and the cross-bridge (7.23) test structures are listed in Table II. The factors F_0, F_L, and F_A listed in Table II are defined in the preceding paper (8). The offset factors, F_0, measured with an automated data acquisition system are significantly larger, because of thermal voltages in the relay scanners, than those measured on a system where the digital voltmeter was connected directly to the voltage contacts. The linearity factors, F_L, are quite small being less than 0.02% which indicates that the conduction mechanism in these test structures is ohmic. As expected, the asymmetry factors, F_A, indicate that the Greek cross (7.18) is more symmetrical than the cross bridge (7.23); however, since F_A << 10%, the van der Pauw formula can be used without correction to compute the sheet resistance.

As an example of how electrical line width measurements can be utilized in process control, wafer maps of sheet resistance and effective line width W_e from Eq. [2] as determined from measurements on the cross bridge (7.23) are shown in Fig. 8. Each wafer map is divided into five increments indicated by symbols given in the key. The numbers listed in the left-hand column are measured parametric values. The numbers in the right-hand column are the number of devices

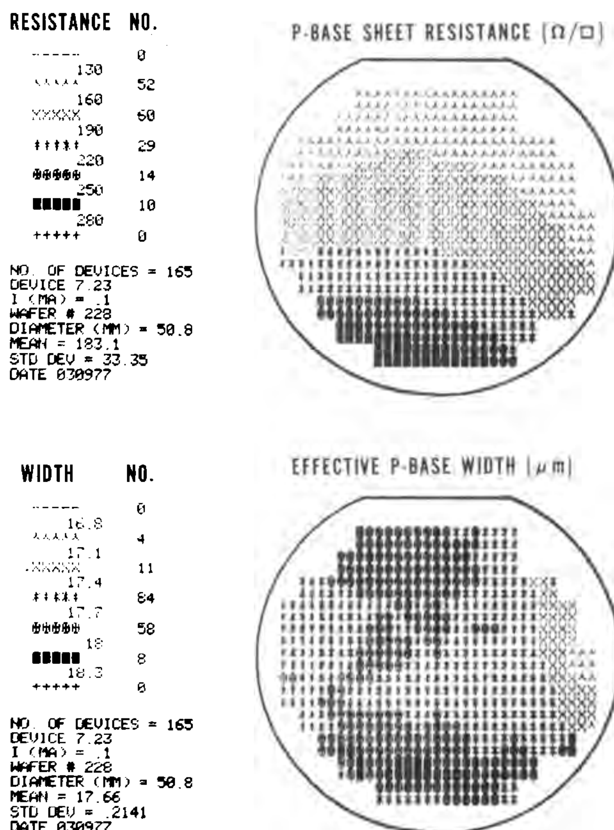

Fig. 8. Wafer maps of a p-type base diffusion into a 9 Ω·cm n-type substrate as analyzed by the cross-bridge test structure (7.23).

measured in each increment. Every other symbol shown in the wafer map represents a measured point; from these values the remaining symbols were obtained by interpolation. The sheet resistance shows a rather large top to bottom variation which is indicative of a diffusion problem; however, the effective line width shows a reasonably flat profile which is indicative of good etch control. Similar wafer maps have been reported elsewhere (6) for both the base and emitter sheet resistors using separate cross and bridge structures.

The use of the cross-bridge method in evaluating the width of very narrow diffused (or implanted) layers should be viewed with caution. This situation occurs when the incremental lateral diffusion width αX_j is comparable with the over-all width. In fact, the caution applies to any layer in which strong lateral resistivity gradients exist. In such cases the effective sheet resistance determined at the cross may not be the correct value for use in the computation of the effective width from Eq. [2]. The method described here has also been applied to the measurement of the line width of phosphorus emitter diffusions with a sheet resistance of about 1 Ω/□ (5, 6). In addition, the width of aluminum metallization with a sheet resistance of about 0.03 Ω/□ has been measured.

Conclusion

It was demonstrated that effective line width can be determined from electrical measurements on diffused bridge and van der Pauw sheet resistors and that these electrical measurements agree with those determined from optical photomicrographs of the sheet resistors. The method is sensitive to width changes of the order of ± 0.1 μm (± 4 μin.). A new cross-bridge sheet resistor was developed; wafer maps of the sheet resistance and line width illustrate the utility of this structure for process control.

The advantage of electrical line-width measurements is that they can be made quickly and at low cost using automatic data acquisition equipment with sufficient voltage resolution. Thus these measurements are important because of their potential use as process control and design vehicles in the manufacture of semiconductor devices.

Boron Determination in Silicon by the Nuclear Track Technique

ABSTRACT

The nuclear track technique was used for the determination of the boron dopant density in silicon. It was found that boron in the range of 10^{15}-10^{20} atoms/cm^3 could be detected. The resistivity of the silicon specimens as a function of the boron density determined by the nuclear track technique compares well with the work of Wagner relating resistivity to boron density. The results obtained by the nuclear track technique show some scatter, but in general agree with those determined by the junction capacitance-voltage method.

Boron is the most common dopant used in the preparation of p-type silicon single crystals for the microelectronics industry. The resistivity of the silicon is a function of the amount of boron present as a dopant in the crystal. It is desirable to have a chemical technique which can determine the boron density

Key words: alpha track, boron, dopant density, nuclear track technique, silicon.

for comparison with that obtained from electrical methods. Neutron activation analysis, a useful technique for many other impurities in silicon, is not suitable for the analysis of boron. Other methods have been cited in the literature including electron microprobe, nuclear backscattering, microchemistry, and alpha spectroscopy. However, of these methods only alpha spectroscopy (1-5) is able to measure the boron dopant density in the 10^{15} cm^{-3} range. This paper describes the use of the nuclear track technique (NTT) (6-9) as a new way of determining the boron density in silicon. The NTT is based on the same nuclear reaction as α spectroscopy, but a different method of detection is used. Silicon crystals containing boron densities[1] between 10^{15} and 10^{20} cm^{-3} were analyzed by the technique and the results are compared with junction capacitance-voltage measurements and the work of Wagner (10).

In brief the NTT is based on the number of radiation-damaged areas produced in a dielectric material in contact with the silicon. These radiation-damaged areas are a result of α particles and ^7Li recoil particles (9) that are produced during thermal neutron bombardment of the boron by the nuclear reaction $^{10}B(n,\alpha)^7Li$. The latent radiation damaged areas or tracks are made visible in the dielectric material by chemically etching that material. Then the number of α tracks per unit area in the detector is determined and assumed proportional to the boron density (atoms/cm^3) in the silicon. The path length of the α particle [with a primary energy of 1.44 MeV (11)] in silicon is ~2.5 μm and that length times the area yields the volume sampled.

Experimental

Sample preparation.—Specimens for analysis were obtained from boron-doped silicon crystals grown by the Czochralski process with a <111> growth axis. Some of the specimens were prepared from wafers supplied by commercial vendors and others from wafers cut and polished at NBS. Prior to scribing or cutting into sections for analysis, four-probe resistivity measurements were made on the back side of the wafers following the standard procedure (12).

For most of the specimens, the uniformity of the resistivity across the wafer was measured. For other specimens the uniformity had been previously checked by one of the following measurements on a companion wafer cut from the same crystal: four-probe measurements at center and half-radius positions or spreading resistance measurements along a diameter. All wafers showed resistivity variations of less than 5% between center and half-radius positions and no fine structure was observed in the spreading resistance.

Analytical procedure.—In the analytical procedure, a square specimen, typically 7.5 mm on a side and 0.3 mm thick was sandwiched between two pieces of the detecting material, a cellulose acetate butyrate plastic (250 μm thick), vacuum heat sealed in polyethylene and irradiated in the thermal neutron pneumatic facilities of the NBS Research Reactor (13). The irradiation time and position in the reactor were dependent on the anticipated boron density. Time in the reactor ranged from 1 sec to 10 min for a typical thermal neutron flux of 1.33×10^{13} $n \cdot cm^{-2}$ sec^{-1}. Following irradiation, the detectors were separated from the silicon specimens and chemically etched in 6.5N NaOH for 5 min at 72°C. The etched detectors were then rinsed with distilled water and air dried. The detectors were mounted on microscope slides and the visible α tracks, as seen in Fig. 1, were counted wtih the aid of an optical transmission light microscope. The area for counting was 1500 μm^2; usually several such areas on the detector were counted and averaged to compute the boron density for the specimen.

[1] In the chemical literature, concentration (*i.e.*, μg/g) is the commonly used term, but herein density is used in referring to atoms/cm^3.

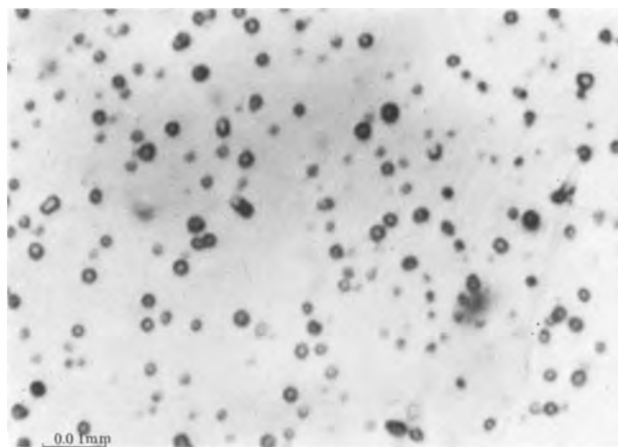

Fig. 1. Photomicrograph of α particle tracks in an etched cellulose acetate butyrate detector which was in contact with boron-doped silicon during neutron irradiation.

Standard reference materials, SRM 619 Trace Element Glass Standards, containing known densities of boron in glass (7) were simultaneously irradiated with the silicon samples. The boron density in the silicon was obtained by comparing the track count from the silicon with that from the boron in the SRM 619 Standards with a correction for the range difference of the α particle in the dissimilar matrixes (14). The correction is simply the ratio of the density of silicon (2.33 g/cm^3) to that of glass (2.5 g/cm^3). In later irradiations, a silicon sample previously analyzed with respect to the SRM's was used as a secondary standard.

Discussion of Results

In Fig. 2, the boron density by the nuclear track technique is plotted against specimen resistivity as determined by four-probe measurements. Also shown is the resistivity-dopant density relationship of Wagner (10) which was derived from measurements on silicon implanted with boron. The amount of boron retained in the silicon was determined by integration of data obtained from incremental sheet resistance and

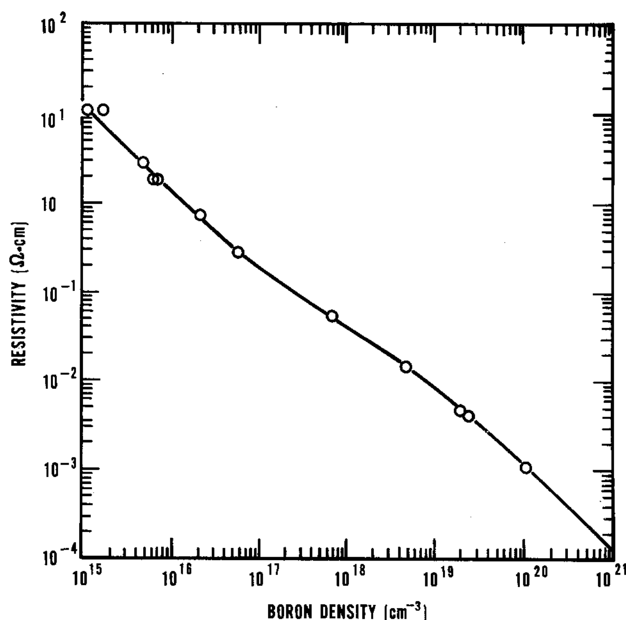

Fig. 2. Resistivity of p-type silicon at room temperature as a function of boron density determined by the nuclear track technique. Also shown is the resistivity-dopant density curve of Wagner. The error bars (1 std. dev.) associated with these data points lie within the symbols shown.

Hall effect measurements on layers which were sectioned by anodic oxidation. A mobility value as a function of boron density was derived which made the integrated dose equal to the implanted dose. The mobility expression was then used to calculate the curve shown in Fig. 2.

A boron density of about 10^{15} cm^{-3} (~8 ppb by weight) appears to be the lower limit of measurements by the nuclear track technique based on results obtained on a 135 ± 5 Ω · cm silicon sample. The Wagner curve predicts a boron density of 9×10^{13} cm^{-3} for this specimen compared to a value of 4.5×10^{14} cm^{-3} from the NTT measurements. The discrepancy at this point is due to interference from detector background. The interference is due to the α particle which originates in the oxygen present in the cellulose acetate butyrate *i.e.*, $^{17}O(n,\alpha)^{14}C$. Lithium and oxygen in the silicon also produce interfering α tracks during neutron irradiation, but these impurities do not interfere significantly until their concentrations are high, *i.e.*, ≥200 μg/g for lithium and ≥10 mg/g for oxygen. Since the maximum solubility of oxygen in silicon is 20 μg/g (3×10^{18} atoms/cm^3), oxygen in the silicon is not a factor in determining the lower limit of detection.

The accuracy and precision of the present results are illustrated by a graph of $1/\rho N$ as a function of boron density where ρ is the measured resistivity and N is the boron density determined by the nuclear track technique. The values are plotted in Fig. 3 along with others obtained from resistivity measurements (15) and junction capacitance-voltage (*C-V*) measurements (16) for boron density on wafers fabricated with the NBS-3 (17) and NBS-4 test patterns. The nuclear track technique data scatter somewhat at low boron densities but the general agreement with the junction *C-V* values and the Wagner mobility curve is apparent. One source of scatter is the fact that the lateral homogeneity of the boron was observed to vary as much as ±10% within the counting area.

The boron density by the track technique was compared with that obtained from the junction *C-V* method for companion slices from three of the silicon crystals for which data are shown in Fig. 3. The results are shown in Table I. The good agreement suggests that compensation by n-type impurities is probably not significant as the track technique measures total boron density whereas the junction *C-V* method measures the difference between the p- and n-type dopant densities.

Conclusions

The nuclear track technique has been shown to be a useful method for the determination of boron in silicon for boron densities in the range 10^{15}-10^{20} cm^{-3}. A plot of the resistivity of the silicon specimens as a function of the boron density determined by the track technique agrees with the trend of the Wagner curve relating resistivity to boron dopant density. Values of boron density from the track technique agree well with those obtained by the junction *C-V* method on companion slices from the same silicon crystals.

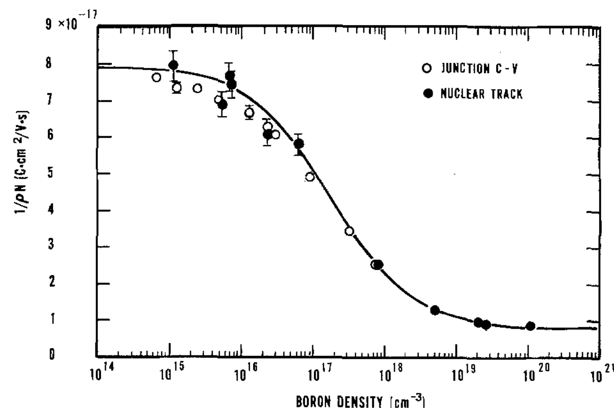

Fig. 3. Values of $1/\rho N$ (ρ = resistivity, N = boron density) at 300°K as a function of boron density obtained from nuclear track or junction *C-V* measurements. The solid curve is from the Wagner relationship between resistivity and dopant density. Error bars not shown in the ordinate direction are less than the size of the symbol. All error bars in the abscissa direction for boron density lie within the symbols.

Solidus Isotherms and Isoconcentration Lines in the System Ga-In-Sb

Michel F. Gratton and John C. Woolley

Physics Department, University of Ottawa, Ottawa, Ontario Canada K1N 6N5

ABSTRACT

Solidus isotherms and isoconcentration lines have been experimentally determined for the Ga-In-Sb ternary diagram by means of the technique of annealing samples in the two-phase liquid-solid field and quenching, a method shown previously to give good results for the pseudobinary section. The results are compared with data predicted by the simple solution model. In this analysis, the linear temperature dependence of the interaction parameters $\alpha_{Ga\text{-}Sb}$, $\alpha_{In\text{-}Sb}$, $\alpha_{Ga\text{-}In}$, and $\alpha_{GaSb\text{-}InSb}$ has been examined and also the effect on the predicted data of variation in the values of these parameters. It is shown that while the model can give values of liquidus isotherms in good agreement with the available experimental data, the predicted solidus isotherms and isoconcentration lines are very different from the experimental data. No reasonable variation of the α parameters can eliminate this latter discrepancy and it is seen that in the case of this particular ternary system the simple solution model is of no value for prediction of solidus data.

Because of the possibility of using ternary III-V alloys in various technological applications, considerable interest has been focused during the last few years on the investigation and prediction of the relevant ternary phase diagrams. Following the model developed by Guggenheim (1), a number of workers (2-8) have made calculations for various parts of the general ternary diagrams. Much of the work has been concentrated on the form of the pseudobinary sections $A_xB_{1-x}C$ since these contain all of the solid phases of interest technologically and for which there exists a considerable amount of experimental data (9-10) for comparison with theoretically predicted values. Most of the remaining work has been concerned with the prediction of liquidus sheets and with solidus isoconcentration lines (*i.e.*, a line giving the composition values of points on the liquidus sheet which are in equilibrium with a solid phase of given composition), data which are of importance in the liquid phase epitaxy technique.

In the present work, the Ga-In-Sb diagram has been considered and experimental measurements made to determine the isoconcentration lines. These, together with liquidus isotherms previously determined (5, 8, 11), are compared with theoretical values obtained from the simple solution type of analysis carried out previously (5, 7, 8). The values of the input parameters have been carefully considered to see if any over-all agreement between experiment and theory is possible in this particular case.

Theory

For all of these types of ternary diagram, the data are calculated from the conditions for equilibrium between a general ternary liquid solution A-B-C (Ga-In-Sb in this case) and a pseudobinary solid solution AC-BC (GaSb-InSb here). The theory has been presented by various workers (2-8) and hence only the necessary final equations are given here

$$\ln \gamma_{AC} = \ln \frac{\gamma_A \gamma_C}{\gamma_A^{sl} \gamma_C^{sl}} + \ln 4 \frac{N_A N_C}{x} + \frac{\Delta S^F_{AC}}{RT} (T^F_{AC} - T) \quad [1a]$$

$$\ln \gamma_{BC} = \ln \frac{\gamma_B \gamma_C}{\gamma_B^{sl} \gamma_C^{sl}} + \ln 4 \frac{N_B N_C}{1 - x} + \frac{\Delta S^F_{BC}}{RT} (T^F_{BC} - T) \quad [1b]$$

$$RT \ln \gamma_{AC} = \alpha_{AC\text{-}BC} (1 - x)^2 \quad [2a]$$

$$RT \ln \gamma_{BC} = \alpha_{AC\text{-}BC} x^2 \quad [2b]$$

$$RT \ln \gamma_A = \alpha_{AB} N_B^2 + \alpha_{AC} N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC}) N_B N_C \quad [3a]$$

$$RT \ln \gamma_B = \alpha_{AB} N_A^2 + \alpha_{BC} N_C^2 + (\alpha_{AB} + \alpha_{BC} - \alpha_{AC}) N_A N_C \quad [3b]$$

$$RT \ln \gamma_C = \alpha_{AC} N_A^2 + \alpha_{BC} N_B^2 + (\alpha_{AC} + \alpha_{BC} - \alpha_{AB}) N_A N_B \quad [3c]$$

where the γ's are activity coefficients, the α's interaction parameters, N_A, N_B, and N_C concentrations of the three elements, x the mole fraction of AC in the solid phase, and ΔS^F_j and T^F_j the entropy of fusion and melting temperature of the compound j.

Calculations

Vieland (12) has given the relation for the liquidus curve of a binary system A-C with a line compound AC as

$$\alpha_{AC} = -\frac{RT}{2(0.5 - c)^2} \left[\ln 4c(1 - c) + \frac{\Delta S^F_{AC}}{RT} (T^F_{AC} - T) \right] \quad [4]$$

where c is the atomic fraction of C. From this, Thur-

Key words: ternary phase diagram, simple solution model, solidus isotherms, solidus isoconcentration lines.

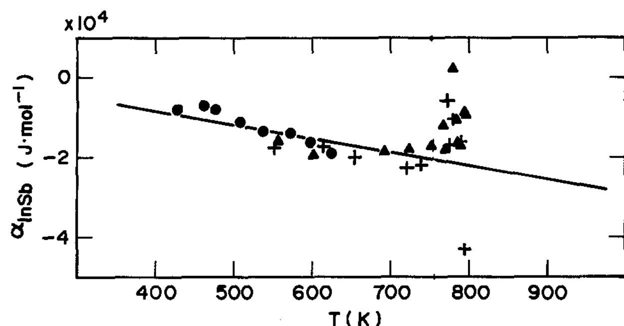

Fig. 1. InSb. The interaction parameter $\alpha_{In\text{-}Sb}$ as a function of temperature. The line shows the least squares fit. ● Hall (17), ▲ Liu and Peretti (16), + Pogodin and Dubinsky (18).

mond (14) has shown empirically that for Ga-As, α has a linear dependence on temperature and has suggested that the same form applies for α in other III-V systems if only in the range where the saturated liquid phase is dilute, *i.e.*, well away from the compound AC. Ilegems and Panish (15) have indicated that this linear behavior is due to the liquid phase being effectively a simple solution and they give evidence that the binary liquid III-V systems are effectively simple over a large concentration range.

Here, the binary phase diagram data of Liu and Peretti (16), Hall (17), and Pogodin and Dubinsky (18) for the In-Sb system have been analyzed using Eq. [4] with T^F_{AC} and ΔS^F_{AC} equal to 798°K and 59.91 J·mole⁻¹·°K⁻¹, respectively (19). To produce consistent data, the resutls of Pogodin and Dubinsky were corrected by −8°K to take into account the accepted melting point value of InSb. The variation of α_{InSb} with T for the composition range from pure In to the eutectic point (32 atomic percent In) is shown in Fig. 1. The data in the temperature range 400°-770°K have been fitted by a least squares method to the relation $\alpha = p + qT$ and the values obtained are given in Table I. Above $T = 770$°K, the data clearly deviate from linear behavior and this may be explained by the suggestion that linearity applies only in dilute solutions. However, the values of $\alpha_{In\text{-}Sb}$ are quite sensitive to small variations in experimental values in this range, and it was found by varying T by ±5°K or c by ±0.02 that for values somewhere in these ranges the value of $\alpha_{In\text{-}Sb}$ was brought back to the linear form indicated above. Thus it is possible that the apparent deviation from linear form at concentrations close to InSb is due to small experimental errors in the observed values.

A similar analysis of the available data for the Ga-Sb system (17, 20-22) has been carried out using $T^F_{AC} = 985$°K and $\Delta S^F_{AC} = 66.11$ J·mol⁻¹·°K⁻¹ (19). Similar results were obtained and the resulting value of $\alpha_{Ga\text{-}Sb}$ is given in Table I.

Values are needed also for the parameters $\alpha_{Ga\text{-}In}$ and $\alpha_{GaSb\text{-}InSb}$. In previous work, the binary diagram data of Bros *et al.* (23) and Macur *et al.* (24) are usually quoted for the evaluation of $\alpha_{Ga\text{-}In}$ while the value of $\alpha_{GaSb\text{-}InSb}$ is usually obtained by a fit to the pseudobinary liquidus and solidus data (9) or from the calculations of Foster and Woods (25). In all cases the parameter values have been assumed independent of T. Joullié *et al.* (8) determined both $\alpha_{Ga\text{-}In}$ and $\alpha_{GaSb\text{-}InSb}$ from the pseudobinary data by solving equations equivalent to the present Eq. [1], [2], and [3] for composition values from the liquidus and solidus curve. However, they used the data for one temperature only and again assumed that $\alpha_{Ga\text{-}In}$ and $\alpha_{GaSb\text{-}InSb}$ were independent of temperature.

Here, the pseudobinary liquidus and solidus data have been used to determine both $\alpha_{Ga\text{-}In}$ and $\alpha_{GaSb\text{-}InSb}$ as a function of temperature over the range between the melting points of the two compounds. At each temperature, appropriate composition values from the liquidus and solidus curves (9) were inserted in Eq. [1], [2], and [3] and values of $\alpha_{Ga\text{-}In}$ and $\alpha_{GaSb\text{-}InSb}$ determined. There was appreciable scatter in the graphs of α *vs.* T for each case, as the α values were very sensitive to the values of x used in the calculations. However, it was found that in each case the value of α could be written as a linear function of T and the values determined by least squares fit are given in Table I.

For comparison purposes, Table I gives the expressions for $\alpha_{Ga\text{-}Sb}$, $\alpha_{In\text{-}Sb}$, $\alpha_{Ga\text{-}In}$, and $\alpha_{GaSb\text{-}InSb}$ determined here and also those used by Blom and Plaskett (5), Panish and Ilegems (7), and Joullié *et al.* (8). For ease of comparison, values are given for each α at 650° and 900°K.

Using the values of the various α's derived above, Eq. [1], [2], and [3] were solved with sets of values of N_{Ga}, N_{In}, and N_{Sb} over the whole ternary diagram to yield values of T and x. The values were then appropriately interpolated to give liquidus and solidus isotherms and solidus isoconcentration lines for the Ga-In-Sb system and the curves so obtained are shown in Fig. 2 and 5. The liquidus isotherms are found over most of the composition range to be in fairly good agreement with those determined previously (5, 8), even though, as is seen from Table I, the α values used were in some cases rather different. It appears that the predicted isotherms are not in general very sensitive to the values of α's used. The main discrepancies between the present results and those of Blom and Plaskett (5) and Joullié *et al.* (8) are at points close to the pseudobinary section. The present results are tied to the measured pseudobinary data by the method used for determining $\alpha_{Ga\text{-}In}$ and $\alpha_{GaSb\text{-}InSb}$ and hence will be in better agreement with those experimental data. This is discussed further below.

Experimental Methods and Results

Experimental results for the liquidus isotherms are already available (5, 8, 11) and are shown in Fig. 2. It is seen that there is reasonably good agreement between the available experimental data and the present theoretical values. The experimental points of Blom and Plaskett (5) for 600°C do not fit well with the present curves but neither are they in good agreement with the values in the pseudobinary section (9, 26, 27).

The present experimental work has been the determination of solidus isotherms and hence isoconcentra-

tion lines in the region of the diagram between the pseudobinary section and the Ga-In binary (*i.e.*, $0 \leq N_{Sb} \leq 0.5$) The technique used was that described previously for the determination of the solidus curve of the pseudobinary section and which was found to give good agreement with standard DTA measurements (9) and also with data from "first-to-freeze" analysis of stoichiometric melt growth samples (27). Samples of various compositions were weighed out, sealed under a reduced pressure of argon in quartz ampuls, and melted by holding for 1 or 2 hr at a temperature above the melting point of the compounds (usually 800°C). The temperature of each sample was then reduced to the required values and the sample annealed to equilibrium. In the two-phase liquid-solid field below the liquidus sheet, because the solid phase is very finely dispersed throughout the liquid phase, annealing for 24 hr was quite sufficient to attain this equilibrium condition. A small number of samples were annealed for times up to 20 days but showed no change from the condition observed after 24 hr annealing. Over the anneal period the temperature was kept constant at ±2°C, and its mean value determined to ±2°C by means of a calibrated Pt-Pt 13% Rh thermocouple. At the end of the anneal, the sample was rapidly quenched by plunging into an oil bath so that the equilibrium solid phase was frozen in and no solid diffusion occurred. The lines of this solid phase were easily determined in an x-ray powder photograph. The homogeneity of this solid phase was clearly demonstrated by the sharpness of the x-ray lines, the K_α doublet being clearly resolved, and by the fact that no variation could be observed in different x-ray specimens taken from the same quenched sample. The lattice parameter of the equilibrium solid phase and hence its composition were thus determined (9). The position of the phase on the pseudobinary section plus the composition of the initial sample clearly define the position of the tie-line on the phase diagram. To check further the consistency of the results, in one or two cases further samples were investigated, which lay on the tie-lines so determined. In each case, the solid composition found was in good agreement with the previous value, confirming that a two-phase tie-line had been obtained. To determine the liquid end of the tie-line, knowledge of the liquidus sheet is required. Since, as indicated above, the predicted liquidus isotherms are in good agreement with the available experimental data, these have been used here to determine the composition of the equilibrium liquid phase, being the point of intersection of the tie-line and the corresponding liquidus isotherm. A typical set of tie-lines, for $T = 525$°C, is shown in Fig. 3, while the data for the other temperatures investigated are given in Table II.

From these data, solidus isotherms can be drawn, and examples plotting composition of solid phase (x)

vs. gallium concentration of equilibrium liquid phase (N_{Ga}) at fixed temperature are shown in Fig. 4, both experimental values from the above data and predicted values from the theoretical analysis being shown. Finally, from these solidus isotherms, solidus isoconcentration lines have been constructed and are shown in Fig. 5, again both experimental and theoretical values being given.

Discussion

The input data for the calculated phase diagram results are mainly in the four α parameters. Here, each has been assumed to vary linearly with temperature and its value obtained from the known data of an appropriate binary or pseudobinary section. Although previously it had been suggested that these

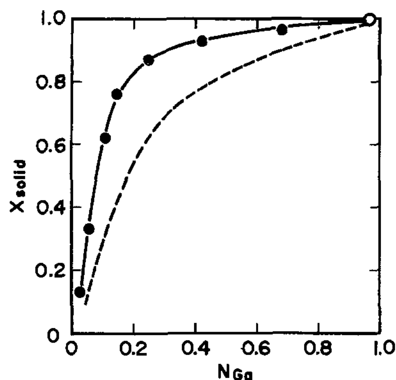

Fig. 4. The 475°C solidus isotherm of the Ga-In-Sb system. —●— Present experimental data, ○ Koster and Thoma (21), ------ present theoretical calculation.

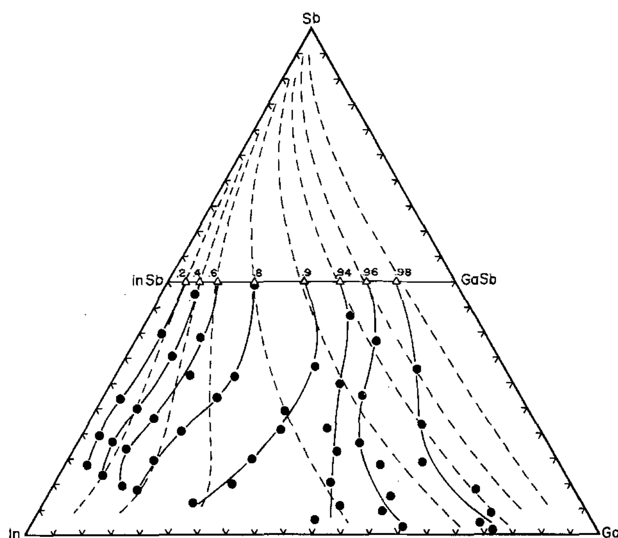

Fig. 5. Solidus isoconcentration lines in the Ga-In-Sb ternary phase diagram. —●— Present experimental data, ------ present theoretical calculation.

α values could be obtained from ranges of dilute solution only, it appears that consistent values of α can probably be obtained over a very wide range of composition of the relevant section as indicated by Ilegems and Panish (15). Comparison of the predicted data obtained with the present values of α and those of previous workers (5, 7, 8) indicates that the form of the liquidus isotherms is not very sensitive to the exact value of α.

In the present work, the method of determining $\alpha_{\text{Ga-In}}$ and $\alpha_{\text{GaSb-InSb}}$ ensures that a good fit to the data of the pseudobinary section is obtained, which was not the case in some of the previous work. In all cases, the fit to the liquidus isotherms in the range 350°-500°C is good. However, the present choice of α values gives a slightly worse fit to the 300°C liquidus isotherm data than that of Blom and Plaskett (5) and Joullié *et al.* (8). Thus even for the liquidus isotherms, it appears that no single set of α values gives an excellent fit over the whole range of composition considered here, but that reasonable agreement with experiment can be obtained with a careful choice of α values.

One factor which may influence the fit to experimental data in this particular case is the value of the ΔC_p term in Vieland's equation for chemical potential, *i.e.*

$$\mu_{AC}^{so} = \mu_A^{sl} + \mu_C^{sl} - \Delta S^F_{AC}(T^F_{AC} - 1)$$

$$+ \Delta C_P \left[T^F_{AC} - T - \ln\left(\frac{T^F_{AC}}{T}\right)\right] \quad [5]$$

Throughout the analysis the ΔC_p term has been assumed to be negligible. While this is true in most cases, calculation shows that for the case of In-Sb the ΔC_p term can at low temperatures become a nonnegligible part of the right-hand side of Eq. [5], (*e.g.* 6% at 500°K). Thus neglecting this term could have some effect on the value of $\alpha_{\text{In-Sb}}$ calculated and on the predicted form of the low temperature liquidus isotherms.

In the case of the solidus isotherms and isoconcentration lines, as previously suggested by Panish and Ilegems (4) and by Antypas (11), there is very little agreement between measured and predicted values (Fig. 5). Varying the input values of the α parameters over the range given in Table I changed the predicted curves to a small extent but in no case could agreement with experiment be obtained, since the differences between experimental and theoretical values were always very large. While the experimentally determined values of the solidus isotherms and isoconcentration lines required a knowledge of the liquidus isotherms, as indicated above, the predicted values in that case are sufficiently close to the experimental values that little error is to be expected in the results quoted here. No reasonable set of liquidus isotherms can be designed which would cause the experimental solidus results to agree with the predicted values.

Thus it is clear that for the Ga-In-Sb ternary system the simple solution model has serious limits on its usefulness. It can be used to give reasonable values of liquidus isotherms, but solidus data predicted by this method in the temperature range 300° to 712°C are of no practical value.

In a review by Panish and Ilegems (7) of a number of these alloy systems, it is indicated that fair agreement between predicted and experimental values of the solidus parameters can be obtained for the ternary alloys involving phosphorus and possibly aluminum but that the agreement is poor for the heavier systems such as $Ga_xIn_{1-x}As$ and $InAs_ySb_{1-y}$. Clearly the use of the simple solution model to predict solidus data is only of value if one can predict the cases for which the model gives valid results. One possible factor in this consideration is the temperature, since it would appear that the lower the range of temperature concerned the worse is the agreement. Thus one possible reason for the discrepancy between prediction and experiment is the ΔC_p term and the associated Vieland equation. But as indicated above the ΔC_p term is significant only below 600°K and hence should have little effect even in the upper temperature range of the solid phase of the $Ga_xIn_{1-x}Sb$ alloys. However, Jordan and Weiner (28) have shown that Vieland's equation is exact only if α is a linear function of temperature and as has been seen above, this may not be the case here.

A second possible factor in this temperature range is that association in the liquid phase may become important (29). However Jordan has indicated that this effect is mainly of importance when the liquidus curve of the appropriate binary system shows a cusp around the line compound (*e.g.*, Zn-Te, Cd-Te) and should not be important for systems showing the smooth "convex" liquidus curves typical of most III-V combinations.

Purification and Characterization of Metallurgical Silicon

T. L. Chu,* G. A. van der Leeden, and H. I. Yoo

Southern Methodist University, Dallas, Texas 75275

ABSTRACT

Metallurgical-grade silicon is a convenient starting material for the preparation of solar cell-grade silicon. The purification of metallurgical silicon by the treatment of its melt with gaseous reagents and in some cases followed by unidirectional solidification, has been investigated. The purified material was analyzed for major impurities by the atomic absorption technique. Single crystals have been prepared from purified metallurgical silicon by the Czochralski technique, and their electrical properties, such as electrical resistivity, carrier mobility, and diffusion length, were measured.

At present, silicon solar cells are manufactured from semiconductor-grade single crystalline silicon, doped to a carrier concentration of about 10^{16} cm^{-3}, by the diffusion technique. Semiconductor-grade silicon is produced from the metallurgical-grade material (about 98% purity) by (*i*) the conversion of silicon into trichlorosilane, (*ii*) the purification of trichlorosilane, and (*iii*) the thermal reduction of trichlorosilane with hydrogen. This sequence of processing is tedious and expensive, and the cost of silicon is increased from $1/kg to $60/kg. The use of semiconductor-grade silicon is a major factor contributing to the high cost of solar cells. It is generally recognized that the purity of silicon required for solar cells is considerably less than the purity of semiconductor-grade silicon. The development of solar cell-grade silicon at a cost significantly below that of semiconductor-grade silicon is essential for the terrestrial utilization of solar energy.

Metallurgical silicon is a convenient starting material for the preparation of solar cell-grade silicon. It contains aluminum (up to about 0.75% by weight) and iron (up to about 0.5%) as the major impurities; other impurities include boron, chromium, copper, magnesium, manganese, nickel, titanium, and vanadium at concentrations of up to several hundred parts per million. Most metallic impurities have deep levels in silicon and act as traps or recombination centers with large cross sections for capture of minority and majority carriers. These impurities reduce the minority carrier lifetime and must be removed as completely as possible.

To overcome the high cost of purification of metallurgical silicon via the halide intermediates, several direct purification techniques were attempted during the fifties. For example, the treatment of pulverized metallurgical silicon with aqua regia, sulfuric acid, hydrofluoric acid, etc., has been claimed to produce silicon suitable for microwave diodes (1). The gettering of molten metallurgical silicon with fused silicates has been reported to reduce the concentrations of iron and aluminum from 4.4 and 1.8% to 1.2 and 0.8%, respectively (2). Also, the treatment of molten metallurgical silicon with an equimolar mixture of oxygen and hydrogen chloride has been found to increase the purity from 98 to 99.99% (3).

During the past few years, there have been renewed interests in the direct purification of metallurgical silicon for solar cell purposes. For example, the zone-refining, crystal pulling, and other unidirectional solidification techniques have been shown to be effective in removing substantially the metallic impurities because of their low segregation coefficients in silicon (4-7). The chemical treatment of molten metallurgical silicon has also been reexamined (8-9). Although single crystals have been grown from purified metallurgical silicon to fabricate solar cells, their electrical properties, such as carrier mobility and diffusion length, have not been characterized.

* Electrochemical Society Active Member.

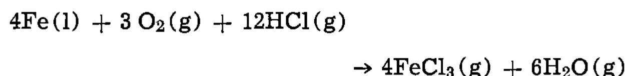
Key words: chemical treatment, diffusion length, Hall mobility, unidirectional solidification.

In this work, the purification of metallurgical silicon by the treatment of the melt with chlorine, a chlorine oxygen mixture, hydrogen chloride, and hydrogen fluoride has been further investigated, and the results compared with the earlier work. Also, in some experiments, the chemical treatment of the melt was followed immediately by unidirectional solidification in a one-step process. Furthermore, single crystals have been grown from purified metallurgical silicon, and their electrical properties, such as Hall mobility-temperature relation and diffusion length, were measured.

Thermochemical Considerations

The chemical treatment technique is based on the reactivity of the impurities in molten metallurgical silicon toward halogens or hydrogen halides to form volatile halides. The available information on the free energy of formation, in kilocalories/mole, of the halides of silicon and the major impurities in metallurgical silicon at 1700 °K is summarized in Table I (10-12). Since all chlorides have negative and relatively large free energies of formation and are volatile at the melting point of silicon, the treatment of molten metallurgical silicon with chlorine should result in considerable purification. Also, chemical equilibrium is presumably established during the chemical treatment due to the high temperature used. Thus the reaction between aluminum and chlorine is thermochemically more favorable than that between silicon and chlorine, while the reaction between iron and chlorine is less favorable than that between silicon and chlorine.

Hydrogen chloride or hydrogen fluoride also reacts with silicon and major impurities in metallurgical silicon, such as aluminum and iron, to form chlorides or fluorides. The standard free energy changes of these reactions, in kilocalories/mole, at 1700°K are summarized in Table II. The data indicate that aluminum can be preferentially removed and that iron is essentially inert under these conditions. However, the formation of volatile iron trichloride becomes more favorable by using a mixture of oxygen and hydrogen chloride according to the equation



$$4Fe(l) + 3\,O_2(g) + 12HCl(g) \rightarrow 4FeCl_3(g) + 6H_2O(g)$$

The standard free energy change of this reaction at 1700°K is −30.5 kcal/mole of iron. On the other hand, silicon and boron will compete for oxygen since the free energies of formation of silicon dioxide (s), silicon monoxide (g), and boron oxide (g) at 1700°K are −146, −60, and −183 kcal/mole, respectively. The preferential removal of boron from molten silicon by water vapor or oxygen has been demonstrated (13).

Experimental and Results

Apparatus and chemical analysis.—The apparatus used for the chemical treatment of molten metallurgical silicon and the unidirectional solidification of the resulting melt is shown schematically in Fig. 1. It consisted of a fused silica tube of 69 mm ID containing a silica crucible in a graphite susceptor, and gas inlet tubes were provided to flow argon through the fused silica tube and to introduce the gaseous reagent into the melt. To carry out the purification process, metallurgical silicon was placed in the fused silica crucible, and with argon flowing through the silica tube, the graphite susceptor was heated externally with an rf generator. After the silicon became molten, the reagent was bubbled through the melt until about 10% of the silicon had been reacted and volatilized. When unidirectional solidification of the melt was desirable, the graphite susceptor was slowly lowered out of the rf coil so that the melt solidified from the bottom of the charge in the upward direction.

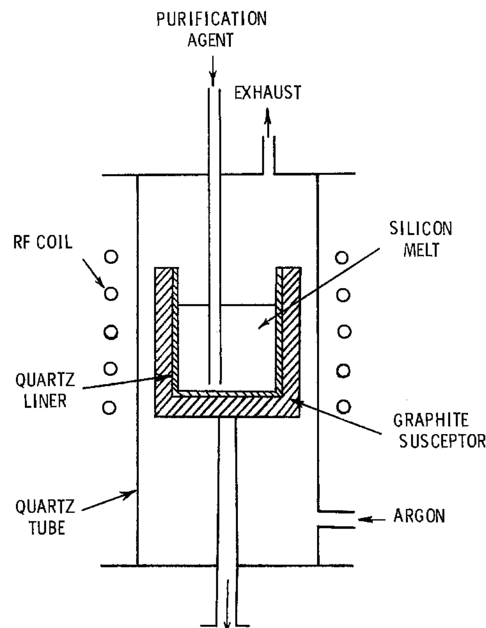

Fig. 1. Schematic diagram of the apparatus for the purification of metallurgical silicon.

The sampling of chemically treated metallurgical silicon for analysis is important in order to obtain meaningful results. Since a small amount of silicon (<1g) is generally used for analysis and the solidified material after chemical treatment is highly inhomogeneous due to the small segregation coefficients of impurities in silicon, improper sampling could result in a considerable error. To overcome this problem, a relatively small amount of metallurgical silicon, 20-25g, was used in the chemical treatment experiments, and the entire charge was dissolved in a nitric acid-hydrofluoric acid mixture. Aliquots of these solutions were analyzed for aluminum and iron, the major impurities in metallurgical silicon, by the atomic absorption technique. Some results on the effectiveness of oxygen, chlorine, a chlorine-oxygen mixture, and hydrogen fluoride for the purification of metallurgical silicon are shown in Table III. It appears that chlorine and chlorine-oxygen mixtures are similarly effective in reducing substantially the concentration of aluminum in metallurgical silicon, in agreement with the results of Dosaj *et al.* (9). However, no appreciable change in the concentration of iron was observed in all

Table III. Impurity concentration, parts per million by weight, in chemically treated metallurgical silicon

Al	3000	590	<50	<50	100
Fe	3400	2900	2300	2500	2700

cases. These results may be related to the thermochemical data discussed previously. Since aluminum is chemically more reactive than silicon, chemical treatment of the melt is effective for the preferential removal of aluminum from metallurgical silicon. The chemical treatment technique cannot reduce the concentration of iron in silicon to any appreciable extent due to the stronger reactivity of silicon. The ineffectiveness of chemical treatment for the removal of iron has been reported by Hunt *et al.* (6); however, considerably lower iron content in chemically treated metallurgical silicon has been reported by others (3, 9) due presumably to improper sampling techniques.

When the purification of metallurgical silicon was carried out by a combination of chemical treatment and unidirectional solidification, the resulting material was cut into wafers perpendicular to the direction of solidification. Wafers from four different positions (bottom, 1/3 from the bottom, 2/3 from the bottom, and the top) were used for analysis by the atomic absorption technique. The results of analysis of chlorine-treated and unidirectionally solidified metallurgical silicon are shown in Table IV; it is noted that the concentration of iron in the bottom half of the charge has been reduced substantially due to its low segregation coefficient (14). The emission analysis of two sections of a chlorine-treated and unidirectionally solidified sample is shown in Table V, together with the impurity content in metallurgical silicon. These results are in qualitative agreement with the results reported by other investigators (9).

Czochralski crystals from purified metallurgical silicon.—To further evaluate the usefulness of chemical treatment for the purification of metallurgical silicon, single crystals of about 2.5 cm diam were grown from chlorine-treated, chlorine-oxygen treated, and chlorine-treated plus unidirectionally solidified (lower 2/3 of the ingot only) metallurgical silicon by the Czochralski technique at a rate of about 10 cm/hr. Approximately 75-90% of the charge was pulled. The ingots were sliced, and the upper, middle, and lower sections of each ingot were analyzed for aluminum and iron content by the atomic absorption technique. The results are shown in Table VI. The crystals pulled from the chlorine-treated and chlorine-oxygen treated metallurgical silicon have very similar distribution of aluminum and iron. The concentration of iron is significantly lower than that in the starting material due to the low segregation coefficient of iron in silicon. However, the concentration of iron increased rapidly along the length of the crystal indicating that the diffusion of iron from the melt at the solidifying interface was a slow process. The concentrations of aluminum and iron in the crystal pulled from the chlorine-treated and unidirectionally solidified metallurgical silicon are below the detection limit of the atomic absorption technique.

Table VI. Impurity concentration, parts per million by weight, in Czochralski crystals pulled from purified metallurgical silicon

	Cl_2 treated		Cl_2-O_2 treated		Cl_2 treated and unidirectionally solidified	
	Al	Fe	Al	Fe	Al	Fe
Top section	<100	<10	<100	<10	<100	<10
Middle section	<100	700	<100	480	<100	<10
Bottom section	150	11,700	<100	21,300	<100	<10

The slices from the upper section of the ingots were chemically etched with a nitric acid-hydrofluoric acid mixture to remove the mechanical damage. They were all p-type. The resistivities and Hall mobilities in these slices were measured at room temperature by the van der Pauw technique (15). The ohmic contacts to the specimen were made by evaporating titanium-silver to the surface through a metal mask, followed by annealing in a hydrogen atmosphere at 550°C. The room temperature resistivities are approximately 0.32, 0.26, and 0.14 Ω-cm for chlorine-treated, chlorine and oxygen-treated, and chlorine-treated plus unidirectional solidified material, respectively. The differences in resistivities are presumably related to the differences in the extent of compensation. Their Hall mobility-temperature relations in the temperature range 81°-350°K are shown in Fig. 2. In this temperature range, the crystal from chlorine-treated plus unidirectionally solidified metallurgical silicon have higher mobilities than those from chlorine-treated and chlorine and oxygen-treated metallurgical silicon. Thus, the incorporation of unidirectional solidification into chemical treatment provides a more efficient way for the purification of metallurgical silicon than chemical treatment alone. However, the room temperature mobilities in all crystals (81, 108, and 127 cm^2/V-sec for chlorine-treated, chlorine and oxygen-treated, and chlorine-treated plus unidirectionally solidified materials, respectively) are

significantly lower than those in semiconductor grade silicon of similar carrier concentrations [higher than 200 cm^2/V-sec (16)]. Furthermore, the mobility-temperature relations peak at temperatures considerably higher than those observed in semiconductor grade silicon of similar carrier concentrations. These results indicate compensation in crystals pulled from purified metallurgical silicon.

Figure 3 shows the plots of $\sigma/\mu_H q$ *vs.* $1/T$ for all three crystals, where $\sigma/\mu_H q$ is directly proportional to the net carrier concentration. These relations are linear with a slope of $-E_I/2k$, where E_I is the ionization energy of the dopant. The ionization energy deduced in this manner is 0.044-0.052 eV, suggesting boron as the acceptor impurity. Furthermore, the relatively slow change in Hall mobility with temperature (μ_H in the chlorine-treated plus unidirectionally solidified material varies approximately with T^{-1} in the temperature range 150°-350°K) indicates that the donors have similar ionization energies as the acceptor.

The minority carrier diffusion length in silicon slices was measured by the steady-state surface photovoltage method at room temperature (17). In this method, the surface of a semiconductor is illuminated with chopped monochromatic radiation with energy slightly higher than the energy gap of the semiconductor. When $t << L$, $d >> L$, $\alpha t << 1$, $\alpha d >> 1$ (where t is the depletion layer thickness at the surface, d is the specimen thickness, L is the diffusion length, and α is the optical absorption coefficient), and the carrier injection is at a low level, then the incident light intensity at various wavelengths required to produce a given surface photovoltage is a linear function of the reciprocal absorption coefficient for each wavelength. Thus, the extrapolation of the incident light intensity *vs.* the reciprocal absorption coefficient plot to zero intensity yields "diffusion length" as the negative intercept. Figure 4 shows the diffusion length data for a silicon slice from chlorine-treated plus unidirectionally solidified metallurgical silicon, where the optical absorption data of stress-relieved silicon were used. A least squares fit of the data yields a diffusion length of 25 ± 2 μm. As a comparison, silicon slices from chlorine-treated and

chlorine-oxygen treated metallurgical silicon had diffusion lengths of (4-5) ± 1 μm, again indicating the effectiveness of unidirectional solidification.

Summary and Conclusions

The purification of metallurgical silicon has been carried out by the chemical treatment and, in some cases, followed by unidirectional solidification. The treatment of molten metallurgical silicon with chlorine or a chlorine-oxygen mixture has been found to be effective for reducing substantially the concentration of aluminum in silicon. However, the concentration of iron was not appreciably lowered by the treatment of molten metallurgical silicon with chlorine, oxygen, a chlorine-oxygen mixture, or hydrogen fluoride. Because of the low segregation coefficients of most metals in silicon, the use of unidirectional solidification following chemical treatment provides an efficient technique for the purification of metallurgical silicon. The extent of purification is in qualitative agreement with that obtained by similar methods reported by other investigators.

ABSTRACT

The effects of high substrate phosphorus impurity levels on the kinetics of thermal oxidation of <111> oriented silicon have been studied for a dry oxygen ambient in the temperature range 800°-1100°C. The observed enhanced oxidation rates with phosphorus doping levels $\gtrsim 10^{19}/cm^3$ are found to be consistent with a simplified interpretation of the linear-parabolic oxidation model together with phosphorus redistribution effects. The linear rate constant B/A increases substantially at all temperatures, implying significant change in the $Si\text{-}SiO_2$ interface reaction rate, though apparently with only slight effect on the associated activation energy. The parabolic rate constant B increases somewhat at lower temperatures, indicating a finite change in oxidant diffusion through the oxide, possibly via an additional diffusion mechanism at high phosphorus concentrations, with reduced activation energy. Reasonable closed-form approximations to these phosphorus concentration dependencies of the oxidation rate constants are described.

Thermal oxidation of silicon remains an essential part of integrated circuit technologies, both bipolar and MOS, being used for such diverse purposes as masking against dopant diffusion, passivation of active device regions and junctions, insulating "field regions" between active devices, and, in the gate dielectric, as an actual component of active MOS devices. Often encountered is the growth of thermal oxide over silicon that is heavily doped with donor or acceptor levels not infrequently approaching the solid solubility limit of the impurity in silicon. Typical examples are bipolar emitter regions and MOSFET source and drain regions. This situation, together with the demonstration that oxide growth rates over silicon with impurity levels $\gtrsim 10^{18}$ cm^{-3} are significantly greater than rates over lightly doped silicon (1, 2), has prompted a continuing investigation of the effects of dopant impurity levels on oxidation rates and mechanisms. Part of this investigation has been a quantitative study of thermal oxidation of heavily phosphorus-doped, <111> oriented silicon in a dry oxygen ambient. The results of this study are presented here.

General Theory

A brief review of general oxidation theory indicates qualitatively what may be expected in the case of heavily doped substrates or diffused regions. The macroscopic model of Deal and Grove (3) for silicon oxidation by water or dry oxygen involves the diffusion of the oxidizing species from the ambient through an existing oxide to react with silicon at the Si/SiO_2 interface. Analysis based on requiring continuity of steady-state flux of the oxidant through the ambient/oxide/interface structure yields the familiar linear-parabolic growth relationship (3)

$$\frac{x_o^2}{B} + \frac{x_o}{B/A} = t + \tau \qquad [1]$$

where x_o = oxide thickness, B = parabolic rate constant, B/A = linear rate constant, t = oxidation time, and τ = correction factor which accounts for an initial oxide thickness x_i, or effective x_i due to an observed initial accelerated growth rate in dry oxygen.

For thick oxides and oxidation times long relative to a characteristic time $A^2/4B$, the first term on the left-hand side of Eq. [1] dominates, resulting in parabolic, diffusion-limited growth. Under these conditions, B is the dominant rate constant and is given by

$$B = 2D_{eff}C^*/N_1 \qquad [2]$$

where D_{eff} = effective diffusion coefficient of the oxidant in the oxide, C^* = equilibrium concentration of the oxidant in the oxide, and N_1 = number of oxidant molecules incorporated per unit volume of oxide grown. B exhibits an Arrhenius temperature dependence with activation energies of 1.2 eV for dry O_2 and 0.71 eV for H_2O, apparently reflecting the activation energies for the diffusivity of O_2 and H_2O, respectively, in SiO_2 (3).

For thin oxides and oxidation times short relative to $A^2/4B$, the second term on the left-hand side of

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
Key words: oxidation kinetics, rate constants, silicon, phosphorus.

Eq. [1] dominates, resulting in linear interface reaction-limited growth. B/A is the governing rate constant under these conditions and is given by

$$\frac{B}{A} = \frac{kh}{k+h}\frac{C^*}{N_1} \simeq k\frac{C^*}{N_1} \quad [3]$$

where h = gas phase transport coefficient for the oxidizing species from the ambient to the outer oxide surface and k = Si/SiO_2 interface reaction rate constant. An activation of energy of 2 eV is observed for B/A for both dry O_2 and H_2O ambients, apparently determined by the energy required to break a Si-Si bond (3, 4).

In an idealized interpretation, then, factors likely to influence the interface reaction rate should alter B/A, while those affecting oxidant diffusion will change B. Sufficiently high impurity levels in the substrate should be expected to modify the interface reaction. Similarly, high impurity content in the oxide may affect diffusivity of the oxidizing species. The relative magnitudes of such effects should depend on the particular impurity involved and its behavior during oxidation.

Specifically, phosphorus, as with the other commonly used donor impurities arsenic and antimony, diffuses more slowly in the oxide than in the silicon and tends to segregate at the interface in favor of greater phosphorus levels on the silicon side. As a result, a pile-up of phosphorus at the interface to levels greater than bulk concentrations in the silicon may occur during oxidation, with relatively much lower levels in the oxide. In addition, the pile-up should be more substantial for H_2O than for dry O_2 oxidation due to even slower diffusion relative to oxide growth rates (5).

Therefore, oxidation regimes dominated by the linear rate constant should exhibit greater dependence on heavy phosphorus doping level than should regimes dominated by the parabolic rate constant. Shorter oxidations which are interface reaction rate limited should show greater variation with heavy phosphorus doping than should longer oxidations which are diffusion limited. The influence of heavy phosphorus doping via large B/A variations should also diminish or saturate with increasing oxidation temperature, since diffusion-limited oxidation dominates at shorter oxidation times with increasing temperature.

Over-all, then, this qualitative model indicates that greater influence of heavy doping levels of phosphorus (and also arsenic and antimony) should be seen at shorter oxidation times and lower oxidation temperatures, and that these effects should be greater for H_2O than for dry oxygen oxidations. The validity of this simple model for the enhanced oxidation rates observed over N^+ regions will now be considered quantitatively.

Experimental Procedures

Substrate preparation.—Because silicon wafers with phosphorus impurity levels $\geq 10^{19}$ cm^{-3} are not readily available, heavily doped samples were prepared by diffusion of phosphorus using a standard $POCl_3$ source into lightly phosphorus-doped, 10-15 Ω-cm <111> oriented substrates. Predeposition and drive-in schedules were chosen to produce diffused phosphorus profiles that were flat, within 10% over at least the first 2μ into the silicon. Drive-ins were done in an N_2 ambient to minimize oxidation and hence redistribution of the phosphorus during preparation of the samples.

Five types of heavily doped samples were prepared with target impurity levels ranging from $\sim 5 \times 10^{19}$ cm^{-3} to essentially solid solubility (at standard furnace temperatures). The resulting diffused impurity profiles were measured for electrically active phosphorus concentration using both spreading resistance and incremental sheet resistance via anodic oxidation. Agreement between the two measurement techniques was excellent, giving the values in Table I. Reproducibility of diffused phosphorus impurity levels from run to run of sample preparation was checked using the electrical measurement techniques and found to be very good. Total chemical phosphorus concentrations and hence the percentage of the species electrically active in the diffused samples were studied with both sputtering Auger[1] and SIMS techniques, also with generally good agreement, as shown in Table I. The relation between chemical and electrical values found is consistent with published results (6). Both electrical and chemical phosphorus profiles appeared sufficiently flat to allow treating the samples as effectively initially uniformly doped at the measured surface concentrations for purposes of first-order analyses of results from oxidations of the prepared samples.

Table I. Electrically active C_{BE} and chemical C_{BC} dopant concentrations in heavily phosphorus-doped samples

Sample	C_{BE}	C_{BC} SIMS	C_{BC} AES
A	$(\sim 10^{15})$	—	—
B	5.1×10^{19}	5.5×10^{19}	5.2×10^{19}
C	7.2×10^{19}	1.5×10^{20}	8.2×10^{19}
D	1.8×10^{20}	2.4×10^{20}	2.8×10^{20}
E	2.8×10^{20}	4.5×10^{20}	5.0×10^{20}
F	3.2×10^{20}	7.0×10^{20}	6.8×10^{20}

Oxidation and measurement procedures.—Samples of each of the five selected heavy substrate doping levels, together with a control wafer of the lightly doped substrate from which the heavily doped samples were prepared, were next oxidized together at various times and temperatures. In each case, the samples were subjected to standard cleaning procedures and then placed horizontally on a quartz boat in order of increasing substrate doping level, with the lightly doped control farthest upstream and the most heavily doped sample farthest downstream relative to gas flow in the oxidation furnace, such that possible effects of out-diffusion of phosphorus into the ambient from the more heavily doped wafers might be minimized. The wafers were then pushed rapidly directly into the oxidizing ambient in the furnace for the desired oxidation time, or, for times of 1 hr or less, pushed into nitrogen and allowed 5 min to come to temperature before the oxidizing ambient was initiated. With completion of the desired oxidation time, the samples were fast-pulled directly from the oxidizing ambient.

Resulting oxide thicknesses were measured using multiple-beam interferometric techniques to avoid uncertainties of possible effects on the optical properties of the samples due to high phosphorus impurity levels in the silicon and the oxide. With these experimental methods, reproducibility of oxide thickness was found to be well within the accuracy of the interferometric measurement technique (±25Å).

Data evaluation.—A quantitative measure of the increase of oxidation rate with heavy phosphorus doping may be obtained via extraction of effective rate constants from the data using the macroscopic linear-parabolic oxidation model. Conventionally, extraction is achieved using the alternative form of the general growth relationship (3)

$$x_o = B\left(\frac{t+\tau}{x_o}\right) - A \quad [4]$$

Thus, a plot of x_o *vs.* $(t+\tau)/x_o$ yields B as the slope and $-A$ as the intercept. However, τ itself is a function of B, B/A, and x_i. At a given oxidation temperature, the value of τ will decrease with heavy substrate doping and becomes very difficult to determine directly by extrapolating a curve fit to the experimental x_o *vs.* t data. This is especially true in view

[1] Auger measurements were done by J. S. Johannessen, C. R. Helms, and W. E. Spicer of Solid State Laboratory, Electrical Engineering Department, Stanford University.

of the nonlinear nature of the fitted lines when growth is most rapid, and the possible scatter inherent in data points for very short oxidation times.

It will be shown, though, that the apparent initial thickness x_i varies relatively only slightly with heavy phosphorus doping about the value of $x_i \simeq 200$Å typically seen for dry oxygen oxidation. That is, the initial rapid growth mechanism responsible for the apparent nonzero x_i for dry O_2 oxidation seems relatively unaffected by heavy phosphorus doping. To first order, then, assumption of a constant $x_i \simeq 200$Å appears reasonable, and analysis may proceed employing another alternative form of the general relationship

$$(x_o + x_i) = B\left(\frac{t}{x_o - x_i}\right) - A \quad [5]$$

A linear plot of $(x_o + x_i)$ *vs.* $t/(x_o - x_i)$ produces, as before, B as the slope and $-A$ as the intercept.

Experimental Results

An extensive series of oxidations were done in a dry O_2 ambient at temperatures of 800°, 900°, 1000°, and 1100°C. The data produced are shown in Fig. 1 and 2 as oxide thickness *vs.* oxidation time curves for each of the five heavily doped sample types and the lightly doped control. At each temperature, the bottom curve represents the lightly doped control and agrees well with published data for <111> substrates, while the additional curves represent the heavily doped samples, in order of increasing substrate doping. Specific doping levels are indicated in Table I.

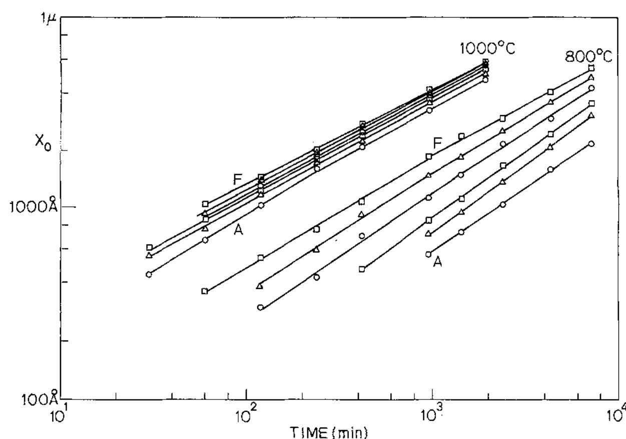

Fig. 1. Oxide thickness *vs.* oxidation time for <111> oriented silicon in dry O_2 ambient with substrate phosphorus doping level as parameter, at 800° and 1000°C.

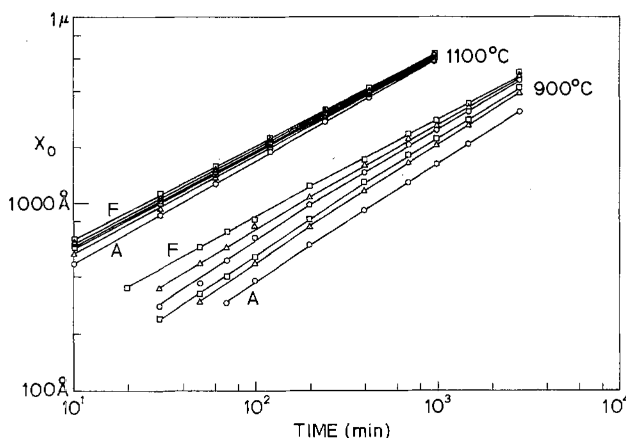

Fig. 2. Oxide thickness *vs.* oxidation time for <111> oriented silicon in dry O_2 ambient with substrate phosphorus doping level as parameter, at 900° and 1100°C.

The data in Fig. 1 and 2 already lend qualitative support to the predictions based on the simple interpretations of doping effects presented earlier. Clearly the greatest relative variations of oxide thickness occur at the shorter times and lower temperatures, the regions in which the interface reaction and hence B/A are expected to dominate, indicating that the increasing substrate phosphorus level has a very strong effect on the interface reaction. At the longer times and higher temperatures, in the diffusion-limited regime, substantially less variation of thickness with doping is seen, implying that oxidant diffusion and the parabolic rate constant are influenced to a much smaller extent by the increasing substrate phosphorus levels. Indeed, a few selected oxidations at 1200°C, when the characteristic time $A^2/4B$ for lightly doped substrate oxidations is only about 0.5 min and therefore oxidation is effectively entirely B dominated, produced essentially no variation of oxide thickness with increasing phosphorus doping that could be resolved within the limits of interferometer accuracy.

Extrapolation on linear scales of thickness *vs.* time to the effective initial oxide thickness x_i attributable to the initial rapid growth mechanism shows only slight variation around 200Å as the substrate changes from lightly to heavily phosphorus doped. Thus, to first order a constant $x_i \simeq 200$Å may be assumed, as described above.

Discussion

The variation of the effective B/A and B values with increasing initial substrate total chemical phosphorus concentration, representatively illustrated in Fig. 3 for 900°C dry O_2 oxidation, exhibits dramatically the expected behavior. B/A, reflecting interface reaction-limited oxidation, increases sharply by more than an order of magnitude as the phosphorus level rises toward solid solubility. On the other hand, B, which represents the diffusion-limited regime, is affected only slightly by the increasing substrate phosphorus doping. Clearly, the predictions of the simplified interpretations presented have been convincingly confirmed. We now consider the effects on B/A and B in detail.

Linear rate constant.—The temperature dependence of B/A is shown in Fig. 4, where log (B/A) is plotted against $1/T$ with substrate doping level as a parameter. The lowest points are the values found for the lightly doped control samples, while the higher points correspond, respectively, to the increasingly heavily phosphorus-doped substrate types used. To a reasonable approximation, Arrhenius temperature dependence may be assumed for the effective B/A values

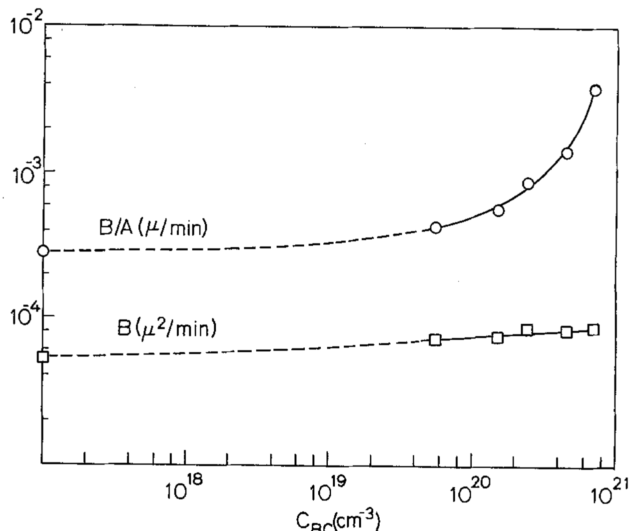

Fig. 3. Oxidation rate constants *vs.* initial substrate chemical phosphorus doping level at 900°C.

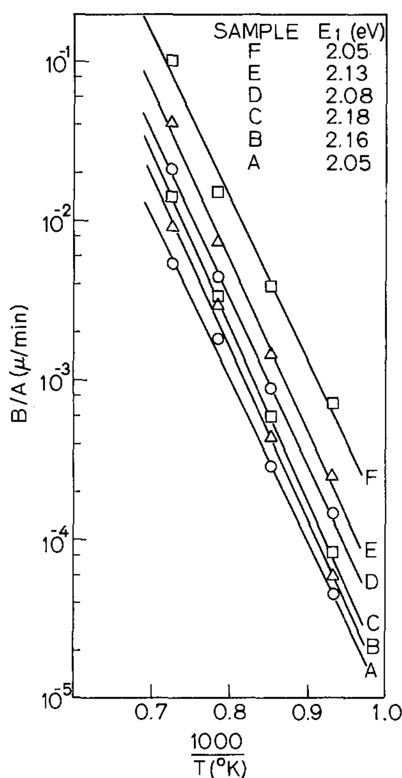

Fig. 4. Linear rate constant temperature dependence and effective activation energies with substrate phosphorus doping level as parameter.

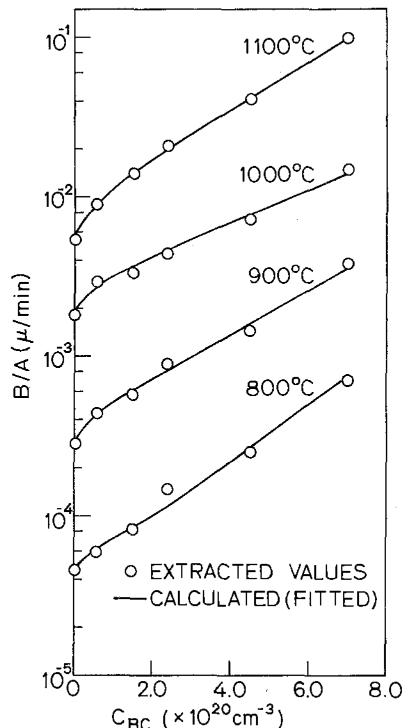

Fig. 5. Linear rate constant vs. initial substrate chemical phosphorus doping level with oxidation temperature as parameter.

corresponding to each substrate doping level, leading to the least squares fitted lines and apparent activation energies of the figure.

High impurity levels may produce the large increases of effective B/A by altering the activation energy and/or the preexponential factor. Apparently the basic limiting activation energy of approximately 2 eV associated with the interface reaction is not substantially altered by the high phosphorus levels, while significant dependence on dopant concentration may be found in the preexponential factor.

Some indication of the nature of this dependence may be gained via examination of the variation of B/A with concentration at a given temperature, as was done in Fig. 3 for 900°C. The sharp increase of the linear rate constant suggests an exponential dependence of C_{BC}, the initial chemical substrate phosphorus concentration, a possibility that is tested further by investigating the variation of log (B/A) with C_{BC} in Fig. 5. Evidently log (B/A) eventually exhibits roughly a linear dependence on C_{BC}, and hence B/A an exponential dependence on C_{BC}, at each given temperature, but only after a stronger initial increase. There may be a slight temperature dependence in the magnitude of this initial increase, but to a large extent the substrate background phosphorus concentration dependence is very similar at all temperatures.

Clearly, many closed-form relationships for this C_{BC} dependence may be used to approximate this data to varying degrees of complexity, in the absence of an accurate physical model for that dependence. A fairly simple form, producing a reasonable first-order approximation, might be

$$\frac{(B/A)}{C_0 e^{-E_1/kT}} \equiv (B/A)' = 1 + k_1 C_{BC}^{n_1} e^{k_2 C_{BC}} \quad [6]$$

where $C_0 e^{-E_1/kT}$ is the published temperature dependence of the linear rate constant for lightly doped substrates with $E_1 \simeq 2$ eV (3). Thus, the exponential eventually dominates, but the power law dependence produces the stronger initial increase. Optimal k_1 and k_2 values may be found by rewriting Eq. [6] in the alternative form

$$\log\left[\frac{(B/A)' - 1}{C_{BC}^{n_1}}\right] = \log k_1 + k_2 C_{BC} \quad [7]$$

Plotting $\log\left[\frac{(B/A)' - 1}{C_{BC}^{n_1}}\right]$ *vs.* C_{BC} should therefore produce a linear dependence with intercept log k_1 and slope k_2, for an appropriate value of n_1. Such analysis indicates that a value of $n_1 \simeq 0.5$-1.0 should be used, with $n_1 \simeq 0.5$ giving particularly consistent linear dependences. Thus, the curves plotted together with the experimental B/A values in Fig. 5 have been calculated using $n_1 = 0.5$ and the resulting appropriate k_1 and k_2 values. Agreement appears very reasonable. The fitted k_1 and k_2 values are presented *vs.* $1/T$ in Fig. 6, confirming that the temperature dependence is relatively slight when compared with the over-all dependence of B/A. In fact, appropriate constant values of k_1 and k_2 independent of T conceivably could be used for all temperatures. While agreement not surprisingly is not as good, using values of $k_1 = 5.9 \times 10^{-11}$ $cm^{3/2}$ and $k_2 = 3.0 \times 10^{-21}$ cm^3 gives reasonable agreement with the experimental results over the entire temperature range investigated.

Parabolic rate constant.—B has been found to be a much weaker function of high phosphorus concentrations. Nevertheless, it does appear to increase somewhat with concentration, as seen in Fig. 7, where log B is plotted *vs.* $1/T$ with substrate doping as a parameter. At each temperature, the lowest point represents the lightly doped control while the higher points correspond to the heavily doped samples. It is apparent that, unlike the case for B/A, the concentration dependence of B varies significantly with temperature. Dopant level has a greater effect at lower temperatures and virtually no effect at 1100°C. Also, for a given doping level, the net temperature dependence is not readily reconcilable with a single activation energy Arrhenius relation, implying changes in activation energy and a temperature-dependent preexponential factor, or addition of a new, phosphorus-related term with different activation energy. Figure 8, presenting log B *vs.* C_{BC} with temperature as parameter, empha-

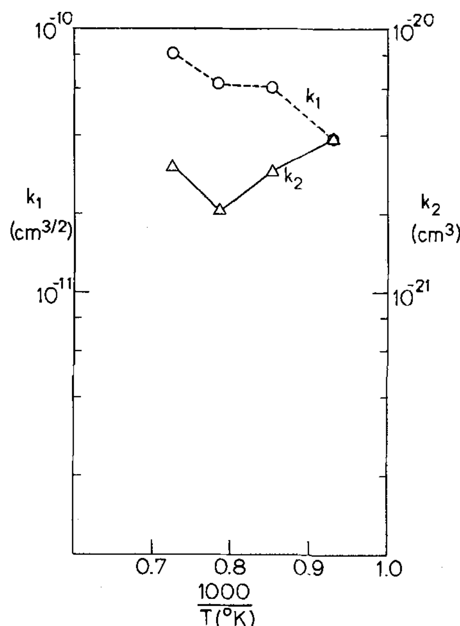

Fig. 6. Fitted parameters vs. $1/T$ for linear rate constant dependence on initial substrate chemical phosphorus doping level.

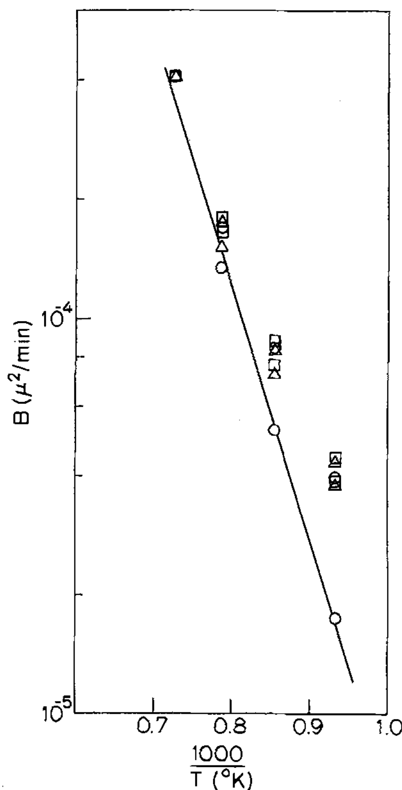

Fig. 7. Parabolic rate constant temperature dependence with substrate phosphorus doping level as parameter.

sizes this additional temperature dependence. Further, the dopant concentration effects at a given temperature become evident. As substrate doping level increases (and consequently the lower phosphorus level in the oxide also rises), B first increases rapidly and then begins to "saturate," increasing only very slowly, if at all.

As with B/A, a convenient closed-form approximation of the B variations may be made. For convenience, no new explicit T dependence is included, but the fitted "constants" should then reflect any dependence thus hidden. The initial rapid rise and subsequent sluggishness suggest a possible power law dependence on dop-

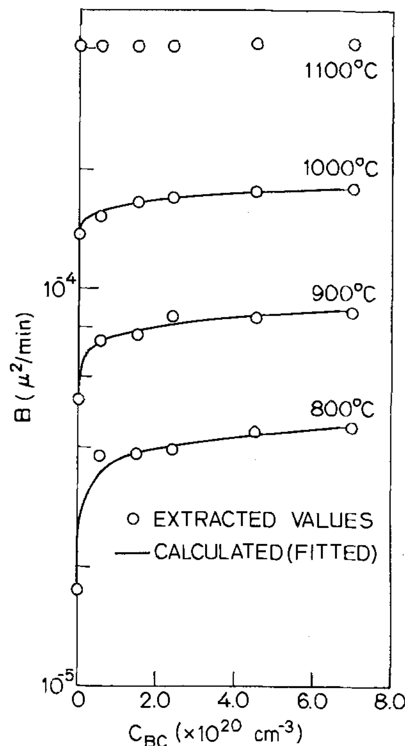

Fig. 8. Parabolic rate constant vs. initial substrate chemical phosphorus doping level with oxidation temperature as parameter.

ant levels. Initial substrate phosphorus level is used as the variable for this analysis, though actual levels in the oxide should be more directly relevant. (This factor will be discussed below.)

$$\frac{B}{B_0 e^{-E_2/kT}} \equiv B' = 1 + k_3 C_{BC}^{n_2} \quad [8]$$

where $B_0 e^{-E_2/kT}$ is the published temperature dependence of the parabolic rate constant for lightly doped substrates with $E_2 \simeq 1.2$ eV for dry O_2 (3).

Appropriate k_3 and n_2 values may be extracted in a manner analogous to Eq. [7]. This approach was used with the extracted B values for 800°, 900°, and 1000°C, with surprisingly good linear relations found. The calculated curves in Fig. 8 illustrate the very reasonable fit to the extracted B values produced by the above relation with the k_3 and n_2 values shown vs. $1/T$ in Fig. 9. The expected additional T dependence is clearly evident in k_3 and possibly, to a lesser extent, in n_2. A new additional activation energy is strongly suggested, and this will be explored.

Factors affecting data interpretation.—Analysis to this point has been based on C_{BC}, the initial substrate chemical phosphorus level prior to oxidation. However, as mentioned previously, all common dopants redistribute during oxidation, with phosphorus "snowplowing" in the silicon to produce an increased interface concentration $C_{SC} > C_{BC}$, and reduced effective levels in the oxide $C_{ox} < C_{BC}$. Further, the relative magnitudes of the pile-up and oxide phosphorus levels increase as dopant diffusivity decreases relative to oxidation rate (5); that is, for H_2O rather than O_2 oxidation, for lower temperature oxidation, or for lower initial phosphorus concentration (7).

Thus, for analysis of the effects on B/A or the interface reaction, the actual doping parameter realistically should be C_{SC} rather than C_{BC}. The effective B/A values found will correspond to higher C_{SC} values, tending to shift the B/A data points to higher values along a dopant concentration axis. And, since the relative amount of pile-up decreases as C_{BC} increases and as temperature increases, these shifts may be greater for the lower concentration points at lower temperatures.

A time-dependent effect may further complicate consideration of dopant redistribution. The first-order

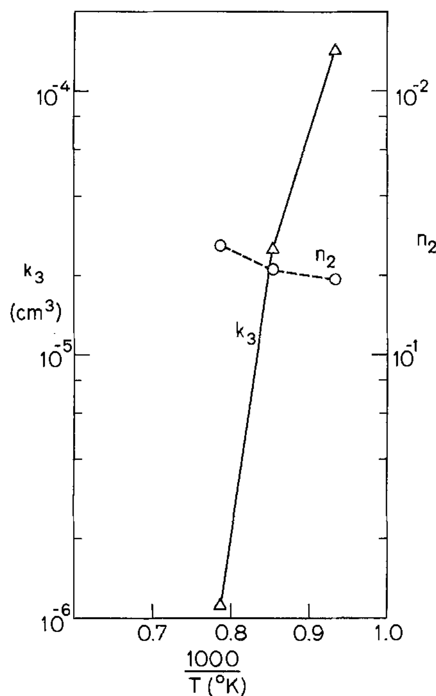

Fig. 9. Fitted parameters vs. 1/T for parabolic rate constant dependence on initial substrate chemical phosphorus doping level.

theory mentioned (5) assumes parabolic oxidation, or the same $t^{1/2}$ dependence as for dopant diffusion, to find a "steady-state" time-independent dopant redistribution. Yet, oxidation must proceed through a linear growth period before achieving parabolic growth, and consequently redistribution should be subject to a finite time-dependent transient period before achieving a steady-state value. Onset of essentially parabolic oxidation may be reasonably taken as achievement of steady-state pile-up conditions. Therefore, the characteristic time $A^2/4B$ is useful as a measure of the duration of the transient period. In any event, since B/A is most relevant in this linear growth transient period, the effective B/A value found may actually be an averaged value corresponding to a time-averaged C_{SC} value presumably less than the steady-state phosphorus C_{SC}. Evidently, then, time dependence may offset somewhat the shifts along the concentration axis from the initial C_{BC} value toward the greater C_{SC} values.

Nevertheless, redistribution and pile-up of phosphorus should produce a net "forward" shift of the heavily doped substrate points in a plot of extracted B/A *vs.* dopant level such as that of Fig. 5, reducing the apparent initially rapid increase of B/A with heavy substrate doping, to produce possibly a solely exponential dependence on C_{SC}, of the form

$$B/A \simeq C_0 e^{-E_l/kT} e^{k'C_{SC}} \quad [9]$$

There may also be uncertainty of B/A values due to the method of analysis (8). Since changes in B are relatively slight, the "source" of the large B/A increase seen is the significantly reduced A value or the intercept in the $(x_o + x_i)$ *vs.* $t/(x_o - x_i)$ plot of the data. As temperature and high dopant level rise, this intercept moves increasingly toward a value of 0, or an infinite B/A. Possible error due to data scatter produces much greater error in extracted B/A value as T and C_{BC} increase. So, particularly for the heaviest phosphorus-doped substrate types, the 1100°C B/A values, for example, may contain significant error which, while not important in calculating actual oxide growth because of increased B dominance, may alter apparent activation energies for B/A.

Extraction of B as the slope of $(x_o + x_i)$ *vs.* $t/(x_o - x_i)$ should, on the other hand, produce comparable errors for all the conditions studied, and such potential errors should not be as significant in consideration of B. Transient effects should be less significant as well, since B does not really become meaningful until parabolic oxidation is approached, precisely the time at which, presumably, redistribution approaches its steady-state value. Redistribution itself and its temperature dependence must be considered, however. The actual dopant level of importance in B or oxidant diffusion should be C_{ox} rather than the C_{BC} used in the analysis. Also, the effective B values for a given heavily doped substrate type may then correspond to different C_{ox} values as the magnitude of redistribution varies with temperature.

It is apparent that accurate measure of C_{SC} and C_{ox}, and their possible time dependence, for a given C_{BC} and oxidation condition would be highly desirable in furthering realistic and meaningful analysis and interpretation. Such efforts are being pursued currently using sputtering Auger and ion microprobe techniques and will be reported in a future publication.

Possible mechanisms.—Some indication of possible physical mechanisms for the effects of heavy substrate phosphorus doping on oxidation may be drawn from the present data. Intuitively, the enhanced oxidation rates observed in this study may be related to chemical, electrical, or even mechanical effects of the heavy doping.

For example, the very high phosphorus levels enhanced by redistribution pile-up at the interface may, by size mismatch relative to Si of substitutional phosphorus or by "interstitial" cluttering or precipitates (9, 10), create lattice strain and, therefore, alter the Si-Si bond strength that has been linked to the limiting activation energy of the interface oxidation reaction. Further, the preexponential factor of the interface reaction may include such components as the number of interfacial Si atoms or the number of "available" interfacial Si bonds that have been suggested as the source of differences in oxidation rates for various Si wafer orientations (11). Possibly, the high interfacial dopant levels could affect such factors to produce increased oxide growth rates as well.

In fact, the analysis of the temperature dependence of B/A with C_{BC} as the parameter suggested strongly that the primary effect of heavy phosphorus levels is on the preexponential factor. So, as simple an effect as an increased interface "roughness," leading to higher numbers of available Si bonds and attributable to phosphorus atoms, clusters, or precipitates, could explain the enhanced interface reaction.

These dopant-related effects on B/A may not be purely mechanically induced. The thermodynamics of the interfacial oxidation reaction may well be affected, such that the Gibbs free energy change driving force for the reaction would be altered significantly. Also, the position of the Si Fermi level will be altered by such high dopant levels, even at the high temperatures of thermal oxidation, to create electrical effects on the interface reaction rate.

Heavy phosphorus effects on B or diffusion of the oxidizing species in the oxide are relatively smaller, but they do exist. If B were unaffected, then at long t the oxide thicknesses resulting from the various heavy doping levels and enhanced B/A values should approach that of the lightly doped control. This behavior is not apparent in the data, especially at low temperatures.

These real effects on B should be related to the phosphorus level found in the oxide. The trends observed appear to agree at least qualitatively with redistribution theory (5). That is, pile-up and C_{ox} should increase as T decreases such that the effect on B for a given initial C_{BC} is greater at lower temperatures. The relative amount of C_{ox}/C_{BC} decreases at the highest substrate phosphorus levels, resulting in C_{ox} levels varying less than C_{BC} levels. Consequently, the B increase, or enhanced oxidant diffusion, tends to "saturate" quickly at the high C_{BC} values.

The analysis above suggests that oxidant diffusion in the oxides grown on heavily doped substrates may be subject to a phosphorus-related term, with different activation energy, in addition to the diffusivity term governing diffusion in "pure" oxides. Quite reasonably, diffusion in a phosphorus-rich region of the oxide would present a different, presumably reduced activation energy. So, this new diffusivity, multiplied by a phosphorus concentration factor related to the "richness" and/or the extent relative to the total oxide of the phosphorus region of the oxide, might combine with the diffusivity remaining in effect in the rest of the oxide. Since C_{BC} rather than C_{ox} has been used in this concentration factor, the apparent slightly T dependent power law form of the factor might reflect the tendencies of redistribution of C_{BC} to produce C_{ox}. The greater temperature dependencies of the two activation energies, in any event, would produce the over-all nonlinear $1/T$ dependence observed for log B in oxidation of heavily doped substrates.

Much additional information is obviously needed to resolve fully the possible mechanisms suggested or implied by the present data. Work being performed currently, including effects of heavy arsenic, antimony, and boron doping, combined effects of substrate orientation and heavy doping levels, H_2O oxidation of heavily doped substrates, and other aspects of heavy doping effects on oxide and the $Si\text{-}SiO_2$ interface, may produce some of the additional clues and information needed.

Conclusions

Enhanced thermal oxidation effects in the heavily phosphorus-doped silicon regions commonly seen in integrated circuits have been studied, producing some indication of possible physical mechanisms explaining the greatly increased B/A and somewhat enhanced B macroscopic model rate constants. In the absence of more complete quantitative physical models, closed-form relations have been presented, giving good approximation to the effects which have been shown to be most substantial at lower temperatures. As the trend in technology is toward lower temperature processing in view of the larger wafers being used, these heavy phosphorus-enhanced oxidation effects appear very likely to impact integrated circuit technology. In addition, careful design of processing schedules can make use of these enhanced oxidation effects to, for example, reduce gate-to-source and gate-to-drain capacitance in MOS transistors.

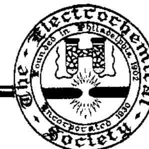
Brief Communication



Disclosure of Dislocation Loops and Dislocation Dipoles in GaP by Chemical Etching

C. Werkhoven

Philips Research Laboratories, Eindhoven, The Netherlands

Since chemical etching is fast and in principle nondestructive, this technique is, at least for III-V single crystals, widely used for the assessment of defects. An analysis of the microscopic structure of extended defects and the identification of microdefects as can be performed by TEM is difficult to obtain with the etching technique, however.

It is shown in this paper that on the conditions of an optimized etching time and the use of high magnification optical microscopy techniques, information about the submicron structure of defects in GaP single crystals can be obtained. For this purpose the $R\text{-}C$ etchant (1) was used because it requires short etching times at a moderate bath temperature, *viz.* 65°C, and because it is a preferential etchant for the {111} P growth plane leading to faceted, triangular-shaped etch pits which have a distinct apex at the emergence point(s) of the defect.

The etched surfaces were examined with a Zeiss interference contrast Photomicroscope II. On 9 × 13 cm^2 prints a final linear magnification of 2600X was obtained using the 100X objective with oil immersion. The high optical quality of the microscope allowed even further enlargements of the negatives.

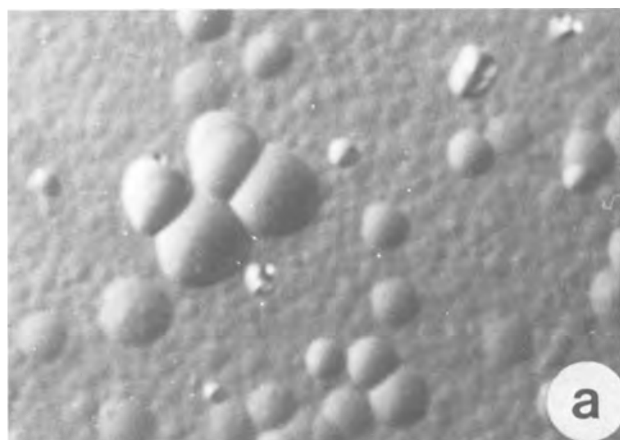
The observations presented apply to LEC-pulled substrate wafers and layers grown by LPE on these wafers. Prior to etching, the {111} P surfaces were chemically polished in a Cl_2-saturated methanol bath to avoid etch pits due to damage. The appearance, the growth, and also, in the case of small microdefects, the disappearance of the etch pits was followed by choosing the appropriate etching steps. Finally, the etching features of the substrate crystals and the layers are compared in order to establish possible correlations.

In GaP substrate material etch pits due to extended dislocations [D pits (2, 3)] and to unidentified microdefects [S pits (2, 3)] have been observed previously. The new etching phenomenon reported here can unambiguously be assigned to small dislocation loops. These loops give rise to etch-pit pairs (DL pits) when they are intersected by the surface. A typical property of the DL pits was that they disappeared upon continued etching, *i.e.*, the pairs grew together and finally one shallow etch pit without apex (like the S pits) was left. At the same time new pairs became visible at other sites on the surface. This behavior established the localized nature of the corresponding defect. The change from a structured etch-pit pair to a nonfaceted shallow pit took place within 1 min etching time. This is shown in Fig. 1.

The distance between the apexes, which equals approximately the diameter of the loop, varied from crystal to crystal but was always found to be 0.5-2 μm. In some pairs the apexes were connected by a ridge, similar to that found for large stacking faults. It is therefore concluded that the latter loops are faulted loops such as observed by TEM (4, 5).

The highest density of dislocation loops was found in macroscopically "dislocation-free" crystals, *viz.*, 5×10^5 cm^{-2}. In highly dislocated (D-pit density $\sim 10^5$ cm^{-2}) crystals the density was lower and occasionally even zero dislocation-loop densities were observed. The latter phenomenon might be due to variations in as yet unknown growth parameters.

The number of shallow pits left behind by dislocation loops increases rapidly as the etching process proceeds (the etching rate for an unstirred solution is about 0.2 μm/min). It will be obvious then that, at the above-mentioned density of dislocation loops, short etching times are required to avoid an accumulation of etch pits.



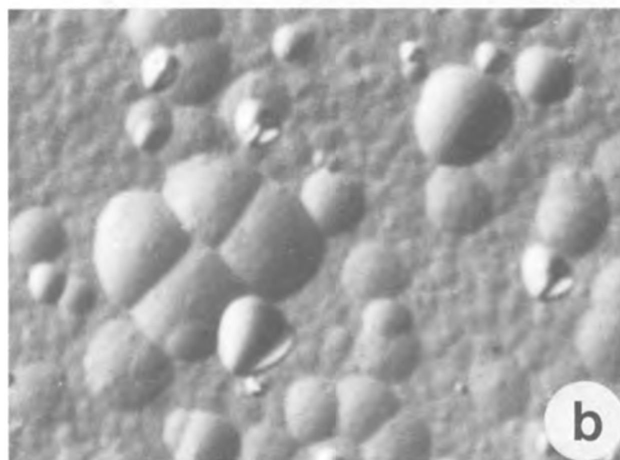


Fig. 1. Etch pits in the same area of a "dislocation-free" GaP substrate after: (a) 1½ min; (b) 2½ min etching time. The change to shallow pits and the appearance of new etch-pit pairs indicate that they correspond to small dislocation loops (DL pits).

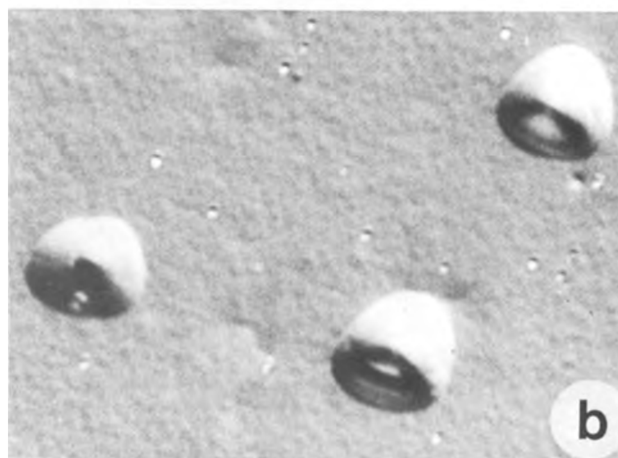

Fig. 2. Etch pits due to dislocation dipoles (DD pits) in an LPE layer grown on a "dislocation-free" substrate. The separate dislocations of the three dipoles in this area are spatially resolved after: (a) ¾ min etching time; but (b) have grown together after 3 min etching time. The other features in the photographs are due to surface irregularities.

Like for the substrate material both single and paired etch pits were observed in LPE material. The etch-pit pairs could only be resolved at high magnifications and using very short etching times, *i.e.*, ~ 3/4 min. In contrast with the etch-pit pairs in the substrate material, however, prolonged etching did not change them into shallow pits; only faceted single pits were left after 3-5 min etching time, as is shown in Fig. 2. In that stage of etching the originally paired pits were therefore hard to distinguish from the single pits. These findings indicate that both the single [D pits (3)] and the paired etch pits correspond to extended defects.

Upon correlating the surface density of the substrate defects and those of the epitaxial layer we observed that (*i*) the density of etch-pit pairs in the layer was about equal to that of its substrate for growth on "dislocation-free" substrates, and (*ii*) in layers grown on substrates without dislocation loops no etch-pit pairs were revealed. In the latter case the density of single pits in the layer was equal to that of its substrate. We therefore assign all etch-pit pairs in the layer to dislocation dipoles (DD pits) which originate from interfacial dislocation loops in the substrate. A feature like this was already observed by Petroff *et al.* (6) by means of TEM. The single pits in the layer are dislocations of the substrate which propagate into the layer.

Summarizing, it is demonstrated that the assessment of defects on a submicron scale in GaP is possible using high magnification optical microscopy techniques and properly etched surfaces. Using these techniques a correlation is established between the defect structure of epitactically grown layers and their substrates.

On the Thermal Analysis of Li/$SOCl_2$ Batteries

P. Bro

P. R. Mallory & Company, Incorporated, Burlington, Massachusetts 01803

The Li/$SOCl_2$ system provides a higher energy density primary battery than does any other system, 1.24 whr/cm^3 and 612 whr/kg (1), and it is of interest for many applications, some of which involve capacities in excess of 10,000 ampere-hours. For high capacity batteries, the thermal design factors may become quite important, and a requirement exists for data on the magnitude and the rate of heat generation associated with the discharge of such batteries.

An examination of the generally accepted primary discharge reaction (2,3):

$$2\ Li + SOCl_2 \longrightarrow 2\ LiCl + SO^*$$

shows that an unstable species, SO*, is formed that may be expected to react further (4) with the evolution of heat in excess of that calculated from the cell overvoltage and the cell current. Furthermore, since the SO* reactions appear to be slow, the excess heat effect may be expected to depend on the temperature, the discharge regime, and the cell design, and it would be expected to continue beyond the termination of the discharge per se.

We have found that the excess heat may be a significant quantity that needs to be taken into account in the design of high capacity Li/$SOCl_2$ batteries. This may be illustrated by some of the data from our laboratory, Table I. The data were obtained with "D" cells discharged at 25.0°C under low rate conditions. They show that the excess heat may be comparable to that calculated from the cell current and the overvoltage. There is no simple relationship between the excess heat and the discharge conditions. The total heat effect increases with the current, as expected, but the ratio of the total heat effect to the electrochemical heat effect increases at first and then decreases as the current increases from 5 ma to 20 ma. This dependency may be explained in terms of a reduction of the unstable species at the cathode.

The purpose of this brief note is to emphasize that the analysis of the heat transfer in high capacity Li/$SOCl_2$ batteries must allow for the excess heat attributable to the non-electrochemical reactions associated with the discharge process. We expect to discuss the heat generation in Li/$SOCl_2$ cells in more detail in a forthcoming paper.

Table I. The Excess Heat Evolution in Li/$SOCl_2$ "D" Cells at 25.0°C

Annealing of GaAs Solar Cells Damaged by Electron Irradiation

Gilbert H. Walker* and Edmund J. Conway

NASA Langley Research Center, Hampton, Virginia 23665

The object of this communication is to report measurements illustrating thermal annealing of radiation damage in GaAℓAs/GaAs solar cells and to give the approximate magnitude of the short-circuit current recovery.

GaAℓAs/GaAs solar cells are of interest for space applications such as the Solar Power Satellite and near-Sun missions. With the achievement of 18.5 percent AMO efficiencies in the laboratory (1), research is being focused on the radiation damage properties of GaAℓAs/GaAs solar cells. Initially, the effect of 200°C annealing on the short-circuit current of 1 MeV electron irradiated GaAℓAs/GaAs solar cells has been studied. GaAℓAs/GaAs solar cells were grown by the etch-back epitaxy process (1). The cells had very deep junctions (approximately 4 μm) with a GaAℓAs layer thickness of 0.3 to 0.5 μm. The substrates were n-type, Si doped GaAs with a carrier concentration of 2×10^{17} carriers/cm^3. The p-type, Zn doped layer had a carrier concentration of 8×10^{18} carriers/cm^3. Back contacts were Sn-Ag and front contacts were Pd-Ag.

These deep junction cells were irradiated with 1 MeV electrons at NASA Lewis Research Center. A total of 20 cells were exposed, five at each of four fluences (10^{13}, 10^{14}, 10^{15}, and 10^{16} electrons/cm^2). A fluence of 10^{16} electrons/cm^2 is equivalent to the

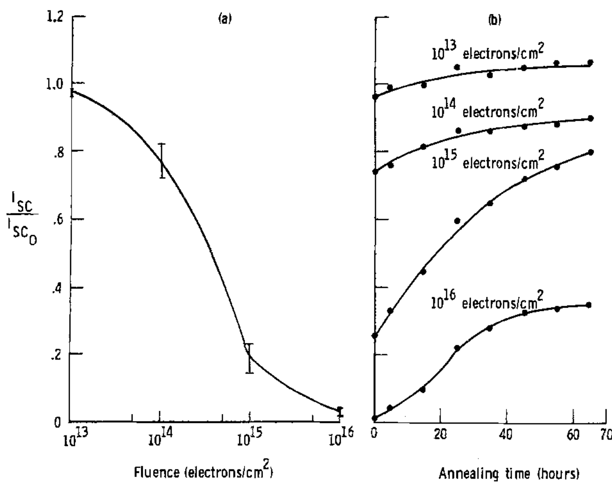

Figure 1.- Ratio of final short-circuit current to initial short-circuit current as a function of (a) 1 MeV electron fluence, and (b) annealing time at 200°C for deep junction GaAℓAs/GaAs cells.

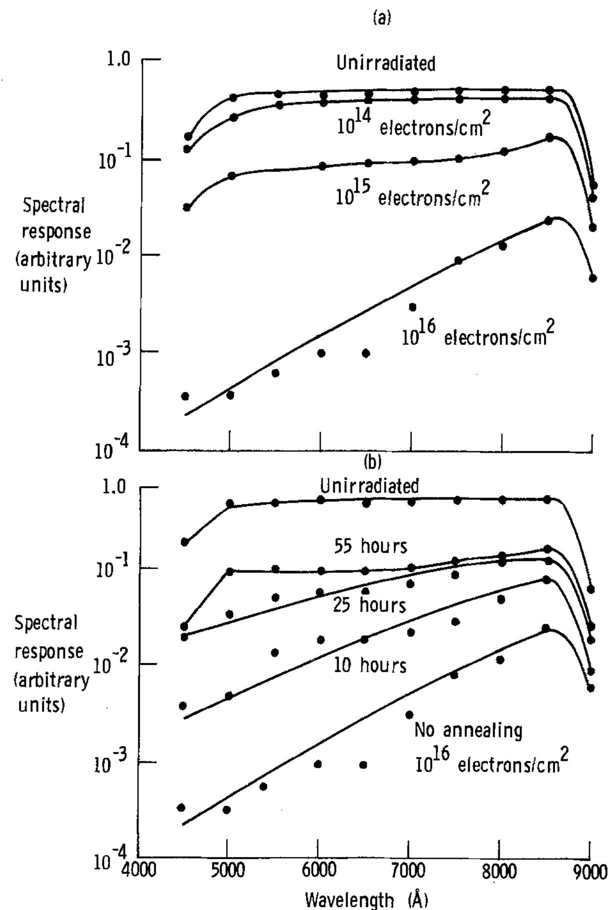

Figure 2.- Spectral response of deep junction GaAℓAs/GaAs cells: (a) unirradiated and for fluences of 10^{14}, 10^{15}, and 10^{16} electrons/cm^2, and (b) unirradiated and at 10^{16} electrons/cm^2 for various annealing times at 200°C

*Electrochemical Society Active Member
Key Words: Solar Cells, Radiation Damage, Annealing, Gallium Arsenide

electron exposure a solar cell with a 50 μm cover glass would encounter after 30 years in geosynchronous orbit. Flux levels were held such that the cells remained at ambient temperature during irradiation.

The short-circuit current under simulated AMO illumination and relative spectral response of each cell was measured both before and after irradiation. Figure 1(a) shows the ratio of the short-circuit current after irradiation to the short-circuit current before irradiation for the four fluence levels. As expected, these deep junction cells show severe degradation of short-circuit current and thus provide good vehicles for studying radiation damage in GaAℓAs/GaAs solar cells.

Figure 2(a) shows typical relative spectral response curves for unirradiated cells and cells irradiated at 10^{16}, 10^{15}, and 10^{14} electrons/cm^2. Irradiation produces a large decrease in the spectral response of the cells. Note especially the large decrease in the short wavelength response for the heavily damaged cells. This decrease in response is indicative of degradation in minority carrier diffusion length in the p-region.

A method that has been used for healing ion damage in semiconductors (2) and for healing radiation damage in semiconductors is annealing. In order to investigate the effect of annealing on the short-circuit current of 1-MeV electron-damaged cells, a representative cell at each fluence was annealed in vacuum of 10^{-5} Torr at 200°C. Measurements of short-circuit current and relative spectral response were obtained at intervals during the annealing.

Figure 1(b) shows the ratio of short-circuit currents as a function of annealing time at 200°C. The cell irradiated at 10^{13} electrons/cm^2 recovers all of its lost short-circuit current after annealing at 200°C for 15 hours. Additional annealing produces short-circuit currents slightly higher than the undamaged cell current. This is probably caused by either additional contact annealing or an increase in minority carrier diffusion length. The short-circuit current ratio of the cell irradiated at 10^{14} electrons/cm^2 recovers from 0.75 to 0.88 after annealing at 200° C for 65 hours. The short-circuit current of the cell irradiated at 10^{15} electrons/cm^2 was degraded to 0.25 by irradiation; however, after annealing at 200°C the degradation is reduced to only 0.74. The short-circuit current ratio of the cell irradiated at 10^{16} electrons/cm^2 was only 0.03; however, after annealing at 200°C the short-circuit current ratio recovered to 0.34.

Figure 2(b) shows the spectral response of the cell irradiated at 10^{16} electrons/cm^2 after different annealing times. While the entire spectral response recovers with annealing, there is significantly more recovery at the short wavelengths. This is indicative of minority carrier diffusion length increase with annealing time.

The short-circuit current recovery of 1 MeV electron damaged solar cells is significant for space applications. Assuming that the same type of annealing recovery occurs for cells irradiated with electrons of different energies and for cells irradiated with protons, it may be possible to periodically anneal GaAℓAs/GaAs solar cells while in space thus significantly prolonging the life of GaAℓAs/GaAs solar cells in space. Also, GaAℓAs/GaAs solar cells operated at high temperatures (200°C) may continually anneal radiation damage and never be degraded to any significant extent.

Increase of the Rest Potential of Nonstoichiometric Lead Sulfide in 0.1M Borax with its p-Semiconducting Character

Claudio Gutiérrez and M. C. López

Instituto de Química Física Rocasolano, Madrid-6, Spain

We report here what we believe is the first experimental proof of the influence of the semiconducting character of a sulfide on its electrode potential. The system under study was lead sulfide in 0.1 M borax, both in air and under N_2.

EXPERIMENTAL DETAILS

The synthesis of PbS and conditioning of its semiconducting character have been described elsewhere (1). PbS was obtained by a wet method and vacuum dried. Cylindrical pellets were made in a hydraulic press. The pellets were conditioned in an evacuated Pyrex cell for not less than a week at 500°C in a system of two furnaces; the temperature of the other end of the cell, which contained a small amount of sulfur, could be varied from 50 to 200°C. The p-character of the PbS increases with its sulfur content, and this, in turn, increases with increasing temperature of the sulfur furnace (t_S).

The cylindrical pellets of PbS were joined to the end of a glass tube with Araldite; electrical contact was made with mercury. Three kinds of previous treatment were used: the "polished" electrodes were rubbed with No.400 sandpaper; for the "washed" electrodes this treatment was followed by immersion for a few minutes in 0.1 M Na_2S; and, finally, the "aged" electrodes were "washed" ones which, after having been used for electrochemical measurements, had been rubbed with No.400 sandpaper.

The Pyrex electrochemical cell was conventional. A saturated calomel electrode was connected to the cell with a double salt bridge; all the potentials are given with reference to this electrode. The solutions were 0.1 M borax, pH 9.2. When necessary nitrogen (N 47 from S.E.O., purity ≥99.997%) was bubbled through the solution; the residual oxygen concentration, measured with an Oxygen Analizer, Model 2010, from Delta Scientific, was 0.2 mg/l.

Key words: rest potential, non-stoicheiometry, lead sulfide, semiconducting character.

RESULTS

Semiconducting character of conditioned PbS.--The thermoelectric potential and Hall coefficient measurements of conditioned PbS are given in Table I. The transition from n to p semiconducting character corresponded to a sulfur temperature of about 110°C, which is in fair agreement with the value of 104°C found by Brebrick and Scanlon (2). Contrary to the expected behaviour, the value of the Hall coefficient for the n samples did not increase monotonically in absolute value with sulfur temperature up to the transition temperature; this lack of a monotonical decrease of the concentration of conduction electrodes could be due to the presence of impurities. On the other hand, the p samples showed the expected behaviour: the Hall coefficient decreased monotonically in absolute value with increasing

Table I. Thermoelectric potential and Hall coefficient of conditioned PbS pellets.

t_S/°C	Thermoelectric power/mV/°C	Hall coeff. cm^3/C
53	-0.25	-23.8
58	-0.26	- 6.2˙
60	-0.27	-29.2
66	-0.29	-16.9
101	-0.24	-10.6
108	-0.23	-11.1
115	+0.34	+ 9.3
132	+0.29	+ 8.5
195	+0.26	+ 8.0

sulfur temperature, which corresponds to a monotonical increase in the concentration of holes, these being produced by the ionization of an increasing excess of sulfur atoms.

Potential of PbS in borax.--The potential of PbS came to a steady value after a time from 10 to 40 minutes. The final rest potentials are given in Table II. For the three kinds of previous treatment, and both in air and under N_2, the rest potential increased with increasing temperature of the sulfur furnace t_S, i.e. with increasing *p*-character of the PbS, the largest potential difference being that of 320 mV for "polished" electrodes under N_2. This difference is nearly as high as the energy gap of PbS, which is of 0.41 eV (3).

Table II. Rest potentials, E, of PbS electrodes in 0.1 M borax (mV vs. SCE)

"	58	-425	-280

The potential of PbS under our experimental conditions is certainly a mixed (corrosion) potential in which an anodic reaction (oxidation of PbS) and a cathodic reaction (probably reduction of O_2, as in germanium (4)) take place at the same rate on the surface. The increase of the final potential of PbS with its *p*-character could be due to a change of the exchange current i_0 for one or both of the processes with the variation of the semiconducting character of PbS. An increase of i_0 for the cathodic reaction with increasing *p*-character of germanium was postulated by Lovreček and Bockris (5) to explain their finding that the rest potential of *p*-Ge was 5 mV more positive that of *n*-Ge.

ACKNOWLEDGEMENTS

The authors wish to thank Dr.J.A. Pajares for the Hall effect measurements, and Dr.F. Colom and Dr.M. Sánchez for their valuable help. One of us (M.C.L.) is indebted to the Ministerio de Educación y Ciencia for a P.F.P.I. scholarship during three years.

Simple Method of Fabricating and Passivating High Power Pin Diodes

A. Rosen, G. A. Swartz, F. C. Duigon, and A. M. Gombar

RCA Laboratories, Princeton, New Jersey 08540

In this paper we describe the fabrication of a moat configuration deep-diffused PIN diode which is used as a switch in a microwave circuit.

A PIN diode is composed of an undoped I-region bounded by a heavily-doped P-type layer on one side and by an N-type layer on the other. When the diode is reverse-biased, the I-region is swept free of mobile charge carriers so that the diode approximates a low-loss capacitor. During forward biasing, holes and electrons are injected into the I-region from the P and N layers, forming a dense plasma of electrical charges, which ultimately converts the previous high-resistivity I-region into a conducting medium. In this stage, the PIN diode acts like a fixed resistor.

The moat configuration device, Fig. 1, has been developed in order to eliminate shadowing of the diode junction by the metal overhang during deposition of a sputtered passivation layer. The evaluation of PIN diodes passivated by rf bias sputtered SiO_2 and Si_3N_4[1,2] and having film thicknesses of 2250Å and 2500Å respectively utilizing this technique has included a temperature bias test (blocking test) in addition to the moisture resistance, temperature cycling, and thermal shock tests (MIL-STD-883A). In this test, diodes were reverse-biased up to 400 V at temperatures of up to 175°C without any failure.

PIN diodes which have a 150 μm thick mesa structure with a metal overhang (Fig. 2) in contrast to the moat configuration which is only partially etched, have been passivated with SiO_2 and Si_3N_4 using the sputtering technique. These diodes have shown excess current leakage, and under severe reverse bias tests eventually burned at 130°C. By contrast, diodes from the same batch which were passivated by the use of plasma-deposited silicon nitride layers have survived the blocking test up to the required temperature of 175°C. The sputtering technique was found to be inadequate due to metallization shadowing of the junction (overhang), which prevent uniform coverage. The passivation by plasma deposition was more uniform. The moat configuration, which eliminates the overhang, permits the utilization of either sputtering or plasma techniques, and is an attractive way of processing high-power PIN diodes.

The silicon wafer, with an n^+ contact layer on one surface and a p^+ contact layer on the opposite surface, is metallized on both sides, Fig. 3. Metallization contacts are defined on the p-side by utilizing photoresist techniques, after which moats are etched to produce a mesa structure. The moat diameter, which is 5 mils larger than the metallization diameter, is defined also by photoresist and the silicon is etched to a depth of 25 μm. This procedure eliminates metal overhang (Fig. 3.). A spreading resistance plot of the p^+n^- and n^+n^- structure made by probing the conductivity of an angle-lapped wafer section is shown in Figs. 4 and 5.

The moat configuration diode, having multilayer passivation with SiO_2 and Si_3N_4 by the sputtering technique, withstood all tests in accordance with military specifications MIL-STD-883A. A reverse bias test of 400 V (blocking test) was performed at temperatures up to 175°C for 160 hours without any failure.

Diodes fabricated by this simple method

have also demonstrated good uniformity and high yield. The electrical characteristics of the moat configuration PIN diodes are similar to those described before with the exception of breakdown voltage (V_{BD}). V_{BD} obtained with the negative level mesa is 800 V as contrasted with 1000 V PIN diodes previously described.[4,5]

Chlorine—Caustic Soda

I. Production and capacity.—Total chlorine production in the United States and Canada for 1976 was 11,374,000 tons. This was an increase of 12.7% over the 1975 figure but 4.8% below the record high of 11,942,000 tons in 1974. Breakdown of chlorine and caustic production figures are as follows (1, 2, 57):

Chlorine production	United States	Canada
First half of 1976	5,077,000 tons	486,000 tons
Second half of 1976	5,290,000 tons	521,000 tons
Total in 1976	10,367,000 tons	1,007,000 tons

Caustic production (liquid and solid)	United States	Canada
1976 (100% NaOH basis)	10,147,000 tons	922,000 tons

Although production for the year was up considerably, the industry was still below the traditional rates of capacity use. Both the United States and Canada had increases in the capacity use rate; in the United States this increased from 72% in 1975 to 80% in 1976, while in Canada the rate went up from 68% to 75%.

During 1976, new or expanded facilities started up at seven locations in the United States. One new facility went on stream in Mexico, none in Canada. Production capacity will be increased considerably over the next 2 years. A number of large expansions and new plants are in various stages of engineering and construction. (See Table 1A and 1B)

There has been no appreciable change in chlorine capacity by production method, viz (9):

	United States	Canada
Diaphragm and membrane cells	73.7%	68.0%
Mercury cells	21.4%	32.0%
Other	4.9%	None

II. Prices and markets.—Chlorine production increased considerably during the year but, over-all, the industry did not fully recover from the recession in 1975. Production dropped in several chlorinated hydrocarbons, and there were no indications that this trend will be reversed. Chlorine producers were faced with higher energy prices and other operating costs. Chlorine prices in the United States were relatively stable in 1976. Late in the fourth quarter, Gulf Coast prices were raised $10 to $135 per ton. Prices in other regions, which ranged from $135 to $150, remained unchanged (10).

There were no major changes in markets or usage of chlorine, *e.g.*, vinyl chloride, propylene oxide, solvents, inorganic chemicals, pulp and paper, and water and wastewater treatment. Significant increases in chlorine demand growth will be required over the next 2 years to balance present unused production capacity plus the large increments of new capacity. The impact of new air emission standards on the plastic industry is unknown. Fluoro-chlorocarbon producers may experience further declines in demand. Chlorine used in pulp bleaching, which accounts for about 13% of chlorine production in the United States, has had a growth rate of only 3.5% during the last few years. This could drop to 2% if changes in bleaching are accepted (11).

The demand for caustic during the year was weaker than for chlorine, and producers in many locations were faced with high inventories. An economic slump in the aluminum industry followed by a slow recovery affected the chlorine-caustic balance in 1976. Although aluminum metal production is up considerably, there was a lag in caustic demand as the aluminum industry was gradually reducing high inventories of alumina. Caustic prices in the United States fluctuated downwards slightly and at year end were in the $140-$160 per ton range. Imported bulk caustic in the Gulf Coast regions was running considerably below published prices. The situation in Europe was similar as producers were faced with extremely high inventories due to below normal activity in alumina production (12, 13).

The pattern of caustic consumptions remained essentially unchanged and main markets were in the following areas: organic chemicals, pulp and paper, inorganic chemicals, soaps and detergent, alumina, petroleum, rayon, and cellulose. Approximately 10% of caustic production was exported. Growth of aluminum demand in automobiles, containers, etc., and amount of recycle will have a bearing on caustic demand. Another unknown is in the pulp and paper industry where competition from soda ash is possible. Increasing the recycle of pulping chemicals will reduce usage of caustic. Demand for certain agricultural chemicals is high (7, 14).

There were no changes in chlorine or caustic markets in Canada where the industry is highly dependent on the pulp and paper economy. Over 50% of the total chlorine production is consumed in pulp bleaching. Second largest usage of chlorine is vinyl chloride. Caustic imports accounted for 12% of the total 1,042,000 tons consumed in 1976. Breakdown of the caustic usage pattern in Canada for the year was as follows:

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. It presents a summary of published information on production and developments in the chlor-alkali and related industries and on other electrolytic industries. The material presented herein has been gathered from many sources, as noted in the reference list, and does not necessarily represent the opinions of the authors.

* Electrochemical Society Active Member.

Pulp and paper	62%
Propylene oxide	10%
Alumina	7%
Soaps and cleaners	6%
Inorganics	5%
Rayon, cellulose	2%
Other uses	8%

Caustic demand was depressed due to a slowdown in pulp and paper production and a prolonged strike in the aluminum industry. Expansions planned in the plastic industry will alter the use pattern of both chemicals and chlorine-caustic balance. Although imports will drop, Canada is expected to remain a net importer of caustic (2, 15).

Steady growth of 5% annually through 1985 was predicted for chlorine and caustic by one major United States producer. This was based on adequate energy and a balanced demand for both products. Vinyl chloride which is also the largest outlet was stated as the strongest market for chlorine whereas pulp and paper was the weakest. For caustic, organic chemicals were predicted as having strong markets and alumina a weak market during this period (7).

Changes in demand for both chemicals and lower growth rates were predicted for the next decade, according to a United States market consultant. Uncertainties in future demand for chlorine in chlorinated compounds, increasing cost and availability of energy, and environmental-related costs were given as factors that could affect future growth (16).

III. Membrane cells.—Worldwide interest and effort in the development of ion-exchange membranes and commercial testing of cell systems is continuing at a high level of activity. Major incentives for chlorine-caustic producers to test new membranes and evaluate membrane cell technology are: lower over-all energy consumption, high purity products, replacement for asbestos, mercury cell conversions.

Commercial operation of a membrane plant, rated at 40,000 metric tons per year of caustic soda, was announced by Asahi Chemical Industry Company of Japan. This plant has been in operation since April 1975, at Nobeoka on Kyushu Island. Initially, commercial testing was done with du Pont's Nafion® membranes but more recently a perfluorocarboxylic acid membrane developed by Asahi Chemical is being substituted for the du Pont membranes. The major advantage claimed with their own membrane is better current efficiency which is over 90% for caustic concentrations up to 40%. Electrolyzers are large and a single unit is capable of producing 10,000 metric tons per year of caustic soda. Along with the membrane cell, Asahi Chemical designed a special heat-recovery evaporator (17).

Another Japanese firm, Asahi Glass, reported producing 200 metric tons per month of caustic soda since

September 1975, at Osaka City. Performance disclosed after 6 months of testing was 90-92% current efficiency with 40-41% caustic, power consumption of 3300 kW-hr per metric ton of caustic soda. The type of membrane is not known (18).

More recently, Tokuyama Soda announced startup by January 1977, of a 1,000 metric tons per month of caustic soda pilot plant at Tokuyama City. Both du Pont's and their own membrane will be tested in the commercial size cells (19).

Diamond Shamrock Corporation announced startup of a membrane cell circuit at its Muscle Shoals plant in Alabama. The cells will replace mercury cells now operated at this location. The membrane used will be Diamond's modification of du Pont's Nafion®. Production of 30-40% caustic at 85% current efficiency was stated (20).

Toyo Soda plans to construct a new 2,000 metric tons per month caustic soda plant at its Sakata factory with provision for 50% expansion. Hooker MX® membrane cells will be used (21).

Asahi Chemical has licensed its membrane cell technology to Denki Kagaku Kogyo for a 40,000 metric tons per year caustic soda plant at Omi (22).

The first membrane cell plant in Europe will be at Uddeholms pulp and paper complex in Skoghall, Sweden. Cells used will be Diamond Shamrocks' new membrane cell. The plant, rated at 20,000 metric tons per year of chlorine, is scheduled to start up by the end of 1977 (23).

du Pont is proceeding with engineering for a plant to manufacture Nafion® or perfluorosulfonic acid products. No date has been set for start of commercial production (24).

Maruzen Oil Company in Japan will start regular production of its new ion-exchange membrane in the fall of 1976. Unlike du Pont's and other membranes of the fluorine type, Maruzen's membrane is suitable for use in "three-cell" type of electrolyzers (25).

IV. Developments.—The Bureau of Mines is studying the feasibility of recovering chlorine and iron oxide from ferric chloride. During a test with low density ferric chloride, the chlorine product reached a concentration of 92% with the balance being oxygen. Economics were not discussed but the process indicates feasibility of producing chlorine from recycle (26).

The Japan Soda Industry Association is sponsoring development work at Kyoto University on fused salt electrolysis using the β-alumina diaphragm method. Current efficiency on laboratory scale tests was almost 100%. Cell voltage at 50 A/dm^2 was given as 3.18V (27, 28).

Asahi Glass Company has developed a method for removing salt from the diaphragm cell caustic process. This method is capable of reducing salt to less than 0.1% in 50% caustic, and costs were given as one-third of those for existing methods. The company is working on technology which will reduce the salt content to less than 0.02% in 50% caustic (29).

Diamond Shamrock Corporation has acquired research facilities, patents, and other assets in the field of industrial electrochemistry previously owned by Electronor Corporation (31).

Supported by the National Science Foundation, the University of North Carolina is developing chemical modification techniques for electrodes. Reactive molecules were covalently bonded to the surface of an electrode. Such molecules did not interfere with the electrochemical effectiveness of the electrode but can be used to perform reactions in tandem with the electrochemical ones at the electrode. They can provide a more favorable environment for the electrochemical reactions or participate themselves as intermediates in electrochemical reactions occurring at the surface of the electrode. Research workers are searching for a reversible electroactive surface molecule which could be bound selectively to electrodes to assist the electrochemical reaction (32).

Researchers at Pennsylvania State University claim that iodine may replace chlorine as a swimming pool disinfectant. Iodine is more effective against organic matter, does not irritate the eyes, and is easier to monitor. One drawback is its ineffectiveness against algae (33).

New developments in ozone generators for sewage and water treatment have resulted in significant reductions in the cost of producing ozone. Ozonation as a replacement for chlorination is gaining in interest. The city of St. Johns, Newfoundland, is installing Union Carbide's ozonator for treatment of their 11 million-gal/day potable water supply. A joint development by Accelerators, Incorporated, Austin, Texas, and R. P. Industries, Incorporated, Hudson, Massachusetts, has produced a generator which can produce ozone at energy-consumption cost of less than 10 cents per pound. This new approach produces ozone from untreated air in an electron beam generator. A prototype system is being installed at Marlboro, Massachusetts, to treat 1 million gal/day of water discharged from a sewage plant (34).

V. Mercury Cells.—There were no new mercury cell plants in the planning or construction stage in the United States or Canada during 1976. The 80 tons per day chlorine plant, Prince Albert Pulp Company, Saskatoon, Saskatchewan, will be converted from mercury cells to membrane cells supplied by Asahi Chemical Industry, Osaka City. Diamond Shamrock at their Muscle Shoals, Alabama, site announced conversion of mercury cells to membrane cells of their own design. Capacity was not reported (20, 35).

Conversion from mercury cells to other types of cells in Japan has been further delayed. At the end of September 1975, the original goal of 64.6% conversion set by the Japanese Ministry of International Trade and Industry (MITI) was not reached as only 34.5% was converted to mercury-free methods. The March 1978 date for completion of the second-phase conversion program is also seriously lagging, and the goals will have to be revised. By April 1976, only 59.3% was converted. Delays were attributed to the severe recession, difficulties in raising capital, equipment deliveries, uncertainties with respect to diaphragm cell *vs.* membrane cell technology and low rate of capacity utilization (36, 37).

Efforts are continuing toward further reduction in the level of mercury discharge from plants. Osaka Soda and Okayama Chemical carried out investigations and process modifications at their plants and reported achieving less than 1.5g mercury per ton of NaOH in a new plant and less than 2.5g in an older type plant (38). A closed mercury cell process developed by Kashima Chlorine and Alkali will be used by Diamond Shamrock in their United States plants. Requirements of 1g mercury per ton of chlorine were reported. (39).

New ion-exchange resins, ImacTMR®, developed by Akzo Chemie, Netherlands, are reported to be more selective than other resins in mercury removal from effluent streams. Levels in chlor-alkali plant effluent have been reduced to 5 ppb mercury with the new resins, compared to 0.1-1 ppm for other resins and methods (40).

United States production of primary mercury in 1976 totaled 20,000 flasks (76 lb). This was produced in four mines, three in California and one in Nevada which was starting to supply a larger share of the market. Secondary production dropped 53% below that produced in 1975. The General Services Administration established a new strategic stockpile goal of 54,004 flasks and at year end the stock pile contained 191,407 flasks. Stocks of 28,500 flasks held by producers, consumers, and dealers at year end were only slightly below 1975 year-end stocks (41).

Consumption of mercury for 1976 was estimated at 65,000 flasks, a 25% increase over the previous year. Usage by chlorine-caustic producers was essentially unchanged from the reported 15,200 flasks in 1975 (41).

World production of mercury dropped about 3% to 242,300 flasks in 1976. Producers in Mexico and Italy reduced or completely shutdown mercury mining operations. Canadian mining operations which closed down in 1975, because of the poor economy, did not reopen in 1976. There were reports that producers in Spain, Italy, and U.S.S.R. dropped out of international marketing of mercury (41).

EGAM, a mercury producer in Italy, shut down in October for 3 1/2 years to upgrade facilities and improve operating economics (42).

VI. Health and environment.—There is an increasing tendency to equate chemicals, particularly chlorinated organics, with carcinogens. However, there is no agreement on how to establish safe levels of exposure or on what constitutes an acceptable risk. Methods in use today provide only qualitative indications in many instances and test results are difficult to express on a quantitative basis. More long-term testing is believed to be necessary, and it will be some time in the future before test results can be translated into "meaningful and practical regulations" (43-45).

A spokesman for the Synthetic Organic Chemical Manufacturers Association predicts carcinogens as a long-term problem for the chemical industry. The science of toxicology, already complex, is further complicated by a number of governmental agencies with different philosophies. The Occupational Safety and Health Administration (OSHA) is expected to announce new standards for chemical carcinogens in 1977 or early 1978. The new regulations and sequence of testing for carcinogens can have far-reaching implications (46).

Two chlorinated organics, trichlorethylene and chloroform, have been singled out by the National Cancer institute as probable causes of cancer in humans. Based on animal tests, the findings were considered definitive for animals, but the extent of risk in humans cannot be predicted. However, it can serve as a warning on possible carcinogenicity in humans (47).

The Toxic Substance Control Bill is expected to become law on January 1, 1977. All chemical producers will be subject to terms of this bill. The main feature of this legislation is that manufacturers will not be able to commercialize new chemicals without notifying the Government. Producers of chemicals which have been linked with health hazards such as chlorinated organics can expect closer scrutiny. The U.S. Environmental Protection Agency (EPA), under this bill, will require 90 days notice before manufacture and distribution of chemicals that may be considered as risks in public health or to the environment (48).

Tighter controls are being imposed on the plastics industry, as in-plant control of vinyl chloride monomer (VCM) emission was extended to cover the industrial community. With authority under the Clean Air Act, the EPA has declared VCM as a hazardous air pollutant. Air emission standards proposed would reduce VCM entering the air within a 5 mile radius of the plant by more than 90% when compared to emission standards in 1974. These new standards, announced October 21, allow plants only 90 days to comply with the regulations. Vinyl chloride, ethylene dichloride, and polyvinyl chloride producers are presently seeking extensions of up to 2 years in order to install control equipment. Higher PVC prices are anticipated as a result of additional control equipment and higher operating costs (49, 50).

Environment Canada is proposing to reduce atmospheric emissions of mercury to 5.3g per day for each 1000 kg of chlorine production. Total atmospheric release from mercury cell plants is expected to drop from the current 12 tons to 2 tons mercury per year. Some plants, particularly older facilities, will require further capital expenditures (51).

Recognition of the potential dangers from airborne asbestos emissions is increasing. The proposed regulation under discussion would reduce the limit to 0.5 fiber per cubic centimeter in a time weighted 8 hr average. Establishment of a dose-response level has been difficult. Medical surveillance and studies on workers exposed to asbestos emissions are continuing in many countries. OSHA has emphasized the complexity of the regulatory process which results in a long lapse of time from issuing a proposed standard to publication of a regulation. Against a background of strict emission limitations, Johns-Manville indicated that the supply is lagging the demand and the industry is 2-3 years away from starting new asbestos mines (52).

The National Institute for Occupational Safety and Health (NIOSH) has recommended to OSHA that exposure of workers to chlorine be reduced. NIOSH proposed an exposure limit of 0.5 ppm for periods of not more than 15 min. The present standard is 1 ppm for a time-weighted average 8 hr per day (53).

The Food and Drug Administration (FDA) is asking for information on the safety and use of chlorine in food processing. The exposure of a wide variety of foods to chlorine when used as processing aids is coming under closer scrutiny. Safety data to justify such uses will be reviewed by the FDA and general guidelines covering the safe use of chlorine in food processing will eventually be published (54).

Burning of PVC plastics can release significant amounts of methyl chloride which is capable of dissociating into chlorine atoms and destroying the ozone layer in the stratosphere. The two main sources of man-made methyl chloride were cited as combustion of PVC plastics in wastes and fires in buildings containing PVC materials of construction. Unless combustion of PVC is rigidly controlled, release of methyl chloride is expected to rise as a result of greater use of PVC materials (55).

The EPA is urging a worldwide approach to the control of fluorocarbon emissions in the air by regulating emissions and conducting atmospheric research. EPA is preparing a 10 yr research budget for stratospheric research (56).

Other Alkaline or Chlorine Compounds

I. Caustic potash.—Production of caustic potash in 1976 was 226,800 tons as 88-92% liquid. This is an increase of 6% over the previous year (57).

The caustic potash market improved somewhat during the year but production plants were still running well below capacity. Total United States production capacity of 335,000 tons per year is made up from six producers. viz. (59):

IMC	95,000
Diamond Shamrock	87,000
Monsanto	55,000
Hooker	53,000
Pennwalt	25,000
PPG	20,000

The price of caustic potash remained at $7.50 per 100 lb, 45% basis, throughout 1976. In November, a new price of $8.00 was announced and this will become effective January 1, 1977 (59).

United States production of marketable potassium salts dropped slightly from 2.5 million in 1975, to 2.4 million tons in 1976, expressed as K_2O equivalent. About 2 million tons or 82% of the production came from New Mexico with the balance from Utah and California. Potassium muriate from Canada constituted nearly 3.8 million tons as K_2O equivalent or 96% of total imports (58).

The price of standard bulk potassium muriate from Canada and New Mexico dropped to 55-70 cents per unit of K_2O (20 lb of K_2O) during the June through August period. Prices for the fall season (September through January) were quoted at 70-75 cents per unit. Prices for the spring season (February through May) of 1977 are expected to increase by 5 cents per unit (60, 61).

During the second half of 1976, there were indications that the potash market was slowly improving as inventories dropped and shipments increased. Based on reports from the first World Fertilizer Conference, growth in potash can be expected as increased consumption of fertilizers will be necessary to assist in meeting the world's food production requirements. A world potash demand of 31 million tons was predicted by 1980 (62, 63).

A degree of uncertainty with respect to raw materials exists as the result of the Saskatchewan government's first move to nationalize the potash industry. Duval Corporation's 1.5 million tons per year plant was purchased by Potash Corporation of Saskatchewan, a Crown company. The $128.5 million purchase price was short of the $150 million price sought by Duval. Engineering is proceeding with a 25% expansion of the mine. Negotiations are in progress for the purchase of two more potash companies. The Government is planning to buy a 51% interest in the potash industry and only use expropriation if purchase agreements cannot be negotiated. Although the Government has given assurance of unrestricted supplies with no manipulation of prices, there is some skepticism in the United States by government and industry. About 70% of the Saskatchewan potash is marketed in the United States (63-65).

International Minerals and Chemical Corporation (Canada) is engaged in a potash exploration project in the Salt Springs region of New Brunswick. The company is encouraged by core data which are showing potash averaging 28-32% K_2O. It is too early to determine the economic feasibility of the project. Core testing is expected to continue for 1 to 1 1/2 years. The company is also engaged in exploration of potash deposits in Northern Ontario. First-phase drilling tests indicated yields of about 24 million tons of recoverable potash. However, commercial development of the deposit cannot be justified under current economic conditions (66, 67).

II. Soda ash.—Domestic production of soda ash increased 7.6% from 7.13 million tons in 1975 to 7.6 million tons in 1976 (68). Natural soda ash (trona) increased from 4.33 to 5.19 million tons (69), while synthetic (Solvay process) soda ash decreased from 2.80 to 2.42 million tons.

Expansion in capacity for natural soda ash continues. Total capacity was estimated to be 7.3 million tons per year at the end of 1976 and is expected to be 8.8 million tons per year by the end of 1977.

Most natural soda ash is mined in Wyoming. FMC Corporation's 0.75 million tons per year expansion of the Green River, Wyoming, soda ash plant will make it the world's largest at 2.5 million tons per year (70). Texasgulf, Incorporated, joined other Wyoming producers when a 1 million tons per year plant started production in October; this plant is expandable to twice its present production capacity (71, 72). About 1.8 tons of ore were mined for each ton of soda ash produced. Stauffer Chemical Company was adding 0.2 million tons per year to the company's existing 1.35 million tons per year capacity. Allied Chemical Corporation has 2.2 million tons per year capacity. Numerous other companies held trona leases in the Green River area. The Green River formation contains an estimated reserve of 50 billion tons of ore (73).

Natural soda ash is also produced at Searles Lake, California, by carbonation of lake brines. This process has produced about 400,000 tons per year for the past several years. Kerr-McGee is expanding their facility from 0.145 to 1.3 million tons per year at a cost of $175 million, the expansion to be completed in 1977 (74).

The number of synthetic plants decreased from four to three with a total capacity slightly greater than 2 million tons (75, 76). Diamond Shamrock shut down its 800,000 tons per year Painesville, Ohio, plant at year end. Reasons cited for closing the plant, started up in 1912, were the plant's age, stringent pollution-control standards, escalating energy costs, and competition from natural soda ash. The remaining synthetic producers are Allied at Syracuse, New York, BASF Wyandotte at Wyandotte, Michigan, and PPG Industries at Corpus Christi, Texas.

Consumption in the United States was estimated to be 7.0 million tons in 1976, an increase of approximately 7% over 1975 (68). Approximately one-half is used in glass making, another quarter is used in formulation of detergents, and the rest in miscellaneous uses.

Exports and imports are a small component of the soda ash market. Exports, primarily of refined material, increased to an estimated 502,000 tons, 7.6% of production. Imports for consumption were negligible at 1,000 tons.

Average prices of soda ash in 1976 were up 19% from the previous year (77). List prices on December 31, 1976, ranged from $57 to $71 per ton. In general, synthetic soda ash is $15 to $20 per ton more expensive, f.o.b. plant, than the natural product.

III. Sodium chlorate.—Sodium chlorate production in the United States for 1976 was a record 196,400 tons. This represents a 17% increase over the 1975 total of 167,700 tons (57).

Production capacity in the United States is 253,500 tons per year with facilities at 12 locations. In Canada, sodium chlorate is produced in 11 facilities for a total capacity of 226,000 tons per year (78, 79).

Demand for sodium chlorate remained strong throughout the year with tight supply situations occurring on the west coast. By midyear, chlorate capacity in North America was sold. Pulp bleaching remains the principal market for sodium chlorate. More chlorine dioxide, derived from sodium chlorate, probably will be required as pulp mills increase chemical recycle. Pulp and paper producers are forecasting the possibility of continuing short supply situations in 1977 (80, 81).

Effective July 1976, the price of bulk sodium chlorate was raised from $250 to $280 per ton. In December, further increases brought the price of bulk up to $300-$310 per ton. Similar price increases were experienced in Canada where end of year prices for bulk sodium chlorate were $250-$256 per ton (82-85).

The ERCO Industries division of Albright and Wilson, Limited, will expand chlorate output at several locations. At Buckingham, Quebec, a 12,000 ton per year expansion is scheduled for April 1977. An additional 15,000 tons per year is slated for the first quarter of 1978. This will bring ERCO's capacity at this location to nearly 77,000 tons per year. At the Vancouver location, modifications to electrical equipment and electrolyzers are expected to add 6,000 to 10,000 tons per year. The company's total capacity in Canada should reach 125,000 tons per year in 1978. A 50,000 ton per year sodium chlorate plant on the Gulf Coast was announced by ERCO. The first phase of 20,000 tons is scheduled for the first quarter of 1979 (86, 87).

More recently ERCO Industries, Limited, announced plans to build a new chlorate plant at Thunder Bay, Ontario. Initial capacity of 25,000 tons per year will consist of 15,000 in the first stage for early 1979 completion and 10,000 in the second stage (88).

In November, Dow Chemicals canceled its planned facility at Thunder Bay. The plant was to have an initial capacity of 30,000 tons per year and was scheduled to go onstream in 1977 (89).

Pennwalt Corporation will construct a new sodium chlorate plant at its Tacoma plant site. Capacity was not disclosed. First phase is expected to go onstream in early 1978 (90).

The Electrochemical Division of International Minerals and Chemical Corporation plans to build a 40,000 ton per year sodium chlorate plant at its Orrington, Maine, plant site. Start up is scheduled for mid-1978 (91).

Olin announced construction of a 6,000 tons per year plant at its chlor-alkali plantsite in Niagara Falls, New York. Start up is scheduled for late 1977, with two-thirds of production going to captive use (92).

Table 2. Summary of new or expanded sodium chlorate plants

Producer	Capacity, tons per year	Completion
1. ERCO Industries		
Buckingham, Que. Canada	Expansion — 12,000	April 1977
Buckingham, Que., Canada	Expansion — 15,000	1st Quarter 1978
North Vancouver, B. C. Canada	Expansion — 6,000-10,000	1977
Thunder Bay, Ont., Canada	New — 1st phase — 15,000	1st Quarter 1979
	2nd phase — 10,000	—
Gulf Coast, U.S.	New — 1st phase — 20,000	1st Quarter 1979
	2nd phase — 30,000	—
2. Pennwalt Corp. Tacoma, Wash.	New — 1st phase — —	1st Quarter 1978
3. International Minerals and Chemical Corp. Orrington, Me.	New — 40,000	Mid 1978
4. Olin Corp. Niagara Falls, N.Y.	New — 6,000	4th Quarter 1977

Stanchem, Beauharnois, Quebec, increased production to 33,000 tons per year, a 10% increase, by installing metal anodes developed by Kema-Nord and PPG Industries (78).

New or future expansions of sodium chlorate plants in the United States and Canada are summarized in Table 2.

Metals

I. Aluminum.—United States production of primary aluminum was 4,240,000 tons in 1976. Although this represents a 9.3% increase over the 1975 figure, production for 1976 was still 13.5% below the record year of 1974. Total aluminum supply for 1976, was 6,370,000 tons which was a 14% increase over the previous year but still well below the 7.3 million total for 1974. Secondary recovery of aluminum for 1975, totaled 1,451,000 tons. This was a 23% increase over the previous year (93). Recovery from the 1975 recession in the aluminum industry was slow. At the start of 1976, primary aluminum producers were operating at a 75% rate and by mid-March the rate was still only 76%. However, production gradually improved to 85% by midyear and by year end had climbed further to 94% of capacity. Canadian producers operated at 80% at the beginning of the year, dropped to 42% during the strike, and by year end were at 71% (94, 95).

With prospects for improvements in aluminum demand and due to lower inventories, idle capacity was restarted at various locations (96-98). Another reason for bringing on idle capacity was the Alcan strike in Canada. The 5 month strike crippled nearly 600,000 tons per year capacity and full production will be delayed another 3 months due to damaged potlines (99, 100).

Imports of crude, semicrude, and scrap aluminum were up by about 55% over the previous year. Exports of crude and semicrude increased by 20% compared to 1975. Total metal inventories of aluminum decreased gradually by about 10% during the year (101).

United States aluminum producers raised the price of primary ingot from 41 to 44 cents per pound in April. A further increase to 48 cents went into effect in August (102, 103). Tight supplies in early 1977 were predicted by economists, and this could result in further escalations in price (104).

The slow economic recovery in the aluminum industry resulted in postponement or cancellation of a number of new alumina projects, viz. (105-108):

1. The 880,000 tons per year refinery in Ireland proposed by Alcan and two partners.
2. West Pacific Alumina's 800,000 metric tons per year refinery on Mindanao in the Philippines.
3. A 400,000 metric tons per year refinery planned for Bintan Island in Indonesia by Sumitomo Chemical, Showa Denko, and Nippon Light Metal.
4. Pacminex's option to build a 1.2 million metric tons per year refinery in West Australia.
5. Comalco's 320,000 metric tons per year at Gladstone, Australia.
6. Alcan's 200,000 tons per year smelter in Quebec.

New projects in different stages of planning or construction were announced, viz. (101, 109-113):

1. A 1 million metric tons per year plant, built by a consortium including France's PUK, will be located on the Black Sea in Russia.
2. Russia will assist Indonesia with a 600,000 metric tons per year refinery on Bintan Island.
3. Reynolds Metals and partners are planning a 1 million tons per year refinery in Wagerup, Australia.
4. An aluminum project agreement between Brazil and Japan will include a 320,000 metric tons per year smelter at Belem.
5. Completion of a second 70,000 tons per year potline at New Madrid, Missouri, was announced by Noranda.
6. The feasibility of adding an additional potline at Alcoa, Texas, is being studied by Alcoa.

The U.S. Bureau of Mines expects the United States demand for aluminum to grow about 6% per year until 1985, and then relax to a growth of 4.5% per year over the next 15 years. A major uncertainty is usage of aluminum in the automobile industry. Recycled aluminum is expected to show steady growth. By 1989, 40% of the United States requirements could be met by secondary aluminum (114, 115).

Aluminum producers in the Pacific Northwest, who have a 31% capacity of United States total, may be faced with a power crisis in the mid-1980's. Bonneville Power may not be able to renew their power contracts which are based on cheap hydroelectric power. Power from other sources will be more expensive (116).

A trend towards more aluminum in automotive use in order to improve fuel economy is predicted. Present usage of 87 lb per car is estimated to increase up to 9[illegible]-100 lb for 1977. Forecast figures are 150-300 lb for 1980, and by 1985, this is expected to rise to 200-425 lb per car. Another reason for increased use in automobiles is Aloca's development of new sheet alloys which offer scrap compatability and other improved characteristics (117-120). A new aluminum radiator was developed by Union Carbide (121).

The industry's goal of reducing energy consumption by 10% from 1972 to 1980 appears to be possible. Since 1972, the industry has achieved a 6.5% reduction (122).

Bauxite production in the United States, an increase of about 11%, was 2 million tons in 1976. Imports of dried and calcined bauxite were about 13 million tons, up slightly from 1975, but below 1974 imports. Jamaica, Guinea, and Surinam remained the main sources of bauxite. Alumina imports, which largely came from Australia, were about the same as 1975 (101).

Alcoa and the Jamaican Government reached an 8 year agreement on levies and a 40 year agreement on ownership of Jamaica's bauxite mining and refining facilities (123). Separate settlements between Jamaica and Reynolds and Kaiser were reported to be very close to final agreements (124). Disputes between Revere and Jamaica over the government's bauxite production levy have not been resolved (125).

Present distribution of known bauxite reserves is estimated as follows (126):

Africa	38%
Australia	25%
America	22%
Europe	8%
Asia	7%

The Jamaican Bauxite Institute's latest estimate of Jamaican reserves is 2 billion tons (127).

A major milestone in new process technology was achieved when Alcoa energized cells in late May at its new smelter at Palestine, Texas. Initially rated at 15,000 tons per year, the plant will eventually be increased to 300,000 tons per year. This process cuts 30% off the most efficient power requirement for a net of 4.2 kW-hr/lb. Instead of electrolyzing alumina directly, chlorine is used to produce aluminum chloride, which is then electrolyzed. The chlorine is recycled. In addition to the energy saving, the process is free of fluoride emissions, the working environment is improved, and power interruptions can be tolerated (128, 129).

The Energy and Mineral Resources Research Institute at Iowa State University is working on two different processes to obtain alumina or aluminum chloride from flyash which has an average alumina content of 22% (130). The Bureau of Mines is coordinating a cost-sharing program with nine companies to develop processes for recovering alumina from domestic nonbauxite materials. Kaolinitic clay was tested in the first two processes (101).

According to a Russian foreign trade journal, the U.S.S.R. has developed techniques for the production of alumina from nepheline, alunites, kaolin, shale, ash, and other alkali-free alumo-silicates. Southwire Company of Carrollton, Georgia, has licensed a U.S.S.R. alumina-aluminum process. An 8,700 tons per year pilot plant at Golden, Colorado, will produce alumina from alunite. The process yields alumina and potassium sulfate (131, 132).

The United States EPA has set pollution control standards for new and modified smelters. Removal of 95% of the fluoride emissions from the air before discharge will be required (133).

II. Beryllium.—Data on production of beryllium metal and products are not published. However, production is believed to have increased from depressed 1975 levels (134).

Brush Wellman, Incorporated, and Kawecki Berylco Industries, Incorporated (KBI) are the only substantial producers of beryllium in the free world. Brush extracts beryllium from bertrandite ores ($Be_4Si_2O_7(OH)_2$), mined in Millard County, Utah, while KBI relies on imported beryl ores (135). Brush Wellman announced a planned expansion of the extraction facilities at Delta, Utah. The expanded facilities will also have the capability of processing beryl ore. When completed this will represent about 90% of the extraction capability in the free world (134).

Metal consumption in 1976 was thought to be equal to or slightly less than in previous years, which was estimated to have been 260 tons. The market breakdown based on contained beryllium was estimated to be: 70-80% beryllium-copper alloys, 15-20% beryllium metal, and 4-8% beryllium oxide. This represents an increase in usage of the alloys and a decrease in the use of the metal.

Alloys with copper containing 0.5-2.0% beryllium have greater strength and resistance to fatigue and corrosion than copper, and are used for a wide variety of specialty products. Beryllium metal is used in aerospace and nuclear applications. The oxide is employed as a refractory and in electronic devices.

Prices for beryllium metal, quoted as 5 in. rod, remained unchanged at approximately $155 per lb during 1976 (136, 137). The price of imported beryl ore (10-12 BeO) rose from $30 to $42 per short ton.

The over-all production and consumption of beryllium ores in 1976 was about the same as in 1975 (135). In the first 10 months of 1976, 815 tons of beryl were imported. This can be compared to 1,550 tons in 1975, and to the peak importation of 6,422 tons in 1969. The major source of the imports was Brazil followed by France, India, Australia, and other countries.

Exports of beryllium metal, alloys, waste, and scrap totaled 163 tons in the first 11 months of 1976, compared to 17 tons for the similar period in 1975. The major importers were the United Kingdom and Japan (134).

As of November 30, 1976, government stockpiles of beryllium contained 229 tons of beryllium metal, 7,387 tons of Be-Cu master alloy (4% Be) and 17,986 of beryl. These were unchanged from year end 1974. During 1976, the General Services Administration announced new stockpile objectives: for beryllium metal, 895 tons, an increase from 88 tons, and for the master alloy, 16,710 tons, an increase from zero. The stockpile objective for beryl remains at zero (135).

III. Chromium.—Although the demand for chromium was higher in 1976 than in 1975, it did not reach the record demands established in 1973-1974. Total chromite consumption was 1,040,000 tons and all three consuming industries reported increases in consumption, viz.

Metallurgical	20% higher
Refractory	10% higher
Chemical	10% higher

Consumption of chromium alloys was 22% higher than the previous year due to increased production of stainless steel (138).

Imports of chromite which totaled 1,350,000 tons is only slightly higher than in 1975. Shipments were higher from South Africa, Finland, and Turkey but lower from U.S.S.R., Rhodesia, and Philippines. Shipping problems and political disputes plagued the Rhodesian and South African chrome industry. Due to delays in shipments from some countries, India was offering chrome for export (138-140).

Imports of ferrochromium, although down 16% from the previous year, are still at a high level, and this has resulted in higher inventories at producer and consumer locations. The 1976 total was estimated at 270,000 tons. Depressed demands for ferrochrome alloys are expected to continue in 1977. Inventories remain high and there was an oversupply of imported alloys. The situation is not expected to improve until stocks of steel products diminish (138, 141).

Despite opposition from domestic ferrochrome producers, it appears likely that the Byrd Amendment of 1972 would be repealed and embargoes on Rhodesian chrome would be reimposed. Dependence on Rhodesian chrome has been dropping steadily. Countries such as Brazil and Turkey have made substantial expansions in chrome mining and smelting. If the embargo is imposed, activity in domestic production will increase. Mine owners reported production capacity of mines in Del Norte County, California, at 120,000 tons per year (147).

On October 1, the Federal Preparedness Agency established new government stockpile goals for chromium materials. Inventories in government stockpiles of refractory and chemical grade chromite were below the new goals at year end (138).

Foote Mineral discontinued its chrome alloy business (142).

There was essentially no change in published chromite prices from those of 1975. High-chromium chromite also remained at the same price. Year-end prices were:

High-chromium Russian	- $136 per ton
High-chromium Turkish	- $120-129 per ton
High-iron South African	- $35-$42 per ton

Chromium alloys dropped in price. United States charge chromium decreased from 50 cents per pound to 43 cents by year end. Low-carbon ferrochromium dropped from $1 per pound to $0.85 during the year. Chromium metal increased from $2.44 per pound to $2.63 (138).

The 120,000 tons per year Tubatse Ferrochrome plant at Steelport, South Africa, a joint venture of Union Carbide and General Mining, is not expected to start up until 1977. Union Carbide will discontinue charge chrome production in the United States when ship-

ments of charge chrome start flowing from this plant. The Turkish state-owned plant, Etibank, with a capacity of 50,000 metric tons per year is behind schedule and probably will not start until 1977. Johannesburg Consolidated Investments and Showa Denko plan to start up a $50 million ferrochrome plant at Lydenburg in early 1977. The impact of large power increases in South Africa is not clear. Power rates increased 15% in April, 13% in September, and 25% is expected in January 1977 (143, 144).

Three Japanese companies, Nippon Kokan, Itoh and Company, and Kokan Mining, are studying a chromo ore venture in Kenya (145). The Sudanese government plans to double chromite production from 25,000 to 50,000 metric tons per year over the next 2 years (146).

Increased interest and activity in domestic production of chromite was evident during the year. A firm in California rehabilitated a mine and plant that had been idle since the 1950's. Mining of chromite was last reported in 1961. Mining interest in northern California and southern Oregon reactivated the Cal-Ore Chrome Producers Association and construction of a mill is under discussion (138).

Research is continuing by the Bureau of Mines to recover chromium from laterites and low-grade domestic resources. Successful development could extend world resources of chromium and provide a broader geographical supply base. Research on recovery of chromium from waste material is also continuing (138).

IV. Copper.—Production from primary materials at refineries in 1976 was 1,537,188 tons, 6.5% above 1,443,378 tons in 1975. Smelter production from primary materials was 1,534,622 tons, up 6% over 1,447,128 tons in 1975. Production of refined copper from scrap was 374,480 tons, up 8.7% from 344,480 tons in 1975. Stocks at year end were 189,500 tons of refined copper, 312,000 tons of blister, and 137,913 tons of scrap, essentially unchanged from year end 1975 (148).

Asarco dedicated its new Amarillo facility in June 1976. The plant, which actually came on stream in late 1975, has a capacity of 420,000 tons per year of copper at a cost of $190 million. Copper reaches the plant in three forms: anodes from smelters in El Paso, Texas, and Hayden, Arizona, blister copper from both foreign and domestic smelters, and No. 2 grade scrap. Copper from Amarillo will be available in all shapes used by industry: cathodes, wirebars, cakes, billets, and continuous cast rod (149).

The new solvent-extraction-electrowinning plant of Cities Service Company in Miami, Arizona, went on stream. The plant has a design capacity of 15 tons per day of cathode copper (150).

Anaconda announced plans to reopen its Arbiter plant in Anaconda, Montana, in July (151).

Asarco scheduled closing of the 188,000 tons per year refinery at Perth Amboy, New Jersey (152).

Consumption of primary refined copper (apparent consumption) was 1,825,000 tons, up 39% from 1,310,000 tons. Total consumption (including secondary recovery materials) increased 27.7% from 1,534,505 to 1,960,075 tons (148).

The Federal Preparedness Agency set a stockpile goal of 1.299 million tons of copper. Since the previous stockpile goal was zero, the 20,261 tons from the previous stockpile that remained unsold was transferred into the new stockpile. The new goal is thought to be excessive by many industry observers who note that domestic production is adequate for present national needs (153, 154). Pending congressional action, the government may become a substantial copper consumer.

Mine production, expressed as recoverable copper, increased 19% from 1,413,366 to 1,611,341 tons. Production occurred predominantly in Arizona (63%) followed by Utah (12%), New Mexico (11%), and others (148).

Production start-up at Hecta Mining Company's Lakeshore mine near Casa Grande, Arizona, was delayed by slippage in the construction schedule. Full production was expected in the second quarter of 1976 (155).

After investing more than $30 million in land acquisition and drilling, Continental Oil Company has indefinitely postponed plans for development of its 800 million tons orebody near Florence, Arizona. This decision was attributed to marketing uncertainties (156).

A major copper find south of Crandon, Wisconsin, was announced by Exxon Corporation (157).

Amax has stepped up exploration of the Minnamax copper-nickel prospect in Minnesota (158).

Eisenhower Mining Company will develop a 27,000 tons per year open pit copper mine to work the Palo Verde copper deposit south of Tucson, Arizona. The deposit contains an estimated 125 million tons of ore grading 0.6% copper (159).

Homestake Copper Company has reported finding a new copper deposit in the Keweenaw Peninsula in upper Michigan (160).

Some production cost guidelines were provided by industry spokesmen. According to Arthur Reef, Vice President of Amax Incorporated, the cost of developing a new mining complex in the western U.S. from mine through refinery has risen from $3,500 per annual ton in 1970 to at least $6,500 per annual ton at the end of 1976. By 1980, the cost is expected to be $7,500 in 1976 dollars (161). U.S. copper producers would need a price of 80-85 cents per pound to expand capacity at existing facilities and higher prices to justify construction of a new operation according to Phelps Dodge President, George B. Munroe (162). These remarks were confirmed by J. C. Agarwal, Director of Kennecott Copper Corporation's Ledgemont Research Center, who was quoted as saying that the investment for copper has reached from $6,000 to $6,500 per annual ton and that it would take a price of $1.25-$1.50 per lb to support such an outlay (163).

The price per pound of U.S. producer electrolytic copper (delivered) as quoted by Metals Week opened the year at 63.6 cents just below the average for 1975. It increased to 70.6 cents in May and again to 74.6 cents in July. Strength held through September when the slide, some said "crash", began, which left the December price at 65.8 cents. A general explanation of this behavior was widespread speculation supported by a general anticipation that an over-all economic recovery had set in (148, 164).

Imports exceeded exports but the difference was a small factor in the total domestic market picture. Imports of refined copper were 384,002 tons up 162% over 146,809 in 1975. Exports of refined copper, alloyed scrap and unalloyed scrap were down 28% from 316,641 to 227,000 tons (48).

Free world production of refined copper was 7,362,000 tons, up 6.68% from 6,901,000 tons in 1975, but down 3.9% from 7,660,000 tons in 1974. Each year the United States was the largest producer followed by Japan and Zambia. Free world mine production was 6,431,000 tons of copper, up 1.8% from 6,317,000 tons in 1975, but down 5% from 6,769,000 tons in 1974. The largest producers were the United States, Chile, and Canada (164).

Granby Mining Corporation planned to end operations at the Phoenix copper mine near Grand Forks, British Columbia, because of exhaustion of ore reserves. Production recently had been running 1 million tons per year (165).

Production at the Thierry copper mine near Pickle Lake, Ontario, was started in August after expenditure of about $100 million by Union Miniere Explorations and Mining Corporation. The mine has a 4,000 tons per day mill and concentrator. Reserves are estimated at 15 million tons containing 1.63% copper (166, 167).

The Mexican La Carida copper project is scheduled for startup in 1978. This includes a mine at Nacozari with an initial production rate of 79,000 tons per day of ore and a 500 tons per day smelter at Empaline. Costs are approximately $400 million for the mine and $240 million for the smelter (168).

Devaluation of the peso may permit reactivation of the LaVerde Project, at Michoacan, Mexico. The project was slated to produce 38,500 tons per year of electrolytic copper after an investment of $96 million (169).

Agreements were signed between Texasgulf and the Panamanian government concerning development of the Cerro Colorado copper deposit, perhaps the largest known undeveloped copper deposit in the world. According to current estimates an open-pit mine could produce 33 million tons of ore for at least 70 years. The project is estimated to cost $800 million (170-172).

The Cuajone Project in Southern Peru came on-stream at a completion cost of $655.7 million. When in full production the project will produce 170,000 tons per year of blister copper (173).

Androcollo, in Central Chile, with estimated ore reserves of 330 million tons of 0.7% copper will become a joint venture of Noranda and the Chilean government. Three other large copper properties are still being offered by the Chilean government to foreign investors (174).

Codelco, the state-run copper corporation, predicted that being Chile's largest copper exporting company, it would produce an average of 800,000 tons per year between 1976 and 1980 (175).

A large scale expansion of its Ertsbert copper mine at Tembagapura, Indonesia, is being considered by Freeport Indonesia. In 1975, the mine produced 225,000 tons of copper concentrate (176).

Construction of a 92,900 tons per year copper smelter, the first smelter in the Philippines is expected to start in 1977, with first production in 1978. The smelter using Outokumpu Oy's flash process is estimated to cost $250 million (177).

A 66,000 ton expansion of the tankhouse at Hoboken-Overpelt's Olen (Belgium) electrolytic copper refinery was commissioned in 1975, increasing capacity to 363,000 tons per year (178).

A copper smelter and refinery complex is planned for Onsan, South Korea. The complex will have a capacity of 88,000 tons of cathode copper per year and be readily expandable to 110,000 tons. The complex to cost $180 million is scheduled to start in 1979 (179).

Watching wildflowers may pay off. The Swedish state-owned mining company LKAB has announced discovery of an estimated 22 million tons of 1.0-1.5% copper ore in Viscarra Field, Sweden. The deposit was discovered when a geologist observed that the alpine carnation, a plant which survives in earth having a high copper content, grew in abundance in the area (180).

Deposits of ore rich in copper have been located in Kauria, Bihar, India. These are believed to be the largest known deposits in India (181).

Western Selcast and Mount Isa Mines announced a rich find of copper, silver, and zinc in the Teutonic Bore area northwest of Leonara, Western Australia (182).

A feasibility study of the Ok Tedi copper prospect in Papua-New Guinea has confirmed the existence of at least 275 million tons of copper ore. The government indicated that an operation of about 50,000 tons per day seems certain to go ahead (183).

Deposits roughly estimated at 200 million tons have been found in the Chagai district in Baluchsstan, Pakistan (184).

Low copper prices affected operations at several locations. The Israeli government closed the Timna copper mines (185). The 97 year old mine at Mt. Morgan in Central Queensland, Australia, faced closure by the end of 1976. The work force was reduced and an associated mill was closed in February (186). Plans to double copper production and exports by opening new mines at Quansimi and Tazalaght, Morocco, have been seriously affected (187). Broken Hill South has decided to wind down all operations at the Kanmantoo mine in South Australia, only 4 years after its launching because of continuing losses (188). Mt. Lyell Mining and Railway Company, Limited, is closing down two mines in Queenstown, Tasmania, but keeping its main mine open (189). Plans to build a 132,000 tons per year electrolytic refinery in Cape Province, South Africa, have been shelved by O'Okiep Copper Company, Limited and Tsumeb Corporation. Cost of the project was initially estimated at $44 million (190).

The giant Tenke Fungurume copper project in Zaire was suspended in January because of soaring costs which produced nearly insurmountable financing problems. Later in the year members of the consortium were conducting independent studies on the feasibility of smaller plants (191, 192).

The Polish government announced plans to increase copper output by 70% to 468,000 tons per year for the period 1976-1980. This encompasses enlarging mines at Ubin, Polkovice, and Rudna, opening a new mine at Sieroszowice, expanding smelters at Legnica and Glogow I, and building new smelting complexes at Gedynia and Glogow II (193).

A newly developed copper deposit at Reosk, Hungary, will raise annual ore production to 8-9 million tons. This will eliminate that country's needs for copper imports (194).

The Soviet Union is exploring the possibilities of western involvement in development of the massive Udokan copper mine northeast of Lake Baikal. The deposit is estimated to contain some 2 billion tons of ore averaging 1.3-1.5% copper. Initial construction would be a plant with a capacity of 400,000 tons per year. Cost including mine development, a smelter, and a refinery is estimated at $1 billion (195, 196).

Domestic industry continues to have environmental difficulties. An Arizona decision on water rights may affect massive mining and processing operations south of Tucson (197). Proposed sulfur dioxide regulations for Arizona smelters are not as harsh as expected but they may affect the Phelps Dodge Douglas smelter on which $20 million had been spent to meet state standards when Federal standards were not known (198, 199). Asarco received a 5 year variance for its Tacoma, Washington, smelter on arsenic and sulfur dioxide emission levels after agreeing to spend $4.7 million during that period on emission controls (200). The Environmental Protection Agency and Kennecott Copper Corporation are still at odds over means of meeting sulfur dioxide emission standards at the smelter at McGill, Nevada. The plant has been closed since August 1 (201).

V. Lithium.—The United States continues to remain as the world's major producer and consumer of lithium. Exports, primarily to Western Europe and Japan, amount to about 20% of production. Imports, exports, and domestic consumption increased by about 11% over 1975.

United States and world usage is mostly in the form of chemicals, primarily lithium carbonate; the balance is mostly lithium hydroxide monohydrate. Amount of lithium metal marketed is comparatively small. The pattern of usage is unchanged (203).

Foote Mineral Company and Lithium Corporation of America, with mining and processing facilities in North Carolina, continued as major suppliers. Late in the year, a new processing unit went on stream at Foote's Kings Mountain, North Carolina, plant and added 12 million lb per year of lithium carbonate. Other sources of lithium carbonate were derived from subsurface and lacustrine brines at Searles Lake, California, and Silver Peak, Nevada (202, 203).

Surplus lithium hydroxide was available and for sale by the General Services Administration and by year end about 400,000 pounds had been sold. Stockpile remaining was about 3.1 million pounds (203).

Prices for lithium and various types of lithium compounds increased during 1976, and prices going into 1977 were (204-206):

Lithium carbonate	$0.84 per lb
Lithium hydroxide (monohydrate)	$1.46 per lb

Lithium chloride	\$1.75 per lb
Lithium metal ingots	\$11.60 per lb

Energy developments in two major fields could place a strong demand on lithium reserves. Although commercial development of nuclear fusion is not expected to be completed until the early decades of the 21st century, large quantities of lithium would be required if the breeder-coolant design concept were utilized. Secondly, in the not too distant future, lithium-type batteries could put a strain on supplies of lithium. According to Argonne National Laboratory, commercial introduction of electric cars is anticipated in 1985. Based on design life of 10 years and 25% annual growth rate, batteries for electric vehicles would require 70 million lb of new lithium annually. One of Argonne's high energy primary batteries, a lithium-iron sulfide type, is expected to have a cell energy-density ratio of 80-85 W-hr per lb. The high operating temperature of 380°-450°C has caused design problems with corrosion and materials of construction (207).

Matsushita Electric Industrial Company, Osaka, has developed a lithium-polycarbon monofluoride type of battery which is reported as having the world's highest density. A license has been granted to Eagle-Picher to manufacture and sell the battery in the United States (208).

A lithium-metal sulfide battery similar to Argonne's is being developed by General Motors. Exxon Enterprises has revealed research on a lithium battery that operates at room temperature but has an energy density in the 50-60 W-hr per lb range. These and other researchers of advanced battery systems probably will be encouraged by the Electric Vehicle Development and Demonstration Act which was passed in September. Ultimately, the nonmarine subsurface brines may become a greater source of lithium (207).

VI. Magnesium.—Figures on domestic production of magnesium are not published, but it appears that production was limited by available plant capacity. Dow Chemical, the major producer, has a 111,000 metric tons per year plant at Freeport, Texas. American Magnesium Company at Snyder, Texas, increased production from 4,000 to 5,500 metric tons per year. Northwest Alloys at Addy, Washington, brought its 22,000 metric tons per year plant into production (209, 210).

The NL Industries plant at Rowley, Utah, was essentially out of service for all of 1976. The \$110 million complex completed in 1972 was to produce 40,000 metric tons per year. A series of problems prevented production from exceeding 12,000 metric tons per year. Following an analysis by Norsk Hydro, Norwegian magnesium manufacturer, and a successful series of tests, NL Industries plans to go ahead with a \$30 million modification program and expects to operate at 25,000 tons per year in 1977 (211-213).

United States consumption of magnesium was estimated at 125,000 short tons (214). The largest single market for magnesium is in alloys with aluminum. This accounts for about 50% of the magnesium consumed in the United States. Other uses which are expected to increase in importance are steel desulfurization, die castings, and various applications in the automotive industry.

Prices of magnesium rose during 1976. Beginning at values which had held for all of 1975, 82 cents per lb for ingot and 85 cents per lb for die casting alloy, magnesium prices were increased in steps to 92 cents per lb for ingot and 94 cents per lb for alloy at year end (215-217).

For the first time the United States became a net importer of magnesium in 1976. Total imports were 19,800 tons with the following breakdown: metallic and scrap, 12,968 tons; magnesium content of alloys, 1,820 tons; and sheet, tubing, and other, 20 tons. Exports were 13,441 tons of which 12,279 tons were metal and alloys in crude form and 1,162 tons were semifabricated. Exports were 58.8% below those of 1975 (218).

Outside the United States, Chromasco in Canada has a capacity of 5,000 metric tons per year and Norway produces about 45,000-50,000 metric tons per year. Total production by members of the International Magnesium Association in 1976 was 178,115 metric tons, a slight increase over the 173,597 metric tons produced in 1975 (209). This association does not include producers in the U.S.S.R. who are believed to turn out about 50,000 metric tons per year.

Norsk Hydro has announced plans for a complex at Mongstad, Norway, to include production of 100,000 metric tons of magnesium and simultaneous production of chlorine to feed an ethylene dichloride plant. If tests being conducted at Heroya, Norway, are successful, the company will install an initial increment of 30,000 metric tons per year. Over-all costs are expected to reach \$200 million (209).

VII. Manganese.—There was no production of manganese ore, concentrate, or nodules containing 35% or more manganese in the United States during 1976. Manganiferous ores of lower grade continued to be produced and shipped from New Mexico and Minnesota.

Production of ferromanganese dropped in the latter part of the year but the total consumption of manganese increased. Ferromanganese imports for 1976 surpassed those of the previous record year. Main suppliers of ferromanganese and manganese ore were:

Ferromanganese:	South Africa	35%
	Japan	20%
	France	18%
Manganese Ore:	Gabon	41%
	Brazil	25%
	Australia	17%

New stockpile goals for the various grades of ore and types of manganese were established by the General Services Administration on October 1. Releases from stockpiles continued to be very high and consisted mostly of ore (220).

Price of standard high carbon ferromanganese (minimum 78% Mn) was reduced in early January from \$440 to \$425 per long ton and it remained at this price for the remainder of the year. Prices of imported alloy of the same grade dropped about 12% during the year and by mid-November the price range was \$345-370 per long ton. Prices declined even further in the lower grades of alloy. The price of standard electrolytic manganese metal increased 4 cents per lb to 58 cents per lb. Price declines and uncertainties during 1976 were linked to heavy inventories and a poor economy in the steel industry (220, 221).

Groote Eylandt Mining Company, Australia, completed its planned expansion to 2 million metric tons per year of high grade ore. Further expansion is possible if market conditions are favorable (222).

Anglo-American Corporation is planning to develop an underground manganese mine at Middelplaats, South Africa, with production scheduled to start in 1979. Ore deposits are running 38% manganese (223).

Large manganese deposits have been discovered in Brazil's Carajas Range. Amazonia Mining, a joint venture of U.S. Steel and state-controlled Vale do Rio Doce, will mine the deposits (224).

Minera Autlan at Tamos, Mexico, has started a new facility which will be capable of producing 120,000 metric tons per year of manganese alloys. Plans are to increase output to 800,000 metric tons per year over the next 2 years. There is a growing trend toward location of alloy facilities in countries where ore is produced (225).

United States ocean miners have completed extensive prospecting and are approaching final phases of development. Major technological problems are reported as being resolved and sea testing of prototype mining systems is planned. If production plans mate-

rialize, manganese imports could fall by 40%, nickel by 50%, and copper by 33%. Unfortunately, since these deposits are in the oxidized form in contrast to sulfide deposits, extraction by low cost physical means is not possible. The future is, however, clouded by international legal and political interest. The concept that all nations have a right of access to resources in the seabed is not being universally endorsed (226, 227).

The Panel on Manganese Recovery Technology, National Academy of Sciences, has completed assessment of existing technology for manganese production from domestic resources. The Cuyuna deposits in Minnesota and Aroostook deposits in Maine were considered as the best land-based domestic resources for further development. Deep-sea nodule deposits, particularly some in the Pacific Ocean, have high potential as a manganese source. The lower grade deposits of the Blake Plateau in the Atlantic Ocean may be considered as a domestic resource. The ammonium carbamate process and the sulfur dioxide-roast process were considered as the best processes for manganese recovery. However, neither process has been fully developed (220).

VIII. Nickel.—High inventories of nickel at consumers dropped during the year and there was a general recovery in the demand for nickel. Domestic nickel consumption rose 11% when compared with that of 1975. Primary nickel consumption for 1976 was estimated at 162,000 tons.

The distribution of nickel consumption was essentially the same as previous years: 44% in steels, 21% in nickel and nickel alloys, and 16% in electroplating. Ferronickel increased its share of the domestic nickel market in 1976, whereas pure unwrought nickel lost an equivalent share of the market. This situation was reversed in 1975. An estimated 74,000 tons of nickel was recovered from scrap (228).

Although nickel inventories in the world were high and recovery from poor economic conditions in 1975 was slow, prices moved upwards for most materials. Domestic ferronickel remained fairly steady at $2.16 per lb until October 1, when the price was raised to $2.34. Later in the year, an allowance of 8 cents per lb was announced on all firm orders for delivery in early 1977. The price of pure nickel was quoted as $2.41 per lb, effective October 1, but the old price of $2.20 was expected to prevail until 1977, for major consumers of nickel. The price of imported ferronickel ranged from $2.35 to $2.39 per lb of nickel content, an increase of 9% over 1975 prices (228, 229).

On the domestic scene, Amax Incorporated's nickel refinery in Louisiana is expected to reach its rated capacity of 40,000 tons of nickel during 1977. The one domestic mine in Oregon produced 17,000 tons of nickel from laterite ore and the associated smelter produced 13,000 tons of nickel in ferronickel (228).

United States imports of nickel in 1976 are expected to total 178,000 tons, an increase of 10% over 1975, but well below the record import of 221,000 tons in 1974. Supply sources were (228):

Canada	58%
Norway	8%
Botswana	7%
New Caledonia	5%
Philippines	5%
Dominican Republic	5%
South Africa	4%
Other countries	8%

Production of nickel in Canada was 263,000 tons in 1976, a decrease of 1% from the previous year (242).

Adequate supplies of nickel were available throughout the world during 1976, and new capacity or expansion at various locations appears to be more than adequate towards meeting demands for nickel in the immediate future.

INCO's Indonesian project, scheduled for completion by the end of 1976, will produce 18,000 tons per year of nickel matte. In 1977, INCO will start up the 14,000 tons per year Guatemalan lateritic nickel project (234, 240).

The Agnew nickel project in West Australia, scheduled for production startup in late 1978 of 10,000 metric tons per year of nickel in concentrate, is virtually assured of going ahead. Reserves were reported at 2 million tons with ore containing 3.5-5% nickel. Shimura Chemical will build a 10,000 metric tons per year of electrolytic nickel in Japan. Completion is expected by 1978. Greece's Larco nickel mining company is proceeding with expansion plans at Larymna which will increase nickel capacity by 40,000 metric tons per year (230-232).

An agreement has been reached between the Netherlands based Patino NV and Bureau de Recherches Geologiques et Minieres for development of a nickel project in northern New Caledonia. Production of 30,000-40,000 metric tons per year from garnierite nickel deposits is planned (233).

International Nickel, a subsidiary of INCO, will build a nickel reclamation facility which will have a capacity to process 40,000 tons per year of wastes. Completion is scheduled for mid-1978 (235).

Due to declining levels of nickel ore, Falconbridge Nickel Mines, Manibridge, Manitoba, expects to close its nickel mine by mid-1977. About 185,000 tons per year of ore were produced (241).

The Federal Preparedness Agency on October 1 set the stockpile goal for nickel at 204,335 tons (228).

At present, 70% of world consumption comes from sulfide ores and 30% from oxide ores. A greater shift to oxide-ore deposits is predicted due to rising demands and consumption which is doubling every 10 years. Estimates of world nickel ore reserves are as follows (236):

Sulfide ores—		
14.8% of world reserves	Canada	9.3%
	U.S.S.R.	3.8%
Oxide Ores—		
85.2% of world reserves	New Caledonia	43.0%
	U.S.S.R.	15.5%
	Philippines	7.5%
	Cuba	4.8%

Development work is continuing by a number of countries in recovery of nickel from ocean mining. Nodules contain from 0.2 to 2% nickel. No large scale ocean mining operations are expected for another 15 years due to economic, legal, and political problems associated with seabed mining. United States and Canada are studying proposals to limit seabed mining with output tied to growth projection for nickel consumption (237, 238).

Soc. Metallurgique Le Nickel (SLN) has developed a proprietary electrowinning method referred to as "Resin Ion Exchange and Electrolytic Process," for producing high purity nickel. Initial production will come from a 15,000 metric ton per year refinery at Sandouville. SLN expects to start selling pure nickel in the United States in 1979. Arrangements will be made with Nippon Nickel to produce pure nickel in Japan, probably before 1980. (239).

Interest and development of nickel-copper deposits in the Duluth gabbro continued during the year. Although INCO suspended activity on their project near Ely, Amax is proceeding with a 5,000 ton ore sample for metallurgical testing from their 1700 ft mining shaft near Babbitt. Research by the Bureau of Mines is continuing on a number of projects: recovery of nickel and cobalt from low-grade domestic laterites, production of ferronickel from oxide ores, recovery of nickel and other metals from ocean nodules, and recovery of nickel and copper from ores in the Duluth gabbro complex (228).

Sodium.—Sodium metal production is in a long-term downtrend. According to the Bureau of Mines, produc-

tion in 1976 was essentially unchanged from a total of 144,000 tons the previous year (243).

The total U.S. capacity is 189,000 tons per year, relatively evenly divided among five plants.

The predominant use for sodium metal has been for antiknock compounds. As much as 80% of sodium consumption has been for production of compounds like tetraethyl lead. However, in June of 1976, the Supreme Court refused to hear a petition which would halt the phasedown of lead in gasoline proposed by the Environmental Protection Agency. Because new cars require lead-free fuel, the demand for leaded gas will decrease in any case (244).

Average prices for sodium metal in 1976 were reported by the Bureau of Mines to be 20% higher than in 1975 (243). The 1975 price was reported as 22-22.5 cents per pound.

X. Titanium.—The two domestic producers of sponge, Titanium Metals Corporation of America and R.M.I., Incorporated, have a total capacity of approximately 18,500 tons per year. Consumption and imports for consumption of sponge in 1976 were 13,315 and 1,778 tons, respectively, down from 17,626 and 4,192 tons in 1975 (245). Sponge inventory had reached 1975 levels by year end being 3,633 tons down from 6,300 tons in February 1976. Consequently one can see that production of sponge was well below capacity and well below last year's. The Bureau of Mines notes that production of sponge was 43% less than in 1975 (246).

Imports for consumption of sponge, by source, extrapolated from the first 10 months were Japan, 1,400 tons; U.S.S.R., 275 tons; and UK, 55 tons. Japanese supplies to the U.S. were the lowest since 1964. The two Japanese sponge producers operated at 50% of capacity (247).

Oregon Metallurgical Corporation in Albany, Oregon, announced that it was reactivating its sponge plant in January 1977. The plant, which operated only for a short time, has a reported capacity of 2,500 tons per year (247).

The price of domestic sponge remained constant at $2.70 to $2.75 per pound through the year. Japanese sponge was quoted at $2.65 to $2.70 per pound at the beginning of the year. Both it and Russian sponge dropped to $2.45 in February. Late in the year one Japanese supplier announced a restoration of prices to previous levels, but Japanese sponge was still quoted at $2.45 to $2.50 at year end (247).

Consumption of titanium scrap was 9,211 tons in 1976 compared to 8,317 tons in 1975. Stocks at year end were 5,764 tons (245).

Titanium Fabrication Corporation is negotiating with several Brazilian mining firms concerning the possibility of a joint-venture titanium sponge plant using Ti-Fab's extraction technology (248).

Titanium ingot production in 1976 was 21,614 tons, down from 25,562 tons in 1975. Consumption was 21,004 tons, down from 24,485 tons. (245). During the first 6 months of 1976 smelters were operating at 50% capacity. By November they had increased to 66% with some increase in backlog.

Despite efforts of titanium producers to develop industrial markets, the industry is still dominated by aerospace demands. A modest resurgence in commercial airplane orders supported the market. The distribution of titanium mill products in 1976 was approximately as follows: forging and extrusion billet, 6,500 tons; sheet, strip, and plate, 3,626 tons; pipe and tube, 2,821 tons; rod and bar, 1,260 tons; castings, 239 tons; and wire, 200 tons. Pipe and casting were the only categories where production exceeded that of 1975 (247).

The Federal Preparedness Agency recommended that the Government stockpile goals be increased to 131,503 tons of sponge and 173,928 tons of rutile. At that time the stockpile contained 32,329 tons of sponge and 39,186 tons of rutile (246).

Mine production of titanium minerals, principally ilmenite, decreased to 652,404 tons, 9% below the 1975 level. Imports of ilmenite, mostly from Australia, were 168,622 tons, an increase of 18%. Imports of slag from Canada are estimated at 188,431 tons, slightly less than in 1975. Natural rutile imports, mostly from Australia, were 196,035 tons, an increase of 11%. Synthetic rutile imports were 83,421 tons, an increase of almost 50% (245).

Titanium mineral deposits were reported in southwestern Colorado (251), in upstate New York (252), in southern Tanzania (253), and in the seas around Ratnagiri, India (254). The Australian Government prohibited export of mineral sand concentrates from Frazer Island, Queensland, for environmental reasons. Lost to industry are 793,000 metric tons of rutile and smaller quantities of ilmenite and other minerals (245).

Published prices for ilmenite ore and slag remained constant at $55 and $60 per long ton, respectively. Rutile dropped from $710 to $510 per short ton at year end (249, 250).

Demand for titanium dioxide pigment increased. Domestic production was about 735,000 tons, an increase of 22 from 1975. Pigment exports increased to 20,000 tons and imports increased to 70,000 tons. The latter was attributed to a shortfall caused by a strike at the Sayreville, New Jersey plant of NL Industries (246). du Pont has authorized an additional $20 million of an expected total of $150 million for its 150,000 ton per year plant at DeLisle, Mississippi. Completion is now set for 1979 (255).

XI. Zinc.—Domestic smelter production of slab zinc in 1976, was 535,856 tons, 8% above the 495,937 tons produced in 1975. Producer and consumer stocks at year end, had increased to 199,706 tons, an increase of 9% over 1975 (256).

Ground was broken in Clarksville, Tennessee, for a 90,000 tons per year refinery. The complex, a joint venture of New Jersey Zinc Company and Union Miniere of Belgium, is estimated to cost $100 million. Production techniques to be used are self-contained chemical and electrolytic processes, which permit excellent pollution control. Completion is expected in 1979. Associated with the complex are three mines near Carthage, Tennessee, which are to supply concentrates for the Clarksville refinery. Mine development is now estimated to cost $90 million (257).

National Zinc Company's electrolytic zinc refinery was completed in August but a 3-month strike delayed start-up until year end. The 50,000 tons per year refinery replaces the horizontal retort plant at a cost of $40 million (258-260).

Consumption of slab zinc was 1,127,078 tons, an increase of 22% from 925,330 tons in 1975. Total zinc consumption including ores for other than slab zinc, zinc content of alloys, and scrap, increased 16% to 1,420,002 from 1,231,815 tons. Of the slab zinc, 38% was used for galvanizing, 37% for zinc-based casting alloys, 15% for brass and bronze, 3.6% for zinc oxide, 2.8% for rolled zinc, and 3.6% for other uses (256). A significant factor in the market for zinc is the increase in activity in the automotive market.

It appears that the General Services Administration is out of the zinc sales business. The Federal Preparedness Association set a new stockpile objective of 1,313,000 tons. Previously the stockpile objective had been 202,700 tons with 172,130 tons of surplus available for disposal (261, 262).

Mine production in 1976 was 477,369 tons of recoverable zinc up 17% from 469,355 tons in 1975 (256). Tennessee, Missouri, New York, and Colorado accounted for 60% of the output (260).

Imports for consumption of zinc as block, pig, or slab totaled 695,131 tons, up 85% from 1975. Countries supplying imports included Canada (45%), Mexico (8%), and West Germany (7%). Exports of slab, scrap, and dross were 12,459 tons, up 4%. Imports of ores and concentrates were 155,803 tons of zinc content, down 63%. Chief sources were Canada (80%), Honduras (8%), and Mexico (6%) (256).

Early in January the price per pound of zinc was cut from 39 to 37 cents by Asarco with the rest of the industry quickly following (263). In August, the price was raised to 39 or 40 cents (264). This price hike was rescinded, in October. Some producers made the price reduction retroactive (265). The year closed with average prices at 37 cents per pound (266). On the London Metal Exchange, zinc prices had been quoted in U.S. dollars since late 1975. In June, the Lead-Zinc Producers Association filed a protest with the U.S. Treasury against the 12% rebate offered U.S. buyers of Spanish zinc (267). In December, the U.S. Treasury found that the Spanish government was granting an illegal rebate, but no penalty tariff was ordered pending a final decision on the case (266).

World slab production was 4,247,000 tons, up 2% from 1975, and mine production was essentially unchanged at 4,900,000 tons. Slab consumption increased from 3,829,000 to 4,557,000 tons. World producer inventories were reduced during the year from 700,000 to 500,000 tons, a quantity which is considered large enough to affect the zinc market for some time (257).

Feasibility studies are being made of a smelter with a capacity of more than 110,000 tons per year in New Brunswick, Canada. The cost would be in the area of $200 million with possible production in 1980 or 1981 (268).

An expansion of the electrolytic refinery at LaOroya, Peru, is planned which would increase capacity from 70,000 to 90,000 tons per year and increase recovery of zinc in concentrates from 79 to 84%. Cost is estimated at $65 million (269).

Forty firms were invited for discussions concerning construction of a lead-zinc smelter to process ore from two mines near Navan, Ireland. The smelter will process 100,000 to 150,000 tons of ore per year making it the largest smelter in Europe (270, 271).

Metallgesellschaft's electrolytic zinc plant at Datteln, Germany, operating at reduced capacity to permit installation of new equipment, is increasing production. The $2 million refurbishing program has increased capacity from 110,000 to 140,000 tons per year (272).

Australia's largest zinc refinery, Electrolytic Zinc Industries' Risdon works in Tasmania, was reported as operating at 75% of capacity with decreasing stocks in March as against 60% a few months before (273).

Sheritt Gordon Mines reported that zinc resources in its Ruttan mine in Manitoba may extend further than anticipated. Ruttan reserves at the end of 1975 were placed at 10.9 million tons of open pit ore grading 2.31% and 32.7 million tons of underground ore grading 1.17% zinc (274).

Texasgulf reported excellent results from drilling at Izok Lake in the Northwest Territories. The central zone contains 7 million tons of ore averaging 14.8% zinc plus other minerals. Two other zones have not been delineated (275).

Sabina Industries has released results which indicate an "important discovery" of zinc, lead, and silver in Bathurst-Newcastle area of New Brunswick, Canada (276).

Asarco is presently building a 350 tons per day sulfuric acid plant in Corpus Christi, Texas, to handle SO_2 off-gases from the company's zinc roasting process. Completion was scheduled for late 1976 (277).

New regulations to control emissions from new or modified primary zinc smelters passed by the Environmental Protection Agency were published in the January 15, 1976 Federal Register. These limit discharge of particulate matter and capacity of emissions from sintering machines and emission of sulfur dioxide from roasters. The regulations also require monitoring and recording of emissions (278).

The Electrical Industry

The year 1976 acted very much like a year of economic recovery. Production and consumption of almost everything were up. In particular, consumption of energy was up in all sectors; industrial consumption was up dramatically (279). The electrical industry predicted steadily increasing kilowatt hour sales for the foreseeable future at a rate of about 5% per year (280). By 1995, sales are forecast to be almost three times as great as now. The benefits of a constantly increasing supply of electrical energy are unquestionable (281).

The question, "Where is all of this energy going to come from?" is very important, but it is hard to answer. Oil is an unlikely source (282) as is natural gas (283). There are large reserves of coal, but conversion of equipment to coal-firing is expensive and in some cases not possible, and conversion of coal itself has technical, environmental, and economic problems. Further, there is a question of whether we can develop the capability to get that much coal out of the ground.

The growth of nuclear power is surrounded by uncertainties. There is a major question of public acceptance. Problems of waste disposal can be considered solved only on a limited and temporary basis. At present, construction of new plants is logjammed by increasing regulation and decreasing investment attractiveness. Even the supply of nuclear fuel is not limitless.

What about other sources? Both the present supply and the potential supply of hydroelectric power are significant but limited (284). Geothermal, solar, wind, and tidal power all seem to be dark horses.

We are forced to the conclusion that some present trend will change in the near future. Some possibilities are: lower energy availability, probably at greatly increased price; a dramatic increase in conservation and efficiency of energy utilization; increased use of nuclear energy despite its present hazards; or successful development of one of the dark horses. The most likely future course appears to be some mixture of the above. The mixture will be determined by the decisions which are made, or not made, by industry, by the government, and by the people.

I. United States power generation.—Tables 3-7 summarize the production, installed generating capacity, fuel consumption, sales to ultimate consumers, cost, and average usage of electrical energy for the period January to December 1976. The figures are preliminary and in some cases partially estimated. For comparison, revised final figures are given for 1975, except for Table 5 where a longer time span is examined.

The production of electrical energy from all sources increased by more than 7% from 1975. This included a

Table 3. Production of electrical energy* (285)
(billions of kilowatt-hours)

Electrical utility	1975	1976	% change
Coal fired	852.8	942.4	+10.51
Oil fired	288.8	319.2	+10.53
Gas fired	299.7	294.4	−1.77

(billions of kilowatt-hours)

Consumer	1975	1976	% change
Residential	586.1	610.6	+4.18
Commercial	418.1	442.0	+5.72
Industrial	661.6	722.0	+9.13
Other	67.2	71.1	+5.80
Total	1,733.0	1,845.7	+6.50

Table 7. Cost and average usage of electrical energy (285)

Consumer	1966	1969	1976
	(cost in cents per kilowatt-hour)		
Residential	2.20	2.09	3.47
Commercial	2.06	1.99	3.45
Industrial	0.89	0.91	2.07
	(average usage in kilowatt-hours per year)		
Residential	5,265	6,571	8,326
Commercial	30,133	36,950	50,905
Industrial	1,486,552	1,633,362	1,709,693

decrease in the use of gas and an increase in all other sources including oil.

The distribution of installed capacity shows an increase in every category.

The data on fuel consumption show an increase in use of all types of consumable fuel, except for gas where a continued decrease is observed.

Oil consumption increased more than it had decreased the previous year so that consumption of oil in 1976 was greater than in 1974. Contrary to the established trend, a small increase in the efficiency of fuel utilization was reported. The coal rate per kilowatt-hour was 0.949 for 1976 compared to 0.952 for 1975 and 0.869 in 1966.

The data on sales to ultimate consumers show that, while all categories increased consumption in 1976, the increase in industrial usage was by far the greatest. This suggests that the decrease in industrial usage observed last year was due more to depressed business conditions than to any other reason.

The data on costs reflect an increase of 4.0 to 6.7 percent with the smaller consumers paying the greater increase.

II. Energy from fossil fuels.—As shown in Table 5, consumption of both coal and oil increased between 1975 and 1976. Domestic resources of both oil and gas continue to dwindle. Industry spokesmen feel that current federal policies remove incentives for development of new domestic supplies (287).

The supply of technical manpower for fossil energy research and development was considered inadequate for the present and apt to be seriously short in the near future (288).

The Federal Energy Administration planned to issue orders prohibiting burning of fuel oil to about 10 chemical plants as part of its nationwide program to force conversion from oil to coal wherever possible. A number of utilities have already received such orders (289).

Suspension of the Coalcon coal-to-fuels project is under consideration. ERDA expressed concern about the marginal economics of the process and technical problems with the fluidized-bed carbonizer (290, 291).

On other fronts positive steps were being taken to convert coal into liquid and gaseous fuels. Early in the year, ERDA was pushing for a program providing incentives to develop a synthetic fuels industry equivalent to 350,000 barrels of oil per day in 1985 (292). ERDA selected Conoco Coal Development Company and the Illinois Coal Gasification Group from five firms submitting proposals for plant design on a high BTU-coal gasification project (293, 294). A combined-cycle coal-conversion plant, cosponsored through ERDA is targeted for operation in 1978 at Commonwealth Edison Company's Powerton station at Pekin, Illinois. The plant will use Lurgi technology to convert 24 tons of high sulfur coal per hour into gas to be used in a 25-MW gas turbine (295). Hydrocarbon Research, Incorporated is ready to demonstrate the H-coal process. The demonstration plant at Catlettsburg, Kentucky, costing $80 million is scheduled for completion in 1978 (296). The $60 million coal-to-gas plant located near Flower City, Pennsylvania, using the Bi-gas process of Bituminous Coal Research, Incorporated, was dedicated September 14 (297).

Government actions which failed to provide financing for oil-shale developments and which decreased the price of domestic crude have caused most developers to reconsider development plans even though the results in some cases have been quite encouraging (298). However, Occidental Petroleum was preparing to have a 5,000 barrels per day underground retort in operation by the end of 1976. The company estimates the cost of its *in situ* retorting operation at $250 million and total cost of oil at $5-6 per barrel (299).

A new program aimed at tapping the estimated 500 quadrillion cubic feet of natural gas trapped in shale underlying parts of the eastern United States is being launched by ERDA. Funding in fiscal year 1976 was $10 million for resource evaluation and technology development (300).

Of the $9.5 billion to be spent by United States business in 1976, the electric utilities' share was estimated to be $2.467 billion. Of this, $1.725 billion was for control of air pollution, $602 million was for water, and $140 million was for solid waste (301). An 825-MW unit due online in 1979 at the Bruce Mansfield station in Shippingport, Pennsylvania, will be the first commercial user of Pullman-Kellogg's flue gas desulfurization system. The installation, costing more than $50 million erected, will remove more than 90% of the sulfur from 3.3 million ft^3/min of flue gas from coal containing 4.75% sulfur (302). Initial agreements toward a 2,000 tons per day plant for solvent refining of coal was announced by Wheelabrator-Frye, Incorporated. Southern Company, an electric utility, is expected to consume most of the plant's output (303). Catalytic, Incorporated has been awarded a 3 year contract by the United States Environmental Protection Agency to make a rigorous on-site evaluation of all commercial processes for desulfurizing residual fuel oil (304).

III. Energy From Nuclear Sources.—The very modest increase in nuclear capacity and in nuclear generation demonstrates the difficulties presently dominating the nuclear picture. Four plants were reported as completed in 1976: Bear Valley 1, Pittsburgh, Pennsylvania (852 MW); St. Lucie 1, Fort Pierce, Florida (810 MW); Indian Point 3, Buchanan, New York (965 MW); and Salem 1, Salem, New Jersey (1090 MW) (305).

The number of nuclear power plants scheduled to start up between 1977 and 1986 is 128 with a total capacity of 138,354 MW. The total number of committed nuclear plants is 211 with a capacity of 207,983 MW. This list stretches to 1992 with nine plants listed as indefinite with respect to completion dates. Three plants with a total capacity of 3440 MW were committed in 1976. By comparison in the previous decade an average of 19 plants were committed each year (305).

A freeze on nuclear-power plant construction and a stoppage of new operating permits was ordered by the

Nuclear Regulatory Commission in August pending completion of a study on environmental effects of reprocessing and handling spent fuels. The moratorium was lifted in November (306, 307). The NRC found the risks of siting twin 1150 MW reactors 2.8 miles off the New Jersey coast acceptable (305). However, it remained on the fence on the idea of clustering nuclear plants. Building 15-20 plants could produce a reduction in construction costs of as much as 12% (309).

Factors inhibiting reactor investments by domestic utilities are concern over reactor safety, increasing regulation, which diminishes the utilities control over its own destiny, uncertainties as to future fuel supply, and mounting costs of investment per kilowatt hour.

Six states carried referendum questions on the ballots in November which would make nuclear projects subject to legislative approval. In all six states the proposals were defeated (310).

The disposal of nuclear wastes is the most frequently mentioned aspect of reactor safety. Nuclear wastes exist whether we have nuclear plants or not and the disposal of such wastes is an international problem (311). Sir John Hill of the United Kingdom Atomic Energy Authority expressed the opinion that present techniques for storage of wastes are adequate to allow for a well-researched determination of the best of the possible alternatives (312). A salient concern is that some wastes have half-lives which are much longer than the lives of most social institutions (313). A $900,000 waste treatment facility was completed at the Los Alamos Scientific Laboratory (314).

There is a serious question whether the fuel supply will continue to be adequate. The uncertainty of future power plant construction has limited enthusiasm for construction of plants to supply enriched fuel for the reactors, even if sufficient supplies of uranium ore were available. Government guarantees appear to be required to limit the risk by private industry (315-317).

Sixty percent of the research and development budget of ERDA is earmarked for nuclear work. This includes large outlays for fission reactor development, fusion power development, and nuclear fuel cycle and safeguards (318).

Controversy still rages over the breeder reactor. Professional opinion is expressed on both sides of the question whether adequate safeguards including safeguards against theft of plutonium or sabotage can be built into breeder plants (319-321). The Joint Committee on Atomic Energy concluded that a high-priority effort for developing the breeder reactor is essential for the United State's energy future (322). The Clinch River reactor is now scheduled to begin operating in 1982 (323).

Eighteen countries outside the U.S. are producing electricity with nuclear power. The top three countries were Switzerland with 1006 MW capacity enough to produce 15% of its electricity; West Germany with 7300 MW, 15%; and Sweden with 3180 MW, 13%. Commitments outside the United States include 454 plants with a capacity of 342,355 MW. The list includes 41 countries committed to nuclear power. The most recent are Indonesia, Poland, and Turkey (324).

IV. Other energy sources.—The data in Table 4 indicate a modest increase in primary hydroelectric capacity. It is estimated that one-third of the total possible energy is currently being obtained from such sources. However, development of new sites is limited by economic and environmental factors.

The first national assessment of geothermal sources, published by the United States Geological Survey, concluded that geothermal energy could be a significant factor in the regions in which such resources occur (325). The Northern California Power Agency proposes to build a 165 MW power plant driven by steam from The Geysers geothermal field. Estimated cost of the project is $30 million (326). The first volcanic geothermal well was drilled south of Pahoa on the island of Hawaii. The well, which has a temperature measured at 617°F, was estimated to be capable of generating 10 MW of electrical power (327). The "slim hole" drilling concept using a 4 in. diameter well may significantly reduce the cost of geothermal exploration (328). Geothermal research has reached the stage where some of the real-world problems are beginning to be appreciated. These include the fact that it is hard to come by, expensive, and not as clean as once believed. Even in this context it is a resource which cannot be ignored (329).

Conversion of biomass to fuels and chemical feed stocks by a variety of processes is under consideration. One decisive asset is the sales appeal to the public (330). Weyerhauser indicates that short-rotation forestry using the wood for fuel may be on the verge of viability (331). Battelle Columbus Laboratories have demonstrated conversion of municipal solid wastes to methane on a 0.2 ton per day basis (332). Gas wells are being drilled in a San Francisco trash dump in an effort funded by the Environmental Protection Agency and Pacific Gas and Electric Company to show that methane gas formed by decomposition of municipal refuse can be recovered economically as fuel (333).

The 32 kW of energy produced at ERDA's Sandia Laboratories represent the first significant production of electric power from a solar driven turbogenerator (334). SES, Incorporated, plans to begin commercial manufacture of thin-film cadmium sulfide solar cells by early 1977 (335). ERDA unveiled plans for a modest Solar Energy Research Institute. The first year SERI will have a budget of $6 to $12 million and a staff of 50-75 persons (336).

A large step is being taken in demonstrating fuel cell technology. A 4.8 MW unit, costing $42 million, is being built under joint sponsorship of ERDA, the Electric Power Research Institute, and United Technologies Corporation. (337).

ERDA awarded a $2 million, 38 month contract to General Electric Company for further research work into magneto-hydrodynamics. Under this contract General Electric will investigate the feasibility of closed-cycle MHD power generation using a coal-fired heat exchanger (338).

Under the impetus of increased energy prices the potential of a variety of ocean energy sources is being probed. These include both thermal and tidal energies (339,340).

Under ERDA contracts power generation by windmills will be tested at four sites. The first site, Clayton, New Mexico, will have 200 kW wind-turbine generator in late 1977. Other sites, not yet selected, will be used for testing another 200 kW unit and two 1.5 MW units (341, 342).

Perhaps it is appropriate to close on news of a process which, if not precisely an energy source, is an electrochemical process. Four advanced battery systems are currently being developed on multimillion dollar contracts from ERDA and EPRI. These are to be used in banks with sufficient capacity for load-leveling of generation or consumption cycles. General Electric Company and Ford Motor Company have contracts for sodium-sulfur batteries, ESB, Incorporated for sodium-antimony chloride, Argonne National Laboratory and Atomics International for lithium-iron sulfide or other metal sulfide, and Energy Development Associates for zinc-chloride batteries (343).

75th Anniversary Review Series

Advances in Electrolytic Production of Industrial Chemicals from 1952 to 1977

William C. Gardiner*

Stratford, Connecticut 06497

Industrial chemicals that are produced electrochemically include sodium hypochlorite, caustic soda, sodium methylate, caustic potash, chlorine, sodium chlorate, sodium perchlorate, ammonium peroxydisulfate, hydrogen peroxide, fluorine, and manganese dioxide. Chlorine and caustic soda, or caustic potash, are coproducts of diaphragm and mercury cells, but chlorine is also made by electrolysis of by-product hydrochloric acid. Fused salt cells making sodium and magnesium also produce chlorine; the chlorine is recycled in some magnesium plants. Sodium methylate is made in decomposers of mercury cells by feeding in methanol instead of water.

Twenty-five years ago mercury arc rectifiers were being used at circuit voltages of 500-800V, giving conversion efficiencies of about 90%. They have been replaced by silicon rectifiers which give conversion efficiencies of around 97% at half the circuit voltage. This lower voltage has resulted in much safer operations and the development of cells using currents up to 500 kA. Thyristor control has improved regulation of rectifiers, and vacuum tap changers have quadrupled the life of switch contacts.

Coated titanium anodes are replacing graphite anodes for producing many industrial chemicals. Mr. Henri B. Beer and Dr. J. Cotton, almost simultaneously, discovered that a coating of platinum on a titanium base was resistant when anodic in a sodium chloride solution. Improvements of coated titanium anodes such as those incorporating ruthenium and other metal oxides or mixtures, and improved methods of application followed. The Beer patents were acquired by Oronzio de Nora, Italy, and commercialized around the world under the trademark DSA, dimensionally stable anodes. Electrode Corporation first introduced DSA's in the United States in 1968. Cotton's work was commercialized by Marsten Excelsior Limited, Wolverhampton, England.

Plastics such as Teflon, fiberglass-reinforced polyester (FRP), and improved hard rubber linings for steel are now widely used in all construction.

* Electrochemical Society Emeritus Member.

Electrolytic Sodium Hypochlorite

Most hypochlorite is made by chlorination of caustic soda or lime, but in some circumstances electrolysis is used. For instance, power plants on the seacoast using seawater in their condensers are generating sodium hypochlorite by electrolysis of the seawater for control of algae. Special small cells for chlorinating swimming pools are on the market. Ionics and du Pont are offering a sodium hypochlorite generating system for destroying cyanide-containing wastes in the plating industry. The cells use Nafion (R) membranes.

The Chlor-Alkali Industry

Advances in Alkali-Chlorine Production

Chlorine production in the U.S. has increased about 6-fold in the last 25 years, as shown in Table I. Production capacity was slightly under 7000 short tons per day in the early 1950's; now it is around 41,000 short tons per day. Production in 1976 was 10,267,000 short tons (1). In Canada, the increase in production capacity was from around 500 to 3700 short tons per day now. Mercury cells increased in popularity in the United

States until 1970, when the mercury scare occurred. No new mercury cell plants have been built since then in the United States, although some small expansions of existing plants occurred. Production in diaphragm cells decreased from 80 to 73.7% of the total during the period. In Canada, in the early 1950's, 14% more chlorine was produced in mercury cells than in diaphragm cells, but this has reversed to 36% more in diaphragm cells now. Several mercury cell plants were shut down.

More than 50% of the world's chlorine is now produced with metal anodes with substantial energy saving. They have also stimulated new cell designs that are larger and more economical. The number of chlorine plants has increased from 63 to 69 in the United States, and to 19 in Canada. The size of new installations has increased from 100 to 300 tons per day capacity to ones for 500-1500 tons per day. Chlorine is being made by electrolysis of by-product hydrochloric acid in one plant in the United States using technology from Germany, where there are several plants using the technique. Markets for chlorine have changed in the past 25 years, primarily due to the growth of vinyl chloride, which has increased to the point where it comprises 20% of the total chlorine market, as shown in Table II.

Various health and environmental agencies have discovered dangerous effects from some chlorinated organic products. The potential of carcinogenesis by such compounds as vinyl chloride monomer, chloroform, trichlorethylene, chlorinated biphenyls, and various insecticides has been publicized. Industry is meeting, or preparing to meet OSHA standards for workers and EPA requirements for vinyl chloride monomer emissions to a level of 10 ppm in all exhaust gases, except for emergency relief valve discharges.

The use of chloroform in drug products has been stopped by FDA regulation. Chlorination of city water supplies containing organic matter results in some chloroform in the water. Other means of sterilizing public water systems are being studied. Chlorine dioxide can be substituted for chlorine without formation of chloroform. Removal of organics by adsorption on activated carbon before chlorination is another approach.

The Federal Task Force on Inadvertent Modification of the Stratosphere due to the use of fluorocarbons in aerosols recommended that fluorocarbons in aerosols be banned. The State of Oregon has already banned their use. They are used as refrigerants in most chlorine liquification systems, and, of course, chlorine is used in their production.

Caustic Soda and Caustic Potash

The production of caustic soda has grown from 3,000,000 short tons in 1952 (3) to 11,000,000 short tons as 100% NaOH in 1976 (4). Caustic soda is all produced electrolytically now, whereas in 1952, 17% was made in lime-soda plants, which have since been shut down. The capacity has increased from 4,000,000 to 14,000,000 short tons per year. The trend in uses of caustic soda is shown in Table III. The major change is due to the reduced percentage used by the declining rayon industry.

Six of the 22 mercury cell plants and none of the diaphragm cell plants produced 226,800 short tons of caustic potash, as 88-92% KOH in 1976 (1). Nippon Soda Company Limited established an ion-exchange membrane process for caustic potash using du Pont's Nafion (R) membranes (7).

Developments—Mercury Cells

Through the 1960's there was very active development of mercury cells by Olin-Mathieson, Solvay, de Nora, Hoechst-Uhde, Krebs-BASF, and other companies in Europe and Japan. All of these companies designed mercury cells that were installed in America. The demand for larger plants and development of silicon rectifiers resulted in mercury cell designs up to 500 kA in capacity. Advances included anode designs for improved gas release, adjustable anodes, reduction in use of mercury, reduction in slope of the volt-ampere curve, which permitted higher current densities, operation at higher temperature due to the improved resistance of new rubber linings, improved packing for decomposers, and condensers on individual cells to cool hydrogen so that water and mercury return to the decomposer. Also, advances were made in improved cell layout to reduce the quantity of bus bar material and substitution of aluminum for copper bus bars and development of aluminum-to-steel connections, and optimization procedures using computer programs for cell and plant design. Anode adjustment progressed from individual anode adjustment to group adjustment, to remote adjustment, and finally to remote computerized control with overriding short-

circuit protection. The thickness of the mercury cathode changes with time, sometimes rather quickly, so that danger of touching the anode occurs. This was not serious with graphite anodes, but can melt and destroy metal anodes. Metal anodes have to be kept at a comparatively great distance from the cathode for safety unless short-circuit protection is provided. Fortunately, conditions for a short-circuit build up gradually. If changes in current distribution to groups of anodes are monitored, an impending short circuit can be corrected before a short circuit occurs by raising the anodes. Metal anodes have reduced the amount of cell cleaning required, the anode maintenance, mercury loss due to less "thick mercury," and brine treatment sludge. Cell voltages are less, so that energy efficiency is increased.

The Mercury Problem (6, 7)

Early in 1970, mercury loss from mercury cell plants was recognized in America as a serious hazard to the environment. The Chlorine Institute organized an ad hoc Mercury Committee of representatives of mercury cell operators in Canada and the United States. Effluent plant wastes were dammed up in most plants until methods for reducing and treating them could be developed and put in effect.

In a typical mercury cell plant, the sources of mercury loss were *(i)* brine treatment, *(ii)* drainage, *(iii)* thick mercury treatment, *(iv)* emissions from the cell room area and *(v)* entrainment with caustic and hydrogen. It was necessary to separate sewer and collecting systems for mercury-containing from mercury-free liquids Some systems could be recycled. The mercury-carrying liquids could be reduced and filtered or oxidized with hypochlorite and filtered. Reduced mercury is recovered by roasting the filtered solids and condensing the mercury vapor formed. Oxidized mercury is present as the soluble complex, the $HgCl_4^{=}$ ion, and can be absorbed on one of several proprietary resins, from which it is later recovered. Waste water can also be treated with sodium sulfide under carefully controlled *p*H and excess sulfide conditions, then settled and/or filtered before discharge to remove precipitated mercury sulfide (8).

Brine-treating sludge can be handled by several processes: hypochlorite and chlorine oxidation; electrolytic oxidation with brine; roasting; and acid digesting followed by roasting (8). A multiple-hearth furnace produced lower mercury sludge than an indirectly fired rotary calciner. "Thick mercury" is treated by distillation along with plant solids. Emissions from the cell room area may include effluents from end boxes, mercury pumps, and collection tanks, and ventilation air from the cell room and maintenance areas. A collection system under a slight vacuum is connected to the many vents. Vent gas is cooled and scrubbed with chlorinated brine, which can return dissolved or entrained mercury to the brine system. One proposal is to add a trace of chlorine to vent gas after cooling so as to form calomel, Hg_2Cl_2, which is caught on a suitable filtering material before releasing to the atmosphere. Special mercury adsorbent resins are also available for adsorbing mercury from the vent gas before releasing (7, 9).

Cell room ventilation air is the most difficult problem. Mercury gets into cell room air by evaporation of mercury spilled on the floor and cell parts, and from open cells during maintenance. Mercury exposure to workers was reduced by improving the surface of floors to improve efficiency of prompt cleanup of spills and instituting new procedures in cell maintenance, such as cooling a cell before removing its cover, and replacing it with a temporary cover while the regular cover was removed to a maintenance room. The maintenance room is connected to the vent system for mercury recovery. A multipoint mercury-in-air analyzer-recorder monitors the air exhausted from the cell room. Metal anodes became available about the same time as the mercury problem was recognized. Their use has reduced the frequency of opening cells for cleaning as compared to graphite anode practice, so this helped reduce mercury exposure. A reduction from 0.03-0.04 mg/m^3 to 0.002-0.004 mg/m^3 mercury in cell room air is reported by one operator (7). The current OSHA TLV for worker exposure is 0.05 mg/m^3, and, according to EPA emission standards, mercury emissions are not to exceed 2300g per 24 hr (10).

Both caustic soda and hydrogen contain mercury as they leave the cells. It probably is in chlorine also as entrained chloride, but this is removed in cooling and drying operations, and the chlorine water condensate is returned to the brine circuit. Mercury is removed from hydrogen by cooling and demisting. Then traces can be removed by several methods, such as adsorption on special resins (7, 9), and molecular sieves (11) or activated resin impregnated with KI or silver salts. Some adsorbents can be reactivated, while others are sent to the mercury calciner with other solids. In another process, trace of chlorine is added after cooling, calomel is adsorbed in a filter, and then the hydrogen is scrubbed with caustic soda before use. The calomel can be removed from the carrier by leaching with chlorinated brine, and is then reused. It can also be removed by calcining.

Mercury cell caustic was normally collected, settled, and filtered using diatomaceous earth or alpha-cellulose filter aids. The addition of a layer of activated carbon insured removal of mercury well below the Codex specification of 1 ppm on 100% NaOH basis (12).

Between July 1970 and end of August 1970, the total industrial discharge of mercury was cut from 287 to 40 lb/day. It is now estimated that, through recycling mercury waste, mercury discharges have been reduced at least 95% since early 1970 (13). A closed mercury cell process by Kashima Chlorine and Alkali Company will be used by Diamond Shamrock. Loss of only 1g of mercury per ton of chlorine has been reported (14).

Several mercury cell chlorine plants have been shut down in the United States and Canada. A new chlorine capacity has been built using diaphragm cells rather than mercury cells. In Japan, the government ordered conversion to diaphragm or membrane cells by March 1978. As of December 1976, 42% of Japan's 42 million metric tons per year of caustic soda was still made in mercury cells. The deadline may be extended because synthetic fiber makers will not accept the diaphragm cell caustic soda because of its high NaCl content. The program may even be scrapped because the mercury cell operators have reduced their emissions (1).

An excellent textbook on the manufacture of chlorine and its products has been published. The theory of both mercury cells and diaphragm cells is included (15).

Developments—Diaphragm Cells

Coated titanium anodes have been a great advantage to diaphragm cells. With graphite anodes, the anode-cathode gap increased as the graphite wore away. This increase in electrode gap increased cell voltage and heat evolution, and shortened the life of the diaphragm due to clogging the pores with graphite particles and chlorinated organics. First designs were substituted for metal anodes with similar dimensions to the graphite ones. This was improved upon by adding an adjustable feature (16).

A protected metal bottom supporting the metal anodes has replaced lead and mastic. Cell covers are now made of fiberglass-reinforced polyester. Teflon gaskets are used between cell parts. Asbestos diaphragms swell and become more porous due to loss of fine particles of asbestos. A thermoplastic material has been added to the asbestos to prolong the life of the diaphragm.

Ion-permeable membranes have been tested for diaphragms for many years, but failed to withstand

conditions in the cell. However, du Pont's Nafion (R) membrane material has changed this. Cells are in commercial operation producing up to 20% NaOH with low chloride, using Nafion (R) membranes. They are economical where dilute caustic soda can be used, as in paper mills. Asaki Chemical, in Japan, developed their own membrane material, a perfluorocarboxylic acid, that can produce a more concentrated caustic soda, 20-30%. They utilize hot caustic soda from the cell to supply part of the heat for evaporating the caustic soda to 50%.

Improved diaphragms and membranes as well as new cell designs are under active development here and abroad at such companies as Diamond Shamrock Corporation, Hooker Chemicals and Plastics Corporation, and PPG Industries, Incorporated in the United States, and Asahi Chemical Industry, Limited, Asahi Glass Company, and Tokuyama Soda Company in Japan.

Diamond Shamrock diaphragm cells (16).—Diamond Shamrock Corporation has been experimenting with DSA (R) electrodes since 1966, and they are distributed now by a subsidiary, Electrode Corporation. Cell components have been optimized including an improved current distribution system, assured parallel anode orientation, improved base design, expandable anode, FRP cover, and modified asbestos diaphragm. A comparison of two types of Diamond Shamrock cells is shown in Table IV. These cells can produce 360% more chlorine at 2.5% less power per ton on one-half of the original floor space. The modified asbestos diaphragm retains the good qualities of asbestos, and troublesome properties are reduced. It provides easier hydrogen evolution, prevents swelling, and has longer life, improved uniformity, and improved flow properties, is easy to remove, and can be stored up to 5 months before use. The modified asbestos diaphragm decreased power consumption 6.7%, and their expandable anode decreased it another 7.1%.

Diamond Shamrock has been working with du Pont on application of the Nafion (R) membrane and announced start-up of membrane cells to replace mercury cells at their Muscle Shoals, Alabama, plant. Production of 30-40% NaOH at 85% current efficiency is claimed (17). The first membrane cell installation with D-S membrane cells in Europe at Uddeholm's paper mill complex in Skogall, Sweden, for 20,000 metric tons per year of chlorine, has been announced for startup at the end of 1977 (18).

Hooker diaphragm cells.—Hooker Chemicals and Plastics Corporation has developed a number of diaphragm and membrane cells. Diaphragm cells include the H-2 (80 kA), HU-80, and H-4 (150 kA); the MX cell is a bipolar cell with Nafion (R) membranes. H-2 and H-4 are similar to previous Hooker cell designs, but are much larger in physical size and production capacity. These monopolar cells have a cubic shape with a plastic top, multifingered steel cathodes, and metal anodes. They have thinner, resin-bonded asbestos, [HAPP (R)] diaphragms, closer anode-cathode spacing, and improved electrical conductors. Cathode fingers go all the way across the cell, and are perforated steel plate instead of wire mesh. Current density has been increased from 1.0 A/in.^{2} (1.6 kA/m^2) to 1.5 A/in.^{2} (2.4 kA/m^2). Voltage has been improved, as shown in Table V (19).

Table IV. Performance of two types of Diamond Shamrock cells

Hardware	0.17	0.36
Diaphragm	0.16	0.30
	3.15	4.00

The HU-80 cell was designed together with Friedrich Uhde GmbH with geometry similar to a mercury cell, i.e., a long narrow cell shape, made for installation on columns or an elevated floor, with a jumper under the cells, close coupling of adjacent cells, minimum use of copper, and a rubber-lined cover. A prototype was tested from 50 to 100 kA (15.5-25 A/dm^2) to optimize asbestos and HAPP (R) diaphragms and all cell components. Operation showed a saving of 100 mV in the hardware at 25 A/dm^2 over H-2 cells. A commercial plant is being built, or is in operation, in Sweden.

The MX cell is the result of many years of experimentation with ion-permeable membranes. The promise of success came with metal anodes and du Pont's Nafion (R) membrane. Du Pont cooperated with Hooker in supplying various types of membrane material. Cells with Nafion membranes have been installed at its Tacoma, Washington, plant, and are in commercial operation at Reed Paper Limited, Dryden, Ontario, producing 45 tons per day of chlorine and 9-10% NaOH. Another installation of 73 tons of chlorine per day has been announced for construction at Toyo Soda.

The Dryden plant has 18 cell stacks, each stack operating at 3000A and 14V. Feed and product headers are part of individual plastic cell frames. A stack can be removed to a maintenance area for repair, but some work can be done in place, such as replacing a membrane in 2 hr. New designs operate in the range of 10-15 kA. Latest membranes will produce 30-40% NaOH, with 50 ppm NaCl impurity, on a 50% NaOH basis. Energy consumption is 2806 kW-hr/metric ton NaOH. Cell voltage is close to 4V, compared to 3.5V with diaphragm cells. Extra care in brine purification is required for membrane cells, and solid salt is required as raw material.

PPG-de Nora Glanor (R) electrolyzers (20, 21).—PPG Industries, Incorporated joined with Oronzio de Nora Impianti Elettrochimici in a development called the Glanor (R) Vertical Type 1144 Electrolyzer. It is an 11-cell bipolar electrolyzer, equipped with dimensionally stable metal anodes and cathodes of standard steel wire mesh. The first generation of commercial electrolyzers use deposited asbestos diaphragms, but PPG is actively working on improved diaphragm material and ion-permeable membranes, and has designed the cell to be adaptable to their use.

The anolyte compartment of each cell is connected to an independent FRP brine feed tank by flanged connections. Chlorine escapes from each cell through the brine feed tank. Hydrogen leaves the top of the cathode compartment of each cell, and cell liquor is discharged from a conventional inverted-U pipe system. A gasket of special elastomer insulates one cell from another, and the whole assembly is clamped together with tie rods to form a tight, essentially leak-proof unit. The electrolyzer rests on a steel frame supported on porcelain insulators. Each electrolyzer has a brine level alarm to monitor the level of all cells in the unit.

The bipolar electrode consists of a steel plate to which anode fingers are connected on one side and cathode fingers on the other. This bipolar electrode is set into an 18 in. wide steel channel frame, lined with titanium surrounding the anodes. The electrical connection between anodic and cathodic sections is said to

have a low voltage drop and low fabrication cost. The design is claimed to simplify maintenance including diaphragm depositing, assembly, disassembly, cathode washing, and inspection of electrodes. It is difficult to misalign the electrodes or damage the diaphragms because of features built into the unit and the use of simple assembly jigs and fixtures. A unit with conventional asbestos diaphragms operated 32 months with characteristics shown in Table VI. There were numerous shutdowns for external reasons, which the unit took easily. The unit is 17 ft long × 11 ft wide × 12 ft high over-all. It weighs 85,000 lb empty and 150,000 lb in operation. Conventional asbestos diaphragms have a life of 12-24 months. An automatic cathode washer was developed. The anodes are expected to last 4-5 yr before recoating. The titanium base should withstand a number of recoating cycles. An installation could consist of 8-20 electrolyzers in series, but 14 in 2 rows is suggested. They are placed end to end, 3-5 ft apart. The cell room would be 160 ft long × 80 ft wide. This cell room would produce approximately 415 tons per day of chlorine, so that floor space requirement is 31 ft^2/ton per day of chlorine (2.83 m^2/t/d). Electrolyzers can be elevated or on ground level depending on the transportation system preferred. An electrolyzer is short-circuited with a portable switch without interrupting the circuit. Interconnecting bus bar plates are removed, and the cell transported to a maintenance area. There are 4 plants in Japan and 1 in United States producing 200-500 tons per day in 76 electrolyzers totaling 2000 tons of chlorine per day, and 2500 tons per day are under construction or under contract.

Asahi Chemical's bipolar electrolyzer (22, 23).— In April 1975 Asahi Chemical Industry Company, Limited started operating a plant which put out 40,000 metric tons per year of caustic soda, using a bipolar cell with the du Pont Nafion 315 membrane and coated titanium anodes. Since then they have changed to their own membrane of perfluorocarboxylic acid. They licensed Denki Kagaku Kogyo Company, Limited, and that plant (putting out 60,000 metric tons per year of caustic soda) started in September 1976.

Asahi Chemical found that the maximum concentration of caustic soda obtained by the Nafion (R) membrane cell was 17.6%, at a current efficiency of 80%. Their own perfluorocarboxylic acid membrane can produce up to 40% caustic soda at high current efficiency, but optimum concentration is 21.6%. The membrane has a low electrical resistance. Voltage is less than 4V per cell at current densities of 40-60 A/dm^2 and current efficiency of at least 90%. Cells operate at 90°-120°C for optimum voltage. The membrane has sufficient mechanical strength and toughness so that it can be made in 4 × 8 ft sheets and used in their electrolyzer having a capacity of 10,000 metric tons of caustic soda per year.

Asahi Chemical also developed their own anode coating of a 3 component solid solution, which is over 50% ruthenium oxide plus oxides of titanium and another metal. This coating has a low anode potential and high alkali resistance. Anode and cathode compartments are separated by a partition of explosively bonded titanium and steel. The anode compartment is lined with titanium and the cathode compartment is steel. Vertical plates welded at right angles to the partition plate carry current to electrode surfaces; titanium on the anode side, and steel on the cathode side. Several holes in these vertical conductor plates permit electrolyte circulation. Expanded metal electrodes are welded to the vertical plates and to the channel, forming the rectangular frame around the unit. The voltage drop between adjacent electrodes is about 3 mV at 50 A/dm^2. The effective area of a single electrode is 270 dm^2, and the 32 ft^2 (297 dm^2) membrane is clamped between units using Teflon gaskets. The anode-cathode gap is 2-3 mm. Chlorine and hydrogen are released to the rear portion of electrodes and rise up in compartments behind the electrodes, so that the claim is made that voltage is not influenced by gas generation on electrodes. One electrolyzer has 80 bipolar cells clamped together, and has a voltage of about 300V at 10.8 kA.

Pure brine is fed into the bottom at one end of a unit, and depleted brine and chlorine leave through a pipe at the opposite top corner of the unit, and are then delivered to a collecting main above the electrolyzer. Circulating catholyte (dilute caustic soda) is fed into the bottom of the cathode compartment at the opposite end to the brine inlet. Catholyte and hydrogen leave through a pipe in the top at the other end and discharge into a collecting main, also above the electrolyzer. The collecting mains drain to anolyte and catholyte tanks where the gases and liquids separate. A part of the effluent brine is sent to the salt dissolving tank, and the rest is returned to the anode compartment. The amount of brine sent back for reconcentration is adjusted to maintain salt utilization at about 70%. Reconcentrated brine is conventionally purified, and then passed through a bed of ion-exchange resin for further removal of traces of calcium, magnesium, iron, and aluminum ions. Pure brine is added to the anolyte tank.

Caustic soda solution is recirculated between the cathode compartment and catholyte tank. Water is added to the catholyte stream to maintain the desired concentration. The optimum concentration of catholyte is 20-30% NaOH. Above 25% NaOH the membrane resistance increases sharply. A part of the catholyte is sent to the first stage of the flash evaporator, part of which is returned to the catholyte tank and part of which goes on to the second stage as product, which is heated by steam from the first stage. The final concentration of caustic soda is adjusted by using steam in a final, single effect vacuum evaporator. Considering steam and electric power combined, the optimum catholyte concentration is 21.6% NaOH. This heat recovery evaporator system uses 0.7 metric ton of steam to concentrate 21.6% NaOH to 48-50% on the basis of 1 metric ton of 100% NaOH, and 0.4 metric ton of steam to concentrate from 25% NaOH to 50%. Operating results for the 80 cell electrolyzer are given in Table VII.

Asahi Glass Company (no relation to Asahi Chemical Industries) and Tokuyama Soda Company are both working on membrane cells using membranes of their own development. The Asahi Glass Company cell (24), with their newly developed cation exchange membrane, has operated on a commercial scale since August 1976. It is a monopolar, filter press-type electrolyzer rated at 3000 metric tons of caustic soda per year. The membrane is 1.2 × 2.2m in size, with an anode-cathode gap of 2-3 mm. Membranes had a life of 2 yr on a pilot cell. It produces 40% NaOH containing 0.0009% NaCl. Extra pure brine is required. Pennwalt is de-

veloping a membrane cell system (25) which involves coating the anode in a mixture of asbestos and Kynar (R). In commercial use at one of Pennwalt's plants, the system gives 90% efficiency.

The Japan Soda Industry Association is sponsoring development work at Kyoto University on fused $NaCl$-$ZnCl_2$ electrolysis using a β-alumina diaphragm (25). Current efficiency on laboratory scale tests was almost 100%. Cell voltage at 50 A/dm^2 was 3.18V.

Electrolysis of Hydrochloric Acid

Chlorine is being recovered from byproduct hydrogen chloride with Hoechst-Uhde (27) electrolyzers at 4 plants in Germany and now one at Mobay Chemical, Baytown, Texas, which is increasing its capacity. The Hoechst-Uhde electrolyzer has 30-45 bipolar cells working at current densities of 4-5 kA/m^2. A cell consists of a frame of phenol or cresol formaldehyde plastic containing ducts for products and for inlet and outlet hydrochloric acid. Graphite plates are cemented into the frame to form bipolar electrodes. They have vertical slots on both sides to carry away gases. They rise to the top of the electrodes and pass through openings into proper ducts in the frame. Chlorine together with anolyte passes to one end of the assembly, and hydrogen together with catholyte goes to the other end. A diaphragm of PVC fabric is fixed to the sides of the frame. Rubber-lined steel plates clamp the cells together with tie rods. Electrical connections to the graphite plates in each end frame are made with graphite nipples through stuffing boxes. The electrodes have an effective area of 2.5m^2 and can use current up to 12 kA. An electrolyzer with 30 cells is approximately 3.5m long $\times$ 2.2m wide $\times$ 2.2m high.

The anolyte and catholyte operate in separate cycles, but each has a head tank, a run-down tank, circulating pump, heat exchangers, and filter. The filters remove abrasive particles and precipitates. The electrolytes are maintained at 20-22% HCl and 75°C for optimum results. Part of the 20% HCl from the catholyte cycle is sent to the absorption unit for enrichment to about 30% and returned to the two cycles as required. The two gases are first cooled, and condensed 8-12% HCl is then returned to the catholyte or anolyte cycle. After cooling, chlorine is treated as in alkali-chlorine plants. Hydrogen is scrubbed with caustic soda solution. The chlorine contains less than 0.1% hydrogen with new diaphragms, but they deteriorate after 2 or 3 yr and are replaced when hydrogen rises to 0.5% in the chlorine. Graphite anodes are not attacked in this service. For all practical purposes, any hydrogen chloride can be processed for use in the electrolyzer. Organic impurities have two kinds of effect. They may affect quality of products, or they may clog diaphragms and form deposits on electrodes. Some processing, followed by absorption on activated carbon, may be required. Inorganic impurities containing multivalent ions will reduce current efficiency. Sulfates may attack the anodes. The original article should be consulted for further details.

Chlorine Handling

There have been advances in practically every step of conveying, cooling, drying, compressing, condensing, and shipping chlorine. Chlorine-resistant plastics and titanium have been responsible for many improvements. Automatic analyzers for impurities in cell gas and moisture have improved safety in operation. The use of coated metal anodes has reduced organics in liquid chlorine.

Chlorine is collected from the cells under a slight vacuum in hard rubber-lined steel pipe or FRP plastic pipe. Cell gas is cooled in 2 stages, first with plant water, and then with chilled water, to about 15°C. Plastic or plastic-lined steel towers with ceramic packing may be used for countercurrent, direct-contact cooling with water circulated by plastic or titanium pumps through titanium heat exchangers. Efficient demisters between cooling and drying operations have reduced sulfuric acid consumption.

Drying is still done with 2 or 3 drying towers in series using countercurrent flow of sulfuric acid, starting with 93-98% H_2SO_4 and discarding about 70% H_2SO_4 at the bottom of the first tower to meet wet chlorine. Acid is cooled and recirculated through each tower. Teflon acid coolers and high alloy pumps are available for this service. Demisters are important after drying, particularly if centrifugal compressors are used.

Centrifugal compressors handling up to 600 tons of chlorine per day at 10 atmospheres pressure have superseded nonlubricated reciprocating and acid-sealed compressors. Designers have a choice between high chlorine pressure and relatively warm condensing temperature or lower chlorine pressure and lower condensing temperature. Freon refrigeration systems provide adequate choice. Noncondensible gas or "blow-off gas" is absorbed in caustic soda or milk of lime for bleach, or the chlorine can be absorbed in a chlorinated solvent system and regenerated. Liquid chlorine is distributed in cylinders up to 150 lb in 1 ton containers on flat-bed multiunit railroad cars of 15 tons total capacity, or in railroad tank cars of 16, 20, 55, 85, and 90 tons capacity or in barges up to 1200 tons. For short hauls, there are 16 ton tank trucks. Nearby consumers can get gas or liquid by pipeline. The two largest railroad cars and tank trucks are the most recently approved equipment. All cars, containers, valves, and safety devices used in transportation of chlorine are built to very rigid specifications, developed in cooperation with government agencies and chlorine producers through the Chlorine Institute.

Chlorates

In the past 25 years production has increased from 40,000 to 196,400 short tons per year in the United States. The production capacity is now 254,000 short tons and is increasing. There were 12 U.S. plants in 1976. In Canada, there were 11 plants with a total capacity of 226,000 short tons per year.

The trend in consumption is shown in Table VIII. Sodium chlorate's largest use is in combination with sulfuric acid and a reducing agent such as sulfur dioxide, methanol, or sodium chloride to make chlorine dioxide for bleaching pulp. Other chlorates are made from sodium chlorate by double decomposition and crystallization. Potassium chlorate is used in the manufacture of matches and pyrotechnics. Sodium chlorate is raw material for producing perchlorates. Sodium chlorate is used in weed control, but is being displaced by newer and more selective materials. Miscellaneous uses include textile bleaching, ore processing, and chemical processing.

The application of coated titanium anodes has stimulated new cell designs, permitted higher operating temperatures, and increased cell output. For example, Stanchem, the Canadian Division of PPG Industries, increased capacity 10% by installing metal electrodes developed jointly by Kema-Nord of Sweden and PPG.

Huron Chemicals Limited and Electrode Corporation have developed the EH 120 Multipolar Chlorate Cell Unit (28) (Table IX). With metal anodes, claims are made for improved energy efficiency, increased chlorate concentration ranges, elimination of filtration, and reduction in evaporation. Physical size has been reduced to 1/3 that of old graphite cells of equal

Table VIII. Trend in consumption of $NaClO_3$

Table IX. Operating characteristics of the EH120 cell unit

Current (kA)	10
Bipolar cells per unit	12
Volts per cell, depending on concentration	3.2-3.6
Total voltage (V/unit)	39-43
Current efficiency (%)	91-96
Dimensions: 3.0m high × 2.4m wide × 4.0m long	
Weight: 8600 lb (3900 kg) empty; 63,800 lb (29,000 kg) full	
Energy: C.E. 93.5%, a.c.-d.c. 3% loss, 600 g/liter $NaClO_3$, 100 g/liter NaCl, large plant with more than 3 units, 10 kA—5020 kW-hr/short ton	
Daily capacity for $NaClO_3$ production	3930 lb (1783 kg)

capacity. Units are now offered for 2, 3, and 4 tons nominal capacity of sodium chlorate per day. Two or more bipolar units operate in series electrically and chemically.

Brine with 300 g/liter NaCl and 350-400 ppm $Na_2Cr_2O_7$ is fed into the first unit, and product from the last unit contains up to 600 g/liter $NaClO_3$ and 100 g/liter NaCl. The pH of each unit is individually controlled between 6.5 and 7.5 by addition of hydrochloric acid. Temperature is controlled at 60°-65°C by water-cooled coils in each cell tank.

Several other new cell designs making use of metal anodes and new materials are undoubtedly available.

The electrochemistry and technology of chlorates and perchlorates up to 1969 was reviewed by J. C. Schumacher (29).

Perchlorates

Table VIII indicates that approximately 6000 short tons of $NaClO_3$ were used for perchlorates in 1955 and 27,000 short tons were used in 1974. The major use of perchlorates is as an oxidizer in solid propellants. Potassium perchlorate was used at first, but was superseded by ammonium perchlorate, which is now the most important. Lithium perchlorate has the highest percent oxygen, and has been tested as an oxidizer in propellants, but has not been accepted.

Sodium perchlorate is the principal raw material for the manufacture of perchloric acid and perchlorate salts. Because of the high solubility of sodium perchlorate, it need not be isolated from finished cell solution and can be purified for conversion by double decomposition to other salts. Perchlorate cells consist of steel tanks with cooling coils, which act as the cathode, and bright platinum anodes suspended from the cover.

A typical electrolyte feed is 400 g/liter $NaClO_3$, 400 g/liter $NaClO_4$ and 5 g/liter $Na_2Cr_2O_7$. Feed to the cells may be in parallel or series cascade. If in parallel, the electrolyte is circulated from a feed tank through the cells, is returned to the feed tank until the desired concentration is reached, and then a new tank is started. In series operation, the feed enters the first cell and then cascades from one cell to another, leaving the last cell at the desired concentration. The series system has the advantage that individual cells can be regulated with respect to temperature and current density for most economical production.

Most commercial cells use platinum anodes. Some cells use platinum-covered tantalum or copper. One manufacturer is reported to use lead dioxide anodes. The cells must then be made of nickel or stainless steel because chromate poisons lead dioxide anodes. Typical operating data are shown in Table X. The optimum operating temperature is a compromise. An increase in temperature lowers energy consumption but increases platinum loss.

Table X. Typical data for perchlorate cells (30)

Temperature	35°-45°C
Minimum feed rate	6 liter/min
pH	6.0-6.8
Cathode current density	30 A/dm
Voltage	6.5-7.0
Energy consumption	1.36-1.60 kW-hr d.c./lb
Sodium dichromate	2.5-5 g/liter
Calcium and magnesium	As low as possible
Final sodium perchlorate	As high as purification permits

Hydrogen Peroxide and Persulfates

In the manufacture of electrolytic hydrogen peroxide, ammonium bisulfate is electrolyzed with formation of ammonium peroxydisulfate, $(NH_4)_2S_2O_8$ (also known as ammonium persulfate). This solution can be used either for hydrolysis to hydrogen peroxide or for crystallization of the ammonium peroxydisulfate. Electrolytic hydrogen peroxide is now largely displaced by the chemical anthraquinone (AQ) or isopropyl alcohol processes (IPA). Of the eight plants in the United States making hydrogen peroxide in 1970, only three used electrolysis to make approximately 20% of the 164 million lb per year as 100% H_2O_2. Economics favor the AQ process in general. Ammonium peroxydisulfate must be made by the electrolytic process. No production data were found for the peroxydisulfate, so it may be included in the hydrogen peroxide figure.

Hydrogen peroxide is used for bleaching cotton textiles and some wool. It is also preferred for bleaching ground wood pulp over hypochlorite because it gives high yields of pulp. The uses in 1969 were distributed as follows: textile bleaching, 30%; pulp and paper bleaching, 8%; plasticizers and other chemicals, 26%; glycerine, 15%; miscellaneous, 21%. Other peroxydisulfates can be made by reacting the carbonate or hydroxide to replace the ammonium ion, which is evaporated as ammonia. Potassium, sodium, barium, and lithium peroxydisulfates have been produced in this way. Peroxydisulfates are used for polymerization catalysts, dye fixing, detergent additives, modification of starches, and desizing of textiles. Ammonium peroxydisulfate is used for etching printed circuits. The persulfates are shipped in multiwall paper bags and fiber drums (31).

Fluorine

Fluorine is used in the separation of U-235 from U-238 via UF_6 in the nuclear electric-power industry. It is also used in the manufacture of SF_6, a gaseous insulator for electrical and electronic equipment, and of Freon refrigerants. ClF_3 is used for chemical cutting of oil well casings. ClF_3 and OF_2 are rocket fuel oxidizers. Production of fluorine in 1974 was reported to be 137,000 tons and consumption was 689,000 tons. The annual growth rate of production was reported as 2 and 4% of consumption (32). No explanation was found for the difference between production and consumption in these figures. Plants are operated by Allied Chemical Company at Metropolis, Illinois, and Union Carbide Nuclear Corporation at Oak Ridge, Tennessee, and Paducah, Kentucky (33).

Potassium fluoride containing 40-42% HF is electrolyzed between carbon anodes and steel cathodes. Cells are jacketed and may have internal cooling pipes to maintain 95°C. Cooling water at 58°C is used to prevent crystallization of bifluoride on cooling surfaces. A metal skirt extends down from the cover to keep the H_2 separated from the F_2. A 6 mesh screen below the skirt prevents broken anodes from short-circuiting a cell. It was found that this screen also improved current efficiency. Anodes are 2 × 8 × 20-5/8 in. carbon blades bolted to AISI-4140 steel bars using bolts of the same steel and copper pressure plates. Each anode bar has three 1-1/8 in. copper conductor posts extending through insulating packing glands in the cover. This connection has been a source of trouble, but anode life has been improved to 20 million A-hr. Typical data for a Union Carbide cell are shown in Table XI.

Table XI. Typical operating data of the fluorine cell

Current (kA)	4	6
Operating voltage	8-12	9-12
Temperature (°C)	90-105	90-105
HF in electrolyte (%)	40-42	40-42
Anode area (dm²)	390	390
Current density (A/dm²)	10.3	15.4
Anodes (no.)	32	32
Life of anodes (A-hr)	16×10^6	15.5×10^6

HF and CF_4 are removed from liquid fluorine to less than a total of 0.2% by refrigeration to −140°C. HF can also be removed by passing through NaF in a scrubbing tower. The fluorine is liquified under pressure and low temperature.

Handling fluorine

Nickel, Monel, aluminum, magnesium, copper, brass, stainless steel, and carbon steel are used for handling dry fluorine. All except carbon steel are good down to −190°C. Nickel and Monel are good up to 550°C. aluminium to 450°, magnesium to 400°, stainless steel and carbon steel up to 250°C. Tetrafluoroethylene (Allied's Halon TFE and du Pont's Teflon) are resistant to gas under static conditions.

Equipment must be thoroughly cleaned, such as by flushing with trichlorethylene and then purging with nitrogen. The surface must be passivated by flushing out the nitrogen with fluorine. After 2 hr the equipment surfaces will be passivated. Carbon steel is used for fluorine gas and stainless steel for liquid fluorine. Soft copper or aluminum gaskets are used for flanged connections that have to be broken. Liquid fluorine can be transferred by pressurizing with helium. Nitrogen is unsatisfactory because it is soluble in liquid fluorine.

Fluorine gas is shipped under 400 psi in 6 and 4-1/2 lb steel cylinders. Special liquid nitrogen-cooled Dewar steel tank trucks for 5000 lb of sealed liquid fluorine are approved for use under carefully controlled conditions.

Manganese Dioxide (33)

World production was estimated to be 83,000 tons of synthetic manganese dioxide in 1976, of which Japan produced 40,000 tons and the United States produced 25,000 tons (34). Electrolytic manganese dioxide is used in high capacity batteries where weight and size are of great importance.

Reduced oxide ore is leached with spent electrolyte containing 50g $MnSO_4$ and 67g H_2SO_4 per liter at 90°C. After purification, the solution containing 150g $MnSO_4$ per liter is mixed with an equal volume of spent electrolyte and is fed to electrolytic cells at such a rate that outlet electrolyte is 50g $MnSO_4$ and 67g H_2SO_4.

American cells are graphite lined with graphite cathodes and graphite or titanium anodes, spaced 1 in. apart. The dioxide builds up as a dense, coherent, 6 mm thick or more black coat on the anodes before it is stripped. Cells are covered and maintained at 90°C. Current density is 6-10 A/ft^2 (0.6-1.1 A/dm^2), and current efficiency is normally 80-90%. Stripped oxide is crushed, neutralized with ammonia, soda ash or caustic soda. It is dried cautiously so as not to remove combined water, which would decrease depolarizing activity of the manganese dioxide.

Summary

Advances over the past 25 years in production of sodium hypochlorite, caustic soda, sodium methylate, caustic potash, chlorine, sodium chlorate and perchlorate, ammonium peroxydisulfate and hydrogen peroxide, fluorine, and manganese dioxide are covered. Electrolytic hydrogen peroxide has mostly been displaced by chemical processes during the time period reviewed. Coated titanium anodes in chlor-alkali and chlorate cells are replacing graphite, thus decreasing energy use and cell size. Concern about the effects of mercury and asbestos in the environment has resulted in a shift to modified asbestos diaphragms and membrane cells for chlor-alkali. Silicon rectifiers, centrifugal compressors, titanium, corrosion resistant alloys and plastics have all contributed to advances.

Twenty-Five Years' Progress in Electrowinning and Electrorefining of Metals

G. M. Cook*

Kennecott Copper Corporation, Ledgemont Laboratory, Lexington, Massachusetts 02173

During 1952, the fiftieth anniversary of The Electrochemical Society, several reviews of electrowinning and electrorefining processes were presented in the **Journal.** H. N. Gilbert (1) discussed the history of electrolytic sodium production, J. D. Edwards (2) examined 50 years of development in the Aluminum Industry, W. S. Loose (3) reviewed the 36 years of industrial magnesium production, and A. C. Loonam (4) wrote about the progress that occurred in the electrolytic production of other metals over the 50 year period. By 1952, the electrolytic production of metals was a mature industry. Mantell (5) gives a good description of the commercial electrolytic plants operating at that time. Since then only a few metals such as antimony, zirconium, and titanium have been added, even to the list of those obtained at pilot scale. ASARCO has recently completed a plant for the production of antimony (6). AMAX and Titanium Metals Corporation of America (TIMET) have both produced zirconium at pilot scale (7); and TIMET (6) and New Jersey Zinc (8) have both demonstrated titanium sponge production. The results obtained at TIMET (9) indicate that an electrolytic titanium process is competitive with the Kroll process. In an effort to improve product quality, Alcoa and Moly Corporation, together piloted a Bureau of Mines method for the pilot scale electrolytic production of pure rare earth metals (10). For the most part, the final commercialization of these processes is waiting for an increased demand to require the construction of new facilities.

Process and equipment developments (11-16), on the other hand, have resulted in numerous improvements in the electrowinning and electrorefining of the commodity metals: aluminum, magnesium, sodium, copper, nickel, and zinc. Several improvements have been made in electrolytic plants in general. The following items summarize these improvements and are considered further in the discussion of particular metals.

(*i*) Silicon rectifiers have been used to obtain improved reliability and energy conversion efficiencies on the order of 97% compared with about 94% for mercury arc rectifiers.

(*ii*) Larger cells or increased cell throughput have resulted in increased energy efficiency and improved materials handling.

(*iii*) Increased automation has improved the reliability of electrolytic processes and reduced operating costs.

(*iv*) Improved methods for feed material purification have reduced operating costs and increased yields.

(*v*) Modifications of cells have permitted the use of higher current densities in conventional tankhouses or extraction from low metals content electrolytes in plants of novel design.

(*vi*) Changes in electrodes have been used to increase anode life or metal purity.

* Present address: Argonne National Laboratory, Argonne, Illinois 60439.

Background

The primary emphasis in this review is on the impact of developments in electrolytic metal production upon technology in the United States. As a result of the various technical and economic developments over the past 25 years, there has been a great change in the relative importance of the major electrolytically produced metals. This is reflected in the growth of capacity and consumption for the commodity metals (6, 7, 17). Table I shows the change in the electrolytic plant capacities over the past 25 years. Figure 1 shows the variation in the quantities of the electrolytic metals consumed over the past 50 years. There are basically two categories of metals; the high growth metals which have increased at roughly 9% per year and the low growth metals which have increased at only about 1-2% per year. Magnesium production growth has been rapid and very erratic primarily due to variable military and space requirements. Though aluminum production has grown rapidly, it has been affected to a lesser degree by military requirements. Copper, zinc, and sodium, the low growth metals, have been minimally affected by noncommercial needs.

Much of the economic impact of the metals produced electrolytically in the United States arises in the fabrication steps. In order to put the several metal industries into perspective, it is instructive to examine the statistics for electrolytic metal production in the United States during 1974-1975. This comparison is given in Table II. From these data, it is seen that even though the value of these metals as a group is only about 4/10 of 1% of the gross national product, the impact on the electrical energy consumption is an order of magnitude greater, at over 4%. The increasing cost of this energy has a direct impact on the operating costs of these processes. It is particularly important to aluminum, magnesium, and sodium, which consume large amounts of energy in their electrolytic pro-

duction. Indirectly, the capital investment costs also increase with energy costs. This cost factor is more important to the metals which consume proportionately less energy in the electrolytic step.

In addition to energy, environmental concerns have had an impact on both operating and capital costs by imposing lower emission requirements on production plants. These new requirements have resulted in the need for new processing methods which reduce the emissions to an acceptable level. This has caused the shutdown of outmoded plants on the one hand, and the construction of new electrolytic plants on the other.

Also in the area of environmental concern, both industrial and environmental groups have become aware of the need to increase the extent of recycling of metals to reduce the amount of metal discarded. However, the statistics for the electrolytically important metals, except nickel, do not show a significant increase in the percent of metals recycled over the past ten years. Table III is based upon total scrap recycle. Kellogg (18) indicates that the total scrap recycle includes new or industrial scrap, with nearly 100% recovery, and old or product scrap with a

Cobalt	1.6	1.6
Magnesium	14.2	19.5

highly variable recovery. Typically, old scrap represents 20-25% of metals recycled. (Since year-to-year variations are considerable, Table III gives the 5 year averages for the two time periods.) A great deal of effort is likely to be required to change these percentages drastically. In the case of aluminum, many of the more recent applications have resulted in greater dispersion of the metal (*e.g.*, beer cans). Very recently, industrial efforts have increased the efficiency of collection of used cans to the point where over 25% recycle is obtained.

Fused Salt Systems

The commercial electrolytically recovered metals fall naturally into two categories: (*i*) those obtained from fused salt electrolytes at a high energy cost and (*ii*) those obtained from aqueous solutions at a relatively low energy cost. The fundamental differences between these two categories lead to differences in the technological innovations that are required to improve the recovery processes. On the one hand, operating costs are minimized with fused salt electrolysis, while on the other hand, capital costs are reduced when aqueous systems are used.

The metals produced in large quantities by fused salt electrolysis are aluminum, magnesium (19), and sodium. Much smaller quantities of beryllium (20), calcium, lithium, mischmetal,[1] and uranium are electrowon (21, 22), and pilot scale processes (7) have been used to win hafnium, individual rare earth metals, titanium, and zirconium. Of all these metals, only aluminum is not produced primarily from a chloride-based electrolyte. However, a fused chloride electrolyte is now being used in commercial production even for aluminum.

In recent years the emphasis in the area of electrowinning from fused salts has been in the development of anhydrous chloride electrolytes to reduce energy consumption. In such electrolytes, it is possible to use permanent, chlorine-producing electrodes. This is in contrast to the older processes in which consumable carbon anodes were used to produce CO and CO_2 from the oxygen-containing feed materials. In addition to the savings in carbon, there has been significant reduction in the electrical power consumed for electrowinning.

Aluminum.—During the past twenty-five years, the production of primary aluminum in the United States rose from less than 1,000,000 short tons to nearly 5,000,000 short tons in 1974. In the past two years, the general lessening of economic activity has resulted in significant decreases in the production of all metals. In the case of aluminum, it dropped to below 4,000,000 tons per year in 1975. In spite of this recently reduced demand, the average annual growth rate in the aluminum industry has remained very high at approximately 9%. At the same time, the process has remained essentially unchanged from that invented by Charles Martin Hall in 1886. Modifications in cell design and anodes, and the use of LiF additions (23) to the electrolyte have been important in reducing the energy consumption. The most important modification was simply increasing the size of the individual cells in order to approach adiabatic operation more closely,

[1] Mixed rare earth metals.

thereby reducing the heat losses. During the past 25 years, nearly 95% of the reduction in energy consumption can be attributed to this change. In 1952 the consumption was about 8.5 d-c kW-hr/lb, whereas in 1977, it is estimated to be about 6.5 d-c kW-hr/lb in the better plants. If the Alcoa chloride process lives up to its promise, the power could be reduced even further, to about 4.5 d-c kW-hr/lb. This reduction in the energy consumption is essential to the aluminum industry because aluminum, more than other metals, has been produced in the past using very low cost power. As such a user, it is likely to see higher than average increases in power cost.

A great deal of research and development effort has been directed to the reduction of energy consumption. The conventional aluminum process has been modified and new processes developed. The basic technology of the Bayer-Hall-Heroult aluminum production process has been extremely successful. However, it has shortcomings in addition to its low energy efficiency. The BHH process itself is somewhat capital intensive and the installation of newly required pollution control equipment in existing plants is expensive.

A number of modifications are being made to improve the BHH process (9). These are currently in pilot test by Kaiser Aluminum and Chemical Corporation and in production by Sumitomo Chemical Company. The newly designed plants will include: prebaked anodes; increased anode area; graphite linings on electrodes; computer control of electrode spacing (24); increased control of electromagnetic effects; minimized heat losses; and improved hooding. These factors are expected to lead to an energy consumption of less than 6 d-c kW-hr/lb, a greater on-line time, and a lower labor requirement. Further improvements might be possible by using permanent cathodes such as TiB_2 operating with only a thin layer of liquid aluminum which would permit the use of smaller interelectrode distances. The thick aluminum layer, used in conventional cells, is subject to erratic oscillations by the magnetic fields related to changes in current density.

In spite of these improvements in the BHH process, other competitive processes are on the horizon (25). These other processes use $AlCl_3$ in various steps. Three of these are not electrolytic. The Alcan process (a 5000 TPY pilot plant was operated in 1968) and a "monochloride process" (laboratory scale) proposed by Peacey and Grimshaw both depend upon the high temperature (1300°-1800°C) stability of AlCl and its relative instability at 700°C according to the equilibrium.

$$2Al(l) + AlCl_3 \rightleftarrows 3AlCl$$

The third proposed process (26) for the production of aluminum is the Toth process which depends upon the reduction of liquid aluminum chloride with manganese metal. This process is likely to be costly and to have difficulty meeting purity specifications.

The most promising chloride process is the Alcoa smelting process in which a fused salt mixture, possibly NaCl-LiCl-$AlCl_3$, is electrolyzed in a cell of novel design. This cell reportedly uses bipolar electrodes, thus increasing the number of electrodes per unit volume and thereby reducing plant space requirements and energy consumption. This novel process, as does the BHH process, starts with alumina. However, the alumina is first reacted with coke and chlorine obtained from the electrolysis cell to produce $AlCl_3$. The $AlCl_3$ is sent to the electrowinning cell to produce aluminum and chlorine. A side benefit of the process is a greater tolerance to interruptions of the power to the system, and thus it might be amenable for use as a method for load leveling for a utility facing periodic high demands for power.

Magnesium.—Magnesium consumption has also grown rapidly during the past twenty-five years. Its growth as an export metal has been even more explosive. In 1952, the exported metal amounted to less than 3% of the United States consumption. By 1975, it had reached 35% of internal consumption. Thus while internal consumption and imports grew by a factor of 3, exports grew by a factor of 30. The continued rapid growth of magnesium can be expected as new facilities operate with lower production costs and the demand increases for strong, light-weight aluminum alloys in automotive applications.

A problem which has been associated with magnesium production since it was first produced is that of the presence of water or oxide. The Dow Chemical Company used $MgCl_2 \cdot 1\frac{1}{4}\ H_2O$ to $\cdot\ 1\frac{3}{4}\ H_2O$, as feed to the electrolytic cells. This resulted in the production of mixed gases at a consumable anode. Continuing efforts are being expended to work with anhydrous $MgCl_2$ which permits the use of permanent anodes and produces Cl_2 as a by-product. Under the proper conditions, the additional cost of producing the anhydrous $MgCl_2$ feed is more than offset by lower operating costs. Manpower requirements are reduced since the electrodes are not consumed, thereby requiring less systems work. Electric power consumption is reduced by about 40% since the electrodes are closely spaced. In addition, a credit of 2-9% of the magnesium cost is obtained from the chlorine. The details of the production of magnesium are highly confidential, but general processing descriptions (27, 28) indicate that the trend of future production plants is, indeed, toward the use of anhydrous $MgCl_2$. If a low cost process for producing this metal is to be found, the energy consumption for magnesium production must be greatly reduced.

Sodium.—The production of sodium continues to be carried out primarily by the Downs process. The United States growth rate has been only about 1.5% per year. A depressing feature has been a reduction in the demand for tetraethyl lead, the production of which is the primary user of sodium metal. On the other hand, world consumption has been growing. As a result of this growth, the Tekkosha Company developed a staged aqueous/fused salt electrolysis process which reduces energy consumption, labor requirements, and corrosion problems (29). The first commercial plant went on stream in 1971.

The three stages of this process are: (*i*) Brine electrowinning of sodium to form a mercury amalgam; (*ii*) 240°C fused slag, NaOH-NaI-NaCN, electrorefining of the amalgam to produce a crude sodium; and (*iii*) purification steps to remove mercury and calcium. The low temperature operation improves the system operability and the operating environmental conditions. At the same time, a 20% reduction in energy is obtained. In addition, it appears that this process could be adapted for use with conventional chlorine-mercury cells to produce sodium metal instead of NaOH. If possible, this would lead to an improved flexibility in the productive capacity for sodium.

Rare earth metals.—Mischmetal is the only rare earth metal product produced in large quantities. The growing demand for rare earth-cobalt magnets, ductile iron (15% increase per year in 1973) and high strength low alloy steel (50% increase in 1973) is expected to provide a large increase in the demand for rare earths (7). A pilot scale joint venture of Aluminum Company of America and Molycorp evaluated the United States Bureau of Mines developed process (10) for the production of pure rare earth metals. The electrolyte used consists of a lanthanide suboxide (Ln_2O_3) plus fluoride dissolved in a mixture of BaF_2 and LiF. The 99.9% purity metal (cerium or lanthanum) was obtained at 75-95% current efficiency compared with the 45-50% typically obtained from the conventional chloride-based electrolyte. To date, the market for rare earth metals has not increased to the point where further development of this new approach is economically justified.

Titanium.—In 1952 a question was raised concerning the possibility that titanium and other "rare" metals might be electrowon from fused salt electrolytes. Since that time, the domestic production of titanium sponge has grown from a few hundred tons annually to roughly 21,000 TPY in 1974, or about 19% per year. Commercial production still is carried out by the Kroll process. However, electrolytic pilot plants have been operated by the New Jersey Zinc Company (8), Howmet Corporation, and Titanium Metals Corporation of America (TIMET) (9). The TIMET Division itself has produced several tons of electrolytic sponge. The process (30) offers lower energy and simple pollution control. A small bleed stream of valuable by-products is treated for secondary recovery. As the market improves, it is quite likely that some of the new capacity will be electrolytic.

Aqueous Systems

No new metals have been produced by the commercial electrowinning and refining of metals using aqueous solutions. New processes have been developed; and many processes, some of which were developed over 75 years ago, have been modified only slightly to build the aqueous electrolytic metals industry that exists today. The following examines the changes that have occurred and those that are on the horizon for introduction into commercial plants in the coming years (11-16).

With aqueous electrowinning and electrorefining, the major development efforts have been directed toward obtaining metal: at higher than conventional current densities (31), by using new cell designs (32-38); from new sources such as dilute solutions (39-43), sulfide anodes (44-46), and so forth; and with less manpower, by automation (46).

Many of the developments have a rather general applicability. For example, high surface area packed or fluidized bed cathodes (32-34) have been studied by several investigators. Pilot plant results indicate that these cathodes are economical for obtaining copper, gold, nickel, and cobalt from solutions containing less than 10 g/liter of metal. The metals are removed at relatively high rates and with low power consumption.

The metal content of dilute solutions has been recovered in two ways: (*i*) high surface area electrodes have been used when the solution contains only a single electrorecoverable species (40); and (*ii*) liquid ion exchange is used to separate and concentrate recoverable species (39, 41-43). The concentrated solutions are then amenable to conventional electrowinning.

Ore concentrates have been used as anode material. The first commercialization of such a process was the use of high metal-content nickel sulfide anodes (44) by INCO to produce a cathode grade nickel. Cymet (45) and Envirotech (46) have examined "pulp" anodes which use sulfide ore concentrates. The importance of this approach, rather than a simple leach-electrowin process, is that the rate of metal dissolution is synergetically enhanced so that the leach time can be significantly reduced.

Another factor of major impact is the use of various automated procedures to reduce manpower requirements. A high level of automation has been achieved at Mitsubishi's Naoshima Copper refinery (47) where no personnel are required to work within the operating tankhouse. This may be an example of tankhouses of the future. The first applications of automation that have appeared in more conventional copper and zinc tankhouses are for stripping cathode blanks, electrical short inspection, and loading and unloading cells. A more detailed review of developments follows with the discussion of the production of various electrolytic metals. It is important to realize, when reading these paragraphs, that much of the equipment has broad application even though it is discussed with emphasis on a particular metal.

Copper.—Since 1952 the actual cathode production has increased only slightly in the United States. At the same time, however, the electrolytic copper refinery capacity has increased by 66%. The changes in the methods for electrorefining copper have been minor until the past 10-15 years (48-52). These recent improvements in commercial plants include the following: The changeover to silicon rectifiers for d.c. power is nearly complete. The use of automatic stripping of blanks is progressing rapidly. Automated short detection is obtained in a few plants by infrared scanning of the cells or by computer analysis of cell electrical parameters. Titanium blanks are increasingly specified for starter sheet production and have also been used to produce full term (80-120 lb) deposits. Higher electrolyte circulation rates with careful filtration have permitted some producers to use current densities as high as 325-375 A/m^2. Periodic current reversal has also been used with current densities of 325-375 A/m^2. This technique has reduced the incidence effect of dendritic shorting. The deposit which results has an acceptable, though rough, surface. Other modifications include half cylinder rather than triangular electrical contact bars, plastic instead of lead liners for tanks, plastic capping boards to replace the wooden ones, and aluminum bus bars when the cost of copper was especially highly priced.

Electrowinning is becoming increasingly important since purification and concentration of dilute copper-containing solutions have become possible by using a liquid ion exchange (LIX) step. This process has required significant development efforts to improve cathode quality. Since this copper has not generally been considered to be of "cathode quality," it has not been included in production statistics. The basic failure to meet this standard is the almost invariably high lead content of the copper which has been electrowon. Only recently has Cyprus Mines Corporation been able to sell electrowon copper from two production plants as cathode.

The presence of the high acid electrolytes used in the LIX-electrowon process and the other operating conditions (typically 200 A/m^2 and 40°C) generally produce a product which is contaminated with lead slimes to the extent of about 6-12 ppm lead. The quality is generally high with respect to other impurities. Two approaches have been taken to alleviate this problem: (*i*) reduce the amount of lead in the suspended slimes, and (*ii*) substitute other anodes for the commonly used lead.

Two successful approaches have been taken to reduce the amount or effectiveness of lead in the suspended slimes. In the first approach calcium-lead anodes have been used to replace those of antimonial-lead. The lower corrosion rate in some electrolytes and the improved morphology of the PbO_2 formed on the surface have resulted in lower lead contamination of the copper product. The second approach is the addition of cobalt to the electrolyte, at the rate of 60 mg/liter-2 g/liter. It also improves the PbO_2 morphology.

Efforts have also been made to eliminate the lead substrate by using anodes of titanium with a precious metal catalyzed surface. These are similar to the dimensionally stable anodes used in the chlorine industry. At the present cost, it would be very difficult to justify the use of such anodes for the winning of common metals. As a result, MnO_2 and PbO_2 surfaces have been developed with some success. The remaining major deterrents to the use of these anodes are the brittleness of the deposits, the solubility of MnO_2, and the higher cost of titanium. However, if the use of calcium-lead anodes and cobalt additions to the electrolyte is found not to produce a satisfactory low lead content in a particular copper product, the development of titanium anodes may offer an alternative.

In addition to the preceding developments, which have been applied to improve the performance of existing electrolytic copper production plants, pilot scale

and laboratory work have been carried out to improve future plant performance even more. Much of this developmental work is directed toward the recovery of copper by other means. These include: several techniques to use high current densities with conventional electrolytes; particulate cathodes to permit copper recovery from dilute solutions at reasonable current densities; direct concentrate electrorefining to cathode copper; electroforming during refining (53), and series electrowinning and electrorefining. In addition, laboratory investigations are continuing in the areas of univalent copper electrodeposition by Duval, tapered-profile anodes by INCO and SO_2 depolarized anodes by Conoco. It is reasonable to expect some of these pilot plant and laboratory developments to become part of commercial practice in the next twenty-five years.

At the present time, conventional copper electrodeposition plants are not operating at the optimum current density. Several authors (34, 36) have estimated the optimum range to be 700-1000 A/m^2 rather than the present 200-250 A/m^2. In order to operate at such high current levels, it is necessary to improve the mass transport at the electrode surface. Several approaches have been tried (31). Channel cells with very high fluid flow which require very close electrode spacing, ultrasonic agitation which requires a high energy input and mechanical stirring which requires oversized cells have not been demonstrated to have commercial application. The commercial use of direct flow in the CCS (or SEC) process developed by Continental Copper and Steel Industries, Incorporated, has produced smooth dense deposits at 500 A/m^2. Air sparging on the other hand has been revived by INCO, Kennecott Copper Corporation, and the National Institute for Metallurgy in South Africa. In all cases, it is suggested that operation at 1000 A/m^2 produces high quality copper and is economically attractive. It is anticipated that air sparging will be used commercially in a few years. If such a technique should become commercial on a large scale, it is conceivable that new tankhouses would be built only because of location, or obsolescence, not because of need for increased productive capacity.

Particulate bed cathodes are another area of very active development. In such electrodes, the deposition occurs over some finite bed depth rather than solely in a plane, as in conventional electrodeposition. Therefore, the true electrode area is many times the cross-sectional area. In this manner, the copper contained in dilute solutions can be directly electrowon. A pilot scale fluidized bed electrode has been evaluated by Constructors, John Brown Limited. It has achieved low power consumption with solutions containing 0.5-3 g/liter copper at current densities of several thousand amperes per square meter. However, below 0.5 g/liter the energy consumption rises as side reactions become more important. Kennecott Copper Corporation has been evaluating a pilot scale, packed-coke, bed electrode. It is capable of recovering, with relatively low power consumption, greater than 95% of the copper from solutions containing 0.5-1 g/liter copper in a single pass through the bed. At concentrations below about 0.6-2 g/liter, it appears to be economically competitive with LIX electrowinning.

A final area of development is the use of sulfide concentrates or matte as anodes. These efforts, by many workers, have intensified somewhat since the INCO success using nickel matte anodes in 1961. Two pilot scale cells have been operated by Cyprus Mines Corporation (Cymet Process) and Envirotech Corporation (Electroslurry Process). Precious metal (DSA) anode collectors have been used in both systems with current densities in the range of 800-2200 A/m^2. The copper is not of electrorefined cathode quality. The economics of the process may be reasonable for small production plants using chalcocite concentrates. Further work is needed to evaluate the effect of using other minerals and that of minerals with other impurity contents.

Zinc.—The United States capacity for electrolytic zinc production is almost exactly the same now as it was twenty-five years ago (54), with a corresponding increase in the dependence upon imports. According to "Metal Statistics" (6) the capacity for electrolytic zinc production peaked eight years ago at a level about 50% higher than that of the present. However, the indications are that there will be a rapid rise in the United States electrolytic zinc capacity over the next ten years.

At the present time, the pollution problems associated with pyrometallurgical treatment of zinc and zinc concentrates puts it at an economical disadvantage. As a result, during the past eight years a new generation of electrolytic zinc plants has come on stream (55-60). While capacity in the United States dropped, worldwide over 1½ million short tons per year of capacity has been added. This capacity in foreign countries and the general economic doldrums have combined to slow the recovery in the United States.

Much of the improvement in the new generation zinc plants is in the concentrate preparation and hydrometallurgy (61, 62) rather than in electrowinning. Concentrate preparation consists of several steps. Preleaching is sometimes used to remove magnesium. This is followed by fluid bed roasting with sulfur emissions control. A new development is the use of zinc oxide slurry in the SO_2 scrubbers. For the electrowinning plant, the zinc-rich solution is obtained in two stages. The conventional neutral leach is followed by a hot acid leach. The hot acid leach was developed in the late 1960's to obtain the zinc which was previously lost as zinc ferrite. The iron in this leachate is removed as the sodium or ammonium jarosite or as Goethite while the acid solution is returned to the neutral leach step. In this way, zinc recovery can be increased by several percent.

As already mentioned, the changes in the tankhouse have been relatively minor. For example, even though current densities in excess of 800 A/m^2 are used in some plants, the average current density remains at about the same levels as the mid-1950's, about 400 A/m^2. Operational and electrolyte purity improvements have resulted in longer stripping cycle times. In the 1950's it was on the order of 24 hr, whereas 48 hr is more common at the present time. The existence of this short cycle time has encouraged the development of automatic cathode handling and stripping equipment.

Nickel.—Electrolytic nickel production is presently of negligible economic importance in the United States, with less than 200 tons per year produced. However, the hydrometallurgical techniques for nickel recovery from lateritic and manganese nodule sources are being rapidly developed. It is very likely that nickel will be obtained from LIX treated solutions and that electrowinning of the metal will be carried out on a significant fraction of this solution.

On a world-wide basis, the methods for electrorefining nickel metal have changed little in the past twenty-five years (46). The major innovations have been in electrowinning. Three electrowinning processes are operating to produce nickel on a commercial scale.

In 1961 INCO's electrolytic refinery at Thompson, Manitoba began operation. The novelty of this plant is its use of nickel sulfide anodes. The 20% sulfur, 76% nickel matte is cast directly from the converters. Even with careful cooling the anodes are somewhat fragile. These anodes are placed in bags to collect the voluminous sulfur sludge. The cathodes are placed in cathode boxes into which the purified electrolyte is directed. Electrolysis is carried out at about 220 A/m^2. The cell voltage which initially is roughly 2.8V, climbs as the anode sludge builds up. By the end of the anode life the voltage is nearly 4V.

The Outokumpu process has been used since 1960 to electrowin nickel in cells using insoluble anodes. In

this process the high grade, 65% nickel 28% copper, matte is leached, purified primarily by controlling the process chemistry and electrowon. During electrowinning, the nickel content of the solution is reduced from 75 to 50 g/liter. Consequently, the acid content of the effluent from the cell is about 50 g/liter. This requires that the electrolyte composition at the cathode be controlled. It is accomplished by placing the cathodes into tightly woven bags into which the feed electrolyte is introduced. The result is about 94% current efficiency at 190 A/m^2 with the production of very pure nickel.

In 1971 SEC Corporation became the only commercial producer of electrowon nickel in the United States (37). The small plant produces about ½ ton per day from a refinery waste stream. There are two novel approaches used in the plant. First, the pure nickel electrolyte is obtained by using a liquid ion exchange process to extract the nickel from the waste stream followed by stripping into a nickel electrowinning solution. Secondly, the electrowinning cells are modified to use directed solution flow, which permits operation at 380 A/m^2. By using a 3 g/liter drop in nickel content, there is a very slight increase in acid content. Therefore, the SEC approach eliminates bagging of the cathodes.

The developments in nickel recovery have been significant over the past twenty-five years. It is also likely that the use of new sources of nickel and the use of new technologies, such as that of SEC Corporation, will result in further development over the next twenty-five years.

Other metals.—The United States production of other metals by electrodeposition from aqueous solutions has changed little since 1952. Improvements and other changes in the related area of electroplating are discussed in a separate review. The following three items conclude this review. Two are processes which are speculative or at least not reported upon; the other is a description of a modified and expanded production plant.

Cobalt electrodeposition has not been greatly developed since cobalt generally occurs as a by-product in nickel or copper. The metal is often obtained by hydrogen reduction of solution. In addition, the oxide is frequently an acceptable source of cobalt. Generally, one thinks of cobalt electrodeposition as being similar to that of nickel. However, the deposit is usually brittle and difficult to handle. For this reason, it can be expected that deposition in a fluidized cathode cell might prove to be a most satisfactory method for cobalt metal recovery.

A reportedly new aqueous electrolytic process has been developed for the production of antimony. ASARCO is currently starting up a small plant, based on this process, in Texas. A description of the process is likely to be publicly disclosed in early 1978. The capacity is presumed to be about 2000 tons per year.

In 1963, the Texas City Tin Smelter, now Gulf Chemical and Metallurgical Company, installed an electrolytic tin refining plant with a capacity on the order of 5000 tons per year. Recently, the tankhouse size was increased. This increased tankage and operation at higher current densities has approximately doubled the electrorefining capacity. Except for a higher current density of about 150-185 A/m^2, the electrolytic process (63) is much like that described by Mantell.

In summary, there have been significant research and development efforts carried out since 1952 to improve the electrorefining and electrowinning of metals. Some new processes have been developed and many improvements on existing processes have been made. In the past ten years the state of commercial practice has developed rapidly. In aqueous based processes, the metal recovery and throughput is improving; while in fused salt processes, the energy consumption is decreasing. During the next few years, economic conditions will likely limit changes in present operations to process and efficiency improvements. By the centennial of The Electrochemical Society, it is quite likely that there will be further significant innovations in the commercial electrochemical processes being used to obtain metals.

Diffusion of Chromium in Magnetite as a Function of Oxygen Partial Pressure

James D. Hodge

Institut für Physikalische und Elektrochemie, Technische Universität Hannover, 3 Hannover, Germany

Recently, a great deal of data has been published concerning the diffusion characteristics of magnetite. While all of this data are reliable and in fairly good agreement, many questions still remain concerning the defect structure and transport properties of magnetite. One of these questions concerns the behavior of impurities in magnetite. To date, no reliable data exist in the literature concerning the diffusion of impurities in magnetite. The purpose of this paper is to describe experiments and report results of a study of the diffusivity of chromium in magnetite.

A number of studies have, to date, looked at the tracer diffusivity of iron in magnetite. So far, the most complete set of data for self-diffusion in magnetite is that compiled by Dieckmann and Schmalzried (1). These workers used Fe-59 to obtain tracer diffusion coefficients at various temperatures and oxygen partial pressures. Their results show that a change of mechanism occurs in the middle of the magnetite phase field, *i.e.*, a plot of log $D_{Fe}{}^*$ *vs.* log P_{O_2} shows that at high oxygen partial pressures the slope of the observed curve is always found to be 2/3, while at low oxygen partial pressures the slope is always $-2/3$. A similar $+2/3$ to $-2/3$ oxygen partial pressure dependence was also observed by Halloran (2) in his studies of magnetite at 1380°C. These results are interpreted as meaning that cation vacancies are the predominant defect at high oxygen partial pressures and that cation interstitials are the predominant defect at low oxygen partial pressures. Dieckmann and Schmalzried give the appropriate defect reactions as being

$$2/3\, O_2 + 3Fe_{Fe}{}^{+2} = V_{Fe} + 2Fe_{Fe}{}^{+3} + 1/3\, Fe_3O_4(g) \quad [1]$$

$$Fe_{Fe}{}^{+2} = V_{Fe} + Fe_i{}^{+2} \quad [2]$$

where Eq. [1] is the reaction for the formation of cation vacancies through the dissolution of oxygen in the magnetite lattice and Eq. [2] is the reaction for the formation of cation interstitials via a Frenkel mechanism. The law of mass action, when applied to these equations, yields

$$[V_{Fe}] = KP_{O_2}{}^{2/3} \quad [3]$$

$$[Fe_i{}^{+2}] = K'P_{O_2}{}^{-2/3} \quad [4]$$

(Note: An equation similar to Eq. [4] can also be written for $[Fe_i{}^{+3}]$.)

The excellent agreement between this simple defect model and the observed experimental results indicates that point defects in magnetite behave as an ideal solution, *i.e.*, no complexing or vacancy-vacancy interactions, despite their relatively high concentrations (up to 0.01 cation site fraction). It is assumed that this ideality stems from the presence of large concentrations of Fe^{+2} and Fe^{+3} cations present in the magnetite lattice which can shield vacancies from feeling the effects of any long range coulombic interactions between vacancies.

From the results outlined briefly above, Dieckmann and Schmalzried draw two important conclusions concerning the defect structure of magnetite: (*i*) Thermal disorder in magnetite is of the Frenkel type; and (*ii*) point defects exhibit ideal solution behavior even at high concentrations of defects.

With these results in mind, experiments were performed to determine the diffusivity of chromium in

magnetite in order to study the behavior of impurities in the magnetite lattice and compare this behavior with that observed for self-diffusion. Chromium is an interesting impurity because (*i*) it is a major alloying agent in many steels and should therefore be present in significant amounts in the oxide layers of these steels where a knowledge of its diffusive properties would be useful to steel manufacturers and users, and (*ii*) the Cr^{+3} ion has an almost identical ionic radius as Fe^{+3}, but unlike iron, at these partial pressures of oxygen it exists as a fixed trivalent ion.

Experimental Procedure

Samples were prepared from a Fe_2O_3 starting material which was melted in a controlled argon-air (70:30) atmosphere to reduce it to Fe_3O_4. Once it was melted and reduced, the magnetite sample was slowly cooled from its melting temperature until the sample was solidified. This slow cooling was accomplished by slowly lowering the sample, which was contained in a Pt-30% Rh crucible to reduce the loss of iron due to its high solubility in platinum, out of the hot zone of a vertical carbon element furnace. After solidification, the magnetite sample was quenched to room temperature. Disks of 0.2 cm were cut from the sample with a diamond saw and ground round to a diameter of 0.8 cm with a diamond wheel. These resulting samples contained anywhere from 2 to 10 grains without any visible cracks or pores.

Prior to a diffusion experiment, the magnetite samples were equilibrated at the appropriate oxygen partial pressure. To do this, an experimental apparatus similar to that shown in Fig. 1 was used. The oxygen pressure, which was fixed during the test by using an appropriate CO_2/CO mixture, and the temperature near the sample were determined simultaneously through the use of a solid-state stabilized zirconia electrolyte galvanic cell and a platinum-rhodium thermocouple. The temperature of the sample was measured independently with a second thermocouple. Samples could be brought in and out of the hot zone with the help of an electromagnet as is shown in Fig. 1. After the pre-equilibration anneal, the samples were treated in the following manner: First, they were ground parallel and then polished on one side using a 3 μm diamond wheel. Cr-51 in the form of aqueous chromate solution was placed on the polished surface with a microsyringe and the sample was then dried at about 100°C. After drying, the samples were sandwiched together to reduce evaporation of tracer from the surface of the sample during the test, held under a slight pressure between alumina rods, and then placed in the same furnace at the same temperature and oxygen partial pressure as was used in the pre-equilibration run.

After a diffusion run, which typically lasted from 2 to 5 days, thin layers of the magnetite sample were removed with a 3 μm diamond wheel and the rest activity of Cr-51 was determined. The depth of the diffusion profiles obtained in this manner ranged from 20 to 100 μm. During the grinding operation, the sample surfaces remained parallel to within 1 μm. Between 10 and 25 cuts were performed on each sample. Every diffusion coefficient was determined with two samples.

Usually, in analyzing tracer diffusion data, absorption of emitted gamma rays by the sample is neglected. However, since the energy of the gamma radiation emitted by Cr-51 is relatively low (0.32 MeV), self-absorption of gamma radiation by the magnetite sample cannot be immediately ignored when analyzing data collected in this study. For situations where self-absorption is significant, Frischat and Oel (3) have derived the following expression for the rest activity

$$A(x,t) = A(o,t) \exp(yx) \frac{1 - \text{erf}\left(\frac{x}{2\sqrt{Dt}} + y\sqrt{Dt}\right)}{1 - \text{erf}(y\sqrt{Dt})} \quad [5]$$

where y is the absorption coefficient. It should be noted that to obtain a diffusion coefficient from this equation numerical methods must be used since D cannot be solved for explicitly.

Therefore, to see if this correction for self-absorption would be needed, the absorption coefficient of magnetite was determined by measuring the drop in Cr-51 gamma radiation intensity across samples of various thicknesses. The value obtained in this manner (0.058 mm^{-1}) was sufficiently small and the average depth of the experimental diffusion profiles was sufficiently shallow that self-absorption could be ignored at the experimental temperature used (1200°C) and the more conventional equation for rest activity

$$A(x,t) = A(o,t) \left[1 - \text{erf}\left(\frac{x}{2\sqrt{Dt}}\right)\right] \quad [6]$$

could be used. However, at higher temperatures, where diffusion profiles will be deeper, this correction may have to be made.

Using Eq. [6], the precision of the determination of $D_{Cr}{}^*$ was never worse than ±10%. A determination from a typical experiment is shown in Fig. 2.

Results and Discussion

As was stated previously, all experiments in this study were performed at 1200°C. The results of all experiments done at this temperature are presented in Fig. 3 along with previously measured values for iron self-diffusion (1). From the figure, it can be seen that chromium diffusion exhibits the same oxygen partial pressure dependencies as iron diffusion, *i.e.*, the slope of the log $D_{Cr}{}^*$ *vs.* log P_{O_2} curve is −2/3 at low oxygen partial pressures and +2/3 at high oxygen partial pressures. Two important observations can be

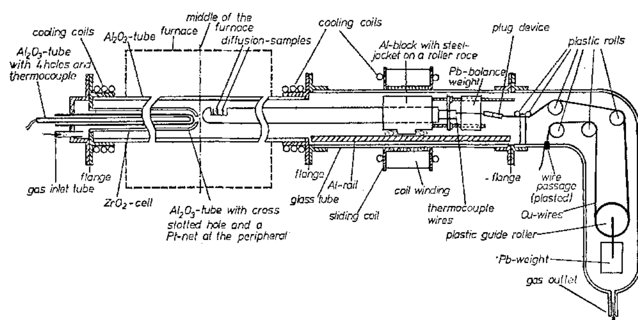

Fig. 1. Schematic of apparatus used for diffusion experiments

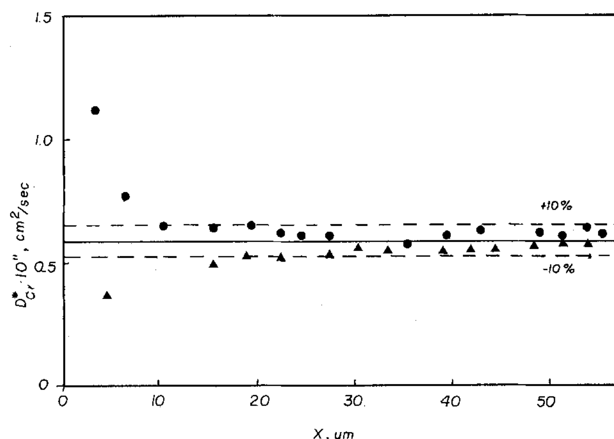

Fig. 2. Typical result of a diffusion experiment. T = 1200°C, $P_{O_2} = 2.95 \times 10^{-5}$ atm.

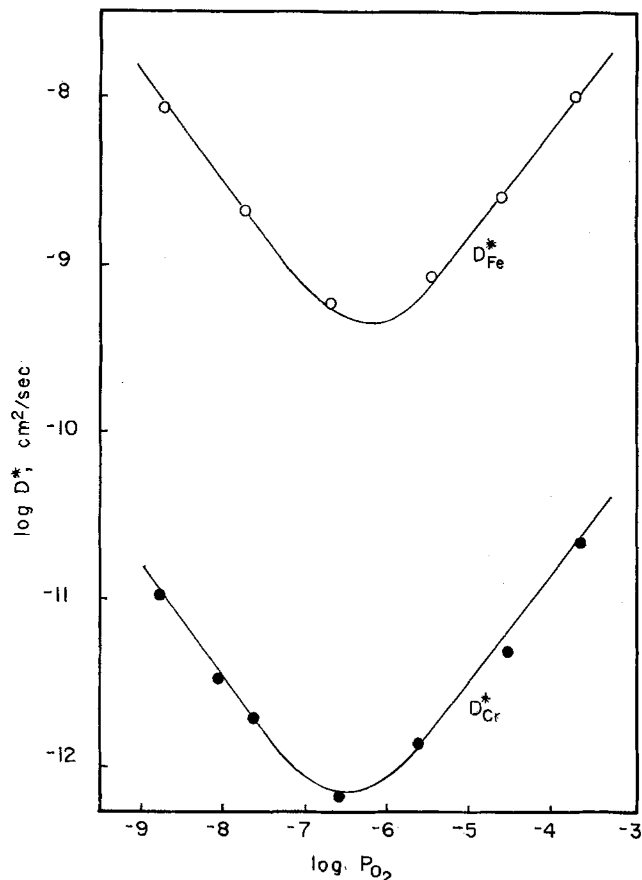

Fig. 3. Chromium tracer diffusion coefficients, D_{Cr}* compared with iron tracer diffusion coefficients, D_{Fe}*, as a function of P_{O_2} at 1200°C.

made from this figure. The first is that the absolute magnitude of Cr tracer diffusion is 2.5 orders of magnitude slower than that of Fe tracer diffusion. This is in qualitative agreement with the Al tracer diffusion estimates made by Petuskey (4). The second observation, which is not in agreement with Petuskey's calculations, is that the minimum in the log D^* *vs.* log P_{O_2} curves occurs at very nearly the same oxygen partial pressure in both Fe and Cr tracer diffusion.

Since the concentration of defects is set by fixing the oxygen partial pressure, it is unlikely that Cr tracer diffusion is low because of a difference in defect concentration between chromium and iron diffusion. Therefore, the reason for chromium's low diffusivity probably stems from a lower jump frequency than iron. Since the ionic radius of chromium is essentially the same as that of trivalent iron, this lower jump frequency is probably not related to a size effect. However, two other possibilities do exist. The first possibility is that in magnetite, because of coulombic interactions with surrounding oxygen anions, a jump by a trivalent cation could be more difficult than a jump by a divalent cation. Since the very high mobility of electrons in magnetite at these temperatures makes it impossible to distinquish between a divalent iron cation jump and a trivalent iron cation jump, this effect would not be noticed in iron self-diffusion experiments. However, at these oxygen partial pressures, chromium exists as a fixed valence +3 ion. Therefore, this effect, if real, should cause a lower chromium diffusivity in magnetite. The second possibility is that the trivalent chromium ion is not as easily deformed as an iron cation and it, therefore requires more energy to jump through its coordinating sphere of oxygen anions. An estimate of this effect can be made by comparing the electronic polarizabilities of the chromium and the iron ions since the electronic polarizability is a measure of how easily an ion's electron cloud can be deformed with respect to its nucleus. A comparison of these values shows that the polarizability of Cr^{+3} is approximately a factor of three lower than that of Fe^{+2} ($1.45\ 10^{-25}$ cm^3 for chromium *vs.* $5.69\ 10^{-25}$ cm^3 for iron) (5). Therefore, this effect could also contribute to chromium's low diffusivity.

In regard to the second observation, namely, the coincidence of the Fe and Cr minima, it should be noted that this indicates that the ratio of vacancy jump frequency to interstitial jump frequency is the same for both iron and chromium diffusion. Why this should necessarily be so is not immediately obvious. However, if it is assumed that the empty octahedral and/or tetrahedral sites in the magnetite lattice are the interstitial positions, intuitively it would seem that a jump from a normal site to an interstitial position and a jump from one interstitial position to another would be energetically similar to a normal vacancy jump and, therefore, the jump frequency ratios mentioned above would be approximately equal if it is assumed that chromium is relatively indistinguishable from iron in the magnetite lattice.

It is also possible that the coincidence of the two minima is merely fortuitous and that experiments at other temperatures will reveal that the minima are not always coincident. Such experiments are presently being performed and the results of these tests will be published along with other impurity diffusion data in a later paper of the series on magnetite by Dieckmann and Schmalzreid.

Summary

Tracer diffusion experiments using Cr-51 as a tracer were performed in order to determine the diffusivity of chromium in magnetite. The results of these experiments were compared with previously obtained values for iron self-diffusion. This comparison showed that although chromium diffusion exhibited the same oxygen partial pressure dependencies, indicating that it diffused via the same mechanisms as iron, the absolute magnitude of chromium diffusivity was several orders of magnitude slower than that of iron. Two possible reasons for this slow diffusivity were advanced, both of which could cause chromium to have a lower jump frequency than iron. The first is related to the fact that chromium has a fixed +3 valence state while iron has a variable valence of either +2 or +3 at these oxygen partial pressures. The second is related to the relative polarizabilities of the iron and the chromium ions. It was also noted that the minimum in the log D^* *vs.* log P_{O_2} curve occurs at the same oxygen partial pressure for both iron and chromium tracer diffusion. The reason for this coincidence is not clear at this time and awaits further experimentation at other temperatures. Such experimentation is currently in progress.

Advances in Corrosion over the Past 25 Years

Herbert H. Uhlig

Department of Materials Science and Engineering,
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

There is little doubt that the factor of corrosion in present materials problems has gained greater recognition than in any time previous. Advances in corrosion control during the past quarter century have noticeably accelerated. Reference to the author's survey in 1952 (1) of some accomplishments in corrosion over the previous 50 years and a glance at the large size of the present corrosion literature here and abroad confirm this trend. Some indication of the magnitude of the latter may be had from Table I which, although by no means complete, presents some representative additions to the secondary and tertiary literature on corrosion appearing during the past 25 years. There are several reasons why this increased recognition and attention to the corrosion problem should have occurred in addition to the usually cited economic factors, the need for greater safety of equipment and structures, and the justified arguments on conservation. For one thing, metals have moved to higher levels of strength and of chemical resistance to uniform corrosion making them unfortunately vulnerable to various unsuspected types of environmental damage and sensitively dependent on stress and on features of design. Environments in turn have become more aggressive and of higher temperatures; even the air in some cities has become polluted to an extent causing metal failures—of, for example, telephone relay springs—in epidemic proportions. On the whole, reported corrosion failures observed as pits, cracks, and intolerable rates of surface attack have proliferated markedly over the recent past.

Advances in corrosion control have served to reduce much of the presently experienced damage, but it is fair to acknowledge that engineering information on the influence of environment on properties of materials continues to lag behind that which is urgently needed. More distressing is the frequent neglect by engineers and architects to use and apply what is already known about corrosion control in their designs of modern structures, machines, and buildings. There are both research and educational gaps that require closing up.

Notwithstanding that much more remains to be done, there has been significant progress made recently in both corrosion theory and practice indicative of the information that should be made available in greater measure. The electrochemical theory of corrosion, still being debated 75 years ago, has received perhaps its most important support through the derivation published in 1957 by Stern and Geary (2) of a simple equation relating electrochemical polarization parameters to uniform corrosion rates. This approach to reaction rate measurements at high or low temperatures, applicable to all structural metals, has been used in many metal-environment systems including the monitoring of metallic (prosthetic) devices for intended use in the human body. Mansfeld (3) has recently provided a general treatment of the theory and limitations underlying this approach to corrosion-rate measurements. Electrochemical techniques in general over recent years have assumed greater importance in all types of corrosion measurements (4).

The elusive subject of the structure and composition of the passive film on metals and alloys, vigorously debated for the past 140 years, has been scrutinized by scientific discussions held at three international symposia (1957 in Germany, 1962 in Canada, 1970 in England) sponsored prominently by this Society among other groups. A fourth symposium was held in Arlie, Virginia, October 17-21, 1977. A joint seminar by American and Japanese scientists active in research on passivity was held in Honolulu in 1975 (5). Many of the contributors to these several symposia have continued to advocate a diffusion-barrier oxide model. But to others, including the present author, the results of coulometry and recently developed surface analyses stress the greater probability of an adsorbed oxygen and nonstoichiometric oxide composition for the passive films on metals like iron, nickel, stainless steels, aluminum, and similar metals (6). One of the ongoing challenges, accordingly, is to relate metal-proton-oxygen ratios in the passive film to observed chemical stability of the film in various electrolytes and at various temperatures, and to outline the factors that cause transformation of the film to stoichiometric oxides having lesser protective properties.

The concept of a critical potential above which the passive film breaks down leading to localized corrosion or pitting has been discussed qualitatively for many years. The quantitative treatment of this subject including the effects of alloying and extraneous anions has more recently received a larger measure of attention (7-11). This information has led to a practical understanding of how best to cathodically protect metals, such as the stainless steels, against pitting attack in sea water and other environments, and also to a better understanding of the proper choice and adequate concentration of inhibiting salts effective for avoiding pitting. These studies help to explain why the 5000 and 6000 series of Al alloys with corrosion potentials active to their critical potentials have generally shown better resistance to pitting in sea water than those alloys of more noble corrosion potentials (12).

Crevice corrosion which initiates in passive metals largely independent of the critical potential has been minimized by choosing alloys whose passivity is relatively stable in acidic halide solutions or in aqueous media within a crevice low in dissolved oxygen. For example the Ti alloys containing a few tenths percent Pd, or the Mo-bearing type 316 austenitic stainless steels are in this category. More alloys possessing this kind of stable passivity are needed to help the engineer design structures where crevices are unavoidable and hence where crevice corrosion poses a threat.

Within the past years, the problem of stress corrosion cracking (SCC) has loomed as especially critical in the design and operation of chemical, oil, and nuclear plants including high pressure gas lines. A detailed mechanism of environmental cracking applying to specific metals and plastics or to materials in general has not yet received over-all acceptance despite the considerable attention focused on the problem. A handicap in this respect is the continuing tendency in some circles to confuse SCC always requiring a tensile stress with intergranular corrosion which does not, even though intergranular corrosion may sometimes result in cracking. The two mechanisms of failure are probably quite different. There is also current confusion resulting from the overlapping of SCC with hydrogen cracking, the latter depending on interstitial hydrogen in the metal. High strength steels, according to Asphahani and Uhlig (13), may fail from either cause depending on the potential range natural to or imposed on the steels. Hence to successfully avoid failure by cracking in a given environment may require knowledge about the cause before applying the remedy. It would seem that SCC in

most metal systems operates by a mechanism unrelated to that of hydrogen cracking, although this matter is still being debated. In any event, protecting against SCC involves choosing the proper alloys, avoiding specifically damaging anions, selecting optimum rolling direction for some cold-rolled materials, *e.g.*, Al alloys, cathodically protecting below the critical potential for SCC in the given environment, and adding inhibiting salts which shift the critical potential to more noble values. Reducing tensile stresses, residual or applied, may increase life but does not generally avoid failure.

Incidence of hydrogen cracking for some metals, *e.g.*, 10% Ni-Fe alloys may also be sensitive to rolling direction, and potentials must be avoided at or below which hydrogen ions discharge at the metal surface, especially in the presence of catalyst poisons like H_2S which favor absorption of hydrogen by the metal. Laboratory and service data show that the face-centered cubic metals, *e.g.*, the austenitic stainless steels, are more resistant than body-centered cubic metals, *e.g.*, the ferritic and martensitic stainless steels, a property that is made use of to avoid hydrogen cracking of ship propellors made of stainless steel, pipe-line hardware, and fasteners for aluminum structures. However, face-centered cubic alloys of compositions that allow heat-treatment to high strength levels are not necessarily resistant to environments notorious for their hydrogen cracking tendencies. Some high strength alloys may also fail by SCC in the presence of moist air. Hydrogen embrittlement (loss of ductility) of Ta can be avoided by applying a thin, not necessarily pore-free, coating of Pt to the surface which acts as a catalyst favoring hydrogen evolution rather than absorption of the gas by the metal (14). A similar catalytic coating applied to high strength steel has been shown in the laboratory to be analogously effective (15).

Failures by SCC are probably much more common in practice than the usual diagnoses of metal failures would indicate, a situation which is still more acute in cases of corrosion fatigue. It has been known for a long time that engineering structures subject to variable stress fail by fatigue, but what is not generally recognized is the magnitude to which the environment contributes to such failures. A well-defined minimum stress (fatigue limit) below which fatigue failures do not occur in any length of time is established for steels in air; no such limit is observed in sea water or fresh waters. Failures in corrosive electrolytes occur at any level of stress given a sufficient number of stress cycles. The traditional explanation of corrosion fatigue has involved the formation of pits by the corrosion process, the pits in turn serving as stress raisers and as nuclei for fatigue cracks. Recently (16, 17), it has been proposed that the environment accelerates plastic deformation of metals at a given stress level independent of pits, thereby favoring the formation of extrusions and intrusions in the metal accompanying the fatigue process. Correspondingly, surface dissolution of polycrystalline brass, copper, and steel has been shown to accelerate slow plastic deformation (creep) of these metals subject to constant stress (18-20). Practical measures to avoid or minimize corrosion fatigue include proper alloy selection for optimum corrosion resistance, cathodic protection to the same approximate potential effective for avoiding uniform corrosion, addition of corrosion inhibitors to the environment, deaeration of aqueous environments (*e.g.*, steels in sea water), surface peening to reduce high surface stresses, and the use of various coatings.

Relatively new organic coatings for metal protection made up of various synthetic vehicles continue to be offered on the market. Such coatings usually but not always provide improved protection to the underlying metal compared to the older standard available paints. In general, all organic coatings, new or old, are permeable in some degree to water and oxygen; in addition their deterioration is affected to a variable degree, depending on the vehicle, whenever they become exposed to temperatures near the boiling point of water. Caution should be exercised in the use of some coatings

and plastics in a confined space; they may exude slight amounts of volatile acids which accelerate corrosion of Zn, Mg, Cd, Al, Cu, and steels. One commercial plastic which exuded trace amounts of amines was found by the present author to cause SCC of brass fixtures exposed to air contaminated by the plastic. Substantial advances in protective organic coatings for use in corrosive environments are limited despite the impressive commercial importance of the field; new ideas are few and far between. As E. L. Koehler (21) expressed it: "(organic coatings) would seem to be an area where basic corrosion research has largely been lagging, with only a handful of investigators giving sporadic attention."

The dezincification of brass has for some time been explained in two differing ways with supporting evidence for either proposed mechanism. The alloy is assumed to corrode with redeposition of Cu in spongy or porous form, or instead the zinc is assumed to corrode preferentially leaving behind a porous residue of Cu or a Cu-rich alloy. Convincing support of the latter mechanism was presented by Pickering and Wagner (22), who proposed that surface divacancies are formed by the corrosion process; these readily diffuse at room temperature into the bulk of the alloy and become filled preferentially with Zn atoms. The Zn then migrates along available diffusion paths to the metal surface and reacts with the corrosive environment. A similar preferential corrosion of Cu in Cu-Au alloys was explained by them along the same lines; here contrary to brass the initial general corrosion of the alloy followed by redeposition of Au is not an equal possibility. Gold does not enter into solution at any time. The formation of divacancies and their interaction with dislocations (dislocation climb) was proposed by Revie and Uhlig (19) to explain the accelerated creep of brass (and other metals) that they observed during anodic dissolution. Correspondingly, divacancies also enter the over-all explanation of corrosion fatigue dependent on environmentally induced plastic deformation, as described earlier.

Direct logarithmic kinetics and two-stage logarithmic kinetics for thin film oxidation of metals have been explained by electron transfer control at the oxide-metal interface (23). Inverse logarithmic kinetics has been explained by high electric field-induced ion migration through the oxide film (24). Differentiation of the two models is made difficult by the limited time over which thin film kinetics is observed; most, although not all, available data for which a differentiation can be made obey the direct logarithmic equation. Pretreatment of clean metal surfaces, *e.g.*, Cu or Fe, with H_2 or N_2 has been found to cause surface faceting with a correspondingly large effect (depending on the gas) on subsequent thin film oxidation rates (25-26). This effect can account for some of the wide discrepancies in reported thin-film oxidation rates.

The introduction of rare earth elements, which mainly improves spalling properties of the metal oxides, has been made use of to improve practical oxidation-resistant alloys, *e.g.*, yttrium added to 25% Cr-Fe alloys. One of the important continuing problems is the adequate protection of Ni-base alloys employed for gas-turbine blades exposed to high temperature air containing small amounts of sulfates in suspension. Various protective coatings are in use, including Ni-Al alloys (27) which on oxidizing form adherent coatings of Al_2O_3.

Among recent practical advances is the increasing use of special low alloy steels called weathering steels for construction of buildings, bridges, and other structures. Painting is not required throughout the life of the structure. The detailed mechanism accounting for the protective, adherent rust-scales forming naturally on such steels is still under study.

The economic application of cathodic protection in media like sea water has been advanced by the recent availability of remarkably corrosion-resistant platinized Ti or platinized Nb electrodes (28). Their long life at relatively high current densities, convenient size, and good mechanical properties under stress and strain give them a marked advantage over the usual electrodes available heretofore for applied current protection. Corrosion resistant titanium anodes coated with ruthenium oxide have found important application in the alkali-chlorine industry (29). Sacrificial anodes of the Zn or Mg variety are now supplemented by Al alloy electrodes containing a small percentage of Sn and sometimes additional Zn and Hg. In chloride solutions, they exhibit a continuing active potential compared to pure Al and account for a large tonnage of Al consumed annually for cathodic protection purposes (30).

Improved bright metal trim for autos has recently been made available consisting of a bimetal strip with stainless steel on the exterior and aluminum in contact with the auto body (31). The aluminum cathodically protects the steel body and its paint coating against otherwise damaging galvanic effects when stainless steel is in direct contact with it. The introduction some years ago of microcracked chromium deposited over bright electrodeposited Ni continues to afford maximum protection against tarnish of the Ni coating (*e.g.*, on auto bumpers) as well as delaying rusting of the underlying steel at pores in the coating.

Continuing urgent needs in the corrosion field include more efficient, nontoxic and inexpensive inhibitors for use in recycled cooling waters. Inexpensive, metallically bright, passive alloys are needed that depend on elements other than chromium for atmospheric corrosion resistance—not an easy goal. As mentioned before, corrosion-protective organic coatings containing reliable and longer lasting corrosion inhibiting pigments and which withstand higher temperatures would be welcome. Alloys with improved resistance to SCC in chemical environments and also resistant to hydrogen cracking (such as in sour gas wells) are urgently in demand. There is also a need for better methods and materials to reduce the little-known fretting type of corrosion which often causes the initiation of fatigue in air or corrosion fatigue in presence of an electrolyte. Fretting corrosion results from the slight oscillatory sliding of one metal surface over another surface, metal or nonmetal, resulting in wear and pitting. A recent book by Waterhouse is available which summarizes the known facts of fretting corrosion (32).

Since 1952 some of the requirements for educating engineers in corrosion prevention have been met by various short courses arranged at several universities and also by the National Association of Corrosion Engineers. The time is perhaps overdue when all students of engineering and architecture will be required to take courses on environmental effects on properties of materials comparable to standard courses now available on mechanical properties. Furthermore, more attention in support of research in corrosion science should be provided in order to supply a basis for improved engineering information. The design of modern structures and machines will continue to suffer without such research. The Electrochemical Society through its Corrosion Division has been prominent in encouraging the type of information that is needed, and in promoting its availability to those who can best apply it to practical situations.

25 Years of Fuel Cell Development (1951-1976)

K. V. Kordesch[1]

Union Carbide Corporation, Battery Products Division, Parma, Ohio

"A fuel cell is an electrochemical cell which can continuously change the chemical energy of a fuel and oxidant to electrical energy by a process involving an essentially invariant electrode-electrolyte system" (1). For good reason, this definition is placed ahead of this review of the past 25 years of "Fuel Cell History" because this time period covers the third cycle in periodic attempts to realize what W. Ostwald (2) envisioned in 1894 as an electrochemical element more efficient than the heat engine which, being based on random energy, is limited by Carnot's law. The practical experiment of W. R. Grove (3) (usually called the first electrolysis fuel cell discovery) was, in its time, just a laboratory curiosity. However, around the turn of the century such eminent physicochemists as Nernst and Haber devoted much effort to direct carbon-oxidizing fuel cells. Their expectations failed due mainly to operating difficulties and material problems; that ended the first period. After World War I, new activities started the second cycle, still aimed at direct coal-oxidizing cells. The final statement by E. Baur (4) in his 1933 summary paper gave the best chance for success to the galvanic element which operated at room temperature in alkaline electrolyte with hydrogen as the fuel. After 1933 followed the "quiet years" before the start of the third cycle which was to progress on an international, worldwide basis.

Bischoff, Justi, and Spengler (1956) were probably the last ones to consider a direct coal-burning fuel cell (with Cu/CuO air cathodes). The findings of the Russian O. K. Davtyan (5) published in 1946 can be considered the start of a new period of development. Davtyan's work and the "Nernst mass" [a solid electrolyte based on ZrO_2 (85%) and Y_2O_3 (15%)] were the starting points for G. H. Broers, working for the Dutch organization T.N.O., together with J. A. A. Ketelaar in the early 1950's laying the groundwork for successful high temperature molten carbonate cells operating on H_2 and CO (6). Broers supplied the gases through porous layers and thus established a steady interface between the electrode structure and an electrolyte-containing solid matrix (of MgO).

Figure 1 shows the construction of this high temperature cell. Early work on high temperature cells paralleling the efforts at T.N.O. was also done at the Sondes Place Research Institute in England by H. H. Chambers and A. D. S. Tantram (7). F. T. Bacon (8) worked on high pressure hydrogen-oxygen fuel cells at Marshall's Flying School, Limited, in Cambridge, England, for 10 years until he was successful with porous nickel gas-diffusion electrodes containing a dual-porosity structure which served to keep the reaction zone gas/liquid/solid stable through gas pressure action and balancing capillary forces.

Figure 2 shows a photograph of Bacon's dual-porosity electrode. His fuel cell was later to become the basis of the NASA-Apollo fuel cell program. Under contract, United Aircraft Corporation, Pratt & Whitney Division, developed the fuel cells which resulted in the most spectacular success for "Fuel Cell Power Systems" achieved to date. Figure 3 shows the schematic diagram of their cell.

A third type of fuel cell emerged in the 1950's, based on the results of studies on carbon electrode activation by K. V. Kordesch and A. Marko (9) at the University of Vienna. Fuel cells with hydrophobic porous carbon electrodes catalyzed with spinels on the air side and Pt on the hydrogen side were operated at high current densities in alkaline electrolytes without pressure at room temperature (E. Baur's prediction of

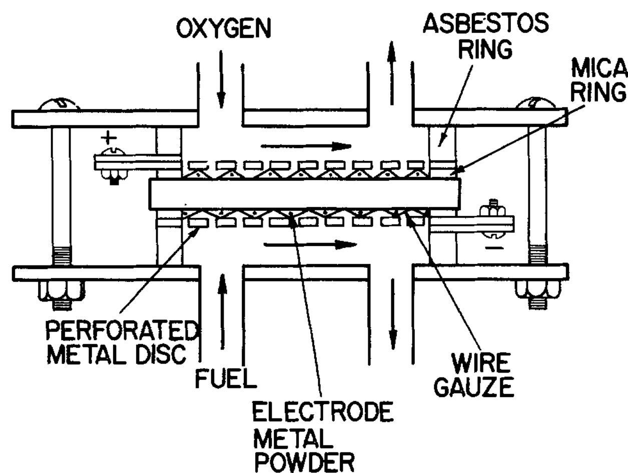

Fig. 1. The high temperature fuel cell of Broers

[1] Present address: Institute of Inorganic Chemical Technology, Technical University of Graz, Graz, Austria.

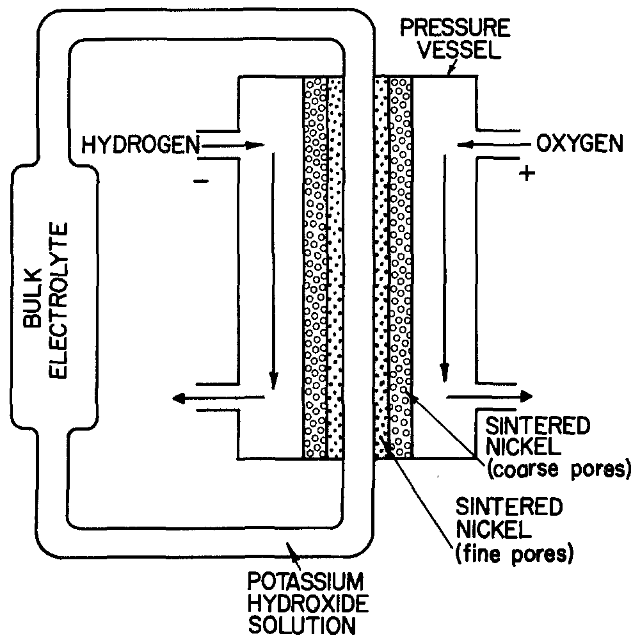

Fig. 3. Principle design of the Bacon fuel cell system

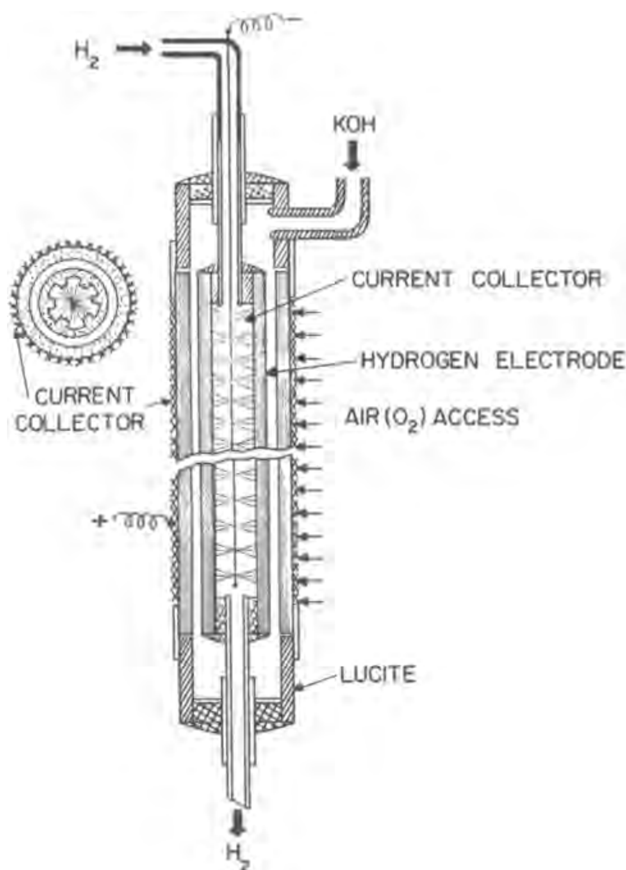

Fig. 4. Concentric hydrogen-air fuel cell

1933 come true). Such electrodes became the basis of the fuel cell systems built by Union Carbide Corporation, first in the tubular shape, and then later as thin composite electrodes using a porous metal and carbon in a layer design. A picture of the early concentric hydrogen-air fuel cell is shown in Fig. 4.

Another significant development of the 1950's was the work of E. Justi's group at the Technical University in Braunschweig, Germany (10). Justi succeeded in producing porous metal electrodes (single pore size and dual-porosity structures) which operated at room temperature without noble metal catalyst. He used Raney structures. Later technical developments at Siemens, A.G. and at Varta, A.G. in Germany were based on the work of Justi's group.

Considering now the significance and the common features of those inventions which materialized in the 1950's (the beginning of our 25-year historic survey), it can be stated that it was the recognition of the need for a stable, large interface between electrode and electrolyte which caused the sudden "breakthrough" in technology. Different designs led to the same result, but all were realized through the following: a porous electrode structure; inert, conductive substrates (*i.e.*, carbon, nickel, metal oxides); catalysts, or pressure, or high temperature for a high reaction rate; wetproofing or gas pressure balance for stability; gases (later also liquids) as a replacement for carbon as fuel; recognizing the fuel cell as a "system" (*i.e.*, as a primary cell with continuously supplied chemicals); learning that success depended on the functioning of the auxiliary components as much as on the electrochemical reactions.

Beginning in the 1950's, electrochemical knowledge had also made tremendous steps forward, not the least of which was due to the fact that fuel cells made excellent electrochemical vehicles to experiment with, but also because they included nearly all of the conceivable principles of physical chemistry and thus were equally challenging to engineers, designers, and theoretical minds alike. Electrode kinetics became known as an important field, superseding the thermodynamic considerations which gave no answers beyond the principle of feasibility.

The porous electrode structure was subjected to rigorous analysis, and models were constructed to explain the behavior of the electrodes under load conditions. The role of the all-encompassing Nernst equation was scrutinized, and it was widely agreed that the overpotential was not the result of but the reason for the changing current flow. Still, the mechanism of the charge transfer at an electrode surface was not clear, and complicated models competed for acclamation.

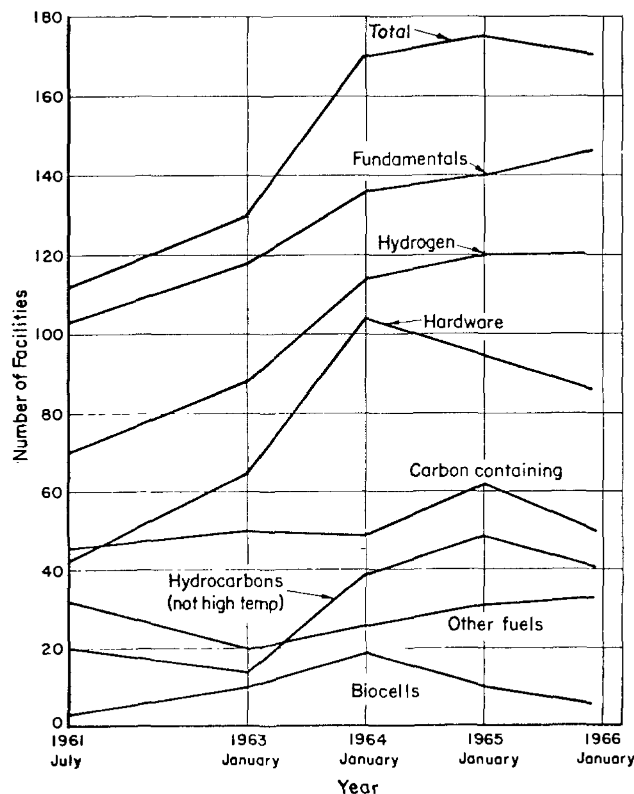

Fig. 5. General topical areas of fuel cell research

Table I. Government-sponsored contracts on fuel cells*

Estimated value of contracts, million dollars							
Totals	Hydrogen	Hydrocarbon	HTFC	Biocells	Other fuels	Publications	Totals
1963	10.82	2.61	0.89	0.93	0.60	—	15.85
1964	11.75	2.45	0.43	0.20	0.74	0.03	15.60
1965	9.44	3.17	0.22	0.20	0.43	0.03	13.49

Estimated value of contracts, million dollars, by government agency								
Totals	Army	Navy	Air Force	NASA	Department of Interior	AEC	ARPA	Totals
1961	1.3	1.8	2.4	0.1	—	—	—	5.6
1962	2.7	0.7	1.5	8.9	1.0	—	0.8	15.6
1963	4.0	1.5	1.0	8.5	0.5	0.2	0.2	15.9

1965	1.6	0.4	0.3	7.8	—	—	3.3	13.5

* Based on project briefs from the power information center, University of Pennsylvania, as referenced by Battelle Memorial Institute of Columbus, Ohio.

Catalysts were developed empirically (without much benefit from theory at the time) and, coupled with hindsight, systems were designed by trial and error. In spite of this, the 25-year history of fuel cells is an honorable period for electrochemistry during which time it was applied to seemingly unsurmountable tasks such as providing the electrical power for a space capsule on a trip to the moon.

With the decline of space programs in the 1970's, fuel cell technology also stopped growing. So, within this 25-year period we also see the decline of fuel cell-related arts and sciences. However, within recent years a revival has started concerning uses and applications for the general public right here on earth for power production on large and small scales.

Before presenting a chronological survey of fuel cell technology, Fig. 5 depicts a representation of the distribution of worldwide fuel cell efforts concerning the various government agencies, industry, and universities. Table I lists the government expenditures for fuel cells (excluding classified programs). Figure 5 and Table I are based on a survey conducted by Battelle Memorial Institute (11) and cover the five peak years of fuel cell work.

Figure 6 lists the number of Chemical Abstract fuel cell citations over the years 1958-1972 (12). A selected bibliography listing the major books on fuel cells and related subjects has also been provided to help in finding more detailed information.

Chronological Survey of Fuel Cell Systems

High temperature cells.—Molten carbonate cells.— Pittsburgh Consolidation Coal Company, under contract to the U.S. Army, continued work on high temperature fuel cells for use with water-gas mixtures (H_2, CO, CO_2, and H_2O) as fuel and air as oxidant (13). Cracking occurred in initial laboratory cell disks made of a solid electrolyte against which porous metal electrodes (3 mm thick stainless steel) were pressed. Later, molten sodium carbonate (soaked in MgO) disks were used, but the disks still cracked and the molten phase leaked from the disks. It was discovered that CO_2 in the air supply stream was necessary to maintain cell operation (with transfer of oxygen across the electrolyte). Further developments produced cells with porous nickel (on the fuel side) electrodes using equimolar sodium-lithium carbonate melts. For improvement of air electrode quality, some lithiated nickel electrodes and silver-pasted cathodes were prepared. At 750°C, these cells produced 75 mA/cm^2 at 0.70V using hydrogen. In the final report (14), cracking of disks and flooding of the electrodes were still mentioned as failure modes.

Work at Central Technical Institute T.N.O. on a U.S. Government contract (15) in Holland continued beyond Broer's research cited in Ref. (6). Their H_2 electrodes used platinum as the catalyst and silver for the cathodes. The principal aim was to lower the matrix resistance by designing the cell in tubular form, whereby the porous metal tube was coated on the outside with metal powder soaked with MgO-$LiNaCO_3$, followed by another layer of metal powder. The inside of the tube constituted one gas chamber and the outside was the other chamber. The fuel electrode limited the output to 15 mA/cm^2 at 0.6V, and the lowest operating temperature was 400°C (Li-Na-K-carbonate-eutectic). As work on this system continued (16), considerable improvements were achieved; current densities up to 200 mA/cm^2 (100 mA/cm^2 for 700 hr at 0.8V) with H_2-CO_2 (1:1) mixtures. In 1969, the superiority of the Li-Na-K-carbonate/aluminate system over that of the MgO-paste systems was established (17).

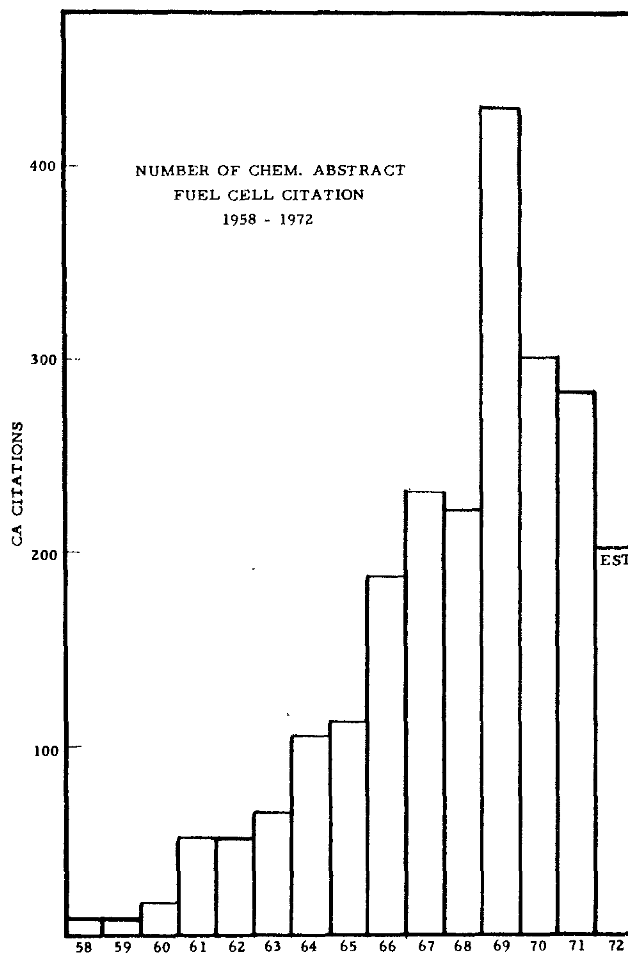

Fig. 6. Number of Chemical Abstracts' fuel cell citations dating from 1958 through 1972.

Texas Instruments, Incorporated, had a molten-carbonate fuel battery program during 1963-1965, with the purpose of producing a 400W unit which would operate on gas from reformed liquid hydrocarbons (18). Porous metal electrodes (of silver) were bonded to the electrolyte disk to prevent leakage; the electrolyte was $LiNaCO_3$ in a refractory MgO disk. The operating temperature was 600°C. Power densities were approximately 0.1 W/cm^2; lifetimes in the 1000 hr range. I. Trachtenberg (19) was the main investigator of these "slurried molten-carbonate cells," in which there was no requirement for structural integrity on the electrolyte component. Interactions of electrolyte stability, silver corrosion, and current density are discussed in Ref. (20).

At the Institute of Gas Technology in Chicago, B. S. Baker and coworkers (21) avoided the use of noble metal catalysts (needed for stability at high temperatures, not really for catalytic purposes). Eutectic mixtures (such as Broer's) allowed operation between 500° and 700°C. Silver fiber cathodes and porous fiber-nickel anodes were used, with reformed natural gas as the fuel. Cost/performance figures of $20/kW-$45/kW were quoted already in 1965.

At General Electric Company, some early work was done by D. L. Douglas (22) on molten-alkali carbonate cells with gas diffusion electrodes, mainly with a ternary electrolyte system.

At Union Carbide Corporation, M. L. Kronenberg evaluated high temperature fuel cells using an impregnated ceramic matrix. The tapered tubular cell construction (which made series cell connections easy and was later used extensively in solid-state cells) was invented at that time (23).

In Great Britain at Energy Conversion, Limited, A. D. S. Tantram originally worked on many different high temperature cell designs (24). Later, most of his work was devoted to Pd-Ag foil anodes (25).

In France at Gaz de France, A. Salvadori developed semi-industrial fuel cell elements of tubular design. Palladium on graphite was the catalyst used, and it consisted of a layer of refractory oxides deposited by flame spraying to establish a matrix. A silver-based thin film was used at the cathode (26). At Electricité de France, molten-carbonate cells were studied by a larger group of investigators (27). A collection citing French fuel cell work can be found in Ref. (28).

In Germany, work on molten-carbonate electrolytes was neglected in favor of the upcoming, and at that time more promising, solid-state high temperature cell systems.

The state of art found in 1969 did not change during the next five years. Because material problems were blamed for lifetime limitations, technology shifted to phosphoric acid fuel cells which could operate also as well on reformed natural gas. Only very recently, however, has the molten carbonate work at the Institute of Gas Technology obtained new importance. United Technologies, ERDA (through the Argonne National Laboratory), and EPRI have sponsored new studies. Performances of over 1000 hr have been quoted. This system is now considered as the "second generation" of fuel cells for power plants (29). Operation at 600°-750°C (without noble metal catalyst) for 40,000 hr (with multistack units) is considered a near-term goal (about 1980). Coal gasification will be an integral part of the system.

Solid electrolyte cells.—In 1960, J. Weissbart and R. Ruka established that cells with electrolytes of the type $(ZrO_2)_{1-x}(Y_2O_3)_x$ could be operated as solid-state high temperature cells. In principle, an O_2 concentration cell of that nature could use any fuel which reacts with oxygen (30). The oxygen-ion transport requirements limited the number of suitable oxides to those of mixed oxides with an imperfect structure. Nernst had already observed such ionic conduction in 1899. The early experimental cells produced accurate emf measurements of the H_2/H_2O, Pt-mixed oxides-Pt, O_2 cell at 1015°C. Current densities of 10 mA/cm^2 could be sustained for two months at that temperature.

Under the sponsorship of the USAF Aero Propulsion Laboratory (31), this system was investigated during 1962-1963, and the Westinghouse hollow cylinder bell-and-spigot design with electrodes applied to the inner and outer surfaces of the solid electrolyte was developed.

Current densities of 150 mA/cm^2 were reported by Archer and co-workers in 1965 (32). Cells measured 1.2 cm diam and were 0.9 cm in length. It was estimated that a 500W unit would weigh 12-20 kg. The platinum coating was 0.7 mm thick at the seals, covered with 1.5 mm of gold. Electrodes in series arrangement were brazed together with a Ni-Au shim. The first contract had the purpose of developing a 100W unit to burn gasified coal.

In 1962 the Office of Coal Research (33) sponsored work to provide design data for a 100 kW unit. To avoid expensive yttrium, electrolytes of the Zr, Ca, and Mg types were tested, with partial replacement of platinum with nickel. Promising results were obtained with perovskite systems such as $LaCoO_3$-$SrCoO_3$. A 100W unit was built from 20 tubes containing 20 cells each. Area per cell was only 2 cm^2. The O.C.V. was 200V. Performance with hydrogen and air was as expected (0.15 W/cm^2). CO was unsatisfactory as a fuel, therefore a catalytic shift reactor was incorporated. The 100 kW design was, most certainly, overambitious considering that cell details had not yet been thoroughly worked out. Doubts appeared concerning the claims that the solid-state high temperature cell was truly an O_2-concentration cell. The inability to operate on CO without a preceding water-gas shift is a major disadvantage and tends to disprove the original theory. Use of hydrogen-oxygen cells for space application was also studied but later abandoned.

The application of tin oxide and indium oxide films to zirconium electrolytes (by vapor deposition) resulted in very low polarization losses during air operation, and in 1967 E. V. Sverdrup and co-workers (34) claimed current densities up to 1000 mA/cm^2 at 1000°C, with operating life of around 1000 hr. The oxide films, however, flaked off with passing time. In 1969 it was estimated that there was enough applicable technology available to construct a fuel cell system which would use coal for central station power generation of 150 kW/m^3 at a cost of $30/kW (35).

Brown, Boveri Research Laboratories at Heidelberg (Germany) designed high temperature solid-state cells. The oxide powders were pressed with ammonium bicarbonate into disks 0.3 mm thick and 40 mm in diameter. Sintering was done with aluminum oxide additives. The active electrode materials were deposited by means of a plasma-spray process. With silver on the oxygen side and nickel or cobalt-iron on the fuel side, the cell was stable up to 850°C (36). Figure 7 shows a drawing of their 10-cell battery. Current densities of 100 mA/cm^2 were achieved, with reported lifetimes in the hundreds of hours.

At the Battelle Institute research laboratories at Frankfurt M (Germany) (37) and at Geneva (Switzerland) (38), solid-state electrolytes of the zirconium type were studied extensively.

In France, extensive studies of solid electrolytes were pursued until 1967 at the University of Grenoble by C. Deportes and co-workers (39). Platinum electrodes were used for studying the various mixed oxide systems.

In Japan, solid electrolytes were studied at the University of Nagoya. The emphasis was on replacement of noble metals with powder-metal sinters on the anode side and ZnO and Al_2O_3-containing electrodes on the cathode side (40).

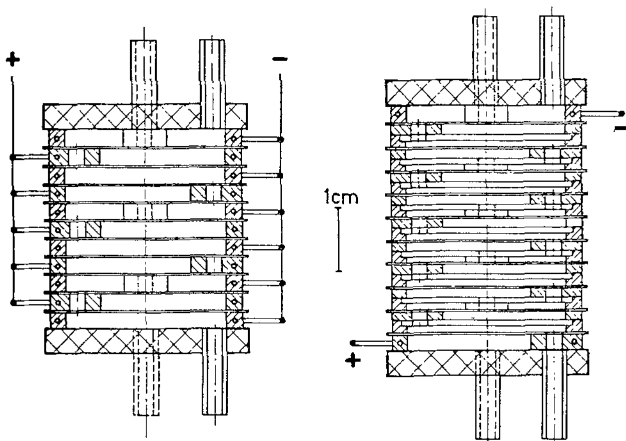

Fig. 7. Ten-cell battery; parallel connection on the left, series connection on the right. ("Solid-state battery.")

In Russia, at the Ural Institute of The Academy of Sciences, such systems as Zr, Ce, and Ca oxides which showed considerable conductivities have been studied since 1960 (41).

At the General Electric Company, W. E. Tragert (42) studied a system containing stabilized ZrO_2 as electrolyte in which was used a silver cathode in liquid form at 800°-1100°C, deviating from the "solid" electrolyte concept, but using to his advantage the high solubility of O_2 in silver.

A hydrogen-fueled power system based on the Westinghouse/Office of Coal Research high temperature solid electrolyte fuel cell has been recently suggested (43). Such cells would be used with pure hydrogen and oxygen (from an electrolyzer), with pure hydrogen (stored) and air, or with hydrogen from a gasifier or reformer and air. Utility use is contemplated, depending on cost, efficiency, and lifetime. Time scale for this application is about 1990.

Medium temperature fuel cells.—Modifications of the Bacon cell.—The hydrogen-oxygen cell developed by F. T. Bacon operated at 200°-240°C with 45% KOH. To prevent boiling of the electrolyte, a pressure of 40-55 atm was required. In this environment, the porous nickel electrodes tended to oxidize and to form a high resistance coating. The heavy and expensive construction was its major drawback. Further developments of the system for the space program were carried on under U.S. Government sponsorship.

At Patterson-Moos Research, Division of Leesona Corporation, the contract with the U.S. Air Force (44) calling for construction and testing of a 1.5 kW Bacon cell was started in 1957. Lithiated cathodes which could withstand oxidation were the first improvement. Although the performance of the finished stack declined within hours, a few of the cells lasted for as long as 2000 hr at 150 mA/cm², thus indicating, in principle at least, that the system could work.

Pratt & Whitney Aircraft, Division of United Aircraft Corporation, started their development of the Bacon cell in 1961. Their first goal was to produce a 250W H_2/O_2 fuel cell unit to demonstrate feasibility for space application. The operating parameters were changed to 260°C with 85% KOH (solid at room temperature) and operation at essentially atmospheric pressure. The current density was 150 mA/cm² at 0.87V (45). Some cells worked for 5000 hr; even the entire module reached 690 hr without failure.

The Apollo project.—Details of the design for the Apollo fuel cell projects have not as yet been fully published. However, principle descriptions are available (46). The Pratt & Whitney power plant, PC3A-2, is characterized in Table II.

Figure 8 shows a picture of the PC3A power plant. Three such units were mounted in the service compartments adjacent to the command modules of the space capsules in all Apollo missions. The moon flight, Apollo 8, lasted for 440 hr; during that time, 291.7 kW-hr of electricity were produced together with more than 100 liters of water. No further units were produced after the Apollo program ended. No exact cost estimates are available for the fuel cell power part of this program; a conservative estimate is $100 million, and perhaps up to $150 million.

Table II. Apollo fuel cell system, Pratt & Whitney PC3A-2 power plant

Number of cells	31
Cell pressure	50 psia
Nominal temperature	400°F (204°C)
Reactant gas pressure	10 psi above cell pressure
Heat and water removal	By hydrogen circulation
Voltage	27-31V
Power	563-1420W
Duration	400 hr
Maximum power	2295W at 20.5V
W-hr/lb reactants	1220 (at 1420W)
Weight	220 lb

During follow-up work planned for future space missions (space shuttle), Pratt & Whitney Aircraft Company developed an advanced 7 kW fuel cell system (1973 model) which improved the specific weight and volume figures nearly a magnitude over the Apollo system. (Fuel Cell Technology Program, Johnson Space Center, NASA, Houston, Texas.)

Low temperature fuel cells.—With carbon electrodes.—The early Union Carbide hydrogen-oxygen (air) fuel cells with liquid KOH electrolyte used baked carbon tubes (20 mm OD, 12 or 14 mm ID) in arrangements of 4 or 9 tube bundles, or (with air)

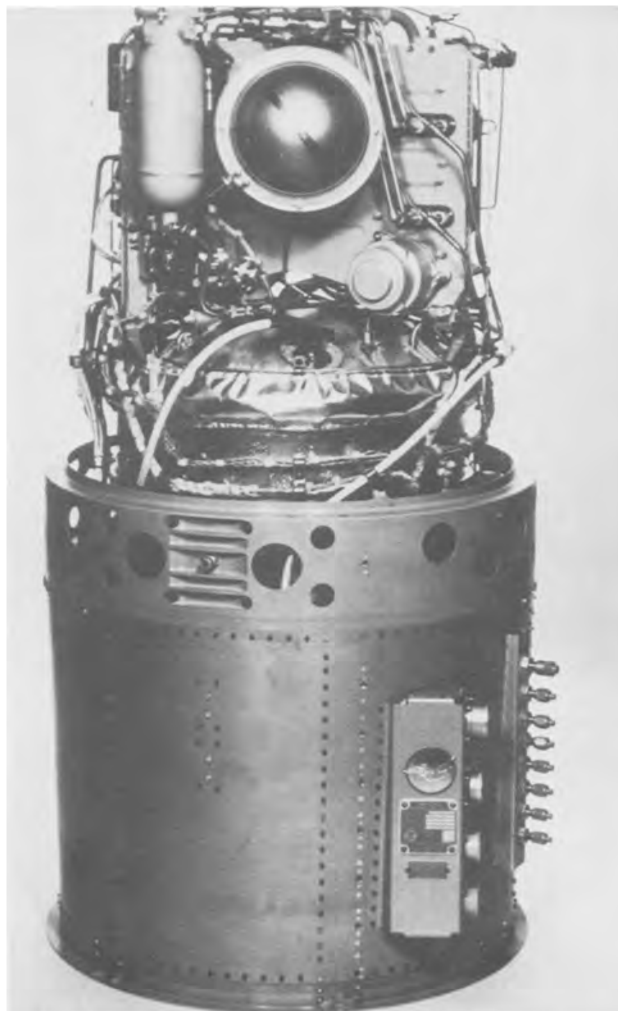

Fig. 8. PC3A power plant for Apollo project

in concentric cell designs with the outer (air) electrode having a 24 mm ID and 30 mm OD (47).

After 1960, the parallel-plate design prevailed; 3 or 6 mm thick carbon plates were surface-activated in the presence of spinels in a stream of carbon dioxide-containing gas atmosphere and subsequently catalyzed with silver or noble metals in the amount of 1 mg/cm^2 of geometric surface (48).

Hydrogen-oxygen batteries (up to multikilowatt output) were built from baked carbon plates during government-sponsored contracts (49-51). The largest electrodes had dimensions of 30 × 30 × 0.6 cm; the largest battery produced 30 kW output.

In 1964, thin composite porous metal/carbon electrodes started to replace the previous heavy voluminous carbon plates (52). These new thin plates were only 1-1.5 mm thick and used the "fixed-zone" principle, thus locking the reaction zone into the confines of the interface between the porous nickel backing (gas side) and the catalyzed carbon layer (electrolyte side). Figure 9 shows a cut through the thin, fixed-zone electrode.

These thin electrodes were used in compact hydrogen-air batteries studied under a government contract (53). Complete systems and accessories were developed (54) and, in an arrangement with General Motors Corporation, a van was equipped with a 32 kW hydrogen-oxygen battery (55). The system could be overloaded up to 150 kW for short periods to provide peak power for the vehicle. The current densities on oxygen were 350 mA/cm^2 at terminal voltages above 0.80V. With air as oxidant, the limiting current densities were 150 mA/cm^2 at atmospheric pressure; 250 mA/cm^2 at 10 atm (absolute). The system operated in water equilibrium conditions at 65°C in 9*N* KOH at 100 mA/cm^2. Most of the water which was produced transpired through the anodes into the hydrogen circulation system.

An experimental electric car was used to test the concept of a "hybrid vehicle" powered by a 6 kW hydrogen-air fuel cell battery in parallel with a lead-acid battery (56). The vehicle had a range of 200 miles with six lightweight hydrogen fuel tanks. Refilling was done within minutes from a high pressure hydrogen supply.

A further significant improvement of the fixed-zone electrode concept was in the change to a double-porosity nickel structure on the electrolyte side to assure proper wetting of the interface and to prevent gas bubble breakthrough at higher gas pressures. The active carbon layer (PTFE bonded) is on the gas side of the electrode, this being a reverse arrangement with respect to the previous design shown in Fig. 9. The improved electrode thereby combined the features of the Bacon electrode with the hydrophobic carbon electrode to improve performance and prolong life (57). Limiting current densities were 500 mA/cm^2 on oxygen, and 250 mA/cm^2 on air. Lifetimes reached 5000 hr. These thin electrodes can be used in rechargeable nickel-hydrogen cells employing existing nickel-cadmium technology (58).

Fig. 9. Fuel cell-lead acid battery automobile

Fuel cells with platinum black "Teflon" electrodes.—American Cyanamid Company produced high performance electrodes for use in alkaline and acidic systems using liquid and matrix electrolytes. The basic principle for manufacture of these types of electrodes is to make a mixture of platinum black (with or without carbon) and "Teflon" [*e.g.*, 3:1 weight percent (w/o)] and apply it to a screen support. For alkaline systems the carrier material is gold-plated nickel screen; for acidic systems a tantalum screen is used (59). The matrix used was asbestos filled with 5*N* KOH, or glass-fiber paper filled with 5*N* H_2SO_4. The Type A electrodes used no extender with the platinum black, and loadings varied from 9 to 40 mg/cm^2; Type B electrodes used graphite as diluent for the platinum black, making it possible to reduce the Pt level to 2.5 mg/cm^2 and still achieve current densities of 100 mA/cm^2 at 0.75V in KOH at 30°C. Operating life at 70°C had been over 1500 hr when 9.5 mg Pt/cm^2 were used. High performance lightweight fuel cell electrodes were especially investigated by American Cyanamid Company for NASA (60).

The General Electric Company's "Teflon"-bonded platinum electrodes consisted, typically, of a Pt screen embedded with a mixture of "Teflon" and catalyst, with a thin porous film of "Teflon" on the gas side. An aluminum foil was used as a backup material to press the mixture into the screen (it was later stripped from the electrode). Loading with the noble metal catalyst was on the order of 30 mg Pt/cm^3. Electrode sizes up to 50 × 25 cm were suggested to be optimal for the U.S. Navy for use in fuel cells for submarine propulsion (61). Electrode structures of this type (62) finally progressed to spaceworthy components and were incorporated in the Gemini space power source.

Similar electrodes were used in fuel cells operating on hydrocarbon fuels. Studies to reduce the amount of platinum led to a loading of 1-2 mg Pt/cm^2 for hydrogen electrodes; using oxygen and hydrocarbons, there was shown to be a direct relationship between platinum loading and performance. Tungsten or tantalum powders as well as boron carbide were tried successfully as diluents. In liquid 6*N* KOH, current densities up to 400 mA/cm^2 at 0.7V were achieved with 35 mg Pt/cm^2. In 5*N* H_2SO_4 at the same catalyst level, a hydrogen-air cell could produce 400 mA/cm^2 at 0.4V. With electrolyte circulating between the electrodes, internal heating produced temperatures up to 70°C at high current densities. Local "hot spot" temperatures were probably far higher, sometimes leading to electrode failure by gas cross-leakage.

Engelhard Industries produced platinum and platinum alloys (especially Pt-Ru) catalysts which were designed for acidic matrix-type electrodes (63). A mixture of the noble metal catalyst and carbon was bonded with "Teflon" to form a thin electrode on a metal screen structure. These electrodes were utilized in phosphoric acid cells operating with alcohols and dissociated ammonia as fuel and air as the oxidant.

Fuel cells with porous metal electrodes.—Gas diffusion electrodes based on a double-skeleton-catalyst (DSK) design had been studied by E. Justi's group at the Technical University Braunschweig in Germany since the early 1950's (64). The principle of these electrodes was first described in early German patents (65). A homeoporous metal structure (to balance the capillary action with gas pressure in an optimal way) is combined with a highly active nonnoble metal catalyst by mixing size-controlled carbonyl nickel powder and Raney alloy powder. Pressing and sintering results in a strong electrode with a "double structure," part of it serving as a coarse skeleton for good conductivity and part acting as a catalyst.

The Raney catalysts were, basically, Al-Ni alloys for hydrogen electrodes and Al-Ag alloys for oxygen electrodes. The aluminum was leached out with caustic solutions. Later special activators and pyro-

phoric inhibitors were added to facilitate production. The German companies, Ruhrchemie A.G. and Steinkohlen Elektrizitäts A.G., financed the early work.

Varta A.G. continued the development work up to kilowatt sizes (66). A special development, the "Eloflux" electrode (67), was unique in its design of electrolyte flow (perpendicular to the electrode surface) and manifolding of multiple cell units. One hundred units of that type were built in small quantities until 1972.

Siemens A.G. followed another path in the further development of the Raney catalyst electrodes to produce the so-called "Schüttelektrode" in which the particles of active materials were sedimented on asbestos without any additional binder. The electrodes were held in place by other layers of porous nonconductive materials (68). These electrodes were used to construct hydrogen-oxygen fuel cell batteries up to kilowatt sizes. Even the powering of automobiles (in hybrid fashion) was suggested (69).

A 7 kW hydrogen-oxygen battery was built by Siemens A.G. around 1976. Development work at Siemens did not stop when most other fuel cell efforts in the United States and elsewhere folded or were reduced to laboratory levels. Work was continued in the direction of lower cost units and air operation (70). The air electrode was based on an ammonia-treated carbon material and the electrode design was comprised of three layers: a hydrophobic cover layer, a hydrophobic working layer, and a porous PTFE cover on the gas side. This electrode is also suitable for rechargeable air cells (71).

Allis-Chalmers Manufacturing Company built hydrogen-oxygen fuel cells based on an electrode consisting of a porous nickel plaque catalyzed with noble metals facing a porous asbestos sheet in which the electrolyte is retained by capillary action. The early cell construction used direct evaporation of the formed water (at the H_2 electrode) as a means for keeping the electrolyte concentration constant in the asbestos matrix (72). As an early demonstration project, a tractor was fitted with a 15 kW hydrogen-oxygen battery in 1959. With a working voltage of 750V, the current of 20A represented a current density of 20 mA/cm^2. Battery weight was 917 kg.

During the years from 1961 to 1965, several large units were constructed under government contracts (73-75). The first was a 1.5 kW unit operating at about 65°C and 5 psig. A 400W unit was built with bipolar plates and the operating temperature was increased to 90°C. It worked for 700 hr.

In order to adapt the Allis-Chalmers cell to space operations, the so-called "static water vapor control method" was invented (76). In essence, a moisture-removal membrane supported by a porous support plaque was added behind the hydrogen cavity. With this principle, the auxiliary controls became simpler, and a 2 kW space fuel cell battery was built for the G. C. Marshall Space Flight Center, Huntsville, Alabama.

This type of fuel cell operated so successfully that this system was visualized as a follow-up system after Apollo to replace it in future space ventures (which were later cancelled). The noble metal catalyst level was high (partly replaced by gold), but the reliability and power/weight requirements of space missions warranted this approach. Testing of such a system continued even after Allis-Chalmers closed down their fuel cell work in 1969. Through the use of nickel boride, their Research Division developed a hydrogen catalyst free of noble metal (77). A very active catalyst for the oxygen electrode was prepared from silver oxalate (78).

Allis-Chalmers also manufactured a 5 kW hydrocarbon-air fuel cell system which employed their 1965 fuel cell technology to produce the hydrogen in a steam reformer unit (79). The biggest problem in this system was reliability of the auxiliary components. However it provided experience for procuring H_2 producers, air scrubbers, and inverters on an engineering scale. A weight breakdown shows for instance, that the fuel cell module weighed only 22% of the unit (150 kg), the reformer weight was 240 kg, and the inverters and auxiliaries together weighed over 300 kg for a total of over 700 kg to achieve only 5 kW net power output (gross fuel cell power: 7.3 kW). Allis-Chalmers also built hydrazine and methanol batteries.

The fuel cell system of ASEA, Sweden, used layer electrodes which consisted of an inactive, coarse, porous layer of nickel, an active intermediate layer of porous nickel with nickel boride, and a fine layer of porous nickel (on the electrolyte side). The propulsion of submarines was a considered application, and a very sizable effort was expended in Sweden to build suitable systems (80). However, accidents prevented the success of the project and it was abandoned. Still, the progress made during this technological phase was considerable and much was learned about the behavior of different electrode designs (81). Some of the results with oxygen electrodes were later applied to rechargeable iron-air systems.

The Electric Storage Battery Company produced microporous metal electrodes for hydrogen-oxygen cells as early as 1960. Larger tubes (2.5 cm diam) or plates made from tiny tubes were fabricated and tested (82). Current densities up to 200 mA/cm^2 and lifetimes of 3000-5000 hr were reported, especially in NaOH. The oxygen electrodes were heterogeneous alloys of 50-90% Ag and 10-50% Ni.

Compagnie Général d'Electricité in France, at the Laboratories in Marcousis, experimented with alkaline fuel cell batteries in sizes up to 2 kW. Oxygen electrodes were based on carbon-silver structures; hydrogen electrodes used porous nickel electrodes of adjusted pore sizes carrying nonnoble metal oxides as catalysts (83).

AEG-Telefunken in Germany developed tungsten carbide catalysts for fuel cell anodes (hydrogen and reformer fuels) in acidic electrolytes (84). Thin electrodes (0.75 mm) reached current densities of 50 mA/cm^2.

At the Battelle Institut in Frankfurt, Germany, tungsten carbide was also studied as an anode catalyst in acidic electrolytes (85). In sulfuric acid at 70°C, the polarization at 50 mA/cm^2 was 0.2V. Such electrodes were also used in phosphoric acid and with different fuels such as formic acid, hydrazine, etc.

Ion-exchange membrane cells.—General Electric Company's fuel cell program was mainly military and space oriented. The electrodes previously described were used in combination with ion-exchange membranes (IEM's) serving as the electrolyte member of the cell. Phenol-sulfonic IEM's were the first types used in a 24V, 200W Navy battery design (1959) which aimed for a weight of 16 kg, including one day's fuel supply. The operating mode desired was 14 hr/day for seven days on hydrogen and air (86).

The life of the IEM's was short if the membranes dried out; therefore, water was retained by wicks on the oxygen side. The ribbed titanium contact plate provided space for it next to the air supply and cooling channels. The cells operated at 15 mA/cm^2 at 0.6V for over 500 hr. One failure mode was the flaking off of the Pt-Pd catalyst (50 mg/cm^2) from the membrane on which it was deposited. The fuel canister and the hydrogen generator (Na-borohydride and acid) of the earlier model was subsequently replaced by a bottle of compressed hydrogen. During the following development work, the cell resistances were reduced by higher contact pressure.

In the HOPE fuel cell program (USAF), the performance of IEM cells under orbital flight conditions was studied. Improvements in heat removal (copper-

plated condensors with radiators) and membrane compositions resulted. Sulfonated (polymer "A") polystyrene resins made it possible to achieve current densities of 100 mA/cm^2 above 0.6V. However, pressure imbalances leading to cross-leaks and drying out of membranes were still troublesome. In view of the Gemini Project (General Electric/NASA) which was showing faster progress in the state of the art, Project HOPE was abandoned in 1962.

A program under Navy sponsorship (87), using "Series D" sulfonated polystyrene membranes, produced large-size electrodes (50 $\times$ 25 cm) which had a "Teflon" coating for improved repellency and a special coolant chamber built into the cells between the anode and cathode (bipolar). Operation at elevated temperatures or on open circuit decreased membrane life. However, some cells survived 4000 hr testing. Extensive studies (88) of airflow management and a new design for electrode collectors increased limiting current densities to nearly 300 mA/cm^2 in 1963.

The Gemini fuel cell system (89) consisted of three modules (32 cells each) in a cylindrical container. This Gemini system used two batteries, each of which could produce 1 kW at 26.5-23.3V. Each battery, including accessories, weighed 31 kg. A description of the long history of the General Electric IEM from the early testing stages to the space flights of Gemini 4 and 5 is provided in Ref. (90). One production battery repeated more than three successive two-week Gemini missions.

In a post-Gemini development at General Electric, new polymer electrolytes have been found which are extremely resistant to chemical oxidation and temperature variations. Cells containing such materials survived 5000 hr of testing. In 1973, high current densities (100 mA/cm^2) and long life expectancies were reported at the end of the NASA acid electrolyte fuel cell program (91) using IEM's. In 1975, the use of IEM hydrogen-oxygen (air) fuel cells was suggested for large power installations for energy storage and peak-load sharing (29, 92).

Matrix (phosphoric acid) fuel cells.—The phosphoric acid-matrix cell has been late in receiving attention as being a type of cell which could be suitable for system development, most probably because that particular acid is a poor conductor and is extremely corrosive, and also because a noble metal catalyst must be used. However, earlier disappointments with hydrocarbon-converted fuel systems using alkaline electrolytes prepared the way for the use of the acidic-matrix cell. O. J. Adlhart (93) at Engelhard Industries, Incorporated, pioneered the use of plastic-bonded electrolytes for acidic systems with the intention of using them for direct methanol or propane cells. The application in phosphoric acid-matrix cells proved to be much more successful, and by 1970 Adlhart's company had built a 1 kW hydrogen-air power system for the U.S. Army (MERDEC) which had a lifetime of 2500 hr at 180 mA/cm^2 (94). The catalyst cost was estimated at \$300/kW. The degradation rates of the catalyst were given as 3 mV per 100 hr at 100 mA/cm^2 and 150 C for hydrogen-fueled cells. The problems with steam reformates were the reduced H_2 utilization and the catalyst-activity reduction by CO, reasons to switch to catalytically cracked ammonia in later systems.

At Pratt & Whitney Aircraft Division W. Vogel, J. Lundquist, and A. Bradford (95) studied the reduction of oxygen on Pt-black electrodes and concluded that a layer of catalyst in contact with a porous "Teflon" layer should give very high current densities even at low Pt loadings providing the Pt agglomerates were interconnected (*e.g.*, with gold). With about 1 mg of Pt-black/cm^2 the voltage drop between open circuit and 100 mA/cm^2 was 0.30V if air was used, and only 0.25V using pure oxygen (measured in 85% H_3PO_4 at 120°C). Using only 0.05 mg Pt/cm^2 (and gold), they measured a drop of 0.3V (with O_2). In a later paper (96) with P. Stonehart, the performance of hydrogen electrodes in phosphoric acid was reported with respect to the CO poisoning effect on Pt. The effect was reduced by increasing the temperature of cell operation to 180°C.

Thin electrodes were studied using carbon paper as substrate and a "Teflon"-bonded carbon layer as catalyst carrier by R. F. Scarr and K. V. Kordesch (97) of Union Carbide with a goal of producing lower cost air electrodes for phosphoric acid cells. The quantity of Pt was held low by impregnating carbon with Pt salts. A tantala cloth soaked with phosphoric acid was used as the electrolyte matrix. Up to 7000 hr operating time were achieved (98). The operation of hydrogen electrodes in acid media is well understood (96, 99). All investigations of declining performance of acidic cells point to recrystallization (increase in agglomerate size) of platinum. This is still an unsolved problem today.

Not much is reported concerning the composition and manufacturing of the "matrix." In earlier experiments, a certain specially prepared type of asbestos was used, and later "gels" consisting of "Teflon"-phosphoric acid mixtures were prepared and further immobilized by fillers of a proprietary nature.

The technical development of the phosphoric acid-matrix cell was carried out with the financial support of a group of gas utility companies in the TARGET[2] program (100). Work at Pratt & Whitney Aircraft Division (now United Technologies Corporation, Power Systems Division) led to the design of 15 kW systems for local power production. Originally, natural gas was considered the preferred fuel which would be steam converted to a hydrogen-rich fuel. The objectives were to develop a competitive system used by utility companies as a load-leveling device and distribution aid which would ultimately lead to a gas-line-supplied electric home or small industrial complex. Today, this goal is even more important because of the present need to shift electric energy production from oil to coal. Hydrogen is really the fuel to be employed with fuel cells, since it can be provided through nuclear power use by electrolysis. Therefore, it is not surprising that plans are presently being made for the development of phosphoric acid electrolyte fuel cell power plants for both on-site and dispersed-power generation. Prototypes of 40 kW units have operated on pipeline gas at 40% over-all efficiency for more than 5000 hr. A 1 MW power plant is scheduled to run on naphtha and air (FCG-1 program). The benefits of fuel cell power plants were recently outlined in an ERDA publication (101). However, there are still problems, and their ultimate economy will be determined by the usual trade-offs between catalyst cost, power density, and projected life.

Other systems—Other fuels.—Acidic methanol cells. —In the period 1960-1963, Esso Research and Engineering (102) studied the oxidation of methanol on platinum black electrodes (8 mg/cm^2) in acids; a complete conversion to water and CO_2 was obtained. At 83°C with 4% methanol in 30% sulfuric acid, the air cell produced 0.4V at 50 mA/cm^2. Nitric acid air electrodes were initially used as cathodes (with membranes); platinum black-screen cathodes were later employed. Lifetimes up to 1000 hr were achieved. A 10 cell stack was built which operated at 20 mA/cm^2 at an efficiency of about 40%.

Engelhard Industries (103) used anodes with "Teflon"-bonded catalysts of the type 60 Pt:20 Ta at 20 mA/cm^2. E. J. Cairns at General Electric operated a medium-temperature (130°C) cell with methanol vapor. With $CsCO_3$ electrolyte, the current density was also 20 mA/cm^2 (104).

[2] Team to Advance Research for Gas Energy Transformation, Incorporated.

In general, acidic methanol-air cells suffered from high catalyst costs and low output figures. Since fuel reacted on both electrodes, either a membrane had to be used or the fuel concentration had to be limited to low levels (0.1-0.5%). In 1964 at Shell Research, Limited, K. R. Williams, D. P. Gregory, and co-workers (105, 106) succeeded in building a 40 cell battery which delivered 300W at 12V at 60°C. They used microporous PVC as the substrate for the air and methanol electrodes, with the space between being used to feed the 1M methanol solution in 6N H_2SO_4. Operational parameters were a compromise in temperature, alcohol level, and cell resistance (separator). The performance of this battery was only 0.55V at 20 mA/cm², and the side products of methanol oxidation were also disturbing.

The kinetics of anodic oxidation of methanol in acidic electrolytes has been studied by S. Gilman and M. W. Breiter (107), and they proposed the reaction to a methoxyl radical and hydrogen as the first step.

Alkaline cells with methanol or methanol-derived fuels.—The anodic oxidation in caustic solution has been investigated by W. Vielstich (108). He used Pt-metal catalysts and found that formaldehyde and formic acid are reaction products which, by themselves, can be used as fuels, finally giving CO_2. The current densities are on the same order (2-5 mA/cm²) as were observed in earlier cells operating with Raney nickel catalysts (109). A large (60W) methanol-air battery for sea buoys was built by Brown, Boveri, and Cie on the basis of Vielstich's studies and was field tested for several months. In later cells, the use of formates and glycols was preferred, mainly because of the far higher current densities and the reduced interaction between the fuel and the carbon cathode with Ag catalyst (110).

Formate-air primary cells and fuel cells have been given very recent attention as high capacity, low cost cells with reversible electrolyte (111). At Allis-Chalmers, methanol-oxygen batteries were built as early as 1962 (80 cells, 500W output). The use of bipolar electrodes with a solid foil as the separator also allowed the operation of small methanol-peroxide systems (112). The larger systems used sandwich-type cells in which grooved, folded stainless steel endplates allowed the flow of the fuel-electrolyte mixture and oxygen. Asbestos was used as a separator-spacer between the electrodes (113). During the development of the Allis-Chalmers batteries, the move to formate ion/oxygen cells was made at a later date (114). The superior current density figures were the main reason for the change.

At Gould-National Batteries, Incorporated, R. E. Biddick and D. L. Douglas (115) constructed a 24 cell methanol-air battery with thin membranes as separators. It was operated in parallel with a sealed Ni-Cd battery as a hybrid power source.

A comparison between direct fuel utilization and separate steam reforming or "internal reforming" of the methanol was made in the design studies of two 6 kW systems at Leesona-Moos Laboratories (116). The availability of thin hydrogen-permeable Pd-Ag membranes necessary for the production of pure hydrogen turned out to be the key factor for cost reduction and high current operation over a long time period.

Considering the difficulties encountered with carbonate removal from the electrolyte (a necessary evil of dissolved methanol fuel cells), it is not surprising that there was a strong shift of emphasis to hydrazine fuel cells as the best representative system for dissolved fuel systems.

Hydrazine cells.—Hydrazine (N_2H_4) can be considered as a liquid "hydrogen fuel," since it decomposes easily into hydrogen and nitrogen at the electrode (catalyst) surface. For this reason the voltage observed is only that of a hydrogen cell and not that of a true hydrazine cell (theoretically, about 0.3V higher). In most systems the hydrazine is added to the caustic electrolyte and measures are taken to minimize interaction with the air or oxygen cathode through the use of a low hydrazine concentration or cathode catalyst with low sensitivity to hydrazine or through the insertion of a membrane.

Hydrazine-air fuel cells in the 1930's were already operating at the Union Carbide and Carbon Research Laboratories (117) in Long Island City, New York. However, since no commercial application could be visualized at that time, the project was abandoned without even reaching patent status. Work on the hydrazine-air system was not resumed at Union Carbide Corporation until 1961 (likewise in other companies), and publications concerning complete systems started to appear in 1962. M. Eisenberg (118) demonstrated a 30W hydrazine-oxygen system and proposed a 300W unit for space application. M. I. Gillibrand and G. R. Lomax (119) in England at the Electric Power Storage, Limited, produced a system intended for lift truck operation, while Allis-Chalmers Manufacturing Company showed a 3 kW hydrazine battery propelling a golf cart using cathodically compressed oxygen stored in a high pressure cylinder (113).

Air electrodes were not used in these early systems because of their poor performance in hydrazine-containing electrolyte unless a membrane was used. Improvements in anode catalysts decreased parasitic losses and subsequently also made it possible to operate with low N_2H_4 concentrations. R. Jasinski (120) replaced noble metal catalysts with nickel boride for H_2 and N_2H_4 anodes. At Monsanto Corporation (121), development of a 60W portable power source was achieved, and a 5 kW battery for a ¾-ton truck was demonstrated for the U.S. Army (122). Originally, eight of these units were planned, but only four were finally installed and those were used in parallel with a lead-acid battery. Asbestos layers were used to prevent hydrazine access to the cathodes, despite the use of only 6% N_2H_4 concentration.

At Union Carbide Corporation a 300W hydrazine-air battery, the "Silent Power Source," was also developed for the U.S. Army (122). Highly active anode catalysts allowed lowering the hydrazine concentration to 1 or 2%, precluding the need for the asbestos sheet for cathode protection, and thus preventing the resistance troubles caused by gas bubbles lodged in the separator. This battery was later improved by the use of "reversed" composite electrodes which protected the carbon from the hydrazine by an inactive porous nickel structure and a very accurate hydrazine-concentration/voltage-sensing system (123). Its power output reached 600W in 1969 (124). At Monsanto Research Corporation a special fuel-feed system based on electrolysis current sensing was developed (125). Efforts at the U.S. Army Electronics Command (126), Fort Monmouth, focused on ultimate simplicity of hydrazine-air cells, trying to avoid the use of mechanical accessories.

During this "high time" of hydrazine-air fuel cells, practically every electrochemically oriented research laboratory worked on hydrazine batteries. A demonstration of a hydrazine-powered motorcycle was given by K. V. Kordesch (127) in 1967. The development of hydrazine-air batteries reached its peak in 1970 after the 5 year evolution of various ideas and technologies at different companies. An excellent summary is given by several authors in the *Proceedings of the 24th Power Sources Symposium* (128) at Atlantic City. After that period, development stopped abruptly with drying up of Government funding, and work has not been resumed to date.

Overseas a similar course of events took place. Interest in hydrazine fuel cell systems was high in England, leading to well-developed batteries (119).

In Germany work centered in academic laboratories where modern methods and techniques were studied (129-132). In Russia hydrazine cells were built at the Moscow Power Institute (133). In France the concept of the dissolved-liquid fuel cell was applied to hydrazine (and methanol) cells by Alsthom as well as in a combined effort with Exxon. This two-phase system was developed by B. Warszawski (134) and actively pursued until just recently. In Japan a comprehensive study of dissolved liquid fuels was made (135) and catalyst work proceeded well. However, except for some research studies, work on hydrazine fuel cells stopped just as abruptly on the international basis after 1970 as it did in the United States.

Ammonia as fuel.—Using ammonia as fuel, the direct oxidation of NH_3 to N_2 and H_2O occurs on selected noble metal catalyst, but to date no technologically viable system has been built. Research efforts at Allis-Chalmers (136) were expanded in the 1960's. M. Eisenberg also operated direct ammonia cells between 180° and 300°C in 1964, and a basic study was reported from the University of Bonn, Germany as late as 1971 (137).

Sodium amalgam cells.—Expectations were quite high in the 1960's when the sodium-amalgam system was transferred from research to the development level. E. Yeager (138) from the (then) Western Reserve University, and the M. W. Kellogg Company investigated this system for proposed use for submarine propulsion (139). A design was prepared for a 1000 kW unit specified by the U.S. Navy, and it represented a system energy density of 30 kW/m^3. Actually, 8 kW units were constructed and tested. The amalgam inlet manifold was designed as a "shower head" to prevent between-cell shorts. The anodes were steel plates, and the cathodes were proprietary porous silver electrodes with a porous plastic surface barrier developed by the Electric Storage Battery Company. After 1963, this system was studied only occasionally (*e.g.*, in Japan), and no commercial application was found for the sodium cell. Figure 10 shows the sodium cell.

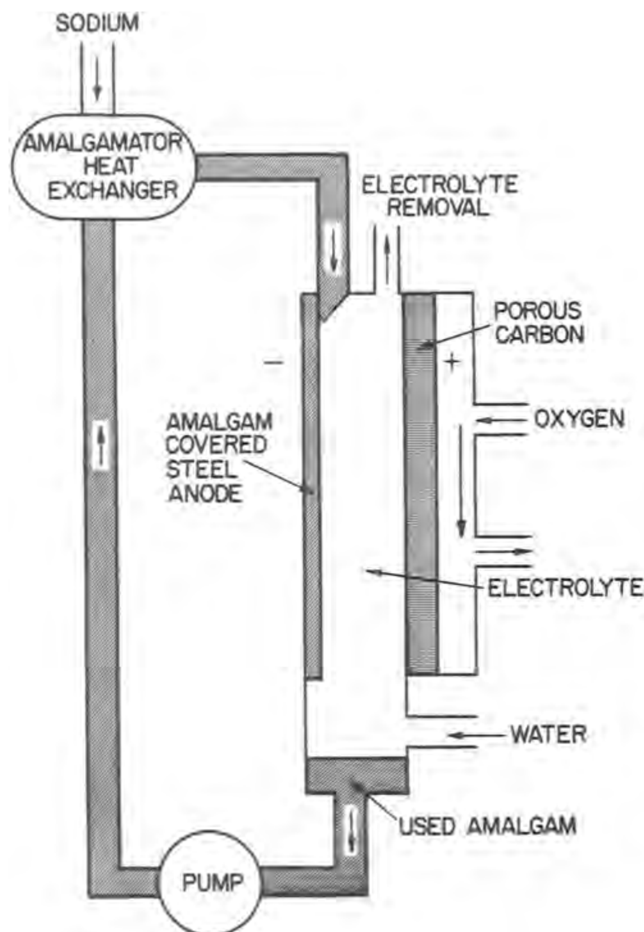

Fig. 10. Principle of the sodium amalgam cell

Regenerative H_2-O_2 fuel cell systems.—Pratt & Whitney Aircraft investigated a storage system whose intended primary source of energy would be secured from solar energy in space (140). In 1960, the fuel cell choice was the "hydrox cell" combined with a zero gravity electrolytic cell.

General Electric Company proposed its 50W ion-exchange fuel cell system (141) for cyclic operation. Single sealed units which contained the produced gases within the cell housing itself were built by Xerox Corporation (142) for NASA. One unit consisted of 34 cells and produced 500W. The good features of the rechargeable H_2-O_2 fuel cells were soon overshadowed by a negative one: the self-discharge by gas recombination could not be prevented, even by the very sophisticated separator designs (initially, asbestos soaked with electrolyte used for that purpose in alkaline cells). It is interesting to note that the difficulties with this system led to the development of the recently very successful nickel oxide-hydrogen systems.

A further enhancement of the early electrolysis electrodes by E. Justi (143) (*i.e.*, the "valve electrodes") was never developed beyond basic principles. Some day, however, these electrodes (at least in principle) may become useful in modern power storage units.

Thermally regenerative systems.—MSA Corporation proposed a lithium-hydrogen cell for cycling between 570° and 1000°C with a Carnot efficiency of 42% (144). It is interesting to note that hydrogen picks up an electron to become a negative-charged ion in this cell. Figure 11 is a diagram showing the cell reactions.

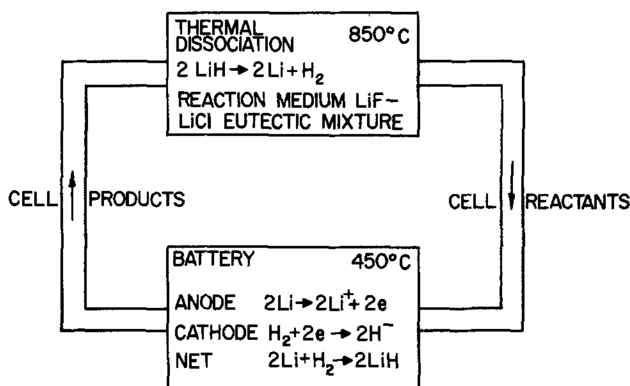

Fig. 11. A thermally regenerative system

Photochemically regenerative cells.—A cell based on the properties of the proflavine-ascorbic acid system was proposed by a research group at Lockheed Aircraft Corporation (145). A survey of photogalvanic systems, including the silver halides was made at the Philco Corporation (146).

Radioactive regenerative fuel cells.—At Union Carbide Corporation, the radiolytic regenerable redox system (cobalt^{60}/H_2SO_4, H_2/Fe^{3+}) was found to be feasible (147). Yielding 5W at 3% efficiency, it could be a way of utilizing radioactive waste material in remote locations. The conversion of oxygen to ozone by γ or ultraviolet radiation was frequently proposed, but conventional oxygen electrodes did not improve with O_3.

Chemical redox systems.—A cell design using continuous chemical regeneration of the two electrolyte solutions was worked on by General Electric Company (148) in the late 1950's. The idea was to produce hydrogen from a gasification plant and to reduce

Ti(IV) to Ti(III), similarly as A. M. Posner in England reduced the stannic/stannous couple in coal in the early 1950's (149). The Br/Br^- couple was used as the (air) oxygen transfer means on the cathode, aided by nitric acid to ease the reoxidation. A 100W system was actually built which consisted of seven cells in series (open-circuit voltage: 0.95V each). Continuing efforts were not successful, however, and the redox systems were forgotten for many years until just recently (150) when their application as large storage devices for electric utilities was considered promising (151).

The nitric acid-oxygen redox electrode.—The electrochemical reduction of oxygen in acidic electrolytes is usually far slower than in alkaline solutions and it requires expensive metal catalysts. It is not surprising, therefore, that efforts were made to use a chemical redox system to attain high current performance. This seemed an especially suitable way to utilize air as an oxidant in direct hydrocarbon fuel cells.

In the HNO_3/HNO_2 systems made by Esso Research and Engineering Company (152), the electrolyte used was H_2SO_4 with only 0.2M HNO_3. The carbon-based electrodes (with Pt catalyst) produced current densities of 75-100 mA/cm^2. Their disadvantage was that for each kW-hr of actual fuel cell operation on air 45g of nitric acid were needed, thus indicating that regeneration was incomplete. Attempts to use the Ce(IV)/Ce(III) redox couple rather than nitric acid were also unsuccessful (153).

Biochemical cells.—The term "bio-electrode" is used to describe an electrode where a microorganism is grown in, or in the immediate vicinity of, the electrode structure. A typical bioanode, for example, could use glucose as feed stock which would then be converted by enzymes (via several intermediate compounds) to ethanol. In the biofuel cell, alcohol is then directly oxidized to CO_2 and H_2O. The cathode may also be a biocathode where, for example, CO_2 can be converted to methane by a methanobacillus. Cells using biological waste products (H_2S, NH_3, alcohols) are called indirect biofuel cells; the electrochemical mechanism is separate from the biological metabolism.

Large efforts were made in the mid-1960's to construct fuel cells along biological principles or in the conventional ways but using waste products. The U.S. Army sponsored contracts with Electric Autolite Company, Magna Corporation, Melpar, Incorporated, Philco Corporation, and the Marquart Corporation over several years (154, 155), wherein final emphasis was placed on indirect systems using fermentation systems as fuel sources. The use of photosynthesis in algae as an oxygen producer is described by Vielstich (156). A magnesium/sulfate biocell was actually built by the Magna Corporation for the U.S. Navy (157). However, difficulties arose due to the low current densities (~1 mA/cm^2) and the side products which, with time, damaged the electrodes.

The use of solar energy for production of biomass may some day bring fuel cell conversion schemes back into the technology.

Direct hydrocarbon cells.—Unfortunately, hydrocarbon fuels are relatively inactive on anodes when compared with hydrogen, hydrazine, or alcohols. M. J. Schlatter at California Research Corporation (158) found early in 1960 that some small current could be drawn from a platinized porous carbon electrode when it was exposed to ethylene or propane and that complete oxidation to CO_2 occurred. Similar reports appeared at that time from other laboratories; W. T. Grubb at General Electric Company (159) and C. E. Heath and co-workers at Esso Research and Engineering (160) oxidized saturated hydrocarbons at platinum electrodes. These findings caused a high number of publications and resulted in a rush to study and develop low temperature hydrocarbon electrodes. Many U.S. Government contracts were initiated and efforts were made to eliminate, or at least reduce, the noble metal catalyst requirements (161).

Space permits only a very few significant contributions to the literature to be named. M. W. Breiter and S. Gilman (162) studied the adsorption of methanol, carbon monoxide, and hydrogen extensively, and new techniques for the study of electrodes by pulsing methods were developed. Electrochemical processes were treated from the standpoint of theoretical electrochemistry (163). H. Binder and co-workers (164) at the Battelle Institut, Frankfurt/M, concentrated on the behavior of noble metal (Raney) catalysts and compared performances in acidic and alkaline electrolytes, Robert Bosch, GmbH in Germany sponsored this work over many years.

An extensive study of hydrocarbon oxidation by-products, especially of the olefins, was published by M. J. Schlatter in 1965. Poisoning of the paraffin electrodes by air or oxygen was reported (165). Still, a hopeful note was taken by H. A. Liebhafsky in his book (B-6) in 1968, expressing the findings that, indeed, CO_2 and water were the only reaction products. However, short lifetimes were the rule with hydrocarbon cells operating at low temperatures (90°C). Raising the temperature to 140°C and using phosphoric acid as the electrolyte improved the current density (0.6V, 50 mA/cm^2), but the problems with irreversible adsorption of oxidized species remained. S. B. Brummer and co-workers at Tyco Laboratories (166) and J. Giner (167) studied octane of extraordinary purity in this respect and used special circuits for potential-step pretreatments of the electrodes.

The platinum-"Teflon" electrodes used were essentially those of W. T. Grubb and L. W. Niedrach (168) and contained platinum blacks. Supported noble metal catalysts and special reduction treatments with borohydride were introduced by the researchers at American Cyanamid Company (169). E. J. Cairns (170) at General Electric experimented with CsF-HF-H_2O electrolytes and obtained up to 200 mA/cm^2 at 150°C with propane. Very thin cells using inorganic membranes (171) as catalyst carriers were also tested for hydrocarbon operation with the hope of achieving better life by reducing cross-leakage.

Indirect hydrocarbon cells.—The use of steam reforming for hydrogen production to supply the anodes of H_2-air (or oxygen) fuel cells became the only way to use hydrocarbons with the expectation of achieving long life for the fuel cell; this was dictated by the high cost of noble metal-rich electrodes. The military contracted for several models of reformers: small portable units using oxidative cracking (172-174) and a multitude of larger units for multikilowatt batteries (175). Figure 12 is a schematic diagram of such a converter/fuel cell system.

Alkaline cells need careful CO_2 scrubbing, while acidic cells needed more platinum as catalyst. Work

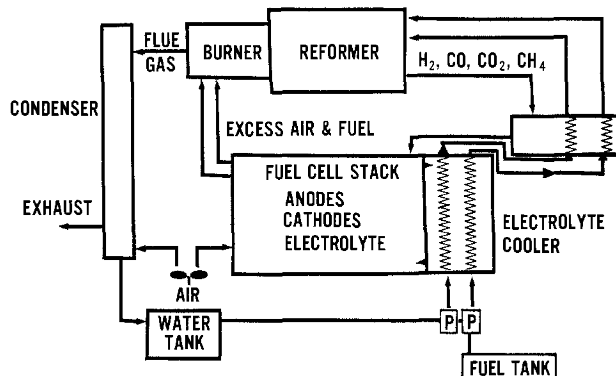

Fig. 12. Schematic diagram of a converter/fuel cell system

on hydrogen generator designs was carried on quite extensively at the Institute of Gas Technology (176, 177). Pratt & Whitney Aircraft designed a 500W hydrocarbon system (178) and Allis-Chalmers delivered a 5 kW hydrocarbon-air system for the U.S. Army (179). Both systems used alkaline electrolytes, and they were the last ones of this type; in a later 1.5 kW system, immobilized phosphoric acid was used exclusively as the electrolyte (180). Esso Research and Engineering (181) studied an acidic indirect system for the U.S. Army, with the goal to utilize octane and JP-4 fuel; 50 mg Pt was used per cm^2 of electrodes! In England, Shell Research, Limited extended the methanol-reformer work to hydrocarbon systems; exceptionally long lifetimes (15,000 hr) were reported (182). The fuel electrodes were hydrogen electrodes and operated in sulfuric acid.

The long lifetimes achieved with pure hydrogen led many researchers to use the Pd-diffusion membranes as a separation means (183). In the article "Internal Reforming Cells," the Pd-Ag membrane was a part of the electrode (184). Very recent work centered on the use of special electrolytes (replacing the phosphoric acid) to accelerate the hydrocarbon reaction. Promising results were obtained with trifluoromethyl sulfonic acid (185) as electrolyte. However, the consensus of opinion of the catalyst specialists is that direct hydrocarbon oxidation is far from practical utilization. The methanol oxidation in acidic or alkaline cells seems to be a far easier way to use the energy stored in coal (186).

It may be significant that the U.S. Army resumed the study of the feasibility of using Kipp-type generators as the hydrogen supply means; at least for small units (30W), the use of metal hydrides seems to be advantageous (187).

Outlook for the Next 25 Years

On the basis of past historic development of fuel cells, it could be predicted that a new wave of fuel cell developments would be starting today. The papers at The Electrochemical Society meetings, Fall 1975 and Spring 1977, and the special session on fuel cells for Fall 1977, show this renewed interest.

The key question is economy. Stationary fuel cell power plants have a better chance of succeeding than mobile vehicular fuel cell batteries, simply on the basis of the maximum dollars per kW which can be spent by the consumer, be it a utility company or the motorist driving an electric car. However, the bigger impact on society would be the fuel cell-operated vehicle with a conversion efficiency of probably 40%.

The technology of fuel cells has not been supported by basic scientific studies to the extent that we can explain catalyst action or even predict ways to improve electrode kinetics beyond the routine methods of engineering and design optimization; *i.e.* making electrodes more conductive, thinner, more repellent, reducing pressure differentials, etc. Hopefully this will change and, with better understanding of the principles, unpredicted improvements may take place, perhaps paralleling the progress of solid-state science over the last decades. This is partly a matter of attracting enthusiastic young scientists to the field—an obligation to be shared by the educational system and industry alike. With growing interest in efficient energy conversion, fuel cells should be the center of attention.

The Electrical Conductivity of β-PbF_2

Wei-Chou Fang*,[1] **and Robert A. Rapp****

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The electrolytic properties of pure β-PbF_2 were studied by a-c conductivity measurements and Hebb-Wagner d-c polarization experiments as a function of fluorine pressure and temperature. The partial ionic and electronic conductivities of β-PbF_2 were determined over a range of fluorine pressure and temperature. Because of the introduction of p-type electronic conduction, the electrolytic domain of β-PbF_2 is truncated at high values of P_{F_2}, with $P_{F_2} = 10^{-21}$ atm at 492°C. At low P_{F_2}, predominant ionic conduction extends to P_{F_2} for the coexistence of Pb and PbF_2.

The electrolytic properties of nominally pure and doped β-PbF_2 and α-PbF_2 have been extensively investigated recently (1-16). Bonne and Schoonman (13) calculated the temperature dependences of the concentrations and mobilities of the interstitial fluoride ions and anion vacancies based on their a-c conductivity measurements of pure and doped β-PbF_2 and existing literature data. Their results indicated that interstitial fluoride ions are the principal mobile species in pure β-PbF_2 for temperatures greater than 300°C. Hebb-Wagner polarization experiments have also been conducted by many authors to elucidate the electronic conductivity in PbF_2. Kennedy *et al.* (4) reported that the electronic conductivity of pure β-PbF_2 at 150°C was p-type. At 25°C Kennedy and Miles (12) could not specify whether the electronic current in β-PbF_2 was carried by electrons or holes. Benz (10) found that pure β-PbF_2 was essentially an n-type conductor from 400° to 600°C. Schoonman *et al.* (8) also found an n-type conductor for pure β-PbF_2 single crystal from 52° to 137°C. Joshi and Liang (9) reported that α-PbF_2 is a p-type conductor.

Both α-PbF_2 and β-PbF_2 are known to be predominant ionic conductors. To elucidate the ionic domain (17, 18) of PbF_2, the determination of the range of log P_{F_2} beyond which electronic conduction becomes appreciable is studied here. Previous studies did not include several well-defined fluorine activities in conductivity studies on PbF_2. The present study consists of measurements of the total a-c conductivity, together with the measurements of the partial conductivity for electrons and electron holes as a function of fluorine activity. These results define the limits for the electrolytic domain for PbF_2. Hebb-Wagner polarization studies of β-PbF_2 also clarify the controversial results regarding n-type conduction as the predominant electronic conduction mode.

D-C Polarization Study

The Hebb-Wagner d-c polarization experiment (19) was adopted for the present study of β-PbF_2. Consider the d-c polarization cell

inert electrode | PbF_2 | reversible (Me/MeF_2) electrode [I]

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
[1] Present address: General Electric Research and Development Center, Schenectady, New York 12391.
Key words: solid electrolytes, conduction, electrolytic domain.

A reversible electrode consisting of a more noble metal (Me) coexisting with its fluoride (MeF_2) provides a fixed and known P_{F_2} on one side of the cell. On the other side, a pure noble metal with low solubility for fluorine serves as an inert blocking electrode. The cell is subjected to various d-c potentials below the decomposition potential of PbF_2. If the right-hand reversible electrode is made negative, under the steady-state condition the ionic current is blocked and the steady-state polarization current i_∞ is then carried exclusively by electrons and electron holes according to the equation

$$i_\infty = i_\oplus + i_\ominus = \frac{RT}{FL}\{\sigma_\oplus{}^\circ [\exp(u) - 1] + \sigma_\ominus{}^\circ [1 - \exp(-u)]\} \quad [1]$$

where L is the cell constant (thickness/area), $\sigma_\oplus{}^\circ$ and $\sigma_\ominus{}^\circ$ are, respectively, the partial electron hole and electronic conductivities at the equilibrium fluorine activity of the reversible electrode and $u = EF/RT$, where E is the applied voltage, **F** is Faraday's constant, and R and T have their usual meaning. The details of the theory have been given elsewhere (19-21).

If the polarity of the applied voltage for cell (I) is reversed (positive reversible electrode), an equation similar to Eq. [1] can also be derived. The usual approach in polarization experiments by all the authors, except Patterson *et al.* (21), has been to assume the validity of Eq. [1] and then evaluate either $\sigma_\oplus{}^\circ$ or $\sigma_\ominus{}^\circ$ according to limiting cases given by Wagner (19, 20).

If the electrolyte is a predominant p-type electronic conductor, and $\exp(u) >> 1$, the equation for the current reduces to

$$i_\infty = i_\oplus = \frac{RT}{FL}\sigma_\oplus{}^\circ \exp(u) \quad [2]$$

An exponentially increasing current will be observed with increasing potential in a plot of i_∞ *vs.* E, while a linear relationship will be observed in a plot of log $(FL/RT)i_\infty$ *vs.* E. The value for the electron hole conductivity $\sigma_\oplus$ can then be calculated from the intercept of the latter plot.

If the electrolyte exhibits predominant n-type electronic conduction, Eq. [1] reduces to

$$i_\infty = i_\ominus = \frac{RT}{FL}\sigma_\ominus{}^\circ [1 - \exp(-u)] \quad [3]$$

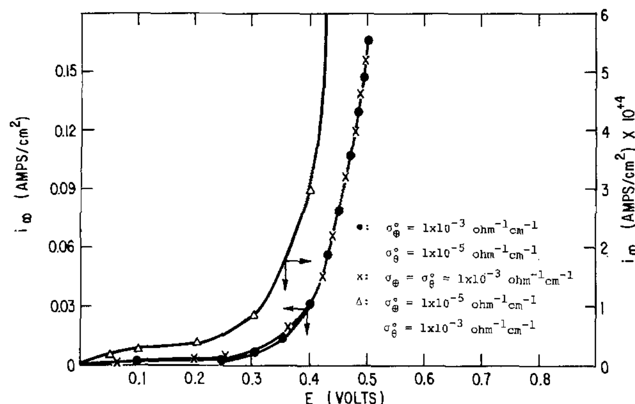

Fig. 1. Calculated i-E curves according to Eq. [1]. $L = 0.2\ cm^{-1}$, $T = 400°C$.

In plots of i_∞ vs. E, with increasing voltage, the current increases and tends to the saturation value. From the plot of log $(\mathbf{F}L/RT)i_\infty$ vs. E, the electronic conductivity can be calculated from the plateau current value which is $\sigma_\ominus°$.

Under certain conditions, the analysis of limiting cases can result in an erroneous conclusion. Figure 1 illustrates i-E plots for the complete Eq. [1] for three limiting cases. Each plot exhibits an apparent exponential curve when the applied voltage is above some value. Obviously, the decision between p- or n-type behavior based on the shape of the experimental plot is not reliable. An improved technique for analyzing polarization data was presented by Patterson *et al.* (21). Both sides of Eq. [1] may be divided by $[1 - \exp(-u)]$ or by $[\exp(u) - 1]$ to obtain

$$i_\infty/[1 - \exp(-u)] = \frac{RT}{\mathbf{F}L}[\sigma_\oplus° \exp(u) + \sigma_\ominus°] \quad [4]$$

or

$$i_\infty/[\exp(u) - 1] = \frac{RT}{\mathbf{F}L}[\sigma_\oplus° + \sigma_\ominus° \exp(-u)] \quad [5]$$

According to Eq. [5], a plot of $i_\infty/[\exp(u) - 1]$ vs. $\exp(-u)$ should give a straight line of slope $\frac{RT}{\mathbf{F}L}\sigma_\ominus°$ and intercept $\frac{RT}{\mathbf{F}L}\sigma_\oplus°$. Analogous equations can be obtained for a positive reversible electrode. Thus the values of both $\sigma_\oplus°$ and $\sigma_\ominus°$ can be simultaneously obtained from a single experimental run. The d-c polarization data in the present study were treated according to this method.

Experimental materials and procedures.—Cubic β-PbF_2 was made by heating the orthorhombic α-PbF_2 (99.99% pure) to over 500°C prior to each experimental run.

A-c conductivity measurements.—The various fluorine activities for a-c conductivity measurements were established through the double cell electrochemical arrangement shown in Fig. 2. The cell was comprised of two symmetrical cells with perforated platinum foils as fluorine gas electrodes contacting PbF_2. Reference electrodes were prepared from nickel-nickel fluoride-calcium fluoride mixtures in a volume ratio of approximately 6:2.5:2 and pressed in a 1.3 cm diam steel die. The calcium fluoride was added to eliminate electrode polarization. The electrolyte CaF_2 was prepared from pressed ultrapure calcium fluoride powder. The fluorine activity P_{F_2} at the platinum foils was fixed by the applied voltage E according to the relation

$$P_{F_2} = P_{F_2}° \ (Ni/NiF_2) \exp\frac{2E\mathbf{F}}{RT} \quad [6]$$

where $P_{F_2}°$ is the equilibrium fluorine pressure of the

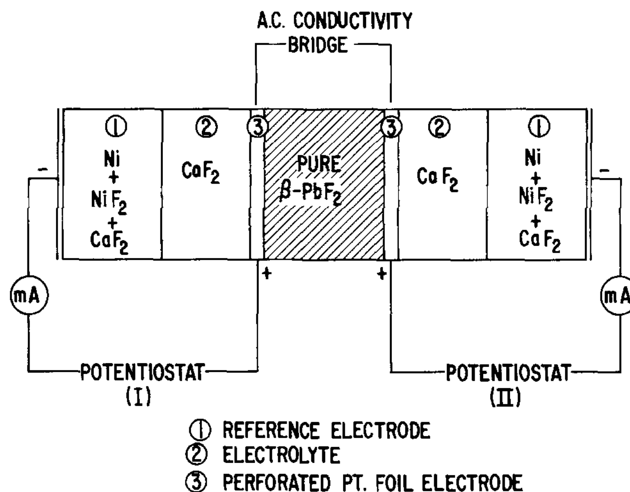

Fig. 2. Experimental cell to study the electrical conductivity of PbF_2.

reference electrode. Preliminary experiments showed that the actual P_{F_2} at the platinum electrodes was a linear function of the current through the cells which was monitored by a Keithley 153 microammeter. The current indicated the existence of a small steady-state fluorine ion discharge at the Pt/CaF_2 interface. This discharge resulted from fluorine escape through the bond between the CaF_2 electrolyte and the platinum foil. Because of the linear relation between the actual P_{F_2} and the cell current, a knowledge of the actual P_{F_2} at the platinum foils was possible. The applied voltages were provided from two potentiostats which were separately supplied with power to avoid an electrical ground loop between the two instruments. Measurements of the a-c conductivity at a frequency of 1592 Hz were made by the Wayne-Kerr Low Universal Bridge B211 which balances the sample conductance and capacitance against standards. When the conductance of a specimen was higher than 0.1 $\Omega^{-1}\ cm^{-1}$ a Wayne-Kerr Low Impedance Adaptor Q211 was used in conjunction with the bridge.

Hebb-Wagner d-c polarization measurements.—Figure 3 shows the cell arrangement for d-c polarization measurements. The reversible electrodes used for this cell were prepared from two-phase equilibrium mixtures of Cu/CuF_2 and Ni/NiF_2. Again, some CaF_2 was added to these mixtures to prevent polarization of the reversible electrode. The blocking electrode consisted of a Pt foil about 0.003 cm thick pressed against a vapor-deposited Au layer.

When Cu/CuF_2 mixtures were used as reversible electrodes at positive polarity, the applied voltages were kept below 640 mV (the difference in the standard Gibbs energies of formation for β-PbF_2 and CuF_2) to avoid the decomposition of PbF_2. On the other hand, for positive polarity at the blocking electrode, the applied voltage could be any value which would avoid excessive F_2 vapor generation (about 2.0V).

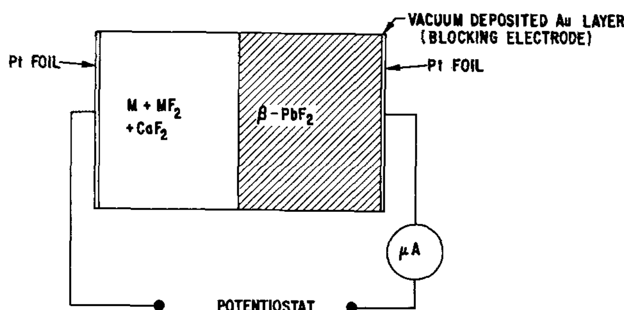

Fig. 3. Cell arrangement for d-c polarization studies of β-PbF_2

If Ni/NiF_2 electrodes are used at positive polarity, the permissible experimental voltage range is too small. Therefore, negative Ni/NiF_2 electrodes are preferred to allow a large applied voltage range (about 2.4V). The steady-state polarization currents were independent of the argon flow rate in the system and were stable over long periods of time.

Results and Discussion

A-c conductivity measurements.—The results of a-c total conductivity measurements are plotted in Fig. 4 as a function of fluorine pressure at various temperatures. By careful examination, there is a very small positive slope for each line. But essentially, the a-c conductivity of β-PbF_2 is independent of fluorine pressure, indicating that β-PbF_2 is a predominant ionic conductor over a wide range of fluorine activity.

D-c polarization measurements.—The converted plot of data for the cell

$$\ominus Ni/NiF_2 \mid PbF_2 \mid Au\oplus \quad [II]$$

according to Eq. [5] is shown in Fig. 5. The values for $\sigma_\ominus^\circ$ and $\sigma_\oplus^\circ$ were obtained from the slope and intercept of the plot, respectively, as already discussed.

The curve shown in Fig. 5 is not a perfectly straight line as was expected, but exhibits an increasing slope with the increasing voltage. Taking the maximum and the minimum values of slope gives

$$\sigma_\ominus^\circ = 3.12\text{-}4.15 \times 10^{-6}\,\Omega^{-1}\,cm^{-1}$$

correspondingly

$$\sigma_\oplus^\circ = 2.14\text{-}1.04 \times 10^{-8}\,\Omega^{-1}\,cm^{-1}$$

for $P_{F_2}{}^\circ$ for coexistence of Ni and NiF_2. This result indicates that $\sigma_\ominus^\circ >> \sigma_\oplus^\circ$; in other words, pure β-PbF_2 is an n-type conductor at the equilibrium fluorine activity for Ni/NiF_2.

To obtain the polarization data for β-PbF_2 at the equilibrium fluorine activity of Cu/CuF_2, cell [III] was used. Positive polarity was applied at the blocking electrode

$$\ominus Cu/CuF_2 \mid PbF_2 \mid Au\oplus \quad [III]$$

Unfortunately, some difficulties arose with this cell. Nonreproducible currents of the order of 1 μA were observed at applied voltages below 0.4V. Further, this cell required 1-1.5 days to reach a steady-state current. As a result, cell [III] with reverse polarity was used. As mentioned earlier, the maximum voltage for cell [III] with opposite polarity is only 640 mV, since higher voltages threaten the decomposition of the lead fluoride. On the other hand, potentials below 0.4V result in very small nonreproducible currents. Because of these two limitations, the voltage range between 0.4 and 0.6V was investigated. A converted plot of data for two such runs is shown in Fig. 6. The analysis yields for run No. 1

$$\sigma_\ominus^\circ = 1.89\text{-}3.81 \times 10^{-9}\,\Omega^{-1}\,cm^{-1}$$

$$\sigma_\oplus^\circ = 4.33\text{-}3.72 \times 10^{-5}\,\Omega^{-1}\,cm^{-1}$$

and for run No. 2

$$\sigma_\ominus^\circ = 6.39\text{-}6.61 \times 10^{-9}\,\Omega^{-1}\,cm^{-1}$$

$$\sigma_\oplus^\circ = 6.93\text{-}6.84 \times 10^{-5}\,\Omega^{-1}\,cm^{-1}$$

The values of $\sigma_\ominus^\circ$ and $\sigma_\oplus^\circ$ show that β-PbF_2 is a p-type conductor in equilibrium with Cu/CuF_2. Therefore, the fluorine activity at which the transition of p-type to n-type takes place falls between $P_{F_2}{}^\circ$ (Ni/NiF_2) and $P_{F_2}{}^\circ$ (Cu/CuF_2).

Figure 7 is a plot of log σ *vs.* log P_{F_2} for pure β-PbF_2; the slopes of log $\sigma_\oplus^\circ$ and log $\sigma_\ominus^\circ$ *vs.* log P_{F_2} approach, respectively, 0.5 and -0.5 at 492°C. These are the slopes expected from a Kroger-Vink diagram for F_i' and $V_F^{\cdot}$ defects in absolutely pure PbF_2, as well as in a doped crystal where an impurity fixes the defect concentration. Since $\sigma_\oplus^\circ$ and $\sigma_\ominus^\circ$ are negligible compared to σ_{ionic}, the total a-c conductivity is essentially equal to σ_{ionic}. Combining the results for $\sigma_\oplus^\circ$, $\sigma_\ominus^\circ$, and σ_{ionic} allows an estimation of the fluorine partial pressure $P_\oplus$ and $P_\ominus$ at which $\sigma_\oplus = \sigma_{ionic}$ and $\sigma_\ominus = \sigma_{ionic}$ at the temperature 492°C. For the condition $\sigma_\oplus = \sigma_{ionic}$, $P_\oplus$ equals 1.0×10^{-21} atm. The P_{F_2} for the condition where $\sigma_\ominus = \sigma_{ionic}$ is far below the P_{F_2} for PbF_2 decomposition and is therefore of no physical significance.

Only two different reference electrodes with differing values of P_{F_2} were used to determine the slopes in

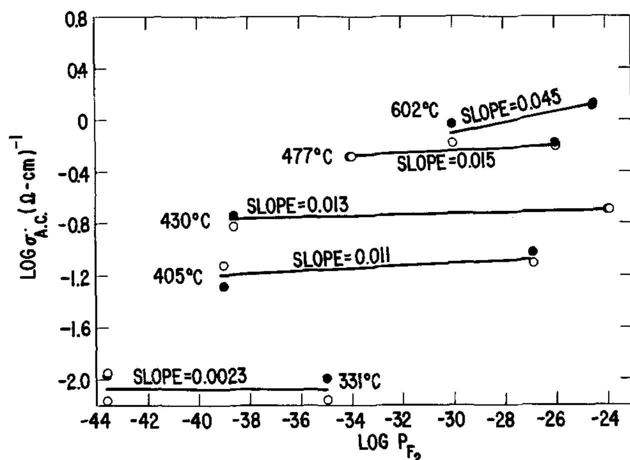

Fig. 4. Fluorine pressure dependence of total conductivity for β-PbF_2 at 330°-600°C. Open and closed circles represent duplicated runs.

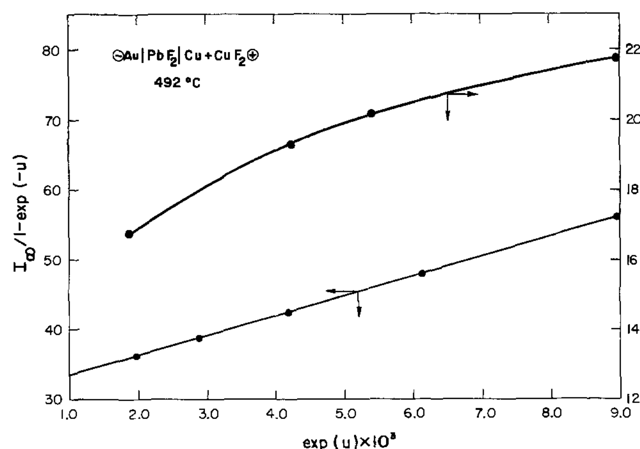

Fig. 6. Converted data for d-c polarization measurements with the cell $\ominus$ Au | PbF_2 | Cu/CuF_2 $\oplus$ at 492°C.

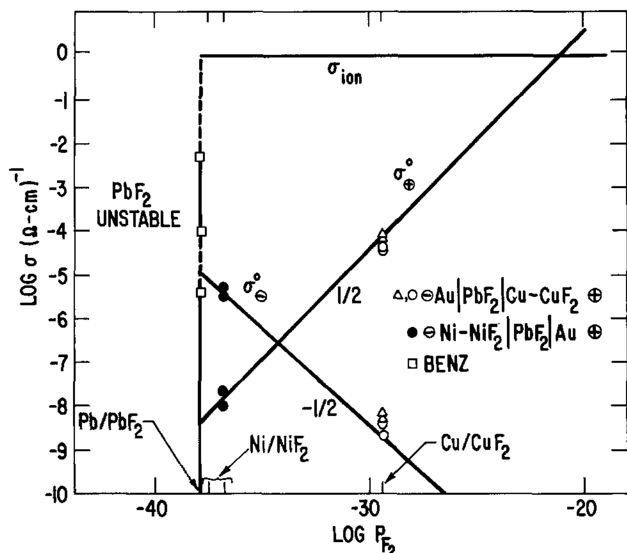

Fig. 7. Plot of log $\sigma_{a\text{-}c}$, log $\sigma_{\oplus}$, and log $\sigma_{\ominus}$ for the polarization and a-c conductivity study of β-PbF_2 at 492°C.

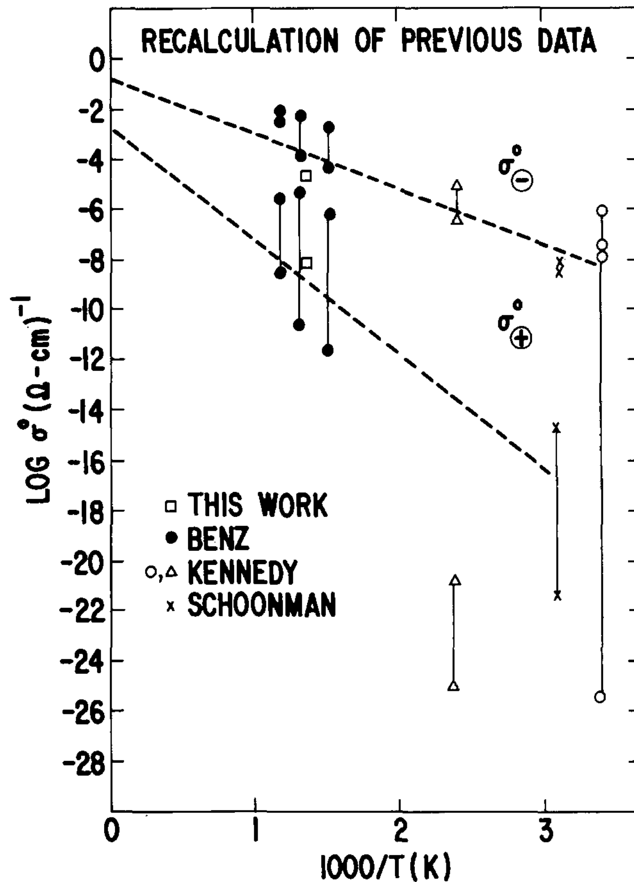

Fig. 8. Plot of log $\sigma_{\oplus}$° and log $\sigma_{\ominus}$° in equilibrium with lead as a function of temperature for β-PbF_2.

the plot of log σ *vs.* log P_{F_2}. These two seem to be the only available fluorides which are solid, have low vapor pressures at relatively high temperature, but yet are less stable than PbF_2.

As mentioned earlier, controversial results of d-c polarization of PbF_2 exist between various authors (4, 8-10, 12). Recalculation of the experimental data of previous studies according to Eq. [4] and [5] becomes necessary and interesting. Data for $\sigma_{\oplus}$° and $\sigma_{\ominus}$° and β-PbF_2 in equilibrium with Pb from these recalculations (4, 8, 10, 12) are plotted as a function of temperature in Fig. 8, extrapolation of the present experimental results for $\sigma_{\oplus}$° and $\sigma_{\ominus}$° from Fig. 7 are also shown on the same plot. Figure 8 shows reasonable agreement among different authors and the present study. Data for $\sigma_{\oplus}$° and $\sigma_{\ominus}$° from Joshi and Liang (9) are not included in Fig. 8 because their results were for α-PbF_2. Figure 8 shows that β-PbF_2 is an n-type conductor in equilibrium with Pb over the temperature range 25°-600°C. This conclusion incorporates the controversial results on polarization experiments from various authors. The improved method for interpreting converted d-c polarization data of Patterson *et al.* was useful in determining both $\sigma_{\oplus}$° and $\sigma_{\ominus}$° in this study. Comparison of electronic conductivities is shown in Table I. The set of values with an asterisk represents the values of $\sigma_{\ominus}$° and $\sigma_{\oplus}$° that fit best in Eq. [4] or [5].

Obviously, opposite conclusions are then sometimes obtained from the simple limiting graphical interpretation and from the improved, converted interpretation of Patterson *et al.*

Conclusions

The a-c conductivity of pure β-PbF_2 has been found to be essentially independent of P_{F_2}. This pressure independence indicates that β-PbF_2 is an ionic conductor over the experimental ranges of P_{F_2} and temperature.

The measurements of electronic conduction of pure β-PbF_2 in the d-c polarization experiment indicates a $P_{F_2}{}^{-1/2}$ dependence for $\sigma_{\oplus}$, and a $P_{F_2}{}^{-1/2}$ dependence for $\sigma_{\ominus}$, in accordance with a simple Kroger-Vink diagram for β-PbF_2. Recalculation of data from previous

* Values of $\sigma_{\oplus}$° and $\sigma_{\ominus}$° best fitted to Eq. [4] and [5].

d-c polarization measurements for α-PbF_2 and β-PbF_2 from various authors, along with the $\sigma_{\oplus}$ and $\sigma_{\ominus}$ from the present study, gives the following conclusion: α-PbF_2 and β-PbF_2 are n-type conductors in equilibrium with Pb. P-type electronic conduction becomes important at high P_{F_2}, with $P_{\oplus} \approx 1.0 \times 10^{-21}$ atm at 492°C. The Patterson method was also applied to recalculate d-c polarization data existing in the literature for $PbBr_2$ and $PbCl_2$. The results indicate that both $PbCl_2$ and $PbBr_2$ are n-type conductors in equilibrium with Pb.

Lithium Dimethyl Sulfite Graphite Cell

Sanjay L. Deshpande*,[1] and Douglas N. Bennion*

Chemical, Nuclear, and Thermal Engineering Department, University of California, Los Angeles, California 90024

ABSTRACT

Reactions occurring at the positive and negative electrodes and in the solution phase of cells of the type Li/$LiClO_4$, DMSU/graphite have been studied. Discharge capability of 36 hr at a current density of 2 mA/cm^2 has been achieved. Discharge potential was about 3.00V measured *vs.* a lithium wire reference electrode. Coulombic efficiency was 100% at 2 mA/cm^2 but dropped rapidly at higher current densities. Charging potentials increased and discharge potentials decreased at higher current densities. Performance of the cell was poor when propylene carbonate was substituted for dimethylsulfite (DMSU) and $LiBF_4$. Changes in the positive electrode materials did not alter performance very much as long as graphite was present.

Lithium is attractive as a possible negative battery electrode because of its strong reducing potential and low equivalent weight. As a secondary or rechargeable electrode, lithium must operate in an aprotic solution. A major problem in developing room temperature, lithium storage batteries has been finding a suitable positive electrode which is compatible with the lithium negative electrode and the aprotic, electrolytic solution. A summary of various lithium battery systems has been presented elsewhere (1).

A possible battery system using a lithium negative electrode, $LiClO_4$-dimethylsulfite (DMSU) electrolytic solution, and a graphite positive electrode has been reported on previously (2-4). It was proposed (2) that a lamellar compound of graphite formed at the positive electrode as a product of the charge storage mechanism

$$nC + LiClO_4 = Li^+ + C_n\,ClO_4 + e^-$$

Some later results (4) suggested that the above reaction is not the dominant reaction and that the solvent, DMSU, is involved more directly in the electrochemical reaction. This paper is intended to determine more clearly the positive electrode reaction and the limits of operating capability when used in a Li/$LiClO_4$, DMSU/C secondary battery system.

Experimental

The electrolytic solutions were prepared by vacuum distilling the solvents and vacuum drying the salts. Further drying was achieved by stirring solvents and solutions with lithium chips followed by filtering. Lithium chips were covered with a white deposit as a result of the drying. The stir-and-filter operation

Key words: nonaqueous solvents, dimethyl sulfite, lithium perchlorate, intercalation, radical cations.

was repeated to expose fresh lithium to the water in the solvent and the solution. Water content was determined using the Karl Fischer technique. Only solutions containing an upper limit of 50 ppm water were used. Graphite powder (99.95% pure, 0.8 μm in size) was used to fabricate the positive electrode. It is a natural graphite originating from Madagascar. Teflon molding powder and Union Carbide National C-34 glue were used as binders. Carbon cloth and titanium foil were used as current collector backing plates.

All experiments were performed in an argon atmosphere dry box. The test cells were glass H-cells as shown in Fig. 1. The two compartments were separated by a fine-size glass frit. Polyethylene stoppers were used to minimize solvent losses by evaporation. Electrode leads came out the top between the polyethylene stopper and the glass wall. The two electrodes, one graphite the other lithium, were held flat to the bottom of their respective compartments by glass sleeves 2 cm inside diam and 1.25 cm high. The sleeves were short enough so they did not block the connecting limb. The liquid level was just above the connecting limb. Each compartment contained about 10 cm^3 of solution. The electrical circuit is shown in Fig. 2. A Perkin Elmer chromatograph, Model 880, with a hot wire detector was used to analyze the electrolytic solution before and after cell operation. Further details of the experimental procedure, sources of material and equipment, and purification techniques can be obtained elsewhere (1).

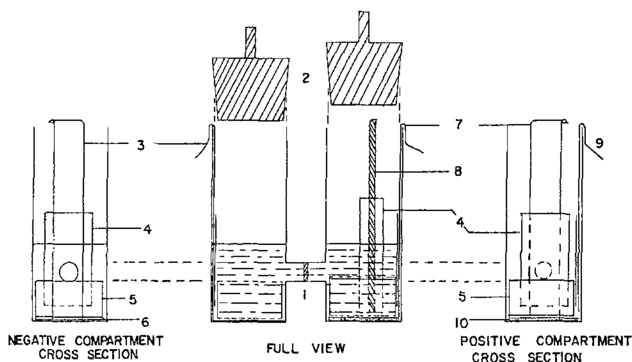

Fig. 1. The H-cell used in all experiments. 1. Glass frit; 2. polyethylene stoppers; 3. negative lead; 4. polypropylene masks for the three electrodes; 5. glass sleeve; 6. negative electrode; 7. positive lead; 8. reference electrode; 9. reference lead; 10. positive electrode.

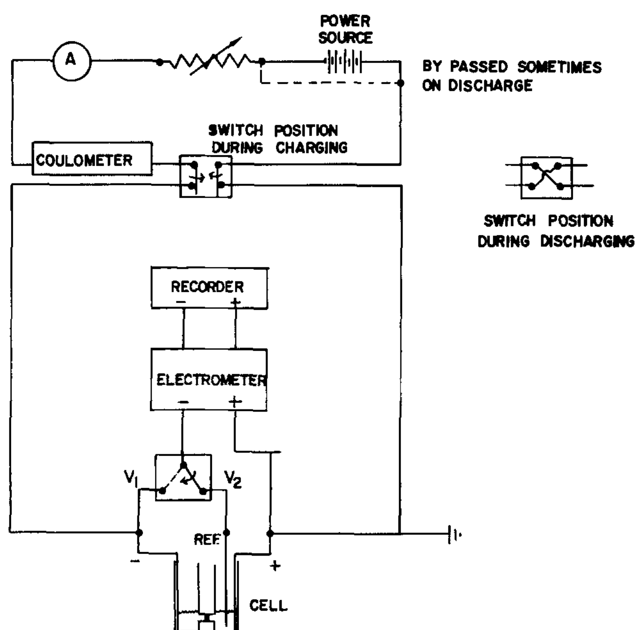

Fig. 2. Electrical circuit diagram for charging and discharging

Both pyrolized and cloth positive electrodes were used. In one case a plain platinum sheet was used. The pyrolized electrodes were made by mixing graphite glue with twice its weight of graphite powder. In one case just the glue was used. The paste was spread on carbon cloth and pressed between two steel plates to form a disk 1.00 mm or less thick. The disk was fired in an argon atmosphere at 800°C for about 6 hr. The result was a brittle, porous disk which adhered well to the cloth. The disk separated easily from the steel plates. The resistance across the cloth disks was about 5Ω. Cloth electrodes were the carbon cloth alone. Prior to use, the carbon electrodes were dried at 50 μm of Hg and 120°C for 6 hr.

In assembling the cells, gas bubbles trapped under the electrodes were shaken free. A thin strip of lithium was placed in the positive compartment as a reference electrode. Strips of polypropylene were placed over electrode leads and the reference electrode wire to prevent a direct current path to them.

The potential between the positive electrode and the lithium wire reference electrode was measured as a function of time while the cell operated at constant charging or discharging current. During one set of measurements, propylene carbonate was used in place of DMSU and $LiBF_4$ in place of $LiClO_4$.

The variables measured were: V_o, the open-ciruit potential right after assembly or a 30 sec interruption in current of the positive electrode *vs.* the reference electrode; V_o', the open-circuit potential after an interruption of a few hours in current of the positive electrode *vs.* the reference electrode; V_1 the operating potential of the complete cell, the positive *vs.* the negative electrode; V_2, the operating potential of the positive electrode *vs.* the reference electrode; V_f, cut-off potential, V_2, when discharging was stopped; Q_{in}, the charge put into the cell during charging; Q_{4V} the charge recovered from the cell with V_2 above 4.0V; Q_{Vf} the charge recovered from the cell with V_2 above V_f.

Potential measurements were made with the positive electrode grounded. Measured values were multiplied by −1 and then reported so that the reported values would conform to the usual sign convention.

Results

Demonstration of reversible electrical storage capacity.—The electrode weighed 0.7245g of which 0.3735g was carbon cloth, 0.2318g graphite powder, and the rest pyrolized graphite glue. Initial thickness was 1 mm and diam 2.0 cm. The electrolytic solution was 1.04 moles $LiClO_4$ per 1000 cm^3 of solution. The initial open-circuit potential, V_o, right after filling was 2.70V. The cell was cycled four times with progressively larger charge in (Q_{in}). Results are shown in Fig. 3, 4, 5, and 6. Charging and discharging was at 3.2 mA (1.0 mA/cm^2) on the first cycle and 6.3 mA (2.0 mA/cm^2) on cycles 2, 3, and 4. On cycle 2, current was increased to 10 mA for short intervals. The curves in Fig. 3, 4, 5, and 6 are typical of many tens of runs.

On the first cycle, two discharge plateaus were observed, one with $V_2 > 4.0V$ and the other with V_2 between 3.0 and 2.8V. Typically, the higher plateau was not observed after the first one or two cycles and following a prolonged (several hours) stand after charging but before discharging. The cutoff voltage, V_f, was 2.5V. The coulombic efficiency on the first cycle exceeded 100%. The excess charge is attributed to reactive impurities initially present in the positive electrode.

On both charging and discharging the potential on prolonged open circuit drifted to $V_o' = 3.75V$. The charge and discharge curves were not significantly affected by long interruptions at open circuit. The sustained discharge for 36 hr at 2 mA/cm^2 demon-

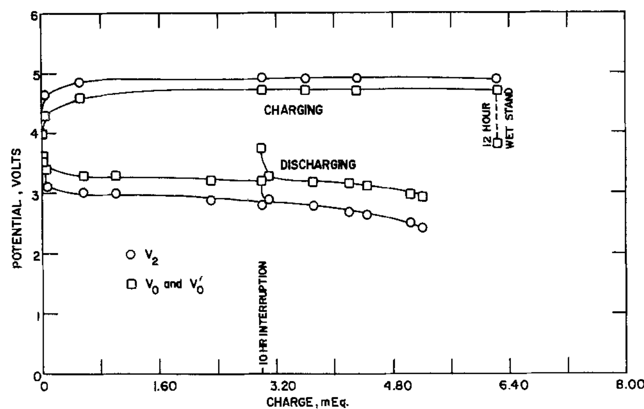

Fig. 5. Galvanostatic charge-discharge curves for the cell Li/$LiClO_4$, DMSU (1.0M)/graphite glue on carbon cloth. Cycle No. 3. I = 6.3 mA; Q_{in} = 6.23 mequiv.; coulombic eff. = 83.4% above V_f = 2.50V; discharge begun after 12 hr of wet stand on charge; positive electrode weight = 0.7245g; graphite = 0.2318g; carbon cloth = 0.3735g; initial thickness of carbon disk = 0.1 cm; top surface area = 3.14 cm^2; resistance = 1.0Ω.

strates a much larger energy storage than the capacity of 1 hr at 2 mA/cm^2 reported by Dunning *et al.* (2). However, Dunning *et al.* looked primarily at the higher, 4.2V plateau; while in this work the lower 2.9V plateau was examined.

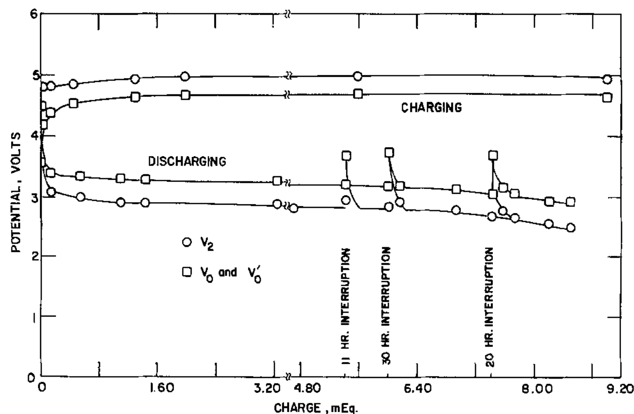

Fig. 6. Galvanostatic charge-discharge curves for the cell Li/$LiClO_4$, DMSU (1.0M)/graphite + graphite glue on carbon cloth. Cycle No. 4. I = 6.3 mA; Q_{in} = 8.92 mequiv.; coulombic eff. = 95.3% above V_f = 2.50V; discharge begun after 0 hr of wet stand on charge; positive electrode weight = 0.7245g; graphite = 0.2318g; carbon cloth = 0.3735g; initial thickness of carbon disk = 0.1 cm; top surface area = 3.14 cm^2; resistance = 1.0Ω.

This comparison is intended to highlight the importance of the lower discharge plateau. Dunning *et al.* used a positive electrode made out of reinforced pyrolytic graphite that weighed 1.4535g and had a cross-sectional area of 8.5 cm^2 (active area was 17 cm^2). About 4 cm^3 of electrolyte solution was used in that test. In comparison, the positive electrode (total weight 0.7245g) reported herein consisted of graphite powder (0.2318g) and graphite glue (0.1192g) and had a cross-sectional area of 3.14 cm^2. About 10 cm^3 of electrolytic solution were present in each half-cell. Table I compares the energy available at the two plateaus. By any criterion, energy available at the lower plateau is higher.

The positive electrode disk swelled from 1 mm thick initially to 5 mm thick after the fourth cycle. The swelling was rapid in the first two cycles, but it swelled little on the last two cycles. The disk remained rigid and adhered to the carbon cloth backing. Final disk resistance was about 3Ω. The surface of the electrode was covered with a thin white deposit. During the charging run of the first cycle, the solution in the positive half-cell gradually turned dark brown. When Anderson Physics Lab ultrapure $LiClO_4$ was used in place of K and K Labs $LiClO_4$, the brown substance did not appear.

The deposit on the negative electrode was dendritic and adhered weakly to the lithium substrate. A white, gelatinous floc appeared at the surface of the lithium. On long cycles a small but steady bubbling appeared on the lithium electrode. The appearance of a white floc agrees with observations of Selim and Bro (5).

Bubbles appeared on the lithium wire reference electrode occasionally during long charging periods, and twice during the 36 hr discharging run it corroded badly enough so that replacement was necessary.

To study the effect of operating current on cell performance, cells of the type just described were operated at varying currents. The results are shown in Fig. 7. Above 2 mA/cm^2 the coulombic efficiency drops rapidly. The current voltage curves are shown in Fig. 8 for charging and discharging. The potentials are average values of the plateau regions. After the high current operation, a cycle was carried out at

6.3 mA (2 mA/cm²) and coulombic efficiency returned to 100%.

In order to check for involvement of electrolytic solution species in the electrode reactions, propylene carbonate (PC) was substituted for DMSU and $LiBF_4$ for $LiClO_4$. The results are shown in Fig. 9, 10, and 11. A comparison of results is shown in Table II. The results imply that DMSU is a necessary part of the positive electrode reaction process and that $LiClO_4$ gives better performance than $LiBF_4$.

The effect of different materials in the positive electrode on cell performance was examined. Results

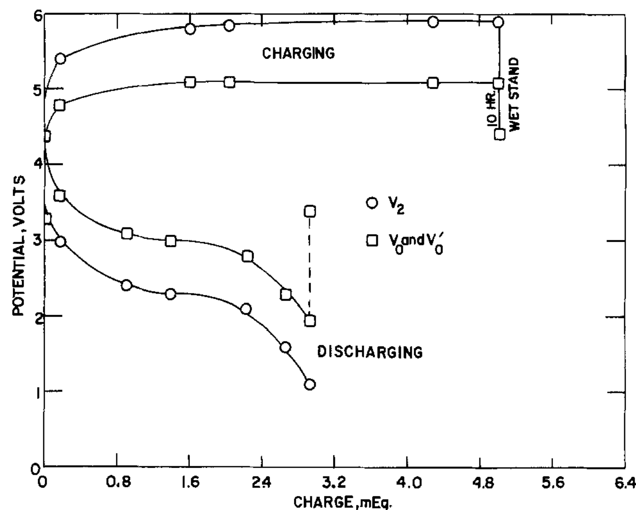

Fig. 9. Galvanostatic charge-discharge curves for the cell Li/ $LiClO_4$, PC (0.89M)/graphite + graphite glue on carbon cloth. Cycle No. 5. $I = 6.3$ mA; $Q_{in} = 5.0$ mequiv.; coulombic eff. = 45.6% above $V_f = 2.0V$; positive electrode weight = 0.6260g; graphite = 0.1980g; carbon cloth = 0.3262g; initial thickness of carbon disk = 0.10 cm; top surface area = 3.14 cm²; resistance = 1.0Ω.

Cycle No. 3. $I = 6.3$ mA; $Q_{in} = 4.16$ mequiv.; coulombic eff. = 72.3% above $V_f = 2.0V$; positive electrode weight = 0.2218g; graphite = 0.0448g; carbon cloth = 0.1540g; initial thickness of carbon disk = 0.04 cm; top surface area = 3.14 cm²; resistance = 3.0Ω.

with bare platinum as the positive showed a fairly flat charging plateau at 5.6V, but no discharge plateau was observed. Pyrolized glue on carbon cloth (no graphite powder) gave typically observed results as shown in Fig. 12. Results using only carbon cloth are shown in Fig. 13. The charging runs were flat at 5.2V and not shown. The coulombic efficiency increased with increased cycling. During run 4, 41% of the 8.52 Mequiv. had been recovered when discharging was stopped because the reference electrode had dissolved away and cell resistance had increased from 1.0 to 2.8 kΩ. However, V_0 was steady at 3.2V. There was bubbling at the lithium counterelectrode and the reference electrode. Although all the carbon

electrodes gave appreciable charge storage, the high surface area electrodes gave the greatest charge retention.

Gas chromatographic analysis was carried out on the electrolytic solution of the positive half-cell at various stages of charge and discharge. A new peak was observed at the end of charging which was not present at the end of discharging. This implies that the oxidizing agent formed on charging is at least partially soluble, and it is consumed on discharging.

X-ray powder diffraction data ($Cu_{K\alpha}$ radiation) on cycled positive electrodes in cells containing DMSU showed a number of diffraction lines that could not be assigned to a known compound. The most intense of these lines had a d value of 4.42Å followed in intensity by the line with d = 7.76Å. Thus, there is evidence for some intercalation of graphite. On samples of positive electrodes from cells using PC as solvent, however, there were only two unassigned peaks with d values of 2.39 and 1.80Å, the latter being more intense. Thus, intercalation of graphite (characteristic d = 3.38Å) in PC solutions is not significant.

Discussion

The need for carbon as natural graphite, carbonized graphite glue, or carbon cloth for charge storage in the positive electrode has been demonstrated by substantial charge storage in the carbon positive electrodes and the inability of a bare platinum electrode to demonstrate charge storage. Graphite or carbon appears to be a suitable catalyst and possibly a participant in the charge storage reactions at the positive electrode. The high storage of the graphite powder-graphite glue compared to carbon cloth alone is attributed to better adsorption properties of the powder plus glue.

The initial swelling of the pyrolized graphite-glue electrodes is attributed to formation of intercalation compounds, possibly intercalation of perchlorate anions and/or the solvent molecules. However, substantial charge storage was achieved with carbon cloth alone, which did not swell. This implies that the intercalation reactions are side reactions which do not contribute significantly to charge storage but help to increase the carbon surface area available for storage of the oxidizing agent produced during charging.

The attack on the lithium wire reference electrode and the new peak observed by gas chromatography of samples taken after charging imply that the oxidizing agent formed during charging is at least partially soluble. It is not expected that intercalation compounds would be soluble. Since the perchlorate ion is already highly oxidized and no chlorine or oxygen gas evolution was observed, it appears that DMSU is the principal reactant. This conclusion is further strengthened by the observations that, when DMSU was replaced by PC, the charge storage capability of the positive electrode, the coulombic efficiency, and the value of the discharge potential all dropped substantially (Table I).

DMSU molecules contain sulfur in the valence state 4. Valence states 5 and 6 are known for sulfur. Thus it is reasonable to expect DMSU to be oxidized during charging

$$(CH_3O)_2SO \rightarrow [(CH_3O)_2SO]^+ + e^-$$

or

$$(CH_3O)_2SO \rightarrow [(CH_3O)_2SO]^{+2} + 2e^-$$

During charging, it appears possible that the initial reaction product, presumably a radical cation, may rearrange or react further. The radical cation is expected to be reduced back to DMSU which would complete the reversible cycle. However, charged species resulting from subsequent rearrangement may form final products other than DMSU during discharge. Since there was a large excess of DMSU in all of the experiments run in this investigation, it has not been established whether or not subsequent cycles complete a reversible cycle or whether fresh DMSU

is oxidized each charge cycle implying that a storage battery type cycle does not exist for this system.

At the negative electrode dendritic lithium deposits were observed to change during discharging into a white floc which could be $LiClO_4$. If that is the case, it is implied that during discharging a local supersaturation of $LiClO_4$ occurs near the negative electrode. This behavior would be expected if the ClO_4^- mobility is much larger than the Li^+ mobility. Since the Li^+ is probably highly solvated, it is reasonable to expect the ClO_4^- ion to have a higher mobility. Preliminary x-ray analysis indicated the white precipitate was $LiClO_4$, but the results were not conclusive.

Activities and Surface Tension of Liquid AgCl-KCl Solutions

Z. Moser,* M. Kucharski, and K. Rzyman

Institute for Metal Research, Polish Academy of Sciences, Kraków, Reymonta 25, Poland

ABSTRACT

Thermodynamic properties of liquid AgCl-KCl solutions were investigated at concentrations of $X_{AgCl} = 0.43\text{-}1.00$ at temperatures of 860°-1000°K by the method of formation cells with chlorine electrode. The partial thermodynamic data of AgCl were interpreted by Krupkowski's method and the relations of activity coefficients of both AgCl and KCl were obtained. Simultaneously, the surface tension measurements of pure AgCl, KCl, and AgCl-KCl liquid solutions were carried out using the maximum bubble pressure method at temperatures of 734°-1220°K dependent on the composition of investigated solutions and the melting points of pure salts. Using the thermodynamic data of bulk AgCl-KCl solutions, results of surface tension, and the calculations of the composition of the surface phase of the thickness 4.29×10^{-8} cm, the activity coefficients of AgCl in this phase were obtained.

Experimental methods dealing with the determination of thermodynamic properties of liquid solutions do not take into account the surface phenomenon, *i.e.*, the adsorption of the surface. On the other hand, the case of equilibrium between the surface phase and the bulk may be considered in order to explain surface properties. In this case, however, it is possible to determine the thermodynamic properties of both phases mentioned above despite the fact that the surface phase is not a separate one. To investigate these problems, thermodynamic properties of the bulk phase were determined by the emf method for the AgCl-KCl liquid solutions, while surface tension measurements of pure AgCl, KCl, and AgCl-KCl solutions made it possible to follow the change of activities in the solution in the surface layer.

Thermodynamic Properties of Liquid AgCl-KCl Solutions

Experimental investigations on AgCl-KCl liquid solutions form part of the studies on ternary salt solutions including AgCl-LiCl-KCl. The aim of these studies is to show the possibility of applying Krupkowski's formalism (1) to salt systems with single charge ions and to verify the similarities between liquid salt and metallic systems. It was shown by Moser and Fitzner (2) when analyzing available experimental data from the literature for the AgCl-LiCl-KCl system on plot $(\ln \gamma_{AgCl})_{X_{AgCl}=0}$ *vs.* X_{LiCl} that, as in the case of liquid metal solutions (3), the deviation from linear dependence forms the term connected with the binary system KCl-LiCl.

Applying the method of formation cells with a chlorine electrode of the following type

$$Ag(s)/AgCl\text{-}KCl(l)/Cl_2(g), \text{graphite} \quad [1]$$

the thermodynamic properties of liquid AgCl-KCl solutions were investigated at concentrations of $X_{AgCl} = 0.43\text{-}1.00$ and at temperatures of 860°-1000°K. The scheme of the cell is shown in Fig. 1. A crucible, 2, made of silica and containing liquid salts, 6, was placed in an alumina crucible, 1. The following were immersed in liquid salts:

A. A high melting glass tube, 13, closed at one end with the orifice enabling contact with liquid salts, in the bottom of which was placed a silver electrode, 3. A silver electrode in the form of a sheet was connected with an alumina tube, 14, by alundum cement. The upper part of the silver sheet was connected with Pt wire, 4, passing through a rubber stopper, 5.

B. Pt-PtRh10 thermocouple, 11, was inserted into a silica tube enabling temperature measurements to ±2°C.

C. An asbestos diaphragm, 7, sealed in a silica tube, 8, separates the two electrode compartments and forms the bottom part of the chlorine electrode. The
