The experiments performed were designed with a number of important findings (38) in mind: if the nickel electrode is held at a base potential corresponding to active dissolution of the metal (0 to +100 mV RHE) and then anodic activation in the +150 to +700 mV range is carried out, when the potential is lowered again to the value of the base potential the observed current may exceed the current observed, before anodic passivation at the same base potential, up to two orders of magnitude. In Trusov's experiments the associated specific charge, 4.4×10^{-4} C/cm^2, corresponds to current flows in the 10-80 μA range; Oshe and Lovachev (36) reached current densities up to 0.3 mA/cm^2.

The experimental procedure followed closely Trusov's (38) scheme using the same electrolyte species and concentration: Fig. 10 shows the monopolar behavior of the anode in a 0.1 mole/dm^3 H_2SO_4 solution. In Fig. 10a typical fast decay is seen at +30 mV potential measured with a mercury-mercurous sulfate reference electrode at 23°C. Upon anodic activation at +330 mV for half a minute, the dissolution

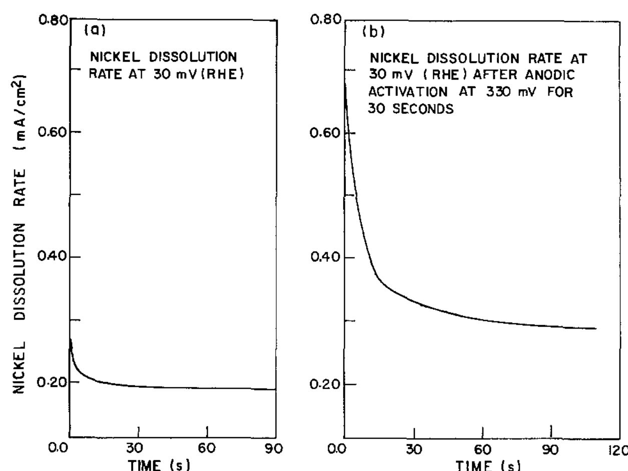

Fig. 10. Typical nickel dissolution rates in monopolar operation (electrolyte, 0.1 mole/dm^3 H_2SO_4; $T = 23°C$). (a) Potential, 30 mV (RHE); (b) potential, 30 mV (RHE) after anodic activation at 330 mV for 30 sec.

rate jumps to a rather high value, which diminishes gradually toward a steady state (Fig. 10b). The total charge density over the 0-90 sec period being computed as 17.67 mC/cm^2 (Fig. 10a) and 30.64 mC/cm^2 (Fig. 10b) by numerical integration, anodic activation under the specific conditions shown is manifest by a relative increase of about 74% in the associated flow of electric charge. A brief analysis of possible components of this flow is as follows.

Oxygen evolution at the nickel anode.—From oxygen overpotential data [Ref. (40), Table IV.8] on nickel, the computed regression line

$$\hat{\eta}_{O_2} = 1.0448 + 0.1466 \log_{10} i \, V (i\text{: A/cm}^2) \quad [6]$$

with a standard error of estimate of 7.39×10^{-3} indicates that at the observed current densities, the oxygen overpotential is in the 0.53-0.57V range and, as such, is higher than the approximate value of the passivation potential at $pH = 0$ and 25°C for Ni [0.36V, Ref. (41), Table II.7]; this value is somewhat modified for the working electrolyte with computed $pH \cong 0.96$. Thus, the contribution of oxygen evolution is negligible at the experimental conditions.

Anode reactions related to impurities in the electrolyte.—Reagent grade H_2SO_4 has at most 0.5 ppm Cu, Pb, and heavy metals; 0.2 ppm Fe and 0.5 ppm Ni in the stock solution; the working electrolyte was obtained by tenfold dilution. This effect, therefore, is likewise negligible.

Anode reactions related to impurities in the electrode.—The only metallic impurity in Ni 200 of quantitative importance and with a stronger dissolution tendency than Ni is manganese (0.25%) with an oxidation standard potential of 1.180V. From the Pourbaix diagram (35) it appears that if Mn were "free" in the nickel electrode, the $Mn \rightarrow Mn^{++} + 2e^-$ dissolution process would compute with a similar reaction involving Ni and Ni^{++}. The actual dissolution rate depending on the surface structure, etc., it does not follow that manganese in the anode would readily dissolve in the electrolyte under anodic activation. This component is expected to be quite small although probably not entirely negligible.

Hydrogen absorption or the formation of excess O_2 on the anode surface.—According to Trusov (38) this contribution is negligible, in contradiction to the statements by Oshe and Lovachev (36). There is no clear evidence that this component is of any importance.

Formation of intermediate oxygen compounds on the surface (39) or the creation of excess dissolution centers (38).—The relative largeness of the charge ratios (see above) favors the latter model where the dissolution centers represent crystallographic disruptions of the surface in the form of atoms "torn" from it. Oxygen on the surface would block such centers. Deactivation is due, according to this model, to the disappearance of dissolution centers which leads to a "self-healing" of the surface. While this model is not entirely convincing it appears that the electrode behavior in bipolar operation might be explained in its terms. In Fig. 11 monopolar and bipolar operations are compared; in the latter, the inner electrode potential was adjusted to 30 mV with respect to the solution potential in compartments 1 and 2, and the third compartment potential was maintained independently at 330 mV. It can be seen that while the anode rotation rate has essentially no effect on monopolar operation, it has a definite beneficial effect on the bipolar mode of operation, the enhancement in the dissolution rate being 2 to 3 times the monopolar rate. One might argue that the combined effect of rotating and wiping is a continuous recreation of dissolution centers, hence a continuously active reaction surface. Apart from the (yet unknown) correct reaction mechanism, the bipolar rotating cell may serve, on proper scale-up, as an improved nickel electrorefining reactor.

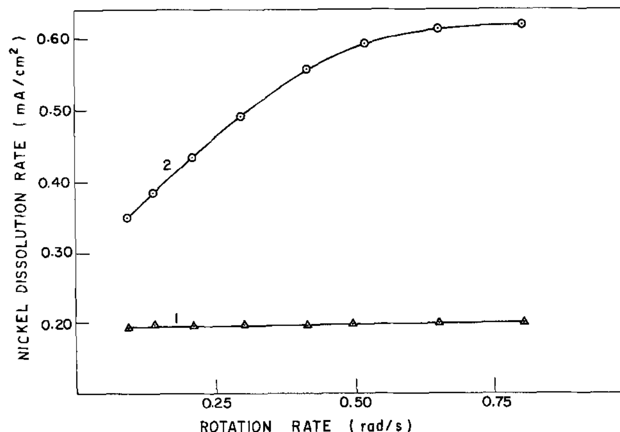

Fig. 11. The effect of rotation speed on the rate of nickel dissolution at a potential of 30 mV. Curve 1, monopolar operation; curve 2, bipolar operation. Anodization potential, 300 mV (RHE) (electrolyte, 0.1 mole/dm^3 H_2SO_4; $T = 23°C$).

Summary

The rotating multipolar, wiped electrode principle has been found useful for a nickel electrode in the following applications:

Redox reactions: As in the instance of platinum, the inhibitive effect of the oxide film can be suppressed and rates higher than those observed in conventional electrolyzers can be maintained. In contrast to Pt, enhancement on Ni, often one order of magnitude, is limited to the low current density region; the rate of enhancement increases with the electrode rotation rate.

Organic compounds which react with oxides of the electrode material can be continuously oxidized at relatively high rates in a multipolar cell and in the region of low electrooxidation current, by means of maintaining an amount of oxide, in excess of the equilibrium value, on the Ni electrode surface. In the region of high current densities, where the electrode is gradually passivated, continuous reactivation may be achieved by repeated removal (wiping) of the passivating surface.

The rotating bipolar, wiped cell is an efficient means of continuous anodic activation for electrolytic metal dissolution processes. Quantitative data concerning various other electrodes would be the subject matter of further experimental studies.

The Electrochemical Behavior of Te(IV) in Sodium Tetrachloroaluminate Melts

J. Robinson and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The electrochemistry of Te(IV) in NaCl:$AlCl_3$ melts has been investigated by a variety of techniques including cyclic and pulse voltammetry, potentiometry, controlled potential coulometry, and the use of the rotating-disk electrode. It was found that in the most basic melts at temperatures above 250°C, Te(IV) was initially reduced by a two-electron step to a soluble Te(II) species which could then be reduced further to elemental tellurium. At lower temperatures and in more acidic melts, Te(IV), which is present in the melt as the chlorocomplexed ion $TeCl_3^+$, is reduced directly to Te which undergoes a complexation reaction with Te(IV) to form Te_4^{2+}. This complexation reaction and the oxidation of Te_4^{2+} have both been extensively investigated and a mechanism for the complexation reaction involving a Te(II) intermediate is proposed.

As part of our continuing investigations into the electrochemistry of inorganic species in sodium tetrachloroaluminate melts, we have, in view of their possible use as cathode materials in molten salt battery systems (1-3), been particularly interested in the behavior of the chalcogens and their compounds. We recently reported on our studies in these solvents of sulfur (4) and selenium (5), which were shown to be reducible to the respective chalcogenide and could also be oxidized to cationic moeties. The nature of these cations was found to be highly dependent upon the composition of the melt. The present paper is con-

cerned with a similar investigation of the electrochemistry of tellurium species in the same solvent system.

In recent years Bjerrum and co-workers have reported the results of several studies, utilizing both spectrophotometric (6, 7) and potentiometric (7) techniques of unusual tellurium cations in tetrachloroaluminate melts. In particular they have reported the existence of the entities Te_2^{2+}, Te_4^{2+}, Te_6^{2+}, and Te_8^{2+}, which are stabilized by the large anions, $AlCl_4^-$ and $Al_2Cl_7^-$, present in the melt, and also Te^{2+}, which is stabilized by Cl^-. The same workers have also studied the chloro-complexes of the Te^{4+} cation in $KCl:AlCl_3$ melts (8, 9), and found there to be four species present, $TeCl_6^{2-}$, $TeCl_5^-$, $TeCl_4$, and $TeCl_3^+$, which are linked by melt acidity dependent equilibria. The solid compounds of the Te_4^{2+} cation, $Te_4(AlCl_4)_2$ and $Te_4(Al_2Cl_7)_2$, have been characterized by Corbett *et al.* (10, 11) who have also identified a tellurium cation of + 1/3 oxidation state.

Despite their possible use in battery systems, the electrochemistry of tellurium compounds does not appear to have been widely studied either in tetrachloroaluminates or any other molten salts. Bodewig and Plambeck (12) have investigated the anodization of Te into a fused LiCl:KCl eutectic and have proposed the reaction to be the oxidation of Te to Te^{2+}. Until very recently, the only study of Te in tetrachloroaluminates was a very brief one, some thirty years ago, by Verdiek and Yntema (13), however, Paulsen and Bjerrum (14) have now reported on a study of the electrochemistry of Te^{4+} in basic and neutral $KCl:AlCl_3$ melts at temperatures between 300° and 400°C. They reported that under these conditions Te^{4+}, which is chloro-complexed in the melt, was reduced reversibly to a soluble Te^{2+} species which could then be further reduced to insoluble elemental tellurium. In view of the known complexity of the redox chemistry of tellurium in these melts, and in particular its dependence upon temperature and melt composition (6, 7), the electrochemical behavior can be expected to be very different at lower temperatures and higher *p*Cl's. The work presented here is primarily concerned with the electrochemistry at lower temperatures (175°C) and over a wide range of *p*Cl's.

In order to investigate the *p*Cl dependence of the electrochemistry of the Te compounds the acid-base properties of the $AlCl_3:NaCl$ molten salt solvent system must be understood. These have been discussed previously (15) and the way the concentrations of the different species present in the melt vary with the $AlCl_3:NaCl$ ratio was shown to be fully described by the following three equilibria

$$2AlCl_3(l) \rightleftarrows Al_2Cl_6(l)\ (K_0 = 2.86 \times 10^7) \quad [1]$$

$$AlCl_4^- + AlCl_3 \rightleftarrows Al_2Cl_7^-\ (K_2 = 2.4 \times 10^4) \quad [2]$$

$$2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^-\ (K_m = 1.06 \times 10^{-7}) \quad [3]$$

where the *K* values are the mole fraction equilibrium constants. The dominant acid-base equilibrium is that described by Eq. [3] where $Al_2Cl_7^-$ is the Lewis acid and Cl^- the base. The *p*Cl (mole fraction scale) of a neutral melt, 50 mole percent (m/o) $AlCl_3$, at 175°C is 3.5; however, a melt of any desired acidity can readily be made by anodizing an Al wire into it (16) until the desired composition, as indicated by the potential of an Al indicator electrode with respect to an Al wire in a melt of known composition (15), is reached.

Experimental

The details of melt preparation and purification, electrochemical cells, electrode construction, electrochemical instrumentation and, experimental techniques have been fully described in an earlier publication (5). The $TeCl_4$ (Cerac Pure Incorporated 99.5% pure) was used as received. Throughout this work the reference electrode is an aluminum wire immersed in an NaCl-saturated melt at the temperature of the experiment separated from the bulk solution by a fine porosity glass frit.

Results and Discussion

$TeCl_4$ is readily soluble in an NaCl-saturated melt at 175°C, and Fig. 1 shows a typical cyclic voltammogram of such a solution recorded at a sweep rate of 100 mV sec^{-1}. There is a well-defined reduction peak (E_p = 1.615V) and a corresponding reoxidation wave (E_p = 1.662V). This particular voltammogram was recorded with a glassy carbon electrode; however, the behavior was identical at a tungsten electrode. Contrary to the observations of Paulsen and Bjerrum (14), no problem was ever encountered with reproducibility at a glassy carbon electrode and in view of the easier surface preparation of these carbon electrodes, they were used throughout this study. Figure 2 shows a series of normal pulse voltammograms, recorded at different pulse widths (t), of a $TeCl_4$ solution for the same conditions as in Fig. 1. The limiting plateau currents were found to be linearly dependent upon $t^{-1/2}$, indicating that within the time scale of these experiments the reduction process is diffusion controlled and a diffusion coefficient for the Te(IV) species of 4.54×10^{-6} cm^2 sec^{-1} was calculated from this data (using an n value of 4 *vide infra*). As a further test of diffusion control, the rising portions of the pulse voltammograms were analyzed. If the product of the reduction is soluble then a plot of log $(i_d - i/i)$ *vs.* E should be a straight line, whereas if the reaction product is insoluble log $(i_d - i)$ *vs.* E will be linear. Figure 3 shows such plots for a 105 msec pulse. It can immediately be seen that the log $(i_d - i)/i$ plot is linear, whereas the log $(i_d - i)$ plot is not, the product of the reaction must therefore be soluble. From the slope of the log $(i_d - i)/i$ plot, a value of $\alpha\eta_\alpha$ can be calculated and this was found to be 1.82. Log $(i_d - i)/i$ plots for the shortest pulse lengths (15 msec) begin to show a degree of nonlinearity; the reason for this effect is discussed in detail later. The reduction was also examined by differential pulse voltammetry and

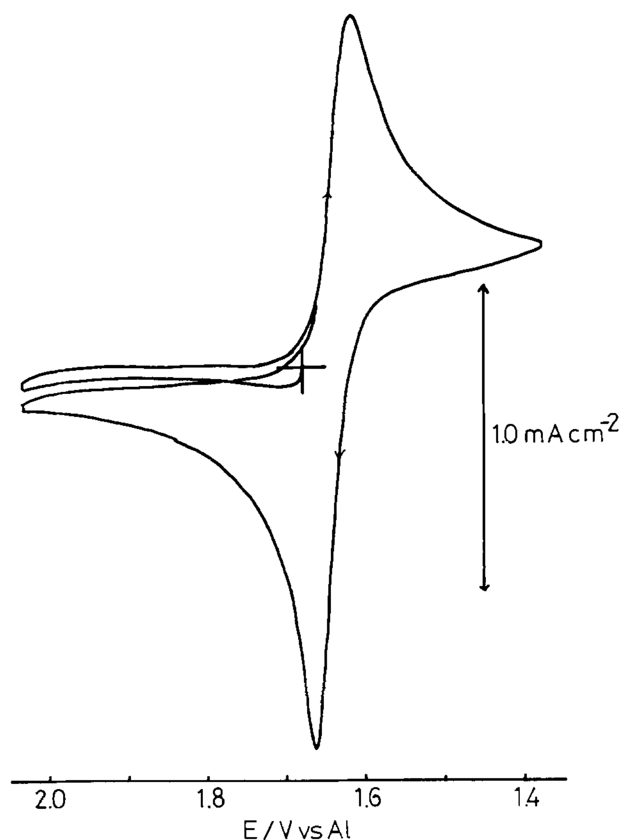

Fig. 1. A cyclic voltammogram at a glassy carbon electrode of a 1.22×10^{-3}M solution of $TeCl_4$ in an NaCl-saturated melt at 175°C. The sweep rate was 100 mV sec^{-1}.

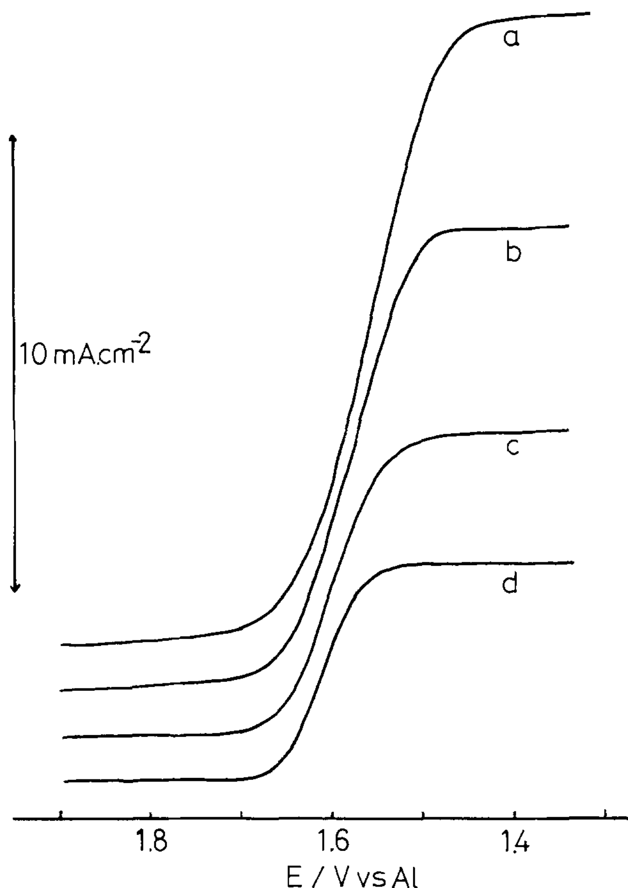

Fig. 2. Normal pulse voltammograms of a 3.55×10^{-3}M solution of $TeCl_4$ in an NaCl-saturated melt at 175°C. The sweep rate was 1 mV sec^{-1}, the delay time was 1 sec, and the pulse lengths were: (a) 15 msec; (b) 25 msec; (c) 55 msec; and (d) 105 msec.

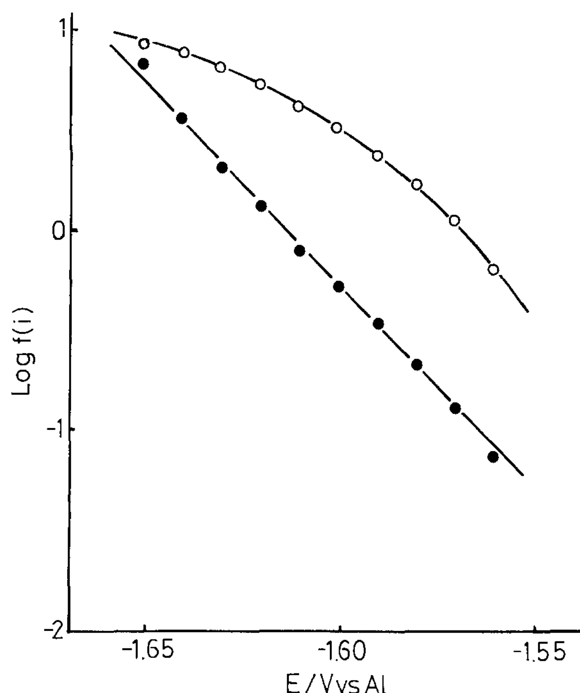

Fig. 3. A kinetic plot for a normal pulse voltammogram of a 3.55×10^{-3}M $TeCl_4$ solution in NaCl-saturated $NaAlCl_4$ melt at 175°C using a 105 msec pulse length [polarogram (d) of Fig. 2]. —○— $f(i) = (i_d - i)$; —●— $f(i) = (i_d - i)/i$.

the voltammograms for the conditions of Fig. 1 and 2 showed a single symmetrical peak. The width of this peak at half height was 39 mV for a 105 msec pulse length and increased with decreasing pulse length. This value of the peak width agrees most closely with that predicted for a reversible four-electron process (34 mV at 175°C). The increase of peak width with decreasing pulse length is indicative of the quasi-reversibility of the reduction. Exhaustive controlled potential coulometry, using a tungsten crucible as the electrode, was carried out to test this conclusion, and the number of electrons per $TeCl_4$ molecule was found to be 3.9 ± 0.1. The electrode reaction must therefore be a four-electron process. At the completion of the coulometric experiment no electroactive species were present in solution in the melt (either oxidizable or reducible) and a finely divided gray precipitate of elemental tellurium was left in the cell. This precipitation, however, only commenced at the very end of the electrolysis when very little Te(IV) was present. It therefore appears that the Te is in some way solubilized by the Te(IV). This phenomenon is discussed in detail later.

The behavior observed here is very different from that reported by Paulsen and Bjerrum (14) at similar values of melt acidity (at 175°C the pCl of an NaCl saturated melt is 1.9 on the mole fraction scale, which corresponds to a value of approximately 1.0 on the molar scale used by Paulsen and Bjerrum). The present work, however, was carried out at a significantly lower temperature. To determine the temperature effect, cyclic, normal pulse, and differential pulse voltammograms were recorded at several temperatures between 175° and 350°C. Figures 4a and 4b show typical cyclic voltammograms at 265° and 350°C, respectively, of $TeCl_4$ solutions in NaCl-saturated melts. It can immediately be seen that the four-electron reduction observed at lower temperatures (Fig. 1) splits into two distinct processes, as also does the reoxidation wave. Analogous behavior was also observed on the normal and differential pulse voltammograms. Exhaustive-controlled potential electrolysis shows that the two waves observed in the cyclic voltammetry at 350°C both correspond to two-electron processes.

These observations are in agreement with the results reported by Paulsen and Bjerrum (14), that in basic-to-neutral tetrachloroaluminate melts at high temperatures, Te(IV) is first reduced to Te(II) and then to Te. No detailed analysis of the pCl dependence of the reduction processes at these temperatures was undertaken here, as there is no reason to suppose that the behavior in $NaAlCl_4$ will be any different to that observed in $KAlCl_4$ by Paulsen and Bjerrum (14); that is that Te(IV) is present as $TeCl_6^{2-}$ and $TeCl_5^-$ while Te(II) is present as $TeCl_3^-$ and $TeCl_2$. It is interesting that the stability of the Te(II) species shows a very strong temperature, as well as acidity, dependence; *e.g.*, at a pCl of 1.9 at

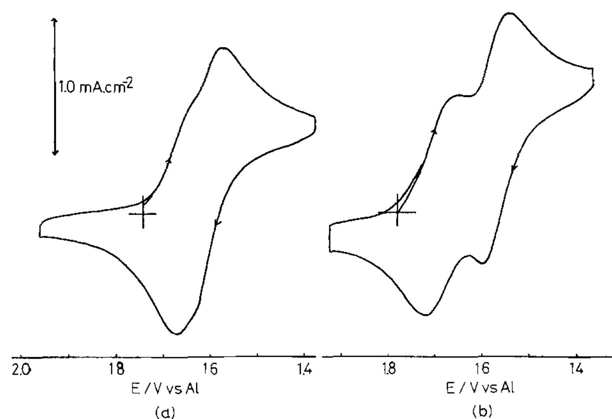

Fig. 4. Cyclic voltammograms of 2.27×10^{-3}M $TeCl_4$ solution in NaCl-saturated $NaAlCl_4$ melts recorded at 100 mV sec^{-1}. The temperatures were (a) 265°C; and (b) 350°C.

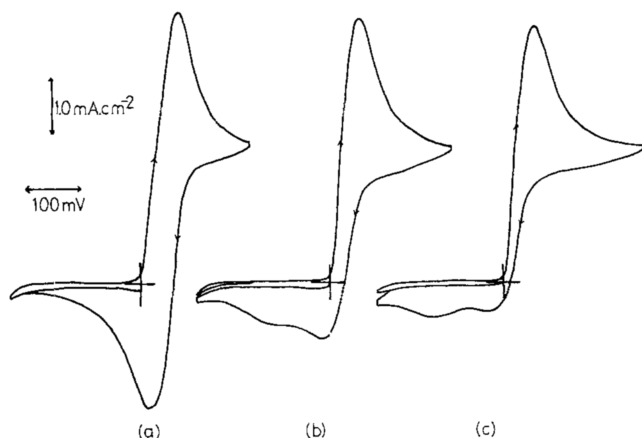

Fig. 5. Cyclic voltammograms of 8.48×10^{-3}M $TeCl_4$ solutions. The melt pCl's were (a) 2.8; (b) 3.75; and (c) 5.1, while the electrode rest potentials were (a) 1.824V; (b) 1.880V; and (c) 1.993V.

175°C the reduction (see Fig. 1) is a well-defined four-electron step, whereas at the same pCl at 350°C it was observed that the reduction showed two distinct two-electron steps.

Already it can be seen that the electrochemistry of Te(IV) in tetrachloroaluminate melts shows remarkable temperature dependence. The remaining part of this study, however, is concerned with the pCl dependence at 175°C. Figures 5a, 5b, and 5c show cyclic voltammograms, at a fixed sweep rate of 50 mV sec^{-1}, of Te(IV) solutions of increasing acidity. It can be seen that the reduction peak moves strongly in the anodic direction as the acidity increases and at the same time the reoxidation wave splits into two, the more anodic wave being broad and rather ill defined. This anodic shift in the reduction wave with increasing pCl suggests that the Te(IV) species, as expected (8, 9), is chlorocomplexed in the melt and that there is a net loss of Cl^- ions in the rate-determining step of the reduction process. At a fixed sweep rate the relative heights of the two reoxidation waves are pCl dependent, the more cathodic one being more prominent at lower pCl's, while at fixed acidity the more positive wave grows at the expense of the more negative one as the sweep rate is increased. The two oxidation waves even become apparent in the most basic melts (pCl = 1.9 at 175°C) at very high sweep rates (100V sec^{-1}). The behavior in the most acidic melts is also very interesting. At slow sweep rates the most negative reoxidation wave is fairly well defined, but on increasing the sweep rate to 1V sec^{-1} it almost disappears; however, on increasing the sweep rate further to 10V sec^{-1} or more it becomes much better defined. To explain all the above complex behavior there must be some chemical steps occurring in the over-all redox processes.

While the results from the normal pulse experiments in NaCl-saturated melt discussed earlier appeared to indicate the reduction of Te(IV) to be diffusion controlled, the results of the cyclic voltammetry do not support this hypothesis. Table I shows the sweep rate dependence of the function $i_{pc}/\nu^{1/2}$, where i_{pc} is the height of the reduction peak and ν is the sweep rate for four values of melt pCl. If the

Table I. The values of the function $i_p/\nu^{1/2}$/mA cm^{-2} $sec^{1/2}$ $V^{-1/2}$ for a 8.48×10^{-3}M $TeCl_4$ solution as a function of the sweep rate ν/V sec^{-1} at four pCl values

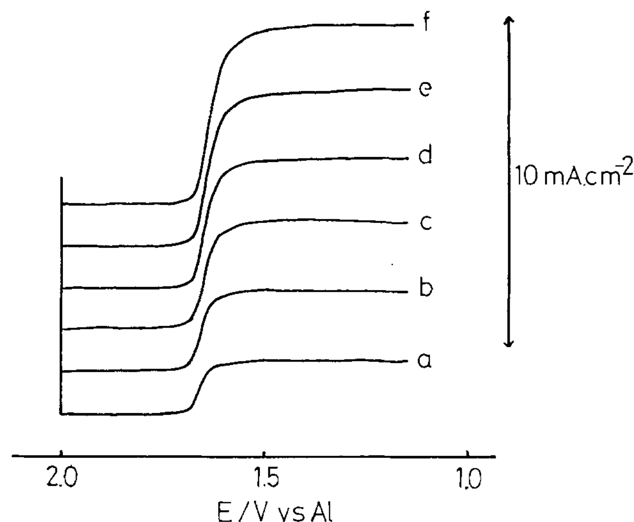

Fig. 6. RDE scans of a 1.852×10^{-3}M $TeCl_4$ solution in NaCl-saturated $NaAlCl_4$ melt. The scan rate was 2 mV sec^{-1} and the rotation rates were (a) 400 rpm; (b) 900 rpm; (c) 1600 rpm; (d) 2500 rpm; (e) 3600 rpm; and (f) 4900 rpm.

process were diffusion controlled, the value of $i_{pc}/\nu^{1/2}$ would be independent of ν. This, however, is clearly not the case here. The value of $i_{pc}/\nu^{1/2}$ decreases with increasing ν, the variation being greatest at the highest pCl's. This behavior is indicative of the presence of a preceding chemical reaction, the rate of which decreases with increasing pCl. At this point it should be mentioned that the normal pulse voltammograms cease to show linear i_{lim} *vs.* $t^{-1/2}$ dependence as the acidity is increased, the value of i_{lim} being lower than anticipated for short pulse times, again indicative of a preceding chemical step.

One of the most satisfactory techniques for investigating preceding chemical steps in electrochemical reactions is the use of the rotating-disk electrode (RDE) Figure 6 shows the results of a series of such experiments for a Te(IV) solution in a tetrachloroaluminate melt. At all the melt acidities investigated, a plot of i_{lim} *vs.* $\omega^{1/2}$ was linear, indicating a diffusion-controlled process. Furthermore when the RDE response was analyzed using a $1/i$ *vs.* $1/\omega^{1/2}$ plot (all current readings being recorded at the steady state) the behavior was typical of that for a process the rate of which is determined by a slow electron transfer, and the values of the heterogeneous rate constant and $\alpha\eta_\alpha$ could be determined (17). Table II gives the values of D, the diffusion coefficient, $\alpha\eta_\alpha$, and k_0^θ calculated for the RDE results at three different pCl's (the determination of the values of the standard electrode potential for the process, required in the determination of k_0^θ, is discussed later). The values of $\alpha\eta_\alpha$ and k_0^θ both decrease with increasing pCl, while the value of $\alpha\eta_\alpha$ at a pCl of 1.9 agrees closely with that determined from the normal pulse voltammetry as do the values of the diffusion coefficient.

The above results can be rationalized in the following manner. The Te formed by the electroreduction of Te(IV) reacts with more Te(IV) to form a complex species which must undergo a chemical reaction,

Table II. Kinetic parameters for the reduction of Te(IV) determined from RDE experiments

pCl	$\alpha\eta_\alpha$	$k_0^\theta \times 10^{3}$*	$D \times 10^{6}$**
4.5	1.27	3.98	4.69
3.8	1.37	7.9	4.71
1.9	1.80	20.0	4.69

* cm sec^{-1}.
** cm^2 sec^{-1}.

probably decomposition to Te and Te(IV), before it can be reduced further. The rate of this latter chemical reaction decreases with increasing pCl as shown by the $i_{pc}/\nu^{1/2}$ values from the cyclic voltammetry. The chemical reaction is not, however, observed at the RDE, as all the Te is swept away from the electrode before it undergoes the reaction with Te(IV). The process at the RDE, therefore, appears as a simple four-electron reduction uncomplicated by chemical steps. The two reoxidation peaks on the reverse cyclic voltammetry sweep both correspond to the oxidation of the complex but by different routes. The more cathodic one corresponds to the oxidation of Te which is formed by the decomposition of the complex, whereas at more anodic potentials the complex undergoes oxidation by a different mechanism, which, judging by the drawn-out nature of the cyclic voltammetry peak, is probably also complicated by chemical steps. At low pCl's the decomposition step is very fast and therefore the more anodic cyclic voltammetry peak is not seen except at very high sweep rates. As the pCl is increased the decomposition reaction slows down and the second peak becomes more apparent at lower sweep rates. At the highest pCl's the second oxidation mechanism becomes dominant. The reappearance in acidic melts of the more cathodic oxidation wave, corresponding to the oxidation of Te as the sweep rate is increased, does not contradict the above mechanism but is due to the fact that the reaction between Te and Te(IV) is not infinitely fast, and at these high sweep rates some of the Te has not had time to react.

The formation of the complex between Te(IV) and Te also explains the solubilization of Te in the Te(IV)-containing melts discussed earlier. It is known from spectrophotometry (6, 7) and potentiometry (7) that Te(IV) and Te form several cationic cluster complexes; however, under the conditions prevailing in the experiments described here the dominant species can be anticipated to be Te_4^{2+} (6, 7). To test this assumption a potentiometric experiment was carried out. A solution of $TeCl_4$ in a melt contained in a tungsten crucible, which also served as the working electrode, was coulometrically reduced in a stepwise manner, and the rest potential of a glassy carbon indicator electrode was measured after each step. When the reduction was nearly complete, the process was reversed and the equilibrium potential of the indicator electrode was recorded after stepwise coulometric oxidations. In this way Nernst plots were readily constructed and these are shown in Fig. 7 for a range of melt acidities. It can be seen that at large values of log $[Te^{4+}]/[Te]$, the electrode potential varies linearly with log $[Te^{4+}]/[Te]$ and the value of the slopes in this region is 22 ± 2 mV, which is in

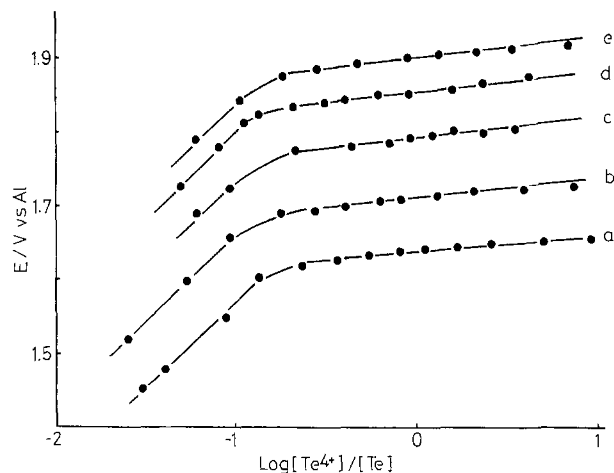

Fig. 7. Nernst plots for the Te^{4+}/Te couple. The melt pCl's were (a) 1.9; (b) 2.75; (c) 3.81; (d) 4.70; and (e) 5.29.

good agreement with the value predicted for a four-electron reduction (22.3 mV at 175°C). There is, however, a break in these plots which occurs consistently at a value of $[Te^{4+}]/[Te]$ of about 0.15 ± 0.02 which corresponds to a $[Te]:[Te^{4+}]$ ratio of 7:1. This supports the complexation reaction between Te and Te(IV) being the formation of Te_4^{2+} according to the reaction described in Eq. [4].

$$7Te + Te^{4+} \rightleftarrows 2Te_4^{2+} \quad [4]$$

with the equilibrium lying well to the right-hand side. At $[Te^{4+}]:[Te]$ ratios less than about 0.15, the rest potential drops sharply and also becomes unstable, possibly due to adsorption of Te on the electrode. Cyclic voltammograms under these conditions show that the concentration of Te in the melt drops sharply as the $[Te^{4+}]:[Te]$ ratio drops below 0.15, indicating the commencement of Te precipitation. Further support of the formation of Te_4^{2+} is the color of the solution which is deep violet [Bjerrum (6) reports a strong adsorption peak for Te_4^{2+} at about 18,000 cm^{-1}.] From the above Nernst plot it is possible to determine the values of the standard electrode potentials, and these are found to vary linearly with pCl as defined by Eq. [5]

$$E^\circ = (1.497 \pm 0.010) + (0.076 \pm 0.003)pCl \quad [5]$$

It is known that the process is a four-electron one; the slope observed, therefore, corresponds most closely with that predicted for $3Cl^-$ ions being lost in the over-all reaction (67 mV at 175°C). The Te(IV) must therefore be primarily present as $TeCl_3^+$, although some more highly complexed species, *e.g.*, $TeCl_4$ and $TeCl_5$, will also be present, particularly at the lowest pCl's. This is in agreement with the results of Von Barner *et al.* (8) who reported the degree of chlorocomplexation of Te(IV) in $KCl:AlCl_3$ melts for the pCl range covered here to lie between three and four. This later work was, however, carried out at a rather higher temperature (300°C).

In view of the complexity of the processes involved, the chemical steps occurring during the reduction will be very difficult to investigate. Those involved in the oxidation of Te_4^{2+} are, however, fairly readily studied at an RDE. Figure 8 shows a series of potential scans, at an RDE, for a solution of Te_4^{2+} in an NaCl-saturated melt. (This solution was prepared by the partial reduction of Te(IV), assuming Eq. [4] to lie well to the right-hand side). It can be seen that at low rotation rates only one wave is present, but as ω is increased, a second, rather drawn out one, appears at more anodic potentials, the behavior of which is analogous to the cyclic voltammetric results discussed earlier. Figure 9 shows plots of the steady-state current as a function of $\omega^{1/2}$ at 1.725V (corresponding to the plateau of the first wave) and at 2.05V (the plateau potential of the second wave). The current at 2.05V is a linear function of $\omega^{1/2}$ and a value of the diffusion coefficient of 7.7×10^{-6} cm^2 sec^{-1} was calculated from the slope of this line. The first wave is, however, only diffusion controlled at low rotation rates and the value of i becomes independent of $\omega^{1/2}$ at large values of the latter, indicating that the reaction has become kinetically controlled. The current is then given by Eq. [6]

$$i = nFkc_o^\infty \quad [6]$$

and if it is assumed that the equilibrium described in Eq. [4] lies well to the right-hand side the value of k, the pseudo-first order homogeneous rate constant, is readily calculated. This was found to be independent of the concentration of Te_4^{2+}, *i.e.*, the rate-determining reaction is first order in $[Te_4^{2+}]$, but highly dependent upon the pCl. The value of log k was found to vary linearly with pCl as described by Eq. [7]

$$\log_{10} k = (0.028 \pm 0.03) - (0.90 \pm 0.10)pCl \quad [7]$$

over the pCl range 1.9-4.0. The values at the lower end

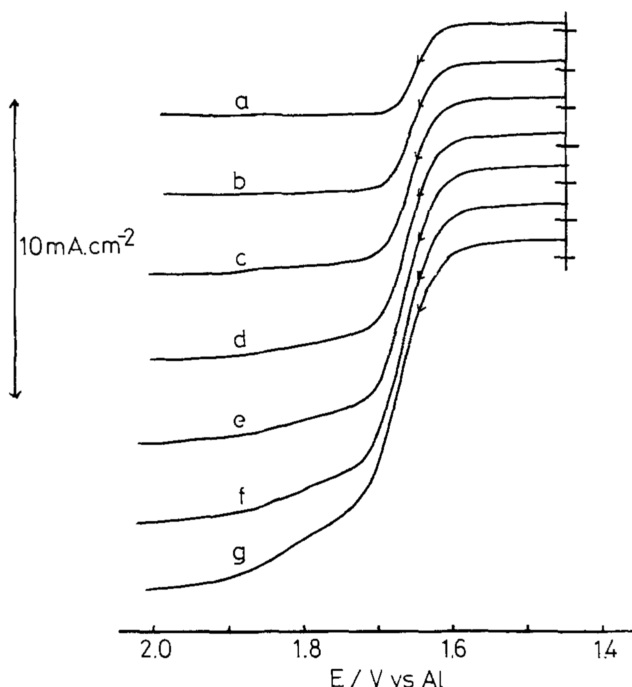

Fig. 8. RDE scans of $7.65 \times 10^{-4}M$ Te_4^{2+} in NaCl-saturated melt. The scan rate was 2 mV sec^{-1} and the rotation rates were (a) 400 rpm; (b) 900 rpm; (c) 1600 rpm; (d) 2500 rpm; (e) 3600 rpm; (f) 4900 rpm; and (g) 6400 rpm.

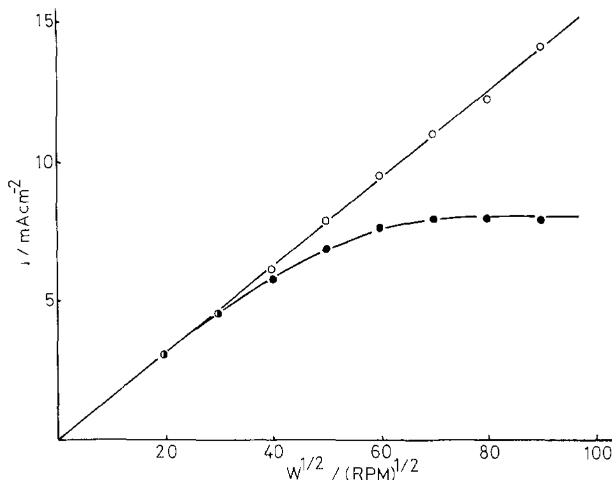

Fig. 9. Levich plots for the oxidation of $7.65 \times 10^{-4}M$ Te_4^{2+} in NaCl-saturated melt at the RDE. The currents were measured at —○—, 2.05V and —●—, 1.725V.

of the pCl range fell slightly off the line possibly because the equilibrium in Eq. [4] is not complete at these acidities. From the slope of the line the reaction must also be first order in $[Cl^-]$, and therefore the second order homogeneous rate constant for the reaction can be calculated to be 0.28 ± 0.05 liter $mole^{-1}$ sec^{-1}.

Any mechanism that is proposed for the over-all redox chemistry of Te(IV) must satisfy the above criteria that the rate-determining step in the decomposition of Te_4^{2+} is first order in $[Te_4^{2+}]$ and $[Cl^-]$ as well as the previously discussed observations that Te(IV) is present in the melt as $TeCl_3^+$ and that the stoichiometry of the reaction between Te(IV) and Te is that given in Eq. [4]. To satisfy these points it is necessary to invoke a short-lived intermediate species in the mechanism, but since the electrochemical investigation provides no clue as to the identity of such a species this precludes the proposal of a unique mechanism. One possible intermediate is a Te(II) species. This seems quite reasonable in view of the fact that such a species was observed in very basic melts at high temperatures and also because Te(II) has been observed spectrophotometrically (6) to be the first product formed when $TeCl_4$ is reduced by elemental tellurium in chloroaluminate melts. A possible mechanism for the reaction of Te with Te(IV) which satisfies all the above criteria is given below by Eq. [8] and [9]

$$TeCl_3^+ + Te \rightleftarrows 2TeCl^+ + Cl^- \quad [8]$$

$$TeCl^+ + 3Te \rightleftarrows Te_4^{2+} + Cl^- \quad [9]$$

where the forward and backward rates of Eq. [8] are both fast and Eq. [9] is the rate-determining step. It can be seen that the decomposition of Te_4^{2+} is first order in $[Te_4^{2+}]$ and $[Cl^-]$, as required, Te(IV) is present as $TeCl_3^+$ and by adding Eq. [8] and twice Eq. [9] we get Eq. [10]

$$TeCl_3^+ + 7Te \rightleftarrows 2Te_4^{2+} + 3Cl^- \quad [10]$$

which has the required stoichiometry.

ABSTRACT

The oxidation of the active, high energy density materials, titanium and titanium hydride, has been studied by electrochemical and electron spectroscopic techniques. The apparent thickness of the oxide was controlled by the magnitude of the applied potential across thin (200-6000Å) films of these materials. Our electrochemical measurements indicated that after irreversible oxide formation, the thin films behaved as typical semiconducting oxide electrodes. A technique of electrochemical aging is described which permits comparison with oxide thicknesses produced by thermal aging. Post mortem analysis by XPS and AES was used to characterize the extent of oxidation of the film surface. Observation of the $dN(E)/dE$ and $N(E)$ Auger spectrum (especially the $L_{III}M_{2,3}M_{4,5}$ transition) indicated that all electrode film surfaces are a mixture of TiO_2, suboxides, and the respective metallic phases (Ti or TiH_x).This observation is confirmed by the predominant XPS Ti transition. The extent of oxide growth into the films was measured by the AES/depth profiling technique and the results are comparable for the two systems to a depth of ~50Å. The results of these experiments are compared for titanium and titanium hydride and are examined with respect to a model for oxide formation and growth.

The oxidation of titanium in its various metallic and metal-oxide forms has received attention by several investigators (1-9). We have previously reported (9) on the electrochemical oxidation of titanium thin film electrodes and on the effect of oxide layer formation on the change of electrochemical reactivity. Studies of the electrochemical oxidation of the surface region (top 5-100Å) of pure titanium thin film electrodes have shown that these thin films serve as a model for the solution and solid-state oxidation of titanium and titanium hydride foil and powder surfaces. Vapor deposited thin film electrodes provide an ideal electrode surface with very high purity as well as predictable and controllable surface structure (9-12). Our surface analytical studies have indicated that freshly deposited, titanium thin film surfaces are not oxide free, but consist of a mixture of Ti metal and various titanium oxides, forming a "prepassive region" approximately 20-50Å thick. Except in ultrahigh vacuum environments, it is probably not possible to produce a fully reduced titanium surface, neither is it possible to obtain such a clean surface for even short times in contact with an electrolyte. Nevertheless, the thin film electrodes show reasonable electrochemical activity and the study of their oxidation provides a model for the passivation of fresh titanium surfaces to depths of 50Å or less.

We present here further voltammetric studies of the oxidation of titanium thin electrodes before and after electrochemical and atmospheric oxidation. The thickness of a passive oxide layer on the thin film electrodes can be estimated by straightforward voltammetric and coulometric techniques correlated to Auger and x-ray photoelectron spectroscopic measurements of these same films (9).

We further report the results of similar studies on the oxidation of titanium thin films which have been hydrided to the γ-phase stoichiometry $TiH_{1.4-1.9}$ (referred to here as TiH_x) (13). Oxidation of these films is similar to the titanium films except that a different two-phase surface composition is observed consisting of an oxide-rich outer layer (≈25-30Å thickness) and a hydride-rich bulk composition. Voltammetric and surface analytical data are presented which support this structure and quantitatively characterize the various metallic and oxide components.

We have intentionally avoided investigations of the electrochemical current/voltage regions where passivation/corrosion phenomena of titanium have normally been studied (high current densities and high overpotentials). Our main emphasis has been only on the passivation of the outer surface region of both the Ti and TiH_x films by electrochemical and atmospheric oxidation.

Experimental

Thin film preparation.—The Ti thin films were electron beam evaporated onto heated (450°C) quartz or alumina disks at a pressure of 10^{-7} Torr and a deposition rate of approximately 125 Å/min. The hydrided films were prepared in the same apparatus as the metal films. After metal deposition the films were equilibrated with purified hydrogen gas to the pressure and temperature to ensure the γ-phase TiH_x, where $x = 1.4$-1.9 (13, 14). Typical film thicknesses were 200-6000Å depending on the experimental requirements as measured by both interferometric and conductance techniques. Once deposited the electrodes were stored under dry, purified argon prior to electrochemical treatment.

Electrochemical experiments.—The electrochemical cell allowed for two potentiostat contacts for potential control and two bridge contacts for d-c conductance measurement at the working electrode (9). The auxiliary electrode was a coil of Pt wire and the reference electrode was a saturated calomel electrode, separated from the electrolyte solution by a quartz frit. All applied potentials in this paper are referenced to the saturated calomel electrode (SCE).

* Electrochemical Society Active Member.

Current and charge were recorded as a function of applied potential using a Princeton Applied Research (PAR) 173 Potentiostat/Digital Coulometer and a PAR 179 Universal Programmer. Surface conductance measurements were made with a Wheatstone bridge/amplifier circuit (15-17). The experimental arrangement allowed simultaneous recording of current, charge, and conductance as a function of applied potential. Capacitance/potential curves were recorded using a technique described previously (9). Scan rates of 5 mV/sec or less were used in all experiments.

Samples were loaded into the electrochemical cell and transported to high vacuum for surface analysis under controlled, inert (purified Ar or N_2) atmospheric conditions.

Surface analysis and data treatment.—Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS) data were obtained on a Physical Electronics 548 ESCA/Auger analysis system. Vacuum was maintained at 10^{-9} Torr or less. AES experiments were conducted using a 1 keV electron beam, 15-30 μA of current, 2 eV modulation at 17 kHz, and a lock-in amplifier time constant of 0.03 sec. Both $N(E)$ and $dN(E)/dE$ spectra were recorded directly from this instrument. XPS data were obtained using a MgKα source at 400W of power. Data were either recorded directly using the output of the photon counter or signal averaged using a Data General, Nova 800, minicomputer with 32 K core and two 1.2 million bit Diablo disks. Deconvolution of overlapping XPS peaks were accomplished using a computer routine similar to published methods (9, 18-22). The XPS spectra were computer-simulated by inputting five parameters: (*i*) the slope of the linear spectral background, (*ii*) the binding energy of each electronic component, (*iii*) the full width at half-maximum of each component, (*iv*) the peak height of each component, and (*v*) the percentage of Gaussian contribution to the slope of the spectral background. The binding energy and Gaussian contribution were evaluated using transitions from standard Ti compounds (22). The binding energy of the $Ti(2p_{3/2})$ XPS peak subtracted from the binding energy of the O(1s) XPS peak is referred to as ΔBE_1 in subsequent discussions (18, 22). Argon ion sputtering was done at 5×10^{-5} Torr with beam voltages of 1 kV and 10-20 mA of filament emission current. Under these conditions, a sputtering rate of 12.5-25 Å/min was observed in our Ti films. The ion beam was always focused so that the electron beam or x-ray source was placed well inside the sputtered area of the film surface.

Results and Discussion

Electrochemical oxidation of Ti films.—The linear sweep voltammetric (LSV) behavior of the titanium thin film electrodes in strong acid media has been previously described (9). We show in Fig. 1a typical behavior in 1*N* $HClO_4$. Anodic currents of between 30-50 $\mu A/cm^2$ were observed at bias potentials in excess of +0.5V *vs.* SCE. If the potential sweep was not interrupted, this current density was maintained up to potentials of +2.7V or greater. At greater bias potentials, a nearly exponential dependence of current with potential was observed, as would be expected for the normal corrosion/passivation reaction of titanium metal (1-6). From XPS and AES analysis data of various Ti thin film electrodes we have hypothesized that the current/potential region between the onset of current flow and the onset of the exponential current/potential dependence represents an oxidation of a region of less than 50Å thickness. This region consists of metal and titanium oxides (TiO, Ti_2O_3, etc.). A true metal/TiO_2 interface is only established at bias potentials in excess of +3.0V. Qualitatively similar LSV behavior was observed using bulk titanium metal which had been freshly etched in

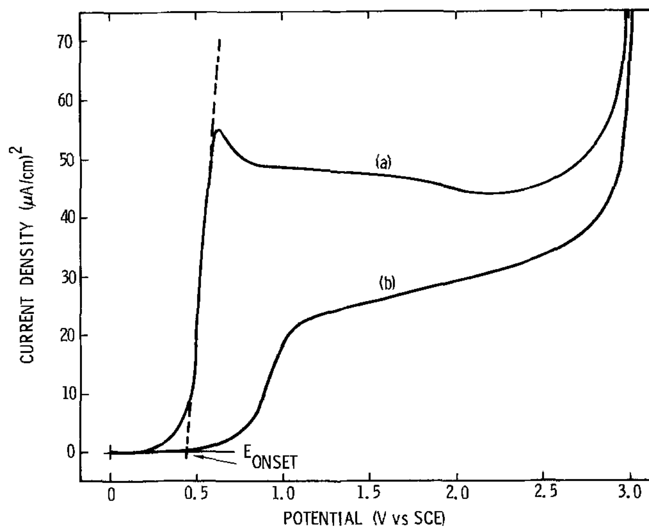

Fig. 1. (a) Typical linear sweep voltammogram (LSV) for a Ti thin film electrode in 1*N* $HClO_4$ at a sweep rate of 5 mV/sec. (b) Typical LSV for a Ti foil electrode which has been etched in HF and in boiling distilled H_2O.

HF and rinsed in distilled water (Fig. 1b). Further linear sweep and cyclic voltammetric experiments to explore the nature of the electrochemical oxidation of this surface region of the titanium thin films were therefore carried out.

We define the onset potential (E_{onset}) as the intersection of the tangent to the current/voltage curve with the potential axis, *i.e.*, where currents are first noted. E_{onset} (cf. Fig. 1a) was measured as a function of *p*H from strongly acidic to strongly basic solutions for titanium thin film electrodes (Fig. 2a). From *p*H = 0-~8, the shift in E_{onset} was −0.020V per *p*H unit, whereas for alkaline solutions, the shift was −0.080V per *p*H unit. Although the current voltage curves had the same qualitative appearance in all the solutions investigated, it is clear that the thermodynamic potential of the oxidation process is lowered by the presence of high concentrations of hydroxide. The potential at which an exponential current/potential dependence was observed also shifted cathodically with increasing *p*H to the same extent as E_{onset}. The over-all *p*H dependence for the oxidation of the surface region of the titanium film is subsequently discussed.

If the potential scan was interrupted or reversed during the voltammetric oxidation of the titanium films, the current quickly decayed to zero (Fig. 3, curve a). No current was seen until an anodic potential was applied which exceeded the previous potential limit (curves b through f in Fig. 3). This is consistent with previously reported data for aluminum passivation (1, 23). A series of such cyclic potential scans was conducted and E_{onset} for each scan recorded as a function of the total oxidative charge transferred (Q_T). Figure 3b shows that there was a linear dependence of E_{onset} with Q_T. The potential or field strength necessary to support oxidation of the surface region of the titanium thin film is clearly dependent on the total oxide thickness formed in this region. We have calculated that a monolayer conversion of titanium to TiO_2 requires approximately 1 mC/cm^2 of oxidative charge, so that an estimate of the oxide layer thickness was made in order to correlate with Q_T (Fig. 3b). The maximum thickness of 50Å is approximate since the surface region is a mixture of metal and suboxides. Using AES and XPS data (9) we estimate the thickness of the "prepassive" region to be approximately 30Å.

The slope of the tangent to the current/voltage linear region above E_{onset}, di/dE, was also monitored as a function of Q_T (Fig. 3b). As Q_T increased, di/dE

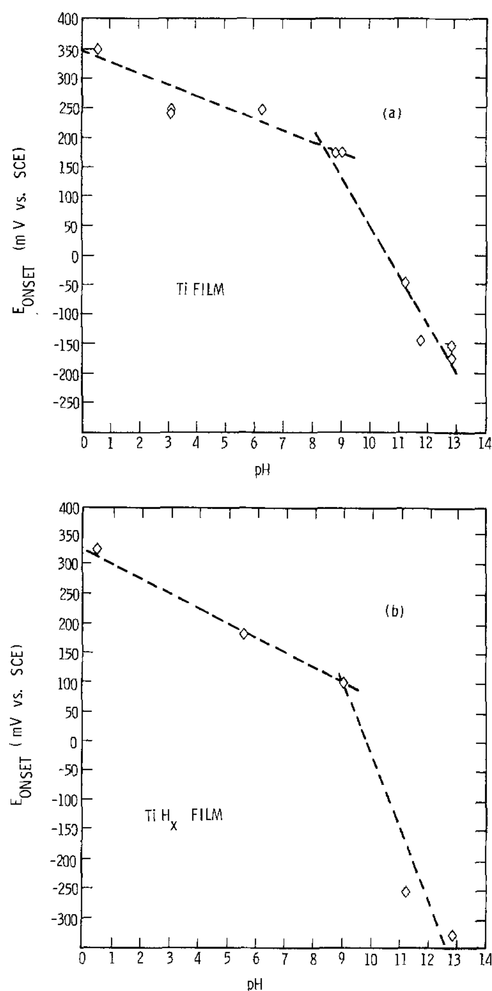

Fig. 2. E_{onset} as a function of electrolyte pH for (a) Ti thin film and (b) TiH_x thin film electrodes.

decreased sharply. The di/dE parameter may be viewed as a measure of the onset of the oxidation process with increasing potential and thus decreases as the oxide thickness (or the barrier to oxide growth) increases.

The characterization of the electrochemical growth of the surface oxide layer was also extended to the atmospheric oxidation of these titanium metal films. Figure 4a shows the voltammograms for several Ti films, heated at 150°C for times between 5 and 60 min. These conditions were chosen to accelerate atmospheric oxidation to experimentally reasonable rates. Figure 4b shows the linear increase in E_{onset} as a function of the square root of air oxidation time, while di/dE decreases almost exponentially with $t^{1/2}$. Note that the maximum current density achieved in oxidation of the surface region also decreased following air oxidation. We can conclude that the extent of

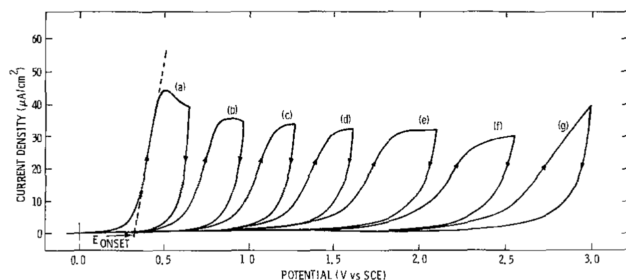

Fig. 3a. Electrochemical oxidation of fresh Ti electrode. The cyclic voltammograms are scanned to a higher applied potential limit on each successive scan. The solution used in this scan was 1*N* $HClO_4$ and the scan rate was 5 mV/sec.

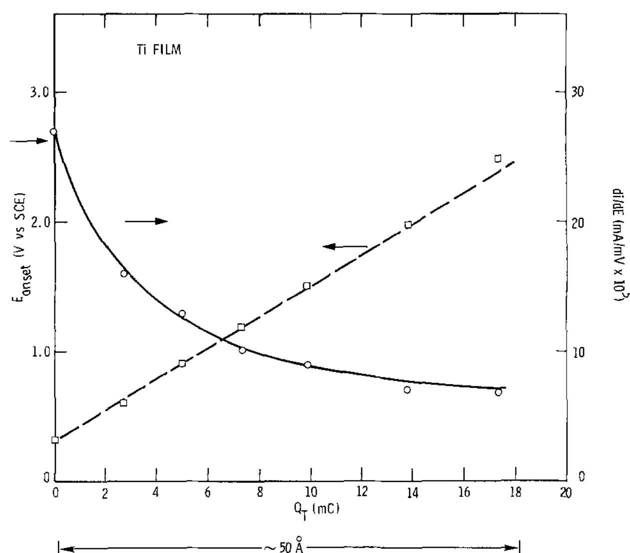

Fig. 3b. The potential at the onset of current flow (E_{onset}) and di/dE vs. the total charge (Q_T) passed at the Ti electrode of Fig. 3a.

electrochemical oxidation, Q_T, and the time of atmospheric oxidation, $t^{1/2}$, are qualitatively equivalent. In both cases it is clear that the formation of a thin layer of surface oxide greatly inhibits further oxidation. If atmospheric oxidation was attempted at room temperature, little change in the current voltage behavior was observed for films left exposed up to several hours. However, extensive air oxidation at elevated temperatures completely oxidized the surface region of the titanium films and the current/voltage behavior of such a film showed only the exponential relationship at high applied potentials. By correlation with the electrochemical oxidation data and previous surface analysis data, it was also possible to semiquantitatively estimate the depth of the surface oxide layer formed by air oxidation (compare Fig. 3b and 4b).

Electrochemical oxidation of titanium hydride films.—The electrochemical oxidation of titanium hydride films proceeded virtually as for the titanium thin film electrodes for bias potentials up to approximately +2.0V. The linear sweep voltammetric behavior of a titanium hydride electrode in 1*N* $HClO_4$ is shown in Fig. 5. Surface conductance and differential capacitance data collected for this type of electrode were similar to the previously reported data for the titanium film electrodes (9). Surface conductance measurements indicated a linear decrease in conductance electron population during the oxidation of the surface region. The capacitance-voltage measurements showed linear $1/C^2$ *vs.* E behavior typical of an n-type semiconductor once the potential was driven past the onset potential. All of the electrochemical data for these electrodes were consistent with the oxidation of a surface region of the TiH_x film of less than 50Å thickness.

Electrochemical and atmospheric aging of the titanium hydride films also proceeded as for the titanium films. Results typical of electrochemical aging up to +2.0V are shown in Fig. 6. As the oxide layer thickness increased, the onset potential (E_{onset}) for oxidation increased and $(di/dE)_{E_{onset}}$ decreased, consistent

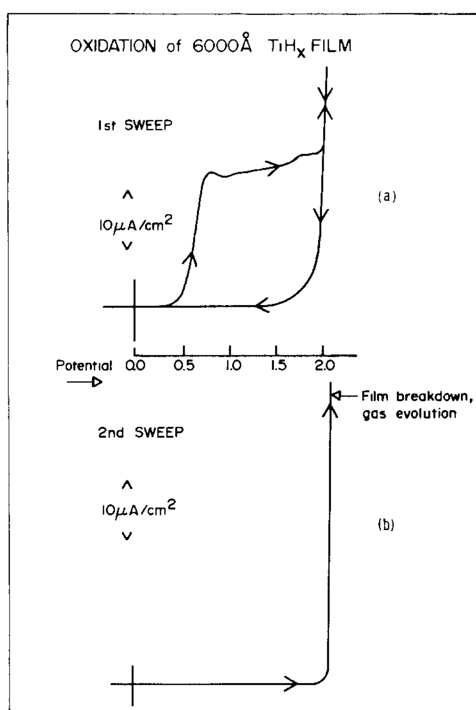

Fig. 5. (a) Cyclic voltammogram for a 6000Å TiH_x film scanned to > +2.0V and back to 0.0V *vs.* SCE in 1*N* $HClO_4$. The scan rate was 5 mV/sec. At ~ 2V the current increases from 30-50 μA/cm² to 0.5 A/cm². (b) Linear sweep voltammogram of electrode in (a) following return of bias potential to 0.0V.

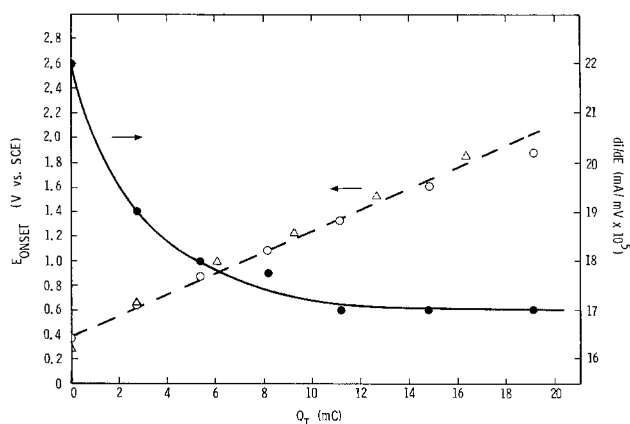

Fig. 6. The potential at the onset of current flow (E_{onset}) and the slope of the linear extrapolation of that onset ramp (di/dE) *vs.* the total charge (Q_T) passed at electrochemically oxidized TiH_x electrodes.

with an increasing energy barrier toward further oxidation. The relationship between E_{onset} and pH was also explored for the titanium hydride electrodes. Similar to the titanium films, E_{onset} shifted cathodically by 25 mV/pH unit up to pH = 7 and approximately 120 mV/pH unit for solutions with pH ≥ 7 (Fig. 2b).

The titanium hydride electrodes also showed a unique voltammetric feature which varied as a function of pH. In strong acid media the voltammetric curves for the titanium hydride electrodes were punctuated at bias potentials greater than +2.0V by a sudden increase in current density from 30-50 μA/cm² to nearly 500 mA/cm² (Fig. 5a). Concurrent with this increase in current density, gas evolution from within the electrode was observed as well as the eventual internal breakup of the titanium hydride film. If the voltammetric scan was reversed before film breakup occurred, the current density decayed to zero and no current was observed until the previous anodic potential limit was reached. At this potential large current densities were again observed (Fig. 5b). Clearly the titanium hydride electrodes possess a surface composition which produces similar electrochemical behavior to the titanium films, until the surface region is fully oxidized. Following this, a different type of oxide/metal interface is created which apparently allows direct release of the bound hydrogen in the metal lattice to form hydrogen gas. As the solution pH was increased, the potential at which film breakdown occurred, shifted toward more negative potentials. In solutions of pH ≥ 10 however, the onset of excessive current densities, gas evolution, and the breakup of the electrode were no longer observed. Current densities of 30-50 μA/cm² were observed, with some fluctuations, at bias potentials beyond 5V. No clear evidence of an exponential current/voltage behavior was observed for the oxidation of the TiH_x films in alkaline media. In the intermediate pH region between strongly acidic and strongly basic media, the TiH_x oxidation showed a tendency to decompose but at variable bias potentials above 2.0V. We believe the variability to be due to small differences in film surface morphology which affect the change in oxidation mechanism. SEM photomicrographs of the Ti and TiH_x film surfaces indicate an average defect or grain size of ~0.1 μm. Capacitance data also indicated a rather porous film surface; C(at 0.0V) = 30 ± 5 μF/cm². We feel that this surface structure will be important in determining the oxidation pathways at intermediate solution pH. It is clear that at alkaline pH, the oxidation mechanism for the titanium hydride films changes to an extent sufficient to stabilize the film in an unusual manner against gas evolution and metal degradation.

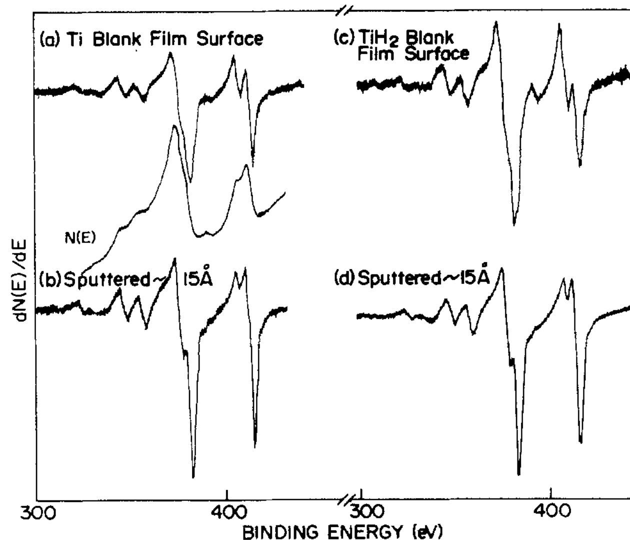

Fig. 7. High resolution Auger electron spectra of the Ti(LMM) and (LMV) peaks for (a) Ti film electrode surface; (b) that film after ion sputtering to remove approximately 15Å; (c) TiH_2 film electrode surface; and (d) that film after ion sputtering to remove approximately 15Å.

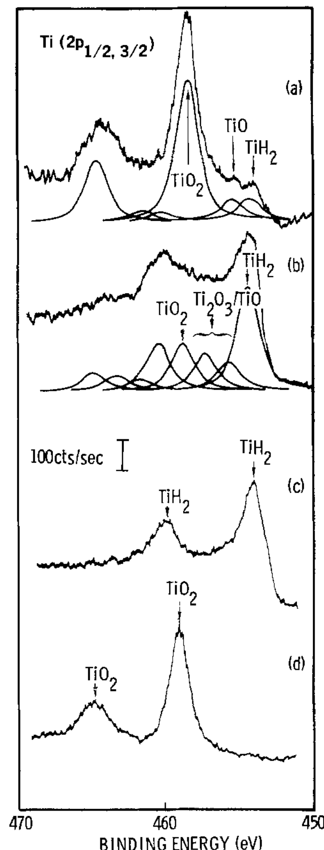

Fig. 8. The $Ti(2p_{1/2,3/2})$ XPS spectra for (a) a TiH_x blank surface; (b) that film after ion sputtering to remove approximately 20Å; (c) the same film after ion sputtering to remove approximately 60Å; and (d) the surface of TiH_x thin film electrode oxidized to 12.5 mC of charge.

Surface analysis of the TiH_x films.—AES and XPS spectra were obtained for the TiH_x film electrodes in an effort to understand the composition of the surface regions of these electrodes and to compare the surface composition to that of the pure titanium films. Figure 7 shows a series of high resolution $dN(E)/d(E)$ AES spectra of the LMM and LMV transitions of titanium and titanium hydride films as well as a typical $N(E)$ spectrum. Some difference was observed between the spectra of the Ti and TiH_x film surfaces, especially in the LMV spectral region (400-430 eV) where spectral shapes are sensitive to chemical composition of the surface (9, 24). Both types of film surfaces showed LMV spectra consistent with a partially oxidized (TiO-like) surface (9, 24-26[1]), however the TiH_x film electrode showed slightly more oxide character than the Ti film. Following ion sputtering of nearly 15Å of the surface region, the spectra became more like those expected for a lower valence form of titanium.

Oxygen-to-titanium ratios were computed from the intensities of the oxygen KLL transitions and the titanium LMM transition, according to previously discussed methods (9, 18, 22). The O/Ti intensity ratio of each film was normalized to the same ratio for a TiO_2 standard material to yield a relative atomic ratio, N_O/N_{Ti}. The TiH_x film surfaces showed a slightly substoichiometric composition, with $N_O/N_{Ti} = 1.8$. This value includes the contribution from all surface oxygen because the oxygen Auger KLL signal does not distinguish between oxide and absorbed oxygen species. The N_O/N_{Ti} surface ratios were slightly higher than those previously observed in titanium films, $N_O/N_{Ti} = 1.6\text{-}1.7$ (9). Ion sputtering of the surface lowered the N_O/N_{Ti} to *ca.* 0.3 within 20-30Å of the surface, similar to the titanium films. Electrochemically oxidized surfaces showed increased N_O/N_{Ti} values at the surface (1.9-2.0), and these values remained high following ion sputtering, depending on the extent of electrochemical oxidation.

The XPS spectra of Fig. 8 were consistent with the above AES data. The TiH_x film surface gave $Ti(2p_{1/2,3/2})$ spectra (Fig. 8a) which were composed chiefly of a TiO_2 component ($\Delta BE_1 = 71.5 \pm 0.2$ eV as for a TiO_2 standard) (18, 22). Smaller TiO ($\Delta BE_1 = 75.2 \pm 0.2$ eV) and TiH_x ($\Delta BE_1 = 76.0 \pm 0.2$ eV) components were also observed which were less than 10% of the TiO_2 concentration. This type of surface spectrum is consistent with either (*i*) a uniform surface composition consisting of TiO_2, suboxides, and titanium hydride, or (*ii*) a TiO_2 layer of less than 10Å thickness overlaying a gradient mixture of suboxides and titanium hydride. We consider the second option to be more likely, although we must consider the possibility that the titanium hydride may be a mixed oxy-hydride compound, *e.g.*, TiO_yH_x. The $Ti(2p_{1/2,3/2})$ spectra of the TiH_x film which was ion sputtered to a depth of *ca.* 15Å below the surface (Fig. 8b) showed spectral components from TiO_2 and suboxides which were nearly equal and were approximately 50% of the intensity of the TiH_x component. This observation would indicate a mixed TiO_y/TiH_x composition of the prepassive surface region. The N_O/N_{Ti} ratios computed from the XPS data [$O(1s)/Ti(2p_{3/2})$ intensity ratios normalized to TiO_2 standard] (22) showed a value of *ca.* 1.6-1.7 at the film surface and *ca.* 0.8 following ion sputtering to ~15Å below the surface. The surface N_O/T_{Ti} ratio was lower than that determined by AES because the O(1s) intensity included only oxide oxygen and not absorbed forms (OH, H_2O, etc.) (18, 22). Ion sputtering to depths of greater than 50Å yielded an XPS spectrum like that in Fig. 8c. The $Ti(2p_{1/2,3/2})$ spectrum was comprised chiefly of the titanium hydride component and the N_O/N_{Ti} ratio decreased to *ca.* 0.2. We have previously noted that the $Ti(2p_{3/2})$ binding energy for the hydrided metal is shifted to higher energies by *ca.* 1.0 eV from that of the pure metal ($\Delta BE_1 = 76.0 \pm 0.2$ eV for TiH_x *vs.* 77.0 ± 0.2 eV for Ti) (22). This chemical shift is consistent with hydrogen bound in the titanium metal in a partially anionic form, although the hydrogen does not appear to be as electronegative as oxygen in the titanium

[1] Lo *et al.* (26) have noted the presence of Ti^{3+} valence states by energy loss spectroscopy in defect-structured TiO_2 surfaces. Similar compositions are expected in the prepassive region of the titanium and titanium hydride films, cf. (9).

oxides. The electrochemical oxidation of the hydride is certainly affected by the chemical form of hydrogen in the metal lattice and the mechanism by which it is removed during oxidation (see discussion below). Following electrochemical oxidation of the TiH_x film surface ($Q_T = 12\ mC/cm^2$), the $Ti(2p_{1/2,3/2})$ XPS spectra reverted completely to that of TiO_2, $N_O/N_{Ti} = 1.9$-2.0 (Fig. 8d), confirming that the oxide interface had been extended to beyond the depth to which XPS could successfully measure a TiH_x component (~25Å).

Conclusions

The previously reported experiments (9) and those discussed here allow a more detailed understanding of the surface region of vapor deposited and clean bulk titanium and titanium hydrides. The first to be discussed is the surface composition of the titanium films. We can picture the surface of the film to consist of a gradient of metal, suboxide (or TiO_2 with oxygen defects) and stoichiometric TiO_2. A graphical illustration of this picture is shown in Fig. 9. The energy barrier for film oxidation is expressed chiefly across the stoichiometric TiO_2 phase (G_1) and the more conductive substoichiometric oxide phase (G_2); the total barrier to further oxide growth is relatively low ($G_T = G_1 + G_2$). Following electrochemical or atmospheric oxidation, the oxide layer thickness is greatly increased, the suboxide concentration diminished, and the barrier to further oxide growth is consequently increased to G_T'. The relative size of G_2' to G_1' has decreased due to the increase in thickness of the nonconductive oxide. Eventually a metal/TiO_2 interface is established. Ionic transport across the metal/metal oxide region becomes the current limiting factor and a normal corrosion/passivation mechanism is established (6).

We can picture the oxidation of the prepassive region of the Ti film electrodes in strong acid solution in a schematic fashion similar to defect-structured TiO_2 electrodes (22)

$$TiO_y \rightarrow TiO_2 + (4 - 2y)e^- \quad 0 < y < 2.0 \qquad [1]$$

[where ionic transport is not included]. In strongly

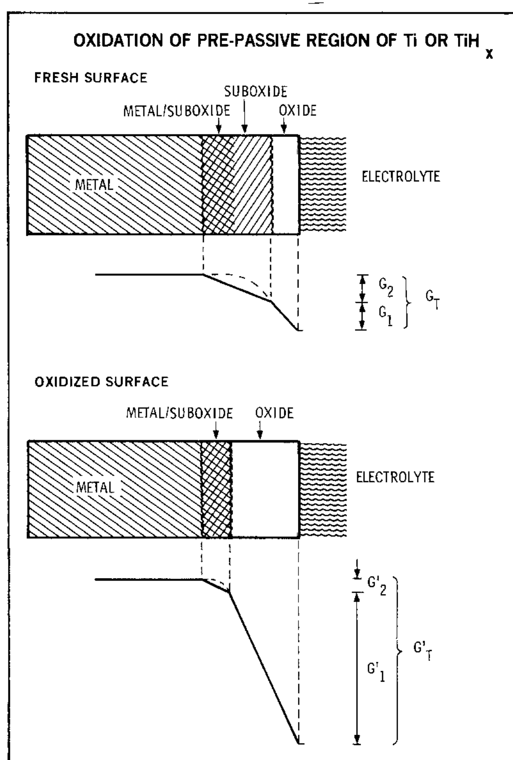

Fig. 9. Proposed model for the composition and oxidation of the "prepassive region" in Ti and TiH_x thin films.

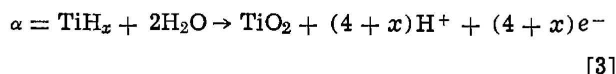
basic solutions, the oxidation may proceed through either TiO_y or $Ti(OH)_{2y}$ reactants, *e.g.*

$$Ti(OH)_{2y} \rightarrow TiO_2/Ti(OH)_4 + (4 - 2y)e^- \qquad [2]$$

Due to the cathodic shift in onset potential with increasing pH, we feel that the latter oxidation process is more thermodynamically favorable in alkaline solutions (2). The Pourbaix diagram for the oxidation of titanium shows a strictly Nernstian relationship between equilibrium potentials of Ti/TiO_2 and *p*H (2, 27). The significance of the change in slope of E_{onset} *vs.* pH as one proceeds to more alkaline solutions remains to be investigated. The surface morphology of the titanium film will influence the surface concentration of oxidizable species, the penetrability of the electrolyte, and, therefore, the onset potential. This morphology may vary depending on the type of film or bulk titanium sample investigated and may affect the slope of E_{onset} *vs.* *p*H.

In the case of the TiH_x films, the picture of the surface composition is somewhat different. It is clear from the XPS data that the surface is still composed chiefly of TiO_2 and suboxides or defect forms of TiO_2 as well as a small amount of the hydrided metal. The type of oxide/metal gradient shown in Fig. 9 can also be envisioned for the TiH_x films. The growth of the energy barrier to oxidation as a function of oxide thickness is analogous to the Ti films. Once the prepassive region is oxidized however, one must consider the different chemistry of the TiH_x/TiO_2 interface that is formed. The oxidation of α-TiH_x (chemisorbed hydrogen from solution) proceeds by a different mechanism than for γ-TiH_x, resulting in the release of protons (2, 27)



$$\alpha = TiH_x + 2H_2O \rightarrow TiO_2 + (4 + x)H^+ + (4 + x)e^- \qquad [3]$$

It is not clear that the α-phase hydride considered in the normal Pourbaix diagram has the same reactivity as the γ-phase TiH_x which is oxidized in these experiments. The XPS data clearly indicate that the hydrogen in the γ-phase hydride is at least partially anionic in nature. It is reasonable to assume that during oxidation of the γ-TiH_x, the hydrogen would be capable of capturing one electron leading to atomic H° formation and subsequently H_2

$$\gamma\text{-}TiH_x + 2H_2O \rightarrow TiO_2 + xH^\circ + 4e^- + 4H^+ \qquad [4]$$

$$xH^\circ \rightarrow x/2H_2 \qquad [5]$$

Reactions [4] and [5] constitute an interesting mechanism for the release of hydrogen from this high energy solid. In strongly acidic media, the direct oxidation of TiH_x to Ti^{+4} and H^+ is thermodynamically inhibited, and direct oxidation of TiH_x with H^+ may also occur

$$TiH_x + 4H^+ \rightarrow \left(\frac{x + 4}{2}\right) H_2 + Ti^{4+} \qquad [6]$$

Such a reaction has been observed for scandium hydride solids in strong acid (28). However, it appears that if the solution *p*H is sufficiently high, consumption of the released hydrogen atom will occur before H_2 gas is formed. The formation of a titanium suboxide or TiO_2 may take place at the same instant, therefore, the oxide/TiH_x interface would be propagated in the same manner as for the prepassive region of the Ti films. The current densities of 30-50 $\mu A/cm^2$ observed for the TiH_x films at applied potentials greater than 2V *vs.* SCE in alkaline solutions do not change, perhaps because of the continually reformed oxide/suboxide/metal hydride interface.

The electrochemical oxidation of both Ti and TiH_x thin films indicates the extent to which a thin, suboxide or oxide surface layer inhibits further oxidation of the bulk material. This thin oxide layer pre-

sents a large energy barrier to further oxide formation, even under high temperature atmospheric oxidation conditions. In the case of the hydrided metal, a release of bound hydrogen is possible with relatively low applied potentials, a fact which may have interesting implications for the release of energy from metal hydrides and their long-term stability in corrosive environments.

The exact mechanism for the corrosion and passivation of various titanium hydride stoichiometries is the subject of further study. Because of their technological importance, further investigation of the release of hydrogen by electrochemical oxidation of hydrided metals is clearly warranted.

Acknowledgment

The authors gratefully acknowledge the excellent technical assistance of P. G. Neiswander. The titanium and titanium hydride films were prepared by Neutron Generator Tube Laboratory, Sandia Laboratories, under the supervision of B. E. Barnaby. The generosity of Professor T. Kuwana, Ohio State University, is also acknowledged for the use of the Physical Electronics, Incorporated, Model 548 XPS/AES Analysis System. This work was supported by the U.S. Department of Energy.

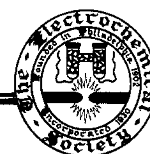
Technical Notes



Use of Alumina as a Sheath for the Pt, CO/CO_2 | Na_2CO_3 Reference Electrode

K. Y. Kim* and O. F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

The viability of electrode polarization (1) as a means for investigating corrosion phenomena in molten salts has been demonstrated (2-6). As this technique is customarily practiced (7), a current is impressed upon an electrode fashioned from the metal under study (the working electrode) using a second, inert electorde (the counterelectrode). The potential of the working electrode relative to the electrolyte is measured to within an additive constant using a third (reference) electrode and a high impedance potential-measuring device. For a given system the current passing through the working electrode is dependent upon this potential and is a measure of electrodic reactions pertaining directly to corrosion processes at the working electrode surface. Meaningful study of corrosion in molten salt systems of engineering concern requires a reference electrode that is not degraded by the system under study, permits variation of the environment of the working electrode over a meaningful range, and is itself not affected by such variation in cell environment.

* Electrochemical Society Active Member.
Key words: electrode, fused salt, polarization.

Considerable attention has been devoted to the study of electrodes for use in molten carbonates involving the electrode reactions

$$\frac{1}{2} O_2 + CO_2 + 2e^- \rightleftarrows CO_3^=$$

or

$$2CO_2 + 2e^- \rightleftarrows CO_3^= + CO$$

occurring at inert metal electrodes (8-23).

In studies in which a reference electrolyte was maintained in a separate compartment from the cell electrolyte, ionic conduction occurred via a restricted channel of the molten electrolyte (8, 17, 20) or via a solid-state process (10, 12, 16), the latter involving either a glass or a K^+-conducting porcelain. In either case a "liquid junction" potential difference may arise; this has been discussed in some detail (8, 10). The liquid junction potential is minimal if (*i*) conduction between the two electrolytes occurs via oppositely charged species whose transport numbers $\simeq$0.5; or (*ii*) conduction occurs via one or more species whose activity is the same in the two electrolytes. The use of a molten conducting path restricts use of the cell in that it precludes or renders difficult use of different pressures in the reference and test compartments, while glasses and porcelains offer very poor resistance to molten carbonate attack.

The present study was designed to test the behavior of recrystallized alumina as a container for a CO/CO_2 reference electrode for use in molten sodium carbonate. The reference electrode studied was comprised of a 20 mil (0.0508 cm) platinum wire immersed in molten sodium carbonate (Fisher Certified ACS) contained in a McDanel Type 998 alumina closed-end tube. The wire entered the electrolyte through a small diameter [¼ in. (0.635 cm) or ⅛ in. (0.318 cm) OD] alumina tube, through which a preset mixture of carbon monoxide and carbon dioxide was introduced at a flow rate of approximately 25 ml/min. Within the electrode compartment, the wire was shaped into a helix to increase the exposed electrode area. The external alumina sheath was ½ in. OD (1.27 cm), with 1/16 in. wall thickness (0.159 cm) and was immersed in the cell to a depth of about 3 cm. The depth of electrolyte inside the electrode sheath was also approximately 3 cm. The cell electrolyte was also molten sodium carbonate and was contained in an alumina crucible. The cell was housed in a vertical retort heated by a glow bar furnace with a proportioning solid-state controller. Cell temperature was measured directly by an alumina-sheathed Pt-10% Rh/Pt thermocouple immersed in the electrolyte; no discernable temperature variation occurred. Gas mixtures were derived through appropriate mixing of bottled CO (Matheson C. P. purity), CO_2 (Norwich medical grade), and a nominal 95% CO/5% CO_2 mixture (Matheson certified mixture, 95.2% CO/4.8% CO_2). Individual and total flow rates were determined with rotameter flow gauges. Initial drying of the electrolyte was accomplished by heating of the cell slowly under vacuum to test temperature. Subsequently, equilibration with the inlet gas was assumed. Equilibrium hydroxide activities have been computed for this system (24) and for low inlet moisture contents are not sufficiently high to significantly alter the carbonate activity in the melt. The accuracy to which the gas mixtures were established was dependent upon the value of P_{CO}/P_{CO_2}. For the worst case, the possible error in volumetric flow rate determination was $\simeq$20%; the cumulative errors for this case yield a maximum uncertainty in electrode potential of $\simeq$20 mV.

The current-voltage characteristic of the reference electrode was determined by impressing a potential from an external d-c power supply between two ostensibly identical reference electrodes and measuring the resulting current with a zero resistance ammeter. A typical curve, using the nominal 95% CO/5% CO_2 mixture at both electrodes at 1000°C, is shown in Fig. 1. Simple ohmic behavior was seen in all cases with observed cell resistance values falling in the range of 0.0282-0.0353 MΩ, the variation apparently reflecting differences in the immersed electrode area from one experiment to the next. Using a geometric factor of 66 cm per electrode, the apparent sheath resistivity is $\simeq$1 MΩ cm. Reported conductivity values for alumina range widely (25), from 10^{-4} to 10^{-10} Ω^{-1} cm^{-1} at 1000°C. A typical analysis for the alumina used in this study is shown in Table I. Conduction at other than very high temperatures is presumed due to impurity cations, with sodium and calcium dominating due to the very basic character of their oxides. Although diffusivity data also show considerable scatter, high temperature data for Al and O diffusion in polycrystalline alumina generally extrapolate to values of the order of 10^{-19} cm^2/sec at 1000°C (26). The data of Oishi and Kingery (27) suggest a reduction in the activation energy for these processes below approximately 1400°C, however, which would lead to somewhat higher values. In contrast, the data of Frischat (26, 28) for Na diffusion in commercial purity alumina, 95% dense, for the range 1223°-1750°C yield an extrapolated value of 5.2×10^{-11} cm^2/sec at 1000°C, and suggest a similar value for Ca diffusion. Assuming this value for both Na and Ca, and further assuming that $z_{Na} = 1$ and $z_{Ca} = 2$, using the values of Table I a resistivity of 250 MΩ cm is obtained for Type 998 alumina at 1000°C. This discrepancy is attributed to one or more of the following reasons: (*i*) A substantial increase in the Na_2O concentration within the alumina due to contact with the molten sodium carbonate; (*ii*) a change in the activation energy for Na transport with temperature, rendering invalid extrapolation of Frischat's data; or (*iii*) A simple manifestation of the tremendous variation in the reported values for diffusivity of various species and for conduction in alumina, presumably attributable to variations in method of preparation, impurity content, and/or measurement technique.

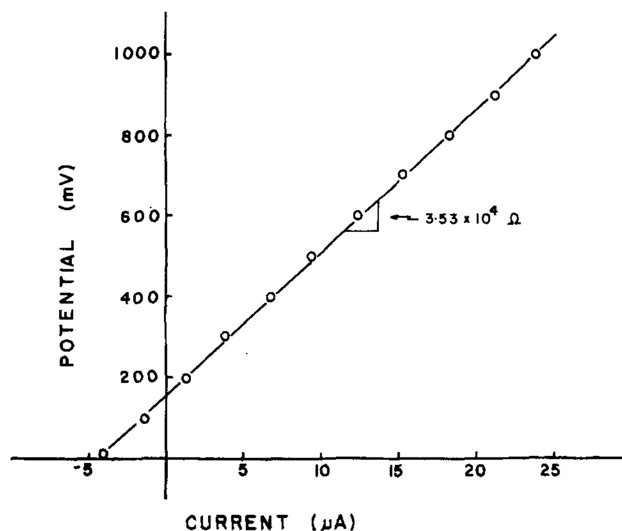


Fig. 1. Current-voltage dependence of cell comprised of two alumina-sheathed reference electrodes.

Nernstian response of the reference electrode was evaluated by maintaining the same cell configuration of two identical reference electrodes, but diluting the flow of the nominal 95% CO/5% CO_2 mixture through one of the electrodes by admixing CO or CO_2. The

Table I. Typical chemical analysis of McDanel Type 998 alumina

Al_2O_3	SiO_2	MgO	Na_2O	CaO	Fe_2O_3	Ga_2O_3	TiO_2	MnO	ZrO_2	K_2O
99.8	0.070	0.050	0.005	0.030	0.025	0.009	0.004	0.001	—	—

range of P_{CO}/P_{CO_2} employed was $0.11 < P_{CO}/P_{CO_2} < 103$, with $P_{CO} + P_{CO_2} = 1$ atm. Assuming only a negligible effect of this dilution upon the carbonate activity, the potential of this cell is expressed by

$$E = E^\circ + \frac{RT}{2F} \ln \frac{(P_{CO_2}{}^2)_r (P_{CO})_w}{(P_{CO_2}{}^2)_w (P_{CO})_r} \quad [2]$$

where E is the measured cell potential; E°, the standard cell potential; and the subscripts r and w refer to the reference (constant) electrode and working (variable) electrode, respectively. The standard cell potential is ideally zero, but nonzero values were observed when tacitly identical gas mixtures were passed through both electrodes. The magnitude of these values was typically in the range of 5-40 mV, with occasional larger values, and was reasonably consistent for a given pair of electrodes. This is within the range of error attributable to the rotameter gauges. For the purpose of evaluating Nernstian response of these electrodes, an effective E° was measured at the start of each series of experiments and subtracted from the subsequently measured potential values. Figure 2 shows such values of $(E - E^\circ)_{meas}$ compared with $(E - E^\circ)_{calc}$; Nernstian behavior is clearly demonstrated.

An additional study was performed to assess the behavior of this reference electrode in comparison to a low resistance reference electrode during an electrode polarization experiment. In this study, three electrodes were involved: The reference electrode, which was either the electrode described or a similar electrode in which a 92% ZrO_2-8% Y_2O_3 crucible [resistivity $\simeq 10\ \Omega$ cm (25)] was substituted for the Type 998 alumina tube; a nickel (Ni 200) working electrode; and a platinum counterelectrode. Although the thermodynamic state of the electrolytes was not fixed, reproducible conditions were established by bubbling oxygen through the reference and cell electrolytes. Potentiostatic polarization was accomplished via a Wenking 68 TS 3 potentiostat, with a Wenking 69 scanning potentiometer providing a potential stepping rate of 2 mV/20 sec. Figure 3 shows anodic and cathodic polarization curves obtained at 1000°C. Similar behavior is evidenced with both reference electrodes. Taking into account the expected difference in rest potential (zero current) of the nickel as measured against the

different reference electrodes, the discrepancy between the curves representing the different reference electrodes is comparable to that between curves representing different scans with the same electrode. During prolonged cathodic polarization under a CO-rich atmosphere, a slight blackening of these electrodes was observed due to the presence of cathodically reduced carbon. This is discussed in detail by Borucka (17). The Y_2O_3-doped ZrO_2 is not suitable for long term use in molten carbonates, becoming severely degraded after 50 hr exposure at 1000°C.

Corrosion Protection of Molten Carbonate Fuel Cell Gas Seals

R. B. Swaroop,* J. W. Sim,* and K. Kinoshita*

Argonne National Laboratory, Argonne, Illinois 60439

A recent study (1) has estimated that a molten carbonate fuel cell integrated with a low BTU coal gasifier will have efficiencies (coal-to-electricity) of about 50%. The higher efficiency and the high grade heat available are advantages that the molten carbonate fuel cell has over the phosphoric acid fuel cell, which is closer to commercial realization. However, the relatively high operating temperature (~923°K) of the molten carbonate fuel cell presents severe materials problems. The metallic cell components (for example, current collectors, cell housings) of the fuel cell are susceptible to corrosion due to the molten carbonate electrolyte and the gas environment at operating temperature. In particular, the gas seal region of the anode housing is subject to extensive corrosion due to the large chemical potential gradient that arises from the fuel gas (H_2 + H_2O + carbonaceous gases) and the ambient environment (generally air) on the inside and outside of the cell, respectively. In addition, the chemical potential gradient between the fuel gas and oxidant gas (O_2 + CO_2) gives rise to corrosion in the gas seal region of the anode housing (2). The corrosion rates of metallic cell components in the gas seals of molten carbonate fuel cells must be decreased in order to increase the life of the fuel cell. A solution to the corrosion problem at the gas seal of the cell housings is described in this note.

One approach to obtain fuel cells that are free of gas leaks is to use the "wet seal" technique (3). In this technique, the wet seal is produced by contacting the electrolyte tile (*i.e.*, an electrolyte structure consisting of unconsolidated particles of $LiAlO_2$ and molten carbonate) with the cell housing, as shown schematically in Fig. 1. The electrolyte in the tile wets the metal housing (typically, Type 316 stainless steel) to form the gas seal at A. The direct contact between the molten salt and the metallic cell housing provides a leak-free gas seal, but produces an environment which leads to electrochemical corrosion in the wet seal region. Therefore, corrosion of the metallic cell housings must be prevented.

* Electrochemical Society Active Member.

Key words: wet seal, lithium aluminate, electrolyte tile, 316 stainless steel.

Two approaches were considered to minimize the corrosion of the wet seal region of the metal cell housings. In one approach various metallic cell components

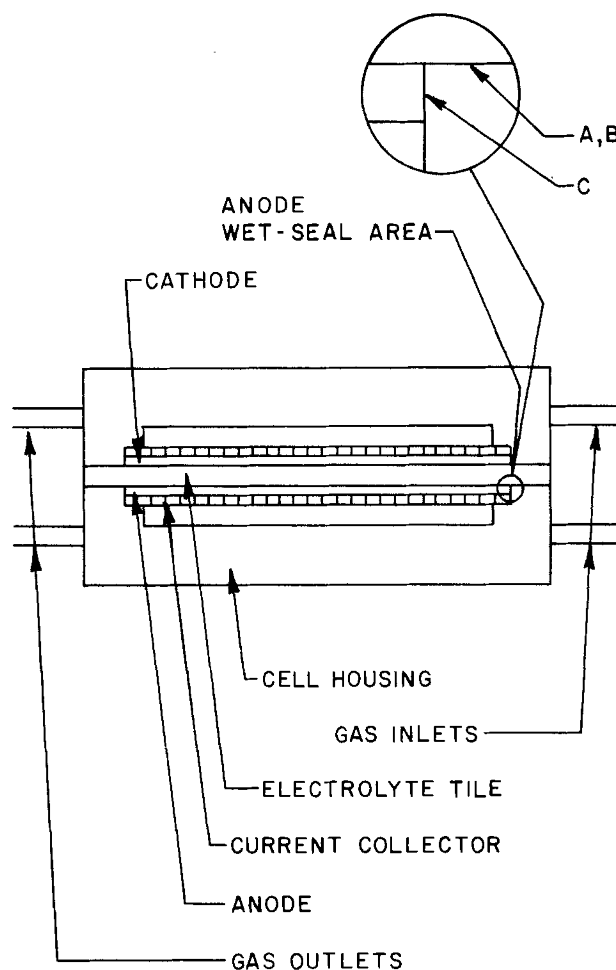

Fig. 1. Diagram of cell housings showing section examined microscopically.

that may be less susceptible to corrosion than Type 316 stainless steel, a state-of-the-art cell component, were examined. Because of the high cost of the alternative component alloys, this approach was not pursued. In the other approach aluminum metal is flame sprayed (performed at Coating Systems Technology Incorporated, North Babylon, New York) onto the seal to a thickness of ~50-70 μm, after which the housing is heated (in vacuum or in helium) to 1275°K for ~30 min to form a diffused layer between the aluminum [probably $(FeNiCr)Al_2$] and the Type 316 stainless steel substrate.

The wet seal region (A in Fig. 1) of the anode and cathode housings in fuel cells (7 cm diam) were aluminized and tested at 925°K. These fuel cells contained an electrolyte tile of 45 weight percent (w/o) $LiAlO_2$ and 55 w/o Li_2CO_3-K_2CO_3 [62 mole percent (m/o) Li_2CO_3-38 m/o K_2CO_3]. The anode gas was 80% H_2/20% CO_2 humidified with H_2O at 300°K, and the cathode gas was 30% CO_2/70% air. One of these fuel cells was operated for several periods of about 500 hr each at 925°K. After each period, the cell was disassembled and the cell housing was inspected for corrosion damage. After the anode cell housing operated in this manner for a total of 2600 hr, it was cross sectioned and examined.

A photomicrograph of a cross section through an anode housing tested for 2600 hr is shown in Fig. 2. The wet seal region consists of a coherent protective layer A (~35 μm thick) on top of an intermediate layer B (~30 μm thick) bonded to the Type 316 stainless steel housing. The aluminized layer extends to a small part of the cell housing (as shown in Fig. 2, area C) as well as to the anode wet seal directly in contact with the electrolyte tile. We believe that a few cracks evident in the protective coating have been produced because of thermal stresses. There was no evidence of corrosion of the cell housing in the areas protected by the aluminized layer, even at the bottom of the protective layer where cracks extended to the intermediate layer. The region of the cell housing which was not aluminized (as shown in Fig. 2, area C) clearly showed an extensive corrosion layer (~35 μm thick). Furthermore, close examination of Fig. 2 shows that the corrosion layer extended beneath the edge of the intermediate layer, which did not appear to have suffered corrosive attack. A few results obtained in other tests indicated that thermal cycling at rates greater than 1 cycle/500 hr does not affect the protective coating and no corrosion was evident in the wet seal area of those cell housings.

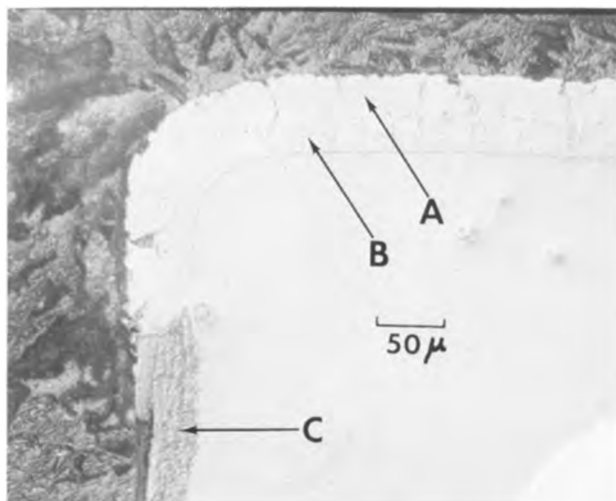

Fig. 2. Photomicrograph of section of anode housing after 2600 hr operation. A, Oxidized aluminum layer; B, diffused aluminum layer; C, Corrosion product at edge of electrode compartment (see also Fig. 1).

Scanning electron microscopy and energy-dispersive x-ray analysis SEM-EDXA) showed that the protective coating in Fig. 2 contained mainly aluminum in the top layer. The intermediate layer also showed the presence of aluminum. X-ray diffraction analysis and SEM-EDXA confirmed that the top protective coating was α-$LiAlO_2$; the intermetallic phases precipitated in the intermediate layer were suspected to be of the types: $NiAl_3$, NiAl, and/or FeAl.

These results indicate that, during initial cell operation, aluminum is converted to an oxide and then subsequently to $LiAlO_2$ by reaction with Li_2CO_3 as follows

$$Li_2CO_3 + Al_2O_3 \rightarrow 2LiAlO_2 + CO_2$$

The corrosion protection to the stainless steel was provided by the $LiAlO_2$ coating. Furthermore, the coating also showed good thermal shock resistance and adherence. At 925°K, $KAlO_2$ would not be thermodynamically stable in the electrolyte tile containing 62 m/o Li_2CO_3-38 m/o K_2CO_3 (4), and would not, therefore, be present. The unprotected areas adjacent to the wet seal were corroded during cell operation as shown in Fig. 2. X-ray diffraction analysis showed that the corrosion product at C mainly consisted of $LiCrO_2$ and $LiFeO_2$ (5) that formed by the reaction of stainless steel and molten carbonate which seeped from the electrolyte tile during cell operation.

In summary, the results of this study showed that a $LiAlO_2$ coating on 316 stainless steel offers corrosion protection to metallic cell components susceptible to corrosive attack in a molten carbonate fuel cell environment, especially at the wet seal areas. Although this note described the corrosion protection of only one stainless steel, namely Type 316, we expect that other stainless steels can be protected from corrosion by the application of an aluminized layer. Based on the above experience, a further improvement for the corrosion protection of wet seals has been developed—the areas of the cell housing covered by an aluminized coating has been increased to also include the areas adjacent to the wet seal. In other words, the regions marked A, B, and C in Fig. 1 as well as the exterior of the cell housing were covered with an aluminized coating. In this manner, the formation of a corrosion layer beneath the edge of the diffuse intermediate layer (see Fig. 2) is prevented.

Acknowledgment

The authors would like to acknowledge B. S. Tani for conducting the x-ray analyses and J. P. Ackerman for many suggestions provided during the course of this study.

Manuscript submitted May 25, 1978; revised manuscript received Aug. 3, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by Argonne National Laboratory.

Analysis of Protective Oxide Films on Copper-Nickel Alloys by Auger Spectroscopy

G. E. McGuire,*[,1] A. L. Bacarella,* J. C. Griess, Jr.,* R. E. Clausing, and L. D. Hulett

Oak Ridge National Laboratory, Chemistry Division, Oak Ridge, Tennessee 37830

Alloys of copper and nickel have found extensive use in saline water environments because the corrosion resistance of such alloys is usually superior to that of copper. Some earlier work has shown that the protective film is primarily a nickel oxide (1). The previous investigation was based upon photoelectron spectroscopic results. This paper describes experiments that have been conducted to determine the surface composition, as well as the elemental depth profile of these same films using Auger electron spectroscopy (AES) and ion sputtering.

The oxide films which protect most oxidation-resistant alloys from further oxidation are so thin that they cannot be examined in section by conventional metallographic techniques. Similarly the use of the electron beam microanalyzer is limited to films thicker than 1 μm both because of its precision and because of the rather deep penetration of the high energy electron beam used to stimulate x-ray emission. Thin film analysis is now frequently obtained by use of Auger and photoelectron spectroscopy in conjunction with argon ion sputtering. It has been shown that the signal obtained by these two techniques arises from the first few (3-20) atom layers (2). It is possible to analyze the first few atom layers and then remove them by Argon ion sputtering to give a depth profile for any desired depth. These features, coupled with the well-known capabilities of Auger and photoelectron spectroscopy to do elemental analysis and to determine chemical states, make the techniques very valuable in studies of protective films on metals.

Experimental Procedure

The 70:30 cupronickel was obtained from a commercial vendor and had the following composition: 68.85% Cu, 29.93% Ni, 0.67% Fe, 0.44% Mn, 10%Zn, and 0.005% Pb. The nickel specimen was made from nickel 200 (International Nickel Company) which has a nominal composition of 99.5% Ni, 0.25% Mn, 0.15% Fe, and 0.06% C. The specimens were machined from ¼ in. rods. The 1.24M NaCl solutions used in the anodization were prepared from reagent-grade material and triply distilled water and had a pH of about 6.4. The solutions were unbuffered, and the pH's reported below are those prevailing at the termination of the polarization.

Specimens of 70:30 cupronickel were maintained potentiostatically at -0.325V *vs.* SCE and -0.360V *vs.* SCE in boiling-refluxing H_2-sparged 1.24*M* NaCl, pH $= 7.4$. Since the passivation potential (SCE) for this alloy in this solution is -0.37V ($E_p = 0.19 - 0.076$ pH) (3), the specimen should passivate. Under these conditions the current decreased from 3.1×10^{-4} to 2.2×10^{-7} A/cm^2 over a period of 224 min as a passive film formed. Other specimens were maintained potentiostatically at -0.500V and -0.450V *vs.* SCE in the boiling-refluxing H_2-sparged 1.24*M* NaCl, pH $= 8.4$. Here, the current density remained constant at 7.0×10^{-6} A/cm^2. Since the potential was below the passivation potential ($E_p = -0.448$V), no film formation was expected. However, since the potential is only slightly cathodic to the passivation potential, some film formation which may not affect the anodic dissolution may occur (3). Bockris, Reddy, and Rao (4) postulated a similar type of film on nickel in H_2SO_4 at room temperature as a precursor to the passivating film.

To obtain a specimen representative of an unoxidized 70:30 cupronickel substrate, one specimen was chemically etched in *ca.* 6*N* HCl and rinsed in triply distilled water. To check the assumption that the surface film formed on the 70:30 cupronickel is an oxide of nickel, one pure nickel specimen was anodized at -0.360V *vs.* SCE in the boiling-refluxing H_2-sparged 1.24*M* NaCl, pH $= 7.5$. The current density for this specimen decreased from 1×10^{-4} to 2×10^{-7} A/cm^2 over a period of 81 min. Another pure nickel specimen was chemically etched in a *ca.* 6*N* HCl solution and rinsed in distilled water. All specimens were rinsed in distilled water and stored dry until examined. Just prior to loading into the spectrometer, the samples were ultrasonically cleaned in absolute ethanol. Another set of samples were prepared in the same fashion at a later time to check the reproducibility of the data. A detailed description of the electrochemistry and preparation has been presented (1).

The Auger electron energy analyzer was of the cylindrical-mirror type purchased from Physical Electronics Corporation. In this design the electron gun is coaxial with the cylindrical analyzer. The electron gun was operated at 5000V with a 5 μA beam focused to a beam diameter of about 25 μm. Adequate signal and resolution were obtained with a 6 eV p-p modulation voltage, a time constant of 0.3 sec, and a scan rate of 2 eV/sec. The signal was recorded as the first derivative of the electron energy distribution, $dN(E)/dE$. The spectrum was scanned from 0 to 2000 eV.

The vacuum chamber was equipped with all metal seals and was ion pumped to a base pressure of 10^{-9} Torr. A residual gas analyzer indicated the base pressure was due to CO, Ar, CO_2, and CH_4. During sputtering the ion pump was turned off and argon added to bring the pressure to 5×10^{-5} Torr. Carbon monoxide was the major contaminant in the sputter gas and it is estimated that its pressure was 1×10^{-8} Torr or less. Sputtering with 2000 eV ions at an argon pressure of 5×10^{-5} Torr was calibrated to remove $\sim$ 50 Å/min from the sample surface. Calibration was based on sputtering through 1000Å tantalum oxide films. The sputter rate calibration for tantalum oxide is only an approximation since the sputter rate of copper, nickel, or nickel oxide will be different. The ion gun was positioned so that ion sputtering could be accomplished during the data-taking process.

There may be a tendency to overestimate the sputtering rate. When a sample undergoes ion bombardment, the central point of focus of the ion beam undergoes the greatest degree of ion etching. The rate of ion etching drops off rapidly at points away from the center of focus. Using this method, we estimated the maximum rate of removal. The Auger signal may originate from regions that have been sputtered to a range of different depths although the electron beam used for excitation is positioned at the center of the sputtered crater. Thus an Auger signal may persist even after the element is removed from the center of the sputtering region (5).

For the majority of elements, a semiquantitative Auger analysis can be made by measuring the peak-

* Electrochemical Society Active Member.
[1] Present address: Texas Instruments, Materials Characterization Laboratory, Dallas, Texas 75080.
Key words: cupronickel, Auger, corrosion, ESCA, saline water.

to-peak intensity of the Auger signal. However, Cu and Ni have a number of intense Auger transitions, several of which overlap. Pure Ni exhibits a peak at 715 eV, Cu and Ni both have peaks that appear at 775 and 850 eV, and pure Cu exhibits a peak at 920 eV. There are also overlapping Auger transitions for Cu and Ni around 61 eV. The normal mode of operation of the AES system did not permit the resolution of the overlapping Cu and Ni peaks at 775 or 850 eV. The Cu concentration was obtained by measuring the intensity of the Cu signal at 920 eV, which has no interfering lines. The contribution from Cu to the overlapping signals at 775 and 850 eV was estimated using the known ratios of the Cu peaks (6). Subtracting the Cu contribution from the total signal leaves the contribution from the Ni. The Ni peak at 715 eV was not used because the signal-to-noise ratio was not adequate.

Results and Discussion

Observations on the "unsputtered" surface.—Typical Auger spectra, obtained for the surfaces before ion sputtering was initiated, are presented in Fig. 1. The main Auger signals that appear are sulfur at 150 eV, chlorine at 181 eV, carbon at 272 eV, nitrogen at 381 eV, oxygen at 510 eV, sodium at 990 eV, and the copper and nickel transitions mentioned earlier.

The surface of the chemically etched 70:30 cupronickel specimen has approximately the Cu-to-Ni ratio expected. This sample has some oxide formation, but the ratio of Cu to Ni in the surface of the oxide has not changed substantially from that of the alloy. The 70:30 cupronickel sample anodized below the passivation potential (Fig. 1B) has a very thin oxide layer that appears to be richer in Cu than Ni. The spectrum from the 70:30 cupronickel sample (Fig. 1A), which was prepared at the passivation potential, shows an Ni signal which completely overshadows the Cu signal that is present. The O/Ni ratio is closer to that of the anodized nickel than that of the chemically etched nickel. The signal from oxygen is present on the surface of the 70:30 cupronickel and the Ni and anodized Ni are very large, but only in the case of the anodized Ni does the oxygen appear to reduce the intensity of the Ni signal. This is reasonable since this is a relatively thick oxide with possible additional adsorbed oxygen on the surface. It should be mentioned that an unknown portion of the oxygen signal on all the samples may be due to adsorbed CO, especially on the "unsputtered surface." We cannot make quantitative estimates of this effect.

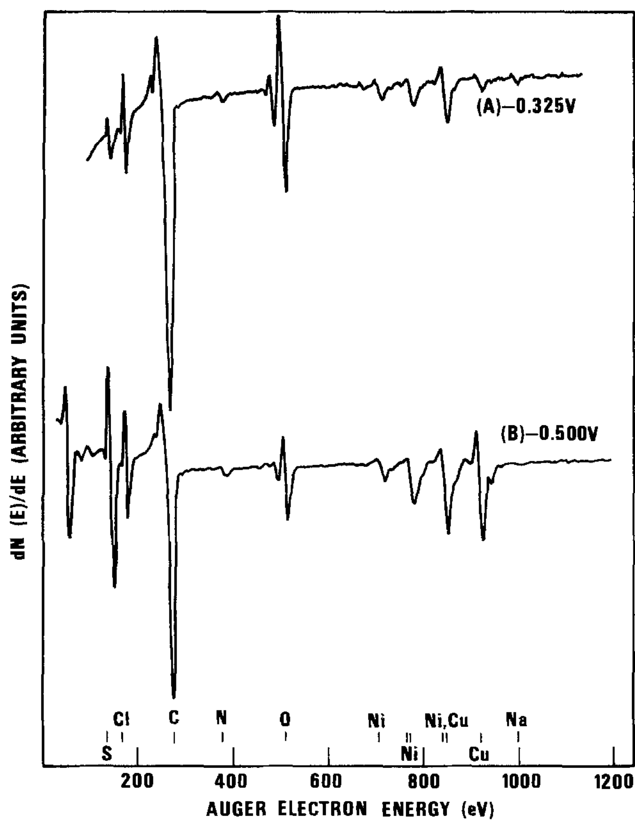

Fig. 1. Auger electron energy spectra for the Cu/Ni alloys before ion sputtering.

There is a strong carbon signal in each of the spectra. The carbon signal builds up quickly from the breakdown of CO under the influence of the electron beam (7), but the carbon layer is easily removed by argon ion sputtering. Initially, the amount of carbon present on the chemically etched samples is much greater than on the anodized samples. This may be a result of differences in the electron beam interactions with CO on the metallic and oxidized surfaces or differences in the interaction of the solvent ethanol with the surface.

Sulfur was found as an impurity on the surface of all the samples examined here. Frequently sulfur has been reported as an impurity on Cu and Ni samples (7, 8) and has been found to diffuse to the surface when samples are heated to elevated temperatures. In these samples neither anodization nor boiling reflux conditions seems to have affected the sulfur concentration at the surface layer. The concentration of sulfur seems to be approximately the same on all the samples including the chemically etched samples.

Sodium and chlorine show up probably as a result of anodizing the samples in NaCl solution. Although the samples were thoroughly cleaned, some NaCl may remain on the surface through adsorption. There is a rather strong chlorine signal, but little, if any, sodium signal. A portion of the chlorine may be appearing as $CuCl_2^-$ (9).

There is a small amount of nitrogen present on each of the samples, probably as adsorbed nitrogen. Using ion bombardment, it was possible to reduce the signals from sulfur, chlorine, nitrogen, and sodium to trace levels within a few monolayers of the surface. The signals from carbon and oxygen were more persistent, primarily because carbon and oxygen were present initially in greater amounts than the other contaminants and also because there may be some CO readsorption on the surface, even during ion bombardment.

Observations during Depth Profiling by Argon Ion Sputtering

Figure 2 presents the ratios of the Auger signal intensity of Cu_{920} to Ni_{848} as a function of the time of ion bombardment for the cupronickel alloy. Figure 3 presents the corresponding ratio of the Auger signal intensity of O_{510} to total metal signal. The ratios of

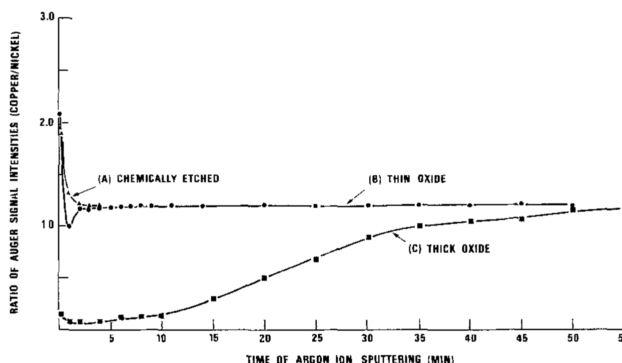

Fig. 2. Sputter profiles for Cu/Ni alloy samples showing the ratio of the Auger signal intensity from copper to that from nickel as a function of sputtering time. (A) Chemically etched; (B) thin oxide; (C) thick oxide. The sputtering rate was 50 Å/min.

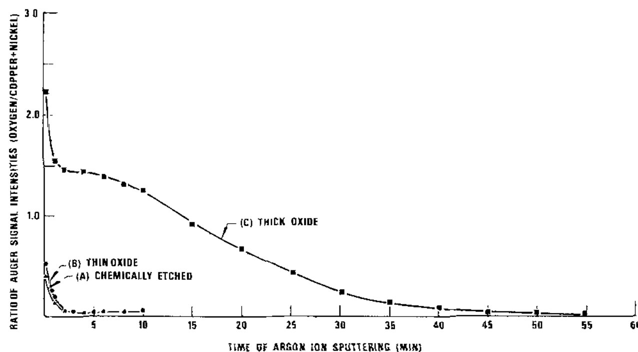

Fig. 3. Sputter profiles for Cu/Ni alloy samples showing the ratio of the Auger signal intensity from oxygen to that from nickel and copper as a function of sputtering time. (A) Chemically etched; (B) thin oxide; (C) thick oxide. The sputtering rate was 50 Å/min.

the peak heights are a better indication of the changing surface concentration than the sample Auger peak heights. Using these curves for depth profile analysis, one can observe that the chemically etched 70:30 cupronickel specimen had a very thin oxide layer that was slightly rich in Cu as compared to the bulk alloy. The oxide layer was very thin and was removed within the first few minutes of ion bombardment. With a sputtering rate calibrated at ~ 50 Å/min, the oxide film on this sample would be much less than 100Å thick.

Examination of Fig. 2B and 2C shows that the first few monolayers of each anodized cupronickel sample have a higher concentration of Cu than the region just beneath the surface layer. The ratio of Cu/Ni in samples prepared at the passivation potential (thick oxide) is below the bulk ratio, indicating that the oxide is largely a nickel oxide. The Cu/Ni ratio becomes smaller, levels off, then increases to the bulk composition as sputtering is continued. In the sample prepared below the passivation potential (thin oxide), the Cu/Ni ratio starts out above the bulk ratio, decreases below the bulk, and then quickly reaches the bulk value. The film is estimated to be less than 100Å.

The O/M ratio of the chemically etched (Fig. 3A) and thin oxide (Fig. 3B) samples reflects a thin oxide similar to the Cu/Ni curves. Figure 3C for the thick oxide shows an initial decrease in the O/M ratio which may correspond to the removal of O_2, CO, or H_2O. The O/M curve then levels off and gradually decreases over several hundred angstroms.

Nakayama *et al.* (10) and Castle (11) suggest that heating a cupronickel sample can cause Ni to migrate to the surface. Migration of Cu or Ni due to thermal effects can be ruled out in this case since the sample was not heated above about 100°C during sample preparation or examination, and self-diffusion rates for copper and nickel would be extremely small at this temperature and alloy composition even considering the possibility of faster diffusion rates along grain boundaries or near the surface (12).

It was reported previously that at anodic potentials below that required for passivation, the relative concentration of copper and nickel at the surface of the film is the same as in the bulk alloy. This suggests either the absence of a film or a film formed by uniform oxidation of the elements in the alloy (1).

Specimens of 70:30 cupronickel exposed to salt water solutions for extended periods of time are usually covered with a thin film. It has been demonstrated, using x-ray diffraction, that this film is Cu_2O, with no detectable nickel present (13). Since the present data indicate the initial films are composed primarily of nickel, the initial decrease in the cupronickel ratios in Fig. 2B and 2C may be an indication of copper oxide formation through adsorption after being hydrolyzed (9). McIntyre *et al.* (14) have presented data on the aqueous oxidation of 66% Ni, 32% Cu that would support this observation.

The oxide layers of the two nickel samples were less than 100Å thick. Initially the O/Ni ratio in the anodized Ni was greater than that of the chemically etched Ni sample, but the oxygen was sputtered away within a few minutes to what appeared to be a rather abrupt interface between the oxide layer and the pure metal underneath.

Conclusions

The use of Auger spectroscopy accompanied by argon ion sputtering has been used to identify unambiguously the surface impurities (sulfur, chlorine, carbon, oxygen, nitrogen, and sodium) on anodized and chemically etched 70:30 cupronickel samples. A very thin film was present on the outermost surface of these samples in which the Cu/Ni ratio is different than the bulk, but there is an underlying oxide layer which is very rich in nickel (below the first few atomic layers).

The underlying layer is approximately 70% nickel in the passivated sample. The sample which did not passivate also had a thin nickel-rich layer, but its oxygen content is lower and the layer is much thinner. It seems likely that this surface is not completely covered with an even, thin nickel-rich oxide but rather that patches of nickel-rich oxide and base metal coexist during anodization. The base metal would acquire a very thin oxide layer during air exposure prior to the Auger analysis, thus explaining the high initial oxygen-metal ratio and the observed profile.

The film may also be a precursor $Ni(OH)_2$ film formed in more significant quantity due to the higher pH (pH = 8.4). At this pH, the thermodynamic potential for the formation of $Ni(OH)_2$ is only 52 mV cathodic to the passivation potential.

Film formation at the passivation potential may be due to the oxidation of a precursor $Ni(OH)_2$ film to $NiO_{1.5\text{-}1.6}$ as suggested by Bockris, Reddy, and Rao (4).

The surface enrichment of Cu in the first few layers of all the cupronickel specimens may be due to surface adsorption of $CuCl_2^-$ (a corrosion product) from the anodizing solution (9).

The Electrochemical Oxidation of Hydrazine and Methylhydrazine on Gold: Application to Gas Monitoring

J. R. Stetter,* K. F. Blurton,*[,1] A. M. Valentine, and K. A. Tellefsen

Energetics Science, Incorporated, Elmsford, New York 10523

Recently (1-3), we have described a series of instruments for monitoring common pollutants, such as CO, NO, NO_2, and H_2S, in ambient air. The operating principle of these analyzers was based on the electrochemical oxidation (electroreduction for NO_2) of the gas at a catalyzed Teflon-bonded diffusion electrode (4), the potential of this sensing electrode being maintained constant at a value at which neither oxygen reduction nor electrolyte decomposition interfered with the measurement of the pollutant (essentially between 0.7 and 1.6V *vs.* RHE depending on the electrode catalyst).

In general, the desirable features of such instrumentation are signal stability, specificity (*i.e.*, the ability to measure a pollutant in the presence of other gases), precision, and ease of operation. Instrument specificity was achieved either by using selective gas filters or by optimizing the electrode catalyst and potential. The latter method was preferred since it eliminated a component from the instrument which had a finite life.

Hydrazine (H) and monomethylhydrazine (MMH) are strong reducing agents with a variety of biological effects and considerable toxicity (5), and they will be used as rocket propellants for the space shuttle. Currently, there is no instrumental technique which can satisfactorily monitor H and MMH and meet the requirements for protection of personnel during handling and storage of these chemicals (6). Therefore, since previous studies of hydrazine as fuel cell fuels (7, 8) had demonstrated the ability to electrooxidize these compounds, we decided to investigate the electrochemical technique as the basis for a hydrazine instrument (9).

In this paper, we describe the electrochemical studies which led to the development of the instrument. Gold was used as the electrode material since CO (the major interferent which cannot be selectively prefiltered) is inactive on it in the potential range of interest (10).

Experimental

The experimental cell was similar to that described previously (1). The electrolyte was either 28% H_2SO_4 solution or 23% KOH solution and these concentrations were selected such that the electrolyte vapor pressure approximated that of the average relative humidity met in practice. The cell had three electrodes. The sensing electrode was a gold-catalyzed Teflon-bonded diffusion electrode (geometric area 5 cm^2, catalyst loading 8-12 mg/cm^2) and was fabricated by applying a mixture of catalyst and Teflon suspension to a Teflon film. The reference- and counter-electrodes were platinum-catalyzed diffusion electrodes, and these were used for convenience in the cell design (3). The potential of the Pt/air reference electrode was checked against a hydrogen electrode in the same electrolyte and found to be 0.98V ± 10 mV in the acid electrolyte and 1.0V ± 10 mV in basic electrolyte. (All potentials are reported *vs.* RHE in the same electrolyte.) The potential of the sensing (working) electrode was potentiostatted *vs.* the reference electrode using an in-house designed and constructed potentiostat.

The electrochemical measurements were made using dilute mixtures (between 1 and 10 ppm by volume) of H and MMH in air (since this was the situation to be met in practice) and also in nitrogen. No difference in electrochemical cell response was noted between the air and nitrogen mixtures during these experiments.

These mixtures of H and MMH were prepared using a dynamic dilution technique (11). The neat liquid hydrazines were injected at a constant delivery rate into a glass chamber through which the diluent gas was flowed at a continuous controlled flow rate. A syringe pump (Sage Model 355) was used to deliver the liquid hydrazine from the 10 μl syringe into the 1.0 liter min^{-1} gas stream, and after mixing they were passed through a Teflon valve exhaust for sample collection.

The vapor mixtures were contained in a 50 liter Teflon bag (Cole-Parmer Company, Chicago, Illinois) prior to their introduction into the electrochemical cell. Samples of the vapor mixtures were collected from the Teflon bag during testing using an impinger filled with acid solution, and they were analyzed using a colorimetric technique (12) which was modified (13). This colorimetric technique was used as the reference standard for all H and MMH vapor mixture concentrations.

Initially, air was passed over the back (gas) side of the potentiostatted diffusion electrode, and the current generated by the electrochemical reaction was measured by determining the potential drop across a standard resistor with a recorder. Subsequently, the air/hydrazine mixture was passed over the back of the electrode at a constant flow rate and the current was measured. The difference between the currents for air and hydrazine was then recorded as the signal due to the electrochemical oxidation of hydrazine in the cell. Similarly, analyzed gas mixtures of NO/N_2, CO/air, and NO_2/N_2 were introduced into the electrochemical cell. The NO/N_2 and CO/air mixtures were obtained commercially (Airco, Incorporated) while samples containing 5 ppm of NO_2 in N_2 were prepared using high purity N_2 and thermostatted permeation tubes (Metronics Associates).

At low gas flow rates (<0.3 l/min), H and MMH interacted with the sampling system and also with the reinforced acrylic used as the electrochemical sensor endplates (gas chamber). These interactions,

* Electrochemical Society Active Member.
[1] Present address: Institute of Gas Technology, IIT Center, Chicago, Illinois 60616.

which can lead to adsorption or decomposition of the reactive vapor, cause changes in hydrazine vapor mixture concentration. They can be minimized by reducing the surface area and reactivity of the surface to which the vapor mixture is exposed prior to analysis. Therefore, for the experiments at low gas flow rates, an electrochemical cell and sampling system was fabricated from Teflon and the length of tubing used in the sampling system was kept to a minimum.

Current/potential curves for H and MMH were obtained by initially potentiostatting the sensing electrode at a constant potential (0.6V in acid electrolyte and 0.8V in alkaline electrolyte) for 24 hr. All experiments were performed at room temperature, 23°C. The current was then measured for zero air and subsequently for the test gases with a gas flow rate of 0.7 l/min through the sensor. The electrode potential was then increased stepwise and the currents at each potential were determined after potentiostatting for 24 hr.

Results and Discussion

The current resulting from oxygen reduction or evolution at the sensing electrode must be small compared with the current due to the oxidation of the test gas at practical concentrations in order to achieve accurate data on the electrooxidation of hydrazine. We have previously reported that this current is indeed small over a wide range of potentials with gold electrodes in acid electrolyte (10). However, the results in Fig. 1 show that the potential range for analyzing pollutants in alkaline electrolyte is much more restricted than in acid solution.

The current/voltage curves for H and MMH were determined with sensors containing acid and alkaline electrolyte. The data in acid electrolytes was irreproducible for both gases at all potentials, and this was probably due to the difficulty in oxidizing the protonated, $N_2H_5^+$, species. As a result, we eliminated acid as a suitable electrolyte for analyzing these low gas concentrations. The data in alkaline electrolyte were

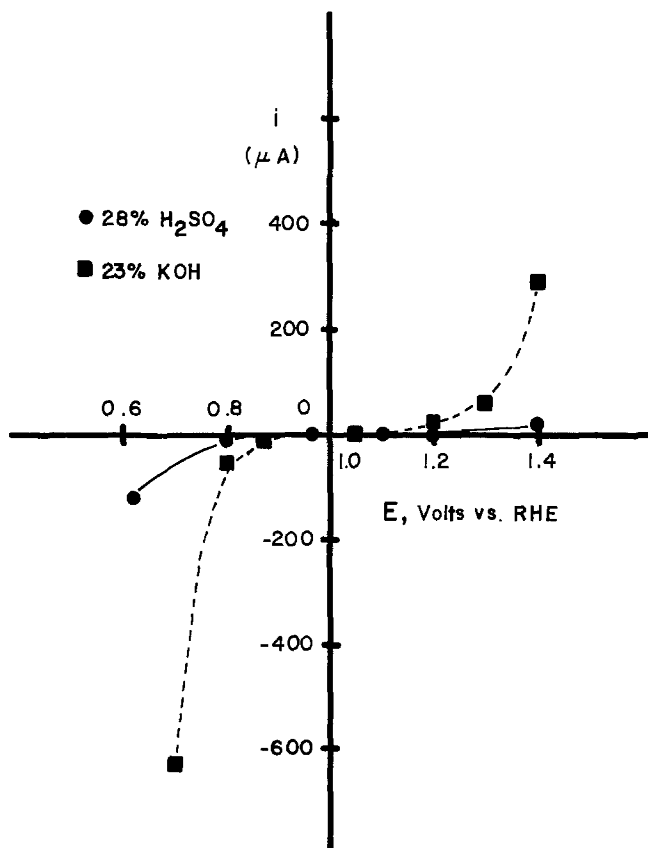

Fig. 1. Current/voltage curve on a gold electrode for zero air passing through the sensor at 0.7 l/min.

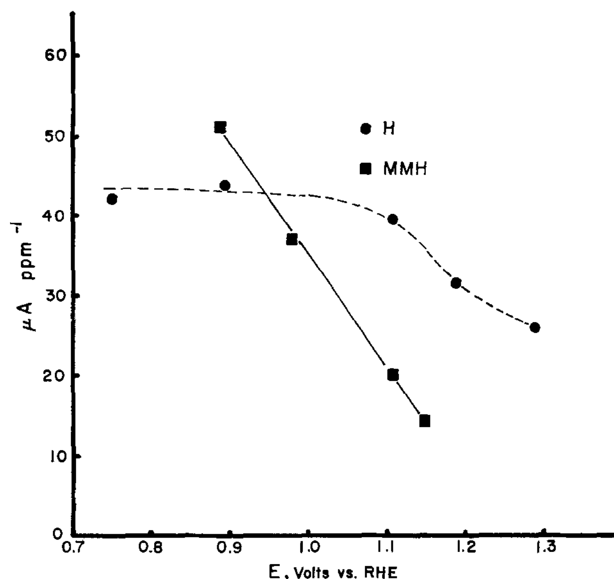

Fig. 2. Hydrazine and monomethylhydrazine oxidation currents on gold electrodes using 23% KOH electrolyte. The gas flow rate is 0.7 l/min through the sensor.

much more reproducible, and the current/potential plot shown in Fig. 2, although obtained with one cell, is similar to data obtained with three other cells. Although the cell specificity and sensitivity was enhanced by using alkaline electrolyte, problems were caused due to the absorption of CO_2 from the atmosphere by the electrolyte. This caused the cell lifetime to be limited to 600 hr of continuous use (9). However, in the instrument application, cell replacement is easily accomplished and extended use is obtained when the cell is utilized in the spot-check mode (13).

In alkaline electrolyte, both hydrazine and MMH were electrooxidized on gold at all potentials in the limited potential range where data could be obtained, and in both cases the maximum signal was obtained at the more cathodic potential. The signals for both gases were approximately 50 μA/ppm at 0.9V and decreased to approximately 20 μA/ppm at +1.2V.

In order for a practical instrument to be designed with these sensors, the instrument must also be specific to the test gas and give a minimum signal to other pollutants present in the practical situation. In this application (11, 13) the common pollutants were CO (present at common levels in the presence of vehicular traffic 10-50 ppm), NO (present in concentrations of 5 ppm due to rocket oxidant), and NO_2 (present at normal atmospheric concentration of 20-50 ppb). Figure 3 shows the current/voltage curve for these gases in the same sensor as used to obtain the data in Fig. 2. As can be seen, the currents-per-unit concentration for these potential interferences were markedly lower than that for hydrazine and MMH at potentials anodic to 0.9V. In general, the cell output increased with increasing environmental temperature (13), however this was repeatable and therefore could be compensated electronically in the instrument application.

From the current/potential results shown in Fig. 2 and 3, an instrument for the determination of hydrazine and MMH was developed (9) with the sensing electrode potential maintained at 1.1V where CO and NO are unreactive and where the signal due to NO_2 is low.

Hydrazines may undergo several charge-transfer processes at an electrode surface, and we used this electrochemical cell to determine the over-all electrochemical reactions for hydrazine and MMH at 1.1V. This technique, which we have described previously (10), is based on measuring the current at a fixed

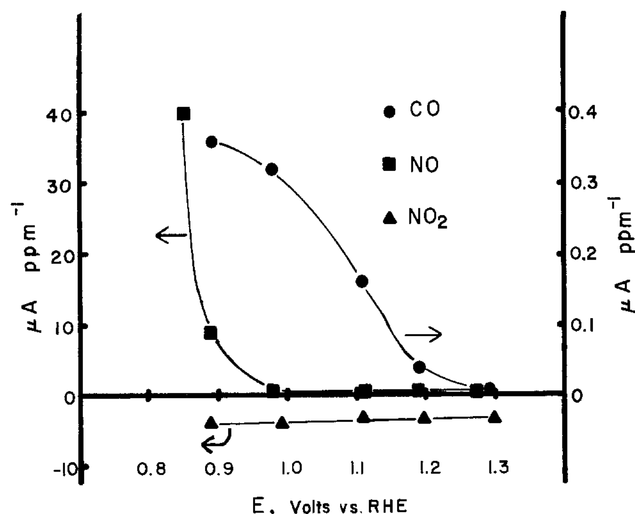

Fig. 3. CO and NO oxidation currents and NO_2 reduction current on a gold electrode using 23% KOH electrolyte. The gas flow rate is 0.7 l/min through the sensor.

potential as a function of flow rate. Less than 100% of the gas is electrochemically oxidized at high flow rates, while at low flow rates, all of the gas is oxidized. Figure 4 shows the experimentally determined current *vs.* flow rate plot for 13.8 ppm MMH and the theoretically calculated current *vs.* flow rate curve. As the flow rate is decreased, a point is reached at which all the hydrazine entering the sensor reacts, and the current (i) at this flowrate (G) is related to the electroactive gas concentration (c) by (14)

$$\lim_{G \to 0} (i/G) = zFc/V \quad [1]$$

where V is the molar volume of the electroactive gas (cm^3/mole).

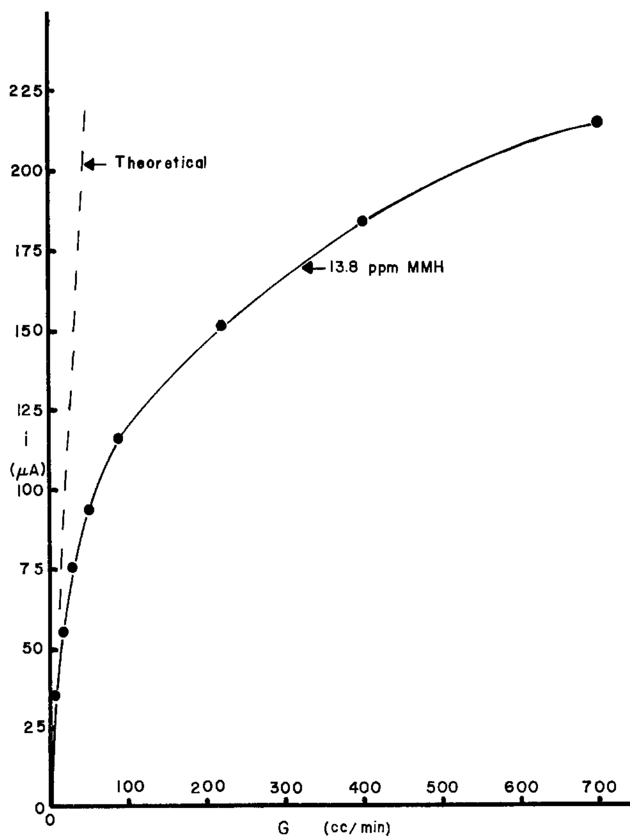

Fig. 4. Experimental and theoretical oxidation currents for 13.8 ppm monomethylhydrazine at 1.1V as a function of the gas flow rate.

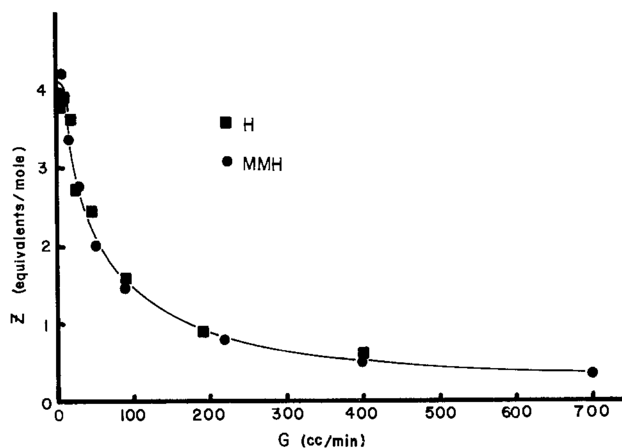

Fig. 5. Apparent values of z (calculated from Eq. [1]) for hydrazine and monomethylhydrazine oxidation at 1.1V as a function of gas flow rate.

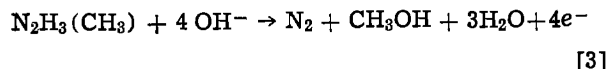
This method was used to determine z for H and MMH oxidation using gases of known concentration using the specially fabricated Teflon cell. The apparent value of z calculated from Eq. [1] was plotted *vs.* the gas flow rate (Fig. 5). Limiting values of 4 electrons per molecule were obtained for both H and MMH oxidation. From these data, it is proposed that the over-all electrochemical process for hydrazine at 1.1V is

$$N_2H_4 + 4\,OH^- \rightarrow N_2 + 4H_2O + 4e^- \quad [2]$$

and for MMH is



$$N_2H_3(CH_3) + 4\,OH^- \rightarrow N_2 + CH_3OH + 3H_2O + 4e^- \quad [3]$$

These over-all processes are in agreement with measurements with platinum electrodes in acid electrolyte for hydrazine (15) and monomethylhydrazine (16, 17).

Solid-State Chloride-, Bromide-, or Iodide-Selective Electrodes

G. Papeschi, S. Bordi,* and M. Carlà

Istituto di Chimica Fisica, Università di Firenze, Firenze 50121, Italy

A new technique for preparing low resistance Ag/AgX (with X = Cl^-, Br^-, I^-) solid-state electrodes from a mixture of silver powder and silver halide is described.

Halide electrodes are extensively considered in the electrochemical literature either for describing preparation methods (1-3), for presenting experimental studies, or for exposing theoretical considerations.

Mention is limited here to the most promising among recent efforts directed toward the development of halide-selective electrodes.

Pungor *et al.* (4-7) and independently, Rechnitz *et al.* (8, 9), describe a halide-sensitive membrane obtained with fine particles of silver halide contained in a polymerized silicon rubber matrix. Mascini and Liberti (10) prepare a membrane pressing at 130°-150°C, a mixture of silver halide and thermoplastic polymer. The membrane of van Osch and Griepink (11) is obtained pressing the ion-sensitive material they prepare by precipitation of the silver halide-sensitive material they prepare by precipitation of the silver halide upon finely divided gold particles. Kolthoff (12) reports that chloride and bromide electrodes can be made with a membrane of fused silver chloride and silver bromide. Lately, Matsushita *et al.* (13) prepare a silver-silver chloride electrode with a twist of two silver wires coated with fused silver chloride to which they add 1% of potassium chloride. The main disadvantages (14) of the silver-fused silver chloride electrodes are the rather high resistance of silver chloride and the fact that this material exhibits large photoelectric potentials. These disadvantages have been eliminated by using membranes of a silver sulfide matrix in which the appropriate silver salt is dispersed in a very finely divided form (14, 15).

Experimental Procedure

Silver powder preparation.—Humid purified silver chloride is added to 1 g/ml KOH solution and digested for 1 hr at 90°C on a hot plate under continuous stirring. The resulting Ag_2O, still in the hot alkaline solution, is reduced with 2M glucose added dropwise until a light gray powder of silver is obtained. After a thorough washing, the powder is dried and then passed through a 5 μm mesh sieve.

Silver halide pellet preparation.—0.1M sodium chloride is slowly dropped in a slurry of 0.1M $AgNO_3$ and silver powder ($Ag:Ag^+$ ratio ranging from 5:1 to 7:10) until an excess of chloride is present. The precipitate is thoroughly washed with distilled water and dried at 110°C. A pellet is made by pressing about 1.5g of the precipitate in a KI-type pellet die with a hydraulic bench press. The compaction pressure used is 7 tons/cm^2. During the pressing procedure the pellet space is evacuated. The pellet fixed at the end of a perpex tubing is sealed with a silver wire attached to the inner face using a silver-based conducting epoxy resin. The outer face of the pellet can be shaped and smoothed with emery paper.

Procedure.—Steady-state potentials are measured *vs.* a B222 Schott double junction half-cell containing 0.1M KNO_3 in the outer chamber, using a Fluke 881 A d-c differential voltmeter. Dynamic measurements are made by the aid of Texas Instrument minicomputer Model T.I. 960 A interfaced with a 12 bit A/D converter. After use, the electrodes are rinsed with distilled water, dried with soft paper, and stored in the dark. Shortly before the measurement the electrodes have to be rinsed with water and then used directly in the test solution.

Results

Calibration curves.—Investigations on the electrode performance showed that the percentage of metallic silver in the precipitate is not critical. Electrodes employing pellets prepared from mixtures with the $Ag:Ag^+$ ratio ranging from 5:1 to 7:10 all exhibited identical behavior. Also, variations in the pressure of compaction do not significantly affect the response characteristics of the electrodes.

Stirring efficiency was not critical in order to obtain reproducible values (±0.5 mV) on repetitive measurements carried out on different days.

The AgX electrodes were tested at a fixed temperature of 25° ± 0.1°C in solutions of sodium halide at concentrations ranging from 10^{-6} to 1M for chloride, 10^{-7} to 10^{-1}M for bromide, and 10^{-7} to 10^{-1}M for iodide. The ionic strength of the halide solutions was adjusted to 0.1 with KNO_3.

In every case the electrode system was allowed to attain equilibrium as indicated by a stable (±0.01 mV) cell emf.

In Fig. 1 the electrode potential is plotted against the halide concentration and the results have been expressed in the form of an equation in the same figure.

Response time.—The response time was evaluated by submitting the electrodes to rapid changes in the halide concentration and recording the relative changes of the electrode potential *vs.* time.

The concentration was changed by addition of a measured small amount of more concentrated solution in order to increase the initial concentration. Potential electrode curves for a chloride electrode are shown in Fig. 2. The rise times measured between the 10 and 90% points are 600 msec (curve A) and 350 msec (curve B) when the chloride concentration is increased 10 and 2 times, respectively.

Because of mixing limitation, the effective electrode response time should be expected to be somewhat smaller. The noise inherent to these wide band measures is about 1 mV pp. The pass band of the measure system was limited numerically by the computer to 20 Hz.

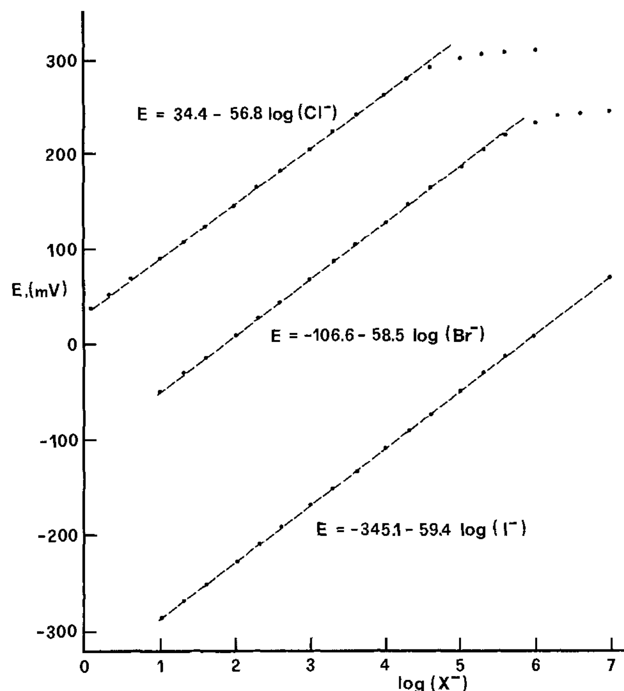

Fig. 1. Calibration curves for the halide solid-state electrode. Concentrations are molar concentrations of sodium halide. Potentials are measured *vs.* the B222 Schott half-cell at 25°C.

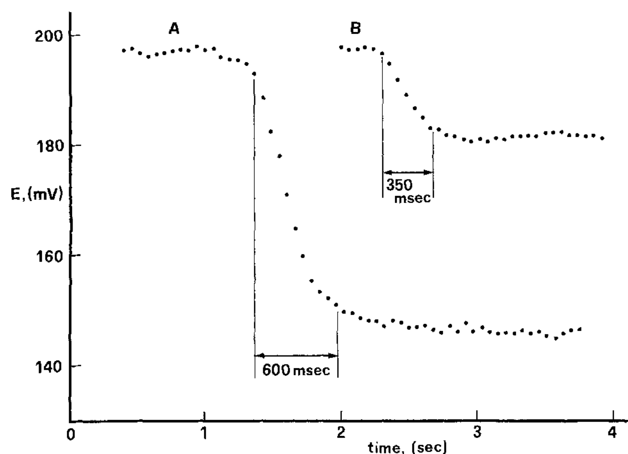

Fig. 2. Dynamic response of the Ag/AgCl electrode. Potentials (*vs.* B222 Schott half-cell at 25°C) sampled by a computer TI 960A interfaced with a 12 bit A/D converter: resolution 100 μV, band pass 20 Hz. A, Chloride concentration increase from 1.10^{-3} to 1.10^{-2}M; B, chloride concentration increase from 1.10^{-3} to 2.10^{-3}M.

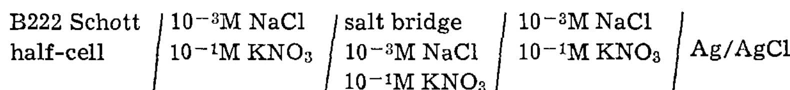
Effect of pH.—The influence of pH was investigated for the chloride electrode, recording the potential of the electrode in contact with a solution containing a fixed amount of chloride ions and nitric acid to be neutralized with sodium hydroxide (Fig. 3). The measurements were started in solution containing 10^{-3}M nitric acid, 0.1M potassium nitrate, and 10^{-4}M NaCl (curve a) or 10^{-3}M NaCl (curve b). The pH was varied by means of 10^{-2} sodium hydroxide and followed by a combined glass electrode.

Thermal temperature coefficient.—The thermal temperature coefficient was measured by varying the temperature of a silver/silver chloride electrode in the cell



while keeping the temperature of the reference half-cell constant (25°C).

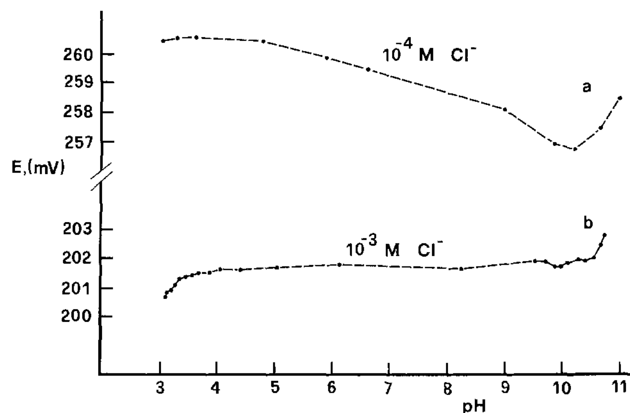


Fig. 3. Effect of pH on the potential of the silver/silver chloride electrode is NaCl solutions of various concentrations.

The electrode potential changes almost linearly with the temperature in the range 5° ÷ 40°C. Fitting experimental data with a second order polynomial yields the following equation

$$E = 184.38 + 0.876\,t - 0.00148\,t^2 \quad (E \text{ in mV}, \quad t \text{ in °C})$$

the standard deviation of experimental data around the fitted function being $\sigma = 37$V.

Conclusion

The electrodes described in this work have a number of interesting features over the conventional silver/silver halide membrane electrodes. They are rugged, yield highly reproducible results, and exhibit a very low electric resistance (0.01 Ω/cm). The ratio between the weight of silver metal and silver halide is not critical as tested when the percentage of Ag^+ in the pellet mixture ranges from 20 to 140%.

Variations of the pellet thickness (between 1 and 4 mm) do not affect the behavior of the electrode.

Moreover, this kind of electrodes has neither an inner reference aqueous solution nor a membrane. Finally, the most evident advantage is that its ion-sensitive surface, when necessary, can be easily renewed by removing the outer surface with fine emery paper.

On the Effect of Finite Rise Time of Pulse Generators on Some Relaxation Techniques for Electrode Kinetic Investigations

Z. Nagy*
Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

In previous error analyses of relaxation techniques for electrode kinetic measurements (1-5) it has always been assumed that the pulses are ideal, that is, the pulse generator has a negligibly short rise time. In practice, the rise time is often only about one order of magnitude less than the measuring time, and for short pulses the two times can even become comparable in magnitude. Equations have been derived for nonideal pulses and are presented here for the galvanostatic single- and double-pulse techniques and for the coulostatic pulse (current impulse relaxation) technique. The real pulses were approximated by pulses having a finite linear slew rate (Fig. 1) which is a good approximation for most modern pulse generators. The resulting equations are too complex to be used for simple graphical analysis of experimental data. However, they can be used for a numerical analysis of the errors resulting from the assumption of ideal pulses in the graphical data analysis. The results can be used to select the maximum rise time for an experiment or to calculate correction factors for data taken with slow pulse generators. The use of these equations is also recommended for the evaluation of kinetic parameters by computer curve fitting, which is more reliable than the graphical techniques (5, 6). In this case, the complexity of equations is not a problem and, as will be shown below, considerable errors can result if the idealized equations are used to evaluate experimental data with pulses having finite rise times.

The derivation follows the same general outline as those of Delahay *et al.* (7, 8), with two exceptions. The current pulse shapes of Fig. 1 are used, and the equations are made more general by removing a restriction of the original derivation (7), namely, that the number of electrons involved in the rate-determining step must be equal to the number of electrons transferred in the over-all reaction. The current-time relation of the pulse shown in Fig. 1b can be written as

$$i = \begin{cases} i_1 t/t_1 & ; \quad t < t_1 \\ i_1 & ; \quad t_1 < t < t_2 \\ i_1 - (i_1 - i_2)(t - t_2)/(t_3 - t_2); & \quad t_2 < t < t_3 \\ i_2 & ; \quad t_3 < t \end{cases} \quad [1]$$

and the Laplace transform of the current is [see, for example, Ref. (9)]

$$\tilde{i}(s) = \frac{i_1[1 - \exp(-st_1)]}{s^2 t_1} - \frac{(i_1 - i_2)[\exp(-st_2) - \exp(-st_3)]}{s^2(t_3 - t_2)} \quad [2]$$

The generalized overpotential-current relation can be obtained, for an over-all reaction of $O + ne = R$, by taking the diffusion overpotential from the Nernst equation

$$\eta_d = \frac{RT}{n\mathbf{F}} \ln \left[\frac{C^s_O}{C_O} \cdot \frac{C_R}{C^s_R} \right] \quad [3]$$

and the activation overpotential from the multistep version of the Butler-Volmer equation (see, for example, Ref. (10, 11)

$$i = i_o[\exp(\alpha_a \mathbf{F} \eta_a / RT) - \exp(-\alpha_c \mathbf{F} \eta_a / RT)] \quad [4]$$

with

$$\alpha_a + \alpha_c = n/\nu$$

At low overpotentials, when

$$\eta_a < \frac{RT}{\mathbf{F}} \text{ and } \frac{C^s_O}{C_O} \approx \frac{C_R}{C^s_R} \approx 1$$

these equations can be expanded to give the total

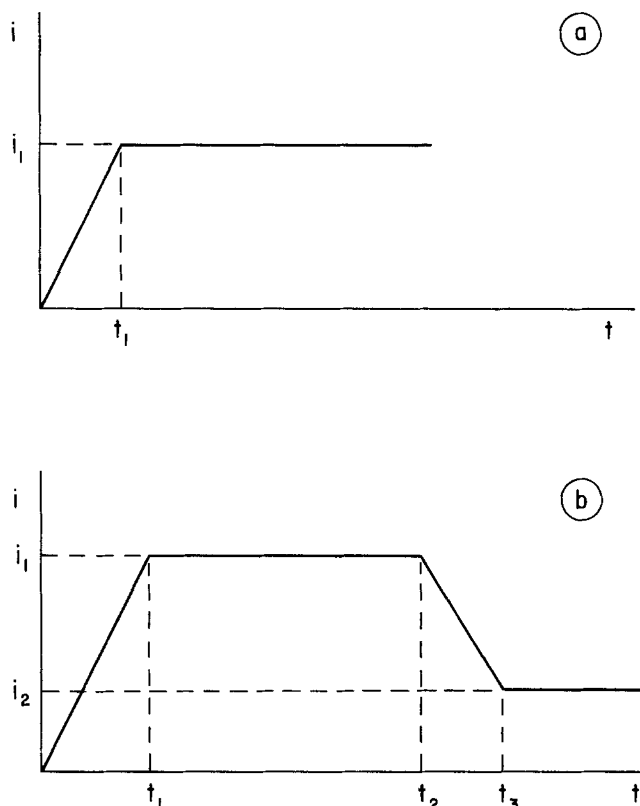

Fig. 1. Current pulse shapes: a, single pulse; b, double pulse (coulostatic with $i_2 = 0$).

* Electrochemical Society Active Member.
Key words: chronopotentiometry, kinetics, overvoltage, transients.

overpotential

$$\eta = \frac{\nu RTi}{nFi_o} + \frac{RT}{nF}\left[\frac{C^s_O}{C_O} - \frac{C^s_R}{C_R}\right] \quad [5]$$

The overpotential-time relation is then derived by solving Fick's equation for linear diffusion for the appropriate initial and boundary conditions (7, 8). Equation [6] is the final result. The same relation for idealized pulses is given in Eq. [7] for comparison

$$\eta = \frac{i_1}{ct_1}[G_2(t) - G_2(t-t_1)] - \frac{i_1 - i_2}{c(t_3 - t_2)}[G_2(t-t_2) - G_2(t-t_3)] \quad [6]$$

$$\eta = \frac{i_1}{c(b-a)}\left[\frac{b}{a^2}G_1(a,t) - \frac{a}{b^2}G_1(b,t)\right] - \frac{i_1 - i_2}{c(b-a)}\left[\frac{b}{a^2}G_1(a,t-t_3) - \frac{a}{b^2}G_1(b,t-t_3)\right] \quad [7]$$

where

$$G_2(y) = \frac{b}{a^4(b-a)}G_1(a,y) - \frac{a}{b^4(b-a)}G_1(b,y) + \frac{ab-(a+b)^2}{(ab)^2}y + \frac{4(a+b)}{3\sqrt{\pi}\,ab}y^{3/2}$$

$$G_1(x,y) = \exp(x^2y)\,\mathrm{erfc}(xy^{1/2}) + 2x(y/\pi)^{1/2} - 1$$

$$a = \frac{i_o}{2\nu nF}\left(\frac{1}{D^{1/2}_O C_O} + \frac{1}{D^{1/2}_R C_R}\right) + \left[\frac{i_o^2}{4\nu^2 n^2 F^2}\left(\frac{1}{D^{1/2}_O C_O} + \frac{1}{D^{1/2}_R C_R}\right)^2 - \frac{nFi_o}{\nu RTc}\right]^{1/2}$$

and "b" is the same as "a" except the expression in brackets is preceded by a minus sign.

Equation [7] differs from the original equation of Matsuda, Oka, and Delahay (8) by the sign convention of the current and by the appearance of the stoichiometric number (ν) in the expressions for "a" and "b." The equations are written for the galvanostatic double pulse technique; the relations for coulostatic pulse can be obtained by setting $i_2 = 0$ (in either case the equations are valid for times $t \geq t_3$). For galvanostatic single pulse measurements, the second term of the equations should be neglected and Eq. [6] is valid for times $t \geq t_1$.

The errors resulting from assuming ideal pulses in the graphical analyses of experimental data taken with real pulses were estimated as follows. Overpotential time data were generated with Eq. [6] and [7] for a series of typical values of the kinetic and double layer parameters and these "data" were then evaluated with the usual graphical techniques. It was found that the ratio of the overpotentials could be estimated by the ratio of the charge passed

$$\frac{\eta_{real}}{\eta_{ideal}} \approx \frac{Q_{real}}{Q_{ideal}} \quad [8]$$

when

$$i_c >> i_f \quad [9]$$

The approximation is good when the ratio of the sum of reaction and diffusion impedances to the double layer impedance is large, that is, at short times (usually a few microseconds). At longer times, the error is overestimated but Eq. [8] still can be used as an order-of-magnitude estimate. A brief analysis for the three relaxation techniques is given in the following.

Galvanostatic Single Pulse

The error in the overpotential will be negligible even for slow pulse generators since the graphical evaluation (7) uses data taken at long times ($\approx$50 μsec), and in this case the charge ratio of Eq. [8] is close to unity. The error in the exchange current density will then depend on the error in the double layer capacity measurement. A serious error can be made in the double layer capacity measurement and, consequently, in the calculation of the exchange current density, if it is determined from the slope of the overpotential-time curves at times $t < t_1$, using the steady current value of i_1. Rather, the capacity should be calculated using the current value at the time of the slope measurement, that is $c = i(t)/(d\eta/dt)_t$. It is assumed, of course, that condition [9] is fulfilled.

Galvanostatic Double Pulse

A heretofore unrecognized advantage of this method was found, namely, that the error in overpotential is nearly completely eliminated by the experimental adjustment of the prepulse to give $d\eta/dt = 0$ at the measuring time [independently of whether the measuring time was taken to be the end of the prepulse or at some later time, as has been recently proposed (12)]. The experimental fulfillment of the above condition assures the correct charging of the double layer capacitance independently of the shape of the prepulse, even at the extreme case when the rise and fall of the prepulse overlap. A correct exchange current density will therefore be obtained, even for real pulses, using the graphical data-evaluation technique of Matsuda, Oka, and Delahay (8). On the other hand, the double layer capacity calculated by the formula of Matsuda (13, 14) will be in error, but can be corrected using the following equation

$$\frac{c_{real}}{c_{ideal}} \approx \frac{Q_{ideal}}{Q_{real}} \quad [10]$$

Current Impulse Relaxation (Coulostatic Pulse)

A considerable error can be expected in the overpotential, since generally very short pulses are used in this method and the charge ratio of Eq. [8] will be far from unity. By application of the usual graphical data-evaluation technique (15), the double layer capacity and the exchange current density will also have the same relative error. For slow reactions (when condition [9] is strictly fulfilled) the results can be corrected by using Eq. [8]. This is, of course, equivalent to the original procedure suggested by Delahay (16). For faster reactions, especially when diffusional effects are not negligible, Eq. [6] should be used in the curvefitting programs (5, 6).

In summary, it has been shown that the neglect of the finite rise time of pulse generators can cause significant errors in the determination of the double layer capacity and the exchange current density of fast electrode systems. The only exception is the galvanostatic double pulse technique which will give the correct exchange current density even with slow pulse generators. Equations are given for computer evaluation of data taking into account the finite rise times of the measuring pulses.

LIST OF SYMBOLS

- c — capacity of the double layer (F cm^{-2})
- C_j — concentration of species j in the bulk solution (mole cm^{-3})
- $C^s{}_j$ — concentration of species j at the electrode surface (mole cm^{-3})
- D — diffusion coefficient (cm^2 sec^{-1})
- F — Faraday constant
- i — current density (A cm^{-2})
- i_o — exchange current density (A cm^{-2})
- i_c — current density used to charge the double layer (A cm^{-2})
- i_f — Faradaic current density (A cm^{-2})
- $\tilde{i}$ — Laplace transform of current density
- n — total number of electrons transferred in the over-all reaction
- Q — charge passed (C cm^{-2})
- R — universal gas constant
- s — Laplace variable
- t — time (sec)
- T — absolute temperature (°K)
- α_a — anodic transfer coefficient
- α_c — cathodic transfer coefficient
- η — overpotential (V)
- ν — stoichiometric number of the reaction

Tantalum Ion Transport Number during the Anodic Oxidation of Beta-Tantalum Films

N. Schwartz*[,1] and W. M. Augustyniak

Bell Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

In this study Rutherford backscattering has been used to determine the tantalum ion transport number during the anodic oxidation of beta-tantalum films. The required marker is the argon uniformly incorporated in tantalum during sputtering. The transport number for Ta^{+n} ions for beta-tantalum anodic oxidation is 0.25 ± 0.02 at 1 mA/cm² and 23.5°C, and there is a weak dependence on the electric field used during the oxide growth. These results are identical to that obtained for bulk alpha-(bcc)-tantalum, which may indicate that the transport number is not controlled by the crystal structure associated with the metal-oxide interface. For metal films which are anodized completely through to the substrate, there is an apparent 1% tantalum excess in the outer portion of the oxide. This effect may be associated with the argon incorporation in the oxide, or a nonequilibrium ratio of Ta/O, or a low atomic weight impurity.

Since the beginning of the utilization of anodic oxide films for electronic devices and decorative coatings (1), there has been a great interest in the unique mechanism which allows growth rates at room temperature in the range of 0.5 nm/sec up to several micrometers in thickness. The basic chemical process is the reaction of two chemical entities, the original metal and oxygen from the electrolyte, which are separated by an intervening solid film. In order for this to occur, species must be transported at very rapid rates (for a room temperature process) through the intervening film. The driving force for such rapid transport is the high electrical field utilized, which is in the range of 10^4 to 10^5 V/m. The transport is assumed to be due to charged ions through the oxide (1). In all studies of the mechanism of growth of anodic Ta_2O_5 before 1965, it was either implicitly assumed or partially demonstrated that the transported entity was the tantalum ion. This appeared theoretically satisfying because the ionic radius of the Ta^{+5} ion is considerably smaller than the O^{-2} ion, and its charge is considerably higher. Both of these properties should lead to faster transport of the metal cation. In 1965, Davies *et al.* (2) demonstrated that both ions generally participated in the transport, and the fraction of the transport attributable to the cation was generally much smaller than that associated with the anion.

Despite the expectation that the knowledge of the nature of the particular ion involved in the growth should have had a large impact on the understanding of the mechanism of growth, little further progress had been made on theoretical models for the process. Studies on tantalum, which has had a central role in the development of models because of the number of experiments associated with it, have shown it (3) to have a cation transport number of 0.243. This number is associated with growth of the oxide on bulk alpha-(bcc)-tantalum. Some studies have shown that the kinetics of oxide growth (4, 5) are slightly different for beta-tantalum (6) films compared to bulk alpha-tantalum; this has been ascribed to a variable amount of interstitial oxygen and nitrogen (5). What has not been considered is whether the transport number of the tantalum ion is different due to the change of crystal structure or the change from bulk to film material. In earlier studies on the composition of oxide films formed on Ta_xN_y (7), and either Ta_xSi_{1-x} (8) or Ta_xTi_{1-x} (9) alloy films, it was assumed that the transport number of oxide films grown on beta-tantalum was the same as alpha-tantalum. The latter two studies (8, 9) involved Rutherford backscattering (10, 11) which allows for a convenient method of determining this number without resorting to radioactive isotopes, chemical sectioning, or sputtering. This technique can easily detect the approximately 4 atom percent (a/o) argon (8, 12) incorporated uniformly in the beta-tantalum film during the sputtering process. The argon at the surface of the metal acts as the inert marker, and the position of this edge lies within the oxide film after growth. The relative position of this edge in the oxide allows the calculation of the cation transport number. The Rutherford backscattering method has been used for this purpose by MacIntosh (13) but utilizing implanted argon in bulk vanadium. This paper concerns the use of Rutherford backscattering technique to detect the position of the incorporated nonradioactive argon in anodized beta-tantalum films.

Experimental

The preparation of the beta-tantalum films, the Rutherford backscattering technique, and the general methods of analysis have been described in earlier papers (8-11). This study on beta-tantalum films differs from the earlier study (8) in that the conditions were optimized to yield a more accurate evalua-

tion of the argon and tantalum spectra. The thickness of the tantalum films on fused quartz was limited to about 75 nm, so that even when the film was completely anodized, the oxide spectrum did not overlap the background silicon and oxygen spectra from the fused quartz substrate. Secondly, the 1.9 MeV $^4He^+$ bombarding time was increased such that the height of the Ta spectrum ($\sim 4.5 \times 10^5$ counts) was about five times higher than previous, while the argon counts ($\sim$1500 counts) were increased from 1.3 to 3 times background.

Three different anodizing techniques were used because the films were relatively thin and slight differences in determining the energy of the leading or back edge of the argon spectrum causes relatively large errors. Due to the energy resolution of the backscattered ion solid-state detector ($\sim$15 keV), there is some ambiguity in determining these energies; these can be quite accurately determined, however, by using the half-height energy for each edge. Some samples were anodized about half-way through at constant current to about 60V; one sample was anodized at constant current to 60V, and when the power supply was switched to constant voltage of 60V, the current decayed to a low value. Most of the samples, however, were anodized completely through at constant current to about 120V, at which time the voltage rose abruptly to a preset maximum value in the range of 130-300V as all of the tantalum was consumed. This anodization method is preferred because the determination of the transition of argon in the oxide to argon in the remaining metal film in the backscattered spectrum did not cause any difficulty. The result of the complete anodization was a transparent Ta_2O_5 film, which only in a few cases had a faint haze of isolated Ta spots; these, however, could not be detected in the backscattered spectrum. For all of the anodizations, the counterelectrode for measuring the voltage was a Pt wire placed within 3 mm of the oxide surface. The electrolyte was 0.01% aqueous citric acid; during the constant current anodization, the voltage difference between the anode and platinum wire was continuously recorded.

Results

Transport numbers.—Figure 1 shows the overlapped Rutherford backscattering spectra of a typical tantalum metal film and the same film anodized completely through. The peaks on the right are for the tantalum atoms in the metal and oxide. Since tantalum atoms are present at the surface in both films, the channel equivalent to the half-heights are identical on the leading edge (higher channels), while the channel half-heights differ on the lower channel side because the thickness of the two films are different. The lower height of the Ta/Ta_2O_5 peak[2] is due to the decreased tantalum atom density compared to the metal film.

The much smaller peaks in the 260-320 channel region are due to the argon in both films; the edges shown below 265 channels are to Si/SiO_2, O/SiO_2, and O/Ta_2O_5. The 308 channel position of the half-height for the Ar/Ta peak is that calculated for Ar at the surface of any film. The half-height position of the Ar/Ta_2O_5 at channel 298.5 indicates that the Ar is below the surface of the oxide. The thickness of the oxide where the argon is absent can be calculated from the shift of the leading edges in both samples, while the thickness of the oxide where the Ar is present can be calculated from the width of the Ar/Ta_2O_5 peak. The sum of the two gives the thickness of the complete oxide. The thickness of the complete oxide can be calculated as well from the width of the Ta/Ta_2O_5 peak.

The exact thickness of any film can be determined from the width of the peak by Eq. [1]-[3]

$$\Delta d = d_s/\rho = \Delta E/S\rho = (\Delta C)(E_c)/S\rho \quad [1]$$

Where

$$S = K_m \left(\frac{dE}{dx}\right)^{in} + \left(\frac{1}{|\cos\theta|}\right)\left(\frac{dE}{dx}\right)^{out} \quad [2]$$

and

$$(dE/dx) = \Sigma w_i (dE/dx)_i \quad [3]$$

where Δd is the thickness; ρ is the known density of the film material; d_s is the surface density in mass/unit area; ΔC is the difference in channels for the half-heights of the leading and trailing edges; E_c is the energy/channel of the detection system ($\sim$4 keV per channel); S is the scattering function where K_m is the kinematic factor; $(dE/dX)^{in}$ is the stopping power at the energy of the entering ion; θ is the angle between the entering ion beam and the detected backscattered beam (*i.e.*, 175°); and $(dE/dx)^{out}$ is the stopping power at the energy of the exiting beam. For mixtures or compounds, dE/dX can be calculated by Bragg's rule (Eq. [3]) where w_i is the weight percent of the particular component and $(dE/dX)_i$ is the stopping power for that component at a given energy.

The transport number of the Ta^{+n} ion, t_m^+, can be calculated from

$$t_m^+ = \frac{d^{Ar}{}_{Ta_2O_5}}{d^{Ar}{}_{Ar/Ta_2O_5} + d^{Ar}{}_{Ta_2O_5}} \quad [4]$$

when d_y^x is the thickness of an oxide film, where x

[2] The terminology Ta/Ta_2O_5 means that the backscattering is from Ta in Ta_2O_5.

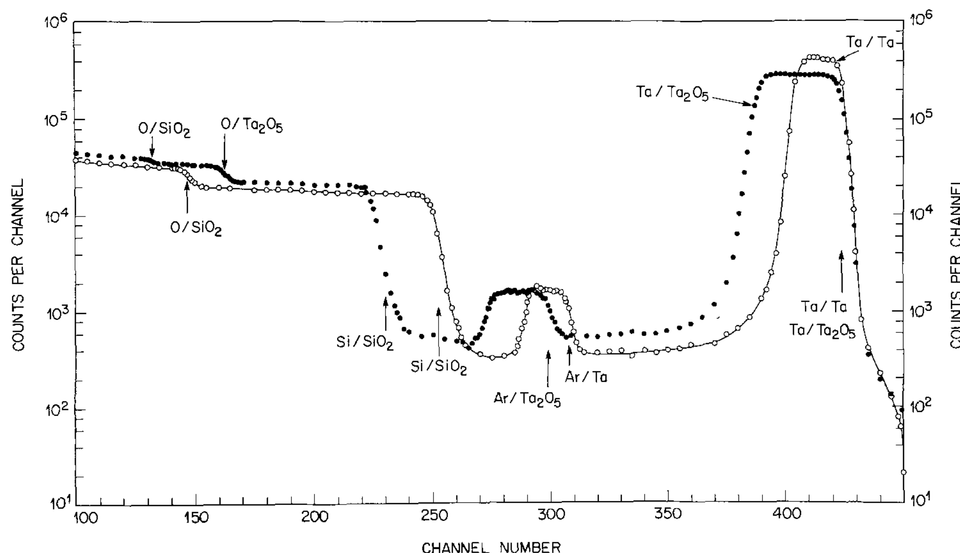

Fig. 1. Typical backscattering spectrum of sputtered beta-tantalum film (Ta) on a fused silica substrate, and an overlapped spectrum of the same film completely anodized to tantalum oxide (Ta_2O_5). The detector sensitivity is about 4×10^{-3} MeV/channel. The vertical arrows show the position of the leading half-heights for the various species (Ar or Ta) in either the Ta or Ta_2O_5 film.

means the thickness is determined from either an argon or tantalum backscattering peak, while y represents either the argon region (*i.e.*, Ar/Ta_2O_5) or argon-free region (*i.e.*, Ta_2O_5) of the oxide film.

This analysis implicitly assumes that the argon acts as a true atomic marker, which has been demonstrated by Pringle for implanted argon (3).

Equation [4] can be transformed by using Eq. [1]

$$t_m{}^+ = \frac{\Delta C^{Ar}{}_{Ta_2O_5} E_c{}^{Ar}}{S^{Ar}{}_{Ta_2O_5}\rho_{Ta_2O_5}} \Bigg/ \left[\frac{\Delta C^{Ar}{}_{Ar/Ta_2O_5} E_c{}^{Ar}}{S^{Ar}{}_{Ar/Ta_2O_5}\rho_{Ar/Ta_2O_5}} + \frac{\Delta C^{Ar}{}_{Ta_2O_5} E_c{}^{Ar}}{S^{Ar}{}_{Ta_2O_5}\rho_{Ta_2O_5}} \right] \quad [5a]$$

$$t_m{}^+ \cong \Delta C^{Ar}{}_{Ar/Ta_2O_5} / [\Delta C^{Ar}{}_{Ar/Ta_2O_5} + \Delta C^{Ar}{}_{Ta_2O_5}] \quad [5b]$$

where

$$\Delta C^{Ar}{}_{Ta_2O_5} = C_{Ta}{}^{Ar} - C^{Ar}{}_{Ta_2O_5} \quad [5c]$$

and

$$\Delta C^{Ar}{}_{Ar/Ta_2O_5} = C^{Ar}{}_{Ar/Ta_2O_5} - C^{Ar'}{}_{Ar/Ta_2O_5} \quad [5d]$$

and ($C_y{}^x$) is the half-height channel of the leading edge and $C_y{}^{x'}$ is the half-height channel of the rear edge of the appropriate peak.

In Eq. [5a], the $E_c{}^{Ar}$ cancel, and the differences in the scattering function $S_y{}^x$, and densities, ρ_y, are so slight that they cancel also. Calculations using both Eq. [5a] and [5b] give transport numbers which differ by 0.9%, while the experimental error, mainly due to the ±0.5 channel-width uncertainty in a 8.5 channel-width thickness of the argon-free Ta_2O_5 region, is ±8%. A schematic figure of the overlapped backscattered spectra from tantalum and completely anodized tantalum oxide is shown in Fig. 2. This figure shows three different possible results: anion transport only,

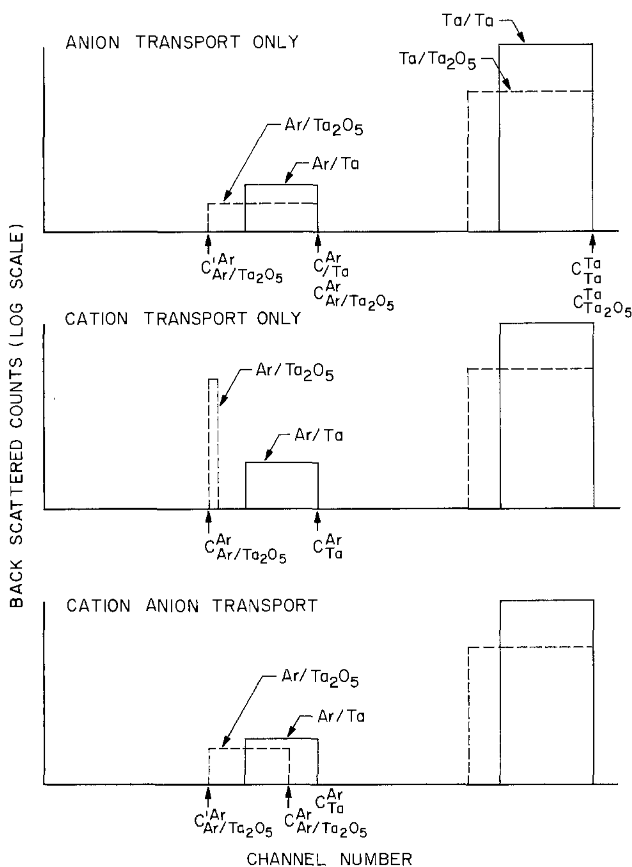

Fig. 2. Schematic backscattered spectra for the three different transport mechanisms. The solid and dashed line peaks on the right are for backscattering from tantalum atoms in the metal and oxide, respectively. The peaks in the left are for backscattering from argon atoms in Ta or Ta_2O_5.

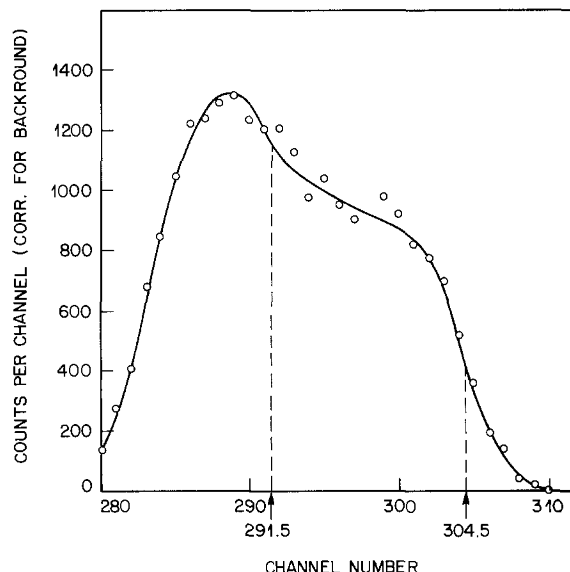

Fig. 3. Backscattered spectrum for argon in a sample which was anodized half-way through. The region from 280-292 channels is for the remaining tantalum film, while the region from 292-305 channels is for the formed oxide film. Counts corrected for background.

cation transport only, and simultaneous cation-anion transport. For the three cases, the width of the total oxide based on the argon spectrum only is: upper, the observed width of the Ar/Ta_2O_5 peak; middle, the difference, $C_{Ta}{}^{Ar} - C^{Ar}{}_{Ar/Ta_2O_5}$; and bottom, the difference, $C_{Ta}{}^{Ar} - C^{Ar'}{}_{Ar/Ta_2O_5}$. The widths of the argon-free region at the oxiae for the three cases in Fig. 2 are: top, nonexistent; middle, the difference, $C_{Ta}{}^{Ar} - C^{Ar}{}_{Ar/Ta_2O_5}$; and bottom, the difference, $C_{Ta}{}^{Ar} - C^{Ar}{}_{Ar/Ta_2O_5}$.

The basic experimental data for the calculation of transport numbers for samples anodized half-way through to only 60V is shown in Fig. 3. The open dots are the argon counts corrected for background. The high peak at channel 289 is due to the argon in the remaining tantalum film, while the lower counts above channel 290 are for argon in the oxide. The half-height channel of 304.5 at the leading edge is shifted down from the original metal film value of 308.5. The half-height channel number of the oxide at the trailing edge can be determined as was done previously (9) as equal to the point at half the value of the maximum at the tantalum metal minus the value of that of the oxide. This leads to a value of 291.5 as indicated by the left-hand dashed vertical line in Fig. 2. The decision about the value at channel 291.5 is slightly uncertain, so as indicated earlier most of the results are based primarily on samples anodized all the way through.

Table I gives the characteristics of the anodized samples, and the transport numbers obtained. Sample number 1 was analyzed in both backscattering runs

Table I. Cation transport number as a function or the type of anodization

4	3		√		√	0.24 ± 0.04

* All anodizations performed at 1 mA/cm² and 23.5°C.

1 and 3, and the calculated transport numbers are identical. Sample 2 is an anodized replicate of sample 3, and the results of the first three samples give a transport number of 0.25 ± 0.02. Sample 4 gives results of lower accuracy because the oxide film was much thinner. The results for samples 3 and 4 agree with the more accurate values obtained for samples 1 and 2. All of the transport numbers are in the range of 0.25 ± 0.02. This agreement indicates that during the constant voltage-soak during anodization, when approximately 25% of the oxide is grown, the transport number is the same as that obtained at constant current. During the constant voltage phase, the current density and field are dropping rapidly, which indicates that the transport of Ta^{+n} is not a strong function of current density or field.

In order to verify this last conclusion, samples were anodized all the way through for current densities which range from 10 to 0.01 mA/cm², where the exposed film area was of the order of 1 cm². Samples anodized at the low current densities had total currents of only about 50 μA; an appreciable electronic leakage current existed, however, which moreover increased as the anodization voltage increased. For these latter samples (*i.e.*, for all current densities below 0.1 mA/cm²), the current density was manually increased to maintain a relatively constant dV/dt on the recorder chart. The actual ionic current density was then calculated from the dV/dt for the given anodization compared to dV/dt for the 0.1, 1, and 5 mA/cm² anodizations, which did not have an appreciable electronic leakage. Films were also anodized at 10 mA/cm², but these resulted in a nonuniform anodic oxide color, presumably due to a nonuniform temperature rise associated with the relatively massive insulating fused-silica substrate.

The transport number as a function of current density is given in Table II. The field associated with the higher current densities was obtained from the observed voltage at the end of the anodizations divided by the oxide thickness obtained from the Rutherford backscattering data. The fields at the low current densities were estimated by an extrapolation of the above data, using Mills, Zobel, and Young's data (3) on films as an extrapolation guide.

The results in Table II indicate that there is a real but weak dependence on current density or field for the cation transport number. The significance of this important result and a comparison to other results in the literature will be discussed in the following paper (14).

Uniformity of the oxide films.—A close inspection of the spectrum for the top of the Ta/Ta_2O_5 peak shown in Fig. 1 indicates a slight concave nature, rather than an expected slight linear increase due to the increased backscattering due to the E^{-2} term (10, 11). This concavity is not observed for partially anodized films or for tantalum metal films.

The raw backscattered spectrum for tantalum in tantalum oxide from Fig. 1 was converted to a distribution of Ta atoms/cm² as a function of depth thickness by making a $(1/E)^2$ correction, as well as corrections in S for the presence or absence of Ar in different portions of the film. The distributions for Ta and Ar are shown in Fig. 4, where the normal-

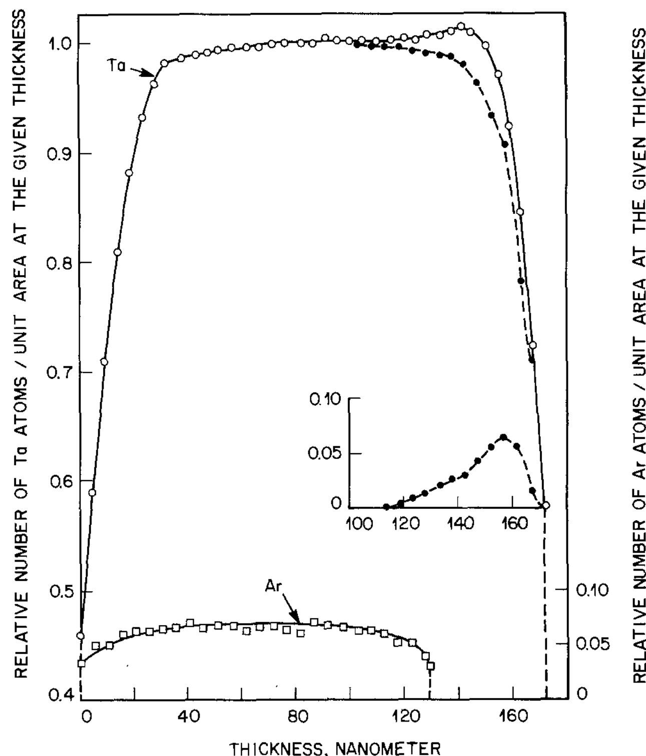

Fig. 4. Corrected tantalum (open circles) and argon (open squares) atoms/unit area as a function of oxide thickness (zero thickness is the substrate/oxide interface). These are corrected from the spectrum in Fig. 1. The upper closed circles are assumed idealized shape of the leading edge based on the corrected shaped of trailing edge. The insert is the difference, and the total "excess tantalum" is calculated from the ratio of the area under the curve in the insert to the area under the curve for the tantalum.

ization factor is the mean of the corrected counts in the region between 62 and 100 nm. The atom ratio of Ta:O:Ar for the entire film is 1/2.65/0.46, but has values of 1/2.65/0.59 for the portion of the film containing Ar, and 1/2.64/0.0 for the portion of the film containing no Ar. The Ta:O ratio is uniform to within the experimental uncertainty of ±5% in the argon-containing and argon-free portions of the film. As Fig. 4 indicates, however, the Ta atom/cm² is greater at the front[3] than at the rear portion by about 1%. The region of higher atom density is almost, but not quite, correlated with the region of the film which is argon free. This sort of deviation does not exist for the original Ta metal film as illustrated in Fig. 5, where the Ta atom density distribution is symmetrical about the middle of the film. The Ta:Ar ratio for this film is 1/0.47, identical to the ratio for the entire anodized film. The deviation for the completely anodized film is typical only for such films, since it does not exist for the partially anodized films. This is illustrated in Fig. 6, where the Ta atom distribution for sample 4 is uniform at the outer edge.

In order to obtain a semiquantitive estimate of the degree of deviation, the front part of the oxide film shown in Fig. 4 was fitted with an expected normal curve based on the shape of the curve at the rear portion of the film. This fitted curve is shown as the dashed curve, and the difference between the real and fitted curves is shown as the insert in the middle of the figure. These extra atoms, if calculated as Ta atoms, are equivalent to a 0.96% total deviation.

This "excess tantalum"[4] feature is not time dependent, since repeat backscattering analyses over a pe-

[3] The "front" edge is the oxide-electrolyte interface, while the "back" edge is the substrate-oxide interface; the "back" edge starts at zero thickness.

[4] The term "excess tantalum" is used for convenience. It could also be a "deficient tantalum" at the rear portion of the film.

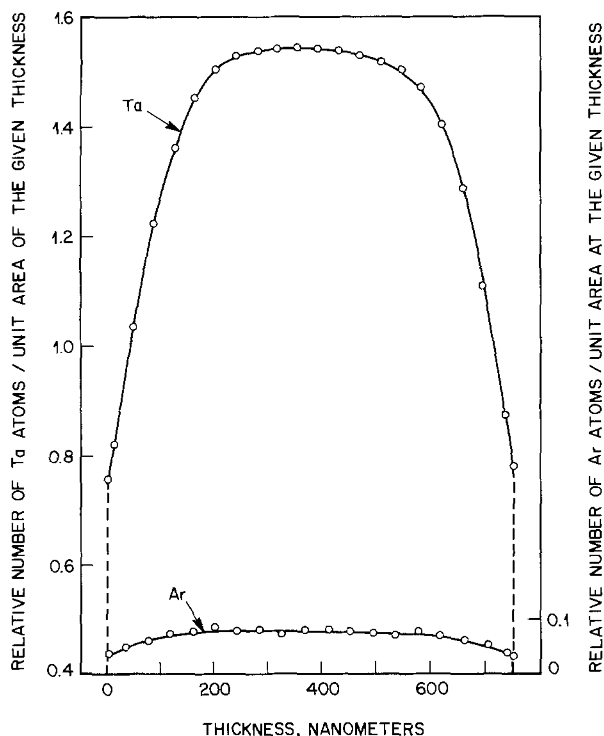

Fig. 5. Corrected tantalum and argon atoms/unit area as a function of metal thickness taken from the raw spectra of Fig. 1. The normalization is with respect to the same normalization of tantalum in tantalum oxide in Fig. 3.

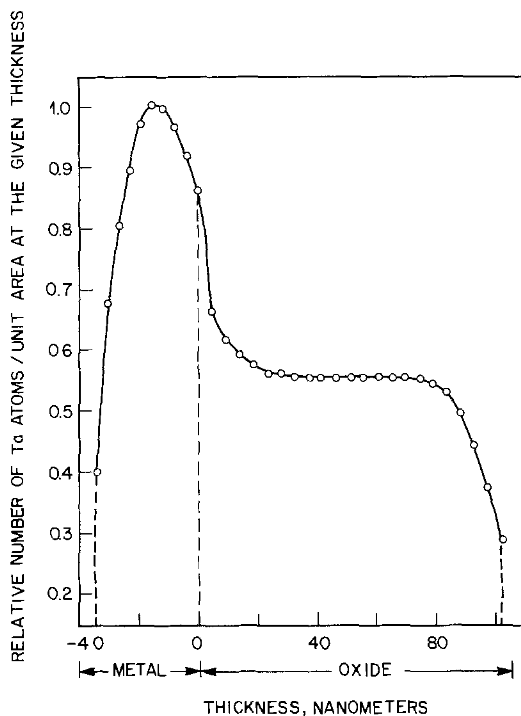

Fig. 6. Corrected tantalum atom/unit area as a function of thickness for a sample anodized partially through. The zero thickness point is taken as the metal-oxide interface, and the normalization was taken as the maximum tantalum atom density in the metal film.

riod of months showed no significant change in the spectrum. Auger analysis, with and without sputtering, showed no presence of tungsten or rhenium at the outer surface of the oxide.

To determine some parameters associated with the appearance of this "excess Ta," the samples prepared at different current densities, and samples prepared at the same current density but with different final voltage overshoots were analyzed, and the results expressed as "excess Ta," determined similar to the insert of Fig. 4. These results are summarized in Table III. No large dependence appears, but the effect appears to diminish to some extent at the higher current densities.

Table III. Dependence of "excess Ta" on current density and overvoltage, 23.5°C

Discussion

The transport number for Ta^{+n} obtained for the completely anodized samples of 0.25 ± 0.02 at 1 mA/cm^2 and 23.3°C is in agreement with the results of Pringle (3) who obtained a value of 0.243 for the anodization of bulk alpha-(bcc)-tantalum. In this study, however, the original metal source is beta-tantalum which has a completely different crystal structure (6) from the bulk material. Proposals for the oxide growth mechanism are characterized as to whether they are kinetically controlled by: (*i*) metal-oxide interface; or (*ii*) oxide; or (*iii*) oxide-electrolyte interface. It has been established by Vermilyea (15) that the kinetics of oxide growth were independent of the orientation of large grain structure of bulk alpha-tantalum, and on this basis concluded that the mechanism was not oxide-metal interface controlled. Young (16) has suggested that this may not be a strong criterion because the generation of cation vacancies may cause an amorphous metal interface. Westwood (5) indicates that the growth kinetics are essentially independent of having alpha- or beta-tantalum structure. The present experiments, where a large change in crystal structure is involved, demonstrate that the cation and anion transport numbers are not controlled by the metal crystal structure.

The present results show, however, that the cation transport number has a weak positive dependency on current density or field. This is an important result which warrants detailed discussion in the subsequent paper (14).

One puzzling feature of the results is the deviation in the tantalum atom distribution in the argon-free region for the completely anodized samples. If it were due only to the difference associated with the absence or presence of argon, this feature should also be apparent in the partially anodized samples, since they have essentially the same transport number.

The effect appears to be specific to the sample preparation of converting the metal completely to oxide film. It is possible that an impurity of the order of 1% of the tantalum existed near at the substrate-metal interface or was distributed uniformly throughout the metal film. Under these circumstances, the massive spectrum of the tantalum would prevent its detection in the original metal film. If it is assumed during the anodization that the impurity has an ionic charge higher than that of Ta^{+n}, then the charge difference would provide a faster transport which would tend to concentrate the impurity at the oxide-electrolyte interface (9). The only likely components which would give such a composite spectrum are tungsten or rhenium which have melting points above tantalum and which can exist in the +6 valence state. If there is a tungsten- or rhenium-enriched oxide surface, it should have been possible to detect it with Auger spectroscopy; this experiment was per-

formed on these samples with negative results, indicating that this explanation is unlikely. Alternatively, the impurity could have a charge less than tantalum and also have an atomic mass less than tantalum. Such a small light mass impurity would have a backscattered spectrum hidden in the background and argon spectra and would be undetectable.

Another possibility is that the Ta/O ratio varies in the film, but the accuracy of the counts associated with the O/Ta_2O_5 peak is not high enough to show such small variations as a function of depth. The improved statistical accuracy associated with counting over a long period of time with respect to the tantalum peak appears to be capable of detecting such small variations. However, a Ta/O deviation would yield such nonstoichiometric films that they would be highly semiconducting and that appears not to be the case for these films.

At present, no clear explanation exists for the origin of this small nonuniformity in the tantalum atom distribution.

Summary and Conclusion

1. The transport number of Ta^{+n} ions in the growth of the anodic oxide on beta-tantalum films is 0.25 $\pm$ 0.02 at 1 mA/cm^2 and 23.2°C. This number is essentially the same as that obtained in bulk alpha-(bcc)-tantalum, which indicates that the transport number is not controlled by the crystallographic nature of the metal-oxide interface.

2. There is a weak dependence of the value of the transport number on current density or field which will be compared to other literature results and analyzed in another paper (14).

3. In metal films which are anodized completely through, there is an apparent higher tantalum atom/cm^2 at the outer portion of the oxide compared to the inner. The origin of this nonuniformity is unknown. Further experiments are required to determine the cause of this feature. However, it is important to realize that the Rutherford backscattering technique has the capability of detecting $\pm$0.5% a/o variations in some cases.

ABSTRACT

A liquid-phase epitaxial technique has been used for growing layers of gallium-doped silicon on silicon. Best results were obtained from the (111) orientation and supercooling gallium melts from 600°C. The solubility of silicon in liquid gallium was determined in the growth system and showed good agreement with published data. The various growth parameters used and their effect on layer thickness, morphology, doping level, and low temperature infrared absorption are discussed. The dopant concentration in these layers was found greater than expected from the published solid solubility curves.

It is well accepted that vapor-phase epitaxy (VPE) has had a revolutionary impact on silicon device technology. It is less well known, however, that, for some applications, epitaxial growth from the liquid phase can also give excellent results. Investigations carried out in many laboratories have shown, for instance, that liquid-phase epitaxy (LPE) possesses advantages over VPE in applications demanding highly doped epitaxial films and high quality p-n junctions at the substrate-layer interface. Thus, LPE has found important applications in the growth of various III-V compound-semiconductors (1-4). Also, this technique has been used to grow low defect-density silicon layers on (111) and (100) substrates (5) as well as for growing thin silicon contact pedestals for use as ohmic contacts on planar-diffused diodes (6).

Key words: silicon, liquid-phase epitaxy, growth studies, epitaxial growth, doped silicon.

With the development of charge-coupled devices in silicon, the use of doped silicon material offers an opportunity for low cost device production of monolithic infrared detector structures. Growth of doped silicon layers by LPE *vs.* VPE is quite advantageous since growth can occur at a much lower temperature making it possible to have a lower concentration of most unwanted metallic impurities.

Layers of heavily doped gallium in silicon (Si:Ga) have been needed for the fabrication of infrared detectors in the 8-14 μm spectral range. In this study, Si:Ga layers were grown on silicon by the LPE method, and their growth properties were examined. Factors which affect dopant distribution, uniformity, and growth layer morphology were investigated using secondary ion mass spectrometry (SIMS), optical microscopy, scanning electron microscopy (SEM), Auger electron spectroscopy (AES), x-ray diffraction, and infrared spectroscopy. The growth conditions found most suitable for the formation of highly doped, smooth layers were sought.

Experimental Procedure

The LPE apparatus adopted for this work was a horizontal solution-growth system similar to systems used for growth of multilayer GaAs (7). The experimental setup is shown in schematic form in Fig. 1. The graphite boat for the growth solution and the silicon substrates were mounted inside the quartz tube which was supported by stainless steel flanges. A palladium-purified hydrogen atmosphere was used for melt back-out and growth. The growth cycle involved the dissolution of silicon from the substrate by the gallium melt to solution saturation, cooling at a controlled rate for growth, and finally separation of the grown layer from the melt. The substrates were phosphorous-doped silicon (11 $\times$ 17 mm), with $n \simeq 8 \times 10^{14}$ cm^{-3} oriented to (110), (110), and (111) within 3°. Prior to growth, the substrates were chemically cleaned using a standard hydrogen peroxide method followed by a 49% hydrofluoric (HF) acid rinse to rid the surface of unwanted SiO_2. The amount of gallium used was determined from consideration of silicon-gallium solubility data, coverage area, substrate thickness, and expected dopant concentrations. In most of the growths reported in this work, 5g melts were used.

Growth Studies

A known weight of gallium was heated with a predetermined weight of silicon to various temperatures (400°-1000°C). The substrate and melt were allowed to equilibrate for several hours. The partially dissolved (etched) substrate was then pushed from the melt and the growth tube was rapidly cooled to room temperature. The silicon solubility in liquid-gallium was obtained from the difference in weight. The data obtained on the different orientations investigated [(111), (110), and (100)] were plotted and compared with the work of Keck and Broder (8). This comparison is shown in Fig. 2 and is in good agreement. The different orientations were exposed to the same growth conditions using a maximum saturation temperature of 600°C. X-ray goniometric and Laue back-reflection studies of substrates before and after layer growth report layers which were truly epitaxial with respect to the substrates. Laue back-reflection x-ray photographs of the epitaxial layers are shown in Fig. 3. The position of spots in these diagrams are indicative of orientation. Here, 3-fold, 2-fold, and 4-fold symmetry corresponded to (111), (110), and (100) orientations, respectively.

X-ray topographs of silicon surfaces of different orientations before and after growth are shown in Fig. 4. All substrate surfaces before growth were essentially featureless, whereas after growth only the (111) orientation appeared smooth and of a similar texture as the original substrate. The shadowing or line patterns in the topographs displayed here were due to improper alignment of the x-ray beam with the layer surface. Similarly, scanning electron micrographs of the same surfaces revealed different layer morphologies, as shown in Fig. 5. Oriented patterns were observed from the (100) and (110) layers while the (111) appeared essentially featureless.

The SIMS profiles of gallium in layers of different orientation are shown in Fig. 6. The (111) orientation has the highest ion count of all the layers. The (111) profile shows a high and decreasing initial gallium count near the surface, a steady increase in counts, and then a reasonable stabilization. The (110) and (100) layers show a deeper region of high initial gallium counts, a continuing decrease in counts, and then stabilization with somewhat comparable trends. The gallium profiles of the layers are strongly orientation dependent. The layers are of comparable thickness and

have a dependent trend in dopant concentrations toward lower values in the order (111) >> (110) > (100) after a depth of 2500Å. It has been suggested that anisotropic impurity segregation might occur in this growth process similar to that reported for germanium by Hall (9) and Dikhoff (10). The remaining studies reported in this paper were performed on (111) orientations.

The saturation temperature is defined as the temperature at which the liquid gallium is in equilibrium with solid silicon (the substrate). Layers were grown from different saturation temperatures (600°-1000°C) at a cooling rate of 15°C/min. The thickness of the layers was determined by an angle-lap and stain technique. The relationship between an average growth rate dependence of the layers with respect to the saturation temperature is shown in Fig. 7. The average growth rates were found, as expected, to increase with increasing saturation temperatures because the silicon concentration in the melt increases. Also, optical microscopic examination of the surfaces, as displayed in Fig. 8, shows increasing surface waviness and undulations with increasing saturation temperatures. It was further observed that layers grown from saturation temperatures greater than 750°C had very irregular interfaces with the substrate and poor thickness reproducibilities from run to run. Thus, the remaining studies reported here were performed at a saturation temperature of 600°C.

Layers were also grown from 600°C with varying rates of heating to the saturation temperature. A cool-

ing rate of 26°C/min was chosen because no temperature programming was necessary. It was obtained by simply rolling the furnace from the growth tube for the duration of the growth. The optical micrographs of the surfaces are shown in Fig. 9. The surfaces of the slowest heating rate (0.5°C/min) show small precipitates or crystallites but no lamellar structure. The 2°C/min surface shows layer crystallites and wide lamellar structures, while the 12°C/min structure shows only the appearance of a lamellar structure.

The scanning electron micrographs, Fig. 10, of the same samples, show the characteristic features found on the various surfaces. The most significant finding is the pyramidal shapes on the surfaces which appear to vary in size and abundance with the various heating rates. However, further studies are necessary to es-

tablish if a systematic variation exists. This type of structure also has been observed for heavily doped arsenic-silicon layers (11), where at maximum doping the epitaxial layers were completely covered with pyramids and cones.

Dopant profiles provided by SIMS are shown in Fig. 11. The layers grown using the faster rates of heating to saturation (2° and 12°C/min) exhibited a more uniform gallium distribution to the substrate. However, the 12°C/min layers repeatedly showed the highest gallium counts which implies the greater gallium concentration.

Layers were also grown from 600°C gallium melts which were not exposed to a prebake treatment and compared with layers from which the melt was baked. Auger electron spectroscopy was used to investigate the relative amounts of silicon, carbon, oxygen, and, if possible, gallium in the samples. The typical Auger sensitivity to most elements is approximately 10^{19} atoms/cm^3. The comparison is shown in Fig. 12 and indicates little if any significant difference in intensities for the various elements. The curves are slightly shifted for display purposes only. Although not shown here, the SIMS analyses showed little difference in the profiles of gallium from the surface into the layer. Thus, it was felt that the baking in H_2 before growth was not a necessary melt pretreatment.

The microscopic topography of a grown layer may reflect the stability (*i.e.*, shape) of the liquid-solid interface as well as crystallographic factors which influence attachment to the solid (12). In examining the surface morphology of decanted metallic solutions, several workers observed corrugated and cellular surface morphologies which were linked to constitutional supercooling (13-17). Andre and LeDuc (18) reported that surface irregularities in LPE-grown GaAs could be eliminated by imposing thermal gradients to eliminate constitutional supercooling conditions. Solomon and DeFevere (19) had observed ripple-like surface morphologies in LPE-grown GaP which they identified as gallium occlusions resulting from constitutional

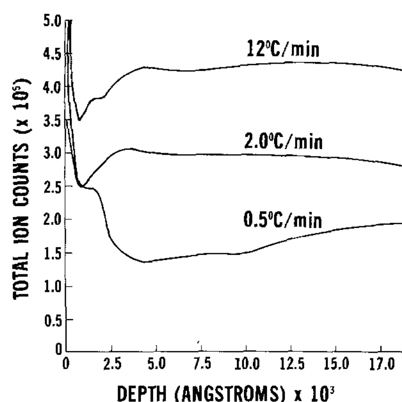

Fig. 11. SIMS profile of gallium distribution of layers heated at different rates to saturation.

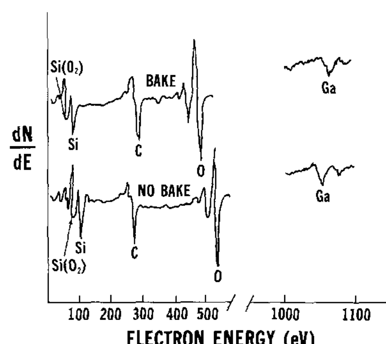

Fig. 12. Auger analysis of layers grown from baked and unbaked gallium melts.

supercooling. On the other hand, Donohue and Minden (20) interpreted this morphology in GaAs layers to result from cellular convection in the growth solution, while Peters (21) suggested surface roughness with substrate orientation.

Practically all of the layers grown in this study have shown lamellar or corrugated structure which may be tied to constitutional supercooling. A series of growth experiments were performed with hopes of shedding light on the origin of the lamellar surface morphology.

As shown by Minden (22), the liquidus temperature approaches a constant value (the interface temperature) as slower cooling rates and thinner melts are employed. Layers were grown from different weights (or volumes) of liquid gallium. The weights used were 5, 2.5, and 1g, respectively. A display of the surface structures of the layers is shown in Fig. 13 along with a surface which was only gallium etched (*i.e.*, no layer growth). Very little difference was found between the 2.5 and 1g melt but a significant difference was shown using a 5g melt. The largest weight melt showed small protrusions indicative of interface breakdown in addition to the lamellar structure. Thus, the principal lamellar structure of layers grown from 5g melts appeared to be connected with constitutional supercooling. This view was corroborated by experiments in which the substrate was melted back and no observable lamellar texture was found.

The trade-off in using a shallow melt is that of layer coverage. It was desirable for most applications and analyses to have large surface coverage. Thus, the 5g melt was used to examine the effects of cooling rates on surface morphology. The cooling rates explored were 0.8°, 2°, and 23°C/min, respectively. Scanning electron micrographs clearly displayed (Fig. 14) the surface texture with its corrugations. The smoothest surface was obtained by using the slower rate of cooling.

Burstein and co-workers examined the low temperature (4°-77°K) absorption spectra of the Group III and Group V elements, acting as acceptor or donor impurities, in silicon (23). These spectra were characterized by absorption continua which terminated at low energies with absorption edges. Below these edges in energy were found series of relatively sharp absorption lines. These spectra have been interpreted as follows: At low temperatures the hole or electrons are "frozen out" at acceptor or donor sites, respectively. A sharp absorption line indicates an optical transition from the ground state of the impurity to one of its discrete excited states. The absorption continuum indicates transitions from the ground state to an ionized state lying in either the valence or conduction band. The infrared transmission spectra obtained by Burstein are shown in Fig. 15. The concentration of carriers in the material was 1×10^{16}/cm^3. Gallium-doped silicon exhibits three prominent absorption bands at wavelengths near 18, 20, and 21 μm. These bands correspond closely to 1s-2p, 1s-3p, and 1s-4p transitions of a hydrogen-like center. The bands below 18 μm are lattice vibration bands of silicon.

The infrared spectra of LPE gallium-doped silicon on 1.35 mm thickness substrate are shown in Fig. 16. Here, the sharp lattice vibration band near 9 μm which is thought due mostly to SiO_2 absorption (24) as well as the bands near 18, 20, and 21 μm which are due to un-ionized gallium centers are absent.

The absence of structure due to Group III impurity centers in silicon was investigated by Newman (25). Newman described some studies of the discrete absorption lines of Ga as a function of the density of the impurity. He found that the spectrum was independent of concentration below 10^{16}/cm^3. However, concentrations above 10^{16}/cm^3 showed broadening of bands and by concentrations above 10^{18}/cm^3, the line structure is almost completely destroyed. He ascribes the concentration broadening of the excited levels by the overlapping of neighboring impurity centers. Thus,

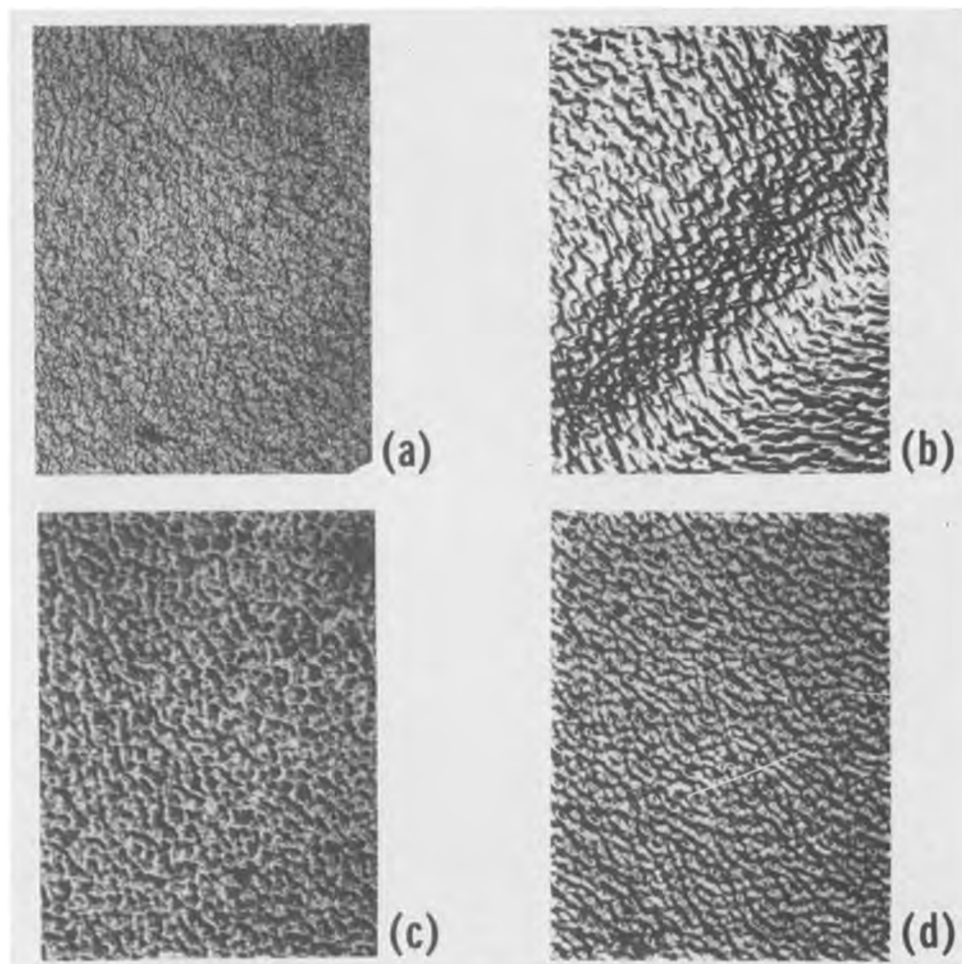

Fig. 13. Surface morphologies of (111) silicon after: (a) gallium etch (5g), (b) layer growth from 5g melt, (c) layer growth from 2.5g melt, (d) layer growth from 1g melt.

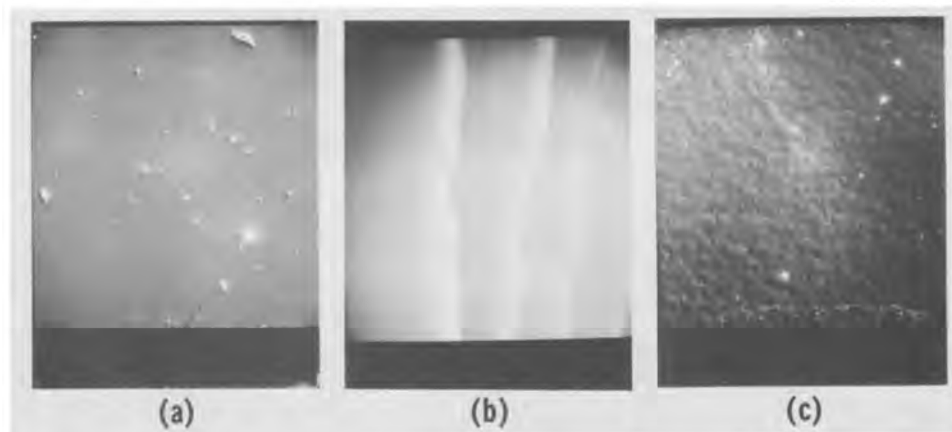

Fig. 14. Scanning electron micrographs of surfaces grown with different cooling rates: (a) 0.8°C/min, (b) 2°C/min, (c) 23°C/min. Magnification 100×.

the absence of the excitation bands in Fig. 16 between 18 and 21 μm is thought due to Ga concentrations $10^{18}/cm^3$ or greater.

Discussion

The criteria used in this investigation to judge the quality of gallium-doped silicon layers were uniformity of: (*i*) surface morphology (a smooth surface), (*ii*) substrate-layer interface, and (*iii*) dopant distribution. The best results, for large area coverage, were obtained when the growth was initiated on (111) orientations, from a saturation temperature of 600°C, and at a cooling rate of 0.8°C/min. Faster cooling rates were found to enhance irregular surface morphologies which suggested constitutional supercooling conditions. Thus, the optimum cooling rate for the growth was dictated by the speed with which silicon atoms diffuse to the growth interface since the total amount of silicon dissolved in the gallium melt is small (0.35 weight percent at 600°C).

When one calculates the distribution coefficient of gallium in silicon at 600°C and determines its concentration in the liquid phase at equilibrium, the concentration of the dopant in the solid phase can be approximated (26). Growth from saturated solutions of 600°C was expected to yield concentrations of gallium in the 10^{17} cm^{-3} range. However, higher values were suggested by SIMS profiling (using an ion-implanted standard), low temperature infrared spectroscopy, and Auger sensitivity.

The theoretical prediction of dopant concentration can be made by the following relationship (27, 28)

$$C_S = k_e C_o (1 - g)^{k_o - 1} \qquad [1]$$

and

$$k_e = \frac{k_o}{k_o + (1 - k_o) \exp\left(\frac{-fd}{D}\right)} \qquad [2]$$

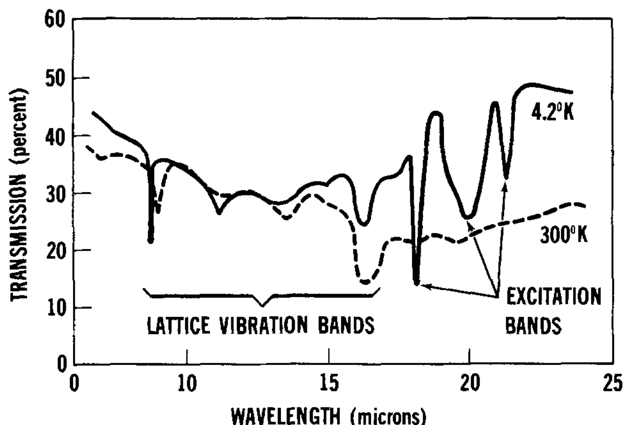

Fig. 15. Infrared transmission spectra of gallium-doped silicon (Burnstein *et al.*) at room temperature and liquid helium temperature. $n_p = 1 \times 10^{16}/cm^3$ and $t = 0.89$ mm (21).

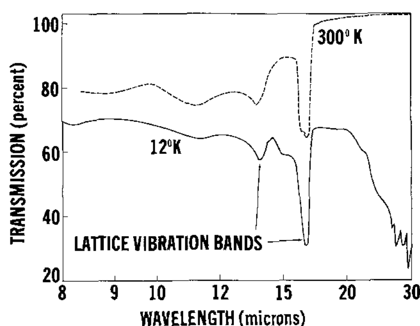

Fig. 16. Infrared transmission spectra of gallium-doped silicon grown by LPE.

where C_S is the concentration of dopant in the epitaxial layer, C_o the average concentration of dopant in the liquid, k_o the ratio of concentrations of the dopant in the solid and liquid in equilibrium with it, g the fraction of liquid that has solidified in the system, d the thickness of the boundary layer through which the solute must diffuse (1-10 mm), and D the diffusion coefficient of the dopant. The effective distribution coefficient k_e, which is defined as the ratio of the concentrations of solute in the solid that is formed to the average value for the liquid, approaches the maximum value of unity as the growth rate (f) increases and $k_e = k_o < 1$ at the very low growth rates.

It was suggested from studies of supercooling while growing that the growth kinetics could closely approximate the one in which nuclei grow rapidly laterally (29). Thus, assuming that the growth rate is infinite, the time for rearrangement of atoms will be so short that the concentration of dopant in the solid (C_s) will equal that in the liquid (C_l). Also in view of the above equations, no stirring or agitation was employed in the present growth system. This permits the incorporation of as much dopant as possible, since the mixing of liquid decreases d and effectively increases the diffusion coefficient D of the dopant (6, 27).

In addition to the effect of dopant concentration and cooling rate on nucleation of layers, impurity atoms and solvent atoms are known to greatly influence the growth morphology. In growing pure Si from a Si melt, (111) planes are the slowest growing and the most stable faces. The epitaxial growth of Si on a (111) substrate can be treated as the growth of a twin having the substrate as a twin plane. According to Wagner (30), in the twin plane having a hexagonal morphology bounded by (111) planes, the reentrant twin edge is a nucleation site for new layers on the edge of the plane, and growth occurs in a (111) direction. However, impurity or dopant atoms and solvent atoms can alter the surface energy of the substrate, thus stabilizing other crystallographic planes. This change affects the morphologies of growth from other orientations. The dopant atoms or solvent atoms act as a preferential etchant which produces a surface with well-defined pits whose facets are definite crystallographic planes. Buckley (31) gives a large number of examples of changes in crystal habit brought about by impurities of solvent atoms due to their effect on the relative growth rate of various faces. These effects have also been considered in detail by Sears (32) who proposed modification of the growth process because of impurities. Thus, it is not surprising that the orientation study in this investigation has shown preferential etching characteristics of silicon in liquid gallium.

Conclusion

The growth of heavily doped gallium in silicon by LPE has been demonstrated. This process was found to be very sensitive to cooling rate, substrate orientation, saturation temperature, and melt volume. The growth rate dependence on saturation temperature and the amount of cooling were determined. The critical parameters which give an optimum growth with respect to surface morphology and dopant distribution were obtained. Layers grown on (111) orientations from a saturation temperature of 600°C and cooled at 0.8°C/min produced the most favorable growth results. Simple solubility arguments were found in error and layers were grown with higher dopant levels than expected. Thus, this technique is thought only attractive where high dopant concentrations ($>10^{18}$ atoms/cm^3) are desirous.

Selective Oxidation of Silicon in High Pressure Steam

H. Miyoshi, N. Tsubouchi, and A. Nishimoto

Computer Development Laboratories Limited, 4-1 Mizuhara, Itami, Hyogo, Japan

ABSTRACT

The selective oxidation of silicon was investigated using a high pressure oxidation apparatus at a steam pressure of 6.6 kg/cm^2 (6.4 atm) and at temperatures between 800° and 1100°C. The conversion characteristics of the silicon nitride film into silicon dioxide film in high pressure steam was analyzed on the basis of the well-known linear-parabolic relationship. The activation energy for the parabolic rate constant was found to be about 3.15 eV, which was about 5 times larger than that (0.7 eV) for silicon. On the other hand, the activation energy for the linear rate constant was about 1.25 eV which was a little smaller than that (2.03 eV) for silicon. The conventional silicon nitride film was found to be able to mask the selective oxidation even in the high pressure steam. The lateral oxidation of the silicon substrate beneath the masking nitride film occurred rapidly with decreasing oxidation temperature at the fixed pressure. The suppression of the lateral oxidation can be achieved by increasing the thickness of the masking nitride film and also by decreasing that of the oxide pad. This high pressure oxidation process was compatible with the conventional atmospheric process.

Selective oxidation of silicon substrate with the use of silicon nitride film as a mask is one of the basic process technologies in modern semiconductor integrated circuit industry. The selective oxidation technology has been applied to form thick silicon dioxide film used as an isolation layer in the integrated circuits. Conventionally, the growth of thick silicon dioxide film has been performed using wet oxidation or H_2/O_2 pyrogenic oxidation at a temperature of about 1000°C at atmospheric pressure and for a very long oxidation time. For example, the oxidation time of about 12 hr is necessary to form the silicon dioxide film of 1.5 μm thick in H_2/O_2 pyrogenic ambient at atmospheric pressure and 1000°C. The long time oxidation treatment of the silicon substrate is known to cause the degradations of some electrical characteristics of the devices of the integrated circuits (1, 2).

On the other hand, the high pressure oxidation methods (3, 4) in steam or dry oxygen ambient are known to reduce the oxidation time to a considerable extent and are expected to improve the performance of the integrated circuits. The masking capability of the silicon nitride film during the growth of thick silicon dioxide film is one of the main interests in the selective oxidation process. Further, the control of the lateral oxidation, by which the silicon substrate to be protected with the masking silicon nitride layer is oxidized, is also of interest in order to define the selective oxidation process for fabricating integrated circuits.

It is the purpose of this paper to report the masking capability of the silicon nitride film against the accelerated oxidation of silicon by using a newly developed high pressure steam oxidation system (5-7) and the control of the shape of the nitride-oxide edge, that is, the lateral oxidation of silicon beneath the mask nitride film in high pressure steam.

Key words: oxidation, silicon nitride, high pressure oxidation, selective oxidation, MOS LSI process.

Experimental

The selective oxidation of the silicon substrate with the use of a masking nitride film was performed using the newly developed high pressure oxidation system. In Fig. 1, the high pressure oxidation apparatus is schematically shown. This high pressure oxidation system is able to perform H_2/O_2 pyrogenic steam oxidation at a pressure up to 9 kg/cm^2 and an oxidation

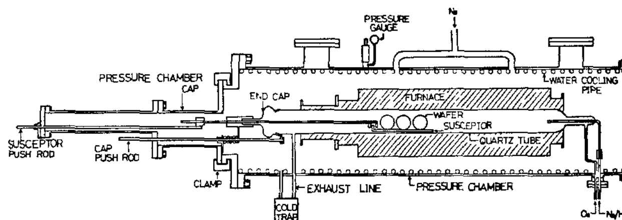

Fig. 1. Schematic diagram of the high pressure oxidation apparatus.

temperature up to 1200°C. In this high pressure oxidation system, a conventional oxidation furnace is set into a high pressure stainless steel chamber (50 cm in diameter, and 180 cm in length). A high quality quartz tube is inserted in the high pressure stainless steel chamber. High purity compressed N_2 gas for charging the stainless steel chamber and compressed O_2 gas and H_2 gas for forming the pyrogenic steam ambient are supplied from liquid N_2, liquid O_2, and compressed H_2 gas sources, respectively. In order to avoid the penetration of contaminants from the outer stainless steel chamber into the quartz tube, the total gas pressure in the quartz tube in which the substrate is oxidized is automatically controlled to be always larger than that of the outer stainless steel pressure chamber by 1 atm during oxidation. This automatic control of the pressure difference between the stainless steel pressure chamber and the quartz tube can be performed with the use of a microprocessor control system. The steam pressure inside the quartz tube can be precisely controlled by controlling mass flow ratio of H_2 gas to O_2 gas. The experiments were carried out with mass flow ratio of H_2 and O_2 being 1.76, and the total gas pressure inside the quartz tube of 7.0 kg/cm^2 (a partial pressure of H_2O should be 6.6 kg/cm^2). The details of the operation of the system have been reported elsewhere (5, 6).

The masking capability of silicon nitride is a very important factor in the selective oxidation process. Therefore, the conversion rate of silicon nitride films into silicon dioxide under the high pressure steam ambient was investigated at different oxidation temperatures. In our experiments, silicon nitride films were deposited on the surface of silicon substrate using a reduced pressure chemical vapor deposition method. The silicon nitride film is converted into silicon dioxide during high pressure oxidation. The converted nitride layer was etched in a buffered HF solution and the thickness of the remaining silicon nitride film was measured by the conventional ellipsometry technique.

In the selective oxidation experiments, a silicon dioxide layer of 300 and 500Å thick was thermally grown on the surface of (100) oriented silicon substrate (6-9 Ω·cm, p type, 2 in. in diameter). The nitride films produced from the reaction of SiH_2Cl_2 with NH_3 at 800°C in N_2 carrier gas were deposited on the silicon dioxide layer and defined by the conventional photolithography and CF_4 gas plasma etching techniques. In our experiments, the thicknesses of the underlying silicon dioxide pad and the masking silicon nitride layer were varied. Selective oxidations were performed by varying the oxidation temperature at a fixed oxidation pressure. Further, the conventional atmospheric selective oxidation was also carried out at 950°C in wet oxygen ambient as a comparison. In the selective oxidation process, the control of the shape of the oxide layer at the nitride-oxide edge, which is usually called "bird-beak," is important for the device designs. The cross-sectional view of the "bird-beak" was examined by using SEM technique.

Results and Discussion

In Fig. 2, the thicknesses of the converted silicon nitride film during the high pressure steam oxidation are shown as a function of oxidation time. In this experiment, the initial thickness of the silicon nitride film to be oxidized was 1000Å and the steam pressure in the quartz tube was kept at 6.6 kg/cm^2. The conversion behavior of silicon nitride film was measured by varying the oxidation temperature from 800° to 1000°C.

The conversion rate of silicon nitride film into silicon dioxide film increases with increasing oxidation temperature under a fixed pressure, as shown in Fig. 2. Auger electron spectroscopic (AES) measurements showed that the silicon nitride film of 1000Å thick was converted into a perfect silicon dioxide film after oxidation at a steam pressure of 6.6 kg/cm^2 and an oxidation temperature of 1000°C for 400 min.

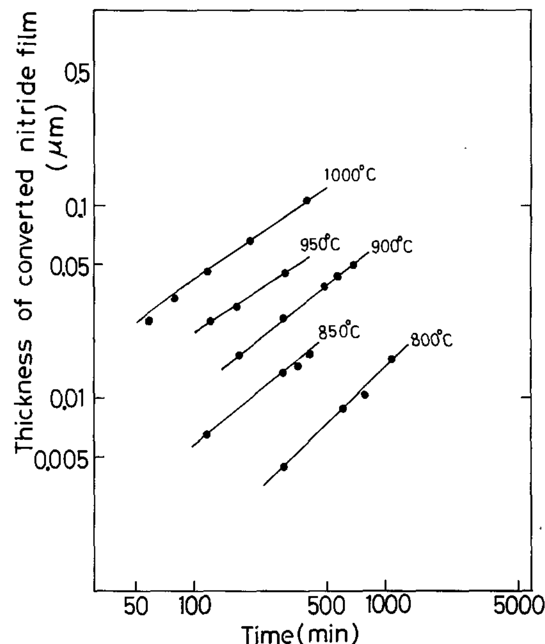

Fig. 2. Thickness of the converted silicon nitride film during the high pressure oxidation as a function of time with temperature as parameter.

The thicknesses of the silicon dioxide film converted from silicon nitride film during high pressure pyrogenic oxidation are calculated from the experimental results shown in Fig. 2 with the aid of the theoretical conversion ratio (1.95) of silicon nitride film into silicon dioxide film. The calculated thicknesses of the thermally grown silicon dioxide layer are shown in Fig. 3 as a function of oxidation time and oxidation temperature. These characteristics are very similar to the oxidation characteristics of a silicon substrate at 1 atm pressure. As is well known, the oxidation characteristics of silicon in dry and wet oxygen and steam ambient at 1 atm pressure are well described by the linear-parabolic relation (8). Thus, it can be said from Fig. 3 that the conversion characteristics will be sub-

ject to the following linear-parabolic equation

$$t_{ox}^2 + At_{ox} = Bt \quad [1]$$

$$A = 2D_{eff}(1/k + 1/h) \quad [2]$$

and

$$B = 2D_{eff}C^*/N \quad [3]$$

where B/A is the linear rate constant, B is the parabolic rate constant, t_{ox} is the oxide thickness, t is the oxidation time, k is the reaction coefficient, h is the gas phase transport coefficient, D_{eff} is the effective diffusion coefficient, C^* is the equilibrium concentration of the oxidant in the oxide, and N is the number of oxidant molecules incorporated into a unit volume of the oxide layer.

The values of A, B, and B/A are calculated from the oxidation characteristic curves shown in Fig. 3 and summarized in Table I. The rate constants obtained from the oxidation of silicon at a steam pressure of 6.6 kg/cm² and different oxidation temperatures are tabulated in Table I. As can be seen from the table, the values of the rate constants A, B, and B/A for the oxidation of silicon nitride film are much smaller than those for silicon. The activation energy E_a for the rate constant B for the oxidation of silicon nitride film was found to be about 3.15 eV, which is about 5 times larger than that (0.7 eV) for silicon. On the other hand, the activation energy E_a for the linear rate constant B/A for the oxidation of silicon nitride film is about 1.25 eV which is a little smaller than that (2.03 eV) for silicon. The value of the activation energy E_a for the linear rate constant B/A for the oxidation of silicon at 1 atm pressure is about 1.96 eV which is comparable with that (2.03 eV) at 6.6 kg/cm². Therefore, the values of the activation energy for the constant A are 1.90 and −1.33 eV for the silicon nitride and silicon, respectively. It should be noted that the values of A decrease with decreasing temperature for the oxidation of silicon nitride which is contrary to the oxidation of silicon. This comes from the high activation energy for B in the silicon dioxide conversion of silicon nitride films. Fränz *et al.* (9) suggested that the reduction of the constant B was caused by the reduction of the equilibrium concentration of the oxidant due to the nitrogen generated during the chemical reaction at the nitride-oxide interface. On the other hand, the measurements (10) with ESCA revealed that the oxidized nitride films were apparently homogeneous and were graded, being nitrogen rich as the nitride film was approached. In the former case, C^* in Eq. [3] should be small and then B is small compared with that for the oxidation of silicon. In the latter case, the diffusion coefficient should be smaller. The experimental results did not clearly show which effect is predominant for the reduction of B. Thus the growth rate of the silicon dioxide film converted from the silicon nitride film may in any event be reduced in comparison with the oxidation of silicon. The decrease of the linear rate constant B/A in the high pressure oxidation of silicon nitride film may be caused by the decrease of the reaction constant k, because B/A is proportional to the reaction coefficient at the nitride-oxide interface.

Further, the experimental results shown in Fig. 2 show that the conventional silicon nitride film can mask the selective oxidation process at high pressure, because the silicon dioxide film of 1.5 μm thick can be thermally grown at 1000°C for 90 min in the high pressure ambient of 6.6 kg/cm².

Typical examples of the cross section of the selective oxidation structure are shown in Fig. 4a and b. In these examples, the thicknesses of the masking nitride film and the underlying silicon dioxide layer are 1000 and 500Å, respectively. The grown-up oxide layer is 1.5 μm in thickness. In Fig. 4a and b, the oxidation was performed at 1100° and 800°C under the pressure of 6.6 kg/cm². As can be seen from comparing Fig. 4a with b at lower oxidation temperature and then longer oxidation time, a deep lateral oxidation occurs and the deep area of the silicon covered with the masking silicon nitride layer is oxidized. Therefore, the profiles of so-called "bird-beak" are apparently varied by varying oxidation temperature and time.

In Fig. 5, a schematical view of the cross section of the selective oxidation structure is shown. In our experiments, the thickness t of silicon dioxide film was always 1.5 μm. In Fig. 5, X axis and Y axis are parallel and perpendicular to the surface of silicon substrate, respectively. Maximum lateral oxide thickness is labeled B. The slope profile from a point $(0, Y_0)$ to a point $(B, 0)$ was investigated. The distance H of the edge of the masking silicon nitride layer from the origin 0 is labeled "a nitride edge height."

In Fig. 6, the normalized vertical oxide thicknesses Y/Y_0 are shown as a function of normalized lateral oxide thickness X/t where t is 1.5 μm. The oxidation temperature was varied from 800° to 1100°C under fixed oxidation pressure. The shapes of the curves shown in Fig. 6 show the slope profile of so-called "bird-beak" section in selective oxidation structure. It can be seen from these curves that the gradient of the curves decreases as the oxidation temperature increases, that is, a sharper slope profile can be obtained at higher oxidation temperature. In other words, as the oxidation temperature decreases and the oxidation time becomes longer, in order to grow the film to a fixed thickness of 1.5 μm, the lateral oxidation beneath the masking silicon nitride layer is more pronounced. For example, for the oxidation at 1100°C, maximum lateral oxide thickness B is about $0.75t$ ($t = 1.5$ μm) which is 75% of the thick oxide layer t. At 950°C, B becomes the same as t. On the other hand, at 800°C, B becomes about $1.22t$, which means the lateral oxide thickness is larger than the vertical oxide thickness, and a strong lateral oxidation of silicon under the masking nitride film occurs. This might result from the deep lateral diffusion of the oxidants along the silicon surface during the long oxidation time (610 min).

In Fig. 7, a normalized maximum lateral oxide thickness B/t ($t = 1.5$ μm) and a normalized nitride edge height H/t are shown as a function of oxidation

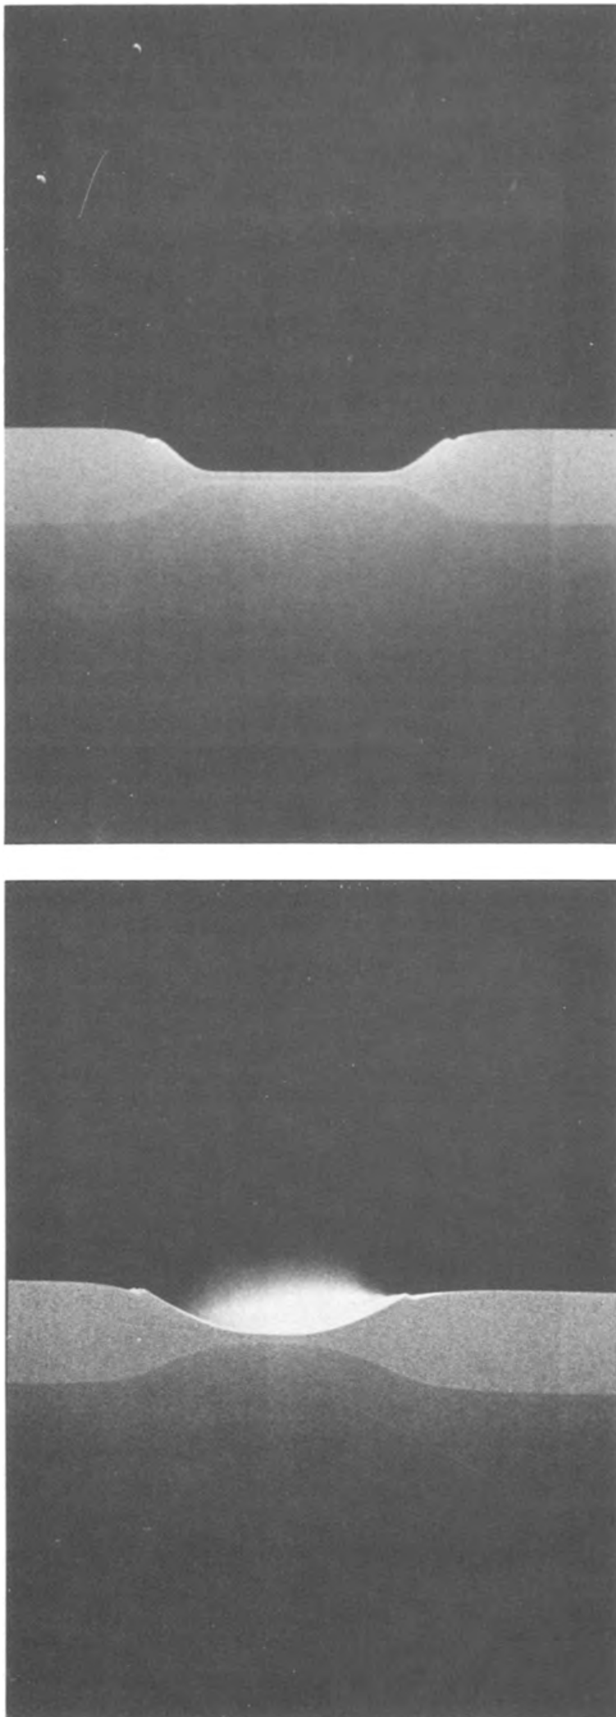

Fig. 4. Typical examples of the cross section of the selective oxidation structure showing the increase of the lateral oxidation as the oxidation temperature is decreased. In (a), the oxidation was performed at 1100°C with a pressure of 6.6 kg/cm^2 and in (b) at 800°C with 6.6 kg/cm^2.

temperature at a pressure of 6.6 kg/cm^2. Further, in Fig. 7, as a comparison, the values of B/t and H/t ob-

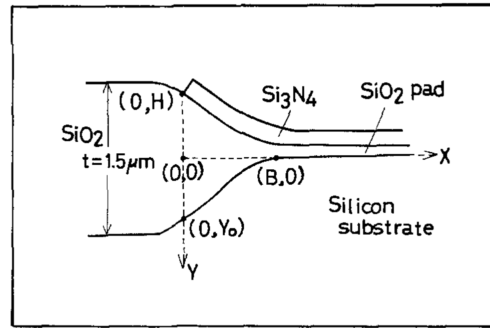

Fig. 5. Schematical view of the cross section of the selective oxidation structure.

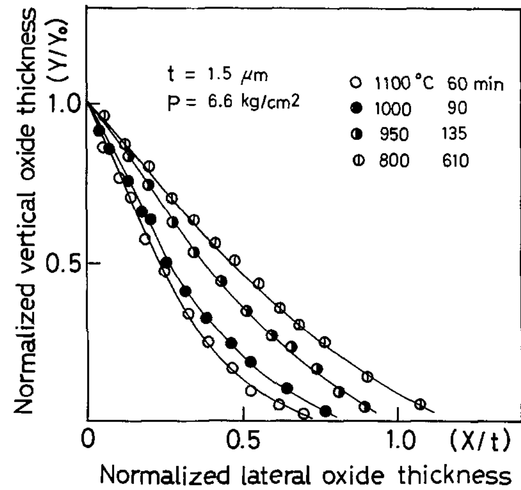

Fig. 6. Shape of the lateral oxidation as a function of the oxidation temperature. Normalized vertical oxide thicknesses Y/Y_0 are shown as a function of normalized lateral oxide thickness X/t.

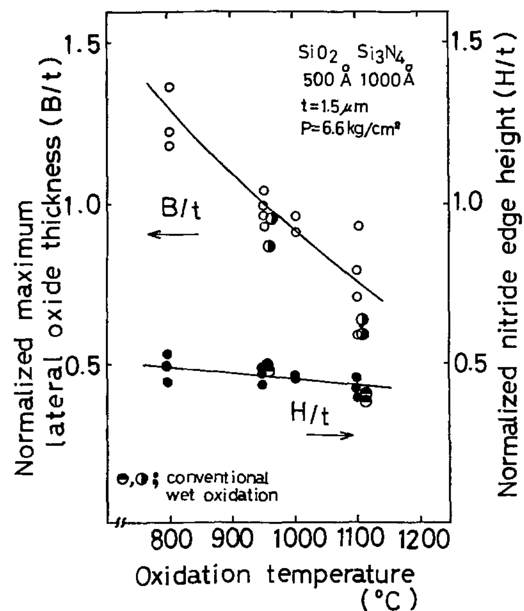

Fig. 7. Normalized maximum lateral oxide thickness B/t and normalized nitride edge height H/t as a function of oxidation temperature at the pressure of 6.6 kg/cm^2.

tained from the experiments performed by the conventional atmospheric wet oxidation are plotted. As can be seen from Fig. 7, the maximum lateral oxide thickness B decreases rapidly with increasing oxidation temperature and B/t becomes larger than 1.0 for oxidation temperatures lower than 950°C, that is, the

lateral oxidation rate is larger than the vertical oxidation rate. Further, a slight difference between the values obtained from the atmospheric oxidation and the high pressure oxidation is obtained as shown in Fig. 7. The statistically summarized experimental results showed the values of the maximum lateral oxide thickness B obtained in the conventional atmospheric oxidation were a little smaller than those obtained from high pressure oxidation. This may result from the difference of the lateral diffusion rate of the oxidant in atmospheric pressure and in high pressure. On the other hand, the nitride edge height H/t decreases gradually with increasing oxidation temperature. There is almost no significant difference in H/t between atmospheric pressure and the high pressure, as can be seen from Fig. 7.

In selective oxidation, the thicknesses of the underlying oxide layer and the masking nitride film may influence the lateral oxidation characteristics. In Fig. 8, the normalized maximum lateral oxide thicknesses B/t are shown as a function of the thickness of the underlying silicon dioxide film for different oxidation temperatures. As can be seen from Fig. 8, there is a tendency for the maximum lateral oxide thickness to increase as the thickness of the underlying silicon dioxide film is increased. This will result from the increase of the number of the incoming oxidants in the underlying oxide layer as the thickness of the oxide layer is increased.

In Fig. 9, the normalized maximum lateral oxide thickness B/t is shown as a function of the thickness of the masking silicon nitride film. In this case, the thickness of the silicon dioxide pad was 300Å. As can be seen from Fig. 9, the value of B/t decreases with increasing thickness of the masking silicon nitride film for different oxidation temperatures. Further, the normalized nitride edge height H/t is also shown in Fig. 9 as a function of the thickness of the masking silicon nitride film. The value of H/t decreases as the thickness of the silicon nitride film increases and does not strongly depend on the oxidation temperature. These tendencies of B/t and H/t are useful for showing how the lateral oxidation is decreased as the thickness of the nitride layer is increased.

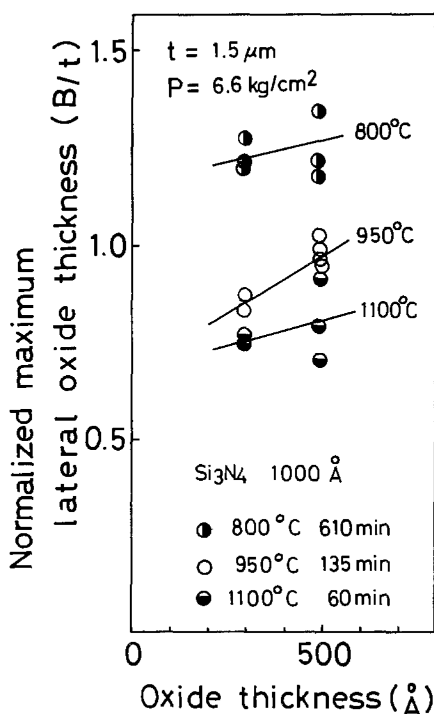

Fig. 8. Normalized maximum lateral oxide thickness as a function of the thickness of the oxide pad.

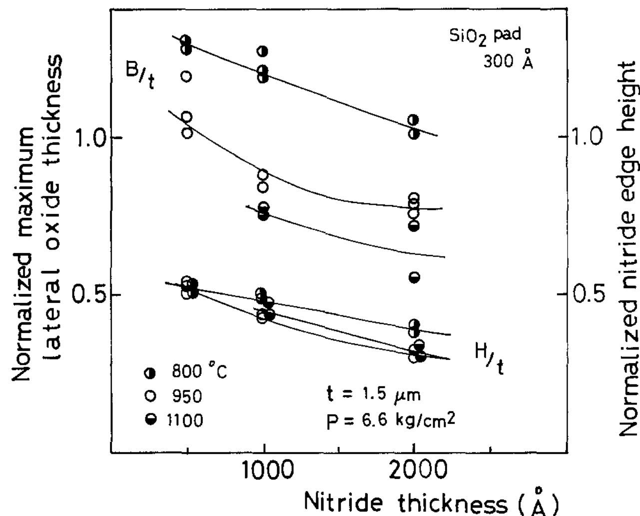

Fig. 9. Normalized maximum lateral oxide thickness and normalized nitride edge height as a function of the thickness of the masking nitride film.

The high pressure oxidation method was applied to the fabrication of a MOS Random Access Memory device with 5 μm minimum line width of the field oxide grown using the high pressure oxidation technique. The selective oxidation was performed using a 300Å dioxide pad and a masking nitride 1000Å thick. The oxidation temperatures were 950°, 900°, and 800°C. The measured electrical performances of the MOS Random Access Memory showed that the selective oxidation process with high pressure oxidation was compatible with the conventional selective oxidation process.

Summary

Selective oxidation of silicon was investigated using the new developed high pressure oxidation apparatus at a pressure of 6.6 kg/cm² and at a temperature between 800° and 1100°C. The conversion characteristics of the masking silicon nitride film into silicon dioxide film was analyzed on the basis of the linear-parabolic relation. The activation energy for the parabolic rate constant was found to be about 3.15 eV, which was about 5 times larger than that (0.7 eV) for silicon. On the other hand, that for the linear rate constant was about 1.25 eV which was smaller than that (2.03 eV) for silicon. The conventional silicon nitride film was found to mask the selective oxidation process even in this high pressure oxidation. The maximum lateral oxide thickness beneath the nitride mask decreases rapidly with increasing oxidation temperature. The thickness of the oxide pad and the masking nitride film influence the lateral oxidation characteristics. The suppression of the lateral oxidation can be achieved by increasing the thickness of the masking nitride film and decreasing the thickness of the oxide pad.

This high pressure oxidation process was found to be compatible with the conventional fabrication process for a high density MOS LSI using the selective oxidation technique.

ABSTRACT

Anomalous generation of pulsive noise was observed in devices masked with SiO_2 during ion implantation in monolithic IC's. It has been found that this is not due to recoil implantation of oxygen in the SiO_2 film, but to dielectric breakdown of the SiO_2 film during ion implantation. This can be completely avoided by coating the SiO_2 mask with thin conductive films such as aluminum or polycrystalline Si just before ion implantation.

Ion implantation has come to be widely used in the processing of MOS IC's and junction FET's. In the case of bipolar IC's, however, ion implantation is confined to the restricted area of bipolar devices in spite of superior density profile controllability. One reason for this might be a development problem of high current ion implantation systems suitable for mass production. Another reason might be related to device characteristics such as noise performance of the ion implanted transistors or resistors.

This paper is an inquiry into the problem of medium dose ion implantation in bipolar devices.

Pulsive Noise Generated by Ion Implantation

For example, high value resistors are fabricated as shown in Fig. 1. In this case, $^{11}B^+$ ions are implanted into resistor area 1, while transistor area 2 is covered by SiO_2 mask 3. But in low noise IC's, there is difficulty in adopting ion implantation. We found that anomalous generation of pulsive noise with the waveform as shown in Fig. 2 is observed in transistors masked with SiO_2 during ion implantation.

Pulsive noise is also called burst noise or popcorn noise and is generated by a large number of imperfections in the crystal (1). On the other hand, most of the samples made by conventional thermal diffusion only exhibit clean noise as shown in Fig. 3. Generally, SiO_2 is used as the ion implantation mask. Therefore, either dielectric breakdown of SiO_2 caused by accumulated charge or infinitesimal knock on (recoil) implantation of oxide atoms in SiO_2 are considered to contribute to the generation of pulsive noise.

Dielectric Breakdown

As shown in Fig. 4 wafer 1 with SiO_2 pattern 3 is grounded through current integrator 2. $^{11}B^+$ or $^{31}P^+$ ions are implanted on the front surface of wafer 1. At the surface of insulating SiO_2 film, area 3, positive charges remain at the surface or at a certain penetration depth of SiO_2, inducing equal minus charges (electrons) from ground to the Si-SiO_2 interface through current integrator 2, thus raising the electric field in the insulating SiO_2 film.

Suppose that all the positive charges remain at the surface of SiO_2 with the thickness of 1 μm. Then the accumulated charge voltage of SiO_2 with the ion dose 1.5×10^{13} atoms/cm^2 of common implanted sheet resistivity of 2-3 k$\Omega/\square$ is given by the following equation

$$V = \frac{q \cdot \Phi}{\epsilon_r \cdot \epsilon_0/d} = \frac{1.6 \times 10^{-19} \times 1.5 \times 10^{13}}{3.82 \times 8.85 \times 10^{-14}/1 \times 10^{-4}} = 710\,(\text{volt})$$

Here, p-n junctions are neglected because there are always small leakage currents under certain bias voltages due to majority or minority carriers even in ideal crystal structures. This accumulated charge voltage (710V) comes near to the few kilovolts per micrometer dielectric breakdown voltage of SiO_2. It can be conjectured that local dielectric breakdown occurs and residual surface damage due to breakdown still exists after subsequent heat-treatment. In this case, dielectric breakdown could be avoided by covering the SiO_2 with a thin conductive film.

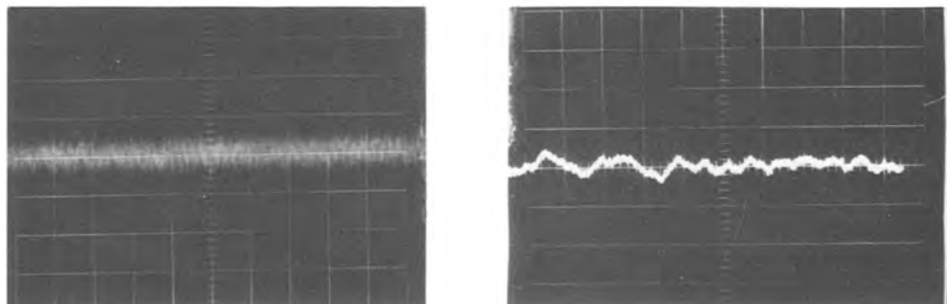

Fig. 3. (a, left) Clean noise waveform (horizontal: 10 msec/div). (b, right) Low frequency component of clean noise (horizontal: 10 msec/div).

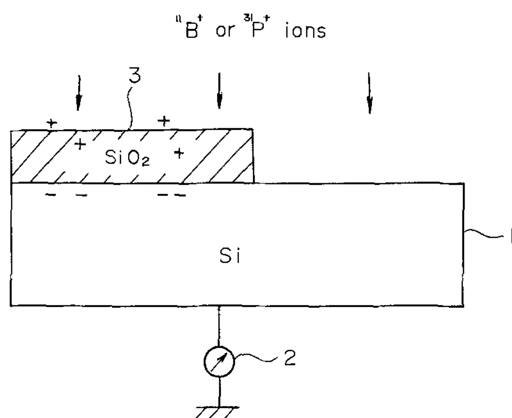

Fig. 4. Mechanism of ion implantation into SiO_2 pattern

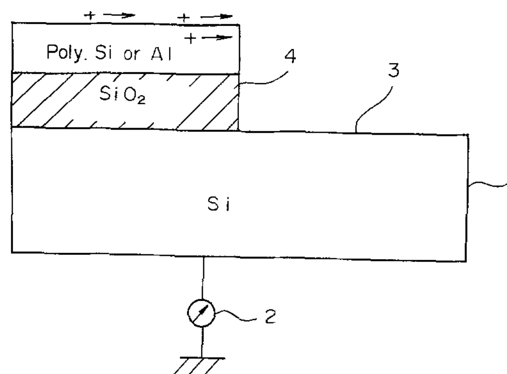

Fig. 5. Countermeasure for dielectric breakdown of SiO_2

Therefore, wafers were covered with either a 1.5 μm thick aluminum evaporated film or a nondoped polycrystalline Si film (SiH_4 at 640°C, 35 min, 0.55 μm thick) over the thermal SiO_2 film as shown in Fig. 5. The aluminum and polycrystalline Si film thickness are chosen equal to those adopted in the conventional bipolar IC's and silicon gate MOS IC's.

In this case, accumulated positive charges travel to the edges of the ion implantation mask 4 and discharge frequently, thus avoiding dielectric breakdown of the insulating SiO_2 film, as this discharge occurs in the range of a few tens of volts per micrometer at the pressure of the ion implantation vacuum chamber.

Knock on Implantation

In order to increase stopping power against incident ions, wafers were covered with chemical vapor-deposited SiO_2 film ($SiH_4 + O_2$ at 420°C, 1 atm, 8 min, 0.5 μm thick), photoresist (40 cp, OMR 83, 4000 rpm, 1 μm thick) or Scotch tape No. 56 (55 μm thick) over the conventional thermally grown SiO_2 film mask.

Experimental Results

Table I shows the processing conditions for each sample. Ion implantation was performed using $^{11}B^+$ ions with an accelerating voltage of 50 kV and doses of 1.5×10^{13} atoms/cm^2. Noise figures of 30-50 npn transistors in each group were measured as shown in Fig. 6.

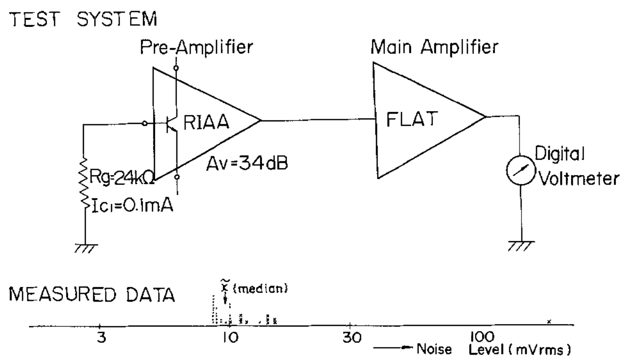

Fig. 6. Noise figure measurement for npn transistor

At first, notice wafers No. 1-4. In these cases, No. 1 is an unimplanted standard sample. Number 4 is ion implanted on to conventional thermal grown SiO_2 only. With regard to the generation of pulsive noise, less than 10% of the units in groups 1 to 3 had this characteristic, compared to over 30% in group 4. The median of noise level is almost constant as long as the generation rate of pulsive noise is below 30-50% because the level of the pulsive noise is distributed very widely as shown in the example of measured data in Fig. 6. There are no distinct tendencies in the median of h_{FE}. Therefore, a conductive film mask such as aluminum or polycrystalline Si is effective in the suppression of pulsive noise.

Then, observe wafers No. 5-9. In these cases, the generation rate of pulsive noise is over 20% in every sample. Therefore, an insulating film mask with increased stopping power against incident ions is ineffective in the suppression of pulsive noise.

In order to confirm the effect of dielectric breakdown, noise figures of bipolar IC's were measured as shown in Table II. The test system for the KC573C device is illustrated in Fig. 7. It is clear that the generation rate of pulsive noise for aluminum- or polycrystalline Si-covered samples (No. 3-6) is comparable to that for samples made by conventional thermal diffusion only (No. 1-2), while the generation rate of pulsive noise in devices fabricated without countermeasures (No. 7-8) is as large as 70%.

Discussion

Standard voltage-ramp-type dielectric strength measurement of thin SiO_2 films was carried out as shown in Fig. 8. N-type epitaxial layers grown over p-type substrates were oxidized at 1020°C in steam for 22 min (about 2400Å thick). The polarity of the applied voltage was chosen to forward bias the p-n junction. Pulse (peak) voltmeter readings indicated in Table III are about 70% of the actual breakdown voltages due to meter current I_M, when the breakdown current I_L is observed by microammeter. As shown in Table III, it is clear that ion implanted wafers with photoresist applied (No. 5-6) have the lowest break-

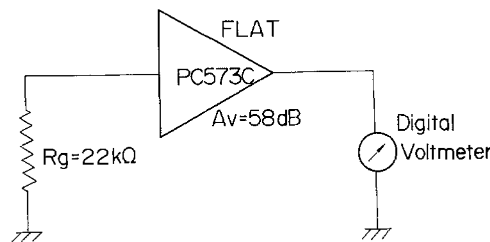

Fig. 7. Noise figure measurement for bipolar IC

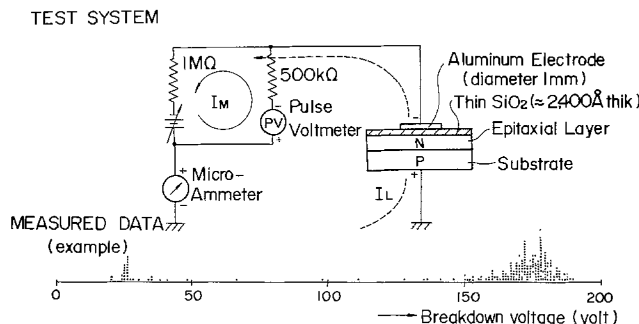

Fig. 8. Standard voltage ramp-type dielectric strength measurement of SiO_2.

down voltages, the highest standard deviation, and the highest percentage of breakdown voltage under 50V. It is concluded that the generation rate of pulsive noise during ion implantation is associated with the dielectric breakdown of SiO_2.

In order to investigate the relationship between the anomalous generation of pulsive noise and lattice defect density of the substrate surface, x-ray rocking curve checks and Sirtl etching were performed. As to the rocking curve check, peak intensity and half-width of the samples were equal to those found for bulk Si. As to Sirtl etching, there was scarcely any damage recognizable in any sample. Corresponding to these results, emitter-base or collector-base leakage current was not prominent even in the samples with the highest noise figure. It is concluded that the surface defect density is not large enough to be detected by these measurements.

The most practical way of introducing a conductive film mask is to cover the entire surface of the substrate with a very thin (for example, 50-100Å thick) aluminum film deposited as in the preparation of electron microscope samples.

Capacitance-voltage curves or surface-state density of the samples was not measured because surface states do not affect the characteristics of bipolar devices as much as that of MOS devices.

Conclusions

The mechanism of medium dose ion implantation into the insulating film mask was investigated. Accumulated charge voltage of the insulating film mask

Crystal Growth and Segregation under Zero Gravity: Ge

A. F. Witt,* H. C. Gatos,* M. Lichtensteiger,* and C. J. Herman

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Crystal growth and segregation in space were quantitatively investigated in a Bridgman-type configuration. It was established that the segregation behavior is diffusion controlled without interference from residual gravity, G-jitter, and surface tension gradients. Radial and longitudinal segregation effects were accounted for by a lateral diffusional dopant redistribution within the diffusion boundary layer brought about by the nonplanar morphology of the growth interface.

The existing gap between theory and experiment in crystal growth and segregation is largely attributed to gravity-induced convection effects which lead to the establishment of boundary conditions significantly different from those serving as the basis of the various theories (1-5). Thus, neither ideal mixing nor complete diffusion control can be achieved in growth from the melt. Moreover, stable boundary conditions cannot be maintained because of time-dependent variations of the convection flow (6).

Attempts to eliminate convection in melts through the application of magnetic fields (7, 8) and by use of capillary dimensions have not been very successful (9). Consequently, it has not been possible to assess the validity of the existing theoretical framework, *i.e.*, to determine the relationship between the equilibrium distribution coefficient and the interface distribution coefficient, the orientation dependence of the distribution coefficient, the origin of the radial segregation effect, and other segregation anomalies (10-12).

The presently reported crystal growth experiment was conducted during the Apollo-Soyuz mission as a part of NASA's program to determine the potential of zero-gravity[1] conditions for basic research and applications in materials processing. It was designed to establish on a quantitative basis the crystal growth and segregation behavior encountered in a zero-gravity environment, to provide a further insight into the unexpected behavior of confined melts observed in the growth of InSb during the Skylab mission (13), and to assess the magnitude and effects of surface tension driven convection.

Experimental Procedure

To achieve the experimental objectives, Ga-doped germanium crystals grown on earth were partially remelted in a confined configuration and regrown in space while current pulses were applied to achieve interface demarcation (11).

Sample preparation.—The germanium crystals used for the experiment were pulled in the <111> direction by the Czochralski method from 225g melts doped with gallium to achieve an average dopant concentration of about $10^{19}/cm^3$ in the solid. The crystals were centerless ground to a diameter of 1.046 cm and cut to a length of 9.5 cm. Their diameter was reduced to 0.843 cm over a length of 2 cm from each end to permit the attachment of graphite cups which served as current contacts for interface demarcation. The crystals were subsequently etched in CP-4 (5 parts conc HNO_3 + 3HF + $3CH_3COOH$) and encapsulated into centerless ground quartz ampuls 12.7 cm long with 1.0 cm ID and 1.5 cm OD. Prior to assembly, each ampul was etched in HF, rinsed successively with distilled water, methanol, and acetone, and dried. The graphite cups were machined to make good electrical contact with the germanium crystals and were fired at 1600°C in a vacuum of 10^{-7} Torr (1.3×10^{-5} Pa) prior to attachment. A schematic diagram of the ampul is shown in Fig. 1. The ampuls were sealed in stainless steel cartridges with an argon atmospere of 40 Torr (at room temperature).

Melting and regrowth procedure.—The flight experiments (as well as ground-based tests) were carried out in a "multipurpose" gradient furnace designed originally for the Skylab mission (13). It was modified with a system of lateral heat shields to permit operation at higher temperatures with controlled heat flow along the crystal from the heat leveler region via the gradient region to the heat extractor plate (see Fig. 1).

Partial remelting of the Ge crystals in space was accomplished by raising the temperature of the heat leveler region over a period of 3.5 hr to 1120°C while

[1] The actual value of gravity was of the order of 10^{-5}G. For convenience this value of G is referred to in this paper as zero.

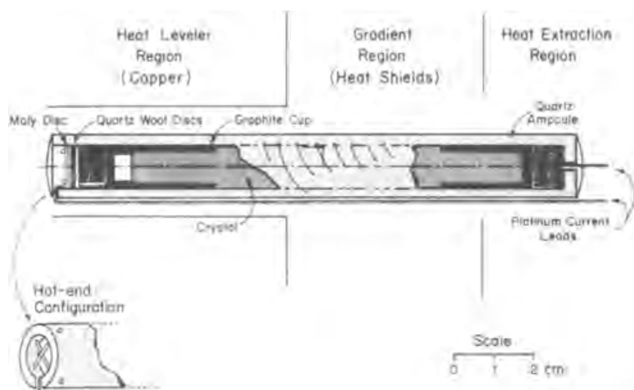

Fig. 1. Schematic representation of growth system and ampul design permitting interface demarcation through current pulsing.

maintaining the heat extractor region close to room temperature. In this thermal configuration a temperature gradient of about 50°C/cm was established in the gradient regions (Fig. 1), designed to locate the solid-melt interface at about 3.7 cm from the cold end of the crystal. To achieve thermal equilibration and to eliminate compositional inhomogeneities in the melt the temperature in the hea leveler region was maintained constant for a period of 2 hr. Regrowth was initiated by programmed reduction of the furnace power input to the heat leveler region (cooling rate 2.4°C/min), which was expected to result in a growth rate of about 5 μm/sec during the early stages of resolidification and in an increase of the growth rate to 10 μm/sec during the late stages of solidification.

Throughout thermal equilibration and controlled cool-down, current pulses of 55 msec duration and an amplitude of 15.5A were transmitted through the growth systems at a repetition rate of 0.25 Hz in order to achieve periodic demarcation of the crystal-melt interface. Following the controlled cool-down cycle (1.4 hr), the power was turned off (passive cool-down) and after 2 hr the system was subjected to forced cool-down by He injection.

A series of ground-based control experiments were carried out in an identical furnace to permit comparison of growth and segregation behavior in space and on earth. These experiments were performed in the same programmed mode as the flight experiments with the furnace positioned vertically (heat leveler up) in order to establish stabilizing vertical thermal gradients (growth took place in the upward direction). The thermal history of the growth system in space, obtained from temperature measurements in the heat leveler region and at the cold heat extractor plate, is shown in Fig. 2.

Analytical procedure.—The crystals grown were subjected to growth and segregation analyses based on procedures described elsewhere (11). For bulk analysis the regrown crystals were cut along the growth direction to obtain 0.2 cm thick slices, containing the growth axis. To permit single point spreading resistance analyses large area ohmic contacts (evaporated and micro-alloyed silver layers) were made on the back sides of the crystal segments and were pressure-bonded with conductive silver paint to brass disks. All mounted specimens were ground with 10 μm particle size abrasive, mechanically polished with Linde A alumina, and chemically polished with a modified Syton HT-30 solution (200 ml Syton, 200 ml H_2O, 5 ml H_2O_2, and 2 ml CH_3COOH). After rinsing, the samples were etched by immersion for 8 sec in a solution of equal parts of HF, H_2O_2, and CH_3COOH.

For quantitative segregation analysis, spreading resistance measurements were carried out first and subsequently the corresponding growth rates determined

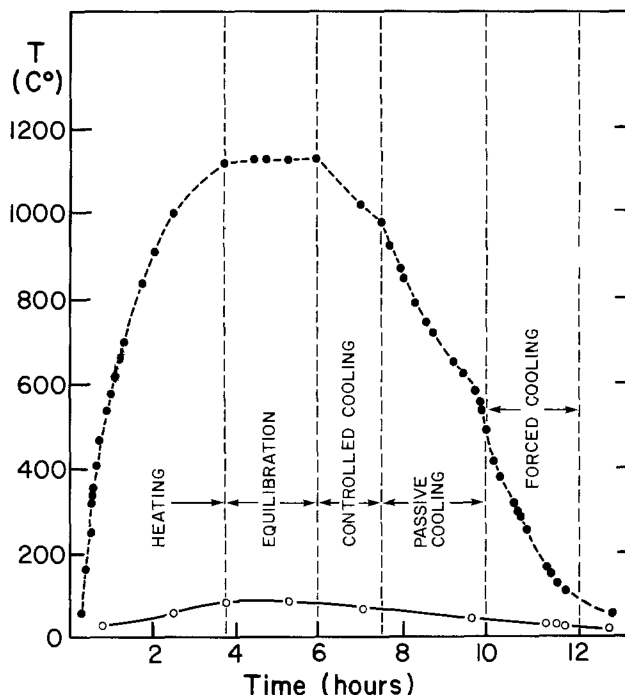

Fig. 2. Thermal cycles of growth experiment; ● temperature in heat leveler region; ○ temperature at heat extraction plate.

from demarcation spacings by interference contrast microscopy. The reproducibility of spreading resistance measurements on stabilized surfaces was better than 2%. After correcting for resistances in the external circuitry the raw spreading resistance data were reduced to normalized resistance using a quadratic progression fit. These data were converted into resistivity using an experimentally determined probe calibration factor based on measurements with samples of well-defined electrical properties. The resistivity data in turn were reduced to carrier concentration by fitting to a computer generated expression for (N_A-N_D) *vs.* ρ employing a spline cubic interpolating polynomial derived from the literature (14) and from Hall-effect data.

Experimental Results and Discussion

Surface characterization.—Each crystal regrown in space was readily removed from its quartz container (Fig. 3) suggesting that the surface morphology of the grown crystal did not conform to that of the container which exhibited microscopic irregularities. Lack of conformity of the regrown crystal with the confining quartz surface was confirmed by interference contrast microscopy. The surface of the crystal grown in space exhibited a random network of ridges (Fig. 4) ranging in height from about 1 to 5 μm. These ridges, which reduced the actual contact area between the crystal and the confining wall to a fraction of 1%, appear similar in nature to those observed on InSb

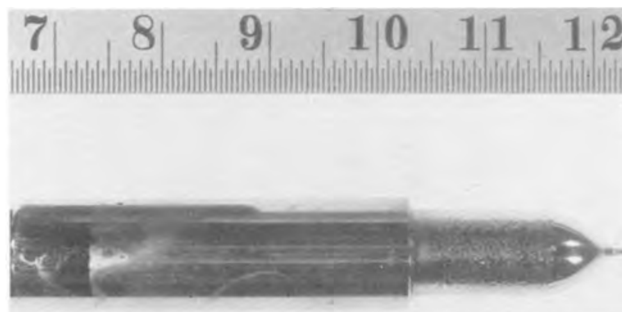

Fig. 3. Germanium crystal with <111> orientation, grown in space, after removal from quartz ampul.

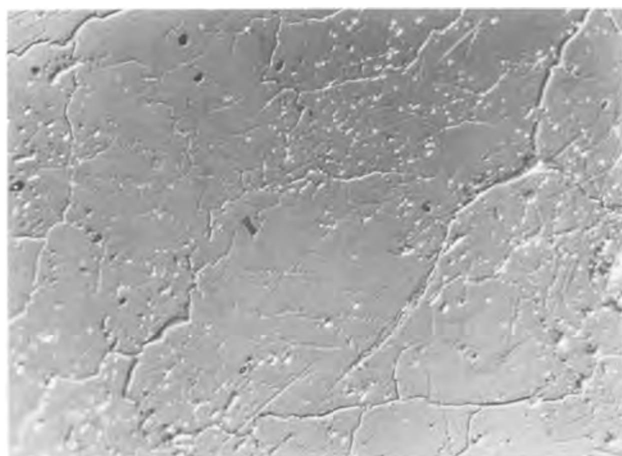

Fig. 4. Ridge patterns on the surface of the <111> germanium, grown in space.

crystals grown on Skylab (13). In view of the fact that liquid Ge expands by more than 3% on solidification it is concluded that under zero gravity conditions the germanium melt does not establish a wetting contact with the confining quartz ampuls and that the ridges observed on the regrown crystals reflect the morphological characteristics of the melt surface in the vicinity of the regrowth interface. In this respect the behavior of the germanium melt in space is fundamentally different from that encountered in ground-based experiments where wetting contact with the confining wall takes place and consequently the solidified material in all instances can be isolated only by dissolving the quartz ampuls in hydrofluoric acid.

The ridge formation, which cannot as yet be explained, could be of fundamental importance for materials processing in space, since it suggests that liquid systems may be placed in partial or complete confinement without significant contact with the confining material.

A comparison of the morphological characteristics of Ge crystals regrown on earth and in space reveals additional pronounced differences. It is found that crystals obtained from ground-based experiments invariably exhibit complete loss of single crystallinity after a growth length of about 2 cm. In contrast, single crystallinity is preserved in the peripheral region of space-grown material to the very last stages of growth in spite of internal matrix breakdown due to constitutional supercooling effects which was expected under the prevailing growth conditions (12) (Fig. 5).

Visual inspection of the space-grown crystals showed abrupt, peripherally asymmetric changes in surface morphology after about 1.5 cm of growth. The location of these morphological irregularities corresponded to the transition from the thermal gradient region to the heat leveler region within the multipurpose furnace. Bulk crystal analysis suggests that these morphological irregularities result from changes in the heat transfer characteristics of the growth system (see below).

Bulk characterization.—Etching analysis.—High resolution etching techniques were refined during ground-based testing to permit, through interference contrast microscopy, the detection of microscopic compositional fluctuations in Ge with a sensitivity of better than $\pm 0.2\%$ at dopant (Ga) levels in excess of $10^{18}/cm^3$.

The basic difference between microsegregation in the segment of the ingot grown on earth and that grown in space is apparent from the dark-field photomicrograph in Fig. 6; thus, compositional fluctuations which characterize the original seed portion grown on earth

Fig. 5. Etched cross section of the last portion of the <111> germanium crystal regrown in space. Note preservation of peripheral single crystallinity in spite of internal breakdown and phase segregation.

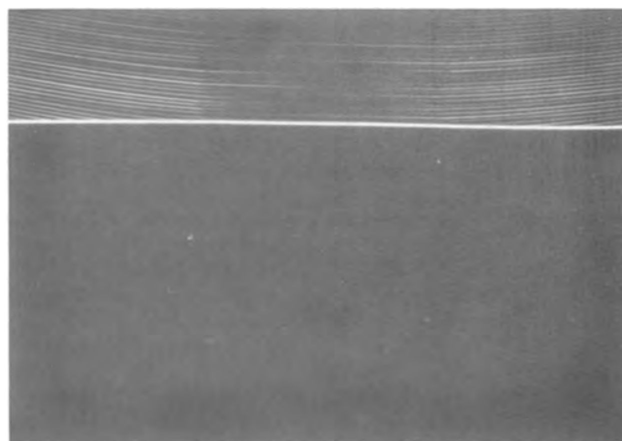

Fig. 6. Etched cross section (under dark-field illumination) of crystal grown in space; space-grown segment (bottom), in contrast to earth-grown segment (top), exhibits no compositional inhomogeneities.

(top portion) are absent in the crystal segment regrown in space (bottom portion). The pronounced demarcation of the original regrowth interface is due to the abrupt decrease in dopant incorporation associated with the initial stages of regrowth.

Details of the microsegregation behavior in the initial regrowth region were observed by interference contrast microscopy and are shown in Fig. 7. Three regions can be identified: a segment of the original seed (top of photomicrograph), a narrow growth band of about 350 μm in length with compositional fluctuations (middle), and the regrowth region exhibiting microscopic compositional homogeneity in which current-induced interface demarcation lines can be readily seen (bottom). The onset of controlled regrowth is clearly evident at the upper part of the bottom region where interface demarcations appear with gradually increasing spacing. Accordingly, the uncontrolled growth of the narrow band (middle) must

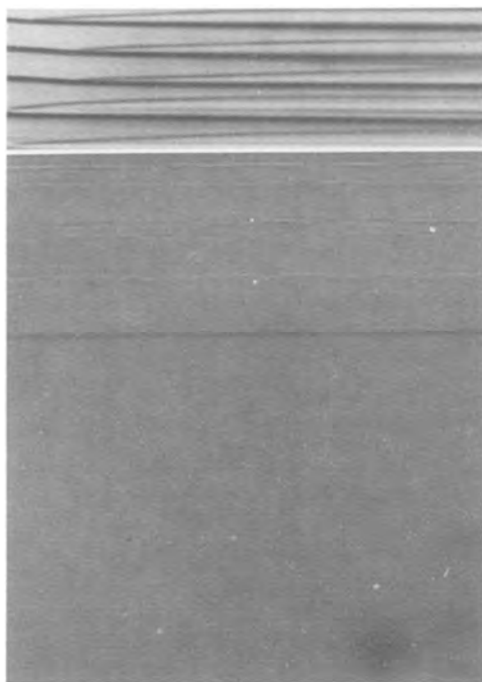

Fig. 7. Segment of Ge crystal partially regrown in space: note seed segment (top) and segment of controlled regrowth (bottom) separated by a region of uncontrolled growth and segregation.

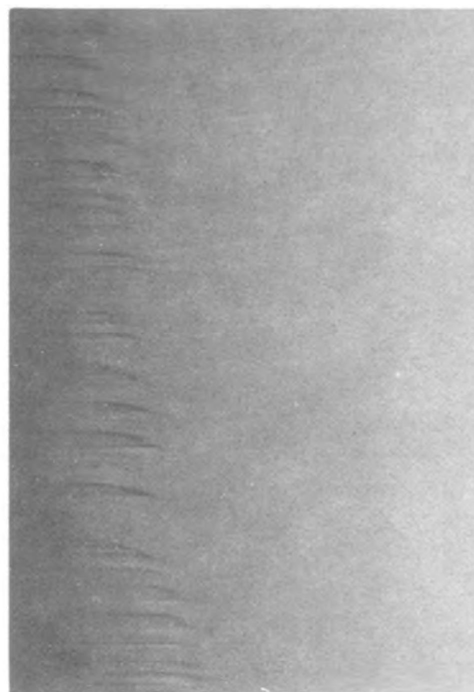

Fig. 8. Peripheral (111)-facet in the space-grown Ge crystal

have preceded the onset of controlled cool-down and, thus, took place during the thermal equilibration period. Similar narrow growth regions of apparently uncontrolled growth, ranging in length from 200 to 1000 μm, were observed also in all ground-based experiments conducted in the multipurpose furnace.

The cause of the uncontrolled growth becomes apparent on examination of the thermal history of the growth system shown in Fig. 2. It is seen that the temperature in the heat leveler region remained constant at 1120°C during thermal equilibration (2 hr) but that the temperature at the heat extraction plate increased slightly during the first hour and decreased by about 20°C during the second hour. This gradient increase associated with the temperature decrease of the heat extraction plate brought about a relocation of the growth interface toward the hot zone. Thus, the observed uncontrolled growth resulted from the thermal drift of the system during the equilibration period.

Etching analysis of the crystals regrown in space revealed that the bulk of the controlled-growth segments are free of microscopic compositional fluctuations for a length exceeding 3.0 cm. The only identifiable compositional changes were associated with peripheral (111) faceting of the growth interface which was found to extend about 0.5 mm into the bulk (Fig. 8) over the entire length of the crystal segment. Actually, these inhomogeneities within the peripheral facet region were identified as off-facet growth penetrations into the facet regions and are due to differences between the on-facet and off-facet distribution coefficient. As such they are not conventional impurity striations which are caused by variations of the growth rate and/or of the boundary layer thickness.

In the crystals regrown during ground-based testing, peripheral (111) faceting could be observed only in a few instances and at isolated locations, although the morphology of the growth interface was the same as in the space-grown crystals. Since peripheral faceting is commonly observed in nonconfined growth configurations (as in Czochralski growth) the present observation of pronounced peripheral (111) faceting in the space-grown material may be considered as indicative of virtually unconfined solidification conditions.

Compositional inhomogeneities of significant magnitude were observed in all space-grown crystals in portions formed during the late stages of growth, in which the crystal-melt interface approached and entered the graphite cup (Fig. 1). There the compositional inhomogeneities could in all instances be related, through the individual interface demarcation lines, to morphological changes of the interface caused by pronounced changes in thermal conditions. Such changes were brought about by the difference in the thermal conductivities of the confining materials (in going from quartz to graphite). The observed morphological changes resulted in interface instabilities followed by interface breakdown. Although no detailed analysis of the interface instabilities has been carried out, it is seen in Fig. 9 that their morphological characteristics conform much more to theoretical predictions than those observed in crystals grown on earth (12).

Quantitative analysis of crystal growth behavior.—The following analysis is based on data obtained from demarcation lines of the crystal-melt interface introduced at intervals of 4 sec during growth. The accuracy of the growth rate data (about ±0.1 μm/sec) is determined by the precision with which the spacings of consecutive demarcation lines could be determined by interference contrast microscopy.

The microscopic rate of growth along the growth axis for the first 2 cm of solidification in space, brought about by a constant cooling rate of 2.4°C/min in the heat leveler regions, is presented in Fig. 10. It is seen that the growth rate is transient at all times, increasing rapidly from zero to 8 μm/sec over the first 10 min and gradually approaching the value of 10 μm/sec during the ensuing growth period. No fluctuations in the growth rate are observed in any portion of the growth region (the scatter of the measurement points falls within the experimental error limits).

From growth experiments carried out in the same growth apparatus under stabilizing vertical thermal gradients on earth it was found that the microscopic growth behavior on earth is, within experimental error, the same as that observed in space. Thus, while unavoidable laminar convection in the melt on earth interferes with the segregation process (see below), it

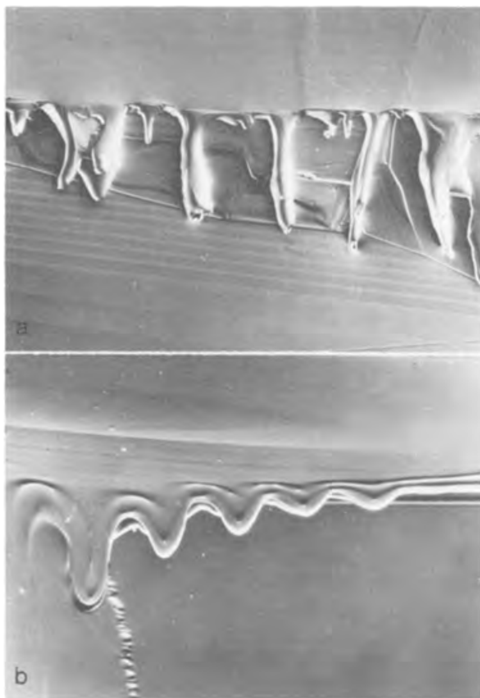

Fig. 9. Advanced stage of interface instability in germanium crystals grown (a) on earth; (b) in space.

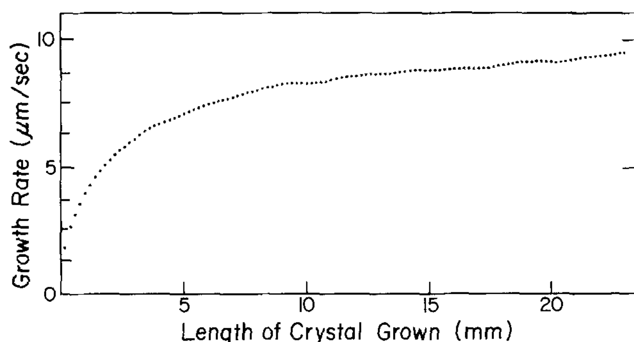

Fig. 10. Microscopic growth rate profiles along the middle of germanium crystals grown in multipurpose furnace. Profiles for growth in space and on earth are the same.

has no significant effect on the microscopic crystal growth rate.

Since the growth interface was found to be nonplanar and since its morphology changed with continuing growth (see below), it was considered necessary to determine also the microscopic growth rates on the peripheral regions of the longitudinal crystal segment (0.5 mm from the left-hand side and right-hand side edges). The growth rates at the left- and right-hand sides of the longitudinal segment are plotted as a function of distance grown in Fig. 11; distance grown is measured from a normal to the growth axis arbitrarily positioned in the uncontrolled-growth region. Thus, the plots reflect the asymmetry of the interface about the growth axis and show that the microscopic growth behavior of the two peripheral regions was different during the initial and during the late stages of growth.

The effect of the differences in the peripheral rates of growth on the morphology of the growth interface is seen in Fig. 12 where the difference of growth length ($\Delta x = x_{left} - x_{right}$) is plotted as a function of time of growth. Since the growth length (x) is measured from a normal to the growth axis, as indicated above, the Δx values reflect the deviation of the interface from a planar morphology. It is seen that originally the left-hand side of the interface was more advanced (into the melt) than the right-hand side. This asymmetry was reduced significantly during the first 500 sec of growth as a result of a larger growth rate at the right-hand side of the interface. The interface morphology remained virtually unchanged during the ensuing growth period of about 1300 sec but after 1900 sec of elapsed time a retardation of the growth rate on the right-hand side (Fig. 11) led to a significant change of the interface morphology.

The characterization of the dynamics of the interface morphology was pursued further by ascertaining the interface shape through the determination of the coordinates of up to 10 points lying on individual interface demarcation lines at varying distances from the original regrowth interface (Fig. 13). It is seen that the original melt-back interface is indeed asymmetric and that the uncontrolled growth during the equilibration period did not result in any noticeable changes in the morphology of the solid-melt interface. With the onset of controlled cool-down the interface morphology underwent rapid changes as evidenced by the shape of the demarcation lines 2 and 3 positioned 0.2 and 5 mm below the regrowth interface, respectively. At the 5 mm position the interface was concave (viewed from the melt) and nearly symmetric; it remained essentially unchanged for a total growth length of 15 mm (demarcation line 5). With continued growth (1900-3300 sec) a progressively increasing change of the interface morphology occurred (demarcation lines 6 and 7) as a result of a decrease of the growth rate on the right-hand side peripheral region of the crystal (see Fig. 11 and 12). During this change the interface apex shifted from the center of the crystal to the periphery.

The above behavior of the crystal-melt interface can be directly related to the thermal environment of the growth system. Thus, it was observed that the seed crystal was not concentrically located within the quartz ampul. Consequently the initial interface was asymmetric and on regrowth the crystal diameter increased asymmetrically, *i.e.*, by 0.5 mm at the right-hand side and 0.05 mm at the left-hand side. The establishment of the stable and nearly symmetric concave interface (with a radius of curvature of 5.6 cm) coincides with the growth of the crystal at constant diameter. The growth perturbation which commences at a distance of about 15 mm from regrowth interface

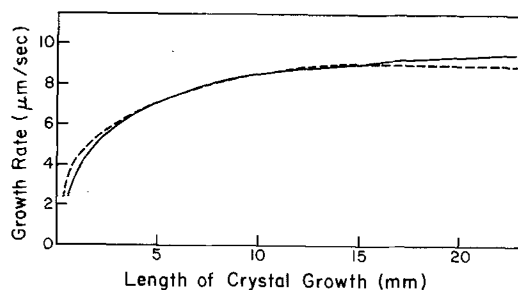

Fig. 11. Microscopic rate profiles along the periphery of germanium crystal grown in space.

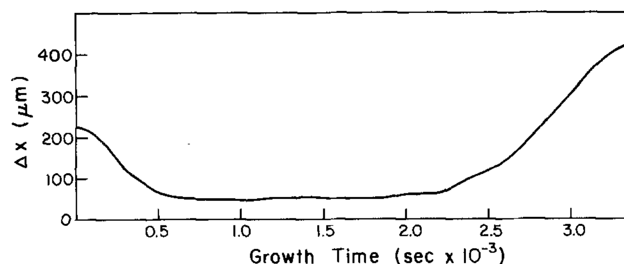

Fig. 12. Difference (Δx) in the peripheral rate of growth as a function of growth time (see text).

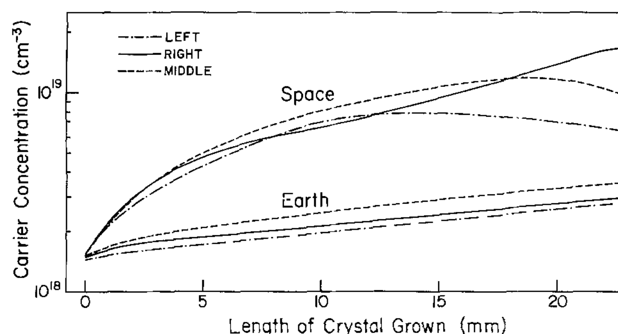

Fig. 14. Longitudinal carrier concentration (dopant) profiles in crystals grown on earth and in space.

coincides with the advancement of the interface from the gradient heating region to the heat leveler region (see Fig. 1) and reflects the changes in the radial thermal configuration within the multipurpose furnace. It is of interest to note that the changes of the interface morphology associated with the changing thermal environment are less pronounced in the ground-based growth experiments.

On the basis of the present growth analysis it is evident that within the gradient-heated region, crystal growth in space proceeded with a stable interface configuration. All observed growth perturbations are accounted for by deficiencies in the thermal characteristics of the growth apparatus.

Quantitative segregation analyses.—Before proceeding with the segregation analysis, the redistribution of Ga in the melt during the 2 hr period of thermal equilibration preceding controlled growth is considered. Taking the average temperature of the melt as 1050°C and the diffusion coefficient of Ga as 2×10^{-4} cm²/sec, the minimum diffusion distance ($\sqrt{Dt}$) of Ga is approximately 1.2 cm in the absence of convection. Accordingly all compositional inhomogeneities in the melt resulting from rotational striations and radial segregation effects in the original earth-grown crystal were eliminated prior to resolidification.

The average concentration of Ga in the earth-grown crystal increased linearly by +5.2 %/cm from the cold seed, where the Ga concentration was 1.3×10^{19}/cm³, to the hot end where the concentration was 1.88×10^{19}/cm³ as determined from Hall-effect measurements). From these data the equilibrium Ga concentration in the melt (complete homogenization), with the seed-melt interface located 3.9 cm from the cold end of the crystal, was calculated to be 1.78×10^{19}/cm³. While uncertainties in the published diffusion coefficient values of Ga in Ge melts (15) do not permit precise calculations, approximations indicate that complete homogenization was approached during the equilibration period. This conclusion is consistent with the fact that in ground-based regrowth experiments, involving crystals of the same macrosegregation profile as those used in space, the composition of the initial portions resolidified were found to have the same Ga concentration as the initial portions resolidified in space (see Fig. 14). In the ground-based experiments compositional homogenization of the melt during the 2 hr thermal equilibration must be considered as having been complete because of the presence of laminar convection which was confirmed by segregation analyses.

The macroscopic segregation behavior is discussed below. Microscopic segregation effects observed on earth and in space are presented in the Appendix.

The segregation analyses of the crystals grown on earth and in space are based on longitudinal and radial composition profiles obtained with 10 μm spatial resolution by spreading resistance scans of longitudinal crystal slices which contained the growth axis. The corresponding growth rate data were obtained as discussed above.

For a direct comparison of dopant redistribution associated with growth on earth and in space, corresponding longitudinal composition profiles are presented in Fig. 14; the microscopic growth rates were presented in Fig. 10. Since both growth experiments were carried out under identical thermal and geometrical conditions, the observed differences in composition reflect directly the effect of gravity-driven convection on segregation. It is seen that for growth on earth the longitudinal increase of the dopant concentration is small and remains essentially constant after a short initial period during which transient segregation behavior is observed. These composition profiles also indicate radially asymmetric segregation which develops during the initial growth and remains virtually unchanged. In contrast, in space, the longitudinal dopant concentration increases rapidly with transient segregation over the entire growth length; radial segregation develops less rapidly than on earth but increases with continuing growth and exhibits pronounced variations.

Segregation on earth.—All features of the composition profiles obtained from the ground-based growth experiment are consistent with convection-controlled segregation, which is amenable to quantitative analysis on the basis of the normal freezing equation (2)

$$\ln \frac{C_s}{C_L} = \ln k_{eff} + (k_{eff} - 1) \ln (1 - f)$$

where C_s is the dopant concentration in the solid for a given fraction f solidified, C_L is the dopant concentration in the melt, and k_{eff} is the effective distribution coefficient.

In view of the radially nonuniform dopant distribution (Fig. 14), transverse compositional profiles were determined at 0.5, 1.0, 1.5, and 2.0 cm from the original regrowth interface to obtain the average Ga concentration values (C_s) for four different fractions (f) of melt solidified. The plot of ln C_s/C_L *vs.* ln $(1-f)$ in Fig. 15 shows full compliance with the nor-

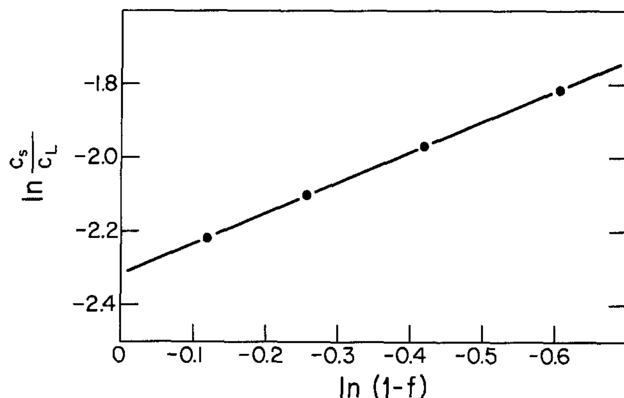

Fig. 15. Segregation analysis for crystal grown on earth

mal freezing equation and thus establishes the existence of convection-controlled segregation with a constant effective distribution coefficient ($k_{eff} = 0.099$) over the entire growth distance. Thus, on earth even under stabilizing vertical thermal gradients unavoidable radial thermal gradients constitute a driving force for the establishment of convection in the melt. The fact that the effective distribution coefficient remained constant indicates that the convective melt flow was virtually unchanged while the aspect ratio of the melt (height/diameter) changed from about 5 to 2.5.

While inadequate knowledge of the radial thermal gradients does not permit a quantitative analysis of the prevailing laminar convection, it is of interest to compare the effects of this laminar free convection on segregation with those of forced convection such as encountered during Czochralski-type growth. According to the BPS model (1) an effective distribution coefficient of 0.099 associated with an average solidification rate of 8 μm/sec requires a solute boundary layer thickness of 300 μm. Using the Cochran analysis (16) for forced convection associated with crystal rotation it is found that the mixing effect due to the laminar free convection in the ground-based experiments is equivalent to forced convection resulting from a seed rotation of 10 rpm.

Segregation in space.—A comparison of the composition profiles of the space-grown crystal (Fig. 14) with the corresponding growth rate profile (Fig. 11) shows that for the growth length in excess of 8 mm neither the radial nor the longitudinal segregation were directly controlled by the microscopic rate of growth. Thus, with a steadily increasing growth rate which was essentially the same on the left- and right-hand side, the dopant concentration in the crystal decreased on the left-hand side from $8 \times 10^{18}/cm^3$ to $6.5 \times 10^{18}/cm^3$ while at the same time it increased on the right-hand side to $1.9 \times 10^{19}/cm^3$. The observed segregation pattern is, furthermore, at variance with melt convection effects. Thus, when the equilibrium distribution coefficient is less than one (as in the present case) convective interference results invariably in a decrease of dopant accumulation within the diffusion boundary layer and, consequently, the value of the effective distribution coefficient will exceed by a small amount the value of k_0 but will remain significantly less than one as observed during growth on earth. Therefore, the observed dopant concentration increase to $1.9 \times 10^{19}/cm^3$, which corresponds to an effective distribution coefficient in excess of one, is in direct contradiction with convection effects.

The segregation behavior, while inconsistent with growth rate and convective effects, can be explained if the morphological characteristics of the crystal-melt interface are taken into consideration. Thus, for growth with diffusion-controlled segregation any deviation of the crystal-melt interface from a planar configuration is expected to result in radially nonuniform dopant incorporation since the diffusion dopant flux into the melt exhibits lateral components which lead to radial compositional variations at the curved growth interface. Accordingly, for a concave (into the crystal) interface the dopant concentration must be higher in the central than in the peripheral part of the crystal. On this basis, the radial segregation shown in Fig. 14 is consistent with the morphological characteristics of the growth interface shown in Fig. 13. Thus, at the onset of controlled regrowth (demarcation 1 in Fig. 13), in the absence of a solute boundary layer, radial segregation must be expected to be uniform. With continuing growth the interface becomes slanted to the left-hand side (demarcation 2) and the associated lateral diffusion flux to the right causes the dopant concentration to become somewhat smaller in the left-hand side of the crystal than in the center and in the right-hand side. After about 20 mm of growth (*e.g.*, demarcation lines 6 and 7) the pronounced shift of the interface apex to the right causes the concentration in the right-hand side regions to become even higher than that of the central region. At the same time the concentration in the central region begins to decrease but continues to remain higher than that on the left-hand side region.

It should be noted that the radial segregation behavior for growth on earth appears also consistent with interface morphology effects. Thus, the concave crystal-melt interface was found to be asymmetric with its apex shifted to the right-hand side of the crystal axis and the dopant concentration was found to be higher in the right-hand side peripheral region. The less pronounced and nearly constant radial segregation effect reflects decreased sensitivity of the interface morphology to thermal perturbations due to the presence of laminar convection which in turn is also responsible for the establishment of a decreased and constant boundary layer thickness.

In view of the fact that no theoretical treatment of segregation at curved interfaces has as yet been developed, it is not possible to analyze the observed radial segregation effect on a quantitative basis. However, considering the origin of radial dopant concentration gradients it appears appropriate to analyze the macrosegregation behavior by averaging the radial compositions and applying the theory for diffusion-controlled segregation as developed for plane front solidification (3). It is recognized that any such two-dimensional analysis of a three-dimensional cylindrical system is inherently limited; however, the potential error associated with the asymmetry of the growth interface is not considered major.

The averaged longitudinal composition profile of a space-grown crystal is presented together with that of an earth-grown crystal in Fig. 16. Here again the initial increase of the dopant concentration as well as its gradual approach to a steady-state value during growth in space are indicative of the absence of convective interference. When considering the various theoretical approaches to diffusion-controlled segregation (3, 17-20), it was found that for the present experimental conditions the treatment by Tiller *et al.*

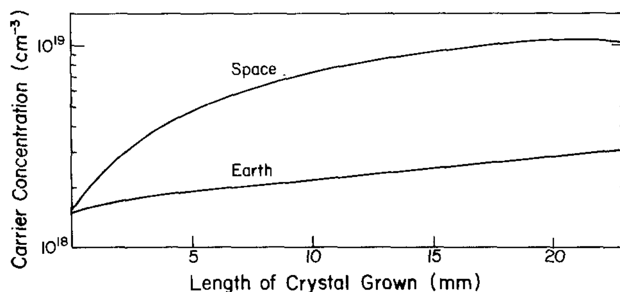

Fig. 16. Averaged longitudinal carrier concentration (dopant) profiles on crystals grown on earth and in space.

(3) can most conveniently be applied, although one of the assumed boundary conditions, *i.e.*, constant rate of growth, is not met in the present system (Fig. 10). Actually, initial growth rate transients are virtually unavoidable in directional solidification because of heat transfer considerations. To make the theory applicable, a numerical approach based on an implicit finite difference equation (21) has been used to account for the growth rate transient. These calculations yielded a compositional profile which was significantly different during the initial transient region from that obtained assuming a constant growth rate, but it was in good agreement for growth distances in excess of 1 cm.

According to theory (3), the dopant concentration (C_s) at a distance x (presently valid for $x > 1$ cm only) from the original regrowth interface is given by the expression

$$C_s = C_L \left\{ (1 - k_o) \left[1 - \exp\left(-\frac{k_o R x}{D} \right) \right] + k_o \right\}$$

The applicability of the above expression to the present segregation data was tested over the growth distance of 1-2 cm by taking the average growth rate, $R = 8.5$ μm/sec and $C_L = 1.78 \times 10^{-4}$ cm^{-3}, $k_o = 0.087$, and the generally accepted (15) value of $D = 1.9 \times 10^{-4}$ cm^2 sec^{-1}. The experimental and theoretical values of C_s, for $x = 1.0$, 1.5, and 2 cm, are presented in Table I (in the second and third column, respectively). It is seen that the agreement between theory and experiment for growth distance beyond 1 cm is remarkably good.

It should be noted that the theoretical C_s values (for $D = 1.9 \times 10^{-4}$ cm^2/sec) are consistently smaller than the corresponding experimental values, which implies that the increase in dopant concentration in Ge during growth in space is faster than predicted for diffusion-controlled segregation. If the present analytical approach is quantitatively correct, then a more accurate value for the diffusion coefficient of Ga in Ge melts is 1.7×10^{-4} cm^2/sec as seen in Table I (third column). While this conclusion may be of questionable validity in view of the difference in assumed and actual boundary conditions, it is apparent that with the appropriate theory for diffusion-controlled segregation, directional solidification experiments in space provide a means for the determination of precise diffusion coefficients which are presently unavailable.

It is recognized that the above quantitative segregation analysis is based on assumptions which require further theoretical and experimental study. However, the self-consistency of all aspects of dopant distribution in the space-grown crystal with diffusion-controlled segregation confirms the absence of any convective interference with the segregation process.

Summary

The crystal growth and segregation behavior in space were quantitatively studied by growth of Ga-doped Ge single crystals. The growth experiments in space were complemented by experiments on earth (carried out in the same system under stabilizing vertical thermal gradients) to permit a comparative analysis of gravitational effects.

Crystals grown in space exhibited a network of surface ridges which reduced the contact area with the confining quartz ampul to less than 1%. A coherent peripheral (111) growth facet, characteristic of unconfined growth, persisted over the entire growth length.

It was established that, in space, diffusion-controlled segregation prevailed with no convective interference from residual gravity, G-jitter, or surface tension gradients. Radial variations in dopant concentration were found to be a direct consequence of the nonplanar morphology of the growth interface which causes diffusion-driven dopant redistribution within the diffusion boundary layer.

Through interface demarcation thermal drift during equilibration of the system and deviations of the growth interface from planar morphology were identified; they were found to be a direct consequence of deficiencies in the thermal characteristics of the growth apparatus and demonstrate the extreme sensitivity of solidification to the thermal environment under diffusion-controlled conditions.

The present study shows that the reduced gravity environment provided in space permits the establishment of solidification conditions under which basic experimental information can be obtained which is essential for advancing our understanding of crystal growth and segregation. It is finally concluded that compositionally homogeneous materials can be achieved in space.

Table I.

x (cm)	C_s (exp) Ga · cm^{-3}	C_s (theor) Ga · cm^{-3} ($D = 1.9 \times 10^{-4}$ cm^2/sec)	C_s (theor) Ga · cm^{-3} ($D = 1.7 \times 10^{-4}$ cm^2/sec)
1.0	7.4×10^{18}	6.8×10^{18}	7.3×10^{18}

APPENDIX

Microscopic Segregation Effects

Segregation associated with uncontrolled regrowth during thermal equilibration.—It was shown that uncontrolled regrowth ranging in length from 200 to 800 μm took place in all growth experiments during thermal equilibration. Attempts to determine quantitatively the growth rates of these regions through interface demarcation were unsuccessful since the spacing of demarcation lines is below optical resolution. The growth rate could, however, be estimated to be about 0.1 μm/sec from the measured time-dependent temperature change in the heat extraction system.

The compositional profiles for uncontrolled-growth regions formed on earth and in space are presented in Fig. 17. It is seen that the Ga concentration in these regions fluctuates and assumes average values of 1.85 $\times 10^{18}$ and 2.1×10^{18}/cm^2, for growth in space and on earth, respectively. It is seen further that the Ga concentration in these regions drops ultimately to 1.55×10^{18}/cm^3, which is the expected equilibrium value ($k_o C_L$) observed at the onset of controlled regrowth. Thus, it appears that during uncontrolled growth nonequilibrium segregation takes place whereby dopant accumulation to levels of 2.1 and 2.4×10^{19}/cm^3 at the crystal-melt interface raises the distribution coefficient to 0.11 and 0.12, respectively. The existence of such an accumulation layer at the growth interface is also consistent with the appearance of compositional fluctuations of up to ±3%. While the observed segregation behavior can be explained through the existence of an accumulation layer, the formation of such an accumulation layer as well as its stability over a period of about 1 hr cannot as yet be explained. Thus, diffu-

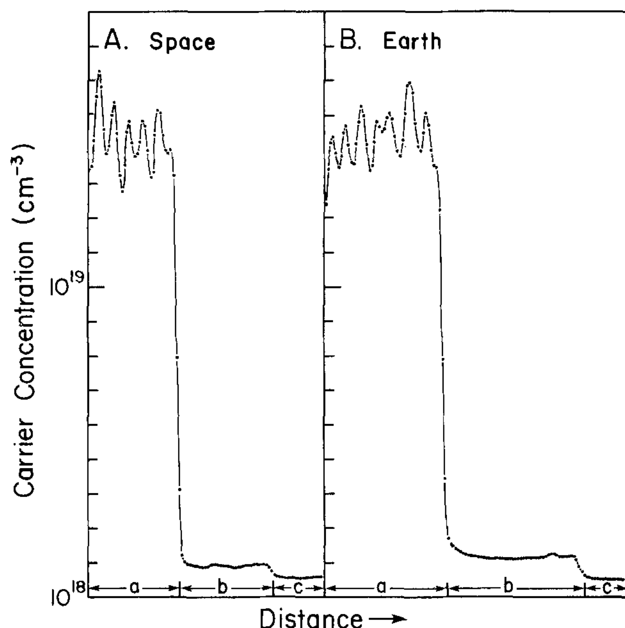

Fig. 17. Carrier concentration (dopant) profiles in uncontrolled growth regions (b) and adjacent seed (a) and controlled regrowth (c) regions of crystals grown in space and on earth.

sion from the seed crystal into the melt can neither account for the dopant accumulation at the growth interface, nor can the accumulation be attributed to electromigration effects (associated with current pulsing) since polarity reversal did not affect the composition within the uncontrolled growth region.

Facet effect.—Interference contrast microscopy of the etched Ge crystal grown in space revealed coherent peripheral (111) facet formation over the first 3 cm of regrowth, during which the growth interface was concave (as viewed from the melt). In addition, extensive central (111) faceting was observed during the later stages of growth (growth distance > 2.5 cm) as a result of changing thermal conditions. For both types of faceting the corresponding segregation behavior was quantitatively analyzed over regions where the microscopic growth rate normal to the crystal-melt interface was identical in the facet and in the adjacent off-facet region and where the facet regions were laterally expanding, *i.e.*, under conditions where the diffusion-boundary layer thickness was identical in the facet and the off-facet regions. The measurements give a ratio [k_{eff} (on-facet)/k_{eff} (off-facet)] of 0.94 indicating that the interface distribution coefficient (k_i) for facet growth differs from that for off-facet growth.

Effects of Diffusion-Induced Strain and Dislocation on Phosphorus Diffusion into Silicon

Satoru Matsumoto, Yasushi Akao, Kiyoyuki Kohiyama, and Tatsuya Niimi

Department of Electrical Engineering, Keio University, Hiyoshi, Yokohama 223, Japan

ABSTRACT

The diffusion-induced strain and dislocation effects on the diffusion of phosphorus into silicon have been investigated. When phosphorus is diffused singly, the diffusion coefficient of phosphorus increases considerably at high concentrations. While, when phosphorus and germanium are diffused simultaneously, fewer dislocations are observed and the diffusion-induced strain is compensated. In strain-compensated diffusion, concentration profiles of phosphorus agree well with the theoretical curves (erfc). It is shown that the enhancement of the diffusion coefficient of phosphorus at high concentrations is attributed to the diffusion-induced strain. Besides, dislocations retard the diffusion front by absorbing excess vacancies, showing the opposite effect of strain.

Effects of diffusion-induced dislocations on diffusion of impurities into silicon have been studied extensively by many investigators. They have reported that diffusion of phosphorus above a certain critical surface concentration or a total amount of dopant causes the generation of dislocations in the diffused region (1, 2). A generation mechanism of excess vacancies due to the climbing motion of such dislocations is proposed to explain the marked enhancement of the diffusion coefficient and emitter-push effect (3, 4). These anomalous phenomena are, how-

Key words: semiconductor, doping, diffusion.

ever, observed in the absence of dislocations (5-7). A retardation of phosphorus diffusion, which is related to the formation of dislocations, is found (8, 9). Excess vacancies generated by phosphorus diffusion are absorbed by diffusion-induced dislocations (10). The generation of dislocations is avoided by the simultaneous diffusion of tin and boron or tin and phosphorus, in spite of diffusion of high surface concentration above the critical value of boron or phosphorus (11, 12).

In this article, to make the effect of dislocations on phosphorus diffusion into silicon clearer, the dependence of the diffusion coefficient of phosphorus on the dislocation density is studied. Furthermore, phosphorus diffusions under conditions of strain compensation due to the simultaneous diffusion of phosphorus and germanium into silicon are investigated. By comparison of the respective diffusion coefficients of phosphorus, which are obtained in the single diffusion of phosphorus and in the simultaneous diffusion of phosphorus and germanium, an effect of diffusion-induced strain on phosphorus diffusion is discussed.

Experimental procedure.—The substrates used were Czochralski-grown p-type dislocation-free silicon wafers of resistivity 1 ~ 3 Ω·cm. They were (111) oriented and were mechanically and chemically polished. Diffusions of phosphorus and germanium into silicon were done with the open-tube system (13) using liquid diffusion sources of phosphorus oxychloride ($POCl_3$) and germanium tetrachloride ($GeCl_4$), respectively. The molar ratio of partial pressure of $POCl_3$ in the total gas stream for the simultaneous diffusion of phosphorus and germanium was regulated to be equal to that of the single diffusion of phosphorus, which was 0.2. The molar ratio of $GeCl_4$ in the total gas stream was also 0.2. Both temperatures of $POCl_3$ and $GeCl_4$ sources were held at 0°C. Vapor pressures of $POCl_3$ and $GeCl_4$ at 0°C are 9 and 23 mm Hg, respectively (14). Diffusions were carried out at 1100°C for 5 min-24 hr in the single diffusion and for 5-60 min in the simultaneous diffusion. The density of diffusion-induced dislocations in the single diffusion was controlled by the diffusion times, that is, the total amount of dopant.

Phosphorus concentrations in the substrate were determined by repeating the measurement of sheet resistivity and anodic oxidation in conjunction with Irvin's curve (15, 16). The average thickness of a thin layer removed by each run of anodic oxidation and HF etching was 240 ± 10Å. It was obtained by measuring the height between the original surface and the surface which was oxidized after ten times oxidation of a dummy wafer, using the interferometer (17). Junction depths were measured by the interferometer after angle lapping and chemical etching. Diffusion-induced dislocations in the surface region were observed by Sirtl etching for 15 ~ 60 sec (18). Dislocation density was determined by counting the number of etch pits at three points on wafer. Germanium concentrations in the substrate were obtained by SIMS (secondary ion mass spectroscopy).

Results

Figure 1 shows the dislocation density as a function of the diffusion time obtained for the single diffusion of phosphorus. The spread of the dislocation density in the figure for 10 and 30 min is due to nonuniformity of the dislocation density across the wafer. The dislocation density shows a tendency to saturate with the increase of the diffusion time, although the dislocation density of 8 hr or more cannot be estimated. At a diffusion time of 8 hr or more, large clusters made by dense dislocation etch pits, which have a diameter of approximately 400 μm, are observed by Sirtl etching.

To avoid the confusion of the figure, three concentration profiles of 5, 30, and 120 min are chosen for

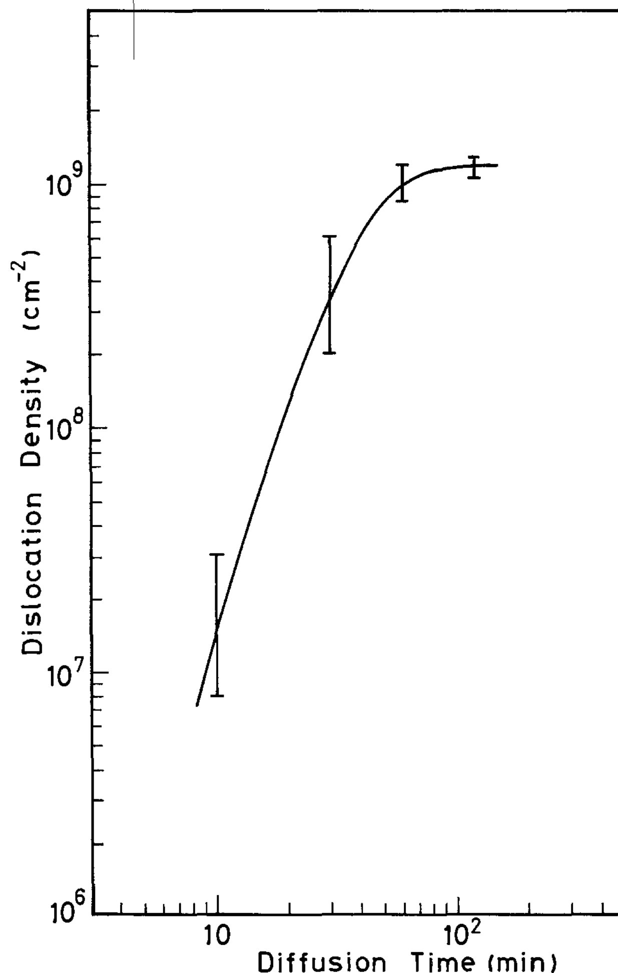

Fig. 1. Dislocation density vs. diffusion time

the single diffusion. These are illustrated as a function of $x/t^{1/2}$ in Fig. 2, where x is the depth from the surface and t is the diffusion time. Plots at the concentration of 10^{17} cm^{-3} are the data obtained by angle lapping. Junction depths obtained by anodic oxidation and by angle lapping agree well. It is found that concentration profiles of phosphorus move inside in the lower concentration region with the increase of the diffusion time. This result means that a retardation of phosphorus diffusion is seen at the diffusion front with the dislocation density. Moreover, junction depths are shown in Fig. 3 as a function of the diffusion time. The broken line in Fig. 3 has a slope of $t^{1/2}$. Junction depths obtained within 2 hr have a smaller slope than that of $t^{1/2}$, showing the retardation of phosphorus diffusion. In order to investigate the relationship between the dislocation density and the diffution coefficient, the diffusion coefficient is determined by the computer simulation from the concentration profile in Fig. 2. The computer simulation is the same method as that previously described (19). Diffusion coefficients thus obtained are shown in Fig. 4 as a function of phosphorus concentration at the points in the bulk. Irrespective of the generation of dislocations, the diffusion coefficient increases considerably with the local concentration of phosphorus above 10^{20} cm^{-3} and has a constant value at lower concentrations. It is also shown from Fig. 4 that the diffusion coefficient decreases in the lower phosphorus concentration region with the increase of the dislocation density (diffusion time).

Figures 5 and 6 show examples of Sirtl etch patterns on the surface of wafers in the single and in the simultaneous diffusions. In the single diffusion of phosphorus, no dislocations are observed for 5 min. Dislocations are, however, generated for 10 min (Fig. 5a) and slip patterns are observed for 30 min (Fig.

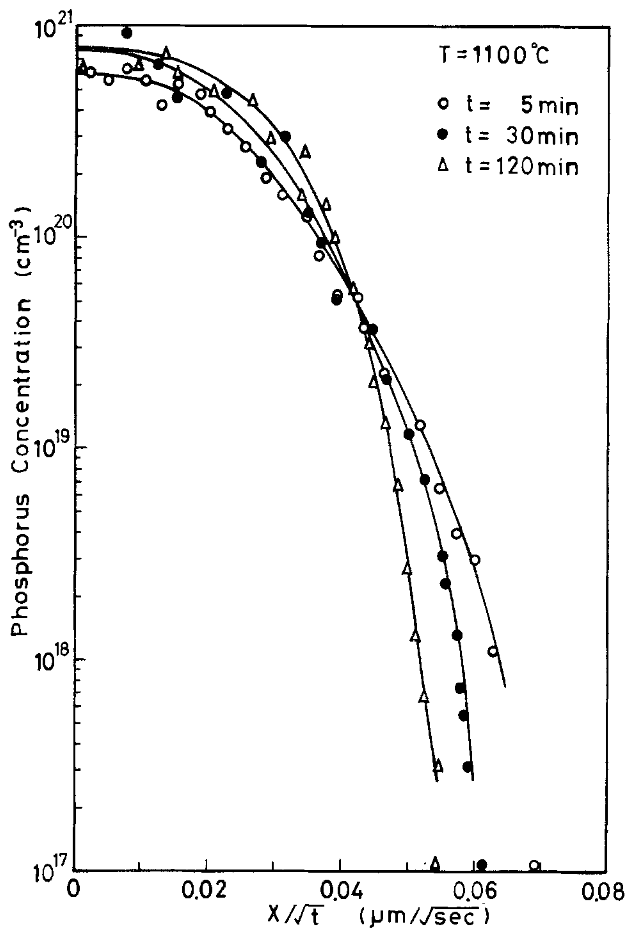

Fig. 2. Concentration profiles of phosphorus as a function of $x/t^{1/2}$ obtained from the single diffusion of phosphorus.

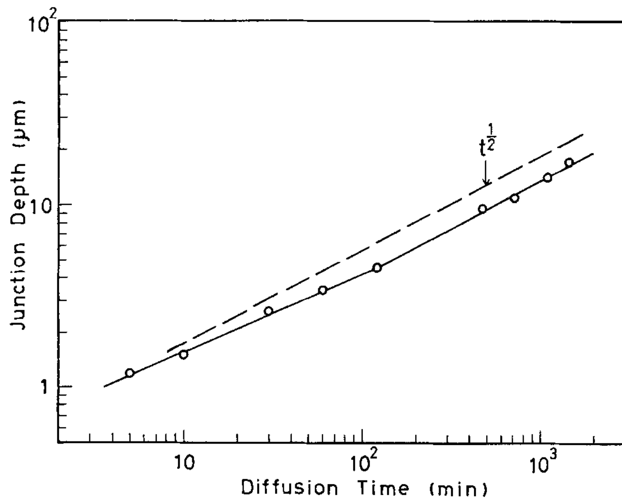

Fig. 3. Junction depth vs. diffusion time. A broken line has a slope of $t^{1/2}$.

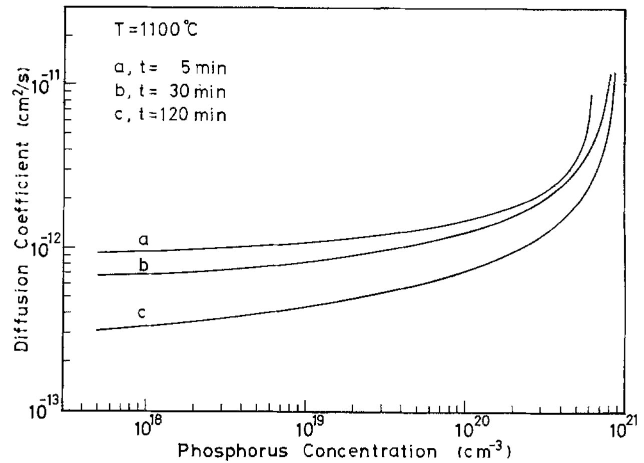

Fig. 4. Diffusion coefficient vs. phosphorus concentration with a parameter of diffusion time (dislocation density) obtained from the single diffusion of phosphorus.

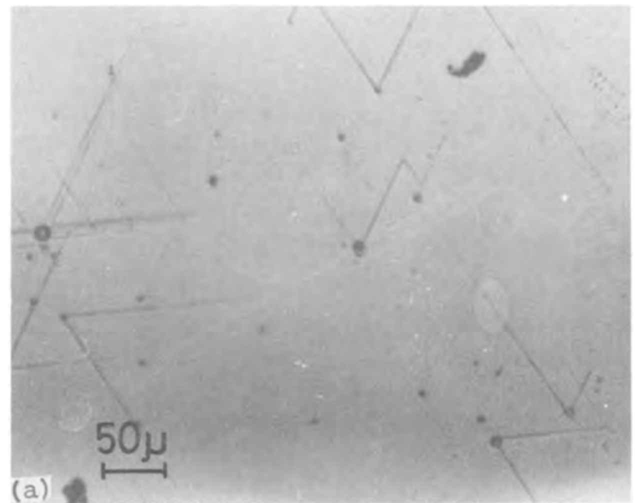

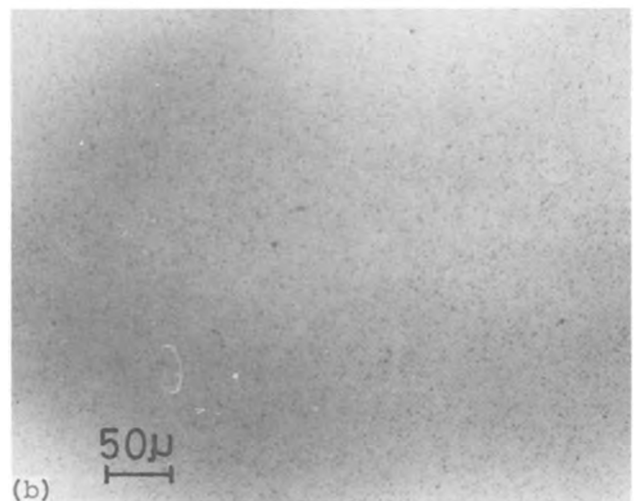

Fig. 5. Sirtl etch patterns for 10 min. (a) Single diffusion of phosphorus; (b) simultaneous diffusion of phosphorus and germanium.

6a). The dislocation densities in such cases are already shown in Fig. 1. In the simultaneous diffusion of phosphorus and germanium, no dislocations are generated for 10 min (Fig. 5b), as well as the case for 5 min. It is also seen that few dislocations are generated for 30 min (Fig. 6b). It has been reported that the sign of the lattice contraction coefficient of germanium in silicon is inverse to that of phosphorus in silicon (20). Therefore, it is considered that lattice strain produced by the incorporation of phosphorus is compensated by the simultaneous incorporation of germanium into silicon.

Figure 7 shows an example of a concentration profile of phosphorus obtained from the simultaneous diffusion for 30 min. In Fig. 7, a concentration profile of phosphorus obtained from the single diffusion for the same diffusion time is also shown. The profile of the single diffusion deviates largely from the theoretical curve (erfc) and the diffusion coefficient depends on the local concentration as described before. On

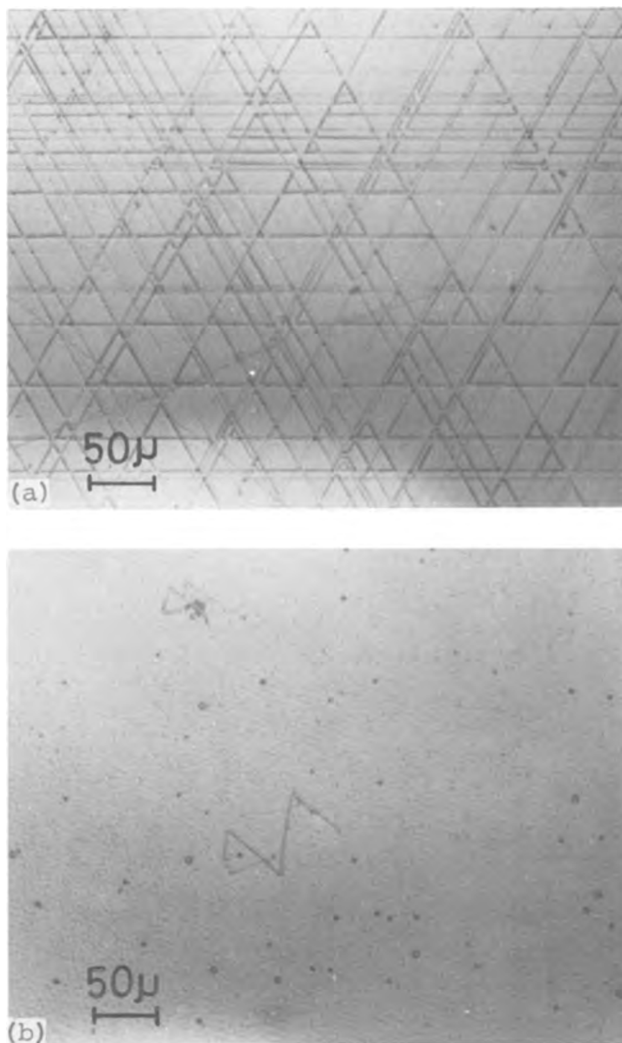

Fig. 6. Sirtl etch patterns for 30 min. (a) Single diffusion of phosphorus; (b) simultaneous diffusion of phosphorus and germanium.

the other hand, the profile of the simultaneous diffusion agrees well with the erfc curve. The value of the diffusion coefficient is given in the figure. A concentration profile of germanium (Ge^+ ion relative intensity) of the simultaneous diffusion for 30 min is shown in Fig. 8. Concentrations are measured at the surface at the depth of 0.3 and 0.6 μm. The broken curve in the figure shows the erfc curve. Concentration profiles of the simultaneous diffusion for other diffusion times (5 and 10 min) also agree well with the erfc curves, whereas the profile obtained for 60 min in the simultaneous diffusion does not agree with the erfc curve. As for this case, dislocations are observed. Thus, this disagreement is considered to be due to the reason that the lattice strain is not compensated sufficiently. Consequently, in strain-compensated diffusion, concentration profiles agree well with erfc curves and the local concentration dependence of the diffusion coefficient is not seen in spite of high surface concentration.

Discussion

Enhancement of the diffusion coefficient.—Diffusion coefficients are schematically illustrated as a function of phosphorus concentration in Fig. 9 based on the result shown in Fig. 7. D_p and $D_{p \cdot Ge}$ are the diffusion coefficients of phosphorus determined from the single and the simultaneous diffusions, respectively, and D_i is the extrapolated value of the intrinsic diffusion coefficient of phosphorus at the diffusion temperature (6×10^{-14} cm^2/sec at 1100°C) (21). It is found that D_p increases considerably at high concentrations and also is larger than D_i over the whole local phosphorus concentrations. The difference between D_p and D_i consists of the two parts, that is, the difference be-

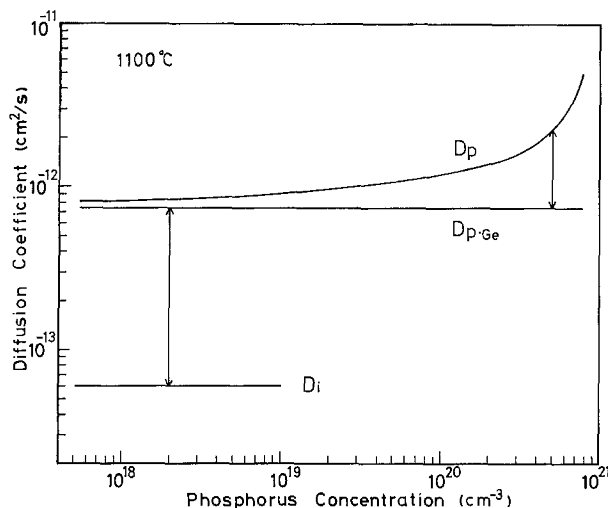

Fig. 9. Schematic illustration of diffusion coefficient as a function of phosphorus concentration.

tween D_p and $D_{p\cdot Ge}$ and the difference between $D_{p\cdot Ge}$ and D_i. That D_p or $D_{p\cdot Ge}$ are larger than D_i means excess vacancies are generated in comparison with the vacancy concentration at thermal equilibrium corresponding to D_i.

The value of D_p in the lower concentration region is nearly equal to that of $D_{p\cdot Ge}$, which is constant. Therefore, it is clear that the difference between D_p and $D_{p\cdot Ge}$, that is, the enhancement of D_p at high concentrations, is attributed to the excess vacancies generated by the strain, and this strain effect is localized. On the other hand, the generation of these excess vacancies has no relationship with dislocations since diffusion-induced dislocations were not observed for short diffusions, while the diffusion coefficient was concentration dependent (see Fig. 1 and 4). From this result, the plastic deformation model (22) based on the interaction between dislocations, which has been proposed to explain the enhancement of the diffusion coefficient of phosphorus at high concentrations, is not considered to be adequate. It is premature to establish a tangible model to explain the difference between D_p and $D_{p\cdot Ge}$. A possible mechanism of the generation of excess vacancies is, however, considered; excess vacancies are generated in order to relax the strain energy due to the incorporation of a large number of impurities (23). This is equivalent to the reduction of the formation energy of vacancy with the increase of impurity concentration, and may be localized. It has been reported, in fact, that the formation energy of vacancy decreases exponentially with the bulk impurity concentration (24). Their empirical equation for the reduction of the formation energy of vacancy is, however, not applicable for the present work.

The difference between $D_{p\cdot Ge}$ and D_i cannot be caused by the strain, because $D_{p\cdot Ge}$ is obtained under strain compensation. It can be seen that the difference is present even at lower concentration and has a dominant factor in the enhancement of the diffusion coefficient D_p. It was shown that the excess vacancies generated by high concentration diffusion of phosphorus extended deeply into the bulk to a depth of at least ~25 μm beyond the diffused region (10). Therefore, the difference between $D_{p\cdot Ge}$ and D_i is due to the presence of the excess vacancies in the deep region. Though the generation mechanism of the excess vacancies is not conclusive, it is considered that the excess vacancies are generated by the dissociation of E centers (phosphorus atom-vacancy pairs) based on the E center diffusion mechanism (6, 25).

Retardation of phosphorus diffusion.—The enhancement of the diffusion coefficient is not attributed to the climb motion of dislocations as described before. Therefore, the mechanism based on the prevention of the dislocation movement by the dislocation network may be inadequate to explain the retardation of phosphorus diffusion. Precipitations of phosphorus atoms at the dislocations may cause the retardation of phosphorus diffusion (26). However, since this effect is considered to be localized in the higher concentration region, it is difficult to manifest the result shown in Fig. 4, in which the diffusion coefficient decreases in the lower concentration region.

Previously, it was shown that excess vacancies generated by phosphorus diffusion were absorbed by diffusion-induced dislocations, using a buried layer technique (10). Therefore, it is considered that free excess vacancies, which are generated by the dissociation of E centers, would cause the enhancement of the diffusion coefficient at lower concentration, if they were not absorbed by the diffusion-induced dislocations. This being the case, retardation of phosphorus diffusion at lower concentration is observed, with this effect becoming larger with time.

Conclusions

The diffusion coefficient of phosphorus in silicon decreases in the lower concentration region with the increase of dislocations. This retardation can be related to the absorption of excess vacancies by dislocations. In the single diffusion of phosphorus, the diffusion coefficient of phosphorus increases considerably at high concentrations, while, in the simultaneous diffusion of phosphorus and geranium, fewer dislocations are observed and the diffusion-induced strain is compensated. Under strain compensation, concentration profile of phosphorus agrees well with the theoretical curve (erfc) and the diffusion coefficient of phosphorus ($D_{p\cdot Ge}$) is larger than the extrapolated value of the intrinsic diffusion coefficient (D_i) at the diffusion temperature. It is shown that the enhancement of the diffusion coefficient at high concentrations is attributed to the strain. The difference between $D_{p\cdot Ge}$ and D_i is suggested to be due to excess vacancies generated by the dissociation of E centers.

ABSTRACT

InP-implanted layers have been annealed using the same phosphorus ambient conditions as would be encountered during the material's vapor phase epitaxial growth. Implanted layers so annealed exhibit sheet carrier concentrations up to 5×10^{14} cm^{-2} with the n-type silicon ion and approximately 10^{14} cm^{-2} with the p-type Mg ion. No indication of outdiffusion is seen on layers that have been profiled. Though the annealing was undertaken in an epitaxial reactor, it is envisioned that a much simplified system would also suffice. The present approach provides an alternative to the more customary dielectric encapsulation whose effectiveness is often impaired by deposition variations.

It is well recognized that ion-implanted semiconductors have to be annealed in order to reduce the damage caused by the irradiation and for the implanted ions to become substitutional. In 3-5 compounds it is generally found that the annealing has to be undertaken at such high temperatures that dissociation of the surface will occur. This is normally circumvented in GaAs, the most widely implanted 3-5 compound, by encapsulating the surface with a thin dielectric film such as Si_3N_4.

Another area where thermal erosion of surfaces can cause problems is during epitaxial growth. An interface region at the initiation of the growth that is heavily compensated is frequently encountered. One of the many possible contributing factors to such an inferior initial growth is the condition of the substrate surface and any erosion that might have occurred as the substrate is brought to the growth temperature. In common with implantation annealing, it is desirable to provide a satisfactory means of preserving the surface.

Here, the annealing of implanted layers in InP has been investigated in a hydride epitaxial reactor to take advantage of conditions established for growth. The gas flow conditions normally encountered in epitaxial growth are used with one notable difference in that no HCl is provided to transport the In. Though it is customary to encapsulate surfaces for implantation annealing, other "capless" procedures have previously been reported. Immorlica *et al.* (1) have described the annealing of GaAs while embedded in a crushed mixture of GaAs and graphite, and Lee *et al.* (2) have likewise annealed unprotected GaAs wafers in an open-ended furnace with a H_2 flow over an arsenic saturated liquid Ga/GaAs solution.

Relatively little implantation has been conducted with InP. In a preceding study (3) which parallels the present PH_3 annealing to be described, it was found that useful n-type layers with sheet carrier concentrations in excess of 10^{14} cm^{-2} could be formed. Both sulfur and silicon were implanted and the layers annealed in conjunction with surface encapsulants (principally sputtered Si_3N_4). In a similar study, but employing a phosphosilicate glass, Donnelly and Hurwitz (4) have reported activation in excess of 75% for moderate dose 10^{14} cm^{-2} selenium and silicon implants. In addition, the acceptors Cd, Mg, and Be were also implanted. Mg gave sheet carrier concentrations as high as 5×10^{13} cm^{-2} from 10^{14} cm^{-2} implants. The same phosphosilicate glass was used in annealing the p-type dopants.

Key words: InP, doping, implantation.

Results

The epitaxial reactor is similar to that described by Tetjen *et al.* (5) and consists of a three temperature zone furnace. The single quartz tube is sealed and continuously purged with H_2. The implanted sample is introduced into the third temperature zone through a large orifice stopcock from a separately purgable section. The first temperature zone from where metallic gallium or indium is normally transported is not used while PH_3 and H_2 are introduced into the center mixing zone and flow over the implanted sample in the third zone. It is apparent that a much simplified system without many of the refinements required for epitaxial growth would be adequate for the purpose of implantation annealing.

A PH_3/H_2 ambient with the PH_3 content between 0.75% and 2.1% was used in an initial series of experiments for heat cycling nonimplanted InP specimens to 700°C for 10 min. Often the initial mirror polish on the surface was either not retained or masked by a surface film. Such effects could not be correlated with the amounts of phosphorus present, as the better surfaces were occasionally observed with the lowest PH_3 content. A reflection electron diffraction examination of a thicker appearing film gave a single crystal pattern with a unit cell parameter corresponding to GaP. A thinner appearing film revealed a superimposed InP pattern as well and showed the film to be of the same orientation as the InP substrate below it. A larger unit cell parameter intermediate to InP and GaP was obtained on this thinner film and it is presumed that it corresponds to InGaP. As GaAs

has also been grown in the reactor, Ga is available within the system and it appears that some deposition occurred even though no HCl was being provided for its transportation. Such difficulties have been overcome by only annealing when the reactor is dedicated for this purpose exclusively.

Figure 1 illustrates the beneficial effect of providing a PH_3 ambient while InP is being heated to 750°C for 10 min. The secondary electron emission SEM picture reveals a high density of rectangular etch pits on a sample heated in H_2 alone. These etch pits are characteristic of the <100> orientation being used. The second sample was similarly treated other than an addition of 0.4% PH_3 to the gas flow. It is apparent at the 100X magnification of Fig. 1 that the integrity of the surface is much better retained. At higher magnification (2000X) there is some trace of etch pit formation. For samples heated in gas mixtures with a PH_3 content of 1 1/3-4 1/2% no surface deterioration was visible at 100X. At 2000X an indication was again obtained that etch pits are beginning to form, but they are not well defined and possibly smaller as the PH_3 content is increased.

The first electrical evaluation was undertaken on a series of samples implanted with silicon at 1 MeV. 3×10^{14} ions cm^{-2} were introduced with the InP at RT and the postimplantation annealing was carried out at temperatures ranging from 675° to 800°C. The resulting sheet carrier concentrations and mobilities are shown in Fig. 2. 1 1/3% PH_3 was used except for two additional samples with 0.4 and 4.5% at 750°C. Only a marginal increase in N_s occurred as the PH_3 content was increased. Generally, the behavior with the necessity of annealing $\gtrsim$ 750°C and the attainment of sheet carrier concentrations $\gtrsim 10^{14}$ cm^{-2} corresponds closely to earlier results on Si_3N_4 encapsulated wafers (3).

Figure 3 shows the results from another sequence of implants that were similar to those of Fig. 2 other than the silicon dose being increased from 3×10^{14} to 1×10^{15} cm^{-2}. 1 1/3 or 4 1/2% PH_3 was used for the annealing of the various samples. Of most significance here is the fact that sheet carrier concentrations of $\sim 5 \times 10^{14}$ cm^{-2}, an order of magnitude greater than in GaAs, can be attained. Layer stripping of one of the samples indicates that peak carrier concentrations of 10^{19} cm^{-3} can be reached.

Any phosphorus loss with a vacancy gradient near the surface could have a profound influence on the distribution of implanted ions. An enhanced outdiffusion causing the dopant distribution to become asymmetric towards the surface might be anticipated. Consequently, some of the layers have been profiled and examined for such an effect.

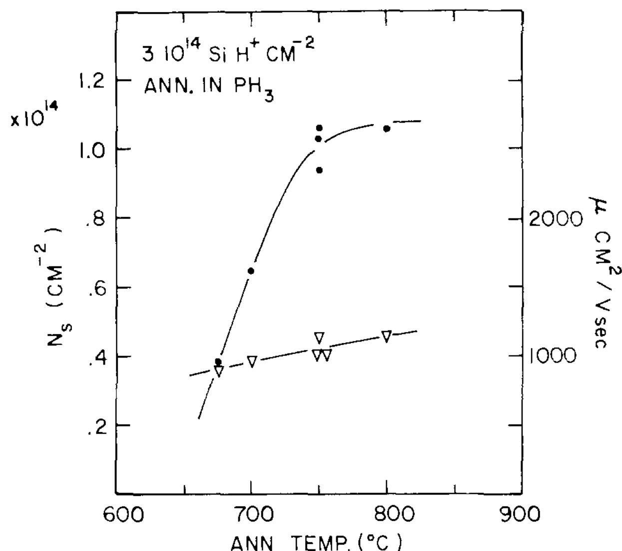

Fig. 2. The effect of annealing temperature on the electrical characteristics of 3×10^{14} Si^+ cm^{-2} implanted layers.

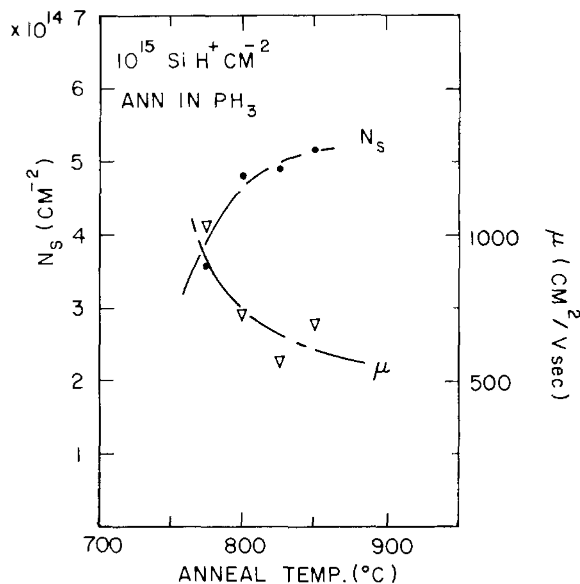

Fig. 3. The effect of annealing temperature on the electrical characteristics of 1×10^{15} Si^+ cm^{-2} implanted layers.

Figure 4 shows two profiles obtained after annealing in ambients of different phosphine to hydrogen content. The profiles were obtained through successive layer removal and Hall measurements. Anodization was used to remove the layers, and the electrolyte consists of 5% solution of citric acid combined with ethylene glycol. This has been described by Hasegawa and Hartnagel (6) in conjunction with GaAs anodization. Both of the samples shown in Fig. 4 were implanted at RT with 1 MeV silicon to 3×10^{14} cm^{-2}. For the annealing at 750°C the PH_3-to-H_2 ratio was changed from 0.4 to 4.5%. It can be seen that there is no discernable difference between the two profiles over the concentration range examined and that no outdiffusion is suggested.

Another indication of how well the InP surface is maintained on heating in low PH_3 content ambients is provided in Fig. 5 where the implantation energy has been reduced to bring the distribution closer to the surface. Doses of 4×10^{14} cm^{-2} were implanted at 200 keV and in each case the profiles are deeper than would be anticipated from LSS theory (7) (broken curve). One of these silicon-implanted layers was

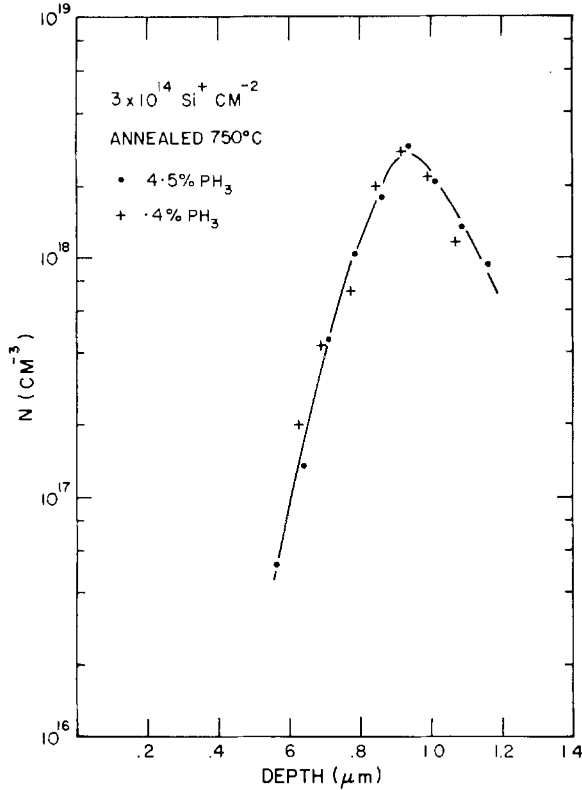

Fig. 4. The profiles of silicon-implanted layers annealed with two different phosphene ambient concentrations.

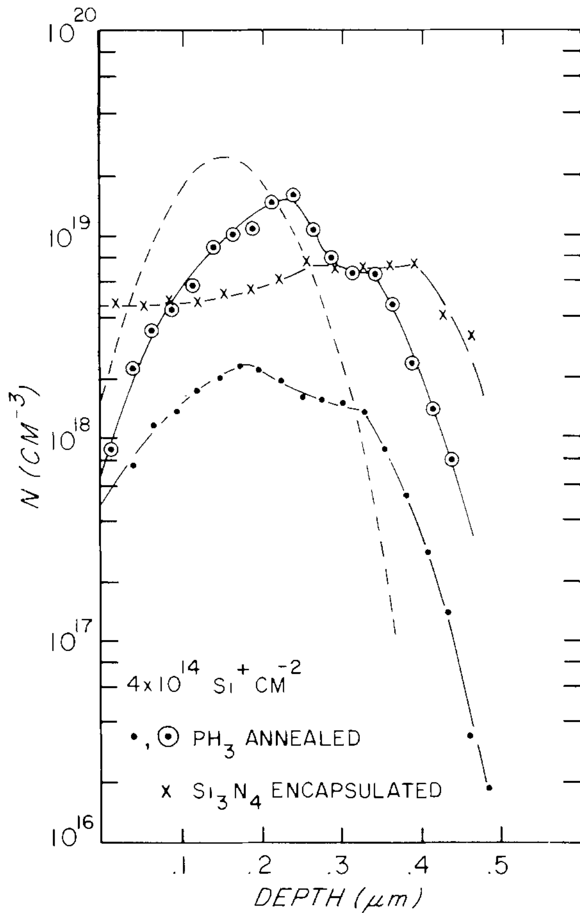

Fig. 5. Profiles of 200 keV silicon implants annealed with Si_3N_4 or under PH_3/H_2 flow. The theoretical distribution is indicated by the broken curve.

annealed at 750°C using a Si_3N_4 protective layer and it is apparent that considerable outdiffusion has occurred in this instance. The as-implanted distribution is better retained for the other two layers which were annealed at 775°C in PH_3. While the net doping within one of these layers is abnormally low, the other with a peak concentration of 1.5×10^{19} cm^{-3} illustrates that doping levels of $\gtrsim 10^{19}$ cm^{-3} are achievable through implantation in InP.

All of the above implants were conducted with the InP at room temperature. In an earlier study it was seen to be advantageous to implant at least sulfur at elevated temperatures (3). Further results concerning substrate heating, but where PH_3/H_2 rather than dielectric encapsulation is used for the post implantation annealing, are presented in Table I. Both Si^+ and S^+ have been implanted, at RT as well as at 200°C, and annealed at either 700° or 750°C. The energy of implantation is 1 MeV and the doses implanted are 3×10^{14} cm^{-2}. It will be noted that only Si^+ gives sheet carrier concentrations $\gtrsim 10^{14}$ cm^{-2} after implanting at room temperature. While there is an increase in the percentage of electrical activity on implanting hot for Si^+, it is not anywhere as pronounced as it is with S^+. However, better electron mobilities are obtained after implanting hot for both ions. This indicates more complete annealing on implanting hot, leaving fewer scattering centers to curtail the mobility.

Table I

Ion	$T_{ann.}$ (degrees)	μ_{RT}	$(N_s)_{RT}$	$\mu_{200°}$	$(N_s)_{200°}$	% activity RT; 200°C	
S^+	700	930	0.08×10^{14}	1380	1.2×10^{14}	3	40
S^+	750	1320	0.79×10^{14}	1780	1.1×10^{14}	26	37
Si^+	700	960	0.65×10^{14}	2200	0.83×10^{14}	22	28
Si^+	750	1030	1.1×10^{14}	2700	1.25×10^{14}	37	42

The behavior of p-type layers on annealing in PH_3 has also been investigated. Magnesium was implanted as an example of a p-type dopant and doses of 2×10^{14} cm^{-2} were introduced at 1 MeV. A sequence of such RT-implanted Hall samples were annealed as indicated in Fig. 6. The PH_3 in H_2 content was 4 1/2% and it can be seen that annealing to ~750°C, similar to what was previously required for silicon, is desirable. The sheet carrier concentrations of $\sim 1 \times 10^{14}$ cm^{-2} give 50% activation, a similar percentage to that

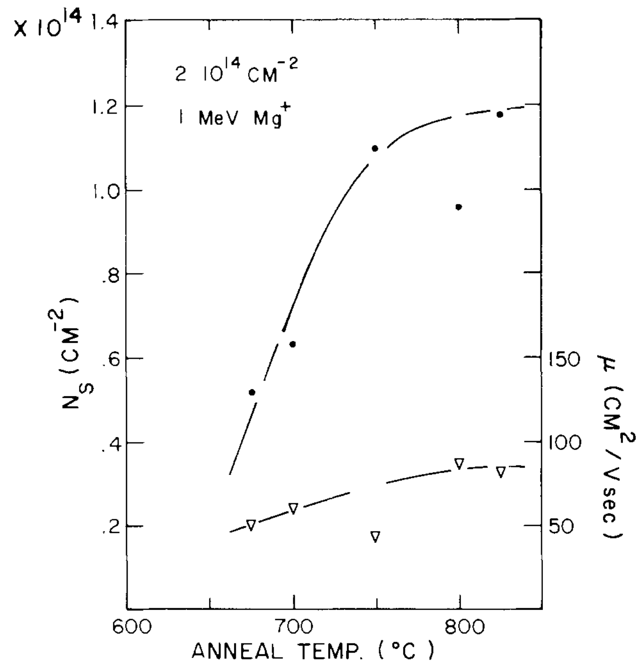

Fig. 6. Sheet carrier concentrations and mobilities for a series of magnesium implants annealed at different temperatures.

already reported for magnesium by Donnelly and Hurwitz (4).

Layers implanted with Mg to 5×10^{14} cm^{-2} and annealed as above failed to produce carrier concentrations any greater than the $\sim 10^{14}$ cm^{-2} level already indicated for the 2×10^{14} cm^{-2} implants. A similar limitation has also been seen by Donnelly and Hurwitz (4). Thus, it appears that a problem exists in attaining high p-type sheet carrier concentrations in InP.

In summary, it has been seen that a PH_3/H_2 ambient provides sufficient protection against thermal erosion on InP surfaces to make it an attractive way of annealing implanted layers without surface encapsulation. It is found that after implanting at RT, both Si and Mg layers have to be annealed to ~ 750°C. The silicon behavior is comparable to that found earlier where surface protection was afforded by sputtered Si_3N_4. While sheet carrier concentrations for the p-type dopant Mg^+ appear limited to $\sim 10^{14}$ cm^{-2}, values of $\sim 5 \times 10^{14}$ cm^{-2} are attainable with Si. It is concluded that no significant dopant outdiffusion occurs, as the profiles of the silicon-implanted layers do not exhibit any noticeable asymmetry toward the surface.

Mechanical Stress and Electrical Properties of MNOS Devices as a Function of the Nitride Deposition Temperature

R. Hezel[1] and E. W. Hearn

IBM Data Systems Division, East Fishkill Facility, Hopewell Junction New York 12533

ABSTRACT

The mechanical stress in memory quality silicon nitride films, the lattice parameter in the silicon substrate, the index of refraction, the dielectric constant of the films, and the saturation shift of the flatband voltage under positive and negative gate voltages in MNOS devices (as a function of the nitride deposition temperature) were studied in conjunction with the fixed interface charge density after fabrication. The nitride layers were deposited by the reaction of SiH_4 and NH_3 on [111] and [100] silicon in the temperature range from 640° to 910°C. No significant dependence of the properties on deposition rate and substrate orientation was found. Index of refraction, dielectric constant, film stress, substrate lattice parameter, and the maximum shift of the flatband voltage show a common characteristic variation with deposition temperature, with a minimum between 710° and 760°C. The relationship of the structural and electrical properties is discussed.

One objective of this paper was to provide information about the stress situation present in thin oxide MNOS memory structures. Another objective was to investigate the relationship between the mechanical stress both in films and substrate and the fixed interface charge density of the as grown structures prior to any electrical stress. Similar investigations have been done for MOS structures (1, 2); however, the stress in the oxide layer is much lower than the nitride stress in MNOS structures.

Experimental data are given and correlations are attempted between the fixed interface charge density, the maximum shift of the flatband voltage under positive and negative gate voltages, the mechanical stress in the film, the effect on lattice parameter of the silicon substrate, the change in index of refraction, and the dielectric constant of the nitride films. These properties were determined as a function of deposition temperature range from 640° to 910°C. ESCA studies were included to obtain the relative oxygen content of the nitride film.

Sample Preparation

The silicon nitride layers were deposited in a horizontal resistance-heated reactor (hot wall) by the chemical reaction of silane and ammonia with nitrogen as the carrier gas. The NH_3/SiH_4 ratio was 1000:1 in the deposition temperature range 640°-910°C. Silicon wafers 32 mm diam [100] orientation (2Ω-cm p-type) and [111] orientation (10Ω-cm n-type), both chem-mech polished, were used as substrates. Before

the nitride deposition, the wafers were cleaned using boiling acetone and trichlorethylene NH_4OH-H_2O_2 and HCl-H_2O_2 solutions.

The nitride layers were deposited directly on the native oxide (approximately 15Å in thickness). No special oxide growth treatment was performed.

Two separate deposition series (one year apart) were made, both with [111] and [100] substrates, n- and p-type, respectively. In the first series ($T = 653°$, 765°, 828°, and 910°C), separate depositions were made for each wafer orientation, whereas in the second series ($T = 640°$, 657°, 728°, 775°, and 885°C), the films were deposited simultaneously on the [111] and [100] substrate.

The average thickness of the nitride layers was 700Å; the thinnest layer was 580Å and the thickest, 840Å. Uniformity across the wafer was better than ± 5%. Thickness and index of refraction were measured by ellipsometry at a wavelength of 5461Å.

Stress Measurements

The film stress measurements were made by measuring the substrate radius of curvature with an x-ray diffraction technique (3). The convention used for tensile and compressive films was: If the film length tends to contract and is restrained from doing so by the substrate, the film is in a state of tension. Conversely, if the film tends to expand, it will be placed under a compressive stress by the substrate.

Silicon nitride is in tension. The magnitude of the curvature is related to the film stress by (4)

$$\sigma_f = \pm \frac{t_s^2}{6t_fR} \frac{E_s}{1 - V_s}$$

where + = tension; − = compression; t_s = substrate thickness; t_f = film thickness; R = radius of curvature; E_s = Young's modulus for silicon; and V_s = Poisson's ratio for silicon.

The values of $E_s/1 - V_s$ for [100] and [111] used were 1.8×10^{12} and 2.3×10^{12} dynes/cm^2, respectively. These were obtained from calculated values in Ref. (4, 5).

Determination of the lattice spacings was made using the Bond method of the Apex unit described in Ref. (6) using the alignment procedure suggested in Ref. (7). The d spacing of the (444) planes were measured for both substrate orientations. The [111] substrates provide a symmetric orientation of the measured planes relative to the sample surface, while the [100] substrates provide an asymmetric orientation. The accuracy of this arrangement has been measured on a standard sample of [111] silicon for the (444) reflections. This value of $a_o = 5.430611 + 0.000003$Å has been reproduced over a one year time period. The deviation over the short duration of this experiment is shown by the error bars in the data plot.

The measured values of d spacing were not corrected except for temperature normalization since the standard corrections used in the Bond method are insignificant for this investigation, especially if relative values are considered.

Electrical Measurements

Standard high frequency (1 MHz) C-V measurements were performed to secure information about the charge density in the MNOS structure. The following relation was used

$$V_{FB} = \Phi_{MS} - \frac{Q_N}{\epsilon_0\epsilon_N} d_N$$

where V_{FB} is the flatband voltage, Q_N is the charge density present at the SiO_2/Si_3N_4 interface, ϵ_0 is the permittivity of free space, ϵ_N is the relative dielectric constant, and d_N is the thickness of the nitride layer. Φ_{MS} is the work function difference between the metal electrode and silicon.

The application of the simple relation above instead of the exact equation for the MNOS structure given in Ref. (8, 9) is justified by the following arguments: (*i*) According to our experiments, oxide charge and surface state density at the Si/SiO_2 interface are negligible (H_2 annealing during nitride deposition); (*ii*) The charges (of density Q_N) of the as-grown structure, prior to any electrical stress, are located at the SiO_2/Si_3N_4 interface (8, 9). (Liquid Ga-In electrodes were used instead of Al to avoid postdeposition annealing and possible stress contributions due to the metal.)

The relative dielectric constant of the silicon nitride films was calculated from the capacitance in the accumulation region of the C-V characteristic curve and the dimensions of the structures (evaporated Al-contacts were used for this determination).

In this study, $\Phi_{MS} = -0.1$V was determined experimentally for the Ga-In alloy and nSi, 10Ω cm, from the linear relationship between V_{FB} and d_N. To obtain the true Q_N values from the C-V curves, special care was taken not to apply gate voltages appreciably exceeding the flatband voltages to prevent changes in V_{FB} by charge injection into the nitride.

The charge storage window measurements were performed by recording the flatband voltage shifts under both positive and negative gate bias. Starting from the C-V curve of the as-grown MNOS structure, a positive voltage was applied to the gate for $t_p = 2$ min ($E_N = 5 \times 10^6$ V/cm), the curve shifted to V_{FB1}. Then a negative voltage of the same magnitude and time was applied, shifting the curve to V_{FB2}. Increasing the biasing time, no further shift occurred. ($V_{FB1} - V_{FB2}$) therefore represents the saturation width of the charge window for the voltage applied.

Results and Discussion

Stress data.—The stress in silicon nitride films is considered to be the sum of the thermal stress σth and the intrinsic σi. The thermal stress is directly proportional to the difference in the thermal expansion coefficients of nitride and silicon and to the difference between deposition temperature and measuring temperature (10). Stress measurements performed exactly at the deposition temperature would enable determination of the pure intrinsic stress component separately. Such measurements were performed in Ref. (10), showing that the (compressive) thermal stress σth is only a small fraction (1/10) of the (tensile) intrinsic stress in the silicon nitride films. Taking this into account, the assumption may be made that the room temperature stress is mainly due to the intrinsic stress in the nitride films.

In Fig. 1 the nitride film stress (tensile) is shown as a function of deposition temperature for both [111] and [100] substrate orientations and two different deposition series. No significant dependence on the deposition rate was found (compare series 1 and 2). The stress shows a similar dependence upon deposition temperature as the index of refraction (Fig. 2) and the dielectric constant (Fig. 3), indicating that the measured room temperature stress is a function of the structure and/or composition of the nitride films.

In Fig. 4, the d-spacing values of the (444) planes of a [100] oriented substrate are shown as a function of deposition temperature. The character of the curve for the [111] case is inverted from that of the [100] case shown in Fig. 2. The explanation for the inversion is as follows: The nitride film is in tension; this places the substrate under compression. The d values of the asymmetric planes relative to the surface in compression are decreased relative to either the unstrained case or the case of a strained [111] oriented substrate (11). The inset in Fig. 4 schematically depicts this arrangement.

The higher the tensile stress in the film, the more compressive is the stress in the substrate and the

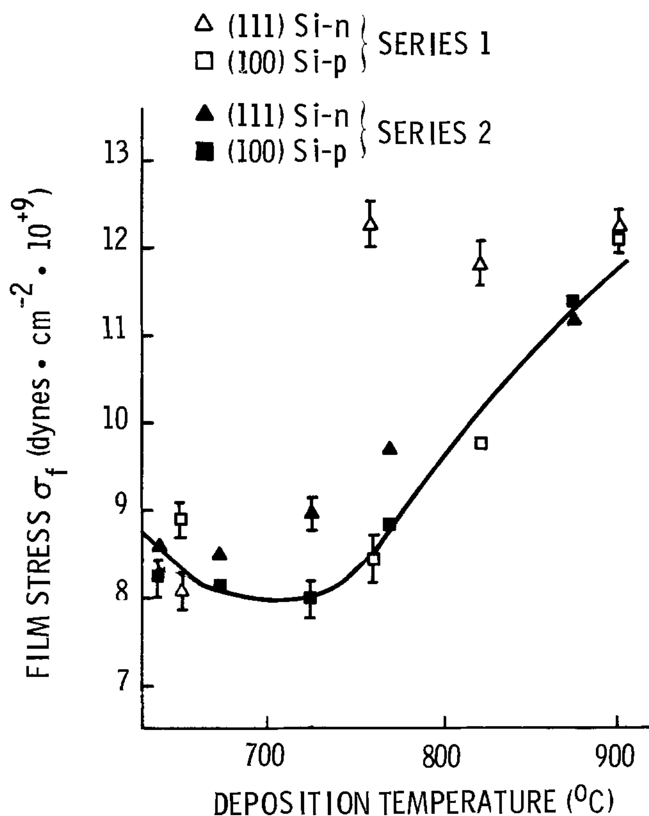

Fig. 1. Mechanical stress in silicon nitride films as a function of deposition temperature. The stress is tensile.

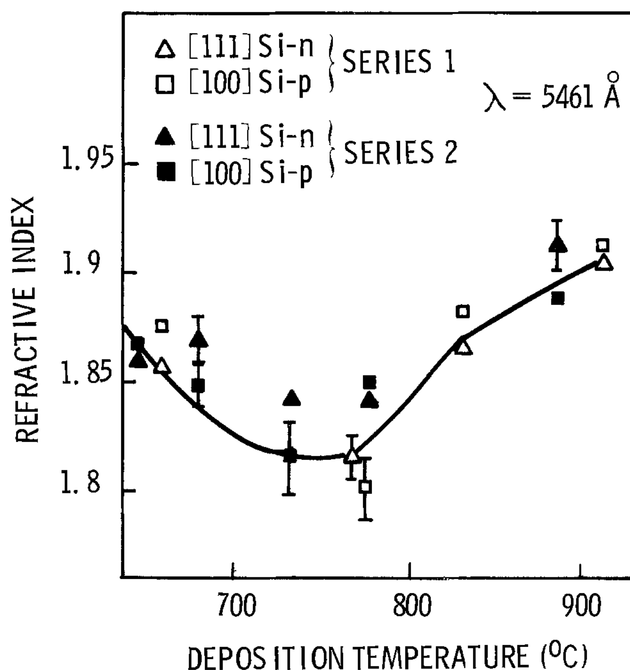

Fig. 2. Index of refraction of silicon nitride films on silicon as a function of deposition temperature.

smaller the d spacing. This is in agreement with our results (compare Fig. 1 and 2). Thus, these measurements have shown that the lattice parameter, and hence the stress introduced into the Si-substrate by the nitride film, follows a similar dependence upon deposition temperature as the stress in the film.

Finally, when one assumes the [100] and [111] orientations to have the same $E/1 - v$ value as suggested in (2), the stress *vs.* deposition temperature curves separate for both orientations, where the [111] curve is lower in value than the [100]. However,

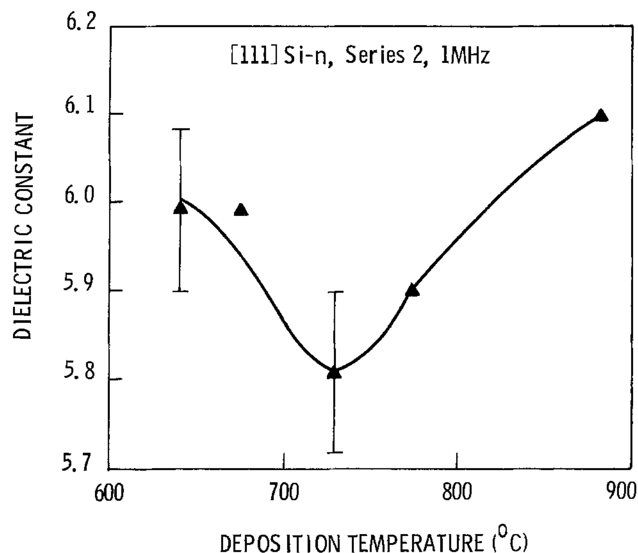

Fig. 3. Dielectric constant of silicon nitride films on silicon as a function of deposition temperature.

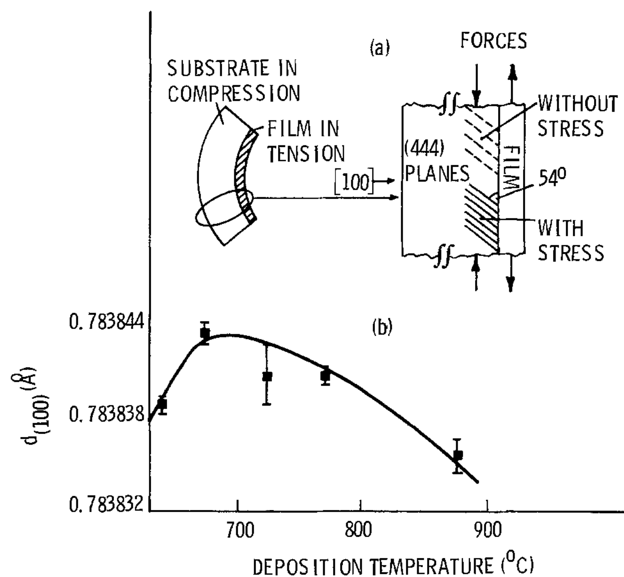

Fig. 4. (a) Schematic diagram showing the contraction of the (444) lattice planes caused by the stress in the film (high stress-low d values); (b) Interplanar spacing values of the (444) planes of a [100] Si substrate covered with silicon nitride as a function of the nitride deposition temperature.

when one uses the calculated values of Ref. (3, 4), these curves are nearly superimposed as shown in Fig. 1. The stress, then, in the film is approximately the same for both substrate orientations. However, the magnitude of the substrate warpage is dependent on the different elastic constants for each orientation.

The dependence of the film stress upon deposition temperature in the temperature region from 600° to 900°C was investigated by several authors [Ref. (10, 12-14)]. In all cases, different deposition parameters and nitride layers much thicker (2000-5000Å) than the ones actually applied in memory structures were used for the investigations. Studies reported in Ref. (10) and (13) found that the stress in the nitride film is decreasing with increasing deposition temperature, while Aboaf (12) reports an independence of the stress and deposition temperature between 500°-900°C.

Deposition Rate

In Fig. 5, the effect of deposition temperature on deposition rate is shown for the two deposition series and substrate orientations. The deposition rates as well as their temperature dependence are different for

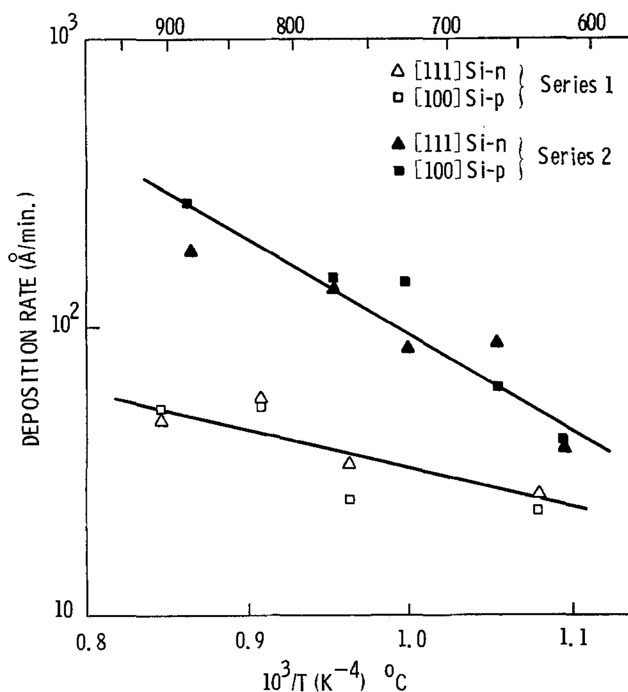

Fig. 5. Deposition rate of silicon nitride films on silicon as a function of deposition temperature.

the two series. From the log rate *vs.* $1/T$ plots, apparent activation energies were determined to be 6.1 kcal/mole for series 1, and 15 kcal/mole for series 2. The reasons for the differences are partly due to different amounts of ammonia and silane (without changing their ratio) and partly due to the properties of the hot wall deposition system itself. The deposition rate can be varied by properly positioning the wafers within the constant temperature region toward the edges of the optimal deposition zone (15). These differences make it possible to study the influence of the deposition rate on the nitride layer properties over the whole temperature range.

The independence of stress and index of refraction with respect to deposition rate points to the fact that the deposition rate in the range used here has only little or no influence upon the structure of the nitride films. This result is in agreement with Aboaf's results (12), but opposite to Irene's (13), where the stress was observed to decrease for decreasing deposition rate. The different experimental conditions may be responsible for the results cited in Ref. (13), where forming gas was used as carrier gas, the NH_3/SiH_4 ratio was much lower (150:1), the index of refraction was much higher, and layers of 2000Å and thicker were used.

Index of refraction.—Figure 2 shows the refractive index (n) as a function of deposition temperature for nitride layers deposited on [111] and [100] Si wafers. Higher values of n at low deposition temperatures pass through a minimum and finally increase to higher n values with increasing temperature. A similar behavior was found for the different deposition series and substrate orientations.

It is important to note that the n values are not dependent on the deposition rate (see series 1 and 2). They increase with increasing deposition temperature beyond the minimum. In Ref. (16), only a slight increase of n in the same temperature range was found, whereas those values published in Ref. (17) are decreasing steadily from $n = 20$ at 700°C to $n = 1.97$ at 850°C. In Ref. (17), a cold wall deposition system and a lower NH_3/SiH_4 ratio were used. Values of n in the same range between 1.8 and 1.9 were reported by Duffy and Kern (18) using similar deposition conditions as in the present work. However, most of the published values of the index refraction of silicon nitride are close to 2.0. Some possible reasons for the observed lower n values and for the deposition temperature dependence reported here are now discussed.

According to the relatively high NH_3/SiH_4 ratio, the films may possibly contain less Si compared to the stoichiometric composition Si_3N_4, resulting in lower values of n (17). The amount of Si may possibly change with deposition temperature.

As shown in Ref. (19), oxygen incorporation into the nitride films during deposition could be another reason for the variation and especially for the low values of n. Oxygen was not intentionally introduced during growth, but it is likely that our system contained enough oxygen to produce an oxy-nitride, especially by the amount of water introduced by the ammonia gas.

ESCA measurements (20) were made, and confirm that oxygen is present and varies with the deposition temperature as shown in Fig. 6. The oxygen content varies inversely with the index of refraction, as expected.

Thus, as in the case of the refractive index, the minimum in the stress-deposition temperature curve in Fig. 1 may also be attributed to the increased oxygen concentration of the nitride films deposited in the temperature range 700°-800°C. Figure 7 shows that the oxygen content is higher at the surface and decreases to a constant level after about 5 min (50Å) cf etch time.

Since an increase of n with film thickness in the range of 600-1500Å was observed in the course of the present work, the thickness has to be taken into ac-

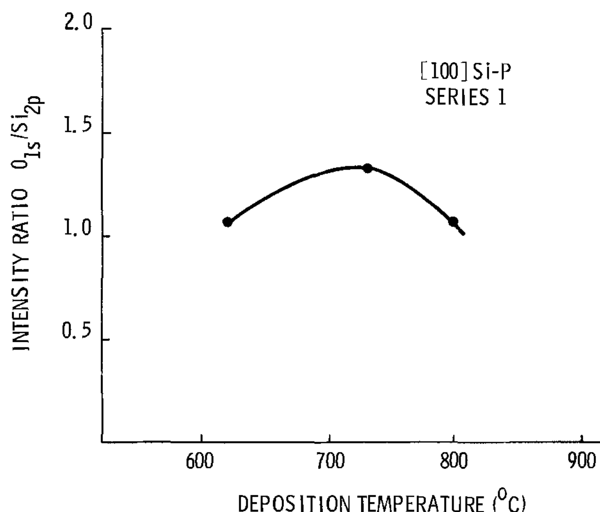

Fig. 6. ESCA data showing relative oxygen concentration vs. deposition temperature.

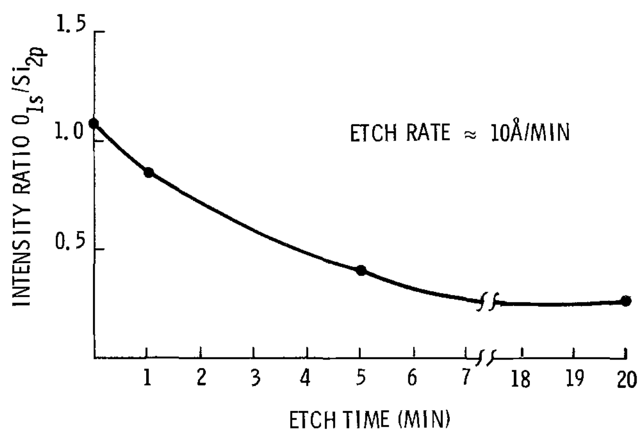

Fig. 7. ESCA data showing relative oxygen concentration vs. etch time (depth from surface).

count if comparisons are made between the n values of different authors.

The relative dielectric constant of the nitride layers was determined for the [111] oriented samples of series 2 as a function of deposition temperature, and the results are shown in Fig. 3. Uncertainties in capacitance, film thickness, and electrode area indicate an absolute error up to 3%. A behavior similar to that of the refractive index with a pronounced minimum at 730°C is obtained.

Interface Charge Density

In Fig. 8 the dependence of the interface charge density on deposition temperature is shown for the two deposition series with [111] and [100] substrate orientations. For comparison, the results reported in (16) are also given. Within a relatively narrow temperature range there is a remarkable decrease of Q_N/q with increasing deposition temperature, finally changing from positive to negative values between 800° and 900°C. Differences in the absolute values exist, but in general the dependence on deposition temperature is similar for all runs. Note especially that the results of Ref. (16) are in good agreement with those of series 2. According to series 2 but in contrast to series 1, there is no orientation dependence of the interface charge density. The results of series 2 are more reliable in this respect, since there are more data points and the depositions on the [111] and [100] substrates were made in the same run, while in series 1 separate depositions were made for the two orientations.

Stress-interface charge density relationship.—According to Fig. 1, 2, 4, and 5 the decrease in charge density at low deposition temperatures corresponds to a decrease in the refractive index, the dielectric constant, the film stress, and the stress in the substrate. In this range, the most significant change of the interface charge density occurs until that temperature at which stress and index of refraction curves reach a minimum. It may be speculated that this minimum corresponds to a turning point in the charge density *vs.* deposition temperature curve. Beyond this point, the further decrease in charge density is slowed down, finally changing from positive to negative values. Since in the temperature range beyond this possible turning point both the stress and index of refraction values increase, a different process seems to be responsible for the interface charges. Thus, the charge density *vs.* deposition temperature curve (Fig. 8) probably represents the superposition of two or even more curves, each caused by different phenomena. Therefore, a similar postulation as expressed for the case of MOS structures in Ref. (1) may also be justified for the MNOS structures that both positive and negative charges are present at the interface, their respective amounts varying with deposition temperature.

It is interesting to compare these results with the data of Stein and Wells (21), shown in Fig. 9. They measured the hydrogen bonding in silicon nitride by multiple internal reflection spectroscopy as a function of deposition temperature between 700° and 900°C. N-H bonding was observed in all films, whereas Si-H bonding decreased with increasing temperature and was not observed in films deposited at 900°C. The interface charge density (Fig. 8) is decreasing in the same temperature range and also becomes zero between 800° and 900°C, changing from positive to negative values.

Furthermore, annealing of these nitride samples above the deposition temperature in nitrogen (22) and subsequent analytical investigations by low energy electron loss spectroscy (ELS) (23) showed a similar result, namely, that with decreasing hydrogen bonding (particularly Si-H) an increase of film stress along with a simultaneous decrease of positive charges occurs. In Ref. (24), changes of several film properties upon annealing are attributed to a densification of the nitride films.

Thus, without knowing the detailed mechanism, it can be assumed that hydrogen in the nitride film (produced by the SiH_4-NH_3 reaction) is at least partly responsible for the stress and charge variation with deposition temperature.

But, similar to the Si/SiO_2 system, a definite stress-interface charge relationship cannot be established for the MNOS structures under investigation, since it is unknown whether (*i*) the changes in structure and/or composition of the film or; (*ii*) the changes in film stress, account for the interface charge density variation with deposition temperature.

Switching data.—To demonstrate the memory quality of nitride films under investigation, the saturation shift of the *C-V* curves for both positive and negative gate voltages were determined as a function of nitride

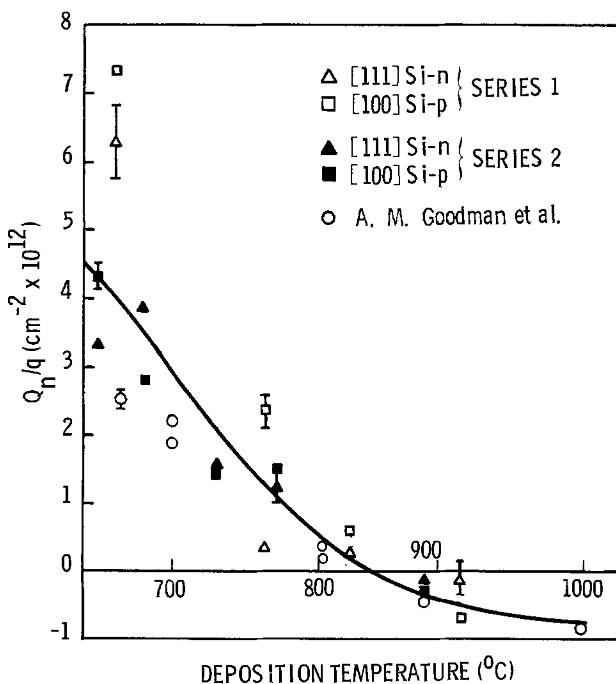

Fig. 8. Interface charge density in MNOS structures just after nitride deposition as a function of deposition temperature.

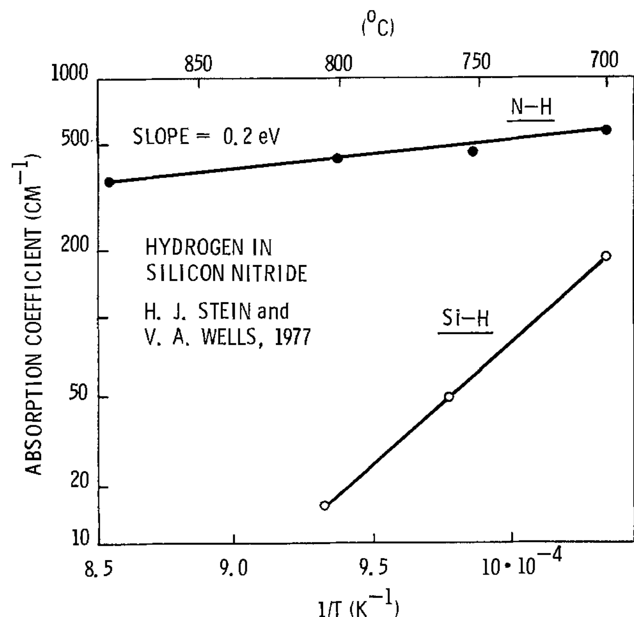

Fig. 9. Hydrogen bonding data of infrared absorption coefficient *vs.* deposition temperature.

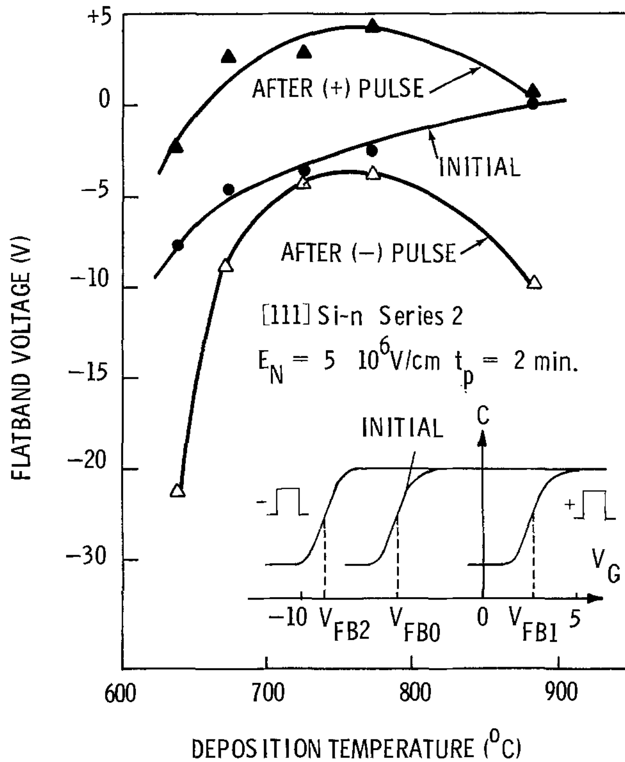

Fig. 10. Flatband voltages of the as-grown MNOS structures and after positive and negative gate voltage pulses (saturation shift as a function of the nitride deposition temperature.

deposition temperature (Fig. 10). From these curves the position of the saturation window relative to the voltage axis and relative to the initial flatband voltage can be determined. As an insert in Fig. 10, original C-V curves are shown before and after application of positive and negative voltages. No significant distortion of the curves due to fast surface states could be detected. In Fig. 11 the width of the saturation window (V_{FB1} − V_{BF2}) as determined from Fig. 10 is plotted as a function of nitride deposition temperature. The width and the position of the saturation window shows a similar dependence upon deposition temperature as the stress in film and substrate, the index of refraction, and the dielectric constant. An especially pronounced maximum/minimum was found between 740° and 760°C, slightly lower in temperature than the minimum shown in Ref. (16) for the maximum positive stored charge for negative gate voltages.

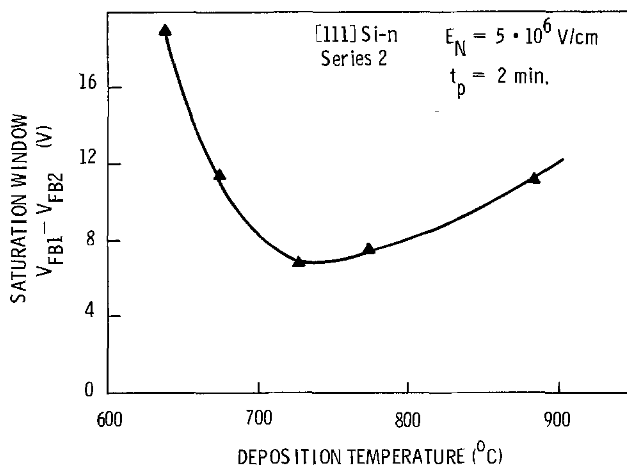

Fig. 11. Differences between the flatband voltages of MNOS devices obtained after positive and negative gate voltage pulses (see Fig. 10, "saturation window") as a function of the nitride deposition temperature.

It is well known from charge centroid studies the traps are not only present at the SiO_2/Si_3N_4 interface but are spatially distributed deep into the bulk of the nitride (25, 8). These results can be taken as another piece of evidence that the memory properties are correlated to the structure and/or composition of the nitride film.

Summary and Conclusions

Memory-quality silicon nitride films were deposited in a hot wall reactor by the reaction of silane and ammonia on [111] and [100] silicon substrates, n- and p-type, respectively. The deposition temperature ranged from 640° to 910°C and the average thickness of the nitride layers was 700Å. Index of refraction, dielectric constant, stress in the film, and the interplanar spacing in the silicon substrate together with the fixed interface charge density of the as-grown samples and the saturation shift of the flatband voltage under positive and negative gate voltages in the corresponding thin oxide MNOS structures were measured as a function of deposition parameters.

No significant dependence of these properties on the deposition rate and substrate orientation was found. Index of refraction, dielectric constant, film stress, *d* values in the substrate, and the maximum shift of the flatband voltage show a similar characteristic deposition temperature dependence with a minimum between 710° and 760°C. The variations in film stress and stress in the substrate as well as those of the switching properties are therefore very likely due to changes in structure and/or composition of the nitride films. The interface charge density *vs.* deposition temperature curve may be characterized by a sharp decrease at low temperatures, a turning point, and a lower decrease at higher temperatures, finally changing from positive to negative values between 800° and 900°C. The position of the turning point probably corresponds to the minimum of the film stress and index of refraction. It may be assumed that both positive and negative charges are present at the interface, their respective amounts changing with temperature.

No definite stress-interface charge relationship can be established for the MNOS structure since it is unknown whether structure and/or composition of the films or the film stress itself account for the interface charge density variation with deposition temperature.

Hydrogen introduced during the silane-ammonia reaction into the nitride films is assumed to strongly influence the properties of MNOS devices.

Acknowledgments

The authors are grateful to J. Ziegler for the accurate preparation of the samples at the Instiut Feur Werkstoffwissenschaften VI, University of Erlangen-Neurnberg, to E. Gorey for the ellipsometry measurements, to C. Hoogendoorn for his assistance during the course of the stress measurements, and to R. Flitsch for the ESCA measurements. Special thanks to Dr. G. H. Schwuttke for the support and encouragement of this work.

Interactions Between Cr and Pt Films: New Cr-Pt Phases

J. Baglin,* F. d'Heurle,* and S. Zirinsky

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Thin film studies are frequently concerned with the characteristics of metastable alloy phases. However, the analysis of diffusion in thin film couples can lead to new contributions to the understanding of the equilibrium state. In Cr-Pt films new ordered phases Pt_3Cr and PtCr have been found. PtCr is slightly tetragonal.

Thin film deposition techniques are often used for the preparation of metastable phases, especially amorphous ones, which can be produced in bulk only by means of drastic procedures such as extremely rapid cooling (1). [The early interest in amorphous alloy films (2-4) continues to the present day when the study of amorphous Si films (5) and that of amorphous magnetic films (6) can almost be considered to constitute independent disciplines.] Evidence is presented here that by the study of diffusion between Cr and Pt films significant additions to the existing Cr-Pt equilibrium diagram could be obtained. These additions are believed to be consistent with thermodynamic requirements, with the theory of ordering transformations, and with crystallography. It may be that, at least in this one case, equilibrium conditions can be more easily reached in films than in bulk samples, where stresses could hinder certain phase transformations. The emphasis here is placed on equilibrium characteristics. Considerations about the kinetics of diffusion in Cr-Pt thin film couples have been presented elsewhere (7-9).

Experimental Procedures

For diffusion studies at low temperatures (about 500°C) the films were deposited from e-beam sources onto oxidized Si wafers at 200°C, the pressure during deposition being in the low 10^{-8} Torr range (obtained through the use of a liquid N_2 shroud surrounding the inside of the deposition chamber), at a rate of about 20 Å/sec. A few diffusion studies were carried out at high temperatures (about 1000°C) with films deposited onto sapphire wafers, at a pressure in the 10^{-7} Torr range. The films were always deposited in the sequence Cr then Pt, without breaking the vacuum. The film thicknesses were usually: Cr-1600Å, Pt-2000Å or Cr-4000Å, Pt-4800Å, for a nominal overall composition near 50 atom percent (a/o). The films were subsequently heat-treated in an atmosphere of highly purified He obtained by flowing the gas over a hot titanium bed. Most of the annealing treatments were carried out for times of 0.5, 2, 8, 32, and up to 128 hr, at temperatures from 420° to 580°C in steps of 40°C.

The films were analyzed by backscattering of 2.6 MeV He ions, and by x-ray diffraction. The standard x-ray diffractometer equipped with a Cu tube was also equipped with a post sample monochromator (bent graphite crystal) which in the present case was particularly useful in eliminating fluorescence from Cr in the samples. Computer control of the diffractometer made it possible to use long counting times when good statistics were required to reveal details of structure which could be lost in old recorder tracings. Care was exercised to check for traces of oxidation (which were not detected), and for reaction of the films with the substrates. In only one of the samples used, after 2 hr at 580°C, was any reduction of SiO_2 by Cr observed. Even in this case there was no indication of any overlap between Cr and Pt in the backscattering spectrum, so that any interference with the Cr-Pt reaction was judged to be negligible. Yet, of course, this interaction at 580°C dictated the use of sapphire substrates for any studies conducted at high temperatures.

Results

Phases formed at 400°-600°C.—A series of spectra from the backscattering experiments are presented superimposed on one another in Fig. 1. The spectra

* Electrochemical Society Active Member.

Key words: equilibrium diagram, Cr-Pt phases, ordering transformation, backscattering analysis, structure of CrPt, thin films of Cr-Pt, diffusion in Cr-Pt.

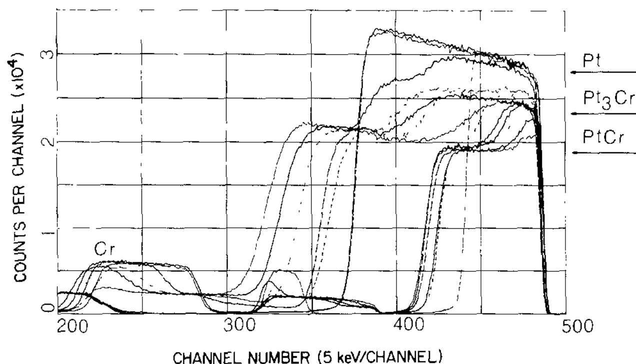

Fig. 1. Superimposed backscattering spectra for thin and thick samples (Cr: 1600, 4000Å and Pt: 2000, 4800Å) annealed for times varying from 0.5 to 32 hr at temperatures from 460° to 580°C. (Note some overlap of the Cr and Pt parts of the spectra for the annealed thick samples).

correspond to both thin and thick samples (Cr-1600Å, Pt-2000Å and Cr-4000Å, Pt-4800Å) annealed for periods ranging from 0.5 to 32 hr at temperatures from 460° to 580°C. The distinguishing feature of these overlapped spectra is the presence of discrete plateaus corresponding to specific compositions: As indicated by the arrows these are Pt_3Cr and PtCr, shown in contradistinction to the pure Pt. Similar features are shown in Fig. 2 for a thin sample annealed in similar conditions; there the discrete Cr levels are clearly shown. They correspond to concentrations of 25 and 50 a/o Cr.

The presence of two different and distinct phases, with specific compositions, in these samples is confirmed by the results of the x-ray diffraction observations. In Fig. 3 the (111) and (200) peaks for a thin sample annealed for 8 hr at 500°C are shown. Two distinct sets of peaks are evident. Their respective positions correspond to two phases with two different lattice parameters, both of which are smaller than the lattice parameter of Pt. For ease of identification the positions of the (111) and (200) diffraction peaks for Pt have been indicated on Fig. 3 by two arrows (on top of the figure). The two phases are ordered as shown by the presence of many superlattice lines which are listed in Table I for the same sample (thin, 8 hr at 500°C). While the intensities of the different lines (see Table I) varied with the heat-treatments, the lattice parameters of the two phases remained constant within the limits of experimental accuracy: ±0.002Å. Since the lattice parameters were measured at room temperature on samples annealed at elevated temperatures, the true lattice parameters must be estimated by taking into account the strains that developed during cooling as a result of the different thermal expansion coefficients of the film material and the substrates (10). For the films deposited on

Si wafers, the quantities required for making the lattice parameter corrections are: the expansion coefficients of Si (3.2×10^{-6}/°C) (11), and of the Cr-Pt alloys, and the Poisson ratio for these alloys, which will be assumed to be 0.33. The expansion coefficient of the alloys is likely to be close to those of the pure metals (8.4×10^{-6}/°C and 9.1×10^{-6}/°C, respectively, for Cr and Pt) (12). For films cooled from 500°C to room temperature the correction to be added to the measured lattice parameters is about +0.010Å. Thus the final value for the lattice dimension of the two phases in Table I would be 3.877 ± 0.005 and 3.825 ± 0.005Å. The respective compositions can then be determined from the comparison of these lattice parameters with the values listed in the literature for Cr-Pt alloys. Such values (13) have been plotted in Fig. 4, where one can see that the desired compositions are very close to 25 and 50 a/o Cr.

It is to be noted that in all of these samples with an over-all composition close to 50 a/o, and annealed in a range of temperatures near 500°C, the Cr-rich

phase β, with approximately 80 a/o Cr, was generally undetectable, or was present only in very small traces. This was true in spite of the fact that the initial transformation of the film couples into CrPt and $CrPt_3$ left an excess of unreacted Cr.

Compounds formed at ~ 1000°C.—Some experiments were conducted with the films deposited on sapphire substrates and subsequently annealed in the vicinity of 1000°C. It is to be noted that the initial adhesion of the films to sapphire was extremely good. Bonding between Cr and Al_2O_3 is sufficiently strong to cause Cr atoms to adopt epitaxial positions with respect to c-axis sapphire (14). However, following heat-treatment in a range of temperature from 600° to 700°C, the films would peel off their substrates when moved from the hot to the cool zone of the annealing furnace. Films annealed above 800°C continued to adhere well to their substrates, although presumably the stresses developed in such films should be higher than in films annealed at lower temperatures. One may hypothesize that at high temperatures Cr and Al_2O_3 react sufficiently to form a good chemical bond between film and substrate, even though the extent of the reaction is too limited to allow for detection by the backscattering technique. Support for this proposition can be found in the use of Cr for the sintering of aluminum oxide powder and the report that Cr may reduce Al_2O_3 with the formation of lower Al oxides (15). Adhesion of a film on a substrate is the result of the competition between two effects: The strength of the chemical bonds across the interface and the shear stresses that develop at the interface as a result of the existence of compressive tensile stresses in the film and substrate. These latter are a strong function of temperature because of the usual difference in expansion of the film and substrate materials. The nature of the interface chemical bonds is also dependent on temperature; van der Waals type forces probably dominate for films deposited on relatively "inert" substrates at low temperature; heating may result in stronger ionic forces. The variations of adhesion with temperature due to the interplay of those two different effects will obviously be extremely dependent on the materials in question. In the case in hand, it must be presumed that at low temperatures the stresses are sufficiently weak to allow good adhesion, while at high temperatures the bonding is sufficiently strong to give the same result. At intermediate temperatures, about 700°C, apparently the stresses have increased considerably while the bonding remains limited, resulting in an over-all lack of adhesion of the Cr-Pt film to the sapphire substrates. Note that here the film stresses are functions not only of the expansion coefficients but also of the volume changes resulting from the interdiffusion of Cr and Pt.

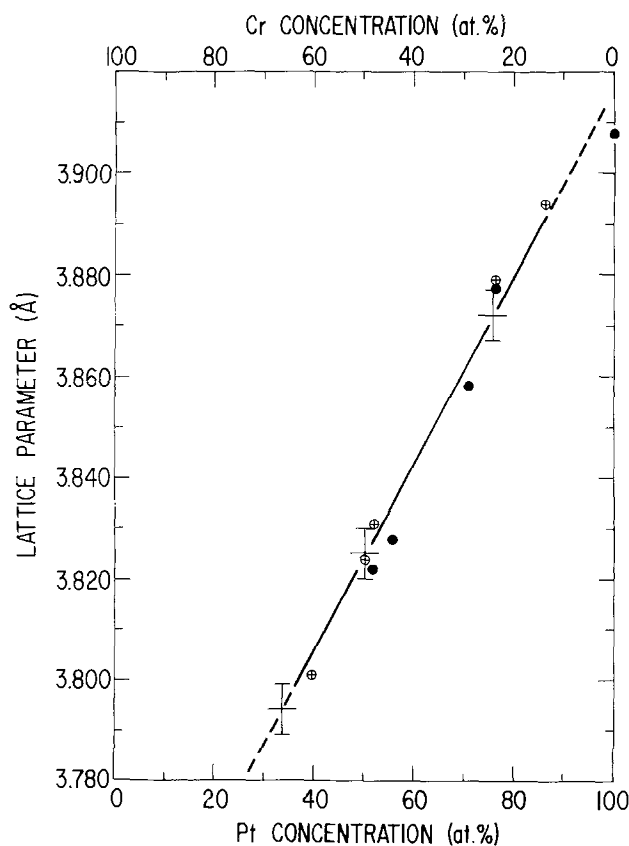

Fig. 4. The lattice parameters of Cr-Pt "solid solution" alloys according to Ref. (13). The composition of the phases considered here can be derived from the three points with error bars.

In the films annealed at high temperatures structural reorganization of the different components (Cr, Pt, and the different compound phases) prevented the clear identification of these components by backscattering experiments (as seen in Fig. 1 for films annealed at low temperatures). When the different products of the diffusion process cease to be disposed in layers, but instead tend to be distributed in parallel positions normal to the substrate, backscattering spectra can give only the over-all composition of the films but no detailed information. However, x-ray diffraction results indicate that in films annealed at high temperatures, as well as in those annealed at low temperatures, different ordered phases can be simultaneously present in the diffusion couples. CrPt and $CrPt_3$ were identifiable in a sample annealed at 1010°C. Moreover, in a sample annealed for 1 hr at 950°C, three phases were detected: PtCr with a lattice parameter of 3.815Å (uncorrected for stress), $PtCr_4$ with a lattice parameter of 4.712Å [complex cubic (13)], and a third phase with a lattice parameter of 3.784Å (face-centered-cubic, uncorrected). This third phase with a strong (111) peak, but also with a weak (210) superlattice peak (other fundamental peaks were present as well), is apparently ordered; one must ascribe to it the formula $PtCr_3$, even though its lattice parameter indicates that it is too poor in Cr to correspond to an exact stoichiometry. As previously, it is necessary here to consider the correction due to the difference in thermal expansion between film and substrate for temperatures up to 1000°C. The respective coefficients are: 10.2×10^{-6}/°C for Pt and 9.4×10^{-6}/°C for Cr (12), while for random orientation sapphire the expansion coefficient must be close to 7.6×10^{-6}/°C (15). The correction to the lattice parameter for these films is also found to be of the order of 0.010Å. Thus the lattice parameter of "Cr_3Pt" would be 3.794 ± 0.005Å, which corresponds to a composition of approximately 65 a/o Cr according to Fig. 4. Finally, the same three phases Cr_4Pt, Cr_3Pt, and CrPt were also identified in a more controlled experiment where a sample with 5400Å Cr and 2600Å Pt (72 a/o Cr) was annealed for 1 hr at 1000°C.

Detailed structural information was obtained on a sample containing 48.5 a/o Pt (analysis by backscattering) and annealed at high temperature (1 hr at 975°C) for complete homogenization. Individual diffraction peaks were scanned consecutively, the counting time being increased (for improved statistics) with decreasing maximum peak intensity. The results presented in Fig. 5 for the (100), (110), (111), (200), and (221, 003) peaks are actual peak tracings, without averaging through data points. The first three peaks (100), (110), and (111) are quite sharp, in the next peak (200, 002) one can see the anticipated splitting of the $CuK_{\alpha 1}$-$K_{\alpha 2}$ doublet on the high θ side, however, the bulge on the low θ side is unexpected for a true cubic structure, indicating a structural deformation. A more obvious evidence of structural peak splitting is visible in the (221, 003) peak. All other diffraction peaks are shown in the Appendix.

Discussion

Dominant phases; key factors.—Ideally, at some point in the process of homogenization of a diffusion couple one should observe all of the phases in equilibrium at the temperature of annealing. Such ideal conditions are rarely encountered in actual practice, where one finds that, depending on the temperature, some phases will form in preference to others in apparent disregard of the equilibrium indications to be gathered from phase diagrams (17). The dominance of one or several phases may be due to a multiplicity of factors. Some are related to equilibrium, such as the respective free energy of formation of the different phases since, other things being equal, one would anticipate the preferential formation of that phase which has the lowest free energy. Others have their origin in kinetic considerations, such as the relative ease of diffusion of the various components in the different phases [see, for example, the analysis of phase formation in Al-Ni (18)]. Moreover, one must consider such factors as anisotropic growth rates, nucleation, and surface free energies (which in films will be related to preferred orientations), as well as stresses due to volumetric changes. Thus diffusion couples should not be expected to yield exhaustive information about equilibrium diagrams. Yet, all observations made on such couples must be consistent with equilibrium, and can deliver new information where previous results remain incomplete (19).

Equilibrium diagram; structures.—In the case at hand the equilibrium diagram is shown in Fig. 6 for the range of temperatures which is of interest. The existing part of the diagram, which is based on a recent study (20), has been drawn in the upper part, between 600° and 1100°C. It implies a continuous face-centered cubic structure from 45 a/o Pt to pure Pt, with a smooth transition (second order transformation) between the ordered and the disordered solid solutions of Cr in Pt. Such indications are not consistent with the present diffusion results.

For detailed information about ordering reactions one may turn to classical studies, which stress either statistical mechanics calculations (21) or thermodynamic relations (22), the latter being more directly relevant to the subject of this paper. In summary, these studies indicate that, as found in the Cu-Au system, the order-disorder transitions in AB_3 and AB face-centered-cubic solutions are first order reactions which mandate the presence of two phase fields in the equilibrium diagram, except at maximum ordering temperature, generally expected at the exact stoichiometric concentrations. In the AB case the matter is made more explicit since the ordered phase must have a lower crystal symmetry than the disordered face-centered-cubic solid solution, since it is impossible to conceive of a simple fcc structure with order at the 50% composition. For example CuAu is tetragonal with alternate layers of Cu and Au on the (001) planes, and CuPt is reported to be rhombohedral, with alternate layers of Cu and Pt on the (111) planes (23). Thus even if the ordered phase CrPt were found to be seemingly cubic, its true symmetry would not be cubic, but perhaps tetragonal with $c = a$.

The diffraction results obtained with the sample containing 48.5 a/o Cr indicate that CrPt is very slightly tetragonal, not rhombohedral. This judgment is largely based on the relative sharpness of the diffraction peaks (111) and (222) relative to their neighbors. Moreover if one assumes an AuCu type of structure (pseudo face-centered-tetragonal, with alternate layers of Cr and Pt atoms along the c axis) the allowed diffraction peaks would be those for which $h + k = 2n$. Then the following reflections should be sharp: (001), (110), (111), (201), (112), (310), (222), (203), (312), (401), (421), and (332); while these reflections should be broad: (200-002), (220-202), (221-003), (400-004), (114-330), (313-331), (420-402-204), and (422-242). This can be observed to conform with the experimental results (see Appendix). By least squares calculations and the use of a Nelson-Riley extrapolation the lattice parameters (uncorrected for stress) were found to be a = 3.822Å and c = 3.811Å from the d spacings for the sharp peaks. [These values, obtained with the computer-controlled diffractometer and good statistics, are to be preferred to the previously reported ones (3.825 and 3.809Å) obtained by visual reading of diffraction angles from a chart record (8)]. Even taking into account respectively the difference in atomic diameters between Cr and Pt (2.54 and 2.76Å) and the difference between Cu and Au (2.56 and 2.88Å), one can see that the c/a ratio for CrPt is much closer to 1.0 than would be anticipated on the basis of CuAu, since for this compound the lattice parameters are a = 3.960Å and c = 3.670Å.

To establish concentration boundaries for the different Cr-Pt phases referred to in this paper is beyond the scope of the present study. For the phases formed at low temperatures, in the vicinity of 500°C, experimental results indicate that the limits should

be quite narrow. The slopes of the traces corresponding to the two compounds in Fig. 1 are indicative of narrowly defined composition limits, although perhaps a case could be made for the existence of $CrPt_3$ with an excess of Pt. CrPt, on the other hand, appears to be extremely narrowly defined, regardless of the presence of both $CrPt_3$ and residual unreacted Cr. The evidence derived from the x-ray diffraction patterns points in the same direction. The lattice parameters of coexisting phases of $CrPt_3$ and CrPt indicate compositions quite close to 25 and 50 a/o Cr, leaving little freedom to extend the composition limits off stoichiometry.

One may speculate as to why the tetragonal structure of CrPt had not been reported previously. Of course, one reason is that the unit cell is almost a cube. Beyond this it is not impossible that in bulk samples stresses may considerably hinder the transformation from the cubic structure to the tetragonal one, while in films there are possibilities for stress relaxation in at least one direction. In this case the films would allow for a closer approach to chemical equilibrium than is possible with bulk samples, which leaves some ambiguity about the definition of the "equilibrium state."

Conclusions

1. Results from diffusion experiments conducted with thin films of Cr and Pt require the existence of two distinct ordered phases $CrPt_3$ and CrPt which are not shown on the presently available equilibrium diagram.

2. In a range of temperature near 500°C the limits of existence of these phases appear to be quite narrow, of the order of a few atomic percent.

3. $CrPt_3$ is ordered face-centered-cubic with a lattice parameter of 3.877 ± 0.005Å.

4. These individual phases were also detected in samples annealed at temperatures in the vicinity of 1000°C. At such temperatures an ordered phase with the presumed structure of Cr_3Pt was also observed. This phase apparently exists off stoichiometry, with a composition of approximately 65 a/o, which corresponds to the maximum "solubility limit" of Cr in Pt.

5. At least in thin film form the phase CrPt displays structural characteristics which indicate that it is ordered and tetragonal, like CuAu. This is consistent with the crystallographic requirements for an ordered phase of this composition and with the thermodynamic requirements for a first order transformation.

6. The lattice parameters of CrPt, a = 3.822Å and c = 3.811Å, indicate a very small tetragonal distortion from the cubic lattice of Pt. These values were obtained from a sample containing 48.5 a/o Cr, deposited on a sapphire substrate and annealed at 975°C. In order to obtain absolute values one would need to make careful corrections for stress effects (presumably about +0.010Å).

ABSTRACT

The transient response of the dopant system of a horizontal, silicon epitaxial reactor has been studied in order to obtain a "transfer function" relating the time variation of the dopant gas flow and the spatial variation of the dopant concentration in the epitaxial film. This transfer function should be useful in fabricating nonuniform dopant concentrations needed for desired device characteristics. The transfer function was obtained from the response of the system to both increasing and decreasing step changes in the dopant gas flow with time. The transfer-function approach was verified by experiments in which the input was an increasing step followed by a decreasing step (approximating a pulse). Pulse widths both longer than and comparable to the decay time of the system were used, and the measured profiles agreed very well with calculated profiles in all cases. The transient and steady-state responses of the dopant system were studied at different growth rates to determine the effect of growth rate on the parameters entering into the transfer function. These experiments showed the presence of two regions of operation and provide insight leading to a better understanding of the doping process.

In silicon integrated-circuit technology, three basic methods are used to introduce dopant atoms into a semiconductor: thermal diffusion, ion implantation, and epitaxy. When thermal diffusion or ion implantation is employed, the distribution of impurity atoms within the crystal can be approximated by either a "complementary error function" (erfc) or a "Gaussian" distribution. In these two cases the depth and the doping levels can be fairly well controlled, but the shape of the impurity distribution is fixed by the method of dopant introduction. In the third case the dopant atoms are incorporated during epitaxial growth, usually producing a uniform impurity distribution in the epitaxial layer. But this is not, at least in theory, the only possible distribution. In contrast with the other two methods, one should be able to obtain a desired variation of the impurity concentration as a function of position in the deposited epitaxial layer by properly varying the dopant gas flow with time during epitaxial growth. Nonuniform doping profiles can be used in specialized devices and could open up new alternatives to the integrated-circuit process engineer. One good example of a device employing a nonuniform doping profile in the epitaxial layer is illustrated in the work of Jackson and DeMassa (1) on hyperabrupt epitaxial tuning diodes.

In order to relate the spatial variation of the dopant concentration in the epitaxial layer $N(x)$ to the time variation of the dopant gas flow $f_D(t)$, the epitaxial reactor can be viewed as a "black-box" with $f_D(t)$ as the input and $N(x)$ as the output (Fig. 1). [$N(x)$ and $N(t)$ are related by the epitaxial growth rate $g = x/t$.] If the black-box behaves linearly throughout at least a limited operating range, the impulse response $h(t)$ (2) characterizing the input-output relation of the reactor can be found experimentally by studying the response of the reactor to a step change in the dopant gas flow (3, 4). By using the expression for $h(t)$ and standard linear systems techniques (2), the response $N(x)$ of the system to an arbitrary input $f_D(t)$ can readily be calculated; alternatively, the input needed for a desired dopant profile can be obtained.

While such characterization of an epitaxial reactor has not been attempted in the past, a brief literature survey indicates that the characterization of transient doping effects is promising. For example, diffusion-rate processes in catalytic reactors have been characterized by "admittance functions" analogous to a-c electrical parameters (5). In that work, the time-varying, output-gas concentrations were related to the time variations of the input gases. Other work on chemical systems has considered diffusion through a boundary layer, adsorption on a surface, and diffusion into a solid (6). Several of the same kinetic processes are important when considering dopant incorporation into epitaxial layers. Here, however, additional physicochemical processes are involved since the output is not a time-varying gas concentration, but a variation

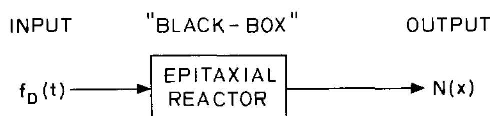

Fig. 1. Dopant system of the epitaxial reactor as a "black-box." $f_D(t)$ = time variation of the dopant gas flow, $N(X)$ = spatial variation of the dopant concentration in the epitaxial layer. $N(X)$ and $N(t)$ are related by the epitaxial growth rate $g = x/t$.

Key words: silicon epitaxy, arsine, silane.

of dopant concentration as a function of position in the deposited epitaxial layer.

It is worth mentioning that varying the dopant gas flow with time in a conventional reactor is not the only way of obtaining a nonuniform dopant distribution in an epitaxial layer. Using a conventional horizontal epitaxial reactor, Nihira *et al.* (7) obtained nonuniform doping profiles by changing the deposition temperature during epitaxial growth by SiH_4 pyrolysis. More recently Becker and Bean (8), using silicon molecular-beam epitaxy, obtained abrupt changes in the gallium doping level of epitaxial layers by rapidly varying the Ga oven temperature (which controls the Ga flux) during growth.

In addition to providing a method of fabricating a desired dopant profile, a transient-response study can produce basic information concerning the various mechanisms involved in the dopant incorporation process. As indicated by Kobayashi and Kobayashi (9), transient studies may reveal the importance of various mechanisms which may not be apparent in steady-state studies.

In this paper, the experiments that were carried out to obtain and verify the expression $h(t)$ characterizing the $f_D(t) - N(x)$ relation of the epitaxial reactor are described. A study of the dependence of $h(t)$ on the silicon deposition rate is also presented. The physical mechanisms involved in the dopant incorporation process will be discussed in more detail in another paper (10).

Equipment and Experimental Details

All of the experiments presented here were carried out in a commercially purchased, horizontal, rf-heated epitaxial reactor (Hugle Model HIER II) operating at atmospheric pressure. The quartz reactor tube has the dimensions 5.1 cm (height) $\times$ 8.3 cm (width) $\times$ 91.4 cm (length) and an effective cross section of 27 cm^2 above the susceptor. The silicon carbide-coated graphite susceptor is 22.8 cm long and is tilted at an angle of 2°. Dopant gases are delivered to the reactor tube through a double-dilution dopant system. Hydrogen was used as the carrier gas at a velocity of 34 cm/sec above the susceptor (at room temperature). Silane was used as the source of silicon, and arsine diluted to approximately 70 ppm in hydrogen was used as the dopant source.

Before each run, the susceptor was vapor etched with HCl and then coated with high resistivity silicon. The wafers were vapor etched with HCl before the epitaxial deposition cycle. Rotometers were used to monitor the gas flow. Temperature measurements were made during the etching and deposition cycles using a calibrated optical pyrometer and corrected for the emissivity of silicon and for absorption in the reactor tube walls. The corrected wafer surface temperatures during etching and deposition were approximately 1180° and 1050°C, respectively. The substrates were chem-mechanical polished, Czochralski-grown, silicon wafers, with (100) orientation and phosphorus doping in the 10^{15} cm^{-3} concentration range.

In the transient study, the dopant profiles in the epitaxial layers were determined by capacitance-voltage measurements on planar p-n junctions, mesa p-n junctions, and deep-depletion MOS structures (11). The epitaxial doping levels chosen in this study ($\sim 10^{15}$ cm^{-3}) correspond to the practical range of doping values of interest in semiconductor devices. In addition, they were compatible with the evaluation technique, being low enough to allow the required depth profiling and high enough to produce a relatively short Debye length (12). The p-n junctions were fabricated by diffusion of boron at 950°C for 30 min, producing a junction depth of approximately 0.6 μm. The oxides of the MOS structures were grown in wet oxygen at 950°C for 40 min and were approximately 1800Å thick. The area of each structure was 3.3×10^{-3} cm^2.

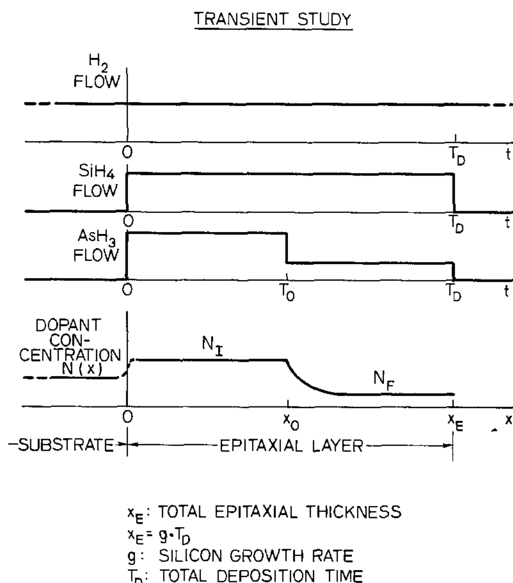

Fig. 2. Step-response experiment, showing the gas flows as functions of time and the dopant concentration as a function of the corresponding position in the epitaxial layer.

Spreading-resistance measurements were used to confirm the capacitance-voltage results. The epitaxial-layer thicknesses were determined from the size of stacking faults on the surfaces of the grown layers.

Experiments, Results and Discussion

Transfer-function determination.—Step response. This experiment allowed the study of the dopant distribution obtained when the dopant gas flow was abruptly changed during the deposition and can be easily understood with the help of Fig. 2. At time $t = 0$ the deposition cycle started, and silane and arsine were introduced into the reactor tube. The silane flow was kept constant throughout the entire deposition cycle, which ended at $t = T_D$. A silane partial pressure of 1.1×10^{-3} atm was used to obtain a growth rate of approximately 0.6 μm/min, which was used in all experiments discussed in this section. At $t = T_0$ the arsine flow was abruptly decreased by lowering the flow setting on the arsine flowmeter located nearest to the reactor tube. The arsine partial pressure was changed from approximately 6×10^{-10} to 2×10^{-10} atm, corresponding to dopant concentrations of roughly 3×10^{15} and 1×10^{15} cm^{-3} in the epitaxial layer.

The solid curve of Fig. 3 shows the measured majority carrier concentration as a function of position in the epitaxial film for a decreasing step change in the dopant gas flow during the deposition. In Fig. 3-7, which show epitaxial-layer dopant profiles, the zero of position corresponds to the Si-SiO_2 interface of the deep depletion MOS structure (see section on Equipment and Experimental Details) and is displaced from the original silicon epitaxial surface by the amount of silicon consumed during the gate oxide growth. In order to ensure that the measured profiles were not limited by the resolution of the capacitance-voltage, data-reduction technique, a theoretical capacitance-voltage curve was generated by solving Poisson's equation using an impurity profile varying more abruptly than the measured one, in a manner similar to that described in (13). The data-reduction program was then applied to this curve. The computed free carrier profile agreed very closely with the starting impurity profile, indicating that the major features observed in Fig. 3 are not artifacts of the analysis technique. Because of the low diffusivity of arsenic in silicon (14), the heat cycling during the fabrication of the MOS and p-n junction C-V structures produced a diffusion length of only 0.01 μm. Spreading-resistance

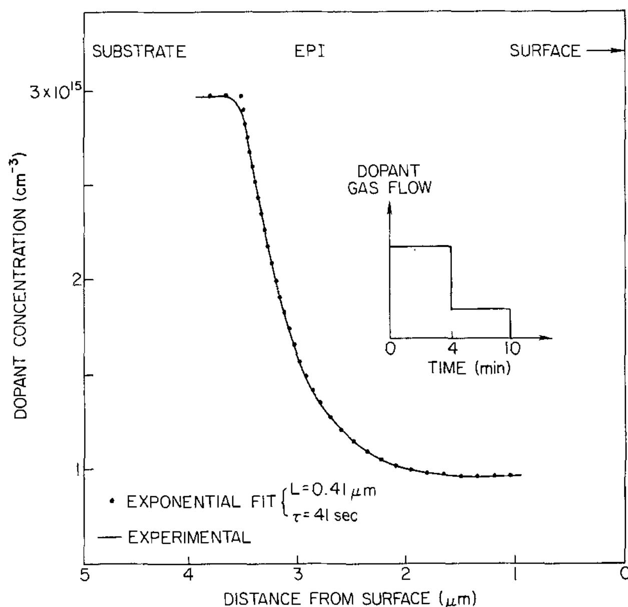

Fig. 3. Solid curve: experimentally observed majority carrier concentration as a function of distance from the surface of the epitaxial film for the decreasing step change in the dopant gas flow indicated in the inset. Dotted curve: exponential fit to the experimental profile.

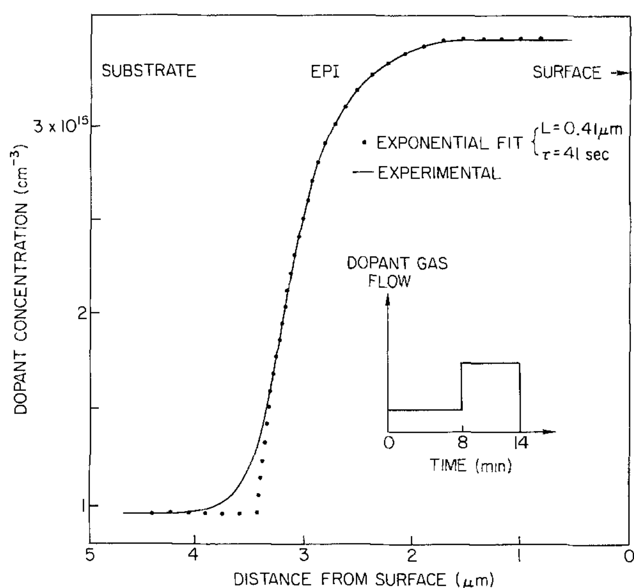

Fig. 4. Solid curve: experimental dopant profile for an increasing step change in dopant gas flow. Dotted curve: exponential fit to the experimental profile.

measurements confirmed that there was no significant difference between the dopant profiles of samples measured after epitaxial deposition and after fabrication of the complete C-V structures.

As shown by the dotted curve in Fig. 3, an excellent fit to the data can be obtained by using the expression (4, 15)

$$N(x) = N_I + (N_F - N_I) \left\{ 1 - \exp\left(-\frac{x - x_0}{L}\right) \right\} \quad \text{for } x \geqq x_0 \quad [1]$$

where, following Fig. 2, $N(x)$ is the dopant concentration at a distance x from the substrate, N_I is the initial doping level for $x < x_0$, N_F is the final doping level, L is the decay length of the exponential, and x_0 is the distance from the substrate corresponding to $t = T_0$. ($x_0 = g \cdot T_0$, where g is the epitaxial growth rate.) For this case $N_I = 3 \times 10^{15}$ cm^{-3}, $N_F = 1 \times 10^{15}$ cm^{-3}, $x_0 = 2.4$ μm, and $L = 0.41$ μm.

The response of the reactor to an increasing step change in the arsine flow is shown in Fig. 4 (solid curve). The growth conditions for this case were similar to those shown in Fig. 2, except that the flow setting of the arsine flowmeter was abruptly changed from a low value to a higher value at $t = T_0$, as shown in the inset of Fig. 4. Equation [1] also fits the measured profile reasonably well (Fig. 4, dotted curve), with the same decay length of 0.41 μm found before. However, the transition in the experimentally measured dopant profile starts more gradually than does the simple exponential function. At least a portion of this discrepancy arises since the measured free carrier profile changes less abruptly with distance than does the dopant profile. The deviation between these two profiles is caused by the lack of local space-charge neutrality resulting from the nonuniformity of the dopant profile (16). The fact that the deviation is more apparent at lower dopant concentrations (*i.e.*, it is more obvious in Fig. 4 than in Fig. 3) is consistent with this explanation. Note from Fig. 3 and 4 that the transition from one dopant concentration to the other occurs in approximately 1.2 μm, corresponding to a time of roughly 2 min.

The impulse response characterizing the input-output relation of the dopant system can be obtained from Eq. [1] to be

$$h(t) = \frac{K}{\tau} \exp\left(-\frac{t}{\tau}\right) \quad [2a]$$

or

$$H(s) = K \cdot \frac{1}{1 + s\tau} \quad [2b]$$

where $\tau \equiv L/g$ is the decay time of the dopant system; it physically corresponds to the time required to grow a thickness of epitaxial silicon equal to one decay length. From Fig. 3 and 4, τ is found to be 41 sec. K is the proportionality constant relating the dopant concentration (N) in the epitaxial layer to the dopant gas flow (f_D) for steady-state conditions: $N \equiv Kf_D$. The reciprocal of K is sometimes called the "effective segregation coefficient" (17). As shown below, Eq. [2] is useful in calculating the dopant distribution $N(x)$ in the epitaxial layer resulting from an arbitrary input $f_D(t)$ or, alternatively, the input $f_D(t)$ needed to obtain a desired profile $N(x)$.

Pulse response.—To verify Eq. [2], a series of experiments was designed in which the input to the system was an increasing step in the arsine flow followed by a decreasing step, the combination simulating a pulse. Four different pulse widths were used: 4.3, 3.0, and 1.8 min, and 48 sec.

Figure 5 shows the measured profiles for the 4.3 min and 48 sec pulses (solid curves), with the corresponding, time-varying, dopant gas flows represented in the insets. For the 4.3 min pulse (Fig. 5a) the resulting profile was a simple superposition of the profiles shown in Fig. 3 and 4 because the pulse width was much longer than the system decay time (41 sec). This was also true for the 3 min pulse. For the 48 sec pulse (Fig. 5b) the higher steady-state doping level was never reached, indicating the limits of the deposition system in responding to arbitrary changes in the dopant gas flow. In this case the pulse width (48 sec) is approximately the same as the system decay time. The doping profile corresponding to the pulse width of 1.8 min showed intermediate characteristics.

Doping profiles corresponding to the input pulses were calculated using the convolution integral (2) and Eq. [2a]

$$N(t) = \int_0^t h(t - t^*) \cdot f_D(t^*) dt^* \quad [3a]$$

After some mathematical manipulation

$$N(t) = N_L(1 - e^{-t/\tau})u(t) + (N_H - N_L)[1 - e^{-(t-T_1)/\tau}] \cdot u(t - T_1) - (N_H - N_L)[1 - e^{-(t-T_2)/\tau}]u(t - T_2) \quad [3b]$$

where N_L is the lower doping level ($\sim 1 \times 10^{15}$ cm^{-3}), N_H is the higher doping level ($\sim 3 \times 10^{15}$ cm^{-3}), $u(t)$ is the unit step function, and T_1 and T_2 represent the beginning and end of the period of high dopant gas flow.

Since the growth rate g relates time to position in the epitaxial film through $t = x/g$, the dopant concentration can be written as a function of position

$$N(x) = \underbrace{N_L(1 - e^{-x/L})u(x)}_{A} + \underbrace{(N_H - N_L)[1 - e^{-(x-x_1)/L}]u(x - x_1) - (N_H - N_L)[1 - e^{-(x-x_2)/L}]u(x - x_2)}_{B} \quad [3c]$$

where $L = g \cdot \tau$ is the decay length, and $x_1 = g \cdot T_1$ and $x_2 = g \cdot T_2$ are the distances from the substrate corresponding to the beginning and end of the period of high dopant gas flow.

In Eq. [3c], the expression labeled A corresponds to the transient at the beginning of the epitaxial deposition. This expression is not expected to be accurate because it was obtained with the assumption that the system is de-energized at $t = 0$; *i.e.*, it was obtained neglecting initial conditions such as autodoping. It also neglects the transient associated with establishing a steady-state, silicon deposition rate. Nevertheless, it may provide an estimate of the duration of the initial transient. Duchemin (18) studied experimentally and theoretically the transient effects before a steady-state doping regime is established at the beginning of the epitaxial growth, and expression A seems to agree well with his results.

The expression labeled B is plotted in Fig. 5 (dotted curves). There is good agreement between the calculated and the measured profiles; the slight discrepancies at the onset of the transitions are probably artifacts due to the absence of local space-charge neutrality (16). In another experiment where the input was an increasing ramp followed by a decreasing step, the agreement between the calculated and measured profiles was also excellent (4). Therefore, it can be concluded that the dopant system can be modeled by a transfer function over a useful operating range.

System delay.—In order to study quantitatively the time that elapses between a step change in the dopant flow and the onset of the transition in the epitaxial-layer dopant concentration, the following experiment was carried out. As shown in the inset of Fig. 6, the dopant gas input consisted of a series of two 48 sec-wide pulses separated in time by 5 min. The series of pulses provided a built-in calibration of the depth scale so that a very short delay between the change of the dopant gas flow and the onset of the transition in the dopant profile could be resolved. The dopant profile measured in the resulting epitaxial layer is also shown in Fig. 6. The distance between the two pulses was determined from the measured dopant profile, allowing a precise calculation of the growth rate. From the growth rate, the depths corresponding to the beginning and end of each pulse were then calculated and are indicated by the arrows shown in Fig. 6. As mentioned above, the zero of position in Fig. 6 corresponds to the Si-SiO_2 interface of the deep-depletion MOS structure, rather than the original silicon surface, and the displacement was accounted for in the calculations. The arrows corresponding to 6.8 and 11.8 min show that there is no appreciable delay ($\lesssim$ 4 sec) between the decrease in dopant gas flow and the onset of the change in dopant concentration in the growing epitaxial film. Since the residence time of a volume element of the flowing gas in the reactor tube is also of the order of 4 sec, the delay mentioned above may be attributed primarily to flow in the forced-convection region. The arrows corresponding to 6 and 11 min seem to indicate that the transition starts before the dopant gas flow is actually increased at the dopant flowmeter, but this apparent discrepancy is related to the lack of space-charge neutrality discussed previously.

The transfer function obtained relates the dopant distribution in the epitaxial layer to the time variation of the dopant gas flow at the flowmeter. When an abrupt change is made at the dopant flowmeter, some time is required before the dopant molar fraction in the main gas stream of the reactor tube reaches a new steady-state condition due to gas flow and intermixing. Consideration of the reactor geometry and the gas flows involved indicates that the time for the gas to be swept into the deposition region is approximately 4 sec, which is certainly short compared to the decay time of 41 sec seen in Fig. 3 and 4. In addition, it is shown in the next section that the decay time associated with the transient response is strongly dependent on the epitaxial growth rate, again indicating that gas-phase flow and intermixing in the main gas stream do not limit the transient behavior and may be neglected in the present discussion.

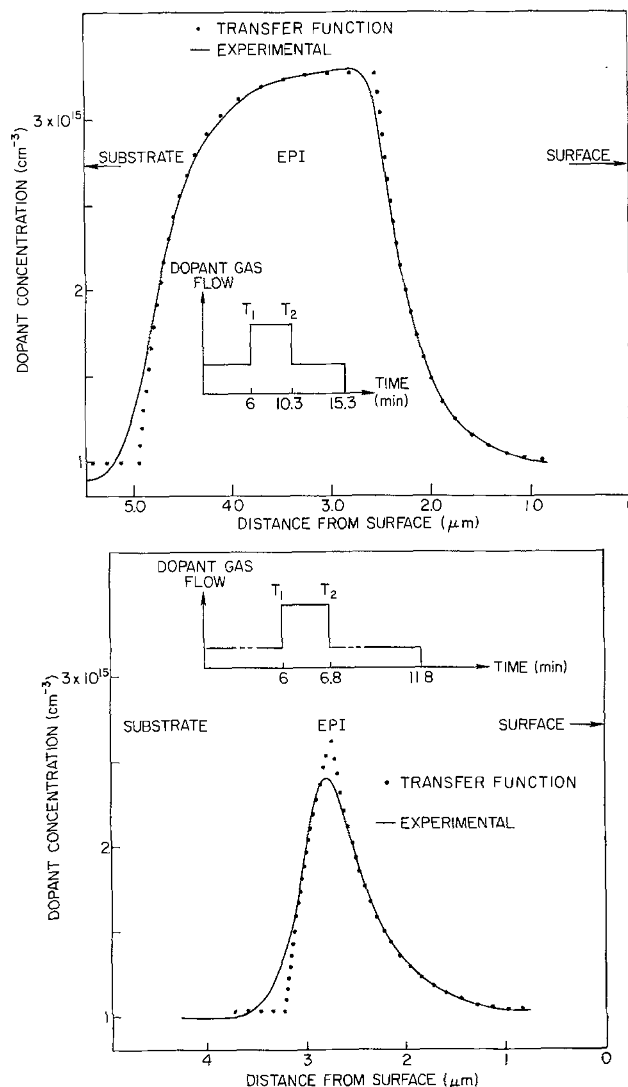

Fig. 5. Response of the reactor to pulse inputs of dopant gas. The times of high dopant gas flow were (a, upper) 4.3 min and (b, lower) 48 sec.

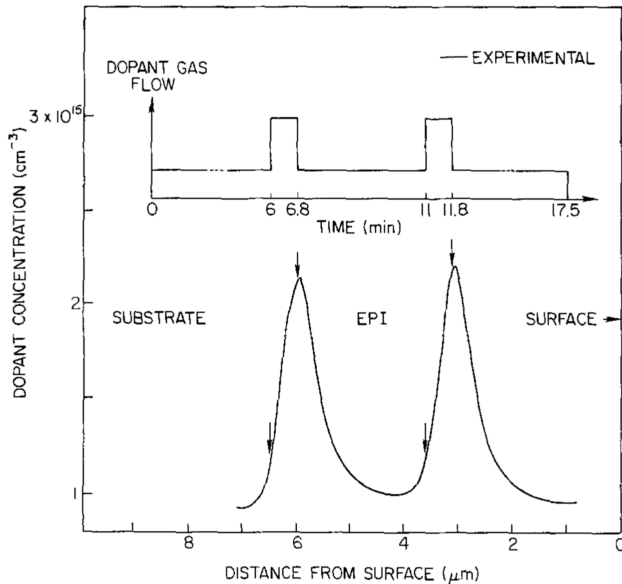

Fig. 6. Reactor response to a sequence of two pulses, each 48 sec long.

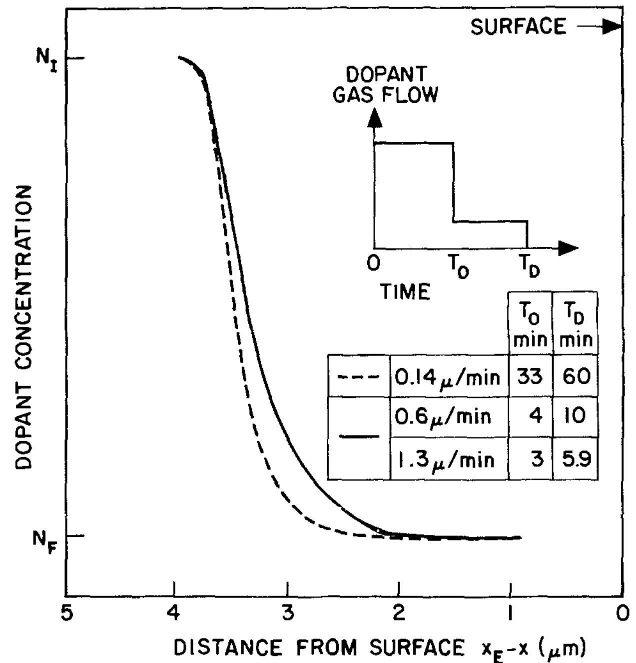

Fig. 7. Measured dopant profiles for different epitaxial growth rates.

Growth-rate dependence.—As shown above, the transfer function of the dopant system contains two basic parameters: τ, related to the transient, and K, related to steady state. To learn more about the doping process and to complete the expression for the transfer function, the growth-rate dependence of these parameters was studied.

Decay-time study.—The objective of this series of experiments was to learn how the growth rate influences the decay time τ. The input to the system was again a decreasing step, as indicated in Fig. 2, and the experiment was repeated at four different growth rates. The silane partial pressure was varied within the 10^{-4}-10^{-3} atm range to produce growth rates of 0.14, 0.32, 0.6, and 1.3 μm/min. The dopant partial pressure was simultaneously adjusted in the 10^{-10}-10^{-9} atm range to compensate for the difference in growth rate and to achieve the two doping levels of 1×10^{15} and 3×10^{15} cm^{-3} in each experiment. Equation [1] was then used to obtain the decay length and the decay time from the measured profiles.

The measured dopant profiles are shown in Fig. 7, together with a table indicating the values of T_0 and T_D in each case. These values were chosen to compensate for the different growth rate in each experiment. The impurity profiles obtained for growth rates of 0.6 and 1.3 μm/min are indistinguishable (solid curve) and differ strongly from the one obtained at 0.14 μm/min (dashed curve), which changes much more abruptly with distance. The dopant profile corresponding to 0.32 μm/min fell between the two shown in Fig. 7.

Figure 8a and b show the decay length and decay time as functions of growth rate. The dashed line in Fig. 8b corresponds to a slope of -1, which in this log-log plot indicates decay times inversely proportional to the growth rate. At 0.6 and 1.3 μm/min, the decay lengths are equal, and the decay times are proportional to g^{-1}, falling on the dashed line. At lower growth rates, the decay length decreases with decreasing growth rate, and the decay time varies less rapidly than g^{-1}, showing a tendency to become constant at very low growth rates. Expressions which fit the experimental data are found to be

$$L = \frac{K_0 \cdot g}{K_1 \cdot g + K_2} \quad [4a]$$

and

$$\tau = \frac{K_0}{K_1 \cdot g + K_2} \quad [4b]$$

where K_0, K_1, and K_2 are constants. The implications of this growth-rate dependence of the transient behavior are analyzed later, along with the results of the steady-state study to be described next.

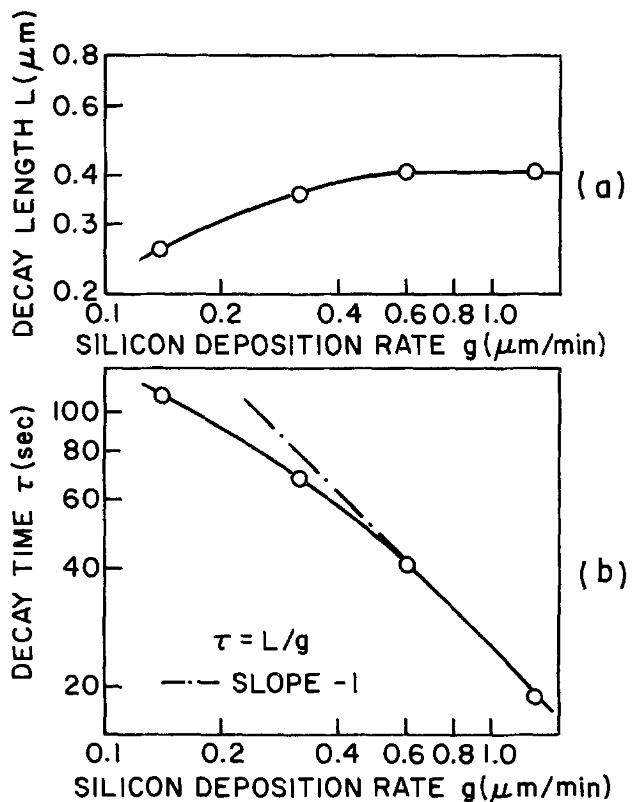

Fig. 8. (a) Decay length and (b) decay time of the transient as functions of growth rate.

Steady-state study.—The steady-state experiments involved an investigation of the effect of the silicon deposition rate on the impurity concentration of uniformly doped epitaxial layers. The arsine partial pressure was kept at 6.2×10^{-10} atm, and the silane partial pressure was varied between 2.7×10^{-4} and 2.3×10^{-3} atm to produce growth rates ranging from 0.13 to 1.2 μm/min. The substrates were boron-doped with resistivities ranging from 1 to 4 Ω-cm. The thicknesses of the epitaxial layers were between 5.5 and 8.1 μm and were measured by a groove-and-stain technique. A four-point probe was used to determine the resistivity of the layers. Carrier concentrations were obtained from Irvin's resistivity data (19) and assumed to be equal to the arsenic concentration in these lightly doped epitaxial layers.

The results of these experiments are shown in Fig. 9, where the dopant concentration of uniformly doped epitaxial layers is plotted as a function of silicon deposition rate. At growth rates greater than approximately 0.5 μm/min, the doping density becomes inversely proportional to the silicon growth rate, as indicated by a slope of -1 on this log-log plot. At lower growth rates, the doping density varies less rapidly than g^{-1} and shows a tendency to become constant at very low growth rates. Similar behavior has been observed by Shepherd for the $PCl_3/SiCl_4$ system (20), by Bloem for the PH_3/SiH_4 system (17), and more recently by Duchemin for the $B_2H_6/SiHCl_3$ and B_2H_6/SiH_2Cl_2 systems (18). The growth-rate dependence of the epitaxial-layer dopant concentration was also investigated by Rai-Choudhury and Salkovitz for the $B_2H_6/SiCl_4$ and $AsH_3/SiCl_4$ systems (21).

The data of Fig. 9 can be used to find the steady-state relation between dopant concentration and dopant gas flow used in Eq. [2]

$$N = \frac{f_D}{K_1 \cdot g + K_2} \qquad [5]$$

Equation [5] may be written in the same form as Eq. [4b]

$$K = \frac{N}{f_D} = \frac{1}{K_1 \cdot g + K_2} \qquad [6]$$

suggesting the importance of similar mechanisms in both the transient and steady-state cases, as is discussed later.

The process limiting the doping in the various regions of Fig. 9 may be localized by considering the temperature dependence of the mechanisms proposed by others on the basis of their steady-state experiments. Bloem (17) suggested that the decrease in dopant concentration with increasing epitaxial growth rate is due to a mass-transport limitation of PH_3 traversing the boundary layer. In this case, for a fixed gas-phase dopant concentration, increasing the growth rate causes the same number of dopant atoms to be incorporated in thicker silicon films, thus decreasing the epitaxial layer dopant concentration. Duchemin (18) explained the same behavior by proposing that the boron incorporation rate is limited by the gas-phase chemical decomposition of B_2H_6 above the gas-solid interface.

The temperature dependence of the As concentration in the epitaxial layer may be used to determine which of these mechanisms limits the As incorporation rate at high growth rates in the AsH_3/SiH_4 case under consideration here. If the As incorporation rate were controlled by AsH_3 mass transport across the boundary layer, the As concentration in the growing film would not change significantly with varying deposition temperature. Under normal operating conditions the deposition of Si from SiH_4 is mass-transport controlled, and the gas-phase diffusion constants of AsH_3 and SiH_4 are expected to have a similar temperature dependence. Thus, the As incorporation rate and the Si deposition rate change in the same manner, and the dopant concentration in the epitaxial layer remains relatively constant. On the other hand, if the As incorporation rate were limited by the gas-phase decomposition of AsH_3, the As concentration in the epitaxial film would increase with increasing temperature, showing an Arrhenius activation energy.

To differentiate between the possible mechanisms, the effect of the deposition temperature on the epitaxial layer As concentration was investigated. Layers were grown at 1025°, 1050°, and 1075°C with an arsine partial pressure of 6.2×10^{-10} atm and a SiH_4 partial pressure of about 2.2×10^{-3} atm, which produced a growth rate of approximately 1.2 μm/min. As indicated in Fig. 10, the As concentration in the epitaxial film decreases with increasing deposition temperature, showing a slope of approximately 30 kcal/mole. The same experiment was repeated several times, always with the same results. Since the temperature dependence does not agree with that expected from either of the mechanisms discussed above, it can be concluded that neither dopant mass transport across the boundary layer nor gas-phase chemical decomposition are dominant in the As incorporation process and that other mechanisms must limit the doping process. It is shown in another paper (10) that the experimental data in Fig. 10 can be explained by considering mechanisms occurring at the growing surface (*e.g.*, adsorption, surface chemical dissociation, site incorporation, etc.).

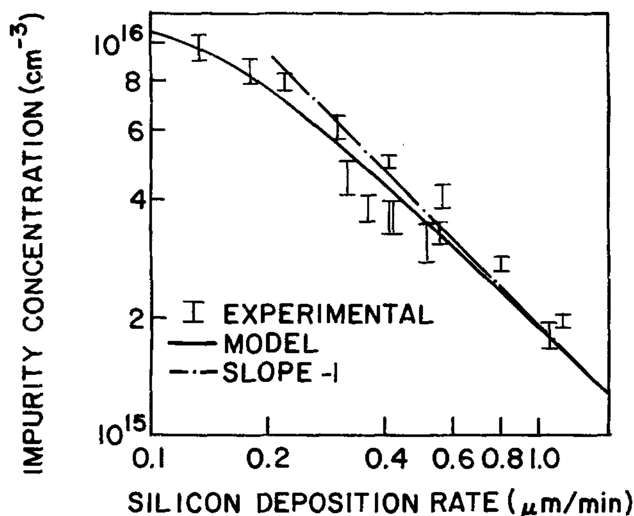

Fig. 9. Dopant concentration of uniformly doped epitaxial layers as a function of growth rate. $P_{AsH_3} = 6.2 \cdot 10^{-10}$ atm, T = 1050°C.

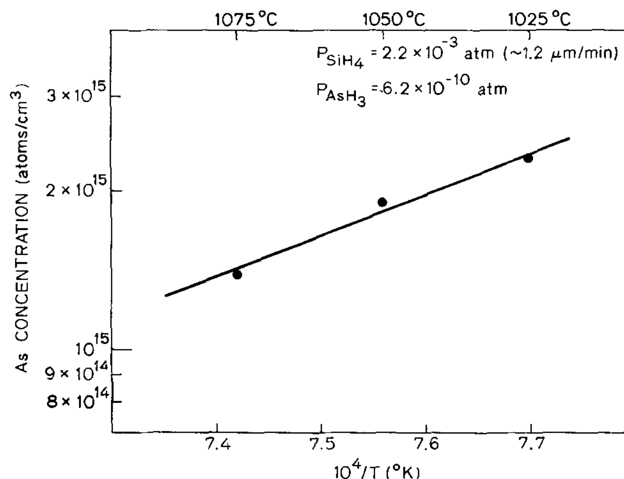

Fig. 10. Temperature dependence of As concentration in uniformly doped epitaxial layers.

Discussion.—By combining the results of the steady-state and transient experiments, some conclusions may be drawn about the mechanisms controlling the doping process.

Low growth rates ($g < 0.5$ μm/min).—Figure 9 shows that at growth rates lower than about 0.5 μm/min, the doping density in the epitaxial films varies less rapidly than g^{-1} and shows a tendency to become constant at very low growth rates. This behavior may be explained by recognizing that lowering the growth rate brings the doping process closer to equilibrium, where it becomes independent of the growth rate. In this region the dopant incorporation process is controlled by the thermodynamics of the various mechanisms entering into the over-all doping process.

High growth rates ($g \gtrsim 0.5$ μm/min).—At higher growth rates the decrease in dopant concentration seen in the steady-state experiments indicates a departure from equilibrium as a kinetic limitation begins to dominate. In this region the limiting mechanism may occur in either the gas phase or on the growing surface of the epitaxial layer. The temperature dependence of the dopant concentration seen in the steady-state experiments has been used to eliminate gas-phase processes as the limiting mechanism, suggesting the importance of surface processes. The influence of surface processes is also indicated independently by the transient experiments. If the over-all doping process were limited by gas-phase mechanisms, the decay time should be independent of the growth rate, while the decay length may be expected to be constant if surface phenomena are limiting. Since the decay length does remain constant at high growth rates, the limitation of the doping process may be attributed to mechanisms occurring at the surface. The nature of these surface mechanisms are analyzed elsewhere (10) where a physicochemical model, from which Eq. [2], [4], and [5] can be derived, is presented.

Summary and Conclusions

The transfer function of the dopant system of a horizontal epitaxial reactor was obtained experimentally by studying the response of the reactor to a step change in the dopant gas flow. This transfer function can be used to calculate the time-variation of the dopant gas flow needed to produce a desired spatial variation of the impurity concentration in an epitaxial layer. To verify the validity of the transfer-function approach, pulses of different widths were used as inputs to the system. The resulting dopant profiles were measured and compared to those calculated using the transfer function; excellent agreement was found. The system delay, defined as the time between a change in the dopant gas flow and the beginning of the resulting transition in the epitaxial dopant concentration, was studied experimentally and found to be negligible compared to the system decay time.

The expression for the transfer function contains two parameters, τ and K, related to transient and steady-state conditions, respectively. The dependence of these parameters on the epitaxial growth rate was studied, showing the presence of two regions of operation depending on the growth rate. At low growth rates ($g < 0.5$ μm/min) both the steady-state dopant concentration and the decay time of the transient tend to become constant, implying that thermodynamics control the doping process. At high growth rates ($g \gtrsim 0.5$ μm/min) the epitaxial dopant concentration and the decay time are proportional to g^{-1}, and the epitaxial dopant concentration decreases with increasing deposition temperature. This behavior is associated with a kinetic limitation on the doping process and is related to mechanisms occurring at the growing surface, rather than in the gas phase.

The Structure and Composition of Silicon Oxides Grown in HCl/O_2 Ambients

J. Monkowski,* R. E. Tressler,** and J. Stach**

Departments of Materials Science and Electrical Engineering, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

The structure and composition of silicon oxides thermally grown in HCl/O_2 ambients were investigated for various oxidation conditions. Oxides were grown in 6-10 v/o HCl at 1150°-1300°C for times of 15 min-6 hr. Transmission electron microscopy in conjunction with x-ray microanalysis has indicated the presence of an additional condensed phase at the oxide-silicon interface, which appears after a certain oxidation time has elapsed. Scanning electron microscopy has shown that after further oxidation, a gaseous compound accumulates at the interface, lifting the oxide from the silicon, and preferentially etching the silicon. A model of the growth mechanisms of HCl oxides, accounting for the additional phase formation, is proposed.

The improved electrical properties of silicon oxides thermally grown in the presence of chlorine have been widely documented (1-7). Recently, ellipsometry in conjunction with scanning electron microscopy (SEM) was used to observe the structure of oxides grown in HCl/O_2 mixtures, and it was found that oxides grown for a certain amount of time in a certain concentration of HCl possessed rough surfaces (8). Additionally, the conditions necessary to initiate the roughness correlated well with the conditions reported to be necessary to achieve mobile ionic sodium passivation.

In order to obtain a better understanding of the formation of the rough oxide, as well as of the origin of the roughness, oxides grown under various conditions were investigated using electron microscopy. Those conditions which were varied included the oxidation temperature, the oxidation time, and the HCl content added to the oxidizing ambient. Scanning electron microscopy was used to view the surface of the oxides, transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM) yielded information on the inner structure of the oxides, particularly at the oxide-silicon interface, and x-ray microanalysis in conjunction with STEM showed the compositional variations within the oxides.

Experimental

All oxidations were performed on (100) oriented, 2-3 Ω-cm, phosphorus-doped, 2 in. diam silicon wafers. Prior to oxidation the wafers were cleaned using an ammonium hydroxide-hydrogen peroxide solution, a hydrochloric acid-hydrogen peroxide solution, a diluted hydrofluoric acid dip, and several deionized water rinses. The oxidations were done in a resistance-heated furnace containing a fused silica tube and a mullite liner.

To ensure high temperature equilibration of the HCl/O_2 mixture, the gases first flowed through the hot zone of the furnace in a 9 mm ID fused silica tube which was located within the larger oxidation tube. At the far end of the hot zone, the gases exited the smaller tube, and flowed back through the hot zone in the oxidation tube, where the silicon wafers were oxidized.

The O_2 flow rate was kept at 1 liter/min (~23 cm/min), and the HCl flow rate was varied to obtain between 6-10 volume percent (v/o) HCl entering the furnace. The wafers were pushed into the furnace in the HCl/O_2 mixture and at the end of the oxidation period, which ranged from 15 min to 6 hr, were pulled out of the furnace in the same mixture. The oxides were grown at 1150°-1300°C.

Prior to viewing by SEM, the oxides were coated with several hundred angstroms of gold to prevent charge accumulation on the sample. Samples for the TEM were prepared by first etching the back side of the wafer with a fine jet (~0.5 mm diam) of a 9/1 solution of HNO_3/HF (9). The etching, which formed a bowl-shaped depression in the silicon, was stopped when the back side of the oxide was exposed. The sample was then flushed with deionized water, leaving a window in the silicon through which the oxide could be viewed. The procedure for preparation of the STEM samples was similar to that of the TEM samples; however, the chemical etching was stopped when several micrometers of silicon still covered the oxide. The remainder of the silicon was etched with an ion thinner to prevent preferential chemical etching of any phases present at the oxide-silicon interface.

Results and Discussion

Additional phase formaiton.—Figure 1 shows an SEM micrograph of an oxide grown in 10 v/o HCl at 1150°C for 1 hr. Bumps of approximately 1-2 μm diam uniformly cover the oxide surface. In an earlier in-

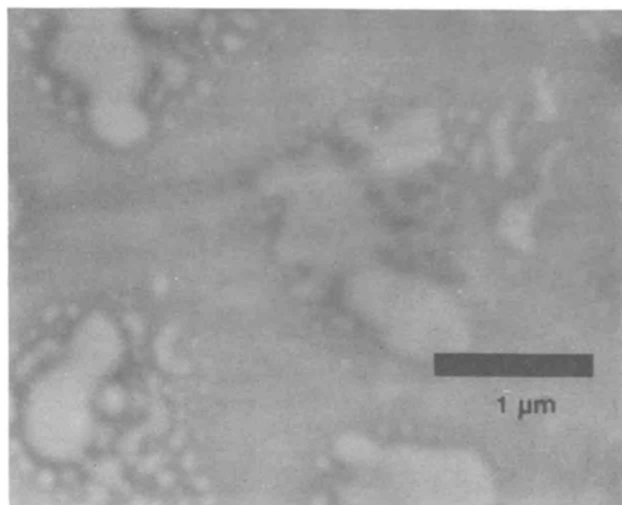

Fig. 2. TEM micrograph of oxide grown in 10 v/o HCl at 1150°C for 1 hr.

vestigation, ellipsometry was used to characterize the growth of these bumps, and it was found that the bumps increase in size as the oxidation time, the oxidation temperature, and the HCl content increase (8).

A TEM micrograph of an oxide grown under the same conditions is shown in Fig. 2. Note the inhomogeneous electron transmission indicative of an amorphous phase within amorphous phase separation. No coherent diffraction was observed, substantiating the noncrystallinity of both phases. The large, isolated regions are approximately 1-2 μm in diam, similar to the bumps seen in Fig. 1.

The additional phase regions grow as the oxidation progresses. Figure 3a shows a TEM micrograph of an oxide grown in 7 v/o HCl at 1150°C for 30 min. Figure 3b shows a similar oxide grown for 60 min. The additional phase, after a longer growth time, is more prominent and occupies a larger fraction of the area. No additional phase was observed at 15 min.

A STEM micrograph of an oxide grown in 6 v/o HCl at 1150°C for 1 hr is shown in Fig. 4. Two contamination spots from the electron beam are apparent near the center of the micrograph. An x-ray microanalysis done with the electron beam outside the additional phase regions (spot on left) yielded the spectrum shown in Fig. 5a. No counts above background (corresponding to a chlorine density of $\sim 10^{15}/cm^2$) are seen at those energies indicated by the markers, which are characteristic of chlorine. However, with the electron beam focused upon one of the additional phase regions (spot on right), the spectrum in Fig. 5b was obtained, clearly indicating the presence of a significant amount of chlorine. Oxides grown under various conditions, ranging from a 30 min oxidation performed with 2 v/o HCl at 1150°C to on oxide grown for 1 hr with 10 v/o HCl at 1300°C, yielded spectra which indicated all of the chlorine to be located within the phase-separated regions.

The chlorine concentration within a particular phase-separated region was found to be very uniform over the entire region. Profiling of a 1 μm diam region showed the chlorine to be undetectable immediately outside the region, but just inside the region the chlorine concentration was observed to sharply rise and remain constant across the entire diameter.

Rutherford backscattering (RBS) has indicated that most of the chlorine is located within several hundred angstroms of the oxide-silicon interface (7, 10, 11). Correlation of the RBS data with the x-ray analysis suggests that the additional phase is located in pancake-shaped regions of 100-300Å thickness and 1-2 μm diam which are situated at the oxide-silicon interface.

Since the majority of the chlorine is uniformly contained in the phase-separated regions, and the dimensions of the regions are known, a rough calculation can be made of the chlorine concentration within the regions.

For example, RBS has shown that for an oxide grown in 7 v/o HCl at 1150°C for 30 min (similar to the oxide shown in Fig. 3a), the chlorine content in the oxide is approximately $2 \times 10^{15}/cm^2$ (10). From TEM investigations it was ascertained that the additional phase covers roughly 10% of the interfacial area. With a thickness of about 200Å, the chlorine concentration is on the order of $10^{22}/cm^3$. This is, of course, a rough estimate, but does indeed demonstrate the relatively high chlorine concentration within the additional phase.

To substantiate the absence of voids under the oxide (which RBS is unable to do), SEM was used to look at the oxide-silicon interface in cross section. No voids were found, indicating that the additional phase is indeed contained in regions only a few hundred angstroms thick. With such a high density of chlorine, the additional phase is very probably condensed at oxidation temperatures.

Interfacial gas formation.—For the fabrication of metal-oxide-semiconductor (MOS) structures, the oxide is typically grown to a thickness of approxi-

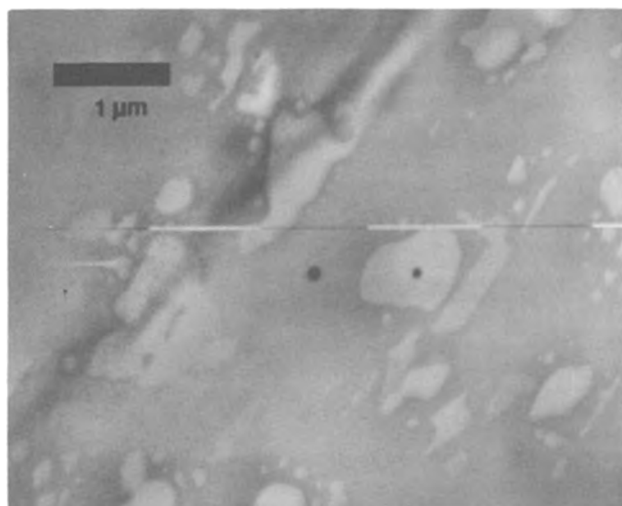

Fig. 4. STEM micrograph of oxide grown in 6 v/o HCl at 1150°C for 1 hr. The two spots are contamination from the electron beam.

mately 1000Å, which requires about a 30 min oxidation at 1150°C. However, to gain further insight into the formation of chlorinated oxides, investigations were made of oxides grown in 10 v/o HCl for oxidation times as long as 6 hr at temperatures of 1150° and 1200°C. Cross-sectional micrographs of an oxide grown for 6 hr at 1200°C (Fig. 6) clearly indicate the existence of bubbles at the oxide-silicon interface. The fine structure created by the condensed phase is seen superimposed upon the larger bubbles, and in addition, a material, perhaps the condensed phase, can be seen in several locations stretched between the oxide and the silicon. Scanning electron microscopy in conjunction with x-ray microanalysis was unable to detect any chlorine in this material; however, this is inconclusive since x-ray analysis on the SEM was unable to detect any chlorine in any of the oxides investigated.

Compressive stress in the oxide has been suggested as a possible mechanism for the lifting of the oxide (12); however, the evidence shown in Fig. 7 and 8 clearly indicates the origin of the bubbles to be the formation of a gaseous compound at the oxide-silicon interface. Figure 7 is an SEM micrograph of the oxide (shown in Fig. 6) after being etched several minutes in an $NH_4F \cdot HF$ solution. The oxide, which has weakened and collapsed, obviously has been stretched. The stretching, which is anticipated in view of the viscoelastic nature of silica at 1200°C, conclusively indicates a tensile stress in the oxide, undoubtedly caused by a gaseous pressure at the interface.

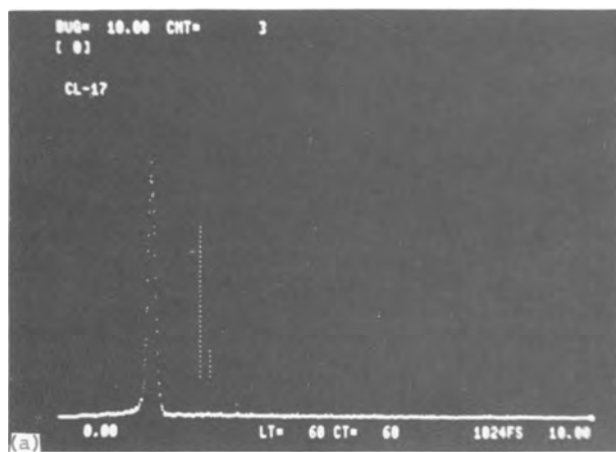
Figure 8 shows the same wafer after the oxide has been completely removed by submersion for 1 min in concentrated HF (49%). Preferential etching of the silicon, which has occurred during the prolonged oxidation at 1200°C, is obvious. The well-defined angle of the walls, the planar surfaces, and the straight edges are especially apparent in Fig. 8c.

The etching is somewhat reminiscent of that reported by Dismukes and Ulmer (13) for the etching of silicon by Cl_2. They noted steps formed in the silicon surface, as well as pits which were about 5 μm on a side. The morphology of the surface seen by Dismukes and Ulmer is not exactly as that seen in Fig. 8; however, Dismukes and Ulmer used (111) oriented wafers, whereas those of Fig. 8 are (100) oriented. Hess and McDonald (12) studied the etching of (111) oriented silicon for HCl/O_2 oxidations at 1100°C, and their SEM micrographs of the silicon surface are strikingly similar to those of Dismukes and Ulmer. Additionally, an SEM micrograph by Hess and McDonald of an oxide-silicon interface in cross section for a wafer oxidized in 1 v/o HCl at 1100°C for 16 hr shows very little lifting of the oxide. The small amount of lifting in conjunction with the substantial amount of silicon removal is an important point which will be addressed later.

Formation of a gaseous phase along with the subsequent lifting of the oxide occurs also for oxides which initially possess only the condensed, chlorine-rich phase discussed above, but which after oxidation, are annealed in N_2 at oxidation temperatures. Figure 9a shows an oxide grown in 10 v/o HCl for 1 hr at 1150°C. Figure 9b and 9c show the same oxide after being annealed 5 and 20 hr, respectively, in N_2 at 1150°C. Whereas no voids are visible under the oxide for the unannealed sample, large voids, similar to those produced by long oxidation times, are seen for the annealed samples. Transmission electron micrographs of the oxides shown in Fig. 9a-9c are shown in Fig. 2 and 10a and 10b, respectively. The development and coalescence of the gaseous phase are evident.

Kriegler has reported a decrease in passivation for oxides which have been annealed in helium at 1150° and 1200°C (6). Corresponding to this decrease in passivation, van der Meulen *et al.* have noted, using RBS, a decrease in the chlorine content of oxides after annealing in N_2 at 1100° and 1200°C (14). Consistent with these findings, x-ray microanalysis of the oxide shown in Fig. 10a has shown a significantly lower chlorine concentration than that found in the unannealed sample (Fig. 2).

Rationalization of findings.—Four phases need to be considered when discussing the microstructural development of oxides grown in HCl/O_2 ambients: silicon, silicon dioxide, the additional condensed phase,



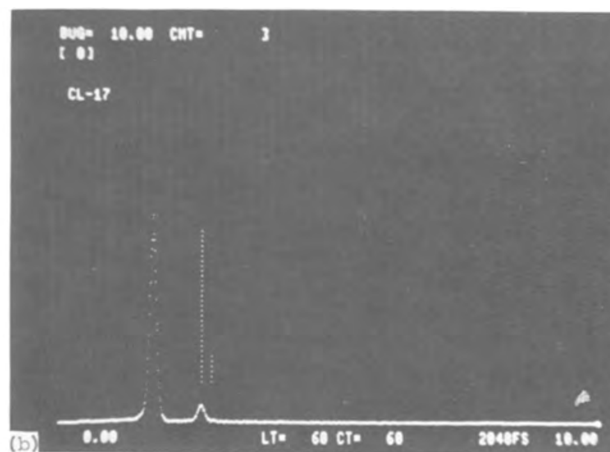


Fig. 5. X-ray fluorescence spectra of oxide grown in 6 v/o HCl at 1150°C for 1 hr (a) outside phase-separated region; and (b) inside phase-separated region.

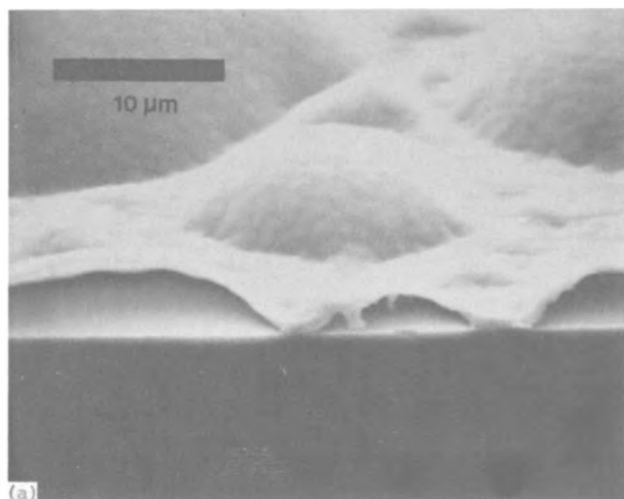

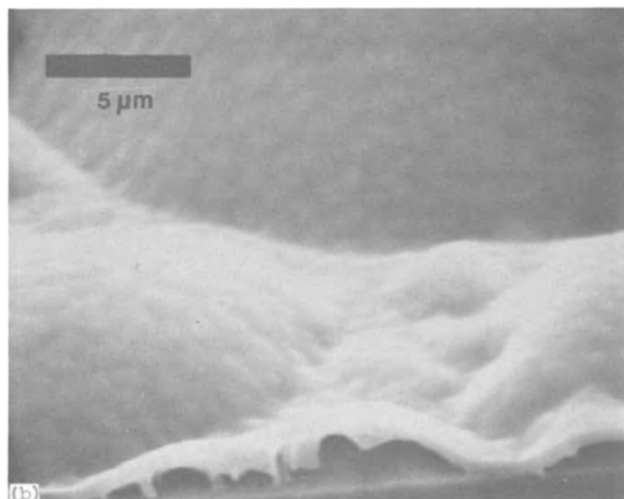

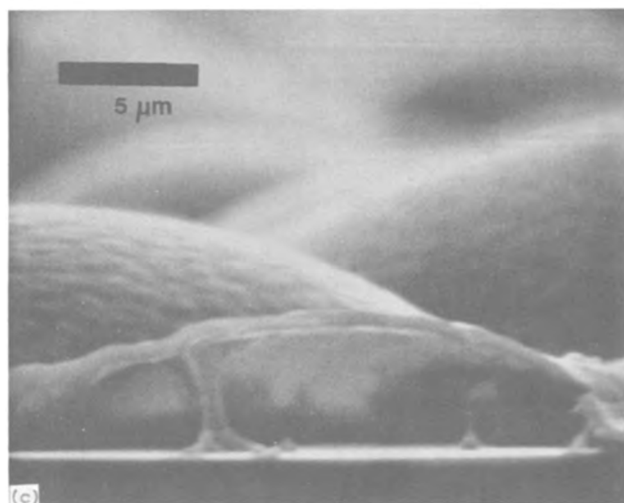

Fig. 6. Cross-sectional SEM micrographs of oxide grown in 10 v/o HCl at 1200°C for 6 hr.

and the gaseous phase at the interface. Silicon dioxide is the first reaction product to be observed for the oxidation of silicon in HCl/O_2 ambients. After a sufficient time has elapsed, the additional condensed phase is noted; for longer oxidation times, or for subsequent anneals, the gaseous phase begins to form.

In studying the simultaneous corrosion of metals by oxygen and a second oxidant (*e.g.*, S_2 or N_2), researchers have found that under the appropriate kinetic and thermodynamic conditions, the reaction products can form layers on the metal (15, 16). With the provision that the activity of each oxidant in the gaseous ambient is sufficiently high to react with the metal, that product yielding the most negative change in Gibbs free energy forms the external scale. Due to the large affinity of most metals for oxygen, this external scale is usually an oxide. If the growth rate of the more stable scale is diffusion limited (where either the metal or the oxidant diffuses through the scale), then the activity of the principal oxidant decreases as one progresses from the outer surface of the scale to the metal-scale interface. Consequently, if the second oxidant is able to diffuse in a sufficient amount from the ambient to this interface, the thermodynamic equilibria at the interface can be reversed from that at the sample surface, such that near the metal, the product of the second oxidant is the more stable. In this manner, an additional phase which is unstable in the gaseous ambient is able to form between the metal and the external scale.

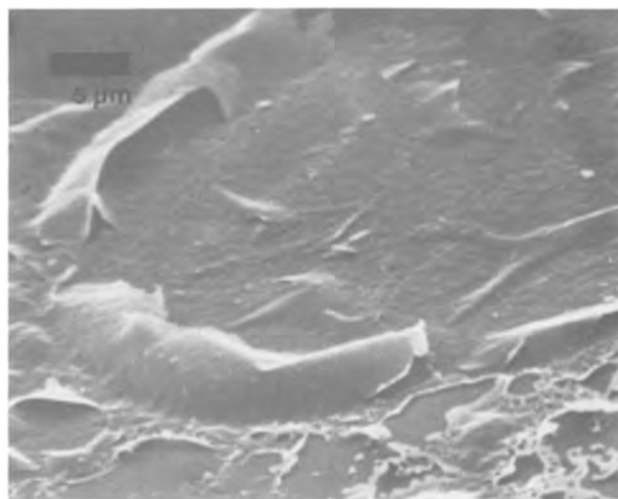

Fig. 7. SEM micrograph of oxide grown in 10 v/o HCl at 1200°C for 6 hr after partial etching in $NH_4F \cdot HF$. Sample tilted 60°.

With some modifications, the growth of HCl oxides closely resembles the model proposed above. In the HCl/O_2 ambient, oxygen is the stronger oxidant and chlorine the weaker oxidant. One apparent discrepancy, though, is the existence of three reaction products in HCl oxides. However, the condensed intermediate phase very likely contains both chlorine and oxygen, and is probably a chlorosiloxane possessing a high concentration of oxygen. Analogous to the metal sulfides or metal nitrides discussed above, this chlorosiloxane would be unstable at oxidation temperatures in large partial pressure of oxygen, and would readily oxidize to SiO_2.

That this phase contains both chlorine and oxygen, and is specifically a chlorosiloxane, is suggested by two observations. Kriegler has found that if a silicon sample is oxidized for 20 min in pure O_2 at 1150°C, and subsequently introduced into an $HCl/O_2/He$ mixture containing 15 v/o HCl and 2 v/o O_2 for an additional 20 min at the same temperature, passivation is attained (7). However, under similar conditions, if the oxide grown for 20 min is introduced into an HCl/He mixture containing 15 v/o HCl, passivation does not occur. Evidently, the chlorine cannot be incorporated into the oxide without the simultaneous presence of both chlorine and oxygen.

In addition, most of the silicon chlorides, as well as those chlorosiloxanes with an O/Cl ratio significantly below 1/2, possess boiling points (at 1 atm) far below oxidation temperatures (17). However, as the O/Cl ratio increases, the boiling points greatly increase, suggesting that the additional condensed phase is, in fact, a chlorosiloxane, rich in oxygen.

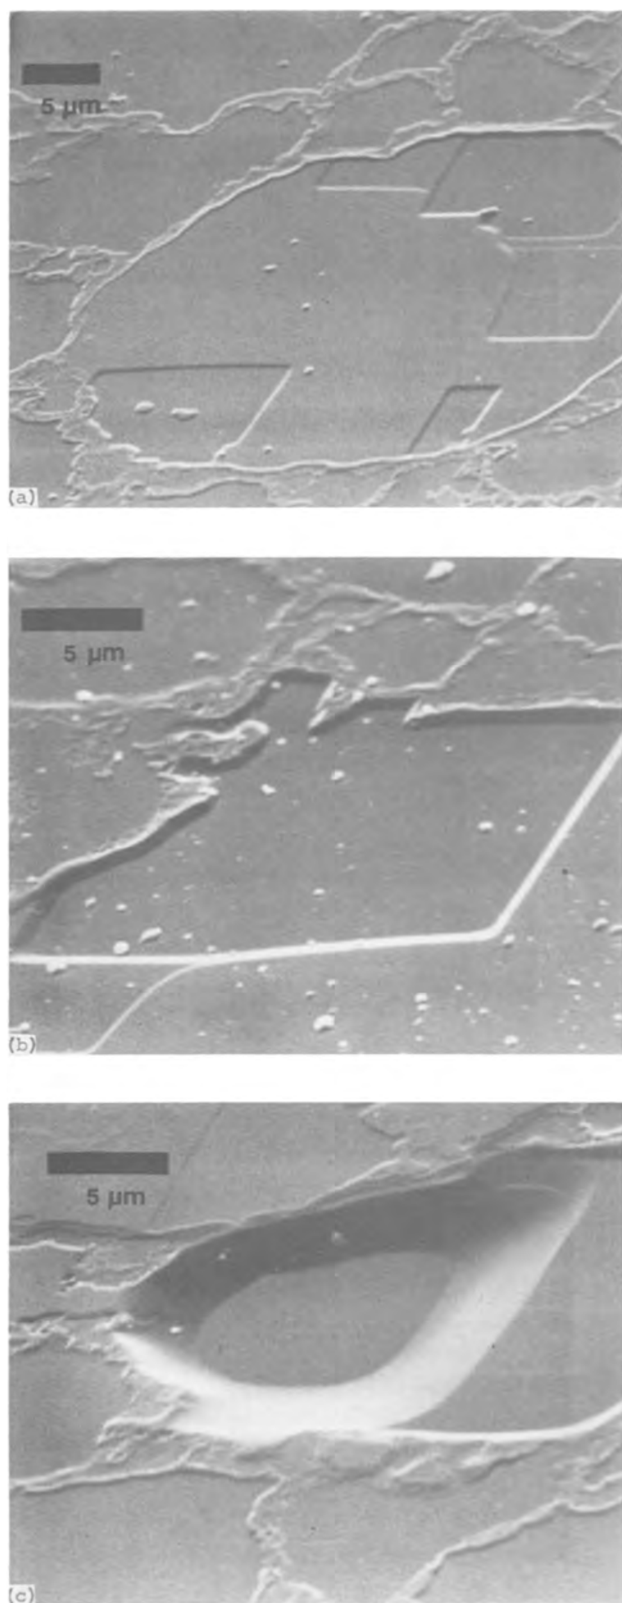

Fig. 8. SEM micrographs of silicon surface after oxidation in 10 v/o HCl at 1200°C for 6 hr with subsequent removal of oxide in concentrated HF. Samples tilted 60°.

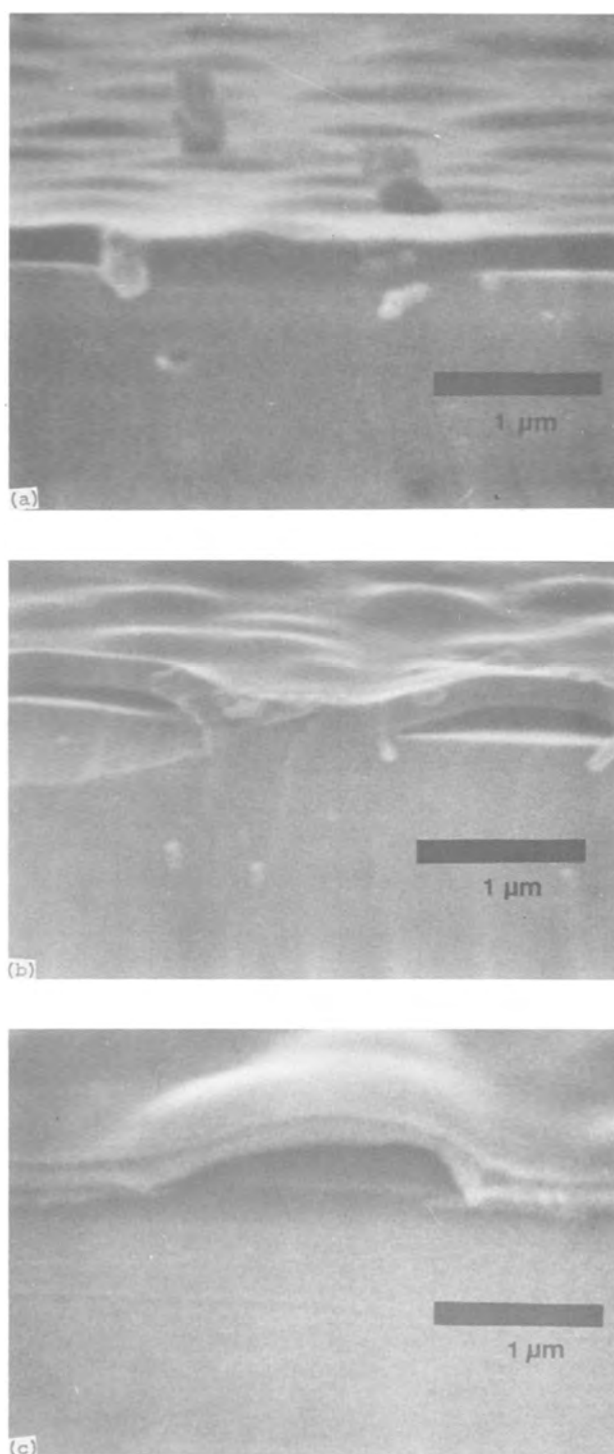

Fig. 9. Cross-sectional SEM micrographs of oxide grown in 10 v/o HCl at 1150°C for 1 hr (a) immediately after oxidation; (b) after subsequent 5 hr anneal in N_2 at 1150°C; and (c) after subsequent 20 hr anneal in N_2 at 1150°C.

If there exists yet another phase in addition to the silicon, the silica, and the additional condensed phase which is stable only in oxygen partial pressures lower than those required for the stability of the additional condensed phase, then this fourth phase would be found sandwiched between the silicon and the additional condensed phase. Such a phase may indeed exist in the form of the interfacial gas.

As discussed above, as the oxygen contents of chlorosiloxanes decrease, the compounds boil at lower temperatures. If the oxide becomes sufficiently thick to severely limit the transport of oxygen to the oxide-silicon interface, or if the oxygen at the interface is depleted by annealing in an oxygen-free ambient, gaseous chlorosiloxanes or chlorides could form. The diffusivity of the interfacial gas through the oxide may be sufficiently low such that the gas could become trapped at the interface lifting the oxide from the silicon. Ultimately, the entire oxide would separate from the silicon; such cases have been reported (12).

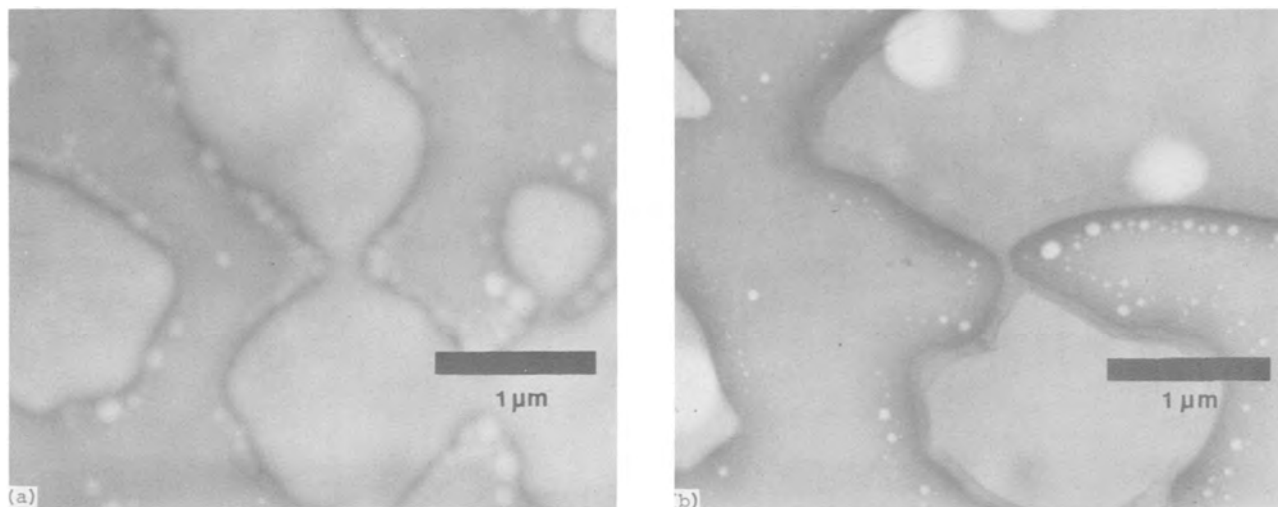

Fig. 10. TEM micrographs of oxides grown in 10 v/o HCl at 1150°C for 1 hr with subsequent (a) 5 hr anneal; and (b) 20 hr anneal in N_2 at 1150°C.

As the gas is being formed, an equilibrium is maintained between the rate of formation and the rate of escape through the oxide. As more gas is formed, the bubble under the oxide becomes larger, creating a larger pressure from the tensile stress in the oxide which increases the flux through the oxide.

The existence of this equilibrium is substantiated by a comparison of Fig. 6a-6c with the SEM micrograph, mentioned above, of an oxide grown in 1 v/o HCl for 16 hr at 1100°C, taken by Hess and McDonald. As compared to the former micrographs, the latter shows very little lifting of the oxide, but clearly indicates a substantial amount of silicon removal, suggesting a significant amount of out-diffusion of a gaseous silicon compound through the oxide. However, in contrast to the oxidations performed in 10 v/o HCl at 1200°C (Fig. 6a-6c), the rate of interfacial gas formation for the oxide studied by Hess and McDonald is significantly lower (due to the lower temperature and HCl pressure), thus requiring a much lower pressure to equalize the rates of formation and escape.

The formation and escape of a chlorine-containing gaseous compound during annealing in an oxygen-free ambient is quite consistent with the deterioration of passivation and the decrease in chlorine content discussed above. Both the passivation and chlorine content were found to decrease most rapidly at the highest annealing temperature, and, in general, were very temperature dependent in the range of temperatures investigated (1100°-1200°C). At the higher temperatures, the depletion of oxygen, the gas formation, and the out-diffusion is most rapid, thus explaining the observations.

The temperature dependence of the thermodynamic equilibria cannot be readily discussed without more information concerning the compositions of both the additional condensed phase and the gaseous phase. Moreover, depending upon the particular compositions of these phases, thermodynamic data may be unavailable in the literature, thus making any detailed calculations quite difficult.

The prediction of the kinetic behavior as a function of temperature is considerably more straightforward, particularly from a qualitative viewpoint. As the temperature increases, the diffusivities of the oxidants in the oxide, as well as the various reaction rates, increase, thus allowing the more rapid development of the chlorine-containing phases. This increase in the rate of development with increasing temperature is indeed observed (8).

Summary

Investigations using electron microscopy and x-ray analysis were done to ascertain the structure and composition of silicon oxides during their growth in HCl/O_2 ambients. Upon first introduction into the oxidizing ambient, the silicon reacts to form an SiO_2 layer. After a sufficient amount of time has elapsed, an additional condensed phase becomes apparent at the oxide-silicon interface. This phase, which contains the majority of the chlorine, remains sandwiched between the SiO_2 and the silicon as the oxide growth continues.

After an even longer growth time, an interfacial gas begins to form. The gas preferentially etches the underlying silicon, and depending upon the oxidation temperature and HCl content, the gas may significantly lift the oxide from the silicon, forming large bubbles. The gas can also be formed by annealing an oxide possessing only the additional condensed phase in an oxygen-free ambient at typical oxidation temperatures.

The formation of the two additional phases has been interpreted in terms of compounds stable at the various partial pressures (or activities) of oxygen found at the oxide-silicon interface under various oxidation and annealing conditions. When the oxide becomes thick enough to sufficiently limit the transport of oxygen to the interface, the additional condensed phase becomes stable. The evidence cited indicates the composition of this phase to be a chlorosiloxane, rich in oxygen. When the oxygen activity is further suppressed, either due to an increase in oxide thickness or a decrease in the ambient oxygen partial pressure, the gaseous compound becomes stable. By its out-diffusion through the oxide, the gas can remove substantial amounts of silicon, yielding a preferentially etched silicon surface.

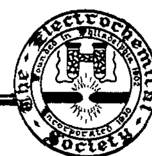
Technical Notes



Application of Interface Demarcation to Multiphase Systems: InSb-Sb Eutectic

Douglas E. Holmes[1] and Harry C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The applicability of interface demarcation to the study of (directional) solidification of multiphase systems was demonstrated with the InSb-Sb eutectic. Thus, the microscopic growth rate and the interface morphology during solidification of the eutectic matrix of a nontransparent system were recorded for the first time. It is the purpose of this communication to demonstrate that parameters introduced in the theoretical models of eutectic solidification can be experimentally determined by interface demarcation.

Interface demarcation (achieved by passing current pulses of known frequency across the growth interface) has been successfully applied to the quantitative study of growth and segregation in elemental (1) and III-V compound semiconductors (2), to the study of interface breakdown due to constitutional supercooling (3), and to the study of semiconductor melt thermohydrodynamics (4). Interface demarcation should be a powerful tool for solidification studies of multiphase systems since the morphology of the solidifying interface and the microscopic growth rates are key parameters in the fundamental analysis of the solidification process (5-8). Interface demarcation has not as yet been successfully applied to the solidification of metallic phases primarily because the Peltier coefficients of metals are generally about an order of magnitude smaller than those of semiconductors; in addition, localized compositional changes brought about by current pulses at the solidification temperature should tend to fade out during cooling to room temperature since the diffusion constants in metals are typically about three orders of magnitude larger than those in semiconductors. The choice of the InSb eutectic was based on the fact that the InSb matrix is a semiconductor and its single crystal growth has been studied with interface demarcation; in addition, microstructure and x-ray (orientation) analysis have been carried out on this eutectic (9).

Cylinders of the InSb-Sb eutectic were prepared from melts (volume fraction of InSb about 0.62) confined in 5 mm diam quartz ampuls and doped with Te to a level of about $10^{19}/cm^3$ for interface demarcation (2). The melts were directionally solidified (under stabilizing thermal gradients) in a vertical stationary configuration by controlled cooling. Electrical current pulses (18 A/cm^2) of 100 msec duration were applied across the solid-melt interface at a frequency of 1 Hz. The apparatus is described in detail elsewhere (3).

The InSb-Sb cylinders were cut longitudinally along the solidification axis polished successively with Linde A, alumina, and Syton (1:1 Syton:H_2O) and preferentially etched (with 1 part acetic acid + 1 HF + 1 saturated aqueous $KMnO_4$ solution) to reveal interface demarcation lines and segregation inhomogeneities.

A typical microstructure of an InSb-Sb eutectic solidified under programmed cooling leading to relatively constant solidification rate is shown in Fig. 1. Interface demarcation lines are present in the InSb matrix but not in the Sb phase. The spacing of the demarcation lines is quite uniform, indicating a fairly uniform solidification rate of approximately 1 μm/sec. Occasional changes in the interface morphology can also be seen. The Sb phase consists of continuous and

discontinuous rod-type regions oriented along the solidification direction. Samples cut perpendicular to the solidification direction revealed that Sb rods have a triangular cross section as reported earlier (9) as well as cross sections of irregular shape.

A longitudinal cross section of a cylinder solidified under controlled cooling conditions is shown in Fig. 2. In this case it is seen that fluctuations in the microscopic solidification rate take place (fluctuations of the spacing of the demarcation lines) as less elaborate precautions were taken, than in the case of Fig. 1, to minimize abrupt changes in the vertical and horizontal gradients during solidification (3).

The importance of interface demarcation in studying eutectic solidification will be demonstrated by pointing out the possibilities for determining qualitatively or quantitatively parameters assumed in theoretical models. Thus, in the theories of lamellar or rod growth in eutectic solidification parameters taken into consideration are the microscopic rate of solidification, the formation and movement of faults or fault lines, the interface morphology (interface curvature) and interface instabilities (5), facet formation by one phase, interface morphology perturbations, their chronological development and wavelength (6-8). Although some of these parameters can be determined in transparent (organic) systems (5), they can only be indirectly inferred in metallic systems.

As seen in Fig. 1 and 2, the microscopic solidification rate of the matrix phase can be determined throughout solidification. The microscopic solidification rate is not constant and can be significantly different from the average solidification rate. It also exhibits local and time-independent variations. Thus, in adjacent InSb regions A and B of Fig. 2 (and most likely in the Sb rod separating these regions) the microscopic growth rate increases by more than a factor of two within 1 sec. Solidification rate variations in an individual InSb region are seen in C (Fig. 2) which appear to be associated with changes of the interface curvature as the interrod spacing undergoes adjustment under transient conditions. Faults and their movement, as discussed in Ref. (5), together with the associated interface morphology and the microscopic rate of solidification, can be observed (see, for example, region D, Fig. 2). It appears that interrod spacing is adjusted by branching of the matrix (region A in Fig. 1). A depression is first formed; by analogy with results in Ref. (5) growth of an adjacent Sb rod takes place rather than a separate Sb nucleation event.

The interface morphology of continuous regions of the matrix phase is clearly delineated by interface demarcation lines. Facet formation (planar interface) for example, is readily identified as in regions E and F of Fig. 2. These facets are inclined to the growth direction by 20°. Since InSb has a strong tendency for facet growth in the <111> direction (7), the growth direction of InSb in the present case is not the <111> (planar interface is in no instance perpendicular to the growth direction), whereas in Ref. (9) it is reported that the InSb matrix grows in the <111> direction.

Changes in interface morphology and branching of coalescence of InSb rods can be readily related. For example, in regions D and G of Fig. 2, interface instabilities (interface undulations) are seen prior to branching of InSb rods. Interface undulation with a

wavelength smaller than the rod width are seen in region H of Fig. 2. Dopant inhomogeneities parallel to the soldification direction in this region delineate undulation valleys; under quasisteady-state conditions the impurity concentration exhibits maxima and minima at undulation valleys and peaks, respectively, as a morphological instability evolves (5); similar behavior was observed in single phase material, *e.g.*, Ge (3). Interface instability with wavelengths much smaller than the width of the rod observed in the present case have not been as yet considered in the existing theoretical models. Interface instabilities with wavelengths greater than interrod spacing cannot be directly determined as the interface demarcation lines are not continuous through the Sb phase. However, the same interface demarcation line can be identified on InSb rods separated by Sb rods by counting demarcation lines of the rods from the point of their branching or merging. In this way an interface undulation can be extrapolated through the Sb phase as shown in the lower and upper parts of Fig. 2; in these cases the wavelength corresponds to more than one Sb and two InSb rods. The identification of the same demarcation line across the matrix phase could be simply achieved by interrupting the current pulses for short intervals of time (longer than the time interval between pulses). In this way, the first demarcation line after each interruption interval would serve as an absolute time reference point (10).

In summary, it was demonstrated that interface demarcation is potentially a powerful tool for the investigation of eutectic solidification. When interface demarcation is employed in conjunction with a composition profiling method, it should become possible to obtain solidification rates, interface morphology, and composition on a microscale and thus establish quantitative relationships between solidification parameters, dynamic morphological adjustments, and interface stability.

A Simple Technique for Silicon Nitride Growth

David Hackleman,[1] Yu. G. Vlasov,[2] and Richard P. Buck*

The William Rand Kenan Laboratories of Chemistry, The University of North Carolina, Chapel Hill, North Carolina 27514

The process of fabrication of ISFET's (ion-selective field effect transistors) includes formation of thin layers of the insulators SiO_2 or Si_3N_4 on silicon. Best results, at least for ISFET's used in moist environments, can be expected from insulating layers of Si_3N_4 or $SiO_2 + Si_3N_4$, rather than SiO_2. The growth of silicon nitride on silicon is usually accomplished through vapor phase epitaxial or sputtering techniques (1-3) which require use of silane mixtures or preformed nitride. Direct nitridation can also be accomplished thermally (4-6) and by glow discharge generation of atomic nitrogen to produce a thin, mixed oxy-nitride layer (5) whose growth is self-limiting. However, thermal generation of N atoms from N_2 requires temperatures of 1200°-1400°C.

Considering the negative free energy for the possible reaction

$$6Si + 3NH_3 = Si_3N_4 + 6H_2$$

it is predicted that a technique should be possible for growth of silicon nitride films on silicon using readily available anhydrous ammonia. A satisfactory procedure has been found in this laboratory when oxygen is rigorously excluded from the reaction vessel. Using a reaction chamber of the type shown in Fig. 1 and a glove bag, isolation of the silicon substrate from oxygen prior to thermal nitridation can be achieved. The experimental conditions used were 800°C for 20 hr in an anhydrous ammonia (2 cfh) atmosphere. "Chemisphere" reagent grade liquid ammonia, manufactured by Lif-o-Gen, Incorporated, was used without further purification. The substrate was first etched in HF in a helium atmosphere before transfer under helium to the reaction vessel. ESCA studies of specimens prepared by the proposed ammonia method and the sputtering method for comparison with a reference specimen heated in air (1000°C) confirm through the observed chemical shifts the creation of Si-N bonds on the surface. In Fig. 2, an ESCA spectrum of a thin,

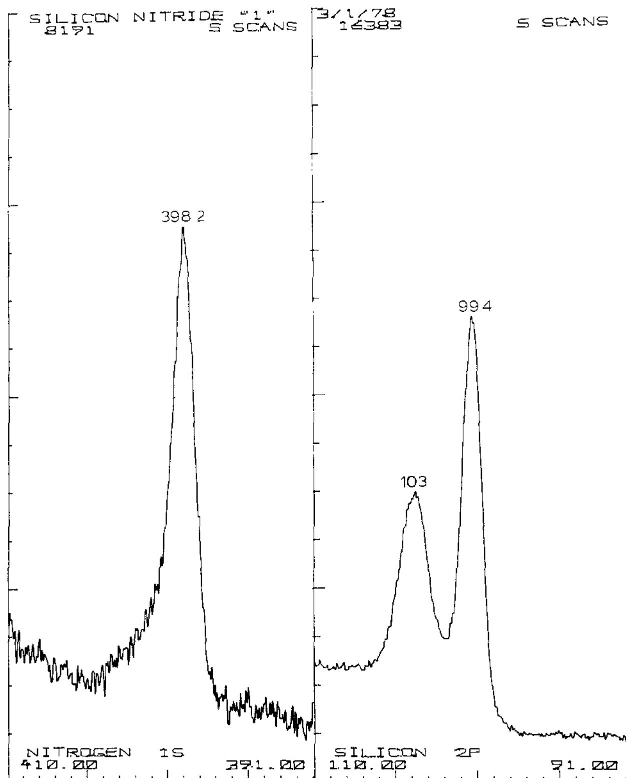

Fig. 2. ESCA of silicon nitride manufactured by this technique, ~ 25 nm thick, Si-*N* at 398 eV; *Si*-Si at 99 eV; *Si*-N at 103 eV; (Si-O is of similar chemical shift, hence the Si-*N* is the defining peak).

colorless layer, estimated 25 nm thickness grown by the ammonia process, shows the presence of N (348.21 eV) and Si (90-100 eV) in addition to expected C and O peaks. Both the oxidized Si(IV) and underlying Si-Si lattice at 99.4 eV are apparent. Figure 3 gives

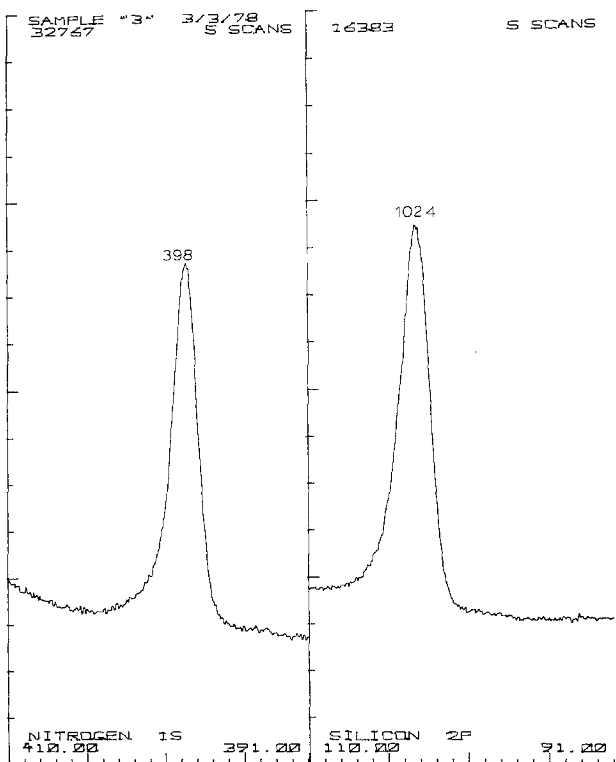

Fig. 3. ESCA of silicon nitride grown by a standard process, ~ 200-300 nm thick (8).

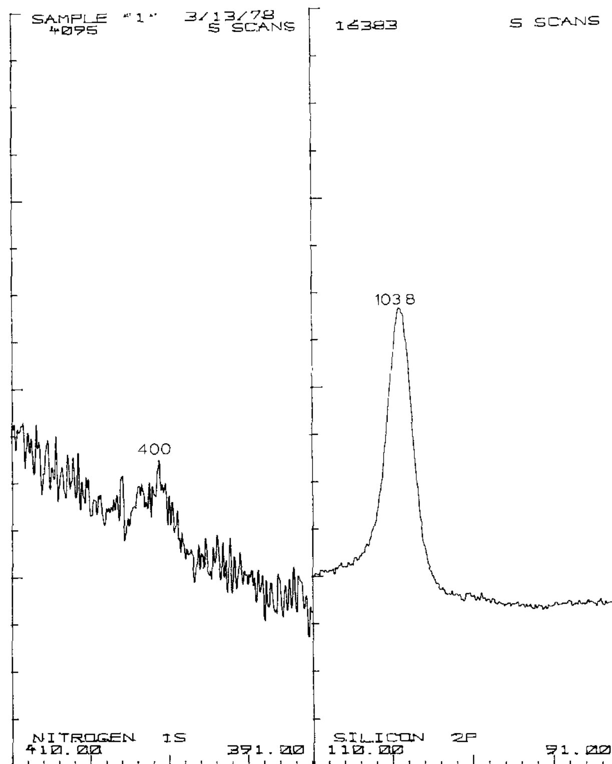

Fig. 4. ESCA of SiO_2 grown 1000°C in air for 3 hr

the results for a thick layer grown by the Si_3N_4-sputtering process. The lattice Si peak is absent. Finally, in Fig. 4 the reference specimen primarily shows a layer of SiO_2 with only a hint of N present.

This technique is simple and provides material of a quality useful for the manufacture of ISFET's. Because the nitride layer ceases to grow when it has formed a thickness great enough to inhibit diffusion of NH_3 or fragments, the process leads to a uniform layer. Further studies of the technique are worthwhile and our present accomplishments have been only briefly reported here.[3]

Mass Spectrometric Detection of Intermediates in Chemical Vapor Deposition of Si_3N_4 from $SiCl_4$ and NH_3

Sin-Shong Lin

Army Materials and Mechanics Research Center, Watertown, Massachusetts 02172

Silicon nitride is known to form adhesive insulating films on silicon substrates, and thus it is an excellent material for semiconductor devices. Numerous investigations (1-4) have been made in past years to examine how the characteristics of deposit films vary with vapor compositions, temperatures, and pressures in chemical vapor deposition (CVD) processes. However none of the studies has been centered on the molecular formation processes of Si_3N_4 in the vapor phase. Although such investigation might not yield direct information concerning the production technology of semiconductor devices, nevertheless it is a fundamental process in the formation of thin film deposits.

The present study is a continuation of the previous work (5) in which many intermediate complexes leading to the formation of Si_3N_4 from SiF_4 and NH_3 were observed. The work reported here is the result obtained from the examination of vapor phase interaction of $SiCl_4$ and NH_3. While silicon tetrachloride and tetrafluoride are very similar in chemical nature, their reactivities are quite different. Consequently the difference derived from their chemical activities was observed in the molecular formation process of Si_3N_4.

The experimental setup (Fig. 1) was identical to that previously employed (5), except SiF_4 was replaced with $SiCl_4$. The $SiCl_4$ vapor was obtained from electronic grade liquid by vacuum extraction, and NH_3 was drawn from a compressed gas cylinder. The CVD reactor was made from two closed-end alumina combustion tubes and a spacer in a coaxial configuration. In order to produce an optimum condition for many complex molecular intermediates to be observed, the CVD experiments were performed in several reactor configurations at temperatures and pressures in the ranges of 800°-1200°C, and 0-80 mm Hg, respectively. The quadrupole mass filter made by Extranuclear Laboratory, Incorporated, was used and operated with ionizing electron beam at 40 eV under varying sensitivities, resolutions, and focusing conditions. Due to the difficulties inherent in the present method of sampling of the condensates through a small opening (such as orifice clogging, pressure fluctuation, and a short measurement time) it is hard to correlate systematically the characteristics of deposits with the variety and abundances of molecular intermediates. Moreover, time and resources are not available for a more extensive investigation at this time.

The identity of an ion is established from mass number and isotopic distribution. Since the chlorine atom has two major isotopes, 35 and 37, the composition of an ion could be determined from the intensities of isotopic peaks. However the presence of the isotopic peaks also complicated observed mass spectra. The majority of observed intermediate ions consisted of large numbers of atoms, and they were usually low abundant, high mass ions. With the quadrupole mass filter operating at low resolution in the high mass range, it was impossible to distinguish these weak peaks in overlapping ion spectra.

Prior to the CVD runs, mass spectra of $SiCl_4$ were taken for reference and comparison. The typical ions

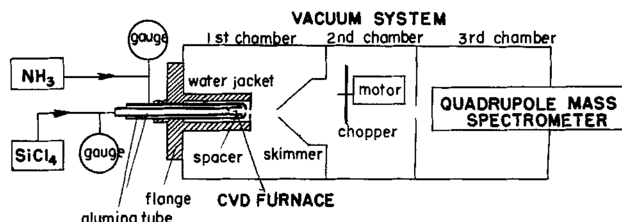

Fig. 1. Block diagram of experimental apparatus. This apparatus consisted of gas inlet lines, a miniature chemical vapor deposition furnace, and a three-stage differential pumping system. The quadrupole mass spectrometer, modulated beam mechanism, and expansion chamber are integral parts of the vacuum system.

present in these spectra are listed in Table I: The ions of $SiCl_3^+$, $SiCl^+$, $SiCl_4^+$, $SiCl_2^+$, Cl^+, and Cl_2^+ in decreasing magnitudes were observed. A trace amount of $SiCl_2F^+$ (less than 0.1%) was detected only at the introduction of the reactant. The intensity of this ion diminished with time, and was not detectable after a few runs. The mass spectra of $SiCl_4$ are very similar to those of SiF_4 (5), except there is no ion derived from the dimeric species $(SiCl_4)_2$.

The chemical reaction between $SiCl_4$ and NH_3 takes place at all temperatures as evidenced by the formation of deposits and gradual clogging of the sampling orifice. Even the mass spectra obtained at the intimate contact position of orifices [Ref. (5), Fig. 2B] where the interaction of these two gases was minimum revealed the existence of a small amount of $SiNH_2Cl_2^+$ resulting from the direct combination of the two vapors. In all CVD runs, the $SiNH_2Cl_2^+$ ion as well as ions derived from secondary collision products containing one or two Si and NH_2 groups together with HCl were always observed. However, a large number of intermediate ion species containing more than two Si atoms was detected only in some specific runs where proper conditions existed for the detection of a large scale vapor phase condensation. At the high mass end of the spectra, the resolution of the mass analyzer was lowered to compensate for the lower sensitivity of the

Table I. Ion species observed in mass spectra of $SiCl_4$

			Abundances***

instrument. Consequently, the identification of these high mass, low intensity peaks could not be accomplished. Ion peaks were detected and recorded up to the limit of the mass analyzer, 900 amu, and the ion intensities were recalibrated for changes in analyzer resolution.

In Table II, the observed ion species derived from intermediate molecules existing in the CVD reaction of $SiCl_4$ and NH_3 are tabulated. The mass number shown in the first column is the position of the most abundant peak of an ion. In the high mass range, the indicated mass may not correspond to a specific ion because of two or more overlapping peaks. The compositions of the ions are indicated in the second column, and they cannot be definitely established unless the isotopic abundance agrees well with the observed peak height. Based upon the empirical fragmentation pattern (6) of chloride molecules, the neutral precursor of the fragmented ion is suggested in the third column. It is most likely (6) that gaseous chlorides predominantly produce the ions of one Cl atom less than the neutrals upon electron impact ionization. The relative abundances of these ions are shown in the last column. The intensities listed are taken directly from spectra and are not corrected for the transmission and the efficiency of the mass detector. Considering all such corrections, however, the total intensity error should not be more than one order of magnitude when comparing the abundance of ions at 100 and 10^{-5} in a relative scale.

* Mass number of the largest peak of an ion.

** Ions are established from mass number and isotopic distribution.

*** Due to the low resolution of the mass analyzer, the low intensity peaks above 248 amu are not identified.

† The intensity data referred to $SiCl_3^+$ as 100 are taken directly from chart 010578 where the largest number of polymeric ion peaks is observed. The CVD condition: $T = 1000°C$; $P = 18$ mm Hg; gas flows = 10 cm³/min. The reactor: Inner orifice = 0.2 mm diam; outer orifice = 0.6 mm diam; spacer = 9 mm long.

These ions, as shown in Table II, are presumably derived from molecular intermediates existing in successive stepwise reactions leading to the formation of Si_3N_4. They were observed in several sets of experiments. The abundances of these ions decrease with increasing mass numbers from the most abundant intermediate ion $SiNH_2Cl_2^+$ in order of 10% relative to $SiCl_3^+$ to the ion at 868 amu in order of 10^{-7}. The positions of these peaks are usually separated among them by units of 35, 28, 20, and 16 amu (± 1 amu due to H atom and error) corresponding to differences of Cl, Si, Cl-NH_2, and NH_2 compositions.

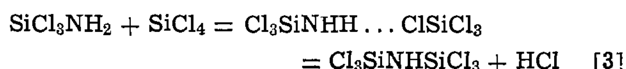
The over-all chemical reaction for the CVD of Si_3N_4 from $SiCl_4$ and NH_3 can be written as

$$3SiCl_4 + 4NH_3 = Si_3N_4 + 12HCl \quad [1]$$

The stepwise reactions leading to the formation of the nitride are suggested (7) to occur through a series of additive intermediates followed by the elimination of HCl such as the formation of the first intermediate

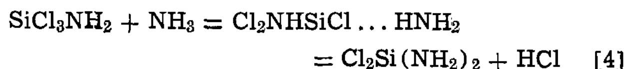
$$SiCl_4 + NH_3 = Cl_3SiCl \ldots HNH_2 = Cl_3SiNH_2 + HCl \quad [2]$$

and



$$SiCl_3NH_2 + SiCl_4 = Cl_3SiNHH \ldots ClSiCl_3 = Cl_3SiNHSiCl_3 + HCl \quad [3]$$

or



$$SiCl_3NH_2 + NH_3 = Cl_2NHSiCl \ldots HNH_2 = Cl_2Si(NH_2)_2 + HCl \quad [4]$$

After successive collisions of these intermediates and reactants, more complex intermediate molecules containing increasing numbers of N atoms should appear. This stepwise reaction generally involves the formation of a new intermediate species and the detachment of HCl from a highly unstable molecular complex. The composition of the new intermediate moves toward Si_3N_4 after numerous collisions in the vapor before striking the surface where further reactions might take place.

The experimentally observed ion species are in good agreement with the above proposed mechanism since the formation of NH and NH_2 groups are the major processes leading to Si_3N_4. The existence of the first intermediate $SiNH_2Cl_3$ confirms the first stepwise reaction [2]. The successive reaction [3] and [4] products, $Si(NH_2)_2Cl$ and Si_2NHCl_6, were supported by their fragmented ions such as $Si(NH_2)_2Cl^+$, $Si(NH_2)_2Cl_2^+$, and $Si_2NHCl_5^+$. The observation of many polymeric high mass ions in the system further indicates that a large scale vapor phase reaction and nucleation exists. Based on the variety of polymeric ion peaks possibly containing many NH_2 units, the stepwise reactions following reactions [3] and [4] seem to proceed not along some particular routes but toward all random directions of collision paths.

The most important ions derived from the first combination of two reactants are similar in the chloride and the fluoride CVD systems, but the successive collision products are quite different. In the fluoride experiment (5), only the ions derived from the first intermediate molecule $SiNH_2F_3$ were observed such as $SiNH_2F_2^+$, $SiNH_2F^+$, and $SiNH_2F_3^+$. In the chloride system, however, intermediates containing more than one NH_2 group such as $Si(NH_2)_2Cl_2$ and $Si(NH_2)_3Cl$ in addition to $SiNH_2Cl_3$ were found to exist. In the CVD of SiF_4, the major polymeric peaks observed were those homologous series of ions separated by a $Si(NH)_2$ unit. In the chloride spectra, the corresponding homologous series of ions were not major peaks. There were numerous unidentified polymeric ions containing a large proportion of NH and NH_2 groups. Since the experimental conditions in both systems were similar, it is likely that the higher reactivity of the chloride accelerates the formation of intermediate molecules containing more NH and NH_2 groups.

In addition to the Si-N-Cl species, some oxygen-containing Si-O-Cl polymeric ion species such as $Si_nO_{2n-3}Cl_5^+$ where n = 2-11, were also observed. These ions were present in minute quantities together with $SiCl_4$ only after a prolonged period of heating. The oxygen-containing species could originate from the interactions between $SiCl_4$ and alumina, silica and water. Examination of the interaction between SiO_2 and $SiCl_4$ in a new alumina tube revealed that no such Si-O-Cl species existed in the present arrangement. Therefore these species presumably result from the interaction between $SiCl_4$ and H_2O.

In summary, the existence of numerous intermediate molecules during the CVD of Si_3N_4 from $SiCl_4$ and NH_3 indicate that vapor phase nucleation and condensation occur at high temperatures in the present system. The extent of the vapor phase reaction is not clear, but the reaction is a dominant process in the Si_3N_4 formation. Although reactions at a surface may alter the properties of deposited films more than the vapor phase reaction, the significance of vapor phase nucleation at low substrate temperatures should be highly emphasized. In the future it might be possible to control the characteristics of deposits by monitoring substrate temperatures and the extent of vapor phase nucleation represented by abundances of molecular intermediates.

A Multiwafer Growth System for Low Pressure Silicon Epitaxy

M. Ogirima, H. Saida, M. Suzuki, and M. Maki

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo, 185 Japan

It has been reported that low pressure epitaxy is very effective for the reduction of autodoping (1-3). The apparatus used in our previous work was a conventional horizontal reactor heated by rf induction, but it has the following two serious drawbacks: (*i*) Glow discharge in a reaction tube below about 2×10^4 Pa (150 Torr), which hinders normal epitaxial growth; (*ii*) large temperature difference between a susceptor and a wafer due to little thermal convection, which induces dislocation.

Moreover, a rectangular fused silica tube, which is usually utilized for obtaining uniform epi-layer thickness, cannot be used at low pressures because of the possibility of implosion. Therefore, some other type of reactor is desirable for a multiwafer growth system for low pressure epitaxy. This report is concerned with a new type of low pressure silicon epitaxial reactor which can accommodate 6 wafers (3 in. diam) at a time.

This apparatus is divided into three blocks, these being a gas control system, reactor, and vacuum system. The sections of the reactor are shown in Fig. 1. The characteristics of this apparatus are as follows: (*i*) Bell jar type reaction chamber; (*ii*) radiation heating; (*iii*) accurate automatic pressure control without changing gas flow rate in the reaction tube.

The bell jar type reaction chamber is safer against implosion. It is also leakage free because it employs only one O-ring seal and there is little leakage in the upstream of the wafer. The inlet gas is injected through the central tube and a T-shaped nozzle. Reacted gas is exhausted from the outlets in the base plate. The substrate holders can be rotated in order to obtain good uniformity of epi layer thickness.

The wafers are heated by infrared lamps. This heating system has several merits and demerits. It causes no glow discharge and few slip lines (dislocations) during heating and cooling processes because of small temperature difference between a substrate holder and a wafer. At low pressures heat conduction due to gas convection is difficult to realize, therefore the temperature gradients tend to be larger than that at atmospheric pressure. The demerits of radiation heating is that silicon is deposited on the walls of bell jar which is made of fused silica when silane is used as a silicon source.

The vacuum exhaust system of this apparatus is shown in Fig. 2. Reacted gas is exhausted by an oil-sealed rotary pump. Amorphous silicon particles in the exhausted gas are removed by a heat exchanger and metal mesh filters. Oil mist is trapped by a liquid nitrogen trap. The pressure in the reaction chamber is detected just below the base plate by a diaphragm vacuum gauge and is controlled automatically by injecting hydrogen or nitrogen into the exhaust piping system. The accuracy of the control system is about $\pm 2\%$ at 10^4 Pa (75 Torr).

The gas control system is assembled with parts made of stainless steel in order to get a leakage-free piping system. The gas flow rate is controlled completely automatically by a mass flow controller.

The effect of pressure on epilayer thickness distribution within a wafer (2.5 in. diam) is depicted in Fig. 3 under a constant flow rate condition. In this case, the best uniformity is obtained at 1.3×10^4 Pa (100 Torr). Above this optimum value of pressure, epilayer thickness is thinner in the downstream position. When the pressure is kept at 1.3×10^4 Pa (100 Torr), the flow rate dependence of thickness distribution is as indicated in Fig. 4. As the flow rate increases, epilayer thickness in the upstream position decreases. This is probably due to the gas-phase temperature variation in the direction parallel to the gas flow as

Key words: epitaxy, doping, wafers.

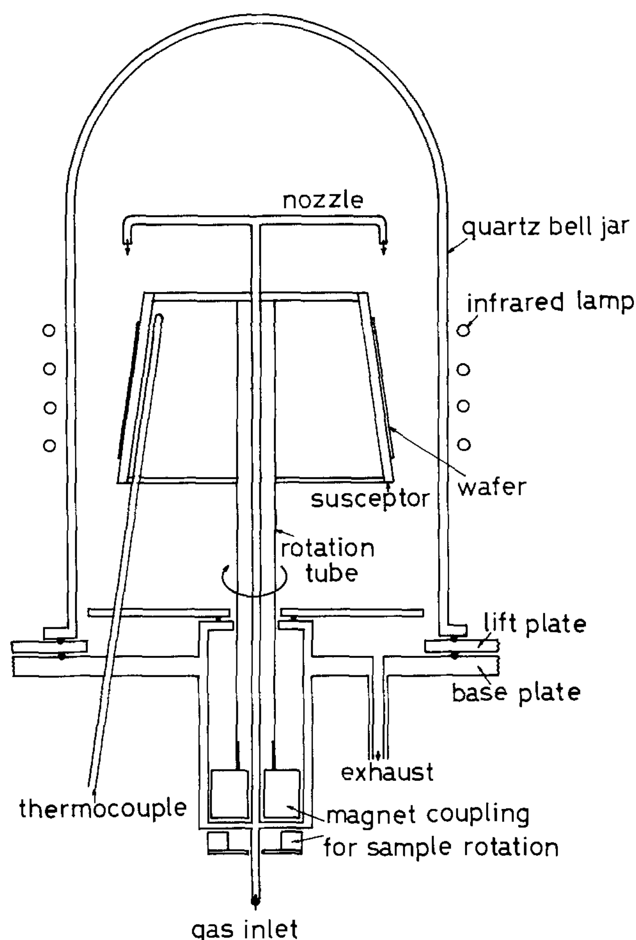

Fig. 1. Reactor structure

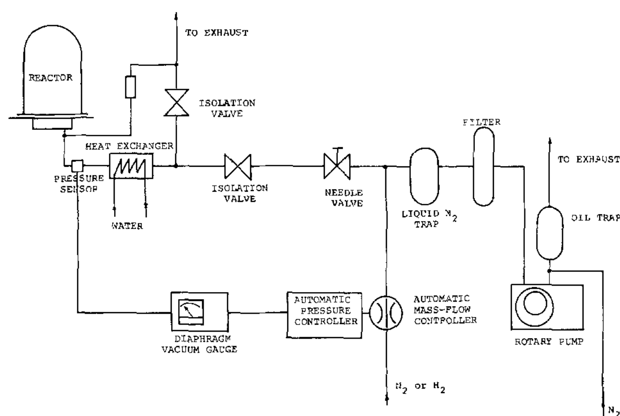

Fig. 2. Vacuum exhaust system

pointed out by Manke and Donaghey (4). In principle, epilayer thickness is thickest at the center of the wafer under an optimum condition and the thickness distribution is usually convex, as indicated in Fig. 3 and 4. When the growth conditions are optimized, the thickness uniformity in a wafer (2.5 in. diam) is better than $\pm 2\%$. The uniformity of epilayer thickness is also dependent on the length of the arms of the gas inlet nozzle (T-shaped nozzle). When it is longer than the optimum value,[1] the epilayer in the upstream position is thinner than that in the downstream position. The use of dichlorosilane improves the thickness uniformity, but involves some loss of the durability of rotary pump and some increase of autodoping.

[1] Optimum value of arm length is dependent on the size of the susceptor holder. In this case, it is as long as the outer diameter of the top of the susceptor holder.

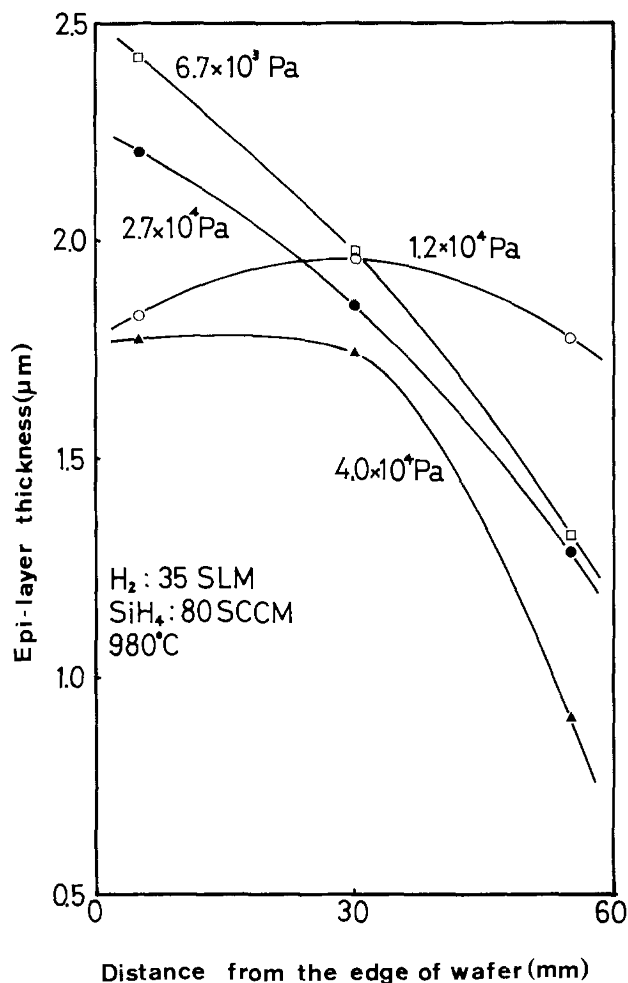

Fig. 3. Pressure dependence of epi layer thickness uniformity

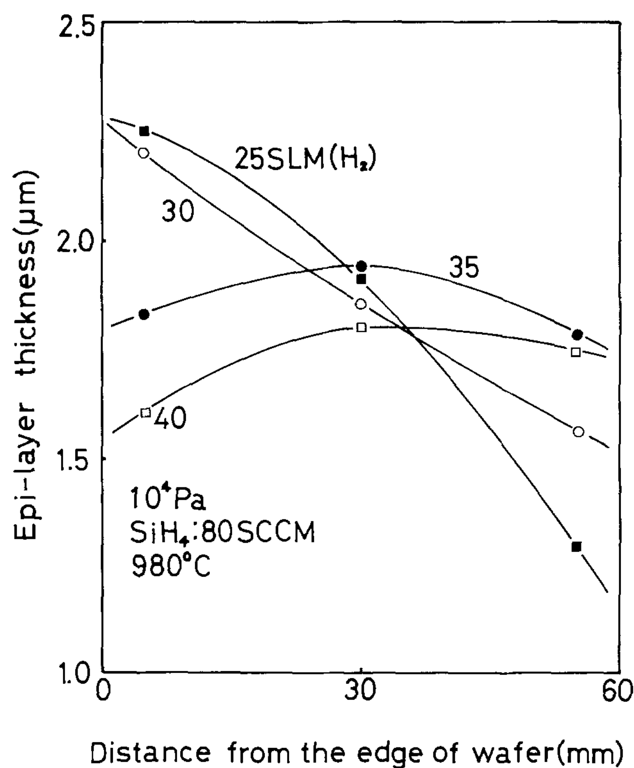

Fig. 4. Dependence of epi layer thickness uniformity on gas flow rate.

As reported previously (1), growth rate decreases with the decrease of pressure in the reaction chamber. Therefore, the molar concentration of the silicon source in a carrier gas has to be increased in order to maintain growth rate at the same level as in usual epitaxy. The dependence of growth rate on silane concentration is represented in Fig. 5. The maximum growth rate at 10^4 Pa(75 Torr) is about 1.0 μm/min.

Generally speaking, defect density [stacking fault (SF), oxidation-induced stacking fault (OSF), and dislocations] in a low pressure epitaxial layer is higher than that in a usual epitaxial layer. These defects are assumed to be due to the following three causes: (*i*) Leakage in the gas control system and reactor chamber; (*ii*) gas desorption of substrate holders; and (*iii*) temperature difference between the wafer and substrate holder.

The second cause, gas desorption, is very serious when graphite is used as a substrate holder. Usually, SiC-coated graphite is utilized as the substrate holder and it has few problems for atmospheric-pressure epitaxy. For low pressure epitaxy, however, gas atoms which are absorbed during loading and unloading of wafers are desorbed at low pressures and high temperatures.

Desorbed gas concentration from a graphite holder was analyzed by mass spectroscopic analysis and the results are indicated in Fig. 6. The sample was maintained at the measuring temperature for 10 min, and the desorbed gas pressure was measured by mass spectroscopic analyzer. After measurement, the cell was once evacuated and the sample was heated stepwise. The peak height of the analyzer was represented by partial pressure of the desorbed gas by means of the calibration curve. H_2O, CO_2, and N_2 gas atoms are desorbed above 200°C. The desorption curve for CO_2 and N_2 has dual peaks and the peak at higher temperature is supposed to be due to N_2 gas. These gas atoms attack the substrate surface and cause SF's and OSF's.

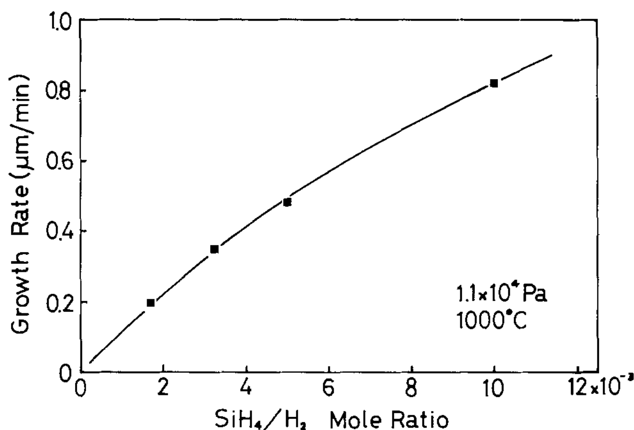

Fig. 5. Growth rate vs. SiH_4/H_2 mole ratio

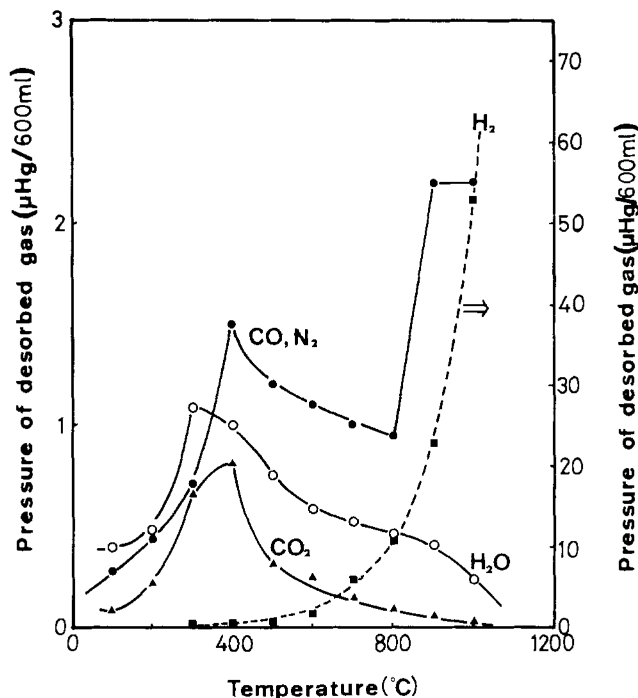

Fig. 6. Gas desorption from a substrate holder (graphite)

To prevent gas absorption and desorption, it is important to coat the surface of the substrate holder with thick (no less than 10 μm) polycrystalline silicon or quartz. Another method is to use a holder made of silicon and/or quartz. In this experiment, by using polycrystalline silicon holders, the density of OSF and SF was remarkably reduced from 10^3-10^4 cm^{-2} to 10-10^2 cm^{-2}.

Sodium-Induced Work Function Shift of Mercury as a Metal-Oxide-Semiconductor Electrode

Gerald A. Corker[1] and Christer M. Svensson[2]

Research Laboratory of Electronics, Chalmers University of Technology, Gothenburg, Sweden

Mercury drop electrodes are often used as metal electrodes in metal-oxide-semiconductor (MOS) structures. Measurements of, for example, the capacitance-*vs.*-voltage relationship (the *C-V* curve) can then be done without vacuum metallizing. From *C-V* measurements on MOS structures many interesting properties of the structures are obtained (1). Among these properties it is also possible to measure the rela-

[1] Permanent address: IBM Research Center, Yorktown Heights, New York 10598.

Key words: semiconductor, electrode, capacitance.

tive value of the metal work function (1). In investigating the work function of a mercury drop we found a very large change in electrode work function, about 2 eV, as a result of only small amounts of dissolved sodium. In the present paper we report on this effect.

Sample No. 1 was prepared from n-type silicon wafers with 2-3 Ωcm resistivity. The wafer was oxidized in dry oxygen at 1200°C to an oxide thickness of 100 nm. A small number of Au dots were evaporated on the oxide as reference electrodes. The sample was then put on a metal backing plate with a liquid InGa alloy in between. We then probed the Au dot with a thin goldplated wire. The *C-V* curve was then recorded by a Boonton 72B Capacitance bridge and an X-Y recorder. In Fig. 1 this *C-V* curve is shown as curve a. A small drop of mercury (about 1 mm diam) was also put on the oxide and probed by a goldplated wire, and its *C-V* curve was recorded. This *C-V* curve is shown in Fig. 1 as curve b. Finally, a similar drop of mercury with a small amount of dissolved sodium was used. The *C-V* curve of this Hg:Na electrode is shown in Fig. 1 as curve c. As can be seen from the figure we observe a very large shift of the *C-V* curve between the Hg and the Hg:Na electrodes. Using C_{FB} (the capacitance for which the semiconductor bands are flat or the electrical field at the semiconductor surface is zero) equals 0.7 C_{max} gives the following flatband voltages from Fig. 1: −0.16V for the Au electrode; +0.04V for the Hg electrode; and −2.13V for the Hg:Na electrode. Thus the sodium induced shift is 2.17V in this case.

During storage in air the flatband voltages were initially stable. After about 2 hr the flatband voltage started to increase on the Hg:Na electrode toward the value of the clean Hg electrode. Probably Na disappears by oxidation in air. After about 24 hr, only about 0.2V shift was left and the mercury drop was covered by a hard, white layer, probably NaOH.

In order to investigate the dependence of sodium concentration in the mercury, we performed the following experiment. Sample No. 2, similar to No. 1 but with 70 nm thick oxide, was placed on a backing plate as above. The mercury was contained in a plastic well with a 3 mm hole, placed on the sample. Each Hg sample was about 0.05 cm³. Hg samples with different Na content were prepared in the following way. Na metal was cut clean under hexane previously dried with Na. 0.0032g of clean Na metal was weighed on filter paper and dissolved in 1 ml Hg. This gives $2.05 \cdot 10^{-3}$ Na atoms per Hg atom in the solution. This solution was then further diluted by volume in test tubes. *C-V* curves were then recorded, starting with the most dilute solution and continuing to the highest concentration. After this the oxide surface was cleaned with water, dried in nitrogen, and again measured with a clean Hg sample. The result of this experiment is shown in Fig. 2.

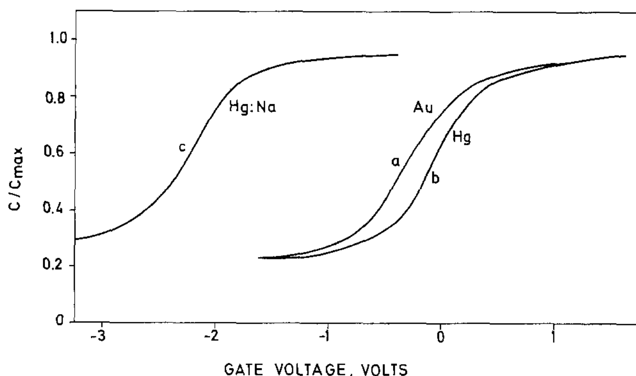

Fig. 1. Normalized capacitance *vs.* voltage for three different electrodes on sample No. 1.

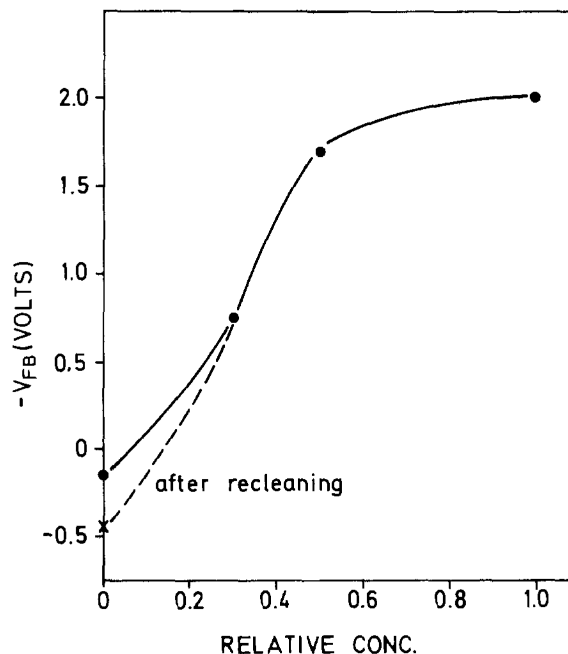

Fig. 2. Flatband voltage of sample No. 2 with mercury electrodes of different sodium content *vs.* the relative sodium concentration. The relative concentration 1.0 corresponds to about 0.002 Na atoms per Hg atom.

From Fig. 2 we can see that the sensitivity for sodium is very large. Already at a relative concentration of 0.3, corresponding to nominally about 60 ppm (Na atoms per Hg atom) the flatband voltage shift is half the total and, at a relative concentration of 0.5 (~100 ppm), the shift saturates. It should be noted that the values of concentration given here are upper limits of concentration rather than reliable values. The reason is that we continuously lose sodium metal through the reaction with water vapor during dilution and experiments. We believe, however, that the real concentration values are not less than half the stated values.

Discussion

It is quite obvious that 60 ppm sodium in mercury could not change the bulk work function of the mercury. Our observations are instead equivalent to the well-known work function lowering which occurs as a result of alkali adsorption on high work function metals in vacuum (2). Sodium-induced work function lowering of a silicon-silicon dioxide interface has also been directly observed by DiStefano (3). In both these cases the sources of the alkali are outside the metal, in vacuum, or in the oxide. In our case the sodium comes from the interior of the metal. Our case is therefore similar to the effect of hydrogen-induced work function lowering of palladium on silicon dioxide (4).

As we expect the silicon-silicon dioxide system to be unaffected by the metal, our observed values of the flatband voltage will be proportional to the metal work function (1). Taking the gold work function to be 5.0 eV (1), we get from Fig. 1: Hg work function 5.2 eV and Hg:Na work function 3.0 eV. Expected values are for Hg 4.5 eV (5) and for a saturated sodium-covered metal surface in vacuum about 2.2 eV (2). Our observed values are thus in reasonable agreement with the proposed model. It should be noted that the oxide surface is not completely unaffected by our experiments since we observed, for example, shifts of the order of 0.2V as a result of recleaning the oxide surface.

Role of Oxide Defect Sites in the Breakdown of NiO Films

B. MacDougall*

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario Canada K1A 0R9

In previous papers the breakdown of NiO films anodically formed on polycrystalline and single crystal nickel in *p*H 2.8 Na_2SO_4 has been studied in terms of both the open-circuit potential decay profiles and the extent of surface pitting (1-5). Open-circuit breakdown of the oxide films occurred in two distinct stages: (*i*) an induction period during which localized chemical dissolution of oxide occurred at defect sites in the film and; (*ii*) pitting and/or undermining of the oxide film as a result of nickel dissolution from oxide-free sites (*i.e.*, pores) in the film. The transition from stage (*i*) to stage (*ii*) was marked by a rapid potential shift to −0.75V (often accompanied by a potential overshoot or "spike") as the exposure of bare nickel set up the corrosion couple: $Ni \rightarrow Ni^{2+} + 2e$; $2H^+ + 2e \rightarrow H_2$. This mechanism for film breakdown was supported by the observation that substantial pitting of the surface occurred only after the spike, the pits presumably developing at those sites where "defective" oxide had broken down. In the present note, a Ni(100) single crystal has been used to investigate further the role of oxide defect sites in the breakdown of NiO films.

Effect of Solution *p*H on Oxide Breakdown

Figure 1 shows the open-circuit decay profiles for Ni(100) electrodes after different times of anodization at 0.0V.[1] Before the potential spike, little breakdown of the oxide film occurs as indicated by the small amount of both recovered surface activity and nickel in solution (Table I) and the absence of surface pitting (Fig. 2a). This was taken to indicate that the oxide at the defect sites, which only covers a small part of the surface, is slowly dissolving in this region

$$NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$$

The effect of the *p*H of the breakdown solution was investigated by anodizing for 1 hr at 0.0V in *p*H 2.8 Na_2SO_4 and then transferring to a *p*H 4.0 solution for open-circuit decay.[2] The time to the spike increased by a factor of three with this increase in *p*H, as would be anticipated from the above reaction.

Role of O_2 in Film Breakdown

To study film breakdown in the region up to the spike, experiments were performed in the presence of dissolved oxygen. The oxide film was formed by anodization at 0.0V for 1 hr in deaerated *p*H 2.8 Na_2SO_4 solution and then transferred to a separate *p*H 2.8 solution to follow the open-circuit breakdown. If this second solution was carefully deaerated, the decay

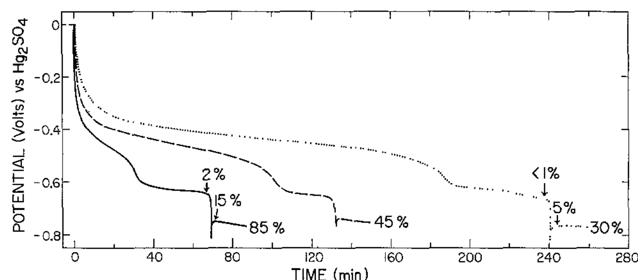

Fig. 1. Open-circuit potential decay, in deaerated *p*H 2.8 Na_2SO_4, of Ni(100) electrodes which had been anodized at 0.0V for various times. (——) 15 min; (– – –) 1 hr; (· · ·) 15 hr. Also given are recovered surface activities at various decay times, obtained by stepping the potential back to 0.0V and measuring the charge required to reestablish passivity. The potential step technique was used for all anodizations.

profile was identical to that obtained without transfer of the electrode. However, if the second solution contained oxygen, the open-circuit decay profile was dramatically altered. Firstly, the induction time before film breakdown increased by a factor of *ca.* five. This increase was associated entirely with the arrest at −0.6V, which in the presence of O_2 was shifted as much as 0.1V anodic, *i.e.*, to −0.5V. In contrast, the arrest at −0.4V did not change at all. Secondly, the recovered surface activity at the potential spike was 20% instead of the usual ~2% obtained in O_2-free solutions. The dramatic effect of O_2 on the arrest at −0.6V suggests that breakdown and repair of an oxide film is operative here, the presence of O_2 being able to keep the film in a state of repair.

The oxide responsible for the potential plateau at −0.6V is a different oxide from that giving rise to the arrest at −0.4V and may have either been present at the defect sites as an inner oxide after the anodization (3) or been formed as a result of repair of the origi-

Table I. Quantity of Ni^{2+} in solution and surface activity recovered, after various times on open-circuit, for both electropolished and anodized Ni(100) in *p*H 2.8 Na_2SO_4

(Quoted values of [Ni^{2+}] refer to that which has dissolved during the open-circuit decay only.)

[1] Potentials are measured *vs.* a Hg/Hg_2SO_4 reference electrode in 0.15*N* Na_2SO_4 (+0.665V with respect to the standard reversible hydrogen electrode). The working nickel electrode is vertically positioned in the cell and is parallel to a platinum counterelectrode in the same compartment.

[2] It has previously been shown that such air exposure of the steady-state, passive NiO film does not affect the breakdown characteristics of the film (2,3,5).

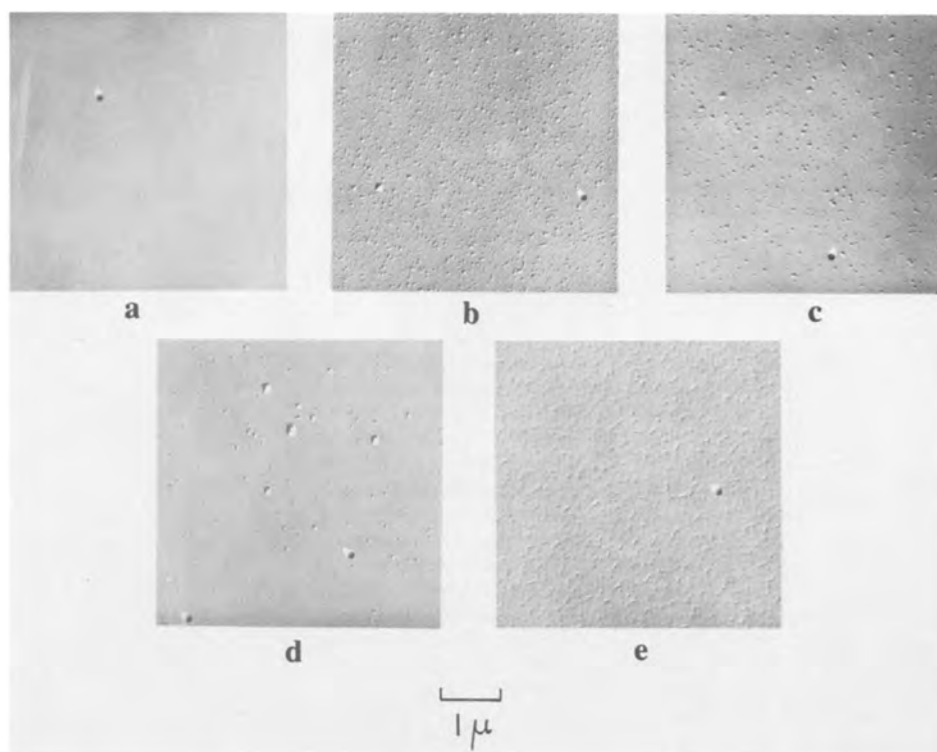

Fig. 2. Electron micrographs of a Ni(100) surface after various electrochemical treatments: (a) Electropolished and anodized at 0.0V for times of 15 min (or 15 hr) followed by open-circuit breakdown to 2 min before the spike; (b) 15 min at 0.0V with open-circuit decay continuing for 20 min after the spike. Recovered surface activity is 85%; (c) As in (b) but with the potential decay continuing for only 5 min after the spike. Recovered activity is 35%; (d) 15 hr at 0.0V with open-circuit decay continuing for 20 min after the spike. Recovered activity is 30%; (e) Electropolished and immersed in pH 2.8 Na_2SO_4 solution for 90 min on open circuit.

nal oxide which has completely broken down at these sites. The results in the absence of O_2 can be interpreted in terms of the spike resulting from breakdown of defect oxide to reveal nickel metal, the hydrogen evolution reaction not being able to repair this oxide. The higher tendency for film repair with O_2 reduction (as opposed to hydrogen evolution) is due to the more positive electrode potential for the former reaction at the cathode areas and its subsequent ability to polarize more strongly the anodic reaction at the pores. This leads to an increase in the oxide-free coverage required to shift the potential to $-0.75V$ and thus an increase in the over-all induction time. The absence of any influence of O_2 on the open-circuit arrest at $-0.4V$ suggests that simple chemical dissolution of oxide at the defect sites is occurring in this region. Consequently, the duration of this arrest should be related only to stability of defective oxide toward chemical dissolution. (It is interesting to note that it is mainly this arrest which increases with time of anodization at 0.0V (Fig. 1), *i.e.*, the time of anodization mainly influences the stability of oxide at the defect sites toward dissolution rather than the ability of the film to repair itself.)

Oxide Undermining After the Spike

The 20% recovered surface activity at the spike in the presence of O_2 indicates that a constant oxide-free coverage is not required to shift the potential to $-0.75V$. This is confirmed for film breakdown in the absence of O_2 where, with an increase in time of anodization at 0.0V from 3 min to 20 hr, the recovered activity at the spike decreases from 6 to 1%. This decrease in recovered activity can be correlated with a corresponding decrease in the density of pits (Fig. 2b and 2d), which means that the number of defect sites has decreased. With increasing time of anodization, the oxide at some defect sites is converted to a more stable form which does not break down during potential decay. The correlation between density of pores and oxide-free area (as determined from the recovered activity) is not, however, a simple one, especially at longer times after the spike. A recovered surface activity of, *e.g.*, 5% is much more effective in removing oxide by undermining after the 15 min anodize than the 15 hr anodize. With the latter treatment, the activity increases from 5 to 30% during 18 min on open circuit after the spike, compared to 5-85% after the 15 min anodize at 0.0V (Fig. 1). The results can be explained in terms of the number of pores which contribute to the 5% oxide-free area. This number decreases with time of anodization and consequently the sites must be somewhat larger to encompass 5% of the surface. This is evident from Fig. 2c and 2d where a recovered activity in the neighborhood of 35% can have associated with it different defect site densities. The smaller number of sites (after the long anodize) will be less effective in removing the oxide film and the activity will increase more slowly. Thus, the important factor in determining the rate of oxide removal after the spike is the number of pores and not the total oxide-free area.

Cathodic Control of Oxide Undermining

The amount of nickel dissolved during a 20 min time period after the spike is 50% higher for the 15 hr anodize at 0.0V in comparison with the 15 min anodize at 0.0V (Table I). On the other hand, the recovered surface activity is much lower after the longer anodization and breakdown (Fig. 1), indicating that the amount of oxide-free nickel surface is lower. The increase in amount of nickel dissolution with corresponding decrease in oxide-free surface exposure shows that the corrosion couple (after the spike) is controlled by the cathodic reaction, *i.e.*, hydrogen evolution on the NiO film. The importance of the cathodic reaction is also evident from the observation that a 20 min open-circuit exposure of electropolished Ni(100), where the surface is 100% free of oxide after <3 min exposure (5), does not result in any increase in the amount of nickel dissolution in comparison with the treatments mentioned above (Table I).

Role of Oxide Film Thickness

The thickness of the oxide films on anodized Ni(100), as determined by oxygen K_α x-ray emission spectroscopy (5), was 9-12Å for either 15 min or 15 hr at 0.0V. The dramatic changes in film breakdown characteristics with time of anodization (Fig. 1) and the absence of substantial changes in measured oxide

film thicknesses can be explained in terms of the presence of oxide defect sites. The defect sites cover only a small part of the surface and therefore changes in the composition (*e.g.*, thickness, stoichiometry) of oxide at these sites will probably not easily be observed. However, these changes can considerably alter both the time to film breakdown and subsequent activation of the surface by oxide removal, as discussed above. Somewhat similar results were reported by Kruger and Ambrose (6) for oxide breakdown on anodized iron in chloride solutions, very large increases in the time to film breakdown being associated with small increases in oxide thickness. Again, the influence of condition of oxide formation on composition and density of oxide defect sites appears to have played the major role.

Etching vs. Pitting

Complete breakdown of the oxide film on electropolished Ni(100) occurs on open circuit within 3 min at pH 2.8 as indicated by the recovered surface activity and the corrosion potential (5). This observation can be explained in terms of the presence of a very large defect site density. The rapid removal of this oxide film is the reason no pitting attack is observed, the nickel dissolution giving only a general roughening of the electrode surface (Fig. 2e). Obviously an oxide film, with a distribution of pores, must be present on the surface for a sufficiently long period of time before detectable pits can be observed (7).

Acknowledgments

The author thanks Mr. G. I. Sproule for the electron microscopy, Mr. A Desaulniers for the A. A. analysis of Ni^{2+}, and Drs. M. Cohen and M. J. Graham for helpful discussions and suggestions.

Erratum

The following comments are written in reference to the article "Growth of $Ga_yIn_{1-y}As$/InP Heterostructures by Molecular Beam Epitaxy," by B. I. Miller and J. H. McFee, which appeared in the August 1978 issue of *This Journal*, Vol. 125, No. 8, pp. 1310-1317.

In Fig. 8, the 77°K photoluminescence peak at 1.368 μm was claimed to correspond to the mole fraction $y = 0.455$ for $Ga_yIn_{1-y}As$. This was derived using the relation

$$E_g(\text{eV}) = 0.410 + 1.094g$$

at 77°K which assumes a linear relationship for E_g *vs.* y. This relationship was shown to hold in Ref. (12). More recent work[1] on $Ga_yIn_{1-y}As$ shows a quadratic relationship for E_g *vs.* y at 77°K, or

$$E_g(\text{eV}) = 0.404 + 0.649y + 0.457y^2$$

which would give a bandgap corresponding to 1.53 μm for $y = 0.47$ at 77°K, close to that reported recently by many researchers. We now know that our photoluminescence spectrum of Fig. 8 showing a peak at 1.368 μm was shifted toward shorter wavelengths by bandfilling (Burstein Shift) which can be significant in materials such as $Ga_{0.47}In_{0.53}As$ where the effective mass is small. The spectrum of Fig. 8 corresponds to a nearly lattice-matched GaInAs layer with carrier concentration $n \sim 10^{18}$ cm^{-3}. More recent work by us on lattice-matched fairly pure $Ga_{0.47}In_{0.53}As$ ($n \sim 10^{17}$ cm^{-3}) reveals that at 77°K the photoluminescence peak is ~1.55 μm.

Polarization Behavior and Structure of LiAlMg Alloy Electrodes

C. A. Melendres,* S. Siegel, and J. Settle

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

In a previous publication in this journal[1] we reported on the results of studies on the structural changes that occur during the cyclic polarization of LiAl wire electrodes. Evidence of electrode comminution with cycling was presented. It was thought that this behavior may be limiting the long term performance and cycle life of LiAl/FeS_x (x = 1 or 2) molten salt secondary cells. In order to buffer structural changes in the LiAl electrode, we proposed the addition of a ternary component into this system. Initial studies in this direction involving small engineering cells have been undertaken by our colleagues in this laboratory.[2] In this communication, we report on the results of an investigation on the effect of Mg incorporation on the structure and polarization behavior of LiAl electrodes.

Electrochemical studies were conducted using a cell and other equipment described previously.[1] Polarographic grade LiCl-KCl eutectic (obtained from Anderson Physics Laboratories, Champaign, IL) was used as electrolyte. The working electrodes were prepared as follows: Ingots of MgAl alloy (consisting of 5 to 20 at.% Mg) were cast from high purity (99.99% Al, 99.9% Mg) materials in a tantalum crucible at ∿700°C. MgAl wire electrodes were prepared from the ingot by melting and then drawing the melt by suction into boron nitride tubes with 1.59mm bore. These wires were electrochemically charged with Li to about 45-50 at.%. A LiAl alloy (40 at.% Li) was used as reference electrode. Examination of electrode structure was done metallographically as described previously.[1] Identification of the phases formed during charging and discharging of the electrodes was made by X-ray diffraction.

Figure 1 shows typical polarization behavior of some LiAlMg electrodes. For comparison, we show that of a LiAl wire electrode at a similar current density. The cathodic polarization curves are for the charging of Li into the MgAl wire of appropriate composition (15 or 19 at.% Mg in Aℓ), while the anodic portions represent the subsequent extraction of Li. We observed that electrodes incorporating Mg are more polarized than LiAl on both charge and discharge. This appears to be more pronounced with increasing Mg content. For the same cutoff voltage on charge, Li-Al-Mg alloy electrodes have therefore somewhat lower Li capacity than LiAl.

The appearance of a number of plateaus is also evident in the curves for the LiAlMg systems. This is indicative of the possible formation of new phases. X-ray diffraction investigation of electrodes in the charged and discharged state revealed the phases given in Table I. Thus, in addition to forming the β-LiAl phase, solid solutions of Mg in Al and the ternary compound $LiMgAl_2$ have been identified. The absence of the α-LiAl phase is surprising. This has not been found even in nearly completely discharged electrodes. If present, the level is presumably <5 wt.% and beyond the detection limit of the X-ray diffraction technique. Another interesting observation is the apparently higher efficiency for the anodic extraction of Li (defined here as the ratio of the amount of lithium removed on discharge at constant current to the amount loaded on the preceeding charge) in the ternary alloy electrode compared to that of LiAl (Table I). The extraction efficiency also appears to decrease somewhat with Mg content of the ternary alloy due to the greater electrode polarization caused presumably by a decrease in lithium mobility in the solid alloy. Only a slight increase in extraction efficiency or lithium utilization with cycling is evident with the ternary alloy electrodes as compared to LiAl.

Metallographic examination of the discharged electrodes revealed the structures shown in Figure 2. The completely discharged portion of the electrodes in Figs. 2a, b and c (outer periphery) has essentially the same composition as the starting alloy *i.e.* solid solutions of Mg in Al, with possibly small amounts of Li. The composition of the partially discharged portion (*i.e.* the core) has not been determined but is believed to correspond roughly to that of the charged electrode. It is worthwhile to note that the morphology of the discharged LiAlMg alloy electrode is significantly different from that of LiAl electrodes shown previously.[1] The

patches of electrode particles are smaller but appear to have continuity. The overall structural feature of the electrode also appears to be intact after 3 cycles, especially for the 15 at.% MgAl alloy (compare Fig. 2c and 2d). In general, from metallographic and optical microscopic examinations, we observe increased structural stability with higher Mg content in electrodes subjected to a few cycle tests. It is obviously not possible to extrapolate this to the long term behavior of large cells. Work along the latter line is being done in a separate program with engineering type cells at this laboratory.

In summary, the incorporation of Mg into the LiAl electrode (at the level of 5 to 19 at. % in MgAl starting material) leads to increased polarization but also to a marked morphological change which appear to result in improved structural stability on cycling and increased efficiency of Li extraction during short term cyclic tests. The α-LiAl phase is eliminated while new binary and ternary phases are formed in addition to β-LiAl. These preliminary results indicate that modification of structure and properties of binary solid alloy electrodes by the addition of a third element may be worth while approach to the engineering development of suitable electrode systems and the improvement of existing ones.

ACKNOWLEDGEMENT

The authors are grateful to Dr. F. A. Cafasso for his continued interest and support of this work. Financial support by the Division of Basic Energy Sciences, Department of Energy, is gratefully acknowledged. We thank B. Tani for taking the X-ray diffraction patterns.

Photo-Assisted Corrosion of Copper

Dennis D. Davis and Dennis L. Johnson

Department of Chemistry, New Mexico State University, Las Cruces, New Mexico 88003

The effects of visible radiation on the corrosion of copper is a sparsely studied field (1). With the increasing use of copper in solar energy applications this effect may become more important in the near future.

Copper normally exhibits very low rates of corrosion in non-oxidizing acidic media in the absence of oxygen. Complexing agents such as the halide ions and the presence of oxygen greatly accelerate the rates of corrosion (2) because of the formation of complexes such as $CuCl_3{}^{2-}$ and $CuCl_4{}^{2-}$. The thermodynamically favored form of copper ion in halide media is $CuCl_3{}^{2-}$, while in the absence of halide, Cu^{2+} ions are favored.

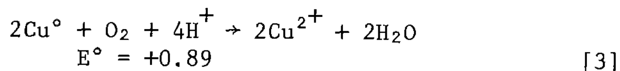
The electrode potentials of copper are fairly well behaved (3), following the Nernst equation with respect to dissolved copper, and complexation not only changes the oxidation state of the dissolved copper but also lowers the electrode potential. Additionally the well-known disproportionation reaction involving Cu(I) aquo ions

$$Cu^\circ + Cu^{2+} \rightarrow 2Cu^{1+} \qquad E^\circ = -0.37 \text{ V} \quad [1]$$

which favors metallic copper, is shifted in the other direction by complexing agents such as halide.

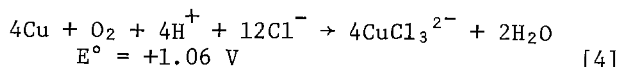
$$Cu^\circ + Cu^{2+} + 6Cl^- \rightarrow 2CuCl_3{}^{2-} \quad E^\circ = +0.34 \text{ V} \quad [2]$$

The oxidation of copper and hence its dissolution is usually accompanied by the reduction of atmospheric oxygen



$$2Cu^\circ + O_2 + 4H^+ \rightarrow 2Cu^{2+} + 2H_2O \quad E^\circ = +0.89 \quad [3]$$

and is even more favored by halide ions



$$4Cu + O_2 + 4H^+ + 12Cl^- \rightarrow 4CuCl_3{}^{2-} + 2H_2O \quad E^\circ = +1.06 \text{ V} \quad [4]$$

The corrosion of copper can be promoted in the absence of a traditional oxidizing agent (O_2, HNO_3, etc) if the reaction sequence shown in Eqs. [5], [6] can be maintained

Key words: copper, corrosion, photochemistry.

$$Cu(I)L_x \rightarrow Cu(II)L_x \quad [5]$$

$$Cu(II)L_x + Cu^\circ \rightarrow 2Cu(I)L_x \quad [6]$$

L = complexing agent such as halide

resulting in the auto-catalytic oxidation of copper metal. Normally oxygen provides the cathodic component for Eq. [5]. Hydronium ions are not reduced under standard conditions, but are reduced to a very slight extent governed by the Nernst equation. The photochemical reaction we have investigated [4-6] for solar energy conversion is the oxidation of copper(I) complexes to copper(II) complexes with concomitant proton reduction driven to completion by light. Thus the photochemical reaction

$$CuCl_3{}^{2-} + H^+ \xrightarrow{h\nu} CuCl_3{}^{1-} + \tfrac{1}{2}H_2 \quad [7]$$

is in actuality the same as Eq. [5] with H^+ as the oxidizing agent. It is suggested from our solar conversion work that corrosion of copper metal should be greatly enhanced in the presence of light when the copper is immersed in HCl solution even in the absence of conventional oxidizing agents. Arbit and Nobe [1b] reported that immersion of copper single crystals in neutral sodium halide solutions alters the photopotentials, but observed no solution photoreactions. The quantum yield for Cu(I) photooxidation is a strong function of acid concentration and approaches zero in neutral solution [6], thus such reactions would not have noted by these workers.

EXPERIMENTAL

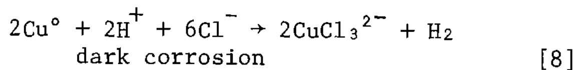
Cleaned copper corrosion strips of approximately 5-7 cm^2 area were immersed in acidic salt solutions in serum-capped Pyrex tubes. The solution contained 0.9 M NaCl and 0.1 M HCl ($[Cl^-] = 1.0$, $[H^+] = 0.1$). The tubes were degassed on a vacuum line and then filled with argon to ensure anaerobic conditions. A control strip was kept in the dark and the sample to be irradiated placed in a

thermostatted (22°C) brass block. Irradiation was accomplished with a 200-w Hg lamp for 12 hrs. Similar results were obtained with ~30 hrs. of direct sunlight but because the experimental variables are much greater with sunlight, we discuss only the lamp experiments. Aliquots were removed via syringe periodically and analyzed for soluble copper by atomic absorption spectrometry. No blue-green color developed which would have indicated a copper(II) complex, so it is assumed that the soluble copper is present as $CuCl_3^{2-}$, a colorless copper(I) complex. The results are summarized in Figure I which represents duplicate experiments and are corrected for the fact that only one-half of the surface area of the irradiated sample actually received illumination, while the backside was subject to the same corrosive effects as the dark sample.

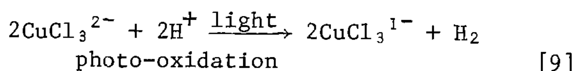
DISCUSSION

The Figure dramatically points out that, for example, after 8 hrs. the illuminated sample has undergone 50-times as much corrosion as the dark sample. These results are in good accord with theoretical expectations on several points:

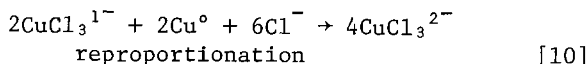
1. Dark corrosion in the absence of oxygen should occur only up to an extent controlled by the Nernst equation (in a nonflowing situation) and should eventually reach an equilibrium situation. This limiting effect is noted in that the dark experiments tend to an average limiting value of Cu(I) concentration in solution of 3×10^{-4} M, while the Nernst equation, $E° = \frac{0.059}{2} \log \frac{[Cu(I)]^2[H_2]}{[Cu°][H^+]^2[Cl^-]^6}$, $E° = -0.165$ V for the reaction, $2Cu° + 2H^+ + 6Cl^- \rightarrow 2CuCl_3^{2-} + H_2$, predicts a Cu(I) equilibrium concentration of 2.7×10^{-4} M.
2. The exponentially increasing corrosion with time of irradiation, log [Cu] dissolved vs time being a fairly linear plot, is suggestive of an autocatalytic mechanism. We suggest the following scheme:



$$2Cu° + 2H^+ + 6Cl^- \rightarrow 2CuCl_3^{2-} + H_2 \quad \text{dark corrosion} \quad [8]$$



$$2CuCl_3^{2-} + 2H^+ \xrightarrow{light} 2CuCl_3^{1-} + H_2 \quad \text{photo-oxidation} \quad [9]$$



$$2CuCl_3^{1-} + 2Cu° + 6Cl^- \rightarrow 4CuCl_3^{2-} \quad \text{reproportionation} \quad [10]$$

then Eq. [9], then Eq. [10], then Eq. [9] etc. in an autocatalytic cycle promoted by light.

3. The parallel slopes in the illuminated experiments suggests the same rate limiting feature is present in all and we propose that this is the intensity of illumination controlling Eq. [9].

CONCLUSIONS

In an anaerobic acidic medium containing chloride ions, corrosion of copper is greatly accelerated by visible light. Such conditions might obtain in solar collectors in which partly saline water is used, particularly if the acidic decomposition products of a heat transfer medium such as glycols are present, and of course if this system is subjected to visible radiation.

Although these are fairly stringent limitations, the photoassisted corrosion of copper is a hitherto univestigated and novel mode of corrosion and etching which may have importance in diverse applications of copper and its alloys.

ACKNOWLEDGEMENT

Electrochemical Behavior of Palladium-Implanted Titanium

E. McCafferty* and G. K. Hubler

Naval Research Laboratory, Washington, D.C. 20375

It is well known that the corrosion resistance of titanium in acids is greatly improved by small alloying additions of palladium (1,2). The purpose of this communication is to report on the electrochemical behavior of titanium surfaces which have been ion-implanted with palladium. The beneficial effect of ion implantation in aqueous corrosion applications has been illustrated by several recent studies dealing with the implantation of various ions into iron (3-5).

EXPERIMENTAL

Samples of pure (99.97%) titanium rod (3/8 inch diam) were mounted in epoxy molds. The exposed surface was abraded through 600 grit emery paper, 6 μm diamond paste, and then given a final polish to a mirror finish with 0.05 μm alumina in a 5% oxalic acid solution. These surfaces were implanted with palladium to a fluence of 1×10^{16} ions/cm^2 at an energy of 90 keV. The resulting palladium concentration profile was near Gaussian shaped and centered at a depth of 240 angstroms. The peak concentration of palladium was 5 atomic percent, with less than 0.1 atomic percent Pd at the metal surface.

For some corroded samples, the Pd concentration profiles were measured by means of high resolution Rutherford backscattering of alpha particles. Experimental details have been given elsewhere (6); but in brief the analysis beam was 2.5 MeV helium, and the scattering angle was 135°. The energy spectrum of backscattered particles was measured with a position-sensitive solid state detector placed in the focal plane of a magnetic spectrometer. This detector system provided a depth resolution of 30 angstroms.

RESULTS AND DISCUSSION

Figure 1 shows electrode potentials for pure titanium, pure palladium, and palladium-implanted titanium as a function of immersion time in boiling (100°C) 1 M sulfuric acid. The time-axis is plotted logarithmically for illustration purposes only. The steady-state open-circuit corrosion potential of pure palladium was approximately 1000 mV more noble than that of pure titanium. The steady-state corrosion potential of the implanted sample was much closer to that of pure palladium than to that of pure titanium.

In the first minutes of immersion, the implanted samples displayed a rapid shift in electrode potential. After one minute in the case of two of the implanted samples and after 1.5 minutes for a third, the electrode potential was -1.0 volts vs. Hg/Hg_2SO_4 and tending toward the potential of pure titanium. In the next few seconds in each case, however, the electrode potential reversed toward the noble direction as the Ti-rich surface dissolved away to expose a new surface region containing an increased concentration of Pd. After about 2 hrs, the electrode potential of the implanted sample was fairly constant and only 150 mV less noble than the corrosion potential of pure palladium.

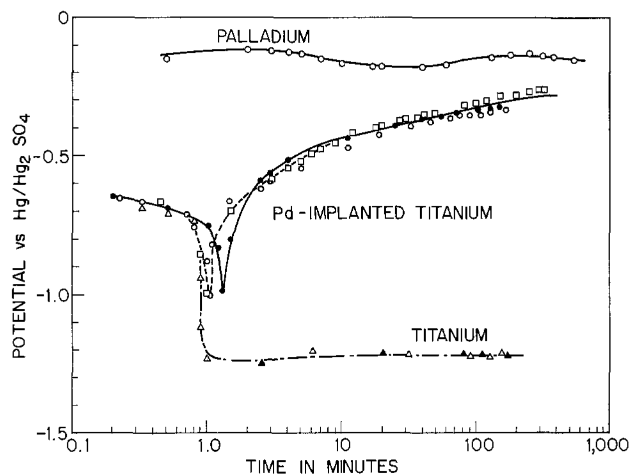

Fig. 1. Open-circuit corrosion potentials as a function of immersion time in boiling 1 M H_2SO_4 for pure titanium, pure palladium, and palladium-implanted titanium.

*Electrochemical Society Active Member

Key Words: corrosion, ion implantation, titanium, palladium.

The buildup of palladium at the surface during the corrosion process was determined by backscattering analysis. Figure 2 shows depth concentration profiles for an as-implanted sample and for samples corroded for two different immersion periods. A significant shift of the Pd profile is evident after only 6 minutes immersion; whereas after 125 minutes, the backscattering spectrum shows that Pd builds up on the surface to a concentration of 20 atomic percent. The total area beneath the Pd profile for all three curves is constant to within the ± 5% error in the measurement, indicating that no Pd has been removed from the surface during the corrosion process.

Figure 3 shows potentiostatic anodic polarization curves for pure titanium, pure palladium, and palladium-implanted titanium in boiling 1 M H_2SO_4. All curves were determined after steady-state open circuit potentials were first established (2 to 2-1/2 hrs immersion). The anodic curve for pure titanium shows the normal active-passive behavior which has been typically observed (1,2,7). Well defined Tafel slopes were not observed in the active region, but the corrosion rate at the open-circuit potential was determined by colorimetric analysis of solution to be 3.7 mA/cm², on the basis that the overall anodic reaction is $Ti \longrightarrow Ti^{+3} + 3e^-$ (7). The implanted samples display a passive current density of 2 to 6 μA/cm , which may be estimated to be the corrosion rate at the open-circuit potential. Thus, implantation with Pd lowers the corrosion rate of Ti by a factor of about 1,000. Anodic current densities for pure Pd are less than the values for the implanted samples for electrode potentials more negative than +0.2 volts vs. Hg/Hg_2SO_4. At more positive potentials, palladium undergoes increased dissolution (8), but the implanted sample does not.

SUMMARY

Ion implantation of titanium with palladium reduces the open-circuit corrosion rate in boiling 1 M sulfuric acid by a factor of about 1,000. The open-circuit corrosion potential is shifted approximately 0.9 volts in the noble direction and is a mixed potential between pure titanium and pure palladium. Electrochemical measurements and Rutherford backscattering analyses indicate that the improvement is due to initial preferential dissolution of titanium and retention of implanted palladium.

Low Melting-Point Compositions in Alkali Metal Metaphosphate/Fluoride Systems

D. Elwell*

Center for Materials Research, Stanford University, Stanford, California 94305

Molten salt compositions of low melting point are often of interest for applications in electrochemistry or as solvents for metal oxides. This investigation was performed in order to find a phosphate-based solvent for the electrodeposition of indium phosphide at temperatures at or below 600°C.

The system Na, K/PO_3, F was investigated by Bukhalova and Mardirosova(1) and the lowest melting-point for any composition in that system was found to be 424°C. Solvents containing Li^+ are expected to have a lower viscosity because of the relatively small mass of these ions, and are therefore preferable for electrocrystallization experiments provided that the liquidus temperatures are similar to or below those of the Na, K system.

In order to accelerate the task of finding compositions of lowest melting point in the Li, Na/PO_3,F and Li, K/PO_3, F systems, melts containing equal molar concentrations of the four constituents in each case were unidirectionally solidified by slow horizontal traverse of a 15 cm long crucible through a furnace. The fraction which solidified last was analyzed and a melt of the composition so determined was subjected to a further unidirectional solidification to test the accuracy of the first analysis. Atomic absorption spectrographic analysis for the alkali melts was found to be reliable to within 1% but electron microprobe analysis for F, P and O did not give reliable data, although intensities were compared with standard materials.

The Li:K ratio in the lowest-melting sample in that system was found to be 1·16(5):1 and the Li:Na ratio for the corresponding composition was 0·98(4):1. A section through the quaternary phase diagram was therefore taken with these metal ratios held constant but with the F:PO_3 ratio varied. The results are shown in Fig. 1, together with liquidus data for the corresponding section in the Na, K/PO_3, F system for comparison.

*Electrochemical Society Active Member.

Liquidus temperatures were determined by a visual method, with the samples contained in vitreous carbon crucibles in argon at atmospheric pressure. The chemicals were of reagent grade and were subjected to a preliminary dehydration at 300°C in vacuo for several hours. This procedure may not remove all traces of moisture and the results may be subject to a small error due to residual moisture.

Since the lower melting point materials formed glasses on solidification, it was difficult to obtain precise measurements and the ultimate test of the state of the material was the observed response of the surface to a force applied via a graphite rod of spectrographic purity. Cycling the sample through the melting temperature was used in attempts to obtain an accurate determination.

Even with this precaution, the data are reliable only to ±10°C. Supercooling was not large compared with this estimated error except in the case of the fluoride-free composition in the Na, K/PO_3, F system, for which a supercooling of 140°C was observed. A separate calibration experiment was performed and temperatures quoted are taken from the mean of two chromel/alumel thermocouples with junctions located in the region previously occupied by the crucibles containing the samples.

The Li, Na/PO_3, F system is seen to give the lowest melting temperatures, the minimum occurring at about 300°C for a composition with 20 m/o fluoride. Both the Li, Na and Li, K systems do not indicate a sharply-defined minimum but the Na, K system (1) appears to exhibit eutectic-like behavior, although the data plotted in Fig. 1 is based on intersections with rather widely-spaced isotherms.

The value of 300°C for the lowest-melting composition compares very favorably with alternative systems. The lowest melting point occurs at 580°C in the system Li, Na/P_2O_7,F(2) and at 612°C in the system Na, K/P_2O_7, F (2).

However, if greater complexity can be tolerated, it should be noted that the system Li, K/PO_3, PO_4 has a minimum melting point at 340°C (3) and fluoride addition may result in compositions which melt below 300°C.

Auger Electron Spectroscopy Analysis of Thermal Oxide Layers of Silicon Carbide

Akira Suzuki,* Hiroyuki Matsunami, and Tetsuro Tanaka

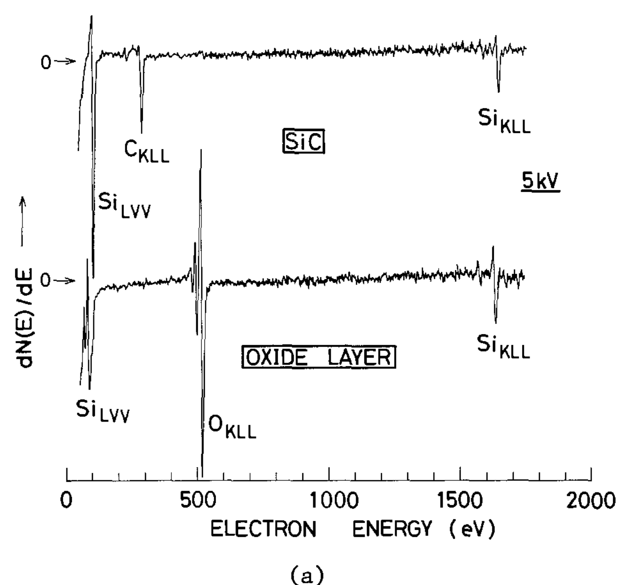
Department of Electronics, Faculty of Engineering, Kyoto University, Kyoto, 606 Japan

Silicon carbide (SiC) is a promising semiconductor material for various electronic devices because of its wide energy gap (1). SiC can be thermally oxidized in the same way as used for silicon (1, 2). The oxide layer is utilized as a protecting film for the SiC surface during the device fabrication (1, 3). However, the oxidation mechanism and the properties of the oxide layer have not been studied in detail. In this communication, some results of an Auger electron spectroscopy analysis of the thermal oxide layers will be described.

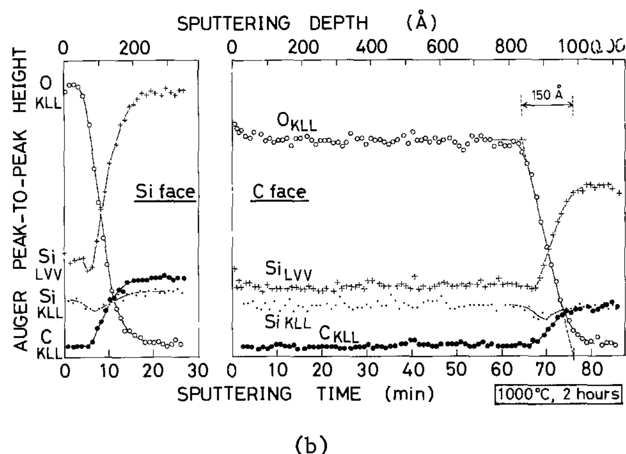
SiC crystals used for the thermal oxidation were 6H-type single crystals prepared by the Lely method. Each crystal was plate-shaped with wide (0001) faces. A typical size was 4x 4x0.5 mm^3. After polishing both the (0001) Si face and the $(000\bar{1})$ C face of each crystal with diamond paste, we set the crystals in a horizontal furnace with the (0001) faces vertical. Thermal oxidation was carried out at 1000°C for 2 hours in an oxygen flow of 100 cm^3/min. The oxygen flow was passed through pure water to saturate it with water vapor (at room temperature).

The oxide thicknesses determined by ellipsometry were 152 Å on the Si face and 908 Å on the C face. A (111) wafer of silicon was also oxidized at the same time for comparison. The oxide thickness on the Si wafer was 1949 Å. The refractive indices of the oxides on the C face of SiC and on the Si wafer were much the same: 1.45-1.46 by ellipsometry.

We carried out an Auger analysis of these oxide layers. Fig. 1(a) shows Auger electron spectra. The upper spectrum is from the SiC crystal, and the lower from its oxide layer on the C face. The accelerating voltage for the primary electron beam was 5 kV, and the beam current was 0.1 µA. The beam was made to scan the sample surface to remove an electron-irradiation effect. The scanned area was 50x 50 μm^2. SiC has three Auger peaks: Si_{LVV},



(a)



(b)

Fig. 1. (a) Auger spectra of SiC and the oxide layer (on the C face). (b) Depth-profiles of the oxide layers on the Si face and on the C face of SiC.

Si_{KLL}, and C_{KLL}. The oxide layer also has two Si peaks, but the spectral form of Si_{LVV} is different from that of SiC, and the Si_{KLL} peak is located at about 9 eV lower energy than that of SiC. It should be noted that the oxide layer does not contain C atoms. The same spectra were obtained from the layers on the Si face of SiC and on the Si wafer. Therefore, these three oxide layers are concluded to be the same (SiO_2 by the reference (4)).

Fig. 1(b) shows depth-profiles of the oxide layers on the Si face and on the C face of SiC. The sputtering was done using an argon ion beam accelerated by 3 kV. The sputtering rate was about 15 Å/min. The vertical values are peak-to-peak heights of the Auger spectra. In the profile for the C face, O_{KLL}, Si_{LVV}, and Si_{KLL} are almost constant throughout the oxide layer. Since the output level of C_{KLL} in the oxide layer is the noise level of our detection system, the C_{KLL} output is zero in the oxide layer. In the interface region between the oxide layer and SiC, O_{KLL} decreases and C_{KLL} increases monotonically. Si_{KLL} shows a dip in the interface region. The interface width on the C face is 150 Å, which was determined by extrapolating the linear change of the O_{KLL} profile to the maximum value and the zero value as shown in Fig. 1(b). The oxide layer on the Si face is much thinner than that on the C face. But the depth-profile in the interface is very similar. The interface width on the Si face is 167 Å. The oxide layer on the Si wafer also showed a similar depth-profile with an interface width of 145 Å.

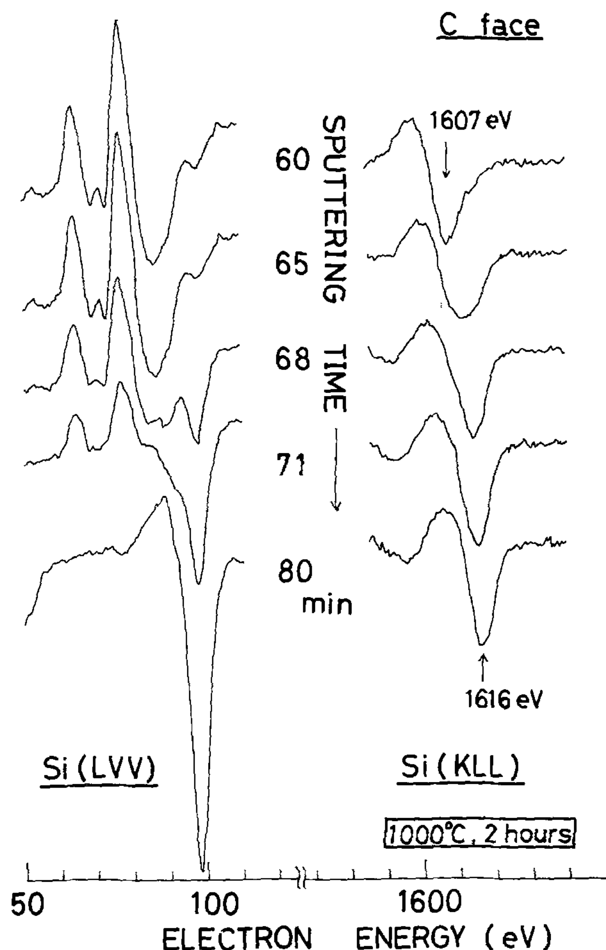

Fig. 2. Spectral change of the Si_{LVV} and the Si_{KLL} Auger peaks in the interface region between the oxide layer and SiC.

Fig. 2 shows the change of the Si_{LVV} and the Si_{KLL} peaks in the interface. The Si_{LVV} peaks change gradually from the oxide to SiC. In the Si_{KLL} peaks, the 1607 eV peak of the oxide decreases with sputtering times, and the 1616 eV peak of SiC appears and increases. At the sputtering time of 65 min, the Si_{KLL} peak is rather broad and the peak-to-peak height is small, owing to the overlapping of the two peaks. This appeared as a dip in the depth-profile in Fig. 1(b).

In conclusion, from the present Auger analysis, the thermal oxide layers of SiC were found to be the same as those grown on silicon.

Properties of Trifluoromethanesulfonic Acid Monohydrate Pertinent to Its Use as a Fuel Cell Electrolyte

T. Sarada, R. D. Granata,* and R. T. Foley*
Department of Chemistry, The American University, Washington, D.C. 20016

ABSTRACT

The electrical conductivities of monohydrate-water mixtures were compared with those of sulfuric acid and phosphoric acid. All three systems show a maximum in the conductivity-composition curve with that of the monohydrate-water system falling at 40-45% of the monohydrate. Trifluoromethanesulfonic acid wets Teflon but water-monohydrate mixtures containing less than 60% of the monohydrate exhibit high contact angles with Teflon. The vapor pressure of the monohydrate was measured by an isopiestic method. A solution of 99.99% of the monohydrate is isopiestic with a solution of 96.83% H_3PO_4. Potential materials of construction for use in trifluoromethanesulfonic acid monohydrate and its water solutions were investigated. Corrosion tests, both stationary and under potential, showed that alloys such as ingot iron, chrome steel. Incoloy 825, tantalum-coated steel, and niobium offer considerable resistance to corrosion in the electrolyte. Certain composites such as pyrolytic graphite, silicon carbide, and boron carbide are chemically stable in the electrolyte.

Electrochemical experiments wherein trifluoromethanesulfonic acid monohydrate (TFMSA-MH) was employed as a fuel cell electrolyte showed that this compound offered several advantages over phosphoric acid which is commonly used as the electrolyte in the acid fuel cell. The rate of electrooxidation of hydrogen and propane was enhanced by an order of magnitude (1, 2) and the electroreduction of oxygen proceeded at a potential about 150 mV higher than that in phosphoric acid.

But the employment of an electrolyte in a practical fuel cell requires other characteristics. To maintain low ohmic losses the electrolyte should possess an electrical conductivity similar to that of sulfuric or phosphoric acid. In current fuel cell practice Teflon-bonded electrodes are employed, the Teflon, among its other properties, serves to waterproof the electrode. Thus an electrolyte that wets Teflon would require changes in the composition of the fuel cell electrode. For operation in the temperature range of 100°-150°C the electrolyte should have a reasonable vapor pressure, again comparable to concentrated phosphoric acid solutions. Finally, the electrolyte should be noncorrosive to conventional materials of construction in the static sense and also when tested under applied voltages to which the fuel cell anode and cathode would be subjected.

These are the problems considered in the present investigation, the over-all objective being the evaluation of trifluoromethanesulfonic acid monohydrate as a fuel cell electrolyte.

* Electrochemical Society Active Member.

Key words: trifluoromethanesulfonic acid monohydrate, fuel cell, acid fuel cell, electrolyte.

Experimental and Results

The electrolyte.—Trifluoromethanesulfonic acid monohydrate was prepared from trifluoromethanesulfonic acid (3M Corporation, fluorochemical acid FC-24) and water by the method of Gramstad and Haszeldine (3). This involved refluxing equimolar quantities of the acid and water and fractionally distilling. The monohydrate distills over at 217°-218°C (756.9 mm Hg). The white needlelike crystalline product melts at 33.8°C in agreement with the literature (3).

Conductivity measurements.—Conductivity measurements were made on the freshly distilled monohydrate and its aqueous solutions using a Type RC-16B2 conductivity bridge made by Industrial Instruments of New Jersey. Constant temperatures of 40° and 80°C (±0.5°) were maintained during this work with a thermostated water bath (Forma Scientific, Model 2095-2). The cell constants for the conductivity cell at the two temperatures were determined using a centinormal solution of potassium choride.

The specific conductances of water solutions of trifluoromethanesulfonic acid monohydrate at 40°C are plotted in Fig. 1. Also plotted, for comparison, are the conductances of sulfuric acid-water solutions and phosphoric acid-water solutions, sulfuric acid being a widely accepted electrolyte for battery systems and phosphoric acid being considered the most suitable electrolyte for acid fuel cells. The values for sulfuric acid were computed to 40°C from data given in Landolt and Börnstein (4) and for 80°C computed graphically from the data of Haase *et al.* (5). The values for phosphoric acid were obtained from a Monsanto publication (6). The conductivities of several solutions of

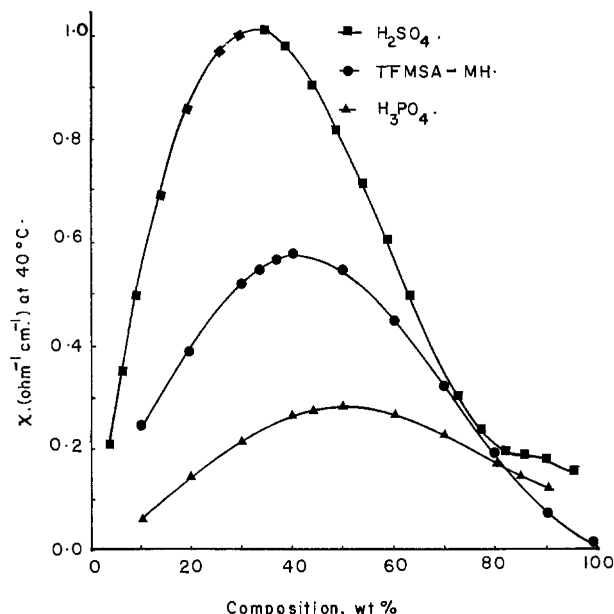

Fig. 1. Conductivities of acid-water solutions at 40°C. —■— H_2SO_4, —●— TFMSA-MH, —▲— H_3PO_4. Sulfuric acid data from Ref. (4), phosphoric from Ref. (6).

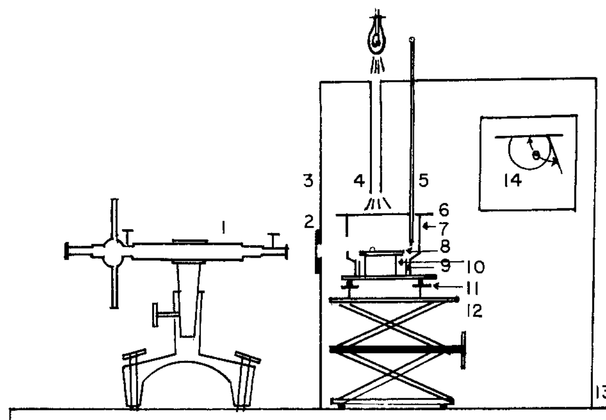

Fig. 2. Experimental setup for the measurement of contact angles. 1, Goniometer telescope; 2, fused silica window; 3, thermostated chamber; 4, light tube; 5, thermometer; 6, glass plate; 7, Teflon shield; 8, test specimen; 9, petri dish; 10, glass platform; 11, leveling table; 12, adjustable support; 13, marble slab; 14, view of the drop profile as observed in the goniometer telescope.

phosphoric acid were checked at random and were found to agree with the literature values. The three systems are all characterized by a composition of maximum conductivity. In the monohydrate system at 40°C the maximum (0.575 Ω^{-1} cm^{-1}) falls at 41% by weight (of the monohydrate) and 30% by volume; at 80°C the maximum (0.8109 Ω^{-1} cm^{-1}) falls in the range of 40-45% by weight.

Contact angle and wetting.—It is common practice in many fuel cell designs to use Teflon-bonded catalytic electrodes to prevent "flooding" of the electrode by the electrolyte. The Teflon serves to maintain a nonwetted surface and makes it possible for the electrode to furnish a solid-liquid-gas interface for the site of the electrocatalytic reaction. In one of the first attempts (7) to build a complete fuel cell with the trifluoromethanesulfonic acid monohydrate electrolyte it it was observed that the electrolyte wet Teflon, rendering that particular electrode essentially inoperative. Thus, the critical problem regarding the tendency of Teflon to be wetted by the compound arose. The wetting problem is here examined quantitatively, not only with respect to the monohydrate, but also with respect to water solutions of the monohydrate in order to establish the extent of dilution of the monohydrate required to achieve a nonwetting surface. The extent of wetting is measured by the contact angle which the liquid makes with the solid. The contact angle of a drop of liquid is defined as the angle which the tangent to the drop makes with the horizontal surface of the substrate at the point where the liquid, the substrate, and the vapor meet. The angle is measured through the drop as shown in the insert in Fig. 2. The basic mechanism of wetting involves more than the contact angle, but the latter gives a valuable inverse measurement of the wetting or spreading property of a liquid on a surface. For contact angles greater than 90°, the liquid is said not to wet the solid and in such a case the drops of liquid do not enter the capillary pores of the solid. At the same time, a liquid is considered to wet the solid only when the contact angle is 0. This is a limiting extreme only in a geometric sense.

Method.—A goniometer telescope was used in making contact angle measurements of the test solutions on Teflon. This instrument gives an inverted, enlarged, high contrast image of the drop profile. The contact angle measurements were made in the vapor of the test solutions. This method solved the problem of choosing between the various types of values used in the literature, *i.e.*, the advancing angle, the receding angle, or the equilibrium angle.

In contact angle measurements, special care is needed in getting a smooth, clean surface of the solid sample. A nonsmooth surface increases spreading and, so, will alter the angle.

The method of Fox and Zisman (8) which involves the application of heat and pressure to the Teflon sample was used to ensure a smooth surface.

Aqueous solutions of trifluoromethanesulfonic acid or monohydrate were made by transferring calculated volumes of the acid or monohydrate from a burette into calculated volumes of deionized water kept in ice-cooled volumetric flasks.

An atmosphere of the vapor of the test solution was insured by the following procedure. A Pyrex petri dish, 5 cm diam, was half filled with the test solution. This was surrounded by a cylindrical Teflon shield which had an open window, 1.25 cm high and 0.64 cm wide. The size of the window allowed two or three drops to be viewed by the telescope without disturbing the specimen. The solid specimen was placed in the dish on top of an optically flat platform of glass so that the top surface would not be flooded by the liquid. The drops were placed on the Teflon surface by the tip of a freshly flamed platinum wire used along with a disposable glass pipette. The average diameter of a drop was about 1 mm. The top of the shield was closed by a glass plate to permit illumination of the drops from above. The setup was mounted on a circular leveling table which, in turn, was placed on a laboratory jack. The assembly was placed inside a thermally regulated chamber. Outside lighting, by a tungsten filament lamp, was guided to the specimen by means of a Pyrex glass tube. A fused silica window on the side panel of the chamber permitted viewing of the drops by the goniometer telescope kept outside the chamber. A thermometer was used to record the temperature. Both the chamber and the telescope were placed on a heavy marble slab to eliminate vibration. Figure 2 shows a diagrammatic sketch of the experimental setup.

Stringent conditions of temperature control are not necessary for these measurements as the temperature coeffiicent of contact angle is very small. Therefore, room temperature measurements were made without thermostated equipment. For higher temperature studies a temperature control was used which had a limit of accuracy of ± 1°C.

For each sessile drop, two values of the angle were taken on either side of the drop. For each sample three

or four drops were studied and the six or eight values were averaged. The maximum deviation from the average was about ±2°, which is the acknowledged limit of accuracy for these measurements.

Results of contact angle measurements.—The results of the contact angle measurements for trifluoromethanesulfonic acid-water mixtures are plotted in Fig. 3. Similar measurements for monohydrate-water mixtures are plotted in Fig. 4. In a comparative sense the acid wets Teflon more readily than the monohydrate, *i.e.*, the contact angle is below 30° as against 73° at room temperature. Acid-water mixtures below acid concentration of 55% weight and monohydrate-water mixtures of 60 weight percent (w/o) or less of the monohydrate can be considered as nonwetting (contact angles greater than 90°). It is interesting to note that a 90% acid mixture presents a contact angle of 56° when freshly made which increases to 72° when the solution is aged. The latter value approaches that of 100% monohydrate which is 73°, the composition of the monohydrate is 89.3% acid. As the solutions become more dilute the contact angles of both the solutions increase with the single exception of 70% monohydrate which exhibits an angle of 80°, lower than the

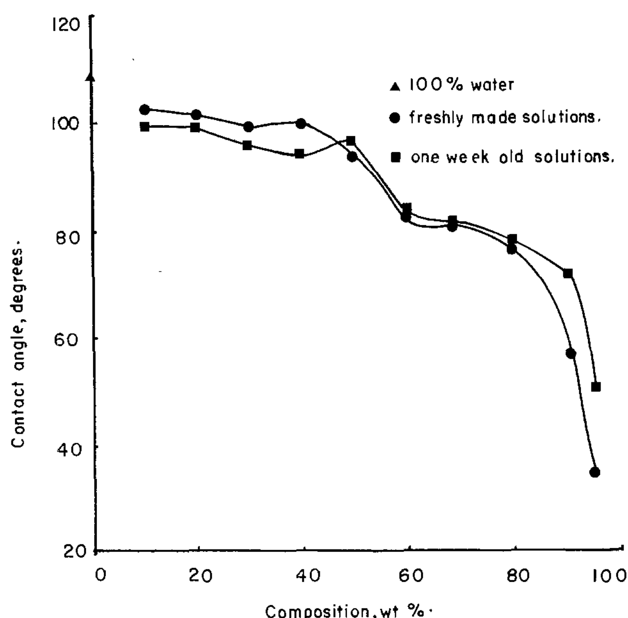

Fig. 3. Contact angles on Teflon of trifluoromethanesulfonic acid-water solutions. ● Freshly made solutions, ■ one-week old solutions.

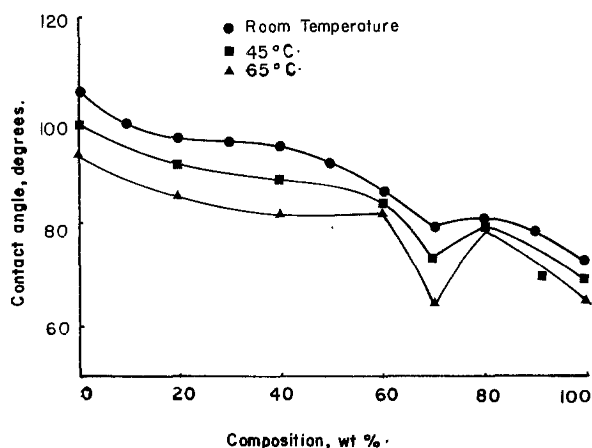

Fig. 4. Contact angles on Teflon of trifluoromethanesulfonic acid monohydrate solutions. ● Room temperature (*ca.* 24°C), ■ 45°C, ▲ 65°C.

values for both 80 and 60% solutions, which are 82° and 87°, all measured at room temperature.

The temperature dependence of monohydrate-water mixtures is very little, as one would anticipate, and mixtures of different compositions show slightly different slopes, again the 70% solution has a sharper decline in the angle when the temperature increases.

Vapor pressure measurements.—Method.—The isopiestic method (9) of measuring the vapor pressure of strong electrolytes was selected for gathering the vapor pressure data of monohydrate solutions. This method employs a comparative technique based on the principle that two solutions of nonvolatile solutes will distill, one to the other, until their concentrations are such that the solutions have equal vapor pressure. At the temperatures chosen for study, monohydrate solutions lose only water as does the "reference" electrolyte, phosphoric acid. Well-documented values are available for the water activities of phosphoric acid solutions of various concentrations over a wide range of temperature (10, 11). Preliminary experiments with known solutions of sodium chloride or ammonium chloride, using sulfuric acid solution as the standard, were made to check the method. The principle of the method is based on the comparison of the vapor pressure of two solutions. Two solutions, A and B, at the same temperature initially, are kept inside a closed system. The solution which has a greater vapor pressure, say solution A, loses water, which condenses on B, resulting in a cooling of A and a heating of B from the heat of vaporization generated. This temperature change will also produce a change in the vapor pressures of the solutions besides the concentration changes, but, if perfect thermal contact is established between the two solutions the distillation of solvent will continue and equalization of vapor pressure will still take place, only in this case, the equalization will be the result of concentration change alone and not temperature difference. Equilibrium will occur, therefore, when this concentration difference is sufficient to equalize the vapor pressures. In the actual experimental measurements, therefore, thermal conductivity between the test solution and the reference solution is of primary importance. A system closed to the outside atmosphere is essential. The equilibration process can take anywhere between one day to one week. The concentration changes are easily determined by the change in the weights of the solutions before and after equilibration. Two sets of solutions are used at a time in a thermostated closed chamber with adequate thermal contact between the solutions. Four Pyrex bottles, two of them containing a small known amount of phosphoric acid of known concentration and two of them containing the test solutions of known concentration are used in each experiment. The bottles fit snugly inside aluminum cylinders which are placed inside an aluminum chamber. The chamber is fitted with a Teflon gasket to keep it airtight. It carries a device by which the individual bottles can be opened or closed without opening the chamber. A schematic of the setup is shown in Fig. 5. This setup is placed inside a thermostated vacuum oven (with temperature control ± 0.5°C) with an airtight door and left undisturbed over a period of one day to several days. The weight change in each case is determined after the bottles are desiccator cooled. From the plots of known vapor pressures of water above phosphoric acid of known concentrations and temperatures, the values for the unknown are read out.

Three concentrations of phosphoric acid, 96.83, 95.3, and 90.87 w/o solutions were found to be isopiestic with TFMSA-MH, 99.99, 93.38, and 92.59%, respectively. The vapor pressure of phosphoric acid of the said concentrations should therefore give the total vapor pressure of the monohydrate solutions of these concentrations. Log P plots of these against 1000/$T°K^{-1}$ are shown in Fig. 6. The plot of 96.83% H_3PO_4,

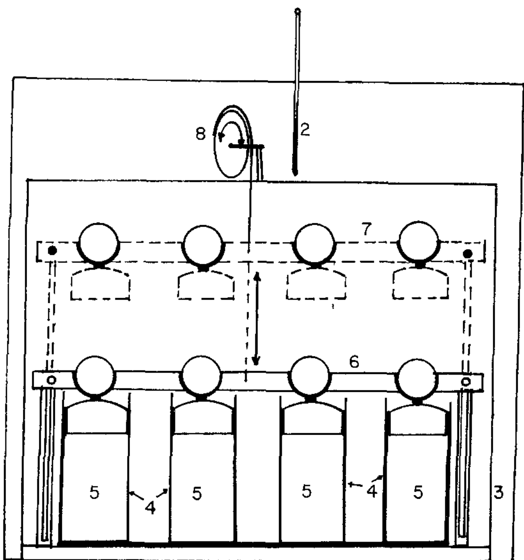

Fig. 5. A schematic of the isopiestic vapor pressure cell. 1, Thermostated oven; 2, thermometer; 3, aluminum chamber; 4, aluminum cylinders; 5, Pyrex bottles; 6, lids, closed position; 7, lids, open position; 8, pulley for raising and lowering the lids arm.

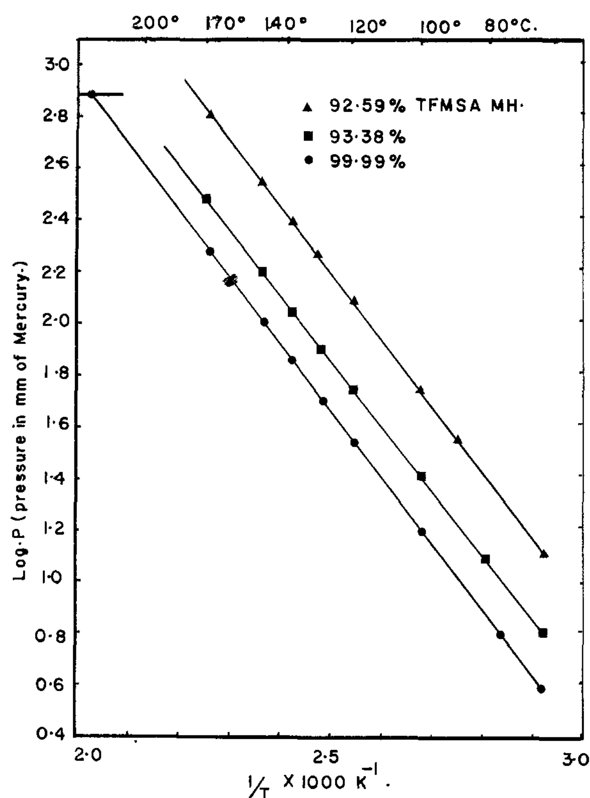

Fig. 6. Vapor pressure of trifluoromethanesulfonic acid monohydrate as a function of temperature.

isopiestic with 99.99% MH on extrapolation to 760 mm gives a temperature value of 219.6°C. The experimental boiling point of the monohydrate is 218°-219°C. The vapor pressures given by this plot can, therefore, be taken as a fair estimate of the vapor pressure of 99.99% MH. Calculation of $\Delta \overline{S}$ vapor (12) from these plots gives a Trouton constant of 23.93 cal $°K^{-1}$ $mole^{-1}$. For water the constant is 26.049, for sulfuric acid it is 20.00, and for methanol 25.00 in the same unit. The calculated value for trifluoromethanesulfonic acid monohydrate from this point is, therefore, in the range expected.

Static corrosion tests.—The objective here was to collect quantitative data on the corrosion of a number of materials, both metallic and nonmetallic, that could potentially serve as construction materials for the fuel cell container, electrodes, or matrices. Some preliminary observations had been made that suggested the monohydrate was less corrosive to the conventional alloys, such as stainless steel Type 304, than phosphoric acid. However, there was virtually no data available in the literature that would relate to elevated temperature (100°C and above) behavior. Thus, measurements were made on a number of metals and alloys that were suggested from their known corrosion behavior in other environments.

Method.—The extent of corrosion suffered by a given sample on total immersion in liquid was determined as the loss in weight. Two temperatures, 100° and 125°C, were chosen and the period of immersion varied from one to eight weeks. Three samples were usually used for each measurement. Weighed and pretreated samples were totally immersed in approximately 20 ml aliquots of the freshly distilled monohydrate or 85% phosphoric acid (Fisher A.C.S. Certified) for a given period of time and left undisturbed. The samples were held in Pyrex test tubes loosely closed with Teflon stoppers. The test tubes were held in a stainless steel rack and maintained at a constant temperature over the period of study.

Materials and Treatment.—The compositions of the metals and alloys used in the tests are given in Table I. Certain composite materials tested as possible matrix materials are listed in Table II. The sample preparation and evaluation followed standard procedures.

Results and discussion.—A preliminary test which measured the corrosion of five metals was run for a two week duration at 100°C. Copper and lead corroded

Table I. Composition of alloys used in corrosion tests

Alloy	Nominal composition (w/o)
Aluminum	99.994
Silver	99.9
Copper	Ficher C · 428 (purified)
Lead	99.9
Platinum	99.99
Titanium (electrolyte)	99.99
Porous nickel	Ni electrode (Union Carbide)
Ingot Iron HP	99.80 Fe, 0.13 Cu, 0.04 Ni, 0.01 Mo, 0.01 Si
Niobium	99.9
AISI Type 304	18.0-20 Cr; 8.0-11.0 Ni; 0.30 C, max; 2.0 Mn, max; 1.00 Si, max; 0.045 P, max; 0.03 S, max; balance Fe
Incoloy 825	42 Ni, 21 Cr, 3.0 Mo, 33 Fe
Hastelloy C	56 Ni, 15 Cr, 3.7 N, 16 Mo, balance Fe
Carpenter 20 Cb-3	34.03 Ni, 19.91 Cr, 2.25 Mo, 3.30 Cu, 0.21 Co, 0.86 Cb, 0.039 C, 0.39 Mn, 0.41 Si, 0.016 P, balance Fe
26-1 Steel E-Brite	26 Cr, 1 Mo, 73 Fe
Titanium (65·A)	C, 0.08, max; N, 0.05, max; H, 0.015, max; Fe, 0.25, max
Tantalum coated steel	Steel plated with tantalum by the "Metalating" process by the General Metals Technologies Corp. Thickness, 0.006-0.008 in.
Chrome steel 430	82.3 Fe, 16.4 Cr, 0.52 Si, 0.40 Mn, 0.26 Ni, 0.058 C, 0.004 S

Table II. Composite materials tested as matrix materials

1. Pyro-Tech, PT 101 (Ultra Carbon Corp.) pyrolytic graphite plated onto graphite, density of coating, 2.2 g cm^{-3}.
2. Pyro-Tech, PT 333 (Ultra Carbon Corp.) graphite treated to produce a silicon carbide coating 0.5 mm thick.
3. Pyro-Bond, 1300 (Ultra Carbon Corp.) graphite coated with silicon carbide by a conversion process.
3. Pyro-Bond, 1300 F (Ultra Carbon Corp.) graphite with surface converted to silicon carbide with a low temperature process; more graphite than 1300.
5. Reaction bonded silicon nitride, NC 350 (Norton Co.) density *ca.* 2.5 g cm^{-3}.
6. Boron carbide (Norton Co.) "Norbide" *ca.* 99% pure, density 2.51 g cm^{-3}, hot pressed, grain size 10-20 μ.
7. Recrystallized silicon carbide (Norton Co.) "Crystar" 99% silicon carbide, density 2.65 g cm^{-3}.

excessively and were dropped from subsequent tests. Iron, stainless steel, and silver offered substantial corrosion resistance and were included in a second series of tests at 125°C extending over five weeks. This series disclosed the outstanding resistance to corrosion afforded by ingot iron, being more resistant than stainless steel. Silver corroded excessively.

A third series of tests included a number of alloys usually ranked as corrosion resistant materials. These are reported in Fig. 7. Niobium- and tantalum-coated steel are remarkably resistant. While both electrolytic titanium and hardened titanium 65A were seriously corroded, ingot iron seemed to develop a passive layer and was consistently resistant to the action of the monohydrate, even in the eight-week study. Aluminum behaved very much like stainless steel Type 304, *i.e.*, it seemed to have both active and passive forms. Some of the more resistant alloys were tested over an eight-week period (Fig. 8). Usually samples of Type 304 stainless steel were included in the tests as a comparative material. This alloy has been studied in previous investigations and a reasonable amount of data are available on the performance of this alloy in phosphoric acid electrolytes. Porous nickel which has been used as a material of construction for gas diffusion electrodes, shows a high degree of resistance. E-brite 26-1, a martensitic steel, is more resistant than the 300 series alloys.

Comparative tests were conducted in 85% phosphoric acid at 125°C for one week. These data are presented as bar graphs in Fig. 9. At the end of one week the corrosion was so extensive that the test was not continued beyond that time.

The refractory materials, silicon carbide, boron carbide, and pyrolytic graphite, showed essentially no weight losses during a five-week exposure. Instead, the porous materials absorbed electrolyte so that in most cases there was actually a gain in weight during the test. The phosphazene polymeric materials, on the other hand, dissolved completely in 24 hr. The quantitative data for the refractory materials are given in Table III. It is possible that prolonged treatment would remove any absorbed solution but it can be stated that there was no deterioration of the material during the five-week exposure at 125°C.

Voltage sweep experiments.—Whereas the static corrosion tests reported above allow the assessment of

each metal or alloy with respect to its resistance to attack by the electrolyte when used as a general material of construction, it is also important to know the behavior of these materials when used as electrode substrates which would see oxidizing and reducing potentials. To evaluate the behavior of the alloys under potential, a voltage sweep technique was used.

Method.—The cell used for the experiments was a three-compartment cell, with an approximate electrolyte requirement of 65 ml. The working electrode in the central compartment of the cell was either a platinum wire sealed into 6.4 mm glass tubing or a metal wire press fitted into a 6.4 mm diam Teflon rod, either

Table III. Corrosion data for some composite materials and chrome steel Type 430 in TFMSA-MH at 125°C for 5 weeks

Material	Change in weight (mg cm^{-2}) (average 3 samples)
Chrome steel (Type 430)	−23.1

Pyro-Tech, PT 333	+0.89
Pyro-Bond, 1300	+5.72
Pyro-Bond 1300 F	+5.17
Reaction bonded silicon nitride	+21.5
Boron carbide	−0.61
Recrystallized silicon carbide	−1.33

of which was connected into the cell by means of a Swagelok fitting made of Teflon. The counterelectrode compartment was separated from the working electrode compartment by a fritted glass disk. The counterelectrode was a platinum mesh cylinder, spot welded to a platinum wire. The reference electrode system was separated from the working electrode compartment by sealing a fritted glass disk behind the Luggin capillary. The reference electrode was of the dynamic hydrogen electrode design of Giner (13). Temperature control was achieved by maintaining the cell in a thermostated air oven. The electrolyte for the cell was pure trifluoromethanesulfonic acid monohydrate.

The working and reference electrode compartments were purged with argon for at least 1 hr prior to beginning a cyclic voltammogram. To ensure complete removal of oxygen, the argon was passed through a stainless steel pipe heated to 400°C containing shredded copper foil. Purging of the cell with oxygen-free argon was continued throughout the experiment except where otherwise noted. Electrode potentials were measured with a Keithley Instruments Model 621 electrometer. Potentiostatic and chart recording apparatus were combined in the Beckman Electroscan 30 electroanalytical system.

Cyclic voltammograms were recorded in the following manner: The cell was allowed sufficient time to achieve thermal equilibrium, to be purged of dissolved oxygen by argon bubbling, and for the working electrode to reach a constant rest potential. The rest potential was recorded (Table IV). The polarization was usually started from approximately rest potential and proceeded initially in the anodic direction. The current measuring range was chosen to be approximately 70-200 $\mu A/cm^2$ in both the anodic and cathodic directions. The working electrode surface areas were on the order of 0.5 cm^2. For the first cyclic voltammograms of a sample, the current scale was chosen so that the low current density behavior could be observed before any gross changes in the surface occurred due to dissolution or film growth. The voltammetric scan was continued in the anodic direction until the current had sufficiently increased anodically (up to 1.5-2.0V). The scan direction was reversed (a manual operation) and the scan continued to at least 0.0V, at which point the scan direction was again reversed. Scan direction reversal was continued in this manner until three consecutive cycles were completed within the same voltage or current limits. The scan rates were between 5×10^{-3} and 5×10^{-2} V/sec, the latter rate being used for rapid initial evaluation of a sample's cyclic voltammetric behavior to avoid excessive sample dissolution due to long electrolysis times. The experiments were run at a temperature of about 120°C which approximates the operating temperature range of a fuel cell in this electrolyte.

Table IV. Rest potentials of various electrodes in trifluoromethanesulfonic acid monohydrate

Sample	Potential (mV, DHE)	Temperature (°C)
Platinum	280	115
Niobium	280	117
Chrome Steel 26-1	270	119
Chrome Steel 430	250	119
Incoloy 825	230	118
Hastelloy C	0	118
Carpenter 20	−40	117
Silver	−70	119
Copper	−120	119
Stainless Steel 304 L	−130	112
Nichrome	−140	119
Ingot iron	−280	119
Aluminum	−460	119
Titanium	−570	119
Lead	−640	119

Figure 10 shows the cyclic voltammogram for platinum at 115°C. The scan is started at about 0 mV, swept anodically to 1500 mV, then cathodically from 1500 to 0 mV. During the anodic scan, platinum exhibits two anodic current peaks, one at 700 mV, the other at 1050 mV. These peaks are due to oxidation of the platinum metal surface to platinum oxide. On the cathodic scan, a single peak is observed at about 750 mV which corresponds to reduction of the platinum oxide. This behavior is in close agreement with the aqueous solution investigations of Kolthoff and Tanaka (14), the references cited therein, and Gilman (15).

Stainless steel Type 304, at 112°C, gives the cyclic voltammogram shown in Fig. 11. The anodic scan shows a somewhat constant anodic current from 0 to 1000 mV after which the current increases rapidly with increasing anodic potential. The current decreases rapidly to nearly zero on the cathodic scan, remaining near zero until 150 mV where the current increases up to commencement of hydrogen reduc-

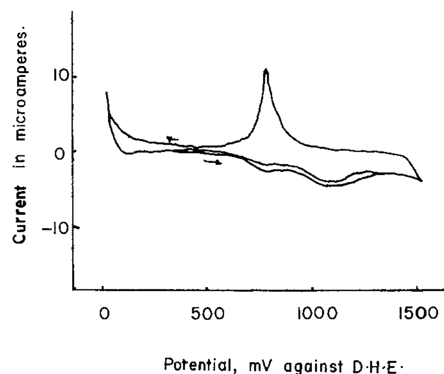

Fig. 10. Cyclic voltammetry of platinum in trifluoromethanesulfonic acid monohydrate. Temperature, 115°C; sweep rate, 25 mV/sec; equilibrium potential, −280 mV; surface area, 0.124 cm^2.

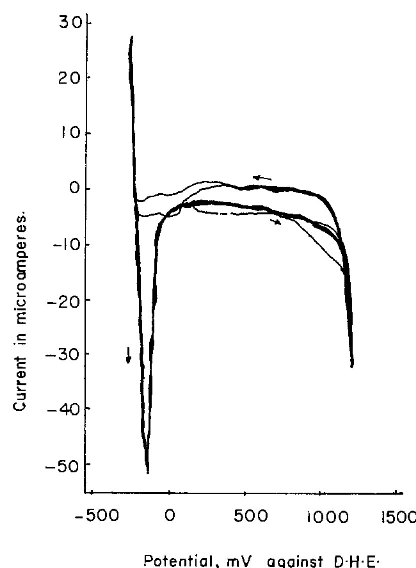

Fig. 11. Cyclic voltammogram of stainless steel 304 in trifluoromethanesulfonic acid monohydrate. Temperature, 112°C; sweep rate, 5 mV/sec, equilibrium potential, −130 mV; surface area, 0.106 cm^2.

tion. On the following anodic scan, a large anodic current is observed at −150 mV and is probably due to desorption of hydrogen or activation of the surface by the hydrogen previously evolved. The anodic current plateau between 0.0 and 1000 mV is low and may be interpreted as residual current and a low sample dissolution rate. Sample dissolution is much more rapid at higher potentials. On the cathodic scan, the current decreases to nearly zero and, considering the later increase in current at 150 mV, these currents may correspond to a passivated state and a loss of the passivated state, respectively. There are no trends pertaining to consecutive scans in these cyclic voltammograms.

The cyclic voltammogram of niobium at 118°C is shown in Fig. 12. The first anodic scan starts at 330 mV. The anodic current increases to a small steady value until a potential of about 1000 mV is reached and the current begins to gradually increase again. The scan is reversed at 2000 mV and the current decreases to zero at 600 mV, where a cathodic current gradually increases up to 0.0 mV. At 0.0 mV, the scan is changed to anodic and the current decreases. The cycle is repeated twice except that the maximum anodic current is reduced on each successive scan. The anodic currents are interpreted as due to surface oxidation of the niobium plus oxidation of the electrolyte, while the cathodic currents are probably due to the reduction of the surface oxides. The trend of decreasing anodic current suggests the buildup of a passivating film. The magnitude of the cathodic currents indicates that there is an adherent reducible film on the electrode.

At the other extreme of reactivity we have one of the very active metals. In Fig. 13 is presented a scan of electrolytic titanium. This again is a fast scan, 50 mV/sec at 119°C. As the potential is increased anodically the current increases rapidly from the beginning with subsequent scans showing a decreased anodic current at the same potentials. The unusual feature seen is the absence of appreciable cathodic currents up to −500 mV. Another feature observed was that the rest potential after the experiment was 50 mV more cathodic than the value before the polarization. This could represent a change in the surface toward a more active species than the start.

The current densities for fourteen materials tested under potential in TFMSA-MH are plotted for specific potentials in Fig. 14. The data were taken from the voltage sweep plot, usually with a rate of 50 mV/sec. The apparent geometric areas were used for the calculation of current densities. The plots of log current density *vs.* potential for each of the materials summarize and compare the general behaviors of these materials under potential. Generally, combinations of high potential and low current density values indicate relative stability of the material at applied potentials in this electrolyte. Using the potential axis (ordinate) of the figure as a horizontal boundary, the

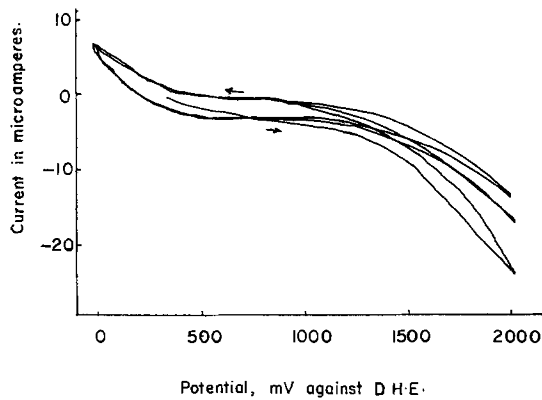

Fig. 12. Cyclic voltammogram of niobium in trifluoromethanesulfonic acid monohydrate. Temperature, 118°C; sweep rate, 50 mV/sec; equilibrium potential, 280 mV; surface area, 0.323 cm².

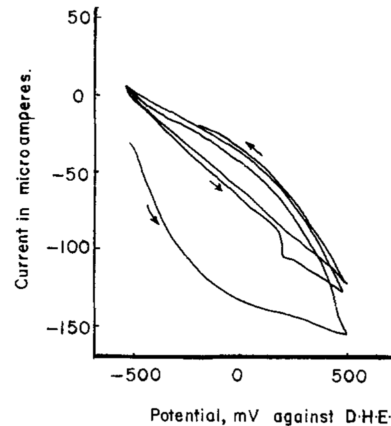

Fig. 13. Cyclic voltammogram of titanium in trifluoromethanesulfonic acid monohydrate. Temperature, 119°C; sweep rate, 50 mV/sec; equilibrium potential, −570 mV; surface area, 0.258 cm².

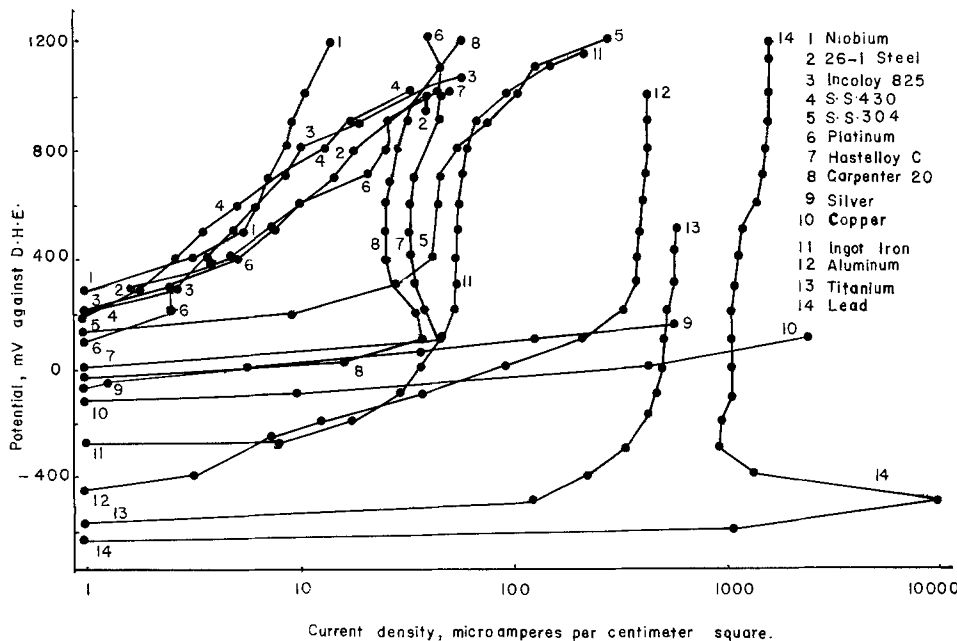

Fig. 14. Comparative plot of potentials vs. logarithm of current density for 14 alloys.

areas under these curves can be considered as figures of merit for these materials. Niobium has the smallest such area and can be considered the most stable material tested. Similarly niobium, chrome steel 430, Incoloy 825, chrome steel 26-1, and platinum are the five most stable materials tested.

Of these materials, Incoloy 825 shows the smallest reduction currents during cyclic voltammetry which shows that it has the highest anodic to cathodic current-time product (coulombs) ratio. This indicates that Incoloy 825 has the greatest net dissolution rate of these five materials under these conditions. Immersion test results given above show that Incoloy 825 has a corrosion rate 1.7 times greater than chrome steel 26-1 for an eight-week period at 125°C. For these reasons, Incoloy 825 should not be considered to be as stable as the other four materials in the group.

Immersion test results for chrome steel 430 show a corrosion rate much higher than Incoloy 825. Hence, this material should also not be considered as stable as niobium, platinum, or chrome steel 26-1. Note that the polarization curves for chrome steel 430, as well as Incoloy 825, were derived from a potential-current cycle after the initial cycle in which larger currents were observed. This had the effect of shifting their polarization curves toward more stable regions. While Incoloy 825 and chrome steel 430 would not be suitably stable at equilibrium, they should be relatively stable while anodically polarized. Hence, based on polarization tests and immersion tests, the most stable materials tested under potential are niobium, platinum, and chrome steel 26-1.

Conclusions

The corrosion investigation has disclosed a number of construction materials that would be resistant to corrosion in trifluoromethanesulfonic acid monohydrate. The corrosion rates of most materials are one or two orders of magnitude less than that in phosphoric acid. The exceptional resistance of ingot iron to attack is surprising but, in general, the nickel-containing alloys such as stainless steel Type 304 are not particularly resistant. Certain refractory materials, such as pyrolytic graphite, silicon carbide, and boron carbide, would be suitable for electrode or matrix applications assuming that they could be made available in the proper form. Several alloys show resistance to corrosion under oxidizing and reducing conditions as demonstrated by the voltage sweep technique.

Contact angle measurements confirm the qualitative observation that Teflon is wet by both the monohydrate and the acid. The wetting tendency is decreased in both cases by an increase in water content in the monohydrate or acid-water mixture. It is estimated that it is possible to retain about 60% of the monohydrate and still have a fairly high contact angle (nonwetting). The addition of water to the monohydrate definitely improves the electrical conductivity of the electrolyte following the pattern of the sulfuric acid and phosphoric acid systems. The maximum conductivity is at about 40-45% by weight of the acid, approximately the composition of the maximum conductivity in the phosphoric acid system, but the conductivity in the monohydrate system is appreciably higher.

Vapor pressure measurements indicate that the vapor pressure of the monohydrate is such as to make feasible the operation of a fuel cell in the 125°-150°C range. Dilution of the monohydrate with water increases the vapor pressure as expected.

The Use of a Microcalorimeter for Analysis of Load-Dependent Processes Occurring in a Primary Battery

D. F. Untereker*

Medtronic, Incorporated, Minneapolis, Minnesota 55418

ABSTRACT

Calorimetry has been proposed as a way of measuring self-discharge rates, particularly in very long-lived primary batteries. A simple model for interpreting calorimetric data from a discharging ideal battery system is developed in terms of the battery's load-voltage curve and limiting thermodynamic quantities. This treatment is extended to include real battery systems where self-discharge and other types of parasitic processes occur. These complications are discussed and the model is applied to the Li/I_2 and Zn/HgO battery systems which are both important to the cardiac pacemaker industry. Anticipated and measured energy losses due to self-discharge in these two systems appear to agree with the levels predicted via calorimetric data.

The determination of self-discharge processes is of considerable importance to both manufacturers and users of batteries. This is particularly true in the medical devices field where unique high energy density cells are being qualified for long-term human use. It is imperative that accurate assessments be made of all parasitic processes occurring in these batteries so that longevity and performance characteristics can be estimated. The classical methods for obtaining such data involve determining relative capacities before and after storage. The problem with such experiments for long-lived batteries is that the storage periods involved are excessively long and are subject to a variety of complex variables. Also, this experimental approach does not take into account any effect of load on the rate of self-discharge processes. It is, therefore, very desirable to obtain estimates of the rates of parasitic processes on a short-term basis rather than having to rely solely on experiments such as those described above. This, in fact, almost becomes a necessity when the expected battery life may be ten years or longer as in the case of many of the newer battery systems used to power implanted cardiac pacemakers (1-3).

One technique suggested to be sensitive enough to measure the rates of parasitic battery processes is calorimetry (4, 5). Calorimetry on a microscale has been used successfully for some time, particularly on biological systems, and there are many papers in this area. New calorimeter designs have made calorimetry very sensitive, currently less than 1 μW (5-7). Preliminary calculations indicate that the power generated by parasitic processes may often be in the 0-20 μW range in small cells such as used for cardiac pacemakers, and thus, microcalorimetry does seem to be an appropriate tool to investigate these phenomena. Indeed, several investigations have already shown that battery processes are detectable via calorimetry (5-7).

The present paper shows the results of several experiments where calorimetric measurements were made on batteries while the batteries were generating external power at various rates. These data are interpreted in terms of a simple thermodynamic model developed in the "Thermodynamic Considerations" section.

Experimental

The data presented in this paper were obtained with a Tronac Model 351RA microwattmeter. This calorimeter is a differential heat conduction type instrument and has a short-term noise level and a long-term stability of about 1 μW. The construction and performance of this instrument are described more fully elsewhere (7).

A simple experimental procedure was used to obtain data. The first step was to preequilibrate the battery; this was done in two stages. First, the battery was placed in a 37° ± 0.5°C air bath which surrounds the calorimeter. After this equilibration step the battery was then moved into thermal contact with the near 37°C water bath in which the calorimeter block is submerged. This bath was held to temperature fluctuations of ±0.0002°C. Following this second step, the battery could be placed inside the calorimeter measurement cavity with minimal disturbance to the calorimeter. Heat from all processes occurring in the battery was then conducted through the thermopiles surrounding the battery causing a change in the thermopile voltage output. Within 90 min the calorimeter was usually within 5 μW of its new equilibrium level. After steady state was established, the battery was removed and the thermopile output returned to its baseline. The caloric output changes found on insertion and removal of the battery were the same within experimental error. A typical experiment including battery insertion, settling, battery removal, and subsequent return to baseline generally required 3 hr or less. In several experiments the time period was longer than this, but in each of these cases kinetics of the battery chemistry appeared to be the controlling factor as the settling time was many times longer than the usual settling time for the calorimeter.

Measurements were made differentially using a dummy battery as a blank. These dummy batteries were made of aluminum and had approximately the same mass as the battery being studied. The use of a metal blank instead of air (empty chamber) was found to decrease the short-term noise significantly, but did not appear to change the average output perceptively. Zero output on the calorimeter was determined via the use of two dummy batteries.

In some experiments reported here the battery was discharged at a fixed rate while calorimeter measurements were obtained. To do this, 36 gauge Cu wires were soldered to the battery's terminals before the experiment was begun. Once the battery was in place, these wires were run through the air bath to two feedthroughs leading outside of the calorimeter. From these points external load resistors could be connected to the battery and its load voltage monitored. Because the air bath was maintained at nearly the same temperature as the calorimeter block there

* Electrochemical Society Active Member.

was very little noticeable effect because of the attached wires. The experimentally measured calibration constant was found to be the same with and without the wires attached to the battery.

A Keithley Model 150B microvoltmeter was used to monitor changes in the thermopile voltages. The output of the Keithley was recorded on a strip chart recorder for a permanent record. The temperature of the calorimeter block was continually monitored and was also recorded by the same strip chart recorder.

The type of calorimeter used for these experiments yields data in terms of heat flux rather than heat. This complements the experiments described here since changes which are a function of current (rate) are of interest. Each of the thermodynamic quantities may readily be converted to an equivalent rate form by assuming the rate to be measured by the current flowing in the external wire. Then, for exampe, $P = 4.18\ \Delta H\ (i/n\mathbf{F})$ where ΔH is in cal/mole, i is in amperes, n and $\mathbf{F}$ have their usual meanings, and P is in watts. Other thermodynamic quantities may be calculated analogously.

The calibration of the calorimeter was done via a 1 kΩ resistor which is embedded in the battery cell holder between the thermopiles. For our calorimeter the calibration factor was 8.45 μW/μV at 37°C. This calibration factor turns out to be independent of the thermal conductivity and heat capacity of the battery and battery holder, as is shown below.

Consider the example in Fig. 1. Heat is generated in the left-hand compartment. The heat flux produced, $\dot{H}$, is constant. This heat may do two things. The first is raise the temperature of its immediate surroundings which have a heat capacity, C_p. The second is transfer through the thermopile to the heat reservoir where it is maintained at temperature T_1. Thus, $\dot{H} = \dot{H}_1(t) + C_p\ dT/dt$, where $\dot{H}_1(t)$ is the heat flux through the thermopile to the reservoir. Eventually, the source surroundings will reach an equilibrium temperature, *i.e.*, $dT/dt = 0$. The time required for this to occur will depend on the thermal parameters of the source compartment and the thermopile. When the steady state is reached, $\dot{H} = \dot{H}_1(t) = \dot{H}_1$. Because heat is passing through the thermopile, a temperature gradient ΔT exists across its faces, *i.e.*, $\dot{H}_1 = \sigma\Delta T$, where σ is the heat conductance of the thermopile. Thus, for any constant heat flux, $\dot{H}$, the temperature difference across the thermopile faces will be the same once $dT/dt = 0$. Since the voltage output from the thermopile is $k\Delta T$ we arrive at the calorimeter calibration constant, σ/k, which is independent of the thermal properties of the source.

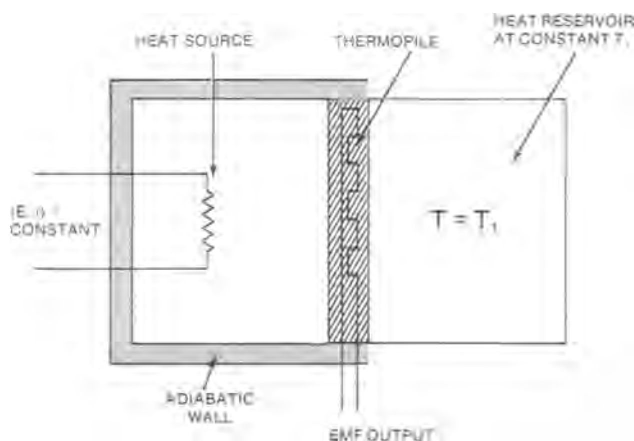

Fig. 1. Schematic representation for steady-state calibration of calorimeter. Heat source in measurement cavity on left. Calorimeter block (heat reservoir) at temperature T_1 on right.

Two commercial varieties of batteries were used in the experiments below. One is the Mallory Model RM-1 cell. This battery is a familiar Zn/HgO alkaline type and has been used to power implantable cardiac pacemakers for several years. It has a nominal open-circuit voltage (OCV) of 1.36V and a capacity of 1.0 A-hr. The second type of battery is based on the $Li/LiI/I_2$ system. In this system lithium and iodine electrochemically react to form a layer of LiI between the reactants. This layer serves as both electrolyte and separator for the battery. In the cells discussed here the iodine is rendered conductive enough to pass current by the addition of a small amount of poly-2-vinylpyridine. Although their chemistry is the same, these two models of Li/I_2 batteries are quite different The Model 742 battery is comprised of two series cells each housed in a sealed plastic cup which are then potted in a stainless steel can, while the Model 755 battery consists of a single cell in which the cathode is poured directly into a stainless steel can. The OCV of the Model 755 is 2.80V and that of the Model 742 5.60V. Their rated capacities are 3.0 and 1.0 A-hr, respectively.

Thermodynamic Considerations

In a search of existing literature no discussion of the thermodynamics involved in calorimetric battery experiments such as those presented here and by Greatbatch (1) was found. The equations presented here are reasonably simple and can be readily derived from basic thermodynamics for a system at constant temperature. Since thermodynamic equations are strictly applicable only to systems at equilibrium, allowances must be made for the errors which develop as a result of the nonequilibrium situation which arises when current is drawn from a cell or parasitic processes occur.

Let us consider the chemical reaction

$$mM + nX \rightarrow M_mX_n \qquad [1]$$

From the First law

$$\Delta U = q + w \qquad [2]$$

where U is the internal energy, q is heat transferred to the system (positive), and w is work done on the system (positive). Thus, internal energy, which is a state function, is proportioned between heat and work. The value of ΔU for a reaction such as [1] is fixed by its chemistry, but the values for q and w depend on how M and X are converted to M_mX_n. In this section of the paper activities of reactants and products are assumed to be constant. However, activities can change in both ideal and nonideal cells and influence calorimetric measurements.

If M and X are combined directly in the calorimeter, w can only be the mechanical work allowed by the nature and geometry of the system and is nearly 0 if all reactants and products are condensed phases. Thus, in this situation q is a measure of $\Delta U_{M_mX_n} \approx \Delta H_{M_mX_n}$. Now consider the same chemical and geometrical system except that M and X are constrained in such a way that the only path for formation of M_mX_n is via electron transport through a wire external to the calorimeter (*i.e.*, we make the system a battery). When a load is placed in series with this wire, electrical energy is dissipated outside of the calorimeter. If $\Delta U_{M_mX_n}$ is fixed by the reaction taking place and work or heat is appearing outside the calorimeter, less heat must appear inside the calorimeter than in the first example. The question then becomes how is $\Delta U_{M_mX_n}$ divided between q and w. As will be seen below, there is a theoretical minimum for q, and the observed proportioning will be determined by kinetic as well as thermodynamic characteristics.

For any system, the maximum amount of external work is done when the process is carried out reversibly. Thus, via Eq. [2], minimum heat must be produced under reversible conditions. The Second

law equations defining the Helmholtz (ΔA) and Gibbs (ΔG) free energies in terms of ΔU or ΔH and entropy (ΔS), Eq. [3a and 3b], turn out to express the necessary relationships since ΔA and ΔG are equal to the reversible electrical work a system is capable of while holding temperature and volume or pressure, respectively, constant

$$\Delta A = \Delta U - T\Delta S \quad [3a]$$

$$\Delta G = \Delta H - T\Delta S \quad [3b]$$

A rearrangement of Eq. [3b] summarizes this when pressure is constant

$$\Delta H = \Delta G + T\Delta S \quad [4]$$

Thus, $T\Delta S$ is the heat generated during the electrochemical formation process when it is done reversibly, the remainder, ΔG, being available for external work. If done slowly enough, this is approached. When polarization or irreversibility comes into play, q is greater than $T\Delta S$ so w_{irr} becomes less than ΔG. The extra energy which is not expended externally ($\Delta G - w_{irr}$) must remain inside the calorimeter. It will eventually be given off as heat; however, it may be temporarily stored and slowly dissipated. This can cause problems if the time scale of observation is too short. An example of this is shown later. There can also be losses in the battery from its own internal resistance. At true steady-state conditions, all of these losses may be lumped together since they all affect the battery by reducing its output voltage. In high resistance batteries such as the lithium/iodine cells studied here, the internal resistance is a dominant correction term.

The Relationship Between the *i-E* Curve and Internal Power Losses

As pointed out above, irreversible effects lead to a reduction in the load voltage of a cell. Furthermore, since a cell's *i-E* curve relates its voltage to its rate of reaction, this curve is the keystone to calculating how power dissipation is distributed between useful external energy and internal heat. This becomes apparent since ΔH and ΔU are independent of rate as long as the reactants and products remain the same. Useful power is then $i \cdot E$ and the internal power loss is the difference between the total for the system, $\Delta H/n\mathbf{F} \cdot i$, and the useful power dissipation. Figure 2 is a composite showing these relationships at steady state when ΔH is more exothermic than ΔG. In order to make the units consistent the load-voltage curve is plotted as $n\mathbf{F}E$ *vs.* $i/n\mathbf{F}$ rather than the more familiar E *vs.* i. The load curve goes from $n\mathbf{F}E = n\mathbf{F}E_{OCV}$ at $i/n\mathbf{F} = 0$ to $n\mathbf{F}E = 0$ at $i/n\mathbf{F} = i_{sc}$, the short-circuit current. Between these extremes, $n\mathbf{F}E_{OCV} > n\mathbf{F}E > 0$ and $0 < i/n\mathbf{F} < i_{sc}/n\mathbf{F}$. For a cell at E_L and i_L, the shaded and hatched areas in Fig. 2 show the internal (dq/dt) and external (dw/dt) power dissipation. The shaded area corresponds to internal power loss, while the hatched area is electrical power available outside the cell. Note that as $i/n\mathbf{F} \rightarrow 0$ both the internal and external power approach zero, but that their ratio does not. The minimum internal power is $4.18\, T\Delta S\, (i/n\mathbf{F})$ even if the cell reaction is carried out reversibly. Hypothetical power-current relationships are shown in Fig. 3. Here three plots illustrate the general shapes of E, P_{int}, and P_{int}/i as a function of i. The i *vs.* P_{int} curve passes through the origin, but the i *vs.* P_{int}/i plot has an intercept proportional to ΔS.

The Self-Discharging System

So far this discussion has only covered the behavior of a cell where there are no parasitic reactions occurring. We now wish to broaden this to include self-discharge and other parasitic reactions which generally occur to some extent in all real batteries. As seen in Fig. 3b, the internal heat produced in a cell in which no parasitic reactions occur always goes to zero as $i \rightarrow 0$. Therefore, the presence of internal power dissipation when $i = 0$ is proof of the occurrence of some parasitic process, and their presence may be ascertained by simply measuring the internally dissipated power at no load.

Parasitic processes can be divided into the categories which affect the capacity or performance of the cell and those which do not. Examples of the former might be chemical self-discharge and case corrosion, and the latter could be curing of epoxy encapsulation. The first type is of most concern although mixtures of the two may be present and the main problem frequently is the difficulty of determining which and how much of each is occurring. The rate of those parasitic processes that do not affect the cell's function are not likely to depend to an appreciable extent on cell load. The detrimental parasitic processes may or may not be measurably affected by discharge current density depending on the time scale of observation, the mechanism the process occurs by, and the physical size and shape of the cell. In the paragraphs below each of these situations is discussed.

Case 1: The parasitic reaction rates are independent of battery load. For this to be, the cell and parasitic reactions must occur or appear to occur in parallel. This can arise in several ways. First, if the cell reaction and the parasitic process are not related in any manner, *i.e.*, their reactants and products are different, or if the two reactions occur in physically separated areas of the battery. A second way is if the geometry of the battery is such that on the time scale of observation the two reactions occur independently. For example, suppose a battery had a catholyte which had electronic conductivity and also slowly corroded the cathode current collector. If mobilities in the catholyte were slow and the distance between the current collector and separator large enough, a true steady state may not be reached during observation and the reactions will appear to occur completely independently. The final way for the reactions to occur inde-

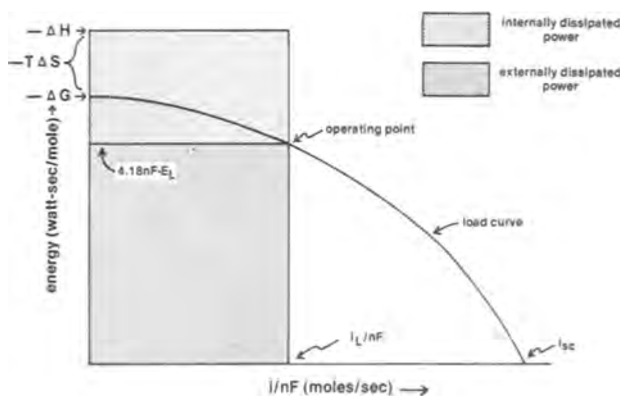

Fig. 2. The steady-state partitioning of total power between internal and external dissipation in an ideal battery via the load-voltage curve.

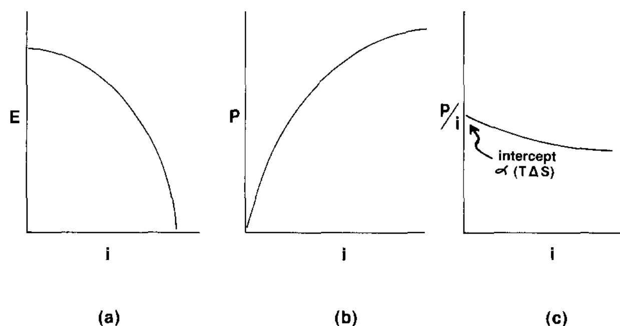

Fig. 3. Generalized hypothetical curves for (a) voltage, (b) internal power dissipation, and (c) internal power/rate; all vs. rate.

pendently is if concentration gradients do not form in the cell, as might be the case if the catholyte had an invariant composition. In such a situation the cell discharge reaction and the parasitic reaction (possibly chemical self-discharge or a corrosion reaction) would occur independently because there is no mechanism whereby the reactions can influence one another.

Case 2: The parasitic reaction rates are dependent on battery load. The usually expected interaction is a decrease in the chemical reaction rate with increasing cell current because of competition for a reactant. This arises as follows when the chemical and electrochemical reactions occur at a common interface. In the absence of electrochemical discharge the chemical reaction rate depends on the existing reactant concentrations and/or diffusion gradients. If the electrochemical reaction rate is then fixed at some value greater than zero and it consumes a reactant common to the chemical reaction, the concentration of that reactant will decrease and its gradient away from the interface will increase. This will cause the chemical reaction rate to decrease. The existence of a concentration gradient is a necessary condition for this behavior if chemical and electrochemical back reactions are negligible or product activities are fixed. Although the above situation only leads to inverse dependencies of the parasitic process rate on load current it is possible to envision a mechanism which would yield the opposite result. For example, if the chemical discharge produced a passive layer which is broken down by the electrochemical discharge, the rate of self-discharge could be greater during the presence of electrochemical discharge than in its absence. This may be what happens in the Li/SO_2 system where a thin protective film is known to form at the Li surface (8) and keep the system from chemically discharging.

Results and Discussion

Experiments of the sorts described earlier were performed on batteries based on Li/I_2 and Zn/HgO chemistry. A typical piece of data is shown in Fig. 4. This strip chart recording covers a nominal 40 hr period and shows the stability of the baseline and settling times involved. After battery insertion and removal the recording goes endothermic because the air bath is generally slightly cooler than the calorimeter block. The short-term noise and long-term stability both appear to be on the order of 1 μW.

Figure 5 shows the calorimetric data obtained while discharging two Wilson Greatbatch, Limited, Model 755 batteries with load resistors external to the calorimeter. One of these batteries (SN5560) had not previously been discharged while the other (SN1126) had been discharged about 10% of its rated capacity. The dissipation *vs.* load plot is curved in each case,

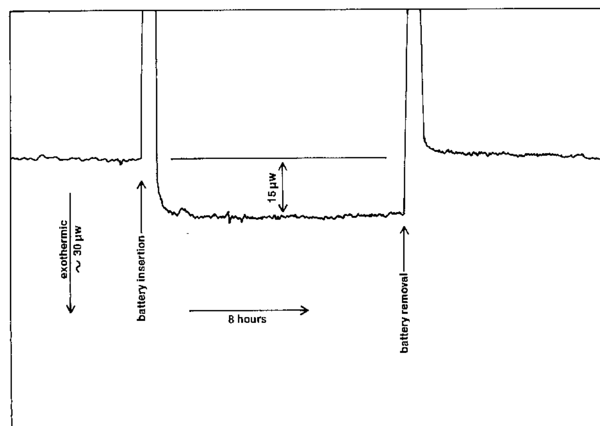

Fig. 4. Typical calorimetric strip chart recording showing noise and stability over a 40 hr period.

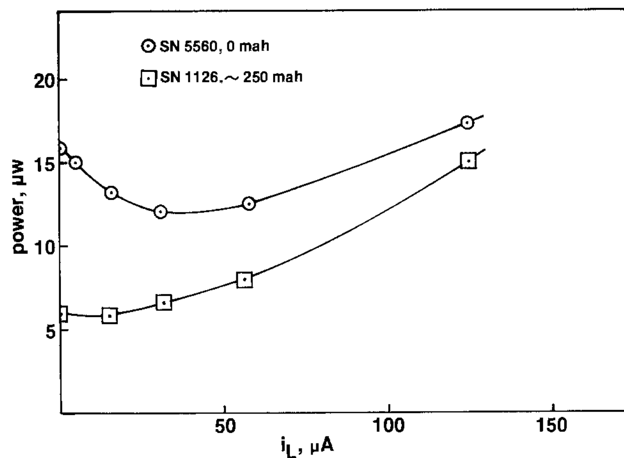

Fig. 5. Measured internal power dissipation *vs.* load current for two Li/I_2 batteries. Both are Wilson Greatbatch, Limited, Model 755 batteries. SN5560 discharged 0 mA-hr: SN1126 discharged ~250 mA-hr.

and in fact both appear to have minima. The next two figures show the effect of correcting the raw data for known current dependent variables. One of these is the entropy correction, $T\Delta S$. Since this is a thermodynamic correction it should only be applied in a true thermodynamically reversible situation. Although the system cannot be running reversibly as long as current is flowing, reversible behavior is being approached to some degree, especially at the low discharge rates encountered here. However, even if this were not the case, this correction still represents an upper bound on the efficiency of the system at any discharge rate. It turns out that for the $Li/LiI/I_2$ system ΔS is very small, 0.1 kcal/°K mole (9), and the entropy correction is negligible in the range shown. However, these batteries are inherently resistive because of the LiI layer, and the iR drop across this layer is a large correction. Since other polarization effects should also take the form of potential drops, a single correction was made by subtracting $i\Delta E$, where ΔE is the difference between E_L and E_{OCV} at the measured current.

The corrected data for the newer battery became nearly horizontal after an initial dip (Fig. 6). The same correction for the partially discharged cell yields a line not nearly as horizontal (Fig. 7). At this time we do not know if all the observed differences are indicative of the states of discharge or whether some might be artifacts of the batteries themselves. However, the author has seen other data on Li/I_2 cells and they show the same initial drop in calorimetric output in the region $i_L < 50$ μA (5). Hart and Hansen

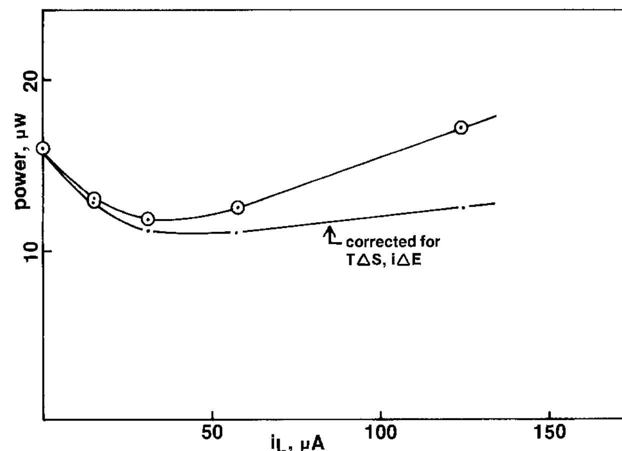

Fig. 6. The measured and corrected internal power dissipation *vs.* load curves for battery SN5560.

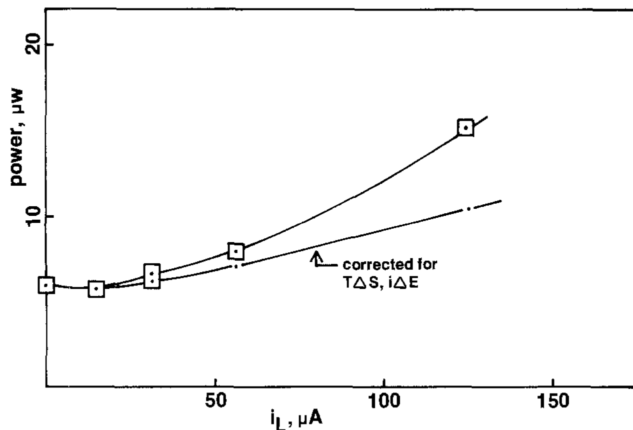

Fig. 7. The measured and corrected internal power dissipation vs. load curves for battery SN1126.

have also shown that the Li/I_2 reaction is essentially 100% current efficient (7) and this leads to speculation that the observation of the initial dip may be due to changes in the rate of self-discharge because of a competition of the chemical and electrochemical mechanisms. Such a mechanism would be expected to be much more noticeable on a new cell, where the protective LiI layer is very thin, than on an older cell, and this is what is observed. It seems likely from these preliminary experiments that most of the calorimetric output observed in the Model 755 battery is due to self-discharge and that at least early in life its rate is quite dependent on current. The positive slopes in Fig. 6 and 7, after correcting for polarization, indicate there is something happening at the higher values of current density. An example of anomalous behavior was also observed. The open-circuit calorimetric output of battery SN5560 cell was observed to be about 16 μW in Fig. 5. This battery was loaded very heavily (to $E_L = 0.5V$) for several hours at 37°C,[1] then inserted into the empty calorimeter chamber. It was expected that the calorimetric output would quickly settle to 16 μW again. What actually occurred was that steady state was not reached for 20 hr, after which time the heat output fell to 15 μW, approximately its initial value (Fig. 8). During the 20 hr period a large exothermic output was observed. Since energy (above self-discharge levels) should not have been dissipated during this period the calorimetric output had to be the dissipation of heat or energy stored while the cell was under load. This calorimetric output (shown in Fig. 9) could be misleading if viewed on too small a time-scale where it was not apparent the data were indicative of a non-steady-state situation. Thus, it is very important in these experiments to observe a long enough period of time so that steady-state behavior is assured.

Since a main purpose of using microcalorimetric measurements is to estimate self-discharge rates, it was necessary to establish how self-discharge might change during the life of a battery. It was stated above that self-discharge is expected to be high initially, then decrease with time and discharge depth. If true, the shape of this curve must be known as a function of time and discharge depth in order to make an over-all estimate of self-discharge losses since a single measurement only gives information at one time and state of discharge. The effect of discharge depth was investigated using a set of rapidly discharged Wilson Greatbatch Model 742 batteries. These batteries are not directly comparable to the Model 755 cells already discussed since their designs are quite different and they are even subject to different accompanying parasitic reactions. Nevertheless, the basic chemistry is the same and the results should be indicative of this generic type of battery.

[1] During the discharge portion of this experiment the battery was kept in good thermal contact with the calorimeter water bath as is normally done during the equilibration cycle before a battery is inserted into the calorimeter. The strip chart recording corresponding to the insertion of the cell into the calorimeter appeared normal during this experiment.

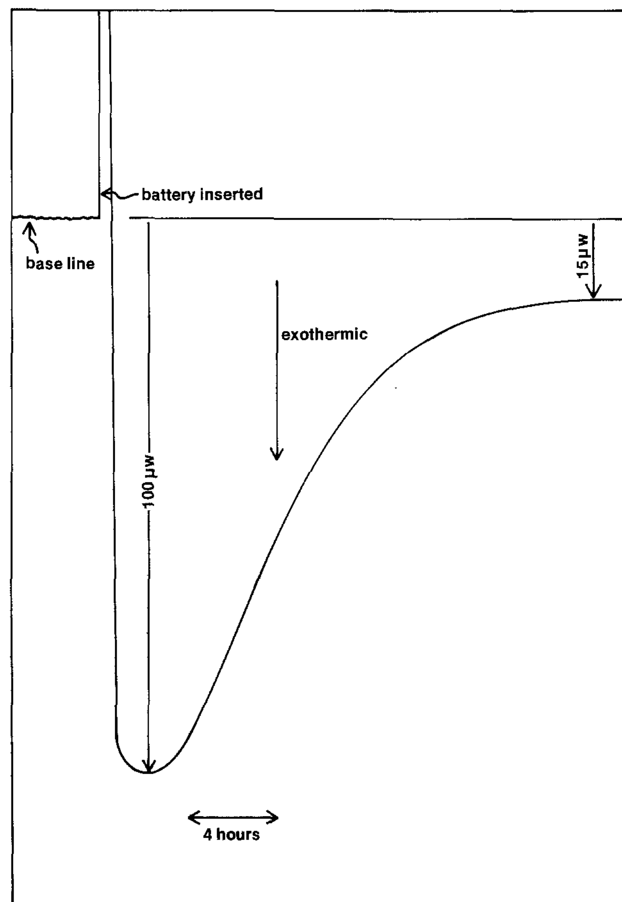

Fig. 8. The calorimetric response to open-circuit relaxation of battery SN5560 after heavy polarization. Settling time about 20 hr. Open-circuit calorimetric output of SN5560 was 16 μW before polarization.

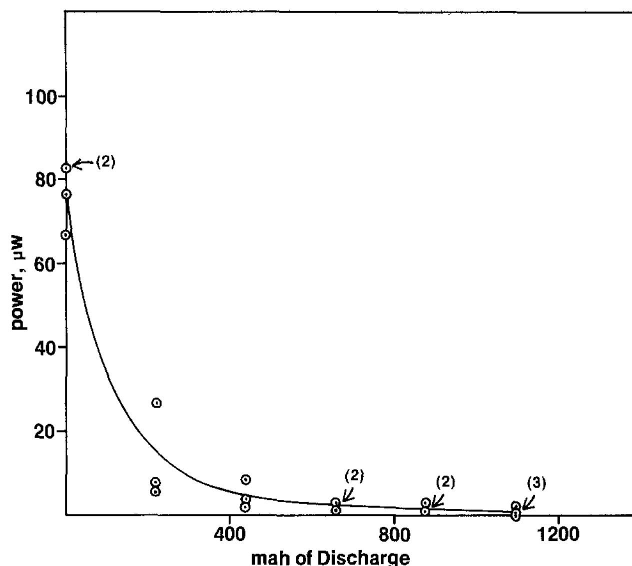

Fig. 9. Plot of calorimetric data for series of Li/I_2 batteries discharged to various depths. Batteries are Wilson Greatbatch, Limited, Model 742. Discharges done at 1 mA constant current at 60°C. Data from 21 batteries. Measurements made at no load.

A group of 21 batteries was discharged to different depths varying between 0 and 100% of the rated capacity of 1000 mA-hr. Calorimetric outputs were measured under open-circuit conditions for the various states of discharge and are plotted *vs.* discharge

depth in Fig. 9. As expected the calorimetric data show a high initial output which, under these conditions, falls to about 10% of its initial level by 40% through discharge. If the heat output is assumed to arise only from the direct combination of Li and I_2, the area under this curve can be integrated and compared with the average power used for normal pacing. Doing this, the fractional loss of energy from self-discharge during battery life is estimated to be 12%. Other experiments show that parasitic processes such as curing of epoxy and polyester may contribute significantly to the heat output observed early in life. This means the 12% estimate is probably high. However, even ignoring these corrections the data yield reasonable agreement with the anticipated loss of 10% or less according to the manufacturer's specifications.

While the experiment described above has real time uncertainties built into it from the accelerated discharge of the batteries, the shape of the curve indicates that calorimetric measurements from batteries discharged to 30% of capacity or even less may be used to obtain total self-discharge estimates in the Li/I_2 system with good precision.

The only pacemaker battery system for which much real-time self-discharge data has been obtained is the Zn/HgO system which has been used in heart pacemakers for many years. Chemical and classical electrochemical determinations of self-discharge in this system have been done (9). These experiments indicate that the direct combination of the reactants is the major degradation mechanism, with evolution of hydrogen also occurring to some extent. An accepted number is 4-5% of capacity loss per year in a Mallory RM-1 cell, which translates into roughly a 30% loss if the battery discharges completely at its pacemaker rate of 15 μA (10). The feeling of those who work with this system is that although its self-discharge rate does decrease during battery life, the Zn/HgO rate is relatively constant when compared to that attributed to the Li/I_2 system (10). An experiment analogous to that leading to Fig. 5-7 was done using a relatively new ($<10\%$ discharged) Mallory RM-1 battery. Both the raw and corrected data are shown in Fig. 10. Since the RM-1 cell is capable of sustaining much higher currents than the Li/I_2 batteries studied, the current scale shown is larger, going to 400 μA. The $i\Delta E$ correction is shown in the square boxes and accounts for most of the difference between the curves. However, in this system $T\Delta S$ is not negligible, and its added correction is shown separately (triangles). While Li/I_2 batteries show a decrease in heat output followed by an increase, that of the Zn/HgO system increases regularly with increasing current density. However, the corrected curve shows the unaccountable heat output becomes nearly constant for $i_L > 100$ μA. This curve extrapolates to about 7 μW at $i_L = 0$. Using this number as indicative of the average level of self-discharge and assuming that only the direct combination of reactants occurs, 25% of the cell's total energy will be lost to self-discharge. This appears to agree well with the data obtained from real-time experiments and experience.

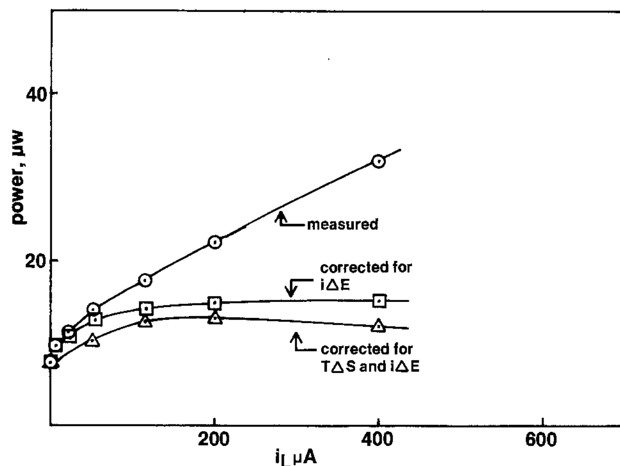

Fig. 10. The measured and corrected internal power dissipation vs. load curves for a Zn/HgO battery. Battery is Mallory RM-1.

Conclusion

The equations developed in the early sections of this paper show that the stored chemical energy in a battery system is proportioned between available and unavailable energy via the battery's load curve and thermodynamic considerations. The simple treatment described here accounts for most but not all of the energy exchanges observed between the Li/I_2 system and its surroundings. The ideal energy distribution is modified by phenomena such as parasitic reactions and nonequilibrium situations. In the Li/I_2 system it became evident that some parasitic reactions, predominantly self-discharge, do occur. There is some evidence the self-discharge reaction is in competition with the electrochemical reaction, which indicates there is some ionic conductivity in the cathode. When the microcalorimetric data were gathered for a group of Li/I_2 batteries which had been rapidly discharged to various depths, they showed that about half of the total parasitic heat loss occurred during the first 20% of discharge. This is very encouraging since the most uncertain part of determining accelerated losses is the extrapolation of early real-time data into the future. An estimate for the total self-discharge during life seems to be on the order of 10% of rated capacity for the batteries utilized in this experiment. How this number translates to other physical configurations of Li/I_2 cells was not specifically determined. For comparison, data on a conventional Zn/HgO battery were obtained and compared with real-time data. The two sets of data seemed to be in good agreement and lend credence to the use of calorimetry for determining self-discharge and parasitic losses.

Powder Electrode Separators for High Temperature Lithium-Aluminum/Iron Sulfide Batteries

J. P. Mathers,[1] C. W. Boquist, and T. W. Olszanski*

Argonne National Laboratory, Argonne, Illinois 60439

ABSTRACT

The feasibility of using ceramic powders for electrode separators in lithium-aluminum/iron sulfide cells was evaluated. Test cells of two different designs were constructed and operated for periods of 1000 and 2000 hr. Thus, the powder separator appears to be a good candidate for use in commercial cells. The advantages and limitations of this type of separator are discussed, and a comparison is made with fibrous separators which are also being developed for these cells.

Lithium-aluminum/iron sulfide batteries are being developed for stationary energy storage on electric utility systems and for electric-vehicle propulsion. Cells for this battery consist of a lithium-aluminum alloy negative electrode, an FeS or FeS_2 positive electrode, and a molten LiCl-KCl electrolyte (mp 352°C) which requires an operating temperature of 400°-450°C (1). An important factor in the successful development of these cells is the identification of an electrode separator which satisfies both the technical and economical requirements of the cell. In lithium-aluminum/iron sulfide cells the separator has two functions: (*i*) preventing electrical contact between the electrodes without unduly restricting ionic flow, and (*ii*) providing a barrier which will retain the active materials of the cell within the electrodes. The latter is important because the active materials are generally in the form of fine powders. The optimum structure and properties desired in the electrode separator have not been fully determined; however, the following general requirements can be stated: (*i*) The separator must be a good electrical insulator to prevent direct electron flow between the electrodes. (*ii*) The materials used in the separator must be chemically stable in the cell environment for the lifetime of the cell (5-10 yr). (*iii*) The separator should be <2 mm thick and contain a large volume of open porosity to minimize the cell weight and the resistance to ionic flow between the electrodes. (*iv*) The pore channels should be <20 μm in diameter to prevent penetration of the separator by the active materials in the electrodes. (*v*) The integrity of the separator must be maintained during any dimensional changes which occur in the electrodes during cell operation. (*vi*) If commercialization of the cell is to be achieved, the separator must have a potential cost of $<\$22/m^2$ and must permit rapid cell assembly.

The requirement for a good electrical insulator precludes the use of metals in the separator. Most organic or polymeric materials are not stable at the cell operating temperature, and none of the polymers which have been tested in cells at ANL appear promising. Therefore, the choice of materials for the separator appears to be limited to ceramics. Chemical reaction with lithium in the cell environment severely limits the number of ceramics which can be used in the cell. A comparison of the free energies of formation of various oxide and nitride ceramics with the free energy of formation of Li_2O and Li_3N indicates that the following ceramics should be stable in the presence of lithium at the cell operating temperature: MgO, BeO, Y_2O_3, CaO, Si_3N_4, BN, and AlN. Thermodynamic stability in the presence of lithium does not insure that a ceramic will be stable in the cell environment, though, because lithium may react with impurities in the ceramic, or a reaction could occur between the ceramic and other materials in the cell environment.

The previous development work on electrode separators for lithium-aluminum/iron sulfide cells has been devoted primarily to fibrous ceramics prepared from BN or Y_2O_3 fibers. These two fibers are the only commercially available ceramic fibers that are compatible with lithium (2). Boron nitride fabric has been used successfully in engineering test cells for periods greater than one year (1, 3, 4); however, it will not meet the cost goals for separators. Papers and felts prepared from BN fibers have been tested in laboratory test cells with very promising results (5) and appear to have the potential for meeting the separator cost goals. Yttrium oxide papers and felts have also been used successfully in laboratory test cells (5), but the potential cost of these materials is less certain than that of BN papers and felts. In addition, recent experiments have indicated that Y_2O_3 reacts with the sulfides present in the cell to form Y_2O_2S (6).

This paper describes recent efforts to utilize ceramic powders for electrode separators. The development of powder separators is being pursued because they facilitate cell assembly, are amenable to low cost mass production, and may permit the use of inexpensive materials such as MgO and CaO which are not available in fibrous form.

Experimental Procedure

The feasibility of using a powder separator was evaluated in Li-Al/LiCl-KCl/FeS test cells which were assembled in the uncharged state [*i.e.,* aluminum metal was used as the active material in the negative electrodes and a mixture of Li_2S and Fe was used in the positive electrodes (7)]. Two different cell designs, shown schematically in Fig. 1 and 2, were evaluated. The cells were cylindrical, with a diameter of 7.6 cm and a height of 2.5-3.5 cm. The negative electrode in both cell designs was enclosed by the lower portion of the cell housing and a 325-mesh stainless steel screen (for particle retention) that was spot-welded to a retainer ring. This retainer ring was not welded to the cell housing and was free to move whenever dimensional changes occurred in the electrode during cell operation. The cell housing and retainer were made from AISI 1008 steel. The negative electrodes were formed by cold-pressing Al wire into circular plaques, and the positive electrodes were formed by hot-pressing a mixture of Li_2S, Fe, and electrolyte powders at a temperature of $\sim$400°C and a pressure of $\sim$11,700 kPa (1700 psi).

In the first test cell, SC-13, the positive electrode was enclosed in a metal compartment made from Hastelloy B[2] (Ni-28 Mo-5 Fe-1 Cr) and Type 304

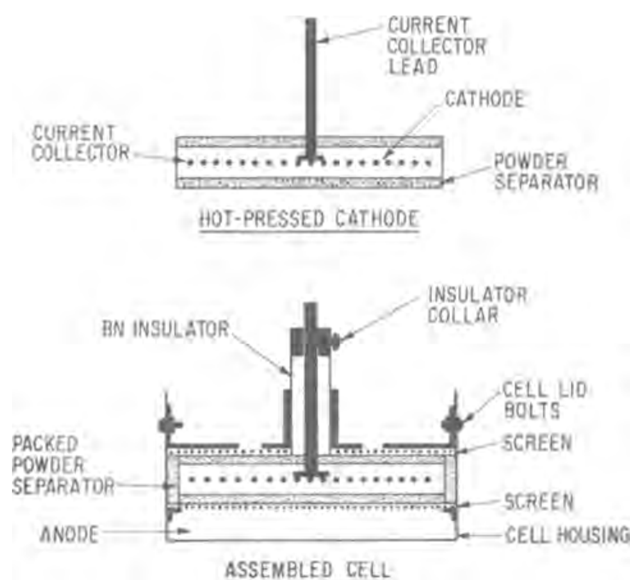

Fig. 2. Schematic diagram of cell SC-14

stainless steel screens which were spot-welded in place. An iron rod served as the positive current lead and was welded to the top of the electrode compartment. The separator consisted of coarse Y_2O_3 powder (150-250 μm, 99% pure),[3] which was poured into place around the positive electrode. Yttria was selected because of its proven compatibility with lithium (2). The coarse particle size was selected to prevent the powder from penetrating the 325 mesh retainer screens. The volume fraction of Y_2O_3 in the separator was 0.40, as determined from packing density measurements, and the separator thickness was about 3 mm. A dense BN sleeve was used to insulate the positive current lead from the cell housing.

In cell SC-14 (Fig. 2), the positive electrode was not enclosed in a metal compartment, and the separator was fabricated as an integral part of the electrode. The positive electrode, current collector, and the upper and lower electrode separators were assembled in a hot-pressing operation using the LiCl-KCl electrolyte as a binder. This unit is shown in the upper portion of Fig. 2. The current collector consisted of a stainless steel screen welded to an iron rod. The separator mixture consisted of 61 weight percent (w/o) coarse Y_2O_3 powder (150-250 μm, 99% pure),[3] 26 w/o fine Y_2O_3 powder ($\sim$5 μm, 99.99% pure),[4] and 13 w/o electrolyte. The larger Y_2O_3 particles were selected because they were not expected to migrate into the positive electrode or through the 325 mesh screen used to cover the negative electrode. The fine Y_2O_3 particles were expected to fill the voids between the larger particles and prevent penetration of the separator by the active materials. After the hot-pressing operation, each separator layer was 2 mm thick and the volume fraction of Y_2O_3 was 0.70. The latter was calculated from the weight of Y_2O_3 used in the separator and the dimensions of the separator after the hot-pressing operation. The sides of the positive electrode were insulated from the cell housing by Y_2O_3 powder (70 w/o coarse and 30 w/o fine) which was packed into place. Unlike cell SC-13, bolts were used to fasten the top lid of cell SC-14 to the cell housing. A dense BN insulator was used to insulate the positive current lead from the cell housing, and a metal collar with a set screw was used to hold the insulator in place.

Assembly of both cells, including the hot-pressing operations, was accomplished in a helium-atmosphere glove box. After assembly, the cells contained a large volume of voids which had to be filled with electrolyte. This was accomplished by (*i*) positioning chunks of solid electrolyte on top of the cell, (*ii*) placing the cell into a furnace which was built in to the floor of the glove box, (*iii*) evacuating the furnace to remove the helium from the voids, (*iv*) slowly raising the temperature of the furnace to melt the electrolyte, and (*v*) repressurizing the furnace to force the molten electrolyte in to any voids. Holes were provided in the top of both cell housings, and in the top of the compartment for the positive electrode of cell SC-13 to facilitate the removal of gas from the cell and loading of electrolyte. The theoretical capacities of cells SC-13 and SC-14 were 19 and 25 A-hr, respectively, with the capacities of the negative and positive electrodes being equal.

The cells were operated in the glove box furnace and were cycled continuously at 450°C, between a discharge cutoff potential of 0.9V and a charge cutoff potential of 1.7V (internal resistance included). The cells were placed on open circuit for 10 min after each charge and discharge. Both cells were operated at a current density of $\sim$20 mA/cm^2 during the first few cycles. The current density was gradually increased during cycles 3-10 until the desired operating current density was reached (76 mA/cm^2 for SC-13 and 60 mA/cm^2 for SC-14). Cells SC-13 and SC-14 were operated for 2000 and 1000 hr, respectively. Operation was voluntarily terminated for post-test examination of the cell and separator. In the post-test examinations the cells were sectioned, and metallographic mounts of the separators were prepared in a helium-atmosphere glove box. Optical micrographs were obtained on a metallograph which was also located in the glove box.

Results

The electrical performance of the cells is summarized in Fig. 3 and 4. These graphs illustrate the coulombic efficiency and percent utilization[5] achieved for each charge-discharge cycle. The coulombic efficiency of each cell remained near 100% throughout the lifetime of the cells. The utilization of both cells declined rapidly during the first 10 cycles of operation when the current density was increased to the desired operating level. The sudden losses in utilization for cell SC-13 were caused by the buildup of gas in the cell. Evacuation of the furnace containing the cell removed this gas and immediately restored the utilization of the cell to its original value. After the first 1000 hr of operation, no further buildup of gas in the

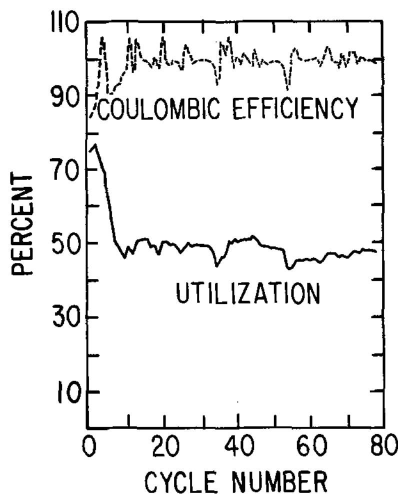

Fig. 4. Electrical performance of cell SC-14

cell was observed. The identity and source of the gas was not determined, but it is believed to have resulted from contaminants introduced with the cell materials. The Y_2O_3 and Li_2S powders used in cell SC-14 were heated in a vacuum at 600°C prior to cell assembly in order to remove any hydroxides, carbonates, or adsorbed moisture. This greatly reduced the buildup of gas during the operation of SC-14 and eliminated large fluctuations in the utilization. Over-all the electrical performance of these cells was judged to be very good.

A section of cell SC-13, obtained during post-test examination, is shown in Fig. 5. A great deal of swelling and distortion of the electrodes was evident. The center portion of the positive electrode had expanded approximately 25%, while the swelling in the negative electrode ranged from 90% at the outer edge to as much as 160% (2.6 × original thickness) near the center. The separator thickness between the electrodes varied from 2-6 mm, with most areas in the range of 2-4 mm (original thickness = 3 mm). A photograph of a cross section of cell SC-14 is shown in Fig. 6. In this cell, the positive electrode had expanded 10% near the center and edges but had been com-

Fig. 5. Post-test section of cell SC-13

Fig. 6. Post-test section of cell SC-14

pressed by 15% in other areas. The negative electrode had expanded 35-55%. Examination of the separator revealed that the thickness varied from 0.5 to 3.0 mm, with most areas in the range of 2.5-3.0 mm (original thickness = 2 mm). The apparent increase in the separator thickness of this cell was an unexpected result, and the reason for this behavior has not been established. Some irregularities in the shape of the positive electrode are visible in Fig. 6. As can be seen on the lower edge of this cell, the positive electrode almost made contact with the negative electrode.

The powder separators in both cell designs showed an ability to conform, at least to a limited degree, to the distortion or curvature in the surfaces of the electrodes. However, excessive swelling of the electrodes or local irregularities which develop in the shape of the electrodes can lead to fairly large variations in the separator thickness. The amount of swelling and/or distortion which occurs in the electrodes can be substantially reduced if the electrodes are restrained. In cell SC-13 the top of the cell was not fastened to the rest of the cell housing, and this allowed the electrodes to expand freely. In cell SC-14 the electrode swelling was greatly reduced by bolting the top of the cell in place. This method of restraint was not completely successful, however, because the bolts were placed through vertical slots in the top of the cell which permitted some upward movement of the electrodes during cell operation. In actual batteries, where the cells are properly sealed by welding and restrained by the battery case, swelling and distortion of the electrodes is expected to be much less of a problem. A small amount of variation in the separator thickness is inevitable as long as dimensional changes occur in the electrodes during cell operation. This will probably be the limiting factor in determining the minimum separator thickness which can be achieved with powders. Based on the present study, the separator thickness might be reduced to the range of 1-2 mm with proper restraint of the electrodes.

The cause of the local irregularities observed in the shape of the positive electrode of cell SC-14 is not known, but this problem can be avoided through the use of a metal frame and screen assembly around the electrode (as was done in cell SC-13). In cells which utilize FeS as the active material for the positive electrode this does not present a problem; however, a difficult corrosion problem is encountered when FeS_2 is used as the active material. At the present time molybdenum is the only metal with sufficient corrosion resistance for use with FeS_2 electrodes. Since molybdenum components are difficult to fabricate and expensive (2), it is desirable to identify the cause of the irregularities observed in SC-14, in the hope that the need for a frame and screen assembly around the positive electrode can be eliminated.

A composite photomicrograph of a section of the powder separator of cell SC-13 is shown in Fig. 7. The 325- and 40-mesh screens used to cover the positive electrode face are visible at the top, and the 325-mesh screen used over the negative electrode can be seen in the lower portion of the photomicrograph. The active material in the positive electrode had penetrated the

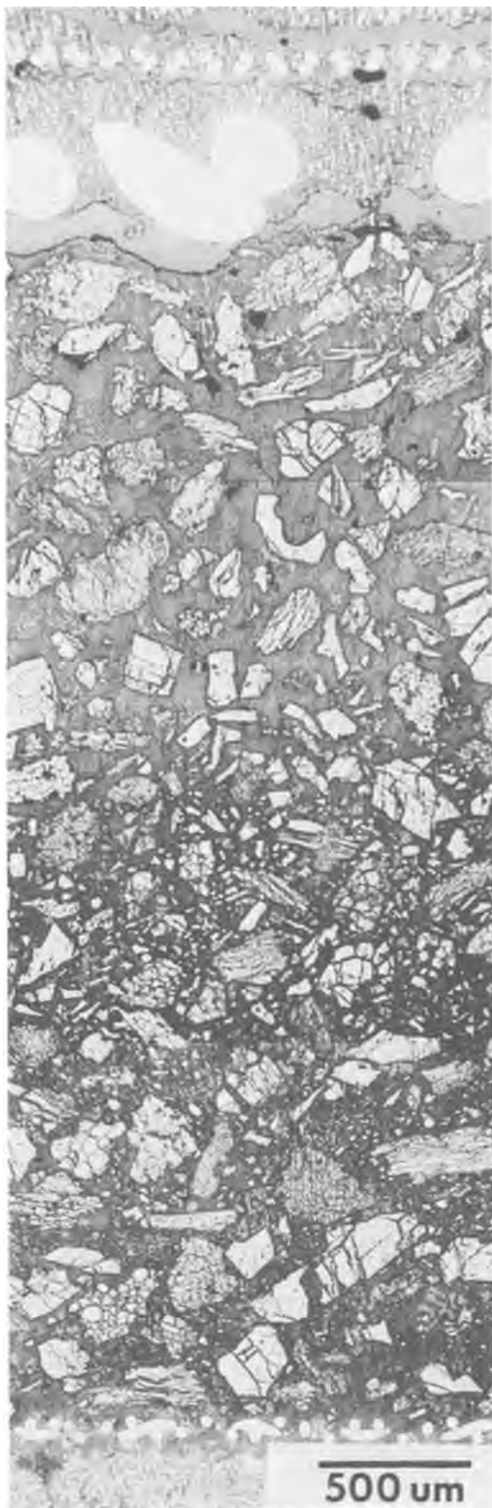

Fig. 7. Powder separator from cell SC-13

two screens used on that electrode, but only a small amount had penetrated the separator. The active material which did penetrate the separator was dispersed and limited to the area immediately adjacent to the electrode. The remainder of the separator (~90%) was free of active materials from the electrodes. No evidence of chemical attack on the Y_2O_3 powder was observed; however, subsequent tests in other cells have shown that Y_2O_3 reacts with sulfides in the cell to form Y_2O_2S (6). The Y_2O_3 particles had a very irregular surface and a fractured appearance before and after cell testing. Most of the small Y_2O_3 particles had settled to the lower portion of the separator, creating a density gradient across the separator thickness. Metallographic examinations indicated a Y_2O_3 volume fraction of 0.48 in the upper portion and 0.63 in the lower portion of the separator. The original volume fraction of Y_2O_3 was 0.40; thus the separator was compressed in this area during cell operation.

A composite photomicrograph of the separator from cell SC-14 is shown in Fig. 8. The very fine, light colored particulate at the top of the photomicrograph is the active material of the positive electrode. The 325-mesh screen used to cover the negative electrode is visible at the bottom of the photomicrograph. As shown in Fig. 8, a well-defined interface existed between the positive electrode and the separator. A few dispersed sulfide particles from the positive electrode were observed in the separator, but these were confined to a small area immediately adjacent to the electrode. Penetration of negative electrode material into the separator was not observed. No visible reaction of the Y_2O_3 powders with any other materials and no variation in the density of the separator across its thickness were observed. The latter was attributed to the fine Y_2O_3 powder used to fill the pores between the larger Y_2O_3 particles. A determination of the volume fraction of Y_2O_3 in the separator by metallographic techniques could not be made because of the difficulty in resolving the fine Y_2O_3 particles. However, an estimate yielded a value of 0.47 for the volume fraction based on the thickness and volume fraction of Y_2O_3 for the separator immediately after fabrication and on the thickness of the separator after cell operation.

Fig. 8. Powder separator from cell SC-14

The above results indicate that the powder separators in both cells are good particle retainers. Even in cell SC-14, which did not have a frame and screen assembly around the positive electrode, the interface between the active materials and the separator showed little evidence of intermixing.

Discussion

The results of these preliminary experiments with powder separators indicate that they are a viable alternative to fibrous paper or felt separators. Each type of separator offers different advantages, and these must be taken into consideration when selecting the optimum separator.

An advantage of the powder separator over paper or felt separators is that it expands the number of materials which can be considered for use in electrode separators. Boron nitride is the only fibrous material presently available which is stable in the cell environment. This fiber appears to have the potential for meeting the separator cost goals of <$22/m^2 when manufactured in large quantities (>22,700 kg/yr); however, the requirement for a large market to lower the cost of the fiber (through mass production) places a difficult burden on the commercialization program for lithium-aluminum/iron sulfide cells. This is a familiar obstacle to the introduction of any new product using a developing technology.

Several possible candidates for powder separators are presently available, and a few of these are listed in Table I. The maximum cost per kilogram which can be paid for each powder without exceeding the separator cost goal of $22/m^2 is presented, along with the current cost per kilogram. This comparison shows that it may be possible to meet the separator cost goal at current prices using MgO or CaO. The cost of material such as AlN and Si_3N_4, which are now manufactured in small quantities, possibly could be reduced to the required price level. Obviously, this would require that these materials be manufactured in large quantities. Boron nitride, BeO, and Y_2O_3 are already produced in sizable quantities and the opportunities for substantial price reductions are probably limited. An important consideration in determining the potential cost of a particular powder will be the degree of purity required. If a very high purity powder (>99%) is required, the separator cost goal will be difficult to reach. Long-term testing of several candidate powders in cells is needed to determine whether they are truly compatible in the cell environment and to establish the required level of powder purity.

Fibrous separators have the advantages of being thinner (0.5-1.0 mm *vs.* 1.0-2.0 mm) and more porous (70-85% *vs.* 35-55%) than powder separators. The greater restriction of ionic transport through powder separators could lead to a loss in cell performance at higher current densities. This behavior has been observed in recent experiments (8). Cells for stationary energy storage batteries are expected to operate at current densities below 60 mA/cm^2 (9), but cells for electric-vehicle batteries may be required to operate at current densities in the range of 75-150 mA/cm^2 to maintain normal driving speeds and in excess of 400 mA/cm^2 during acceleration and hill climbing (10). Thus, powder separators should be adequate for stationary energy storage cells but may not be suitable for electric-vehicle cells. This apparent disadvantage for the latter could be overcome with an inexpensive powder separator (<$11/m^2) which makes possible the utilization of thinner electrodes. An increase in electrode surface area would reduce the requirement for high current densities.

In other respects, the powder and fibrous separators are roughly equivalent: both appear to provide adequate retention of the active materials in the electrodes, both possess the flexibility necessary to maintain their integrity during any dimensional changes that might occur in the electrodes, and both appear to be amenable to rapid cell assembly. Longer term testing of each separator form in engineering-scale cells is required to more fully evaluate their capabilities and to determine their potential for use in commercial cells.

Table I. Cost comparisons for powder separators*

Powder	Cost/kg** ($)	Current cost/kg† ($)
BN	11	44-110
BeO	9	55-66
Si_3N_4	9	44-250
AlN	9	88-375
CaO	7	1-22
MgO	7	0.2-22
Y_2O_3	4	66-77

* Assuming a separator thickness of 1.5 mm and a porosity of 45%.
** Maximum allowable cost for the powders to obtain a separator cost of <$22/m^2.
† The powder cost is dependent on the purity.

Conclusions

Powder separators are promising candidates for use in lithium-aluminum/iron sulfide cells because they maintain their integrity, conform to small dimensional changes in the electrodes, and appear conducive to rapid fabrication and cell assembly. The electrical performance of this type of separators is very good at current densities below 60 mA/cm^2; therefore, it is a good candidate for use in stationary energy storage cells. The relatively low porosity and the greater thickness of the powder separator compared with paper or felt separators could limit its usefulness for electric-vehicle cells, which are expected to operate at higher current densities.

Powder separators provide good retention of the active materials within the electrodes when a metal frame and screen assembly is used around both the negative and positive electrodes. The potential does exist for eliminating the electrode compartment if the development of large irregularities in the electrode shape can be prevented.

The primary advantage of the powder separator is that it expands the number of separator materials which can be considered for use in lithium-aluminum/iron sulfide cells, and this greatly enhances the prospects for achieving the separator cost goal of $22/m^2. Before the potential of this separator can be realized, however, it will be necessary to identify a low cost powder which is compatible with the cell environment. Possible candidates include, but are not limited to, MgO and CaO.

ABSTRACT

An experimental study has been made of the effect of several variables on the creepage rate of alkaline electrolytes along negatively polarized metallic surfaces. The variables studied were (*i*) nature of the cation, (*ii*) electrolyte concentration, (*iii*) external relative humidity, (*iv*) moisture transmission through seal, (*v*) seal compression, and (*vi*) electrolyte additives. A discussion of the mechanism by which these variables influence the creepage rate is given and their relative order of importance is listed.

In a previous publication (1), a description of theoretical and experimental work on the creepage of alkaline electrolytes along negatively charged metal surfaces was given. From an observation by one of the authors (SMD) that oxygen had a marked accelerating effect on creepage, it was shown that the driving force behind this phenomenon was the production of hydroxyl ions in a thin reaction zone above the electrolyte meniscus. This production of alkalinity above the meniscus arises from the electroreduction of oxygen (and/or water) which occurs preferentially in this zone where diffusive transport of oxygen to the surface (or evolved hydrogen away from the surface) has a maximum rate.

In the following text, we would like to address some of the practical aspects of creepage control. Specifically, we shall consider the following: (*i*) Cation mobility from the bulk solution and into the reaction zone should be reduced to delay the creepage. Total or partial substitution of the high mobility alkali metal cations (K^+, Rb^+, etc.) with those of sodium or preferably lithium will be beneficial. The use of gelling agents to increase the solution viscosity is indicated. (*ii*) Electroreduction of water accelerates creepage. Prevention of moisture transmission from high external relative humidity conditions to the reaction zone via the grommet material is desirable. (*iii*) Electroreduction reactions require negatively charged surfaces. Lowering the negative charge in the seal region through the preferred use of electropositive (*i.e.*, noble) metal substrates will aid in creepage control. (*iv*) Electroreduction of oxygen accelerates creepage. Addition of cations from Group II A of the Periodic Table will reduce creepage by raising the overvoltage for electroreduction of oxygen.

Experimental

The conductivity and leakage characteristics of mixed KOH, NaOH, and LiOH electrolytes.—Since equal weight percent KOH, NaOH, and LiOH solutions do not give the same molar hydroxyl ion concentration (40% KOH being equal to 30% NaOH and each 10 molar in hydroxyl ion) electrolyte mixtures were chosen on a mole percent OH^- basis. As a first step, therefore, the effect on the creepage rate of a 10 molar solution was investigated as one replaced the K^+ with Na^+. Figure 1 shows how the calculated

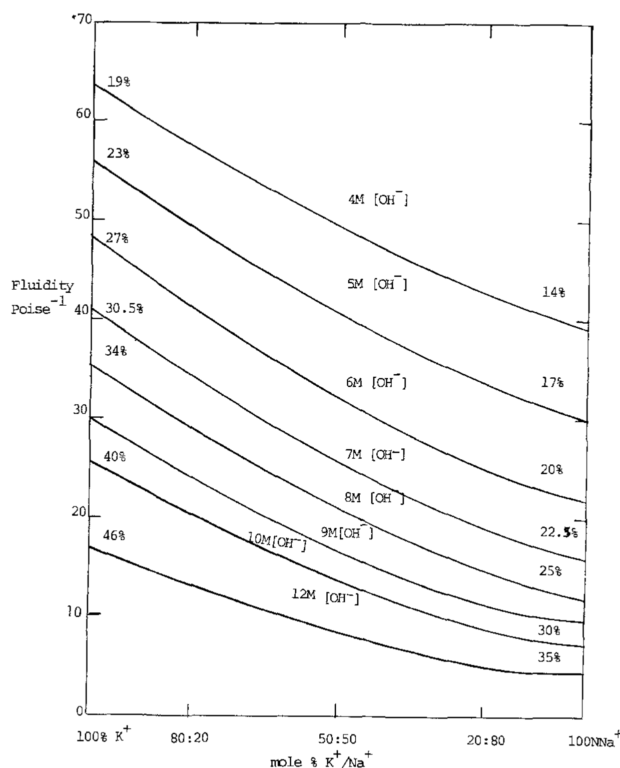

Fig. 1. Fluidity-composition relationships at constant hydroxyl ion concentration for mixed KOH-NaOH electrolytes.

* Electrochemical Society Active Member.
Key words: battery, seals, pressure, electrolysis.

fluidity (reciprocal of viscosity) will change as one switches from K^+ to Na^+. The percent figures given at 100% K^+ are the weight percent figures for the pure KOH solutions while at the other end of the isohydroxyl concentration lines, the percent figures give the weight percent of pure NaOH. It may be seen that there is a uniform decrease in fluidity between 40% KOH and 30% NaOH.

Figure 2 shows typical creepage results for such mixed electrolyte indicating that the creep height declines smoothly as Na^+ is substituted for K^+. [The experimental arrangement for recording the creepage rate is described in full in Ref. (1). The terms "solid creep" and "fine creep" refer to the fact that the creepage layer has two zones. Immediately above the meniscus, the creepage forms a continuous solid film which then merges into a second zone of fine electrolyte spots.] There are, however, three factors which prevent one from switching directly from 40% KOH to 30% NaOH. First, overvoltage effects may increase and adversely influence the cell discharge as one substitutes Na^+ for K^+. Second, cation mobility through the separator may be very important necessitating a substantial concentration of small cations, *i.e.*, K^+, and third, the intrinsic electrolyte conductivity declines as Na^+ is substituted for K^+. There exists, however, a range of electrolyte features which can be considered in an effort to optimize an alkaline cell in terms of satisfactory leakage characteristics and discharge performance in the mixed potassium-sodium hydroxide electrolytes.

In addition to NaOH-KOH mixtures, we investigated those of KOH-LiOH. These are more difficult to display on isoconcentration lines since one can only make a maximum of about 4M LiOH and to obtain, for example, a 6M OH^- solution, one has to mix the 4M LiOH with KOH solutions of greater than 6M. Several KOH-LiOH mixtures with 6M OH^- concentration were, however, formulated as follows (6M being chosen since in the all K^+ case this electrolyte is close to the maximum of conductivity exhibited by KOH solutions)

(*a*) 6M KOH — 100% K^+

(*b*) 66.5 cm^3 7M KOH + 33.5 cm^3 4M LiOH — 78% K^+

(*c*) 50 cm^3 SM KOH + 50 cm^3 4M LiOH — 66% K^+

(*d*) 33.5 cm^3 10M KOH + 66.6 cm^3 4M LiOH — 55.5% K^+

The creepage results for these solutions are shown in Fig. 3 and indicate that most of the creepage decrease occurs between solutions (*a*) and (*b*) with a smaller relative change as one moves from (*b*) to (*d*). A comparison with Fig. 2 shows that a similar reduction in creepage rate can be accomplished with a 40% substitution of K^+ with Li^+ as for an 80% substitution with Na^+.

Figure 4 compares the change in resistance of pure KOH and NaOH solutions as a function of concentration and also indicates the relative conductivity of various mixed electrolytes. As is well known, there is a smooth decrease in conductivity as the sodium ion is substituted for potassium but because the peak conductivity of KOH solutions lies at a higher hydroxyl ion molarity than sodium hydroxide, several of the mixed electrolytes, at high hydroxyl ion concentration, are better conductors than the most conductive pure NaOH solution. There thus exists a broad area between the peak conductivity compositions of NaOH and KOH within which the improved leakage characteristics imparted by the Na^+ ion may be coupled with the good conductivity characteristics of that of K^+.

External humidity and the effect on creepage rate.—There are several possible sources which supply

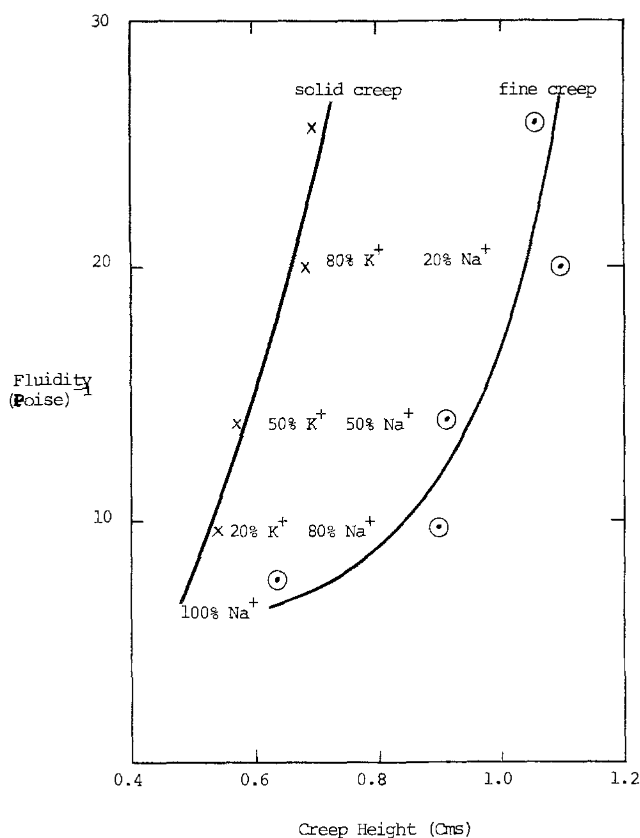

Fig. 2. Fluidity-creep relationships for mixed KOH-NaOH electrolytes of 10M OH^- ion concentration. Strip electrode potential $E = -1.35V$ vs. Hg · HgO.

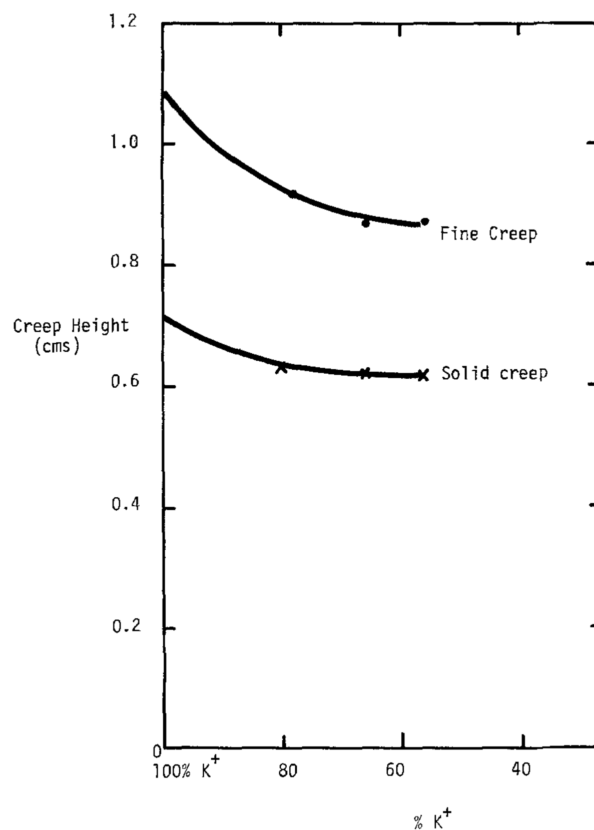

Fig. 3. Creep height after 24 hr as a function of the K^+:Li^+ ratio. $E = -1.35V$.

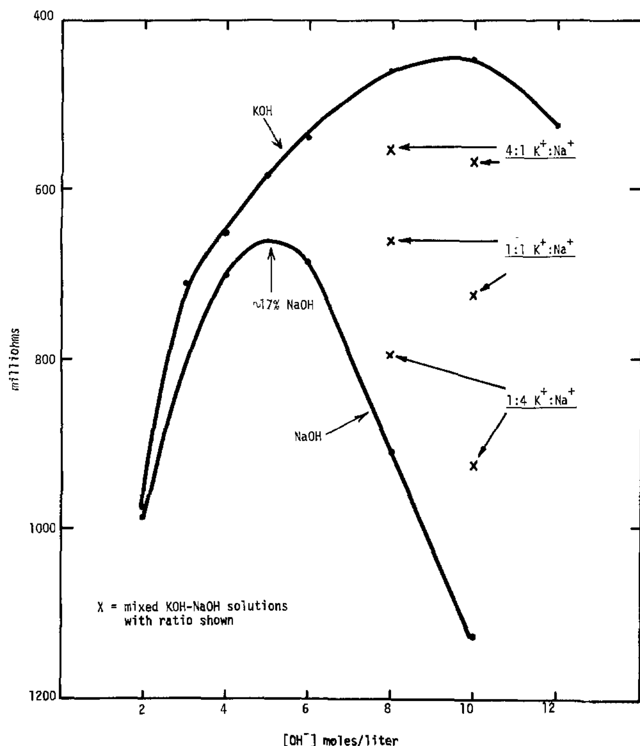

Fig. 4. Relative resistances of pure KOH and NaOH electrolytes within the concentration range 2-12M and of mixed KOH-NaOH electrolytes of 8 and 10M.

water to the reaction zone (1, 2). Water may move from the bulk electrolyte to the zone, it may condense from the water vapor above the electrolyte, or it may penetrate from the atmosphere external to the cell either through the grommet or between the grommet and the negatively charged metal surface. Creepage rates were measured on nickel strips in 35% KOH contained in a sealed dessicator within which the relative humidity could be controlled using sulfuric acid or calcium chloride solutions. The results shown in Fig. 5 are a clear proof that high relative humidities in the vicinity of the reaction zone lead to high rates

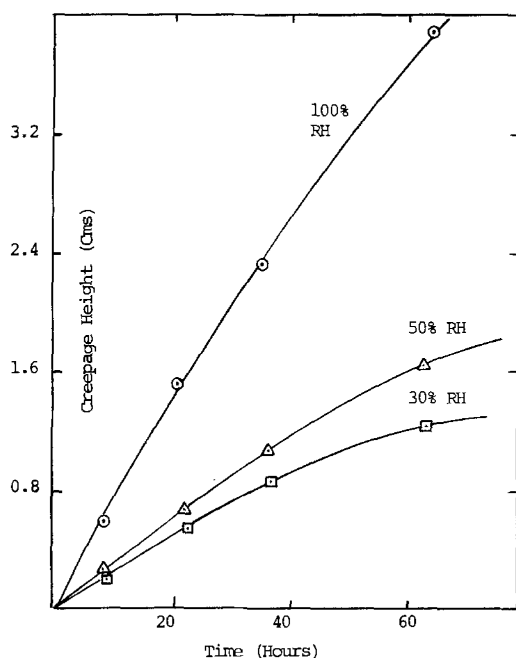

Fig. 5. Comparison of the rate of creepage of 35% KOH along nickel strips at —1.05V vs. Hg-HgO as a function of the relative humidity.

of creepage and are in contrast to those reported in Ref. (2). Such effects have been confirmed for production cells using nylon grommets and this raises the question as to how the cell is able to sense the external relative humidity conditions. Two mechanisms have been identified: (*i*) external electrolysis reactions occurring on the oppositely charged surfaces of the cell due to the presence of ionic conduction across the moisture layer absorbed in the external surface of the grommet, and (*ii*) water diffusion through the grommet to the reaction zone.

External electrolysis reactions—the problem.—Figure 6 illustrates how the presence of an ionic path external to the cell permits a slow discharge reaction to occur through the high ionic resistance E_1 by the electrolysis reactions which can proceed at M_1 (the negative top) and M_2 (the positive can rim). M_1, being negative, will evolve hydrogen according to

$$2H_2O + 2e^- \rightarrow H_2 + 2\,OH^- \quad [1]$$

and also reduce oxygen from the surrounding air via

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \quad [2]$$

while at the positive can rim, oxygen will be evolved via

$$4\,OH^- \rightarrow O_2 + 2H_2O + 4e^- \quad [3]$$

and corrosion of the can rim will occur

$$Ni + 2\,OH^- \rightarrow Ni(OH)_2 + 2e^- \quad [4]$$

to give nickel hydroxide (or more probably, the green basic nickel carbonate) if the can contains nickel but also via

$$2Fe + 6\,OH^- \rightarrow Fe_2O_3 + 3H_2O + 6e^- \quad [5]$$

in the presence of alloys of iron. Many cells stored in high humidity conditions exhibit visual proof of this current flow by the black, branched lines of precipitated corrosion products which grow across the grommet from the can rim.

Due to the movement of negative charge (the electronic current flow) from the zinc inside the cell to M_1 outside the cell, the internal electrolyte can be forced to move by electro-osmotic action along the seal interface (1). If one looks at the negative seal interface in somewhat more detail (Fig. 7), it may be seen that due to the negative charge which is impressed on this surface of the zinc, there is a balancing excess positive charge in any moisture layer between the negatively charged surface and the grommet. These excess positive ions as they move concurrently with the negative surface charge carry water from the internal to the external surface of the cell. [A more complete description of this electro-osmotic movement is given in Ref. (1).]

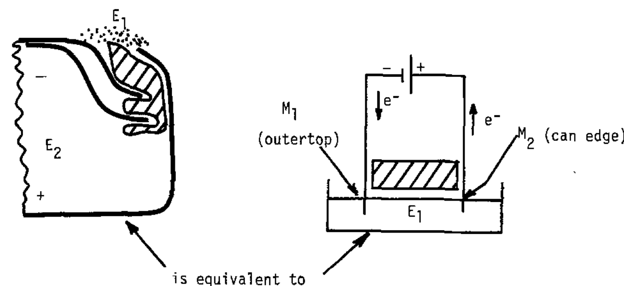

Fig. 6. Illustration of electrolysis reactions occurring on the external surfaces of the cell in the presence of high humidity access to the grommet.

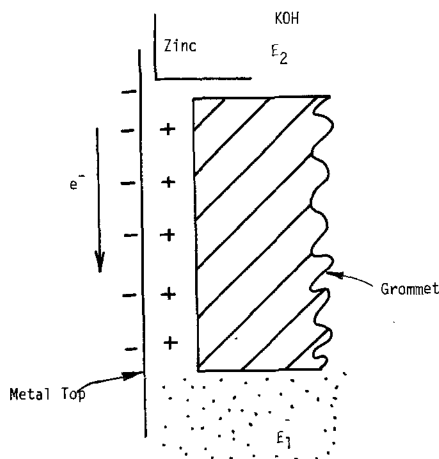

Fig. 7. Charge distribution and direction of charge movement at the negative seal interface of an alkaline cell in the presence of external electrolysis reactions.

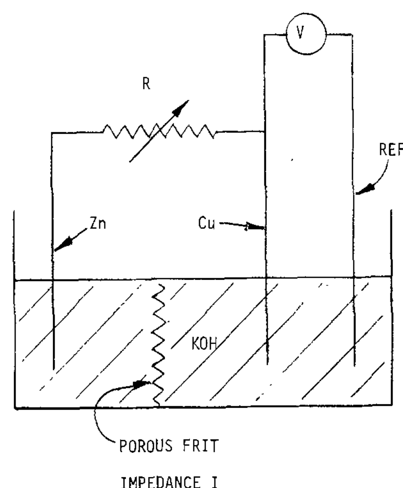

Fig. 9. Illustration of ionically and electronically connected metallic strips of differing composition in a KOH electrolyte.

Water transmission through the grommet.—Accelerated leakage tests conducted by placing cells at an elevated temperature are probably accelerated more by the additional vapor pressure of water present at the higher temperature for a fixed relative humidity than by the elevated temperature itself. For example, if one considers cells containing 40% KOH placed in a 100% RH environment at 20° and 40°C then, at the former temperature, there will be an external water vapor pressure of 17.5 mm H_2O and an internal pressure of 6.2 mm H_20. The difference in water pressure acting through the grommet is thus 11.3 mm. At the higher temperature, the corresponding outside and inside values are 55.3 and 20.1 mm, respectively, giving a net pressure of 35.2 mm through the grommet. The 20°C rise in temperature resulted in a factor of over three increase in the water vapor pressure differential across the grommet. It is clear, therefore, that grommet materials having a high water absorption capability, such as the nylons, will readily transmit external relative humidity increases to the creepage zone in the seal area. Such materials should be protected from high RH conditions to maximize their utility as seal materials particularly when exposed to humid environments.

Based on the above observations, a method was developed to coat alkaline button cells with moisture-retarding barriers. As a simple example of the efficacy of such treatments, we coated experimental[1] cells with Saran (vinylidine chloride-acrylonitrile copolymer) as shown in Fig. 8. Saran was chosen for its known low water vapor (0.10 g/100 in.^{2}/24 hr at 100°F, 90% RH 1 mil) and oxygen (0.1 cm^3/100 in.^{2}/24 hr at 1 atm pressure difference, 73°F, 1 mil) transmission characteristics and was applied from a ketone solution to the surfaces indicated in the figure. The results of tests conducted at 45°C and 100% RH on these experimental cells are presented in Table I. Uncoated cells have a nearly 100% leakage condition after 22 days compared to an approximate 30% frequency after 42 days on coated cells.

The nature of the metal along the seal path.—The rate of creepage of alkaline electrolytes along a potentiostated copper strip is faster than that observed along a nickel alloy strip (*e.g.*, Inconel 600) under the same conditions. The reverse situation is observed in a cell environment where there is a grommet under high compression contacting the metal surface. The reason for this discrepancy lies in the fact that, in an actual seal situation, there is a low electronic resistance combined with a high ionic resistance in the creepage layer itself. Consider the arrangement depicted in Fig. 9 which shows a copper electrode electronically and ionically shorted to a strip of zinc ($R = 0$, $I = 0$). Under these conditions, the copper strip is held at the zinc potential of ~ -1.38V (Hg-HgO) and very rapid creep will occur along the copper strip. In an actual double top cell, one may have several different metal surfaces in the seal area, *e.g.*, Cu and Inconel, which, as shown in Fig. 10, are shorted electronically to the zinc. On the other hand, although KOH is quite conductive, they are not shorted ionically to the zinc since the creepage film between the grommet and the metallic surface is extremely thin and has, therefore, a substantial ionic resistance. A correct experimental simulation of an actual cell condition would be to utilize frits of different porosity interposed between the zinc and copper strips as shown in Fig. 9 where $R = 0$ and I has a finite value thereby introducing a solution resistance between them equivalent to that of the creepage film.

[1] The cells chosen for this study employed no sealant in the grommet area, as is normally practiced in commercial production, and were therefore highly susceptible to leakage.

Table I. Leakage characteristics of RW-44 control and Saran-coated cells as a function of time at 45°C and 100% RH

	Days at 45°C, 100% RH					
	7	14	22	28	35	42
Control cells* % leaking	20	40	93	100	100	100
Saran coated* % leaking	0	0	7	7	26	30

* Without commercial sealant applied to production cells.

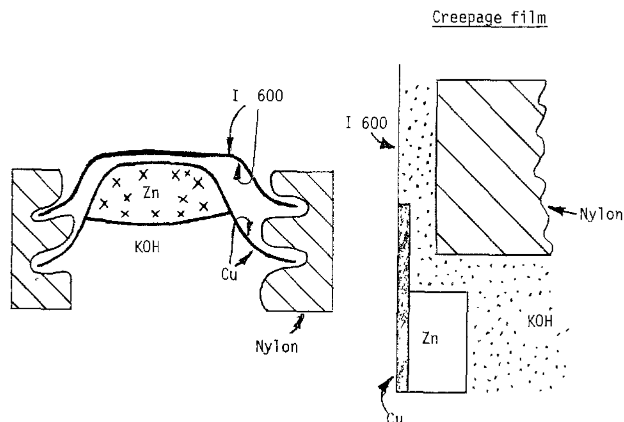

Fig. 10. The shorted electronic path and resistive ionic path established in the seal area of a button cell.

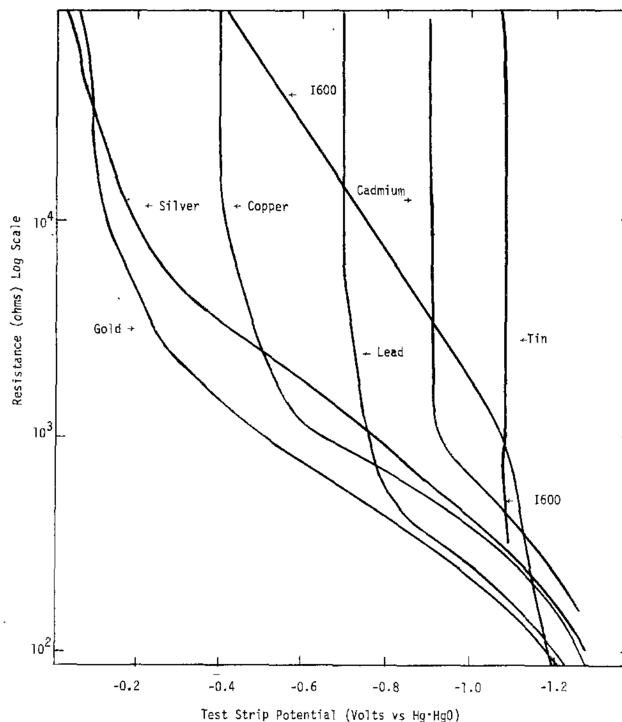
It is evident that if the frit resistance was infinitely large (corresponding to an extremely tight compressive fit of the grommet to the metal surface) then the Cu electrode would be unaffected by being electronically shorted to the zinc and would adopt its own electrode potential of ~ −0.42V (nearly one volt less negative than zinc). In the real case, the electrolyte resistance is not infinitely large so the question raised is, How does the magnitude of the negative electrode potential impressed in the seal area by the zinc vary with the nature of the metal substrate in the seal area and the ionic resistance in the creepage film?

This question was investigated for a series of metal substrates by ionically shorting a large zinc sheet to a one-tenth the size sheet of the metal and adding an electronic resistance between the two, *i.e.,* R has a finite value and $I = 0$ in Fig. 9. The metal strip will come to the same value of potential regardless of whether R is in the electronic loop as a resistor or in the ionic loop as a porous frit of impedance I. The potential of the test strip was measured as a function of R and the trends are shown in Fig. 11a for an argon atmosphere and in Fig. 11b for an atmosphere of air. The trends indicate that if a high compression seal is established thereby increasing the ionic resistance of the creepage film and the grommet has low permeability to oxygen, then the more noble the metal, the lower will be the negative potential in the seal area and hence the lower will be the creepage rate. Under these conditions, a gold-plated surface would most likely be the optimum condition. In contrast with grommet materials having low compressions or having a moderate to high permeability to oxygen, a copper (or copper plated-surface will have



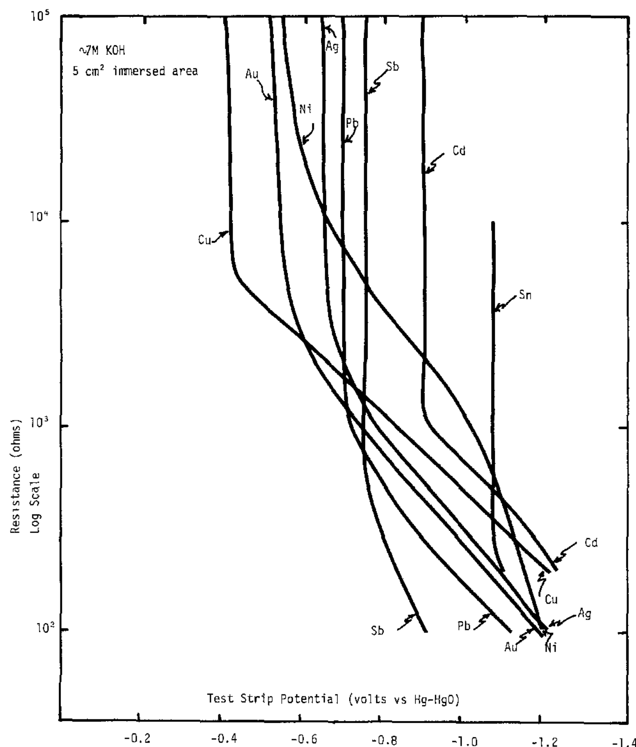


Fig. 11. The electrode potential established at different metal strips when ionically shorted and electronically connected through a resistance *R* as a function of *R* in the presence of (a, upper) argon and (b, lower) air.

the greatest ability to hold the potential in the seal area at the least negative potential.

Electrolyte additives to reduce creepage.—Gelling agents.—Increase in the viscosity of an alkaline electrolyte would generally be expected to reduce the creepage rate (2). Somewhat surprisingly in our study of the viscosity dependence of the creepage rate, we found that the structure and hence the wetting tendency of the gelling agent itself may override the viscosity effect. Thus as Table II shows, Na CMC and Guar Gum both have a tendency to accelerate creepage while with acrylic acid-acrylic ester copolymers the opposite effect is observed. Although

Table II. Effect of 3% sodium carboxy methyl celluose, 3% Guar Gum, 3% acrylic acid acrylic ester copolymer on the creepage rate of 35% KOH along nickel strips held at −1.05V vs. Hg · HgO. Also shown is the effect of saturating 35% KOH with barium hydroxide.

Electrolyte	Mean creepage height (cm) Fini	Solid	
Blank 35% KOH	0.89	0.46	Test chamber No. 1
35% KOH with 3% NaCMC	1.37	0.61	Test chamber No. 1
Blank 35% KOH	1.04	0.64	Test chamber No. 2
35% KOH with 3% Guar Gum	1.5	0.65	Test chamber No. 2
35% KOH with 3% acrylic acid-acrylic ester copolymer	0.91	0.52	Test chamber No. 2
Blank 35% KOH	0.97	0.68	Test chamber No. 3
35% KOH saturated with $Ba(OH)_2$	0.85	0.52	Test chamber No. 3

we have not as yet completed a definitive study of this observation, we believe that while Guar Gum and Na CMC increase the electrolyte viscosity, they tend to reduce the wetting angle of the electrolyte to the metal surface thus increasing the area of the reaction zone.

Effect of the addition of Group II A cations.—Since the electrochemical reduction of oxygen has a marked influence on the rate of alkaline creepage, it would appear reasonable to expect that electrolyte additives which could increase the overvoltage for oxygen reduction would help delay creepage. The Group II A cations are known to behave in this fashion and accordingly the effect of $Ba(OH)_2$ additions to a potassium hydroxide electrolyte were investigated. Table II shows that a reduction in the rate of creepage does result though the magnitude of the effect is relatively small. Several other di- and multivalent cations were tested including Sr^{++}, Ca^{++}, La^{+++}, and Ce^{4+} but, in each case, the solubility of the hydroxide was too low in 35% KOH to produce an effect.

Transfer of positive leakage to the negative terminal.—In this and the preceding paper (1) the discussion has centered on the problem of leakage appearing on the negative terminal of alkaline cells due to factors specific to the negative electrode-electrolyte interface. However, under certain conditions we have observed that a poor positive seal can cause the appearance of "salting" on the negative terminal of the cell. This phenomenon is an interesting consequence of the electrochemical creepage mechanism and may be explained by migration of Na^+ or K^+ ions across the grommet from the positive seal point of leakage driven by electro-oxidation of the leaked electrolyte on the surface of the positive can according to reaction [3] and concurrent hydrogen evolution from the humidity layer adsorbed on the surface of the negative top as in reaction [1] or oxygen reduction according to the reverse of reaction [3].

To demonstrate this phenomenon twelve alkaline button cells were placed in a petri dish having the negative terminal facing up and 30% KOH was poured into the dish to establish a liquid depth of 1-2 mm. Of the twelve cells six had an open-circuit voltage of 1.6V while the remaining were constructed without the active ingredients and did not exhibit an OCV. In addition to the above 12 cells partially immersed in the KOH electrolyte, an additional six "live" cells were placed on a watch glass out of contact with the KOH. After several weeks in a controlled humidity environment the appearance of the cells is as shown in Fig. 12. It may be seen that the six "live" cells in contact with the KOH (6 o'clock position) became heavily encrusted with caustic over most of the negative terminal while the six "zero voltage" cells at the 12 o'clock position remained quite clear. In addition the six "live" cells under the same conditions of humidity, but maintained out of contact with the KOH, did not develop deposits on their negative terminals.

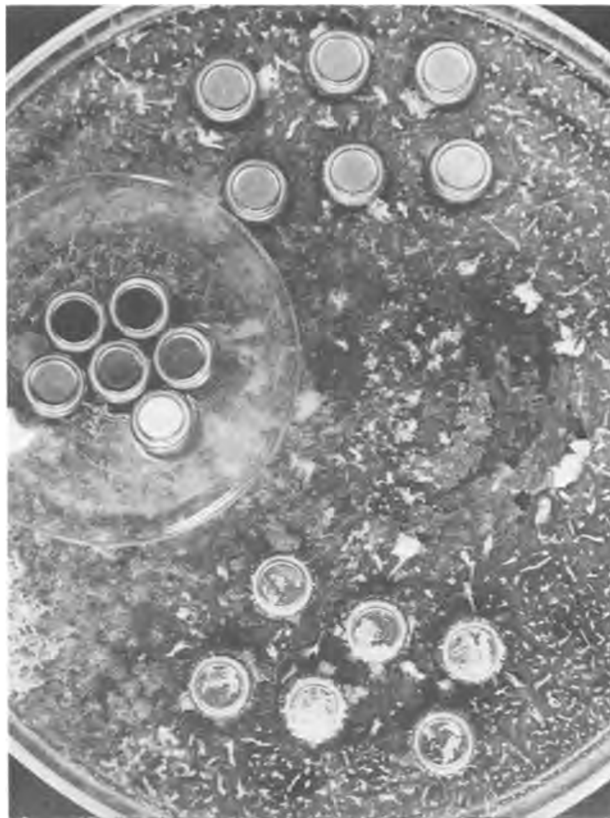

Fig. 12. Photograph illustrating the transfer of KOH electrolyte from the positive to the negative terminal of an alkaline button cell.

This demonstration is a clear illustration that electrolyte may be moved by electrochemical action from the positive to the negative terminal of an alkaline cell and confirms our observations that in such a cell the appearance of leakage on the negative terminal does not necessarily prove that such leakage has exited by way of the negative seal.

Manuscript submitted April 21, 1978; revised manuscript received June 30, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Electrochemical Heaters Utilizing Aluminum Alloy and Magnesium Anodes

S. Gilman* and P. Bramhall

U.S. Army Electronics Research and Development Command, Electronics Technology and Devices Laboratory, Fort Monmouth, New Jersey 07703

ABSTRACT

A short-circuited electrochemical cell made with a saline electrolyte, an aluminum alloy or magnesium anode, and a manganese dioxide cathode may be used as a rather efficient short-term portable heater. The use of a magnesium anode provides somewhat higher heat content but results in the production of considerable hydrogen gas. Certain aluminum-zinc alloys are almost as energetic as magnesium and produce little hydrogen.

If an electrochemical cell is short circuited, its chemical energy is almost completely converted into heat via the various ohmic and nonohmic polarizations occurring in the electrolyte at both electrodes. The heat from such an "electrochemical heater" may be largely transferred by thermal conduction to any material with which it is in intimate contact. One advantage of such an electrochemical heat source over a purely chemical (*e.g.*, thermite) one is that the reaction tends to proceed in a more gradual and controlled manner. Compared to the use of an electrochemical cell with a remote resistive heater, the direct electrochemical heater avoids the problem of inefficient transfer of energy from the cell which becomes particularly critical at high rates of cell discharge.

Electrochemical heaters utilizing aluminum and magnesium anodes and various cathodes have been developed for such applications as protective clothing, diving gear, and the heating of field rations (1-4). Magnesium-manganese dioxide cells with saline electrolyte are of particular interest in the last application where it is advisable to avoid toxic materials and where the service life of the heater is of the order of 15 min (4). One disadvantage of the Mg-MnO_2 cell is that a considerable volume of hydrogen is produced during discharge, presenting a potential explosion hazard. Our purpose in this work was to analyze the performance of the short-circuited Mg-MnO_2 cell and determine if similar but hydrogen-free performance could be obtained by substitution of an aluminum alloy for the magnesium.

Experimental

Preparation of electrodes and electrolytes.—Anodes.—The aluminum alloys for these studies were prepared by Reynolds Metals Company using procedures and heat-treatments similar to those previously reported (5). The alloys were prepared with high purity (99.992%) aluminum as a base; the aluminum was induction-melted, in air, in silicon carbide crucibles. All additions of pure metals were made at a temperature over 705°C and stirred to ensure homogeneity. The melts were treated with gaseous chlorine and then semicontinuously cast into ingots using an aluminum direct chill caster. The ingots were cleansed by scalping the surfaces. They were then heat-treated for homogenization and cold-rolled to a thickness of 0.04 cm. Pure aluminum used in half-cell studies was wire of 0.1 cm diam and 99.99+ purity (Alfa Inorganics). Pure magnesium for half-cell studies was 0.3 cm diam rod of "sublime" grade (Dow). The magnesium for whole-cell studies was "primary grade" (Dow) sheet of 0.028 cm thickness. For whole-cell ("electrochemical heater") experiments, 1 $\times$ 1 cm anodes were prepared from the appropriate sheet stock by fastening a nickel expanded metal screen (5 Ni 7 — 2/0 from Exmet Corporation) to the back side of the electrode using epoxy cement. The bonding was accomplished in a hydraulic press with heated platens (200 kg/cm^2 pressure at 135°C). A tab of screen was left on the sample and a heavy gauge tinned copper wire was soldered to it in such a way that no contact was possible between the solder connection and the electrolyte. Samples of flat stock metals used in half-cell experiments were prepared by pressure cementing a nickel foil contact to the top of a 0.5 $\times$ 2.2 cm coupon and then masking off the nickel contact with silicone rubber, leaving a 0.5 $\times$ 2.0 cm exposed area. Anode surfaces were degreased with trichloroethylene prior to use.

MnO_2 cathodes.—Electrodes were made, or obtained, with various formulations containing MnO_2, graphite, carbon black, graphite fiber, and current-collecting screens. Methods of preparation are reported below for four particular formulations.

(*i*) Electrodes of this formulation were developed (4) and supplied by Power Applications, Incorporated, Valley Stream, Long Island, New York. They were prepared by binding a mixture of MnO_2 (natural ore containing 74% MnO_2), carbon black (Cabot XR-72), and fullers earth (in the weight ratio of 10:2:1), with polytetrafluoroethylene emulsion, to a 20 $\times$ 20 mesh steel grid. The completed cathode was of 0.05 cm thickness and contained 0.035g of MnO_2 ore per square centimeter of electrode area.

(*ii*) This formulation was based on formulations reported by Kordesch (6). A mixture of MnO_2 ("chemical MnO_2 ore"), graphite powder, and carbon black (Shawinigan, 50% compressed) in proportions 43:5:1 was ball-milled for 2 hr. The mixture was then blended with fuller's earth and graphite fibers in proportions 100:5:1. The blend was then mixed with a 5% solution of Lucite in trichloroethylene (percentage of Lucite in final dry mixture was 2.5%), applied to an etched 20 $\times$ 20 gauge stainless steel screen, and air dried. The completed electrode contained 0.07g of MnO_2 ore per square centimeter of electrode area.

(*iii*) Electrodes of this formulation were developed (6) and supplied by Kordesch (Union Carbide Corporation). They were of similar formulation to the ones described in Ref. (2) above but utilized Tekkosha brand MnO_2, three times the graphite fiber content, and no fuller's earth. The finishing electrodes were 0.1 cm thick and contained 0.17g of MnO_2 per square centimeter of electrode area.

(*iv*) This formulation was prepared using the ball-milled mixture of MnO_2, graphite, and carbon black mentioned in fomulation (*ii*) above. The mixture was dry pressed into a porous nickel matrix (45 pore, 0.41 cm thick "Foametal" from Hogen Industries, Willoughby, Ohio) in a manner similar to that reported

* Electrochemical Society Active Member.

Key words: saline cells, manganese dioxide, corrosion.

previously (7). The final structure was 0.1 cm thick and contained 0.2g of MnO_2 per square centimeter of electrode area.

Electrical contact was made to the cathodes by welding a lead to a tab of exposed screen and insulating in such a way that contact between the lead and the electrolyte was avoided.

Electrolytes.—For experiments with complete flat cells ("electrochemical heater" experiments), the cell was assembled in the dry state, using 0.165 cm thick "Webril R-2801" (Kendall Mills) impregnated with NaCl (0.037 g/cm^2) to which water was added just before the experiment. The same electrolyte arrangement was used in the voltage-sweep experiments on cathodes. Experiments on fully immersed anodes and cathodes were performed using a solution of NaCl made by saturating distilled water with reagent grade salt at room temperature.

Procedures for making electrochemical and hydrogen-release measurements.—Electrochemical heater experiments.—Using a 1 $\times$ 1 cm anode and cathode, the cells were assembled in a gas-tight Lucite fixture of very small internal volume in which rubber pads maintained pressure on the cell components and acted as a heat sink. The temperature at the anode-rubber interface was monitored with a Chromel-Alumel thermocouple when desired. All the electrodes used in these experiments were fabricated with screens to which heavy current leads were soldered inside the Lucite fixture, and those leads were also useful in supporting and positioning the electrodes in the cell. The cells were fabricated using the salt-filled Webril electrolyte pad described above. The pad was left oversize at one end, and 0.3 cm wide strips of MnO_2 cathode [formulation (*i*)] were placed in the same planes as the anode and cathode with a 0.1 cm gap between each strip and the adjacent electrode. These served as "dry" reference electrodes for the adjacent anode or cathode. The recorded potentials were then converted to "potentials *vs.* the saturated calomel electrode," by subtracting 0.41V, which takes into account the typical open-circuit voltage of cathode formulation (*i*). The external connection between the anode and cathode was made by means of a calibrated 0.01Ω shunt through which the "virtual" short circuit current was monitored continuously by means of a strip chart recorder (Hewlett Packard No. 7100B). Simultaneous recordings were made of the anode and cathode potentials relative to their respective reference electrodes. The volume of hydrogen gas evolved from a cell was determined using a gas buret. The dry cell was activated just before use by flooding with water for 15 sec and then draining off the excess.

Measurement of anode polarization and hydrogen gas evolution in half-cells.—Anode polarization was studied using wire or 0.5 $\times$ 2 cm foil samples, prepared as specified above. The experiments were performed in a glass-stoppered, thermostated, (25°C) three-compartment cell with a reference saturated calomel electrode (SCE) and a platinized platinum counter-electrode (see Fig. 1). The electrolyte was a saturated solution of sodium chloride; 200 cm^3 of the electrolyte were required for the working electrode compartment and that volume was renewed after each determination. The polarization (current-potential) curves were recorded on an X-Y recorder (Hewlett Packard No. 7047A) while applying an anodic potential scan (speed of 0.001 V/sec) using a potentiostat (Tacussel No. P1T20-2A) and signal generator (Tacussel No. GSTP-2). The reverse sweeps were triggered manually after reaching a top current of 200 mA/cm^2.

Gas evolution was measured for similar anodes under constant-current conditions. The gas evolution measurements were accomplished by means of the glass mantle and bubble flowmeter arrangement shown in Fig. 1. The flowmeter was chosen of either

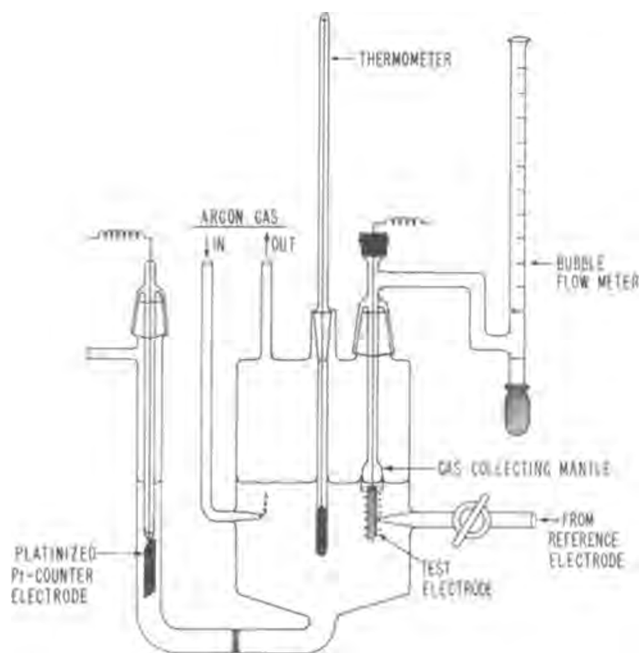

Fig. 1. Glass vessel for polarization and H_2 release measurements

1 or 10 cm^3 volume (depending on the anticipated rate of gas evolution) and the position of the bubble recorded at 1 min intervals. With the 1 cm^3 flowmeter, flow rates as small as 2.2 $\times$ 10^{-4} cm^3/sec (equivalent to an electrochemical H_2 evolution rate of 2 mA) could be read with 90% accuracy within 3 min after initiating the flow, and rates down to 1.1 $\times$ 10^{-4} cm^3/sec (1 mA) could be read accurately after 5 min. The accuracy was tested by generating H_2 at a platinum electrode (with 100% efficiency). The 3 and 5 min delay intervals cited above probably correspond to the very slight lowering of the electrode meniscus (the buildup of gas pressure) required to overcome inertia of the soap film in the bubble flowmeter.

Measurement of polarization and hydrogen evolution of fully immersed cathodes in half-cells.—The procedures used for studying MnO_2 cathodes in an excess of saturated NaCl solution were identical to those described directly above for anodes, except for the type of signal impressed on the cathode. In this case, a preselected constant potential was applied to the electrode ("potential-step" method) and the resulting current-time trace was recorded on a strip chart recorder (Hewlett-Packard No. 7100B). A fresh sample of electrode was required for each new potential imposed. Hydrogen gas is evolved at a MnO_2 electrode at sufficiently negative potentials. The rate of gassing was measured under "potential-step" conditions for cathode formulation (1).

Measurement of polarization at cathodes using an electrolyte pad.—For purposes of fast "screening" of new electrolyte formulations, polarization curves were measured using a cathodic potential sweep. Since many of the electrode formulations were found to give better results when mechanically compressed (thus improving contact between the MnO_2 and the current collector), such experiments were performed using the salt-impregnated Webril pad described above, and a Mg "counterelectrode" in an arrangement similar to that described above for "electrochemical heaters."

Results and Discussion

Thermodynamic considerations.—Table I presents the reaction equations and corresponding thermodynamic quantities for the chemical processes antici-

pated in Mg and Al cells utilizing MnO_2 cathodes (8, 9). The standard enthalpy, $\Delta H°$, the standard free energy, $\Delta G°$, those latter quantities divided by the number of equivalents ($\Delta H°/n$ and $\Delta G°/n$), and the standard cell potential $E°$ were calculated using standard enthalpies and free energies of formation (9). Reaction equations for cells 1 and 3 of Table I correspond to coulombically efficient utilization of both plates of each cell. The equations for cells 2 and 4 are for the reactions producing hydrogen. The hydrogen may be produced at either the anode (corrosion) or the cathode (cathode gassing). The most relevant quantities for heat-production purposes are the enthalpies rather than the free energies. Furthermore, reference to the values of $\Delta H°/n$ is useful if we wish to compare the reactions for the same "internal current" of the cell. Since the values of $\Delta G°$ and $\Delta H°$ are almost identical, the values of $E°$ are almost as valid for purposes of comparison as those of $\Delta H°/n$. From the values of $E°$ we may, therefore, conclude that, for identical cell "internal current" and with no hydrogen evolution, the Al/MnO_2 cell is 12% less energetic than the Mg/MnO_2 cell. On the other hand, much of the total "internal current" of the present Mg cell is directed into the far less efficient hydrogen evolution reaction (reaction No. 2, Table I) If this reaction were eliminated, it could more than compensate for the 12% loss.

Thermodynamic reduction potentials for the individual electrode reactions under consideration here are reported in Table II and are discussed later. The standard potentials listed in the table were obtained from Pourbaix's atlas (10).

Polarization and hydrogen gas release at the anode.—In order to best reflect "practical" conditions, anode surfaces were merely degreased and dried before use. Alternative sandpapering of the anode was found to shift polarization curves to more cathodic potentials without changing the relative positions of the various alloys on the potential axis.

For the purpose of screening of a large number of samples, it was convenient to measure anodic polarization using a linear anodic potential sweep. The samples of 2 cm^2 area were fully immersed in a large volume of saturated NaCl solution thermostated at 25°C. The traces of Fig. 2 were obtained by starting at the respective rest potentials and sweeping toward positive potentials at a speed of 0.001 V/sec. Return sweeps

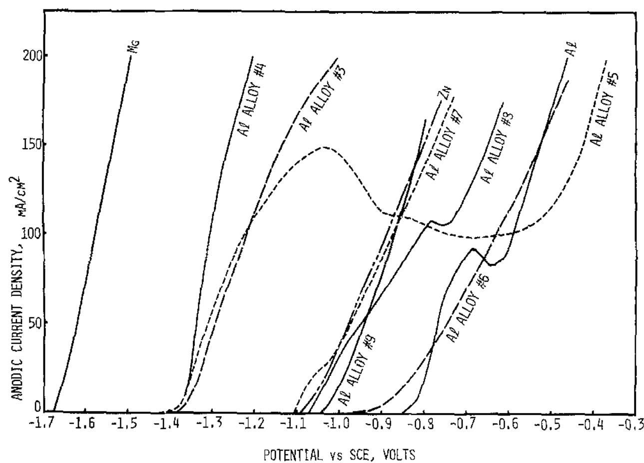

Fig. 2. Anodic polarization curves for several pure metals and aluminum alloys in saturated NaCl solution at 25°C. Alloy compositions are given in Table III.

(in the cathodic direction) were obtained after interrupting the anodic sweep manually at the approximate 200 mA/cm^2 level and then sweeping in the cathodic direction; the resulting traces appear in Fig. 3. A comparison of Fig. 2 and 3 reveals some hysteresis for all of the samples studies. The return sweep for Mg was very similar to the positive-going sweep and is not shown in Fig. 3. The rather pronounced hysteresis for aluminum and its alloys is not surprising considering the fact that aluminum is always covered with a film of γ-Al_2O_3 in near-neutral solutions (5), and that its electrochemical properties depend on the condition of that film, which, in turn, depends on the previous history of the electrode. The behavior of any of the samples, as an electrochemical heater anode, may be expected to fall somewhere between the anodic and cathodic traces, since in such use the current densities are initially high and then undergo gradual decline.

For measurements of hydrogen evolved by the anode samples, it was convenient to impress the various constant current levels listed in Table III. Measurements were made at 1 min intervals for a total of 8 min at each increasing current density. Table III pre-

* Percentage H_2 evolution = $100\, I_{H_2}/(I + I_{H_2})$.

sents the hydrogen evolution rate as a percentage of the total current at the anode after converting the gassing rate to an equivalent current density, I_{H_2}, by using the formula

$$I_{H_2} = 2 \cdot \frac{\Delta V}{\Delta t} \cdot \frac{\mathbf{F}}{22.4} \qquad [1]$$

Where $\mathbf{F}$ is the Faraday constant and I_{H_2} is obtained in amperes/cm^2 if the gas flow, $\Delta V/\Delta t$, is expressed in liters per second per square centimeter of electrode area.

For current densities of 20 mA/cm^2 or higher, the gassing rates were found to stabilize after 2-3 min and the values given are average values for the last 4-8 min of observation. Since direct calibration revealed that a 2-3 min lag is inherent in the flowmeter used for the measurements, no conclusions may be drawn about intrinsic transient behavior of the system in that early period. For the alloys possessing low rates of gassing, the method was not sufficiently sensitive for observations to be made in the allotted time at the lowest current densities.

Referring to Fig. 2 as a guide to the relative anodic behavior of the various anode materials, we see that the polarization of the alloys falls into the approximate 1V span between Mg and pure Al, with the latter the more inactive material and with both operating much below their respective thermodynamic potentials, as listed in Table II. A trace for a Zn electrode is incuded for comparison, although the energy content of Zn is too low for practical consideration. A general pattern of behavior emerges for the alloys if the high current performance of alloy No. 5 is ignored. Those alloys (No. 3, 4, and 5) containing Sn produce the most negative (active) closed-circuit voltages. This is in agreement with observations (5, 11) made during long-term corrosion studies on aluminum alloy/steel couples. It is believed (11) that Sn fosters the high anodic activity by producing cation vacancies which reduce the ionic resistivity of the γ-alumina film. This film normally covers the electrode during use. Additions of Mg and Ga enhance this effect by stabilizing the solid solubility of the Sn in the alloy (12). The H_2-evolution characteristics of alloys No. 3-5 tend to be somewhat better than that of pure Al, particularly at the high current densities, and like Al, are a 2-3 fold improvement over Mg in that regard. A second grouping of Al alloy polarization traces fall between the trace for pure Al and pure Zn (Fig. 2). Alloys 6-9 contain increasing amounts of Zn, and their closed circuit voltages, in line with previous experience with Al-Zn alloys (11), tend to become increasingly more negative and approach the performance of a pure Zn anode. There is, however, no simple correlation between electrode polarization and hydrogen evolution for this series of alloys, if the results of Fig. 2 and Table III are compared. Specifically, alloys No. 7 and 9 have the same Zn content and show very similar polarization behavior, but in spite of these facts alloy No. 7 produces the lowest amount of hydrogen while hydrogen production for alloy No. 9 falls in the same range as for pure aluminum. The fact that alloy No. 8, like alloy No. 7, is also a low gas producer, suggests that indium is more significant than Mg in imparting the nongassing properties to those alloys. Before considering how alloying affects hydrogen evolution, let us consider the thermodynamics of the process. For gassing to occur at all, the electrode potential must be more negative than the thermodynamic value for a reversible H_2 electrode in the same medium. According to Table II, that potential

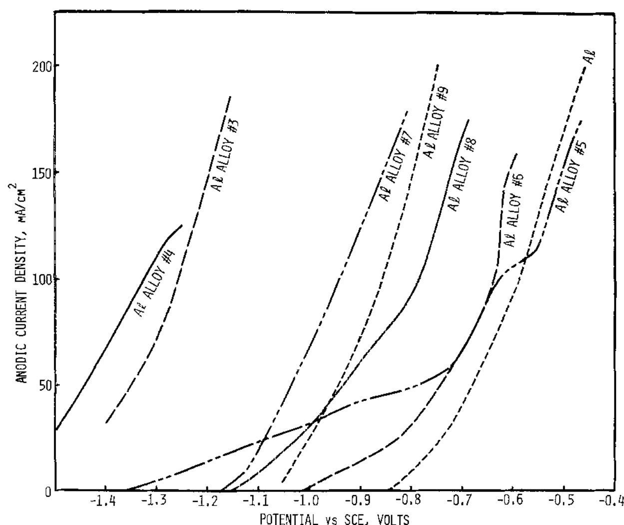

Fig. 3. Anodic polarization curves for several pure metals and aluminum alloys in saturated NaCl solution at 25°C. The curves were obtained after reversing the linear potential sweeps of Fig. 1.

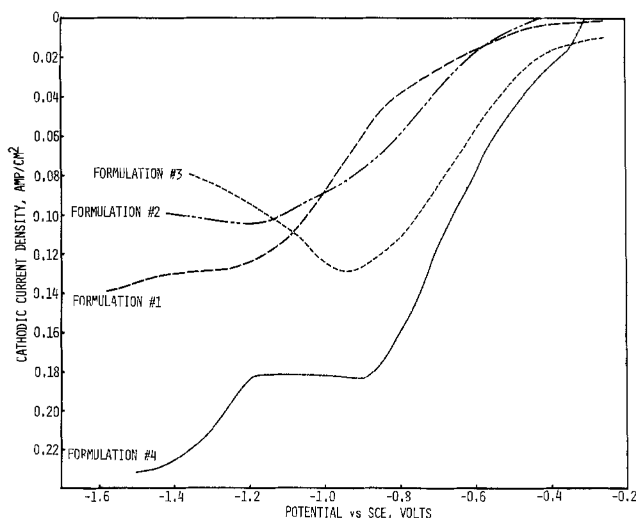

Fig. 4. Cathodic voltage scans of various MnO_2 cathodes. The electrolyte was NaCl solution in a Webril Pad.

could be $-0.650V$ in the original neutral solution and $-0.591V$ at steady state, with the solution completely equilibrated and saturated with hydrated γ-aluminum oxide. Based on those numbers, gassing would not be expected on pure Al or on alloy No. 6 at the higher current densities. However, localized, very low pH values may be expected near the anode surface, particularly at high current densities, corresponding to the production and hydrolysis of $AlCl_3$. For example, based on the reported value of $pKh = 4.9$, the pH of a 1M solution of $AlCl_3$ would be 2.45 and the corresponding reversible H_2 potential would be -0.38, sufficiently positive to account for H_2 evolution on Al and all of its alloys in a sodium chloride electrolyte solution. As for Mg, Table III reveals that the percentage of hydrogen evolved does not generally or systematically drop as the current is raised and the potential approaches that of the reversible H_2 electrode ("negative difference effect") (13). As for Mg, therefore, it may be hypothesized that H_2 release occurs on a very limited, momentarily film-free fraction of the surface. In line with that concept, the role of indium in a Zn-Al alloy could be to modify the physical structure of the film (*e.g.*, adherency, coherency, porosity) so as to minimize exposure of bare surface to the electrolyte.

We shall now turn to the problem of choosing the "best" anode material for an electrochemical heater. From the point of view of lowest H_2 production, Table III reveals that alloy No. 7 appears to be the best choice, with No. 8 a close second choice. Assuming that the solid product of reaction is γ-alumina for both Al and all of the Al-rich alloys, the total heat produced per equivalent of Al consumed in short-circuited cells utilizing any of those anodes and a MnO_2 cathode should be greater for the alloys producing the least H_2 (since reaction 3 of Table I is more energetic than reaction 4). So far, the analysis has been based on thermodynamic and corrosion data only. The role played by anode polarization is discussed later.

MnO_2 cathode polarization and gas evolution at the cathode.—The polarization of a manganese dioxide cathode at high rates of discharge is much more time dependent than that of the Mg and Al anodes with which it might be used. Because of the strong time-dependence, measurements of polarization performed at fixed potential provide the most quantitative guide to performance of the electrode in an electrochemical heater. For this purpose, electrodes of formulation No. (i) measuring 1×1 cm were individually immersed in a saturated solution of NaCl. The area of each sample is taken as 1 cm^2 despite the fact that both sides are exposed, since the bulk of the porous cathode is utilized rather than its surface (the reverse is true for anodes). For each sample, a different fixed potential was applied and the current-time trace recorded. Points taken from the traces are plotted on Fig. 5. From the figure it can be seen that, for time durations at constant potential of less than 1 min, the current tends to increase with decreasing potential. For longer time durations, a plateau value occurs in the lower potential range. A second rise in current follows the plateau at decreasing potentials. The results can be interpreted as follows, based on the observation (14) that the cathodic reduction of MnO_2 tends to be diffusion-controlled soon after the beginning of the process:

(i) At short elapsed time, including up to 12 sec, the reduction is only partially diffusion limited and hence shows considerable potential dependence over the whole potential range.

(ii) After sufficient charge has passed, the reduction process becomes solid state diffusion controlled and, therefore, exhibits a current plateau. Referring to the 1 min points, a plateau is evident from -1.0 to $-1.5V$. At less cathodic potentials than $-1.0V$, the

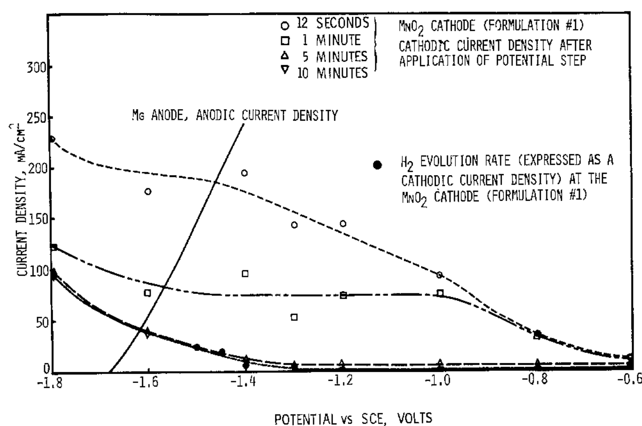

Fig. 5. Polarization behavior of fully immersed Mg anodes and MnO_2 cathodes [formulation (i)] in saturated NaCl solution.

previous activation-controlled current was not sufficiently high to result in diffusional control after 1 min. At more cathodic potentials than $-1.5V$, the current rise is due to electrolytic evolution of H_2.

(iii) As the reduction time increases, diffusional control extends to less cathodic potentials, and the onset of H_2 evolution is more easily distinguished (potentials as positive as $-1.3V$).

To confirm that hydrogen is evolved at the more cathodic potentials, a sample of electrode was first prepolarized at $-1.4V$ for 10 min. The potential was then adjusted to any desired value and gas evolution was measured. The gas evolution rates (measured at 100 sec intervals) were found essentially time independent, as might be expected for an electrocatalytic process. Average rates, converted to currents by means of Eq. [1], are plotted on Fig. 5. The results reveal that H_2 evolution is measurable at $-1.3V$ and it accounts for virtually all of the cathodic current at more cathodic potentials after a few minutes of polarization. The reversible potentials (*vs.* a saturated calomel electrode) of the two processes, which may occur at the MnO_2 cathode, appear in Table II (*i.e.*, a and b). The expressions for the standard potentials were taken from Ref. (10). The pH of the NaCl electrolyte should be 7.0 initially, and should eventually reach 10.45 when thoroughly mixed and saturated with $Mg(OH)_2$ (10). In addition, transient high and low values of pH at the cathode and anode, respectively, are likely during high current surges. Since the reversible potentials from Table II for reaction a at pH's 7 and 10.45 are quite positive, it is apparent that MnO_2 (Fig. 5) is being reduced irreversibly and that improved reduction kinetics would shift the curve to the right on the potential axis. For the H_2-evolution process (reaction b, Table II), it can be seen that gas evolution could begin at potentials as positive as $-0.65V$. The observation that no appreciable gassing occurs until $-1.3V$ largely reflects the fact that carbon (which is present for its electronic conduction properties) is a poor electrocatalyst for the hydrogen evolution reaction.

From Table II it can be seen that the reversible potential of the MnO_2 electrode is $+0.364V$ in the originally neutral solution used here as the electrolyte. Variations in pH during cell discharge can be expected to affect the reversible potential by only a few tenths of a volt. In spite of this, "formulation No (i)" begins to deliver appreciable cathodic currents at potentials over a volt more cathodic than the reversible potential. Such irreversible performance is subject to improvement through structural modifications which decrease internal impedances and improve mass transport in the electrode. Toward that end, a number of different electrode formulations were made for evaluation. These formulations included variation in: (i) the amount of carbon and graphite added for contact between MnO_2

particles; (*ii*) nature of the organic binder (*e.g.*, PTFE, Lucite, polysulfone); (*iii*) addition of agents to increase wetting and porosity (*e.g.*, fuller's earth) nature of the current collector (*e.g.*, screens and expanded metal made of steel and nickel), and (*iv*) the addition of graphite fibers to improve current collection.

For evaluation of samples, the potential-step method, as used to obtain the data of Fig. 5, provides the most in-depth information, but requires multiple samples and is tedious. Therefore, for the present purpose of fast screening, the linear potential sweep method requiring only one sample for a determination was used instead (sweep speed of 0.001 V/sec). Samples of 1 × 1 cm dimensions were discharged against a Mg counterelectrode using a NaCl-impregnated Webril separator pad as the electrolyte. Some of the more promising results appear in Fig. 4. Formulation No. (*ii*)-(*iv*) all offer the promise of improved performance at more positive potentials as compared with formulation No. (*i*). All three improvements utilize graphite fiber additions. Formulation No. (*ii*) and (*iii*) were made with a steel screen current collector, while No. (*iv*) was made with a "foametal" current collector. While cathode performance increases on progressing from formulation No. (*i*)-(*iv*) so does the MnO_2 loading (0.035, 0.07, 0.17, and 0.2 g/cm^2 for electrodes 1, 2, 3, and 4, respectively). Hence, the improvement represents successful utilization of more MnO_2, rather than a fundamental improvement in the kinetics of MnO_2 reduction. From Fig. 4, formulation No. (*iv*) would appear to be the obvious choice for further development. Its vulnerability, however, lies in the fact that Ni is a rather good catalyst in the H_2 evolution reaction. The descending portion of the scan from −1.2V to more cathodic potentials corresponds largely to extensive gas production, which is significant even at more positive potentials. An electrochemical heater using that formulation was nevertheless evaluated and the results are reported in the section below. Formulation No. (*iii*) appears clearly superior to formulation No. (*i*) without an aggravated gas evolution problem, and its further evaluation is also reported in the section below.

Electrochemical performance and hydrogen release at a short-circuited Mg-MnO_2 cell.—The behavior of a "heater" utilizing a Mg anode will serve as an example of the more general case. The results appearing in Fig. 6 were obtained for a cell containing a 1 × 1 cm anode and cathode and a salt-impregnated Webril separator. The "virtual" short-circuit current (across a 0.01 Ω load) density and the individual electrode potentials (referred to a saturated calomel electrode) were recorded after activating the cell by flooding with water for 15 sec and then draining off the excess water. The volume of hydrogen released was measured periodically and converted to an equivalent current density, I_{H_2}, using Eq. [1]. I_{H_2} includes a contribution from both the anode and cathode. The initial large values of I_{H_2}, paralleling the large values of I_{sc}, correspond mainly to hydrogen release at the anode, whereas the longer-term smaller values of I_{H_2} correspond to cathodic release of hydrogen as is discussed below. For the early large currents, the areas under the two curves are approximately measures of the number of equivalents of Mg reacting according to the equations in cells 1 and 2, respectively, of Table I. The initial high surge of current is useful for providing rapid heat transfer. By minimizing the masses of the ingredients, practical cells (4) transfer most of the available enthalpic heat to the object being heated.

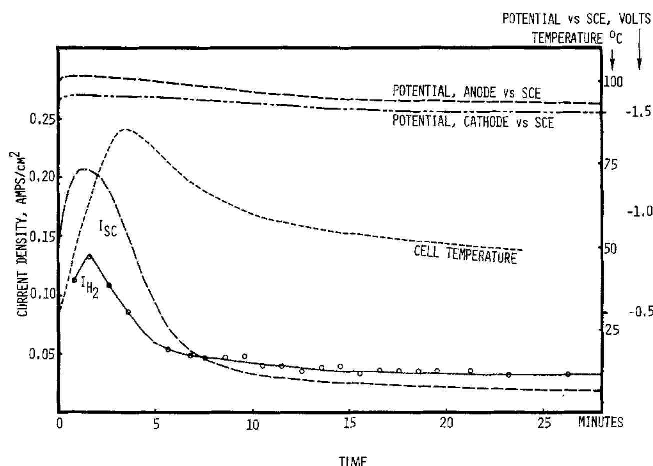

Fig. 6. Operating characteristics of an instrumented Mg/MnO_2 electrochemical heater [cathode formulation No. (*i*)].

Although the respective experimental conditions are somewhat different, the electrode polarization results of Fig. 5 are useful in qualitative interpretation of the results recorded in Fig. 6. For a short-circuited cell consisting of the anode and cathode of Fig. 5 and with negligible electrolyte resistance, the short-circuit current and electrode potential at any instant are determined by the point of intersection of the Mg anodic polarization curve with the appropriate MnO_2 cathodic polarization curve. The intersections of Fig. 5 predict a drop in current from the 200 mA/cm^2 level in the first 12 sec, to below the 50 mA/cm^2 level in 10 min, with that sharply declining current attributable entirely to cathode polarization. The long-term currents (according to Fig. 5) are supported almost entirely by hydrogen evolution. Finally, Fig. 5 predicts a moderate shift in the electrode potentials to more cathodic potentials, conforming to the shape of the anodic polarization curve. This predicted shift occurs during the first few minutes for the more complicated conditions of Fig. 6. The unanticipated long-term positive drift of potentials probably corresponds to electrode polarizations due to the limited volume and shifting pH of the electrolyte in the Webril pad in use here. The short-circuit current (I_{sc}) *vs.* time trace of Fig. 6 exhibits approximately the expected type of current decay after the current peak is passed. The initial rise in current probably corresponds mainly to the "voltage delay" phenomenon normally encountered (15) when a heavy load is first applied to the normally passive Mg anode.

A very significant conclusion based on Fig. 5 is that shifting of the anodic curve to the right would tend to eliminate H_2 evolution at the cathode, the latter being the major source of H_2 evolution after the first 10 min of cell operation.

With the help of Fig. 5, we can return to the problem of choosing the "best" Al alloy to substitute for Mg. In addition to the preference for the lowest corrosion rate, the polarization of the anode plays an important role in three important ways:

(*i*) The distribution of heat through the cell depends on the relative extents of anode and cathode polarization and of electrolyte resistance. For reasons of heat conduction it is best to place the work against the metallic anode and it is therefore beneficial to have the highest polarization (and temperature) at that electrode.

(*ii*) The rate of heat release is proportional to the current density. That rate (or current) depends on the points of intersection of the anode and cathode polarization curves, and will be highest for those anode polarization curves falling closest to that of Mg.

(*iii*) The anode polarization curve helps establish the working potential of the cathode at short circuit. The more positive the anode potentials (and the cathode working potential), the more likely will be the avoidance of H_2 evolution at the cathode. The latter has already been shown to be largely responsible for

longer-term gas evolution. Considerations (*i*) and (*iii*) suggest that the polarization curve of the anode should be as far as possible to the right of that of Mg (*e.g.*, the low-gassing alloy No. 7 of Fig. 2). The problem of lower current densities than for Mg [consideration No. (*ii*)] can be overcome by improvement of the cathode. Figure 5 suggests that other cathode formulations [No. (*iii*) and (*iv*)] might provide superior performance in an electrochemical heater utilizing aluminum alloys because of the significant shift of the polarization curve to the right on the potential axis.

Electrochemical performance and hydrogen release at short-circuited aluminum.—Alloy-MnO_2 Cells.— Figures 7-9 present results for short-circuited cells utilizing an aluminum alloy and three differently formulated MnO_2 cathodes. The plot of I_{sc} *vs.* time for the Mg-MnO_2 cell of Fig. 6 is included for comparison. Figure 7 confirms the expectation that relatively poor results can be obtained with an aluminum alloy anode if the cathode will not support high currents at the more positive potentials. Figure 8 reveals that an improvement in current densities over the Mg-MnO_2 cell can be achieved with an aluminum alloy if the MnO_2 cathode has improved performance at low overvoltages. As anticipated, I_{H_2} is much lower initially than for the Mg cell, corresponding to low corrosion of the alloy. Since the cathode now operates at relatively positive potentials, there is no significant evolution of

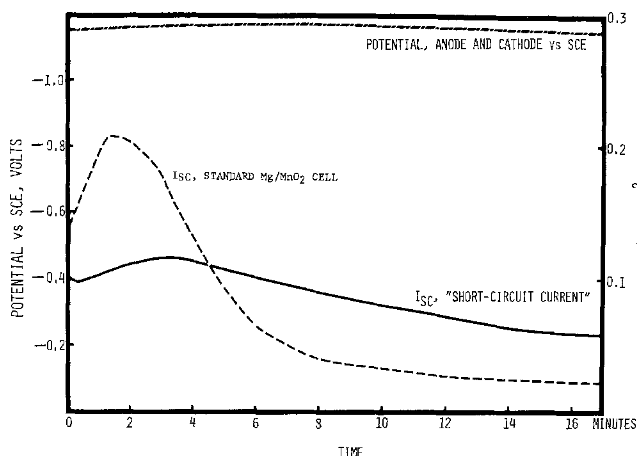

Fig. 7. Operating characteristics of an electrochemical heater made with an Al alloy No. 7 (4.19% Zn, 0.04% In, 0.46% Mg) anode and a MnO_2 formulation No. (*i*) cathode.

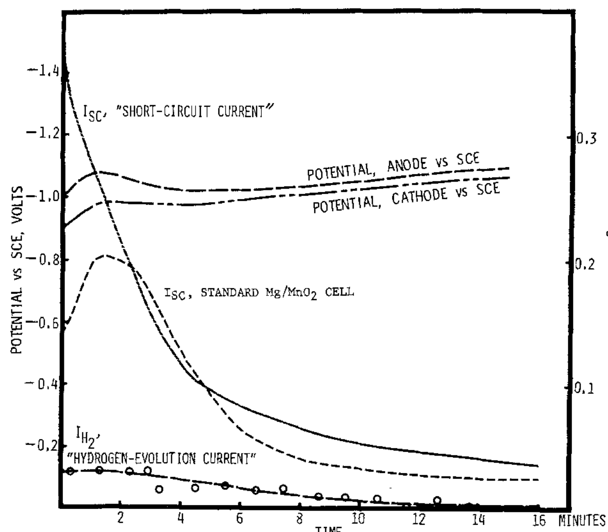

Fig. 8. Operating characteristics of an electrochemical heater made with an alloy No. 7 (4.19% Zn, 0.04% In, 0.46% Mg) anode and a MnO_2 formulation No. (*iii*) cathode.

hydrogen gas there. Hence, production of H_2 eventually drops to very low values parallelling the drop of cell current and rate of corrosion of the aluminum at the anode.

From Fig. 9, even more impressive short-circuit currents are obtainable using cathode formulation No. (*iv*), but I_{H_2} is unexpectedly high. It appears that this results from the use of nickel in the cathode formulation, resulting in catalysis of the hydrogen evolution reaction at both anode and cathode.

Conclusions

The nontoxicity and high enthalpic content of saline Mg-MnO_2 and Al-MnO_2 cells makes them useful as electrochemical heaters (short-circuited cells). The Mg cell provides high short-circuit currents (and rates of heat evolution) but produces H_2 at the anode (corrosion) and at the cathode (due to highly negative operating potential). Cells made with certain Al-Zn alloys also provide high short-circuit currents while producing little H_2 at the anode and virtually no H_2 at the cathode (latter due to relatively positive operating potential).

ABSTRACT

The irreversibility of the oxygen electrode reaction is the main cause of efficiency losses in water electrolysis cells, fuel cells, and some battery systems. At conditions typical for water electrolysis, the effectiveness of various metal oxide electrodes toward oxygen evolution decreased in the order Ru > Ir ~ Pt ~ Rh ~ Pd ~ Ni ~ Os >> Co >> Fe. Poor activities were observed on V, Cr, Mo, W, Mn, and Re oxide electrodes. When mixed with 70 mole percent (m/o) TiO_2, all metal oxides tested except ruthenium oxide were ineffective in catalyzing the oxygen evolution reaction. A catalyst-loading study showed that RuO_2 films on Ti require about 10^{-6} mole RuO_2/cm^2 to mask the effect of the titanium substrate. Either a chemical step or a second electron transfer step appears to be rate determining for the oxygen evolution reaction on oxide electrodes with good electrocatalytic properties. Studies of the oxygen reduction reaction indicate that the activity of oxide electrodes in the cathodic direction is considerably less than in the anodic direction.

The oxygen evolution and reduction reactions are of special importance in water electrolyzers, fuel cells, and in batteries using air cathodes since slow kinetics at these electrodes are the chief cause of efficiency losses in these devices. The ruthenium oxide electrode prepared by the thermal decomposition method is an attractive electrocatalyst for both the chlorine and oxygen evolution reactions (1-7). Electrochemical data for the evolution of oxygen on other dimensionally stable anode (DSA) materials is limited (5, 8-10). Since this investigation was prompted by an interest in improving the efficiency of water electrolysis, experimental conditions typical of commercial electrolyzers were selected (11). Therefore, all studies were made in 30 weight percent (w/o) KOH solutions at 80°C.

Experimental

Electrodes.—Titanium wire (99.7%, 0.8 mm, Alfa) was etched in 10% oxalic acid at 90°C for 1 hr. Coatings were applied by dipping the wire in a solution containing the metal chloride and then heating it in an electric furnace at 300°-500°C for 10 min. Six separate coatings were applied. After the final coating, the wire electrode was heated in the furnace for at least 30 min and then sealed into Teflon tubing. Tetrabutyl orthotitanate (practical, Eastman) was used to vary the mole fraction of a particular metal in the dipping solution.

Electrochemical measurements.—Studies of the oxygen evolution reaction were carried out under experimental conditions which approximate those encountered in practical water electrolysis cells. A one-compartment glass cell was used in which the reference and working electrodes were placed inside and below a cylindrical platinum screen counterelectrode in order to minimize the *IR* effect and any reaction with gas evolving from the counterelectrode. In each experiment, the KOH solution was slowly stirred magnetically. Potentials were always measured *vs.* a saturated calomel reference electrode (SCE).

Potentiostatic current measurements were made with the use of a Beckman Electroscan 30 instrument. Before each investigation of oxygen evolution, the highest anodic current used (about 100 mA/cm^2) was passed for about 5 min, and then current-potential relationships were determined in the direction of decreasing current.

For studies of oxygen reduction, oxygen gas (99.6% min, Linde) was introduced into the solution through a gas diffusion tube to produce a stream of very fine bubbles. Before each experiment, the diffusion-limited current density (10^{-4} A/cm^2) was passed for 5-10

min to build up a steady-state concentration of any peroxide intermediates. Measurements were then made in the direction of decreasing currents.

Results

The Tafel regions observed for the oxygen evolution reaction on Ru, Rh, Ni, Pd, Ir, and Pt oxide electrodes are shown in Fig. 1. For each electrode, the Tafel line shown represents the average as determined from at least three separate studies. Based upon previous studies, the reversible potential for the oxygen electrode is calculated to be 0.03V *vs.* SCE in 30% KOH at 80°C (11).

Table I represents the average values for the Tafel parameters and their standard deviations. Mean values for the experimental transfer coefficient (α) and exchange current density (i_o) are also shown. Experimental results for studies on Os, Fe, and Co oxide electrodes not included in Fig. 1 are found in this table. The small standard deviations show that the results were generally quite reproducible. Nickel oxide electrodes showed the greatest variation, hence six separate studies were made with this electrode. Single studies on V, Cr, Mo, W, Mn, and Re oxide electrodes were also made, but the results indicated poor electrocatalytic activity for the oxygen evolution reaction on these materials.

Table II gives the kinetic parameters for several metal oxide electrodes when mixed with TiO_2 to reduce the fraction of a particular metal oxide to 30 m/o. Comparing the results in Tables I and II, similar parameters are found only for the ruthenium oxide electrode. Results for all other metal oxide electrodes show much larger Tafel slopes and higher overvoltages when mixed with TiO_2.

The effect of varying amounts of TiO_2 mixed with RuO_2 upon the oxygen evolution reaction was also investigated. The Tafel parameters (Table III) show only slight changes as the RuO_2 fraction is decreased to 30 m/o, whereas significant changes occur when the mole fraction of RuO_2 is reduced further. The overvoltage measured at 20 mA/cm^2 showed a similar effect by gradually increasing from 280 mV at 100 m/o RuO_2 to 340 mV at 30 m/o RuO_2 and then showing a sharp increase at lower RuO_2 contents.

By maintaining the same dipping procedure in various dilutions of the original ruthenium salt solution (0.3M), the effect of various loadings of ruthenium oxide on the titanium substrate could be studied. The polarization curves obtained for these electrodes are shown in Fig. 2. The catalyst loadings (based upon apparent areas) ranged from 10^{-5} to 10^{-8} mole RuO_2/cm^2 according to gravimetric measurements. The Tafel slopes suggest that significant kinetic changes occur at loadings below about 10^{-6} mole RuO_2/cm^2 which make the electrodes much less effective for the oxygen evolution reaction. For example, the Tafel slope shows a sharp increase from 67 mV/decade ($\alpha = 1.0$) to 130 mV/decade ($\alpha = 0.5$) at catalyst loadings of 10^{-6} and 10^{-7} mole RuO_2/cm^2, respectively.

The metal oxide electrodes which showed good catalytic activity for oxygen evolution were also studied for oxygen reduction. Kinetic parameters for the electrochemical reduction of oxygen on Pt, Ir, Ru, Pd, and Rh oxide electrodes in 30 w/o KOH solutions at 80°C are presented in Table IV. Linear Tafel

Table IV. Average Tafel parameters with standard deviations for the oxygen reduction reaction in 30 w/o KOH solutions at 80°C

Metal oxide electrode	a/V	b/V	α_c	i_o/A cm^{-2}
Pt	−0.57 ± 0.05	−0.061 ± 0.009	1.1	4.5 × 10^{-10}
Ir	−0.60 ± 0.05	−0.061 ± 0.008	1.3	2.9 × 10^{-12}
Ru	−0.50 ± 0.01	−0.043 ± 0.004	1.6	2.4 × 10^{-12}
Pd	−0.49 ± 0.01	−0.042 ± 0.001	1.7	2.2 × 10^{-12}
Rh	−0.51 ± 0.01	−0.041 ± 0.002	1.7	3.6 × 10^{-13}

lines were observed at current densities between about 10^{-4} and 10^{-6} A/cm^2. A low limiting current (10^{-4} A/cm^2) for oxygen reduction is expected due to the low solubility of oxygen and its low diffusion coefficient in 30% KOH solutions (12).

Discussion

Most commercial water electrolyzers operate at high current densities using electrodes with large surface roughness factors. Improvements in either intrinsic catalytic properties or surface roughness factors contribute to a lower overvoltage, hence it is often difficult to isolate these effects. Burke *et al.* (6) have demonstrated the important role of surface area in the electrochemical behavior of RuO_2 electrodes. Both the preparation temperature and the catalyst loading cause remarkable variations in true surface areas for ruthenium oxide electrodes (6, 7), hence various studies suggest roughness factors ranging from about 1 to 1000 or even higher (3-7, 13, 14). A preparation method similar to this study involving six sequential coatings, 10^{-5} mole Ru/cm^2, and heating at 450°C yields a roughness factor of about 60-80 for the RuO_2 electrodes (14). Anodic studies on iridium and platinum oxide electrodes suggest similar roughness factors (2, 9).

For practical applications to water electrolysis, the Tafel parameter *a* in Table I would represent the experimental activation overvoltage at a high current density of 1 A/cm^2 based upon geometrical area. Using this criteria, the effectiveness of these oxide electrodes for oxygen evolution decreases in the order Ru > Ir ~ Pt ~ Rh ~ Pd ~ Ni ~ Os >> Co >> Fe. A previous study of oxygen evolution on various metals in 30% KOH at 80°C also indicated about equal activities for Ir, Pt, Rh, and Pd electrodes while Ni was slightly better (11). The much poorer performance of Co and Fe oxides might be due to their instability in alkaline solution during prolonged anodic polarization. The exchange current densities do not provide a useful comparison for this reaction due to the wide range of Tafel slopes observed for these oxide electrodes.

The significant decrease in the activity of RuO_2/TiO_2 electrodes when the ruthenium content is less than 30 m/o has been observed in other studies. Kuhn and Mortimer (2) report that i_o values for the chlorine evolution reaction decrease sharply below 30-40 m/o ruthenium. Veselovskaya *et al.* (15) found that the rate of oxygen evolution decreased with a drop of RuO_2 content and that the electrochemical properties of the anode were closely related to the phase structure of the oxide coating. They report that while a part of the TiO_2 forms solid solutions with RuO_2, the TiO_2 phase remaining increased greatly for Ru concentrations below 40 m/o. Comparing Tables I and II, it is apparent that at 30 m/o metal, the effect of TiO_2 dominates for all metal oxides tested except ruthenium. The loss of activity of titanium anodes coated with RuO_2 and TiO_2 probably results from the formation of a nonconductive oxide film at the Ti-active layer interface (16).

The catalyst loading effects (Fig. 2) show that the titanium oxide-like behavior towards oxygen evolution disappears with increasing amounts of ruthenium oxide. It seems that a loading of 10^{-6} mole RuO_2/cm^2 (0.1 mg Ru/cm^2) is required to mask the effect of the titanium substrate. Similar effects have been reported for other noble metal oxide electrodes (9, 17).

From the values given for exchange current densities shown in Tables I and IV, it appears that oxygen evolution and reduction occur on these oxide electrodes by different mechanisms. The i_o values are considerably lower for oxygen reduction than for oxygen evolution. This study, along with previous work (5), shows that oxide electrodes are good electrocatalysts for oxygen evolution but not for oxygen reduction. Oxygen reduction on ruthenium metal is also rather poor, probably due to strong affinity of ruthenium for oxygen (18). Studies of the chlorine electrode on RuO_2 and IrO_2 show that the activity of these oxides in the cathodic direction is considerably less than in the anodic direction (2). The investigation of several other reactions on RuO_2 electrodes indicates poor electrocatalytic features for those involving adsorption steps (13).

The anodic polarization characteristics of oxide electrodes such as the Tafel slopes depend strongly upon the preparation temperature and surface concentration of catalyst (7, 8). Experimental transfer coefficients for the oxygen evolution reaction on ruthenium oxide electrodes are usually either $\alpha \sim 1.5$ or $\alpha \sim 1.0$ (4, 5, 7, 19), whereas $\alpha \sim 2$ on ruthenium metal (18). In alkaline solutions the following oxygen evolution reaction path

$$OH^- \rightleftharpoons OH_{ads} + e^- \quad [1]$$

$$OH_{ads} + OH^- \rightleftharpoons O_{ads}^- + H_2O \quad [2]$$

$$O_{ads}^- \rightleftharpoons O_{ads} + e^- \quad [3]$$

$$O_{ads} + O_{ads} \rightleftharpoons O_2 \quad [4]$$

is suggested by previous studies (9, 20). Under Langmuirian adsorption conditions, the experimental transfer coefficient will be either 0.5, 1, 1.5, or 4 depending upon which step is rate determining. The results in Table I suggest that step [1] is rate determining on Co and Fe oxides, step [2] is rate determining on Ru, Rh, Pd, Ni, and Os oxides, and step [3] is rate determining on Ir and Pt oxides. Oxygen reduction in alkaline solutions usually occurs by a different mechanism which involves the formation of HO_2^- intermediates (4, 21).

Paste Mixing and Curing of Tetrabasic Lead Sulfate Plates for the Lead-Acid Battery

C. F. Yarnell*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A nonreactive paste of $4PbO \cdot PbSO_4$ is prepared by mixing the synthesized compound with water. On continued mixing with water, the $4PbO \cdot PbSO_4$ crystals become more closely packed. Water acts as a bulking agent and if mixed too long, water will separate from the paste. Low density pastes may be produced by adding more water and reducing the mixing time. Pasted $4PbO \cdot PbSO_4$ plates must be cured in an atmosphere containing CO_2. Curing may be accelerated by raising the temperature and enriching the atmosphere with CO_2. Previously dried plates may be cured in as little as 3 min in a steam-CO_2 atmosphere.

In previous papers (1, 2) we have discussed the formation, morphology, and cycle performance of positive plates pasted with $4PbO \cdot PbSO_4$ (tetrabasic lead sulfate). In this paper we discuss the preparation and properties of a $4PbO \cdot PbSO_4$ paste and the curing of $4PbO \cdot PbSO_4$ pasted plates.

A paste of $4PbO \cdot PbSO_4$ is prepared by mixing water with dried, synthesized $4PbO \cdot PbSO_4$ (3). Since this paste is nonreactive, its properties are quite different from a reactive, acid paste. An acid paste is usually prepared by mixing water, lead oxide, and sulfuric acid (4, 5). The properties of this chemically reactive paste and resultant plate are dependent on many factors such as relative proportions of materials, temperature, speed of addition of acid, drying atmospheres, and other (4, 5). Since the $4PbO \cdot PbSO_4$ paste is nonreactive, most of these factors do not affect its properties. The only relevant paste parameters for a $4PbO \cdot PbSO_4$ paste are the relative proportions of $4PbO \cdot PbSO_4$ and water, the length of time mixed, and, perhaps, the efficiency of the mixer.

Lead or lead-alloy grids are pasted with $4PbO \cdot PbSO_4$ and dried in air at 50% relative humidity and 26°C for 3 days (1-3). However, we have observed that when dried in these conditions for only 2 days, dried in a vacuum oven, or dried in nitrogen, the $4PbO \cdot PbSO_4$ pellets "popped" out of the grid when placed in H_2SO_4. Chemical analysis of the $4PbO \cdot PbSO_4$ showed that plates that did not disintegrate in acid contained about 0.2% more CO_2 than those plates that disintegrated. Thus we suspected that CO_2 was needed to cure the plates. This paper shows that $4PbO \cdot PbSO_4$ plates must be cured in an atmosphere containing CO_2 and at a relative humidity higher than 40%.

Key words: lead-acid battery, tetrabasic lead sulfate, battery plate curing.

Experimental

Paste mixing.—In the laboratory, small batches containing 900g of $4PbO \cdot PbSO_4$[1] were mixed using various amounts of water and mixing times. A Kent Mixer was used which has an inverted "U" shaped blade which rotates at 60 rpm about its axis of symmetry in a counterclockwise direction while the mixing pan rotates at the same speed in the clockwise direction.

Small Pb-Ca rectangular grids ($7.6 \times 6.3 \times 0.7$ cm), whose pasteable volume was 29.6 cm^3, were pasted with each batch so that the dried plate density could be calculated. A 32.8 cm^3 (2 $in.^3$) cup was used to measure the wet paste density. The consistency of the paste in the cup was measured with a penetrometer fitted with a cone supplied by the C&D Battery Company. The cone weighed 55.4g and had a conical angle of 50°. The paste and pasted plates were weighed wet and dry to give a measure of the porosity of the plate and paste. Data on six cups and six plates were taken and the results averaged for each batch.

Larger 45.4 kg batches of paste were mixed in a Ross planetary mixer. This mixer does a more efficient job of mixing than the small laboratory model described above. Samples of these large mixes were taken and examined with the SEM. Circular positive Pb grids (6) (31 cm diam $\times$ 0.63 cm) were pasted by a machine (7, 8) which had rollers that pressed the paste into the grid.

Curing.—To understand how the combination of CO_2 and relative humidity could effect the curing of a $4PbO \cdot PbSO_4$ plate, the amount of CO_2 adsorbed by $4PbO \cdot PbSO_4$ was measured as a function of relative humidity. Weighed samples of dried $4PbO \cdot PbSO_4$ were placed in a dessicator containing an atmosphere of

[1] Supplied by the Eagle Picher Company.

pure CO_2 and at various relative humidities obtained by placing different concentrations of H_2SO_4 in the bottom of the dessicator. The relative humidity was measured with a small hygrometer placed in the dessicator. After 24 hr, the samples of $4PbO \cdot PbSO_4$ were dried and weighed to determine the increase in weight due to CO_2 adsorption.

Results and Discussion

Paste mixing.—To make a paste from $4PbO \cdot PbSO_4$, the water used is measured out and added all at once with the mixer running. Initially the mix looks very dry (Fig. 1a). After mixing a short time the paste starts to form up into small spheres (Fig. 1b) and starts to take on a shiny, wet appearance. As mixing is continued the small spheres coalesce with each other to form larger spheres (Fig. 1c) and finally completely join together to form one large sphere of paste (Fig. 1d). On continued mixing the large coherent mass breaks up and sticks to the side and bottom of the container (Fig. 1e).

The above series of stages always occurs regardless of the amount of water used to make the paste or the size and efficiency of the mixer. What changes is the time it takes the paste to reach each stage. The photographs in Fig. 1a, b, c, d, and e were of a paste using 0.138 ml H_2O/g of $4PbO \cdot PbSO_4$. It took 6 min to reach the one sphere stage (Fig. 1d and Table I). If less water is added (see Table I) all of the stages occur at a slower rate. On the other hand when more water is added (see Table I) the different stages occur faster. As the amount of water is increased, it becomes difficult to separate the different stages because they occur so rapidly.

Table I. Pasting data for $4PbO \cdot PbSO_4$

H_2O/g (ml)	Mix time (min)	Average ± standard deviation		
		Penetration (mm)	Cube weight (wet) (g/cm^3)	Porosity of plate (%)
0.11	20.0	68 ± 3	4.560 ± 0.022	41.2*-44.2*
0.12	12.0	84 ± 2	4.404 ± 0.013	43.0-46.5
0.13	6.5	88 ± 2	4.216 ± 0.012	45.2-48.2
0.138	6.0	89 ± 4	4.156 ± 0.027	46.4*-49.9*
0.15	4.25	99 ± 6	4.026 ± 0.019	48.4*-51.6*
0.17	2.25	109 ± 2	3.800 ± 0.018	52.2-54.7
0.17	20.0	139 ± 8	3.910 ± 0.030	51.6-53.2
0.19	1.5	115 ± 5	3.621 ± 0.026	54.7*-57.2*
0.21	1.0	120 ± 8	3.481 ± 0.017	56.9-59.5
0.25	0.5	126 ± 8	3.253 ± 0.026	60.4-63.2
0.30	0.25	167 ± 14	3.042 ± 0.032	64.6-66.6

* Estimated value.

If a large quantity of water is added, the paste may pass into a final stage in which it becomes very liquid (Fig. 1f). As an example of this, when 0.17 ml H_2O/g of $4PbO \cdot PbSO_4$ is used, the Fig. 1b stage occurs after 1.25 min, Fig. 1d after 2.25 min, Fig. 1e at 5 min, and then for the remainder of the time (20 min), it was very liquid as in Fig. 1f. In this stage the paste is too

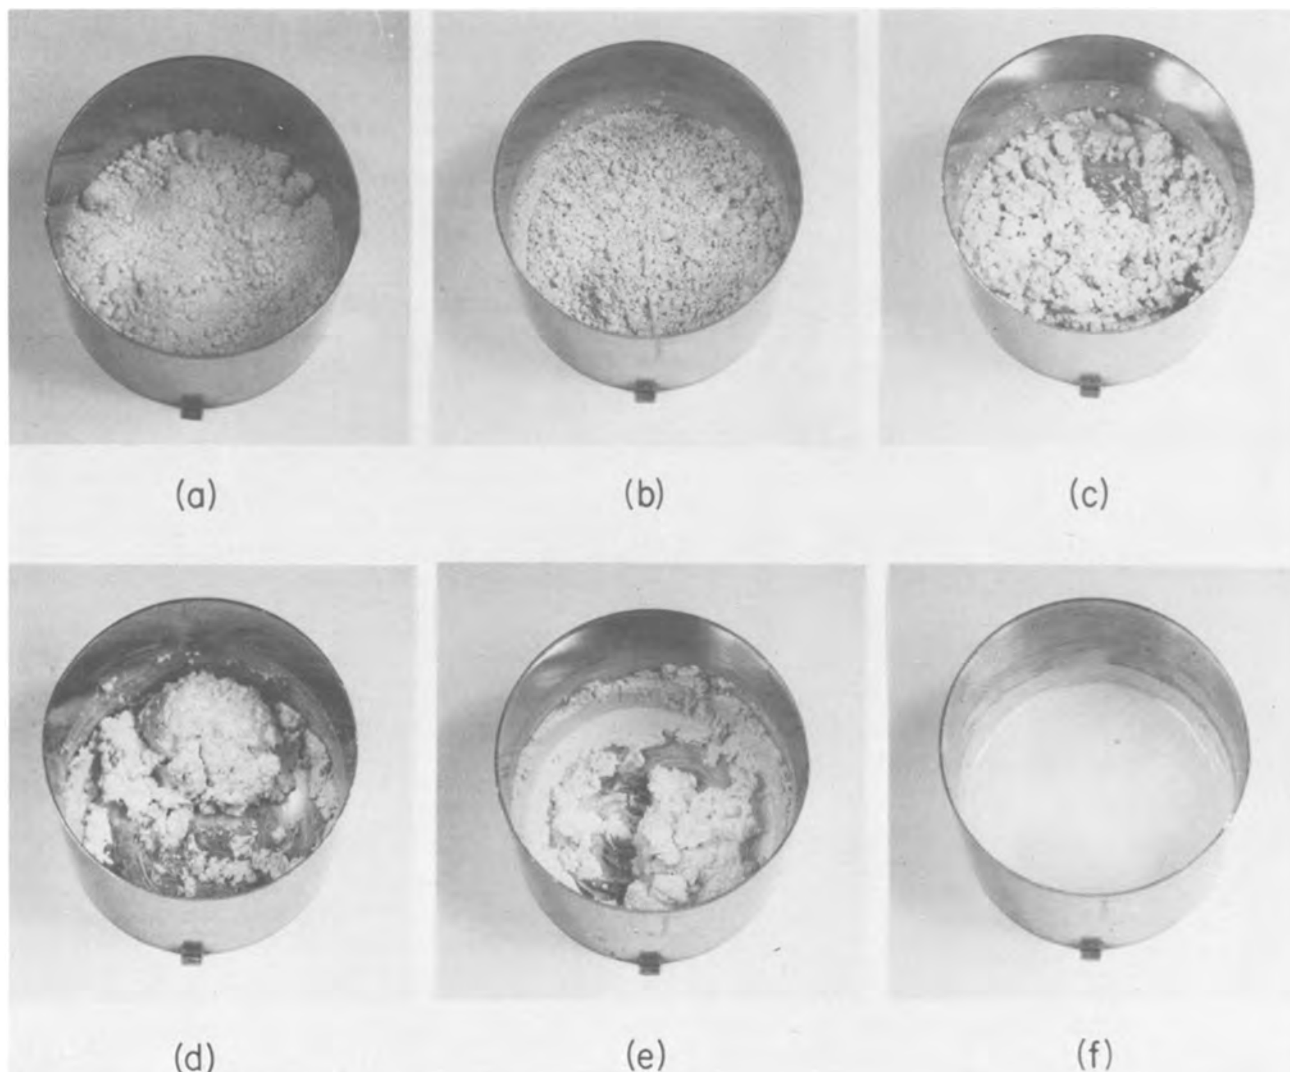

Fig. 1. Small, 900g batch of $4PbO \cdot PbSO_4$ after mixing for (a) 10 sec, (b) 3 min, (c) 4.5 min, (d) 6 min, (e) 20 min, and (f) 20 min. Mix (f) contained 0.17 ml of H_2O/g while all others contained 0.138 ml of H_2O/g of $4PbO \cdot PbSO_4$.

wet to paste and the water separates from the paste. For hand pasting and vibrator pasting (9), the mix can be used at the one sphere stage (Fig. 1d). However, this stage is usually too stiff for conventional machine pasting (7, 8), and the Fig. 1e stage may have to be used.

These same stages were observed using the larger mixer. Samples taken from this mixer were examined with the SEM. Figure 2 shows the dry $4PbO \cdot PbSO_4$ before mixing. Note the open structure. This open, porous structure results in complete absorption of the water when it is first added (Fig. 1a). On mixing to the small sphere stage (Fig. 1b), the crystals become more closely packed (see Fig. 3) and water is visible as evidenced by the shiny appearance of the small spheres. In the final stages (Fig. 1d and e), the crystals become closely packed and aligned (see Fig. 4).

The SEM photographs reveal that as the paste is mixed, the crystals become more closely packed. The mixing mechanically packs, or orders, the crystals so that the longer the paste is mixed, the less porous it becomes. The water acts only as a bulking agent so that overmixing may actually force water out of the paste and lead to a less porous, heavier plate. An important point to remember is once the paste is mixed too long and water settles out, it does no good to remix it, since this causes the crystals to pack even closer together forcing more water out.

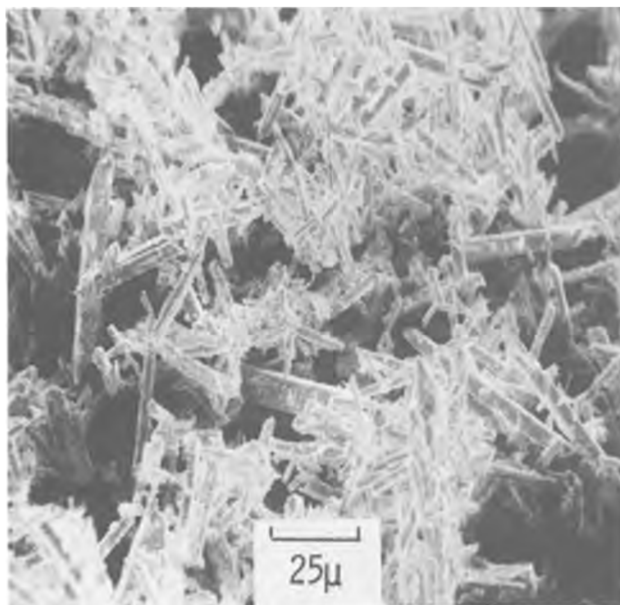

Fig. 2. $4PbO \cdot PbSO_4$ dry powder before mixing. Magnification 500 ×.

Fig. 3. $4PbO \cdot PbSO_4$ paste after mixing for 2 min with 0.138 ml of H_2O/g of $4PbO \cdot PbSO_4$. Magnification 500 ×.

Fig. 4. $4PbO \cdot PbSO_4$ paste after mixing with 0.138 ml of H_2O/g of $4PbO \cdot PbSO_4$ for 20 min. Magnification 500 ×.

Pasting data were taken on batches mixed in the small laboratory mixer (see Table I) and the larger mixer in which the amount of water was varied. Since the one sphere stage (Fig. 1d) is quite a definitive point and also the first stage at which plates can be hand pasted, the small batches were all stopped at this point. The large batches were mixed a little longer and machine pasted. No shrinkage occurred in any of these plates on drying even though the density was quite low for some of the batches. The dried paste densities for paste and positive plates are shown plotted in Fig. 5 *vs.* the amount of water used.

As expected, the density of the paste decreased as the amount of water used in the paste increased. The curve is not linear and the slope decreases as the density approaches that of $4PbO \cdot PbSO_4$ (8.15 g/cm^3). As expected, the plates are denser than the paste since

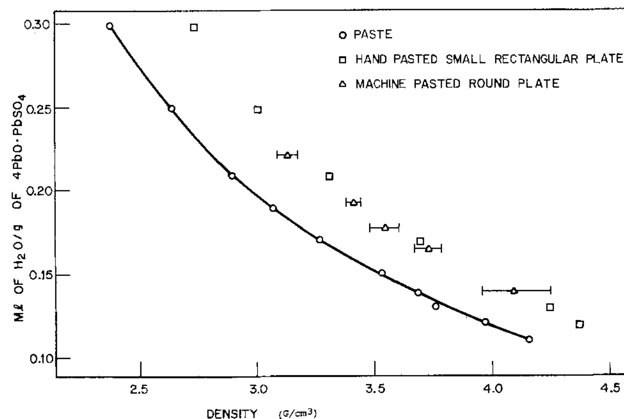

Fig. 5. The density of $4PbO \cdot PbSO_4$ *vs.* amount of water used in the paste for the dried paste, small rectangular plates and circular plates.

the pasting process squeezes some water out of the paste.

Table I gives additional data for the small paste batches plotted in Fig. 5. The mix time ranged from 20 min for the densest paste to 0.25 min for the least dense paste. The latter mix, 0.30 ml/g, is probably the maximum amount of water that can be added and still produce a paste that can be handled and hand pasted.

In Table I all batches were mixed to the one sphere stage (Fig. 1d) except for the 0.17 ml/g batch which was mixed for 20 min. The consistency of this batch as measured by the penetrometer was 139 mm and it was almost too fluid to paste. The cube weight and plate weight were heavier for the 20 min mix, and the porosity was less. This indicated that the overmixing caused some water to separate from the paste.

The porosities in Table I were calculated by two methods and are given as upper and lower values in the last column. The lower values were calculated from the wet and dry plate weights and assuming that all of the water in the wet plates was equivalent to the void volume. The upper values were calculated from the dry weights and the pasteable volume of the grid. The porosity range of the plates was 40-65%. Using Table I and Fig. 5, one could easily achieve any desired porosity in this range. We believe this is a far greater range in porosity than can be achieved with a reactive paste while still using conventional mixing and pasting techniques and without using any inert additives.

Since we believe water acts only as a bulking agent, less water should produce more dense and heavier plates. To achieve consistent plate weights, one must always add the same amount of water and mix only long enough to produce a paste with a workable consistency.

We find that a paste consistency with a penetration from 100 to 120 mm produces a paste suitable for machine pasting. A penetration of 120-140 mm was too wet for proper machine pasting. For hand pasting, a drier paste, 80-100 mm, may be used. Pastes are usually mixed for 10-20 min.

Varying the mixing time also allows the preparation of low or high density plates. A low density paste was produced in the large mixer by mixing 0.275 ml of H_2O/g of $4PbO \cdot PbSO_4$ for 0.5 min. A pellet from this plate is shown in cross section in Fig. 6. The low density plate has a much less ordered or tightly packed crystalline structure as compared to the normal density plate (compare with Fig. 4).

The capacities after two cycles of large circular plates pasted with different density pastes (see Fig. 5) were determined and are shown plotted in Fig. 7. As expected (3), the capacity of the plates increases as the density decreases. However, the low density, high capacity plates do have the disadvantage that they shed faster on cycling.

Fig. 6. Low density $4PbO \cdot PbSO_4$ plate made with a paste using 0.275 ml of H_2O/g of $4PbO \cdot PbSO_4$ and mixing for 0.5 min. Magnification 500 ×.

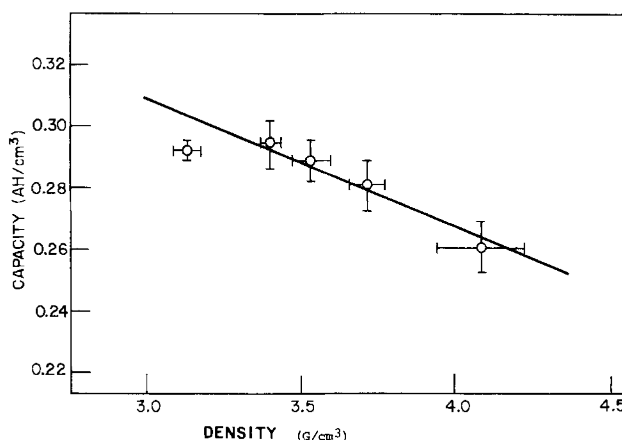

Fig. 7. The density of $4PbO \cdot PbSO_4$ in circular plates vs. their capacity.

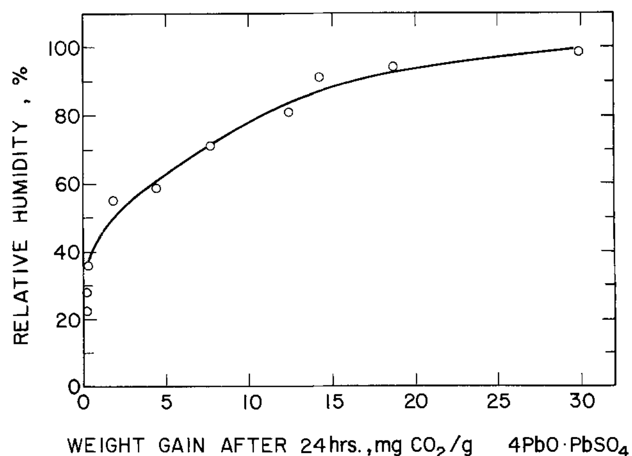

Fig. 8. CO_2 adsorption on $4PbO \cdot PbSO_4$ in pure CO_2 at different relative humidities. Below 35% RH little CO_2 is adsorbed.

Curing.—The amount of CO_2 adsorbed by $4PbO \cdot PbSO_4$ as a function of relative humidity in an atmosphere of pure CO_2 is shown plotted in Fig. 8. A similar plot for air (0.03% CO_2) was not obtained but a sample at 50% RH gained 0.6 mg of CO_2/g of $4PbO \cdot PbSO_4$ after 24 hr. Thus in air, $4PbO \cdot PbSO_4$ would absorb CO_2 at a rate 2 to 3 times slower than in pure CO_2 but we would expect the shape of the curve to be the same. Figure 8 shows that below 35-40% RH very little CO_2 is adsorbed. This explained why our plates were not being cured in the winter when the relative humidity is very low.

The $4PbO \cdot PbSO_4$ contained in a plate dried in the absence of CO_2 is shown magnified in Fig. 9. Note the smooth surface of the $4PbO \cdot PbSO_4$ crystals. Figure 10 shows the interior of a plate cured at 50% RH in air. The rough surface is due to adsorption of CO_2. From the SEM photographs as well as calculations based on the amount of CO_2 adsorbed, this scaly, carbonated layer appears to be about 1000-3000A thick. We were not able to determine the exact chemical composition of this carbonated layer since the curing reaction takes place only on the surface and therefore the amount

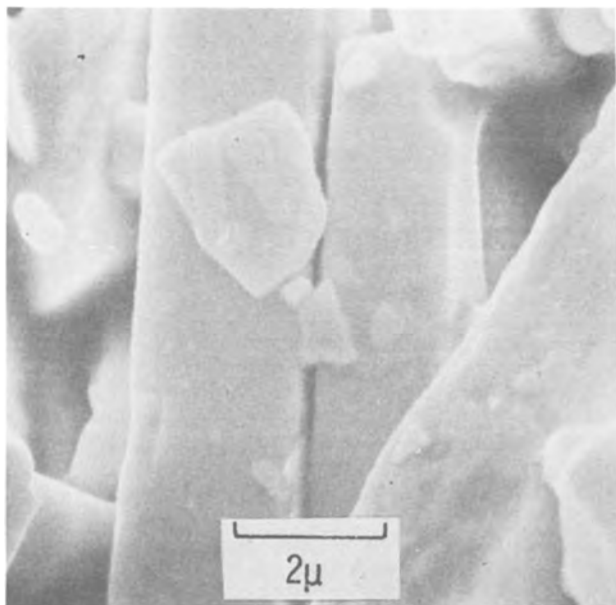

Fig. 9. $4PbO \cdot PbSO_4$ crystals in a plate dried in a desiccator with no CO_2. Magnification 10,000 ×.

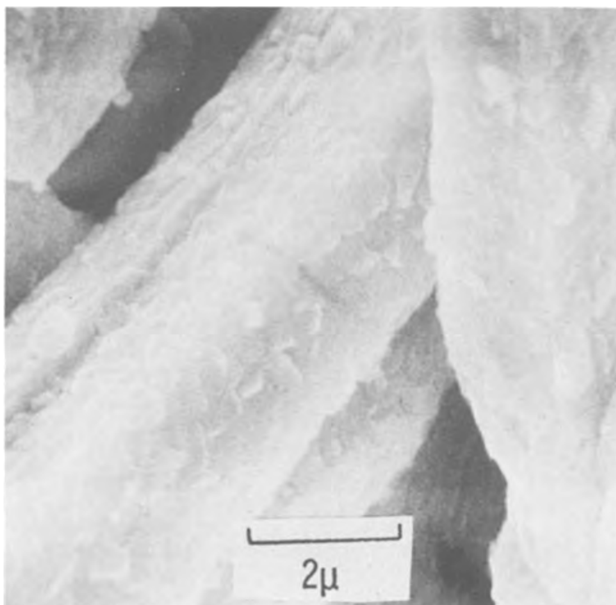

Fig. 10. $4PbO \cdot PbSO_4$ crystals in the interior of a plate cured in air for three days at 50% RH.

present is small. These "cured" crystals of $4PbO \cdot PbSO_4$ are probably held together by bridged carbonate bonds between crystals or perhaps the roughness of the scales locks one crystal to the other so that they may not freely slip by each other.

Schlotter and Fleischmann also observed roughening of $4PbO \cdot PbSO_4$ crystals (10). They postulated that the roughening was due to "abrasion caused by the mixing action." The crystals shown in Fig. 9 and 10 were from plates mixed the same length of time. Since the Fig. 9 crystals are smooth, the rough surface in Fig. 10 is not from mixing but from carbonation. We suspect that the rough surface observed by Schlotter and Fleischmann is also a result of carbonation of the surface of the crystals.

Since H_2O-CO_2 cures the plate, increasing the concentration of CO_2 and/or raising the relative humidity should accelerate the curing. This was done in the laboratory by enriching the atmosphere with CO_2 by either flowing, gaseous CO_2 or by Dry Ice in a chamber at 100% RH. In such a chamber, plates were cured in 4 hr. Figure 11 shows crystals of $4PbO \cdot PbSO_4$ in the interior of one of these plates. The carbonated surface of this plate is similar in appearance to a plate cured for 3 days in air.

An even faster method for curing plates is to put a previously dried plate in a chamber containing steam and CO_2 for 3 min. The interior of this plate is shown in Fig. 12a. Again the surface of the $4PbO \cdot PbSO_4$ crystals was carbonated. The crystals on the surface of a steam-CO_2 cured plate are shown in Fig. 12b. These crystals were not as heavily carbonated as the crystals in the interior of the plate. This same behavior was observed for plates cured in air.

Plates were given repeated 3 min treatments in steam-CO_2. The interior of a plate given 14 treatments is shown in Fig. 13a. The additional treatments did not increase the apparent thickness of the carbonated layer. However, the crystals on the surface of this plate (Fig. 13b) were more heavily carbonated than the plate given one treatment (Fig. 12b). This shows that the surface is more difficult to carbonate.

Since repeated treatments did not noticeably increase the thickness of the carbonated layer, this indicates that the carbonation process is self-limiting and that a plate cannot be overcured. The self-limitation of this process was also verified by measuring the increase in weight of plates as they were repeatedly cured.

Plates cured by all of the methods described above have been formed and cycled. No difference in performance could be detected between those given slow, air-cured treatments and those treated with CO_2 by one of the faster methods.

Conclusions

A paste is made from $4PbO \cdot PbSO_4$ by mixing with water. As the paste is mixed the crystals become more closely packed. When the paste reaches a consistency suitable for pasting, mixing should stop since con-

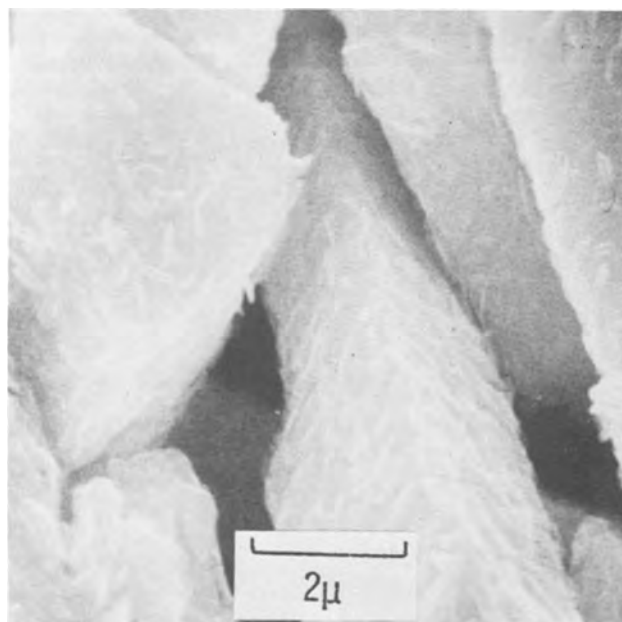

Fig. 11. $4PbO \cdot PbSO_4$ crystals in the interior of a plate dried in an oven and placed in a closed chamber containing Dry Ice (CO_2) and a relative humidity of 100%.

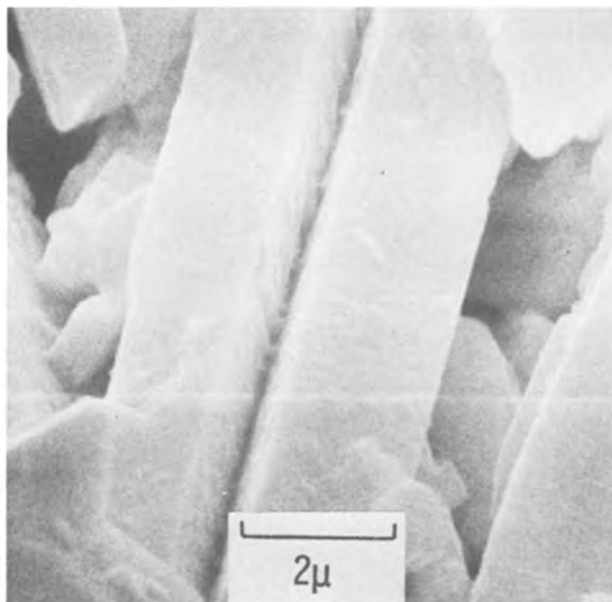

Fig. 12. $4PbO \cdot PbSO_4$ crystals in (a, upper) the interior and (b, lower) the surface of a plate dried in an oven and treated with CO_2 and steam for 3 min.

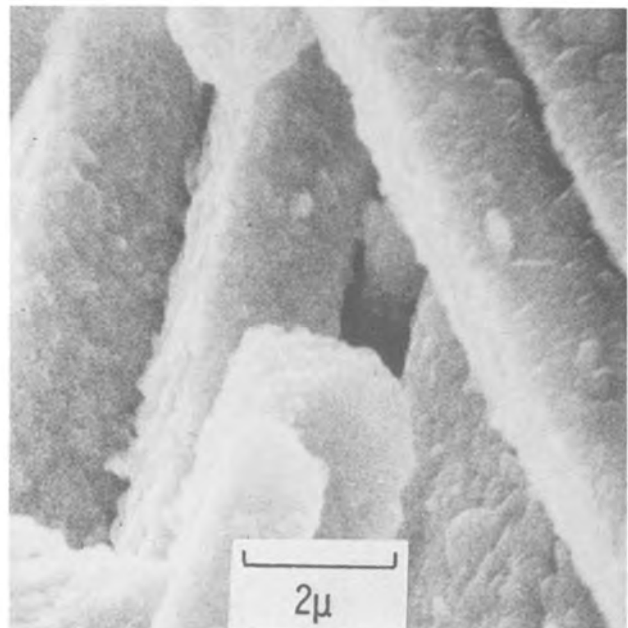

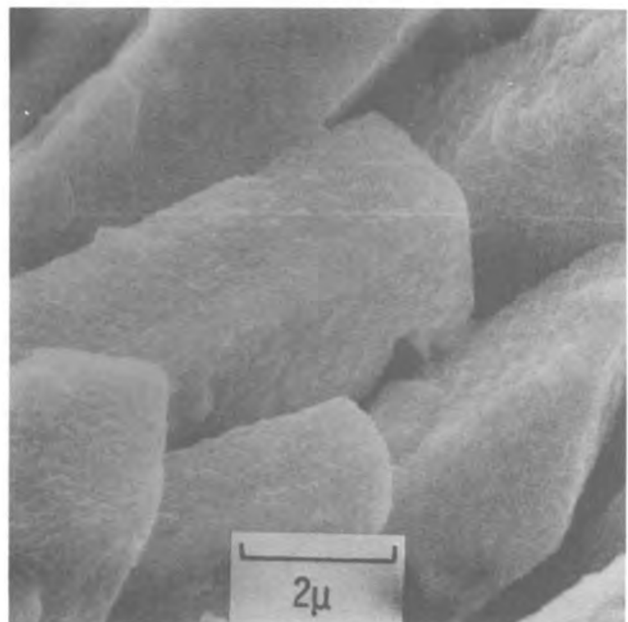

Fig. 13. $4PbO \cdot PbSO_4$ crystals in (a, upper) the interior and (b, lower) the surface of an oven-dried plate given 14, 3 min CO_2-steam treatments.

tinued mixing will cause water to separate from the paste and produce a denser paste and resultant plate. Low density plates may be produced by using more water and mixing for a shorter time.

$4PbO \cdot PbSO_4$ plates must be cured in an atmosphere containing CO_2 and at a relative humidity greater than 40%. Curing causes a scaly carbonated product to coat the surface of the $4PbO \cdot PbSO_4$ crystals. This carbonated product locks the crystals together to produce a hard plate. Curing can be accelerated by increasing temperature, humidity, and CO_2 concentration. After drying, plates may be quickly cured in steam-CO_2 in only 3 min.

The Effect of Depassivation at Specific Crystal Facets on the State of Activation of Nickel Substrates for Electrodeposition

Dennis Tench* and Cameron Ogden*

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

Changes in the surface structure of nickel substrates at open circuit in 65 w/o H_3PO_4 after an anodic etch treatment have been investigated by electrode potential measurements as a function of time, by voltammetric repassivation in neutral sulfate and phosphoric acid solutions, and by microscopic examination. It was found that partial depassivation occurs at specific crystal facets within a few hundred seconds. Studies involving single crystals indicated that the {100} and {110} orientations depassivate within this time frame, whereas the passive film on the {111} surface is more stable. The depassivation process is accelerated by iron impurities in the substrate and this impurity effect is enhanced by the presence of dissolved oxygen, which also enhances the etching of depassivated areas. These data suggest that poor activation of nickel substrates for electrodeposition can result from partial depassivation to form bare spots on the surface, through which appreciable cathodic current can pass without reducing the remaining oxide layer.

As part of the procedure to prepare metal substrate surfaces for electrodeposition, an anodic etch treatment in concentrated acid solution is often used to remove damaged surface layers, scale, and contaminants. If good adhesion of the electrodeposit is to be attained, any oxide film present on the substrate after the anodic etch must be removed prior to plating. In cases where film reduction does not occur in the plating bath before the onset of electrodeposition, this is often effected by a separate cathodic treatment. Such commercial processes do not always yield satisfactory results, and prolonged substrate contact on open circuit with the acid solution after the anodic etch is known to aggravate the problem. During the open-circuit contact, some change presumably occurs in the substrate film which leaves it capable of passing appreciable cathodic current without being electrochemically reduced. Subsequent electrodeposition then occurs over this film, resulting in poor adhesion to the substrate.

Two types of changes can occur in surface films to render them less reducible by cathodic treatment. One is an increase in the electronic conductivity of the film itself, so that current passes through the film without reducing it. The other is local dissolution or reduction of the film to form bare spots, so that most of the current passes through portions of the surface not covered by the film. The results reported here show that electrochemically passivated nickel forms bare spots at open circuit in 65 w/o (weight percent) phosphoric acid by preferential depassivation of specific crystal facets.

The passivation behavior of a given crystal orientation of nickel cannot readily be ascertained from the literature, since there are inconsistencies in the limited results available. For example, the results of Tokuda and Ives (1) indicate that crystal orientation effects are appreciable during active dissolution in 1*N* H_2SO_4, but small during passivation, whereas the results of Yagupolskaya and Movchan (2) indicate that the opposite is true, and Latanision and Staehle (3) report that polarization measurements for Ni in this electrolyte are essentially insensitive to crystal orientation. Likewise, the relative tendency toward passivation in 1*N* H_2SO_4 appears to be {111} > {110} > {100} from the data in Ref. (1) and {110} > {100} > {111} from those in Ref. (2). Weininger and Breiter (4) found the relative order of reactivity toward oxidation in alkaline KOH solution to be {110} > {100} > {111}, but Piontelli *et al.* (5) observed little orientation dependence for the polarization behavior of Ni in buffered pH 3 chloride solution at low current densities (<20 mA/cm^2).

In none of these studies of Ni passivation are the observed crystal orientation effects very pronounced. This may result to some extent from the point-by-point measurement technique usually employed, since excessive dissolution at the less anodic potentials prior to passivation could expose different crystal facets to the solution. Such dissolution could also account for the discrepancies in the published results. In the present work, a strong dependence on crystal orientation was observed for Ni depassivation in 65 w/o H_3PO_4 after an anodic etch treatment at 100 mA/cm^2 for 90 sec.

Experimental Details

The working electrodes were 6 mm diam disks (polycrystals) or 5 mm squares (single crystals) mounted in the rotating-disk configuration (6), flush with the ends of 13 mm diam Kel-F cylinders, by compression molding at elevated temperature (<300°C). Rotating-square electrodes have been shown (7) to give results comparable to rotating disks. Single crystals of 99.95% purity were aligned by reflection x-ray diffraction to give the desired orientation

* Electrochemical Society Active Member.

Key words: depassivation, nickel, phosphoric acid, crystal orientation, electrodeposition.

within ±0.5°. Three types of polycrystalline electrodes were investigated: 99.999% "pure" (PAR magnetometer standard); 99.5% "wrought" (Ni-200, International Nickel Company); and "electrodeposited" (SNR nickel sulfamate bath). Before use, electrodes were polished on successively finer aqueous alumina powder slurries to 0.05 μm particle size. For all studies, Pt and saturated calomel (SCE) were used as the counter- and reference electrodes, respectively.

After an anodic etch treatment at 100 mA/cm² for 90 sec in 65 w/o H_3PO_4 saturated with various gases, open-circuit potentials of Ni electrodes were followed *vs.* SCE as a function of time using a Hewlett-Packard Model 7004B recorder. After various times, electrode surfaces were examined using a scanning electron microscope (SEM). The state of passivation after a given amount of time on open circuit in the H_3PO_4 solution was determined by quickly transferring electrodes to another cell containing argon-saturated 0.50*M* Na_2SO_4 solution and measuring the charge required for passivation on the initial current-potential sweep at 10 mV/sec from −0.50 to 0.80V *vs.* SCE. The electrode potential was controlled using a PAR Model 173 Potentiostat/Galvanostat in conjunction with a PAR Model 175 Universal Programmer, and the charge was determined using a PAR Model 179 Integrating Coulometer. Since electrochemically produced films are stable in this nearly neutral electrolyte, whereas air-formed oxide layers are easily reduced (8), the charge required to repassivate a nickel electrode in this solution is a measure of the amount of surface not covered by an electrochemically produced passive film.

Results and Discussion

Repassivation studies.—Repassivation curves obtained for "pure" Ni in neutral sulfate solution after various times on open circuit in 65 w/o H_3PO_4 solution following the anodic etch treatment are shown in Fig. 1. It is evident that the electrode is depassivating with time at open circuit in the H_3PO_4 solution since progressively more charge is required for repassivation. By comparison with the 18 mC/cm² needed to passivate a freshly polished surface (not shown), the "pure" Ni electrode is still 80% passivated after 75 sec (curve 1), 45% passivated after 200 sec (curve 2), but only 25% passivated after 500 sec (curve 3). These values are probably somewhat low since surface roughening by dissolution has not been taken into account. Curve 4 is the second sweep obtained in each case, indicating that the electrode is irreversibly passivated in this neutral sulfate medium (8).

Similar repassivation curves are shown in Fig. 2 for the relatively impure "wrought" Ni electrode. The trend is the same, but depassivation on open circuit in the H_3PO_4 solution appears to occur more rapidly. Repassivation in the neutral sulfate solution is also more complicated, involving considerable current at the more anodic potentials (>0.1V). The appreciable currents observed on the second (curve 4) and subsequent sweeps indicate that the less pure electrode is also more difficult to passivate.

SEM investigation.—Figure 3 is a scanning electron micrograph of a "wrought" nickel electrode immediately after the anodic etch treatment in oxygen saturated 65 w/o H_3PO_4 solution. The surface is still reasonably flat, except for minor pitting and some grain boundary etching, which is expected for an electrode passivated at a high current density. Figures 4 and 5 show the same electrode after prolonged (20 min) open-circuit exposure to the oxygen-saturated H_3PO_4 solution following the anodic etch treatment. Similar results are obtained for shorter exposure times and in argon-saturated solutions, but the surface features are not resolved so clearly. It is

evident that some grains are practically intact after the open-circuit exposure, whereas others have been severely recessed and roughened by dissolution. This is more evident at the higher magnification (Fig. 5). It is apparent that some grains, presumably of the same crystal orientation, have depassivated on open circuit, permitting dissolution of the underlying metal.

Isolated large pits of the type shown in Fig. 6 are also formed on the "wrought" Ni surface during depassivation in 65 w/o H_3PO_4 solution. In solutions containing dissolved O_2, "comet tails" originating at these pits form a swirl pattern centered at the middle of the rotated electrode. These tails appear dark to the naked eye, but light in SEM pictures (see Fig. 6). Evidently, some species is formed in the pits which reacts with the outer electrode surface as it is swept along by the solution swirling across the rotating-disk electrode. Since the "comet tails" are not observed

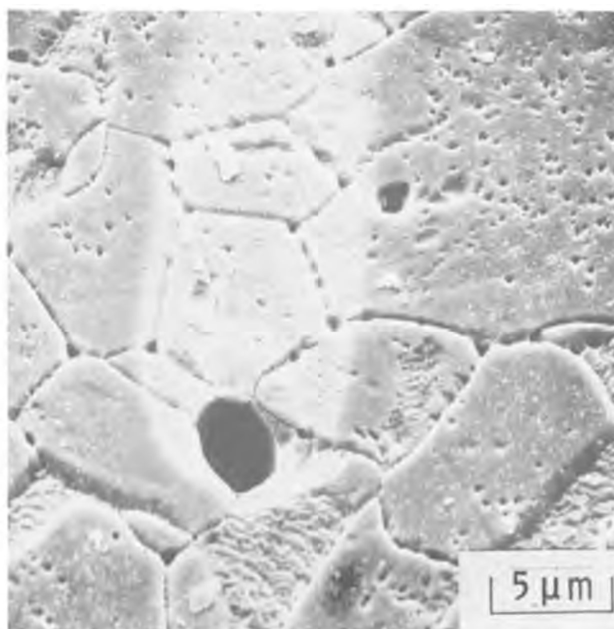

Fig. 6. Different area of the surface shown in Fig. 4

in the absence of dissolved O_2, the species reacting with the surface is probably peroxide (OOH^-), which is known to form as an intermediate in electrochemical oxygen reduction (9). Energy dispersive analysis of x-rays (EDAX) detected an appreciable concentration of Fe inside the large pits, but none at other points along the surface. Thus, these pits, which occur predominantly at grain boundaries, probably result from local dissolution of Fe impurities segregated there during solidification of the metal. These impurities may also catalyze O_2 reduction within the pits.

As discussed in the preceding section, our repassivation measurements indicate that the "wrought" Ni depassivates more rapidly than the "pure" metal. To some extent, these measurements probably reflect repassivation of depassivated impurity centers. However, the electrons provided by dissolution of Fe and Ni at the impurity sites may partially reduce the oxide layer at other points on the surface, which would also be reflected in the charge required for repassivation.

Depassivation also seems to occur at specific crystal facets for "pure" Ni, as shown in Fig. 7. In this case, parallel linear trenches are formed, presumably in line with crystal planes. A similar etch pattern has been observed by Datta and Landolt (10) for transpassive dissolution of Ni in $NaNO_3$ solutions.

Open-circuit voltage measurements.—As shown in Fig. 8, the open-circuit potential (U) of a pure Ni electrode in 65 w/o H_3PO_4 reaches a rotation-dependent cathodic peak about 250 sec after the anodic etch treatment. Such open-circuit behavior during depassivation is unprecedented and does not appear to have been treated in the literature. Considering the repassivation and SEM results, the following interpretation seems reasonable. Initially, U drifts cathodic because the higher nickel oxides formed during anodization are dissolving as part of the surface film and, to some extent, are being reduced by local cell action. At times less than 100 sec, U is independent of the rotation rate, as might be expected if chemical dissolution is kinetically controlled since the repassivation studies show that the surface is still essentially passivated. Significant breaks appear in the film after about 100 sec so that Ni dissolution

$$Ni \rightarrow Ni^{+2} + 2e^- \quad [1]$$

becomes appreciable. These breaks probably occur at

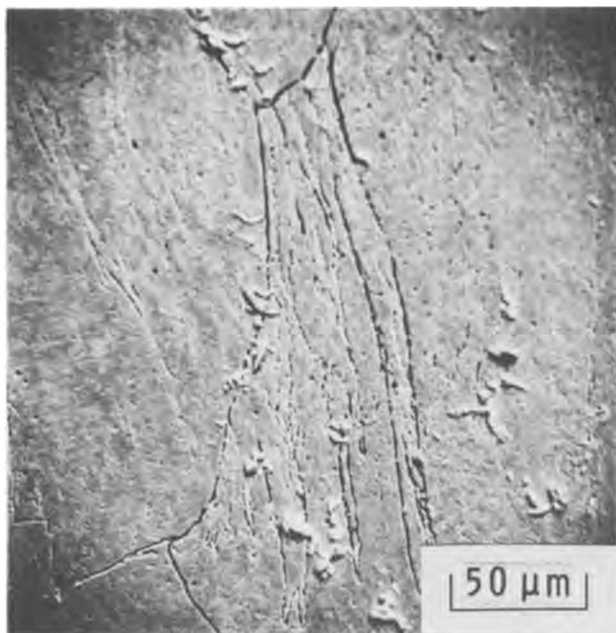

Fig. 7. "Pure" Ni surface after same treatment as for Fig. 4

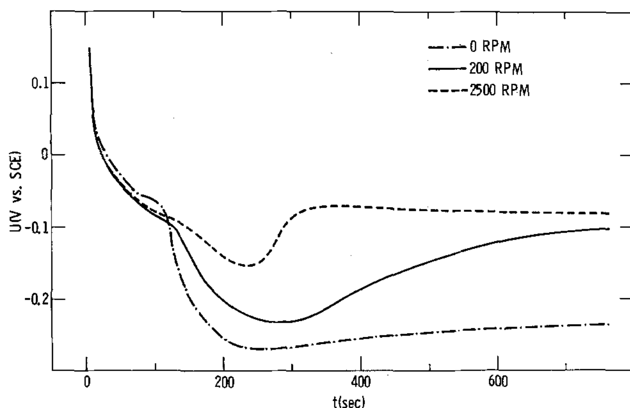

Fig. 8. Time variation of the open-circuit potential of a "pure" Ni electrode (rotated at various rates) after the anodic etch treatment at 200 rpm in air-saturated 65 w/o H_3PO_4 solution.

pits and grain boundaries. The electrons generated are consumed by reduction of protons

$$2H^+ + 2e^- \rightarrow H_2 \quad [2]$$

on the bare Ni within breaks in the film, and to some extent by O_2 reduction

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad [3]$$

When solution mass transport is adequate, the equilibrium between these three reactions establishes a stable corrosion potential. But at the early stages in the depassivation (after 100 sec), H^+ and O_2 must be transported via pits and crevices in the surface film to the underlying bare Ni areas. As these species become depleted at the recessed bare Ni surfaces, H_2 evolution and O_2 reduction are forced to occur on the oxide layer where the overvoltages are presumably higher. Thus, as H^+ and O_2 are depleted within pits and crevices, U drifts further cathodic and the extent of the drift is rotation dependent.

As the pits and crevices in the film widen, eventually exposing entire grains to the solution, mass transport to the underlying Ni is improved. Thus, after 250 sec, the cathodic drift peaks out and U moves anodic to the corrosion potential if the electrode is rotated sufficiently fast to prevent concentration polarization at the depassivated areas. Without rotation,

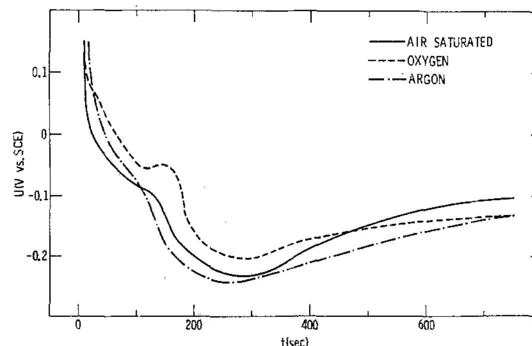

Fig. 9. Time variation of the open-circuit potential of a "pure" Ni electrode at 200 rpm after the anodic etch treatment in 65 w/o H_3PO_4 saturated with various gases.

mass transport to recessed grains and within pits and trenches remains inadequate to establish the corrosion potential.

Figure 9 shows that the voltage arrest at 100 sec is strongly accented in solutions containing dissolved oxygen, indicating that O_2 reduction does play some role in retarding the cathodic drift of U for a "pure" Ni electrode. However, the gas atmosphere has little effect on the magnitude and position of the cathodic peak, indicating that dissolved oxygen is rapidly depleted within pits and crevices and does not significantly affect the over-all rate of depassivation. "Pure" electrodes depassivated for several minutes in air- or oxygen-saturated H_3PO_4, however, acquire a frosted appearance not observed for those exposed to argon-saturated solutions. Electron micrographs show that this results from deeper preferential etching of some Ni grains in the presence of oxygen, which presumably is reduced on the exposed nickel surfaces, and to some extent on the oxide film, enhancing dissolution.

As shown in Fig. 10, the open-circuit electrode potential also reflects the enhanced depassivation rate caused by impurities in the "wrought" Ni substrate. Immediately after the anodic etch, U drifts rapidly cathodic, apparently driven by dissolution of Fe and Ni within pits at impurity centers. Reduction of H^+ and O_2 would tend to halt the cathodic drift at the corrosion potential, but in air- and argon-saturated solutions, these species become depleted within the impurity pits and other breaks in the surface film. Thus, since these reduction processes do not occur readily on the oxide layer, metal dissolution at impurity sites pegs U at a value cathodic to the corrosion potential. This situation seems to be stable for several minutes in the absence of dissolved O_2, even though depassivation is also occurring within specific crystal facets at points removed from the impurity centers (see preceding sections). In air-saturated solutions, O_2 reduction hastens the over-all process so that the corrosion potential is established more quickly (after only a few hundred seconds). It should also be mentioned that restricted mass transport to recessed grains may also play some role in the depassivation

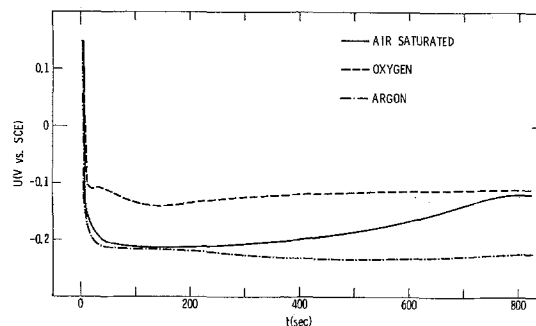

Fig. 10. Same as Fig. 9 for a "wrought" Ni electrode

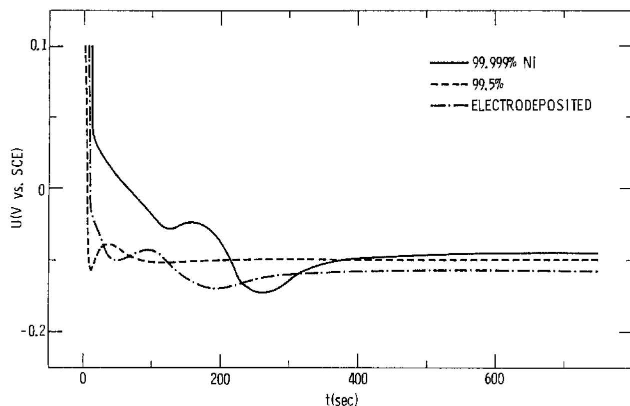

Fig. 11. Time variation of the open-circuit potential of various Ni electrodes at 2500 rpm after the anodic etch treatment in oxygen-saturated 65 w/o H_3PO_4 solution.

process since the grains of the "wrought" material are an order of magnitude smaller than for the "pure" Ni (see Fig. 4 and 7).

In order to exaggerate differences, "electrodeposited" nickel was compared with "wrought" and "pure" nickel substrates at 2500 rpm in oxygen-saturated 65 w/o H_3PO_4 solution. The open-circuit potentials after the anodic etch are shown in Fig. 11. It is evident that electrodeposited Ni depassivates somewhat more slowly than the "wrought" material, but considerably faster than pure Ni, at least initially.

Single crystal studies.—To determine which crystal facets of Ni depassivate after short times on open circuit in phosphoric acid solution, the passivation/depassivation behavior of Ni single crystals was investigated. Figure 12 shows polarization curves obtained at 50 mV/sec in 65 w/o H_3PO_4 after open-circuit exposure for 500 sec following passivation by an anodic sweep to 0.8V (solid lines) and by the anodic etch treatment at 100 mA/cm^2 for 90 sec (dashed lines). The curves obtained after the open-circuit exposure following passivation at 0.8V exhibit sharp passivation peaks similar to those observed for freshly polished electrodes. This indicates that all three crystal facets rapidly depassivate at open circuit following passivation under mildly oxidizing conditions. After open-circuit exposure following the anodic etch treatment, however, repassivation peaks, although somewhat broadened, are still observed for the {100} and {110} orientations, but the anodic current is negligible for the {111} electrode. Thus, passivation under strongly oxidizing conditions produces a stable film on the {111} surface, but not on the {100} and {110} facets which still depassivate rapidly on open circuit.

As shown in Fig. 13, the time variation of the open-circuit electrode potential following the anodic etch treatment also reflects the relative stabilities of the passive films formed on the various Ni facets. The {111} electrode quickly establishes a steady anodic potential of about 0.5V, which presumably corresponds to the equilibrium between a stable passive film and the electrolyte. On the other hand, the {100} electrode appears to depassivate at some points on the surface within 10 sec, so that the potential is driven rapidly to 0.0V by Ni dissolution. As the depassivated areas multiply and widen, Ni dissolution increases and the corrosion potential (−0.1V) is approached. After about 300 sec, the potential drifts more cathodic. This could result from reduction and/or dissolution of a second type of oxide in a duplex structure, but the subsequent reversal to the anodic direction is difficult to explain within this framework. It seems more reasonable that the cathodic drift is caused by restricted mass transport of H^+ and O_2 to the bare Ni areas which have become recessed by dissolution, as

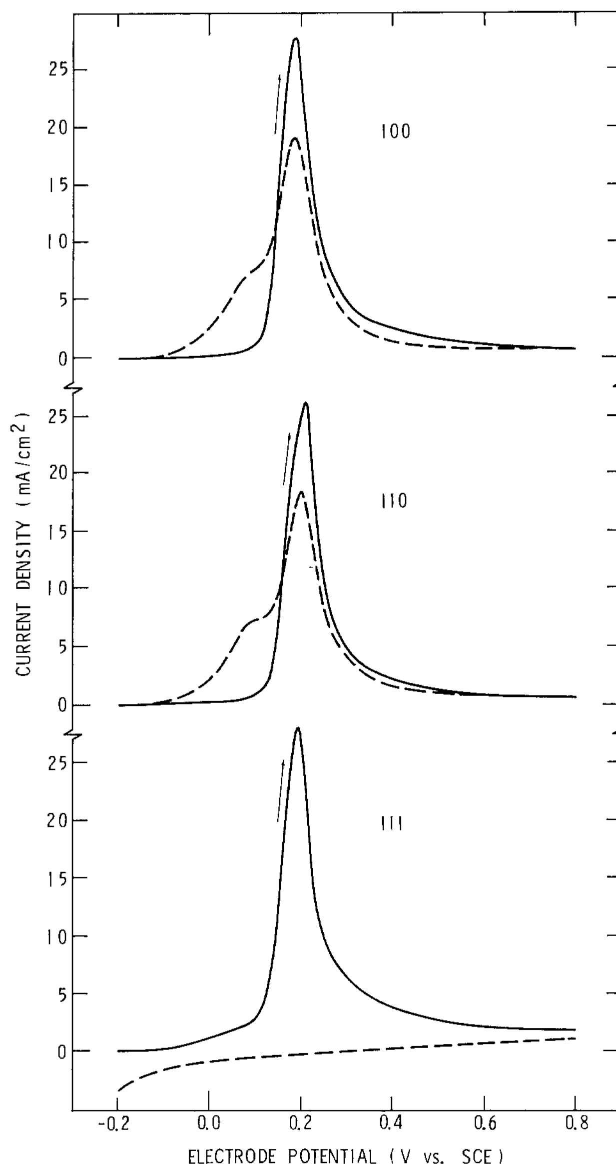

Fig. 12. Anodic polarization curves at 50 mV/sec for single crystalline Ni electrodes rotating at 200 rpm in air-saturated 65 w/o H_3PO_4 after 500 sec on open circuit following passivation at 0.80V (solid curves) and following the anodic etch treatment (dashed curves).

discussed in the preceding sections. Since mass transport is improved as the recessed areas widen, the potential reaches a cathodic peak, then drifts anodic toward the corrosion potential.

The behavior of the {110} orientation is intermediate between the other two. The potential arrest at about 0.5V in Fig. 13 indicates that the passive film on the {110} surface is resistant to dissolution. But the electrode potential rapidly drifts further cathodic after 100 sec, indicating that significant breaks have appeared in the surface film. The depassivation process then proceeds in a fashion similar to that for the {100} surface.

The stable oxide produced on the {111} surface under strongly oxidizing conditions may involve formation of higher nickel oxides, deprotonation, or a combination of the two. Changes in the oxide film thickness are not expected to be important in the passivation/depassivation behavior of Ni (8, 11, 12). Protons probably play a role since we have found that the tendency toward passivation in neutral sulfate solution is in the order {100} > {110} > {111} orientation, which is opposite to the order of oxide

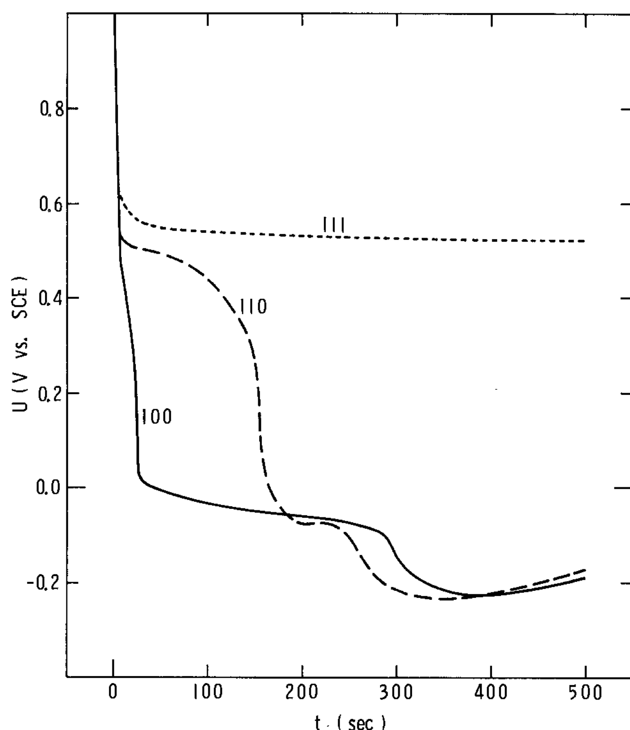

Fig. 13. Time variation of the open-circuit potential of single crystalline Ni electrodes at 200 rpm after the anodic etch treatment in air-saturated 65 w/o H_3PO_4 solution.

film stability reported here for phosphoric acid solution.

Recently, MacDougall and Cohen (12, 13) have suggested that film breakdown on Ni in sulfate solutions occurs by chemical attack at defect sites, followed by undermining of the oxide film by Ni dissolution. Since these authors did not report on the effects of varying solution mass transport, it is difficult to determine the extent to which undermining is important. It seems reasonable to expect, however, that crystal orientation effects would also play a significant role in the sulfate system. On the other hand, the present results are adequately explained by assuming that pits and crevices in the oxide film grow laterally within the confines of specific crystal facets.

Conclusions

The results reported here show that polycrystalline Ni depassivates preferentially at specific crystal facets on open circuit in 65 w/o H_3PO_4 solution following an anodic etch treatment at 100 mA/cm^2 for 90 sec. The tendency toward depassivation increases in the order {100} > {110} > {111} orientations. Iron impurities in the substrate accelerate the depassivation process and this impurity effect is enhanced by dissolved oxygen in the electrolyte. Such partial depassivation can lead to poor adhesion of electrodeposits by permitting appreciable current to pass through bare spots without reducing the remainder of the surface film.

Mössbauer Studies of the Passive Film Formed on Tin in Borate Buffer

A. Vértes, H. Leidheiser, Jr.,* M. L. Varsányi, G. W. Simmons,* and L. Kiss

Institute of Physical Chemistry and Radiology, Lorand Eötvös University, Budapest, Hungary, and Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

Polarization curves of tin were determined potentiodynamically in deaerated borate buffer at pH 8.5. Mössbauer studies were carried out at liquid nitrogen temperature by transmission using foils of aluminum on which a thin layer of tin enriched in ^{119}Sn was electrodeposited. The predominant tin species in the passive film was Sn^{+4}. The thickness of the passive film was a function of the applied potential and ranged from 0.8 to 2.5 nm. The rate of tin dissolution in the borate buffer was insignificant even in the transpassive range. The surface product formed on tin after exposure to air for more than 30 days could not be removed cathodically in the borate buffer. *In situ* emission Mössbauer studies using ^{119m}Sn were largely unsuccessful because of the low specific activity of the available isotope.

The anodic behavior of tin in alkaline solution has been the subject of several investigations (1-11). Seven investigations used hydroxide solution (1-3, 5, 8-10), one investigation used potassium hydroxide solution (11), three investigations used borate solution (3, 6, 9), and three investigations used sodium carbonate solution (3, 7, 9). The general consensus arising from these investigations, based largely on galvanostatic and coulometric studies, is that in the hydroxide and carbonate solutions SnO or $Sn(OH)_2$ is formed at the more negative potentials and SnO_2 or $Sn(OH)_4$ is formed at the more positive potentials. In the region of -900 - -600 mV (*vs.* SHE) it is believed that divalent tin is formed first and is oxidized to tetravalent tin. The situation in the borate solution is much less clear because all the measured parameters are so different from the values obtained in the sodium hydroxide and sodium carbonate solutions. Data summarized in Table I and taken from the paper by Pugh *et al.* (9) illustrate this point. It will be noted that the critical current density for passivity in borate solution is over 4 orders of magnitude less than that required in 1*N* NaOH solution and that the characteristic potential values are different. In the more aggressive solutions authors have also noticed that the anodic oxide is sufficiently thick such that it exhibits color, and the color is a function of the polarizing potential and the time. It appears that divalent tin has a long lifetime and is present on the electrode surface when polarization is carried out in the vicinity of the first maximum in hydroxide and carbonate solutions and that this divalent tin is further oxidized to tetravalent tin at more positive potentials. The situation is far from clear in the borate solution and, in the words of Pugh *et al.* "The general pattern of passivation (as described above) was not followed in sodium borate electrolytes . . . ."

This work was undertaken largely with three objectives in mind: (*i*) to determine the chemical nature of the passive film formed in borate solution under anodic polarization; (*ii*) to determine its thickness under various experimental conditions; and (*iii*) to determine the stability of the passive film under different conditions of polarization.

Previous studies of the oxidation of iron (22) and of the anodic behavior of cobalt by Mössbauer spectroscopy (13) have demonstrated that this technique can be sufficiently sensitive to characterize surface films. In the present studies, Mössbauer spectroscopy in the absorption and emission modes of operation have been used to characterize the passive film formed on tin by polarization in buffered borate, pH 8.5.

* Electrochemical Society Active Member.

Key words: Mössbauer spectroscopy, passivity, tin, tin oxide.

Absorption geometry is the conventional method used in Mössbauer spectroscopy. A single line source, ^{119m}Sn in $CaSnO_3$, which emits 23.87 keV gamma, is resonantly absorbed by a specimen containing ^{119}Sn. The spectrum of the specimen is generated by measuring the absorption (count rate) as a function of velocity of the source. To obtain surface sensitivity, a specimen with a high surface-to-volume ratio is required.

In emission Mössbauer spectroscopy the active ^{119m}Sn isotope is deposited on the surface of tin. The spectrum is generated by resonant absorption of the emitted gamma ray by a single line absorber, $CaSnO_3$ enriched in ^{119}Sn. Auger aftereffects may affect the charge state of emitting ^{119m}Sn nuclei as has been discussed for emission studies using ^{57}Co. Since in the case of Sn both the parent and daughter isotopes are Sn, the formation of atypical valence states by chemical effects within the lattice of the corrosion layer is less likely than that found in the $^{57}Co \rightarrow {}^{57}Fe$ emission spectroscopy.

Experimental

All potentiodynamic measurements and polarization studies were carried out in deaerated buffered borate solution at pH 8.5 and room temperature. Potentiodynamic curves were recorded continuously in both the increasing and decreasing potential mode. The reference electrode in all cases was a 0.1M calomel half-cell and all potentials are given with respect to this electrode.

In order to carry out Mössbauer experiments in absorption geometry of a thin oxide on a tin substrate it is necessary that the volume of oxide/volume of substrate be as large as possible. The strategy adopted was to electroplate a thin layer of tin enriched in ^{119}Sn on both sides of an aluminum foil 0.0065 cm in thickness. Aluminum was selected because of its low cross section for the 23.87 keV gamma ray and its inertness under polarization conditions in the borate electrolyte. Other substrates such as iron and copper were considered and were studied in a preliminary way, but they were discarded because of possible complications from the formation of intermetallic compounds at the copper/tin or iron/tin interface (12).

Deposits with good adherence to the aluminum substrate and satisfactory integrity (*cf.* infra) were obtained when the following procedure was used. The aluminum surface was polished with emery paper, etched in a hot solution of 10% NaOH, and finally immersed for a brief time in 30% HNO_3 at room temperature. The aluminum was thoroughly washed in distilled water and allowed to dry. Tin was electrodeposited at a current density of 0.2 A/dm^2 for 30 sec

Table I. Important parameters derived from potentiodynamic polarization studies of tin in alkaline solutions at 25° as determined by Pugh et al. (9)

Solution	Potential at maximum (mV)	Potential range of second peak	Critical C.D. for passivity (mA/cm²)	C.D. in passive region (mA/cm²)
1N Na_2CO_3	−755	−655-−576	0.55	0.22
0.1N NaOH	−825	−656-−536	5.70	0.02
1N NaOH	−870	−700-−620 (at 40°)	170	0.064
0.1M sodium borate	−566	−517-−417 (at 40°)	0.007	0.002

while the plating bath was maintained at 70°C. The composition of the bath was 25 g/liter SnI_4 in which the ^{119}Sn content was enriched to 89%, 12 g/liter NaOH, 1.5 g/liter CH_3COONa, and 1 ml/liter of 30% H_2O_2. The average thickness of the resulting deposit was determined by dissolution of the tin in 1M sulfuric acid and determining the tin content of the solution by differential pulse polarography.

Mössbauer spectra were recorded on samples passivated in the deaerated borate buffer at various potentials and for various periods of time. After passivation, the foils were immediately plunged into liquid nitrogen and the spectra were recorded while the samples were maintained in the liquid nitrogen. No evidence of a crystallographic transformation to α-tin was detected. The Mössbauer source was $Ba^{119m}SnO_3$ with a 5mCi activity. X-rays generated by the source were filtered from the beam by means of a palladium foil. All absorption spectra are given with respect to $BaSnO_3$ as the reference.

Emission Mössbauer spectra were obtained in the same cell previously used by Simmons et al. (13). Tin was electrodeposited from a dilute solution of $^{119m}SnCl_2$ that was made suitably conductive by the addition of 0.15 ml of 4N HCl and 0.7 ml of 2N NaOH to give a total plating volume of 10 ml. Prior to plating, the tin substrate was mechanically polished, etched in hot HCl, and thoroughly washed in distilled water. The tin deposition was carried out at a current density of 0.1 A/dm² and room temperature for 8 hr. The specific activity of the available ^{119m}Sn was 400 mCi/g and the activity of the electrodeposit was approximately 4 μCi for deposit thicknesses of the order of 14 nm. Emission spectra were recorded using a $Ca^{119}SnO_3$ absorber.

Results

Figure 1 shows the characteristic potentiodynamic curves obtained on the first scan of a cathodically reduced tin deposit on a pure aluminum substrate. Figure 2 shows the curve obtained in successive scans of the same sample after cathodic reduction preceding each scan. Figure 1 shows a peak at −350 mV which is missing in Fig. 2. Potentiodynamic curves of pure tin were identical to Fig. 2. Potentiodynamic curves of pure aluminum also yielded the peak at −350 mV during the first scan and the peak was absent in successive scans. On the basis of these measurements it was concluded that the −350 mV peak represents oxidation of the aluminum surface and that once it occurred it played no further role in the potential range to which the samples were subjected. Aluminum appeared to be a satisfactory substrate for the tin after this artifact was recognized.

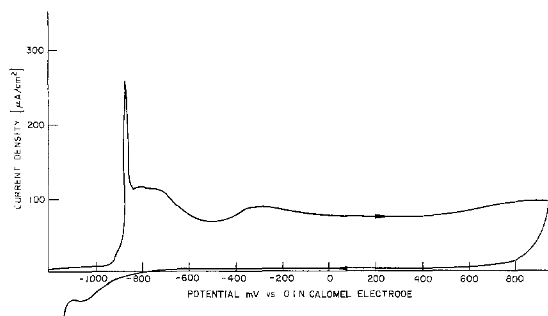

Fig. 1. Characteristic potentiodynamic curve obtained on the first scan of a cathodically reduced tin electrodeposit on a thin-foil aluminum substrate.

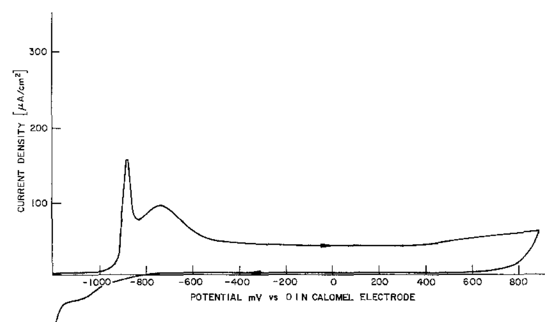

Fig. 2. Potentiodynamic curve obtained on second and successive scans of a cathodically reduced tin electrodeposit on a thin-foil aluminum substrate. Note that the peak at −350 mV present on the first scan (Fig. 1) is now absent.

Figure 3 is the Mössbauer absorption spectrum at 78°K of a tin electrodeposit that was cathodically treated in the borate solution for 10 min at −1200 mV. The center of the peak is located at +2.60 mm/sec and the computer-calculated width at half maximum is 0.99 ± 0.01 mm. These values are typical of those customarily obtained for metallic tin and thus provide good support for the views that (i) the material being studied was metallic tin with similar crystallographic features as that of bulk tin; and (ii) the aluminum substrate had minimal influence. The cathodically treated sample also yields no spectral evidence for the presence of Sn(IV) at the surface so it is felt that any air-formed oxide or anodically formed oxide in a previous experiment was satisfactorily removed by the cathodic treatment. The presence of Sn(IV), rather than Sn(II), is used as the criterion for the surface cleanliness on the basis of the work reported below and the work of Huffman and Dunmyre (14).

A question of utmost importance to this study is the relationship between the area under an absorption peak and the fraction of that species present in the volume exposed to the gamma ray flux. A partial answer to this question was obtained by studying the dependence of the area under the peak and the width at half maximum as a function of the thickness of the

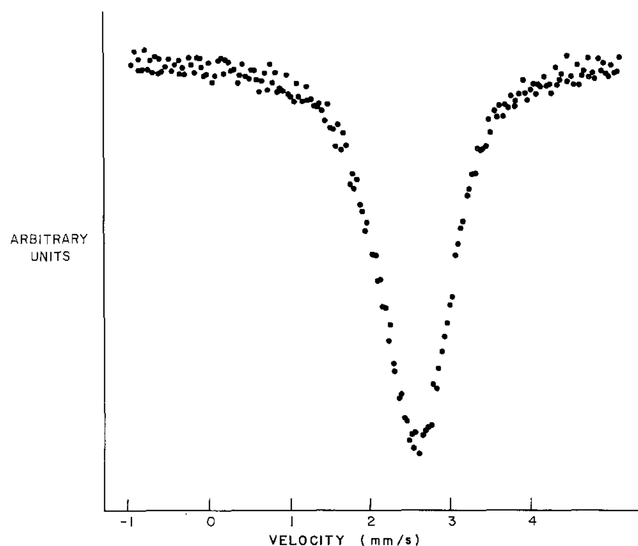

Fig. 3. Mössbauer absorption spectrum at 78°K of a tin electrodeposit that was cathodically treated in the borate buffer for 10 min at −1200 mV.

tin through which the beam traversed under conditions of a standard gamma ray exposure. ^{119}Sn was electrodeposited on an aluminum substrate and different numbers of the foils were compressed together and the Mössbauer spectrum was generated at liquid nitrogen temperature. Data obtained from this study are summarized in Fig. 4. It will be noted that the area under the peak does not depart seriously from a linear relationship with thickness in the range of tin thicknesses studied, namely, 10-30 nm, and that the width at half maximum does not change significantly in this same range. Although similar data were not obtained for tin oxide on tin, it is assumed that the same relationship is obeyed and that the area under the oxide peak is an approximately linear function of the amount present at a standard gamma ray flux.

It rapidly became apparent as this work progressed that the two important spectral components were metallic tin and SnO_2. In order to determine relative fractions of these two species, and thus SnO_2 film thickness, it is necessary to know the relative Debye-Waller factors of Sn and SnO_2. The Debye-Waller factor of bulk SnO_2 at 78°K is of the order of 0.5 (15) and that for tin is of the order of 0.4 (16).

As a first approximation, it is assumed that the Debye-Waller factors of metallic tin and SnO_2 in the passive film are the same at liquid nitrogen temperature and that they are not strongly a function of the thickness of tin nor the thickness of the SnO_2. On this basis it is qualitatively determined that the detection efficiency for SnO_2 is equivalent to a monolayer.

Table II summarizes the Mössbauer parameters calculated from the spectra for experiments in which tin was polarized over a potential range of −890 to +1180 mV after cathodic treatment for 10 min at −1200 mV. The thickness of the SnO_2 was calculated on the basis of an average tin thickness of 28.5 nm on each surface of the aluminum foil. Each run was carried out on a different sample that was electroplated under identical conditions. Three samples were analyzed polarographically as described previously and in all cases the average thickness of tin was equivalent to 28.5 nm. Thus, in Table II the calculated film thickness of SnO_2 is made on the basis of 28.5 nm (57 nm for both sides of foil) in all cases.

A typical spectrum after polarization of a 10 nm thick tin layer for 60 min at +250 mV is shown in Fig. 5. The spectrum is adequately reproduced on the basis of a single peak for SnO_2 and a single peak for metallic tin.

No SnO_2 peak was detected after cathodic reduction of samples that had been stored in a closed container for less than 30 days. Storage of samples for longer times resulted in the formation of surface oxides that could not be completely reduced. No study of this effect

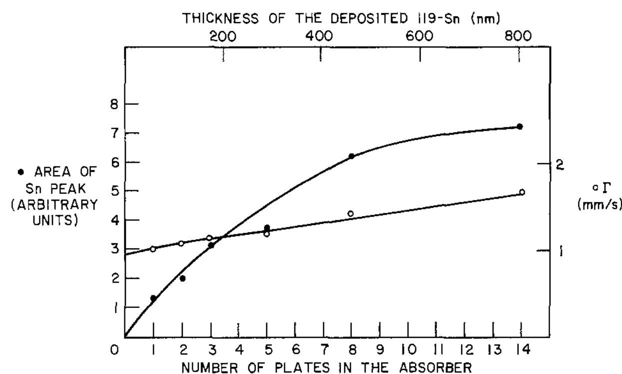

Fig. 4. The effect of thickness of tin on two Mössbauer spectral features.

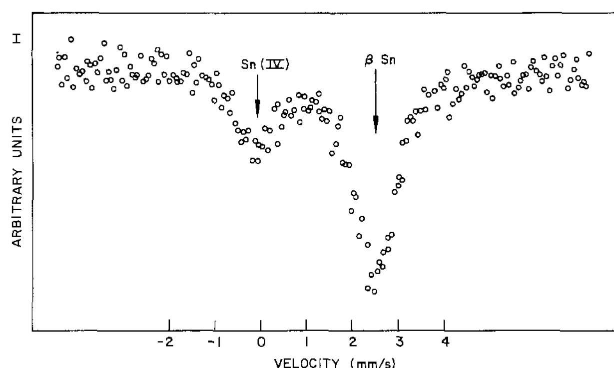

Fig. 5. Mössbauer spectrum of a tin sample polarized in borate buffer for 60 min at +250 mV.

was carried out and samples that were not completely reduced were not used in the polarization experiments.

As stated earlier, many authors have claimed the presence of Sn(II) in the passive film in the more negative range of potentials. In our studies, however, no conclusive indication of Sn(II) compounds was observed in any of the absorption spectra. It cannot be said with assurance that no Sn(II) was present in the passive film; only that it was not present in any significant concentration. It can be said with assurance that Sn(IV) was present over the potential range from −890 to +1180 mV. The Mössbauer parameters for bulk SnO are the following: isomer shift = 2.71 mm/sec and quadrupole shift = 1.45 mm/sec. Analysis of the spectra using these input parameters for the computer fitting indicated that the ability to detect SnO was always within the uncertainty limits as a conse-

* With reference to $BaSnO_3$.
** It was assumed that the Debye-Waller factors for tin and SnO_2 are approximately the same at 78°K.

quence of the fact that the spectrum for metallic tin overlaps that for SnO. On the basis of these attempted fits it was concluded that SnO would have to be present in concentrations equivalent to 0.6 nm before the uncertainty would be exceeded. According to thermodynamic calculations, anhydrous SnO_2 is the stable species relative to anhydrous SnO under oxidizing conditions, but $Sn(OH)_2$ has stability over a limited potential range relative to $Sn(OH)_4$ (17). A recent study of the passivity of tin in hydroxide solution (10) claims the presence of SnO in the more negative range of polarization potentials on the basis of chemical shifts as determined by x-ray photoelectron spectroscopy. The conclusion is tenuous, however, since other authors claim the inability to distinguish between SnO and SnO_2 on the basis of chemical shift alone (18).

The average isomer shift for SnO_2 obtained for all the experiments summarized in Table II was −0.06 mm/sec relative to $BaSnO_3$ with extreme values of −0.20 and +0.08 mm/sec. These values should be compared with an isomer shift of 0.00 mm/sec selected by Greenwood and Gibb (19) after examination of data in the literature. The spectrum of $Sn(OH)_4$ obtained by Cohen *et al.* (20) yields a value of 0.0 mm/sec. Thus, the isomer shift does not give useful information that distinguishes between the anhydrous and hydrated forms of SnO_2.

The data in Table II indicate that at times of polarization of 30-60 min the thickness of the oxide decreased from 2.3 to 0.8 nm over a potential range of −875 to −785 mV and then increased to 2.5 nm as the potential was changed to +1100 mV. A similar change in thickness with potential was observed by Ansell *et al.* (10) during polarization of tin in sodium hydroxide solution. They observed a decrease in film thickness from 3.5 nm at −950 mV (*vs.* Hg/HgO) to 3.0 nm at −850 mV, followed by an increase to 8.6 nm as the potential was increased in steps to +400 mV. No data are available from the current study to analyze the reason for the change in film thickness with potential.

The dissolution of tin, as judged solely by the lack of change in the intensity of the tin peak, was negligible in 60 min at all potentials above −500 mV even within the transpassive region. For example, a tin electrode was polarized at +1050 mV for 400 min, at which potential oxygen was vigorously evolved. The intensity of the tin absorption peak was practically the same under these conditions as it was prior to anodic polarization, thus indicating no significant reduction in the original tin thickness of 28.5 nm in 400 min. Some evidence, however, was found for tin dissolution at −860 mV. Data are presented in Fig. 6 on a log-log plot for the rate of change in current passing through the interface as a function of time at fixed potentials of −860 and +250 mV. It will be noted that at the longer times, in the case of polarization at −860 mV, the current passed through the interface is greater than expected on the basis of extrapolation of the curve from data obtained at shorter times. At +250 mV all the data points fall on a log-log plot over the time interval for which measurements were made. One possible interpretation of the −860 mV data is that dissolution of the oxide is continuously occurring and that some portion of the current is being utilized to replace the dissolved oxide.

The *in situ* emission experiments yielded very poor spectra. The major difficulty encountered was the low activity [typically 4 μCi] of the electrodeposited tin and the low Debye-Waller factor probably due to the very low thickness. Although no data are available to determine how the Debye-Waller factor is affected by thickness, in highly dispersed tin (d = 25 nm) Debye-Waller factors of 0.25 and 0.022 were measured at 93° and 300°K, respectively (21). These results suggest a very low factor for films of 1-2 nm in thickness. The low value may have been avoided during the measurements at 78°K because of the frozen liquid at the surface of the passive film which served as a solid matrix. At this level of activity it was very difficult to separate a spectrum from the background. Figure 7 is a spectrum generated during an 8 day period while the tin electrode was maintained at a potential of −800 mV.

Conclusions

Mössbauer spectroscopy is a suitable technique for studying the passive film formed on tin during anodic treatment. Satisfactory spectra were obtained at 78°K in absorption geometry using layers of aluminum foil on which tin enriched in ^{119}Sn had been electrodeposited. *In situ* emission spectra were obtained using ^{119m}Sn, but the quality of the spectra was limited by the low radioactivity of the thin tin electrodeposit used as a source.

The anodic oxide formed on tin in borate solution at pH 8.5 is resistant to attack by the electrolyte over a potential range of −500 to +1100 mV. Some evidence was obtained that suggested a low rate of dissolution during polarization at −860 mV. The predominant species present in the anodic oxide was tetravalent tin over the entire potential range studied, although no conclusive statement can be made that divalent tin does not exist at the surface in the vicinity of the negative potential at which the current density is a maximum. No conclusive data were generated that permitted determination whether or not the passive film contained water or hydroxyl ions in appreciable concentration.

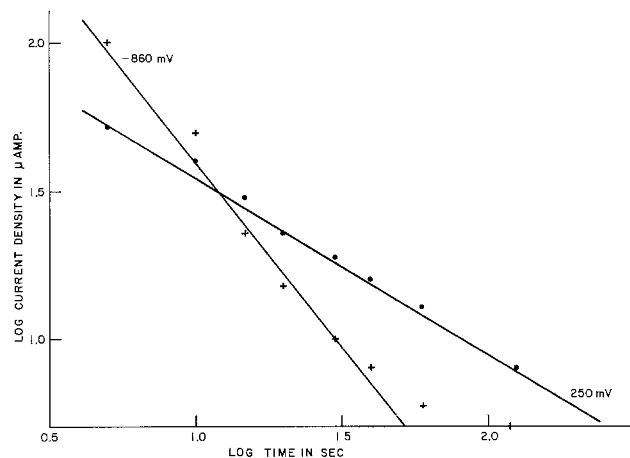

Fig. 6. Log-log plot of change of current with time during polarization of a tin electrodeposit on aluminum at −860 and +250 mV.

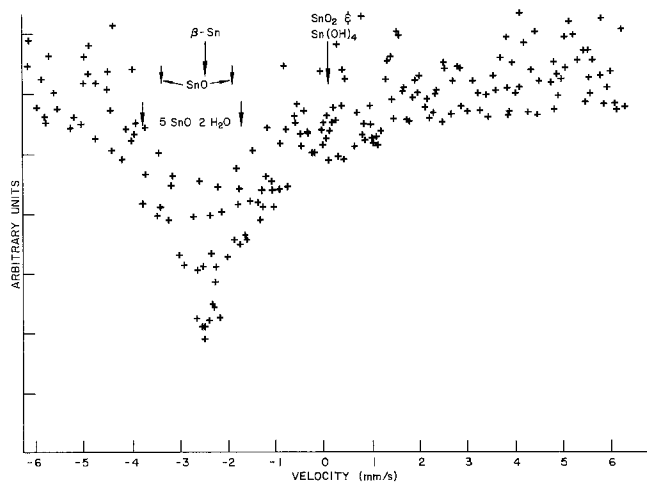

Fig. 7. Mössbauer emission spectrum of ^{119m}Sn on a tin substrate obtained over an 8 day period. The expected positions of peaks due to elemental tin, SnO, $5SnO \cdot 2H_2O$, SnO_2, and $Sn(OH)_4$ are indicated by arrows.

The thickness of tin oxide formed after polarization for 30-60 min ranged from a low value of 0.8-1.1 nm at −785 mV to a high of 2.3-2.5 nm at 1000-1100 mV.

Tin surfaces prepared by electrodeposition, on which oxides had been formed by exposure to air, were satisfactorily reduced cathodically to an oxide-free surface provided that the surfaces were aged in air at room temperature for less than 30 days. Longer aging times resulted in the formation of surface products that could not be readily removed by cathodic cleaning at −1100 mV in the borate buffer.

ABSTRACT

A mathematical model is developed based on a step distribution in the radii of tunnels of etched aluminum foil for electrolytic capacitors which permits calculating the dependence of the *C-V* product (capacitance × voltage) with the anodization voltage. The calculation is based upon a knowledge of the parameters characterizing the distribution. These parameters, namely mean length and radius, width and density of the tunnels of the etched foil, can be easily obtained in the case of high voltage foil by scanning electron microscopy observations. For low voltage foil it is difficult to experimentally define the parameters characterizing the distribution, and therefore the problem must be handled inversely, *i.e.*, the parameters of the distribution function in the radii of the tunnels have been calculated from the experimental *C-V* curve.

The tunnel etching of aluminum foil is a technique usually employed in the manufacture of electrolytic capacitors. The purpose of the etching is to enlarge the useful area of the capacitor, thus increasing the capacitance per unit volume. It is well known that the electrical properties of the capacitors strongly depend on the etch morphology of the aluminum foil. In turn, the etch morphology of the foil is very much influenced by the source of the foil and the pretreatments undergone by the foil, the temperature and the current density of the forming bath, the electrolytes and their additives, etc. (1, 2). Dunn and Bolon (3) have developed a technique for visualizing the tunnel morphology below the surface of the foil. The method consists of obtaining, by anodization, oxide replicas of the tunnels which are observed under the scanning electron microscope (SEM). Using this technique, Jackson (4) has studied the tunnel formation in aluminum as a function of the electrochemical parameters. Dunn *et al.* (5) have developed a simple model in order to calculate the dependence of the storage factor *C-V* of an electrolytic capacitor with the formation voltage. The model assumes that the tunnels are

Key words: capacitor, etching, oxide.

cylindrical in shape and all of the same radius. As can be expected, the model predicts a very abrupt decay of the C-V product when the anodization voltage is such that the oxide entirely occupies the volume of the tunnel.

One of the main objectives of the electrolytic capacitor industry is to obtain that etch morphology, *i.e.*, the size and shape of the tunnels produced by etching, which gives the highest C-V product. In this sense, it is very convenient to have a good knowledge of the variation of the C-V product with the anodization voltage. When there is a distribution of the size of the radii of the tunnels, the decrease of the C-V product with the anodization voltage is less steep than that predicted by the model of Dunn *et al.* In this work, a calculation of the C-V product is made for a simple distribution in the radii of the tunnels. The method can be extended to more complex distributions and it can be applied also to tunnels with conical shape, such as those commonly present in the foils used in low voltage applications (4). The agreement between the experimental values and those predicted by the model is very satisfactory for several types of etched aluminum foils.

Mathematical Model

Equal tunnels.—Dunn *et al.* (5) have calculated the product C_tV (C_t = tunnel capacitance per unit area) of a foil with N tunnels per unit area, all the tunnels having initial radius r and length l

$$C_tV = \frac{\epsilon\epsilon_0}{\kappa} 2\pi d N(l-d) \left\{ \ln \frac{d + [2.56r^2 - 0.6d^2]^{1/2}}{-0.6d + [2.56r^2 - 0.6d^2]^{1/2}} \right\}^{-1} \quad [1]$$

In this expression κ is the anodization constant, *i.e.*, the thickness d of the oxide grown during anodization per applied volt, ϵ is the oxide's dielectric constant, and $\epsilon_0 = 8.85 \times 10^{-12} F/m$.

For subsequent discussions, it is more convenient to write Eq. [1] in the form

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi r(l-d) N F(d/r) \quad [2]$$

with

$$F(d/r) = \frac{d}{r} \left\{ \ln \frac{(d/r) + [2.56 - 0.6(d/r)^2]^{1/2}}{-0.6(d/r) + [2.56 - 0.6(d/r)^2]^{1/2}} \right\}^{-1} \quad [3]$$

The function $F(d/r)$ depends exclusively on d/r, *i.e.*, the ratio between the thickness of the oxide and the initial radius of the tunnels. It therefore represents the occupancy of the tunnels by the oxide, and we shall call it the occupation factor. This function is represented in Fig. 1. Roughly, it varies from 1 for almost empty tunnels ($d << r$) to 0 when the tunnel is completely filled by the oxide ($d = 1.633r$).

A simple distribution of tunnels.—As has been suggested by Morley and Campbell (1), there is in reality a distribution in the lengths and radii of the tunnels. A Gaussian distribution in the length of the tunnels should be easily taken into account in the preceding model. In effect, since the product C_tV in Eq. [2] depends linearly on the length l of the tunnels, we can, in first approximation, substitute l by $\bar{l}$, the mean value of the distribution. The distribution in the radii of the tunnels is evidently much harder to handle. Let us call $D(r)$ the distribution function, *i.e.*, the number of tunnels per unit area with radii between r and $r + \Delta r$. The product C_tV will then be given by

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi\bar{l} \int_{r_{min}}^{r_{max}} r D(r) F(d/r) dr \quad [4]$$

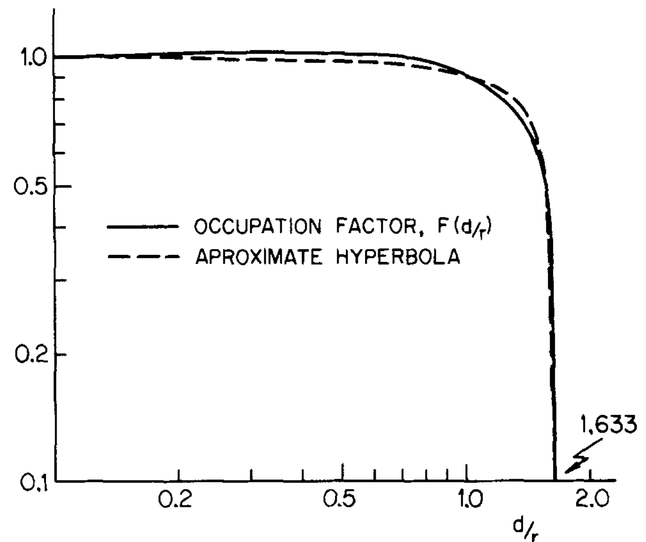

Fig. 1. Representation of the occupation factor $F(d/r)$ and its fitted hyperbola for a single tunnel.

where we have assumed $d << \bar{l}$. The distribution $D(r)$ should also verify the normalization condition $\int D(r) dr = N$.

The integral of Eq. [4] is difficult to evaluate due to the fact that the functions $F(d/r)$ and $D(r)$ are quite complicated in general. Once the function $D(r)$ is known, a numerical integration should be performed, making it necessary to evaluate the expression [4] in each particular case. Our purpose is to find a compact formula that would allow calculation of the C_tV product in most practical situations. The first step consists of assuming a simple distribution function in the radii of the tunnels such as a step function: $D(r) = D_o$ in the interval $r_{min} \leq r \leq r_{max}$ and $D(r)$ equal to zero for all other values of r. The choice of a step function is justified by the fact that the dependence with the anodization voltage that we will get is very similar to that obtained by using a Gaussian distribution, and both can be adjusted quite well to the experimental results. If $\bar{r}$ and $2\Delta r$ are the mean value and the width of the step distribution, respectively, Eq. [4] can be written as

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi\bar{l} \frac{N}{2\Delta r} \int_{\bar{r}-\Delta r}^{\bar{r}+\Delta r} r F(d/r) dr \quad [5]$$

Making the change of variable $r = \rho\bar{r}$ and putting $\delta = \Delta r/\bar{r}$ where δ is a parameter characterizing the relative width of the distribution, we get

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi\bar{r}\bar{l}N \frac{1}{2\delta} \int_{1-\delta}^{1+\delta} \rho F(d/\rho\bar{r}) d\rho \quad [6]$$

In analogy with expression [2], we can write Eq. [6] in the form

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi\bar{r}\bar{l}N\Phi_\delta(d/\bar{r}) \quad [7]$$

where

$$\Phi_\delta(d/\bar{r}) = \frac{1}{2\delta} \int_{1-\delta}^{1+\delta} \rho F(d/\rho\bar{r}) d\rho \quad [8]$$

is the new occupation factor for the step distribution.[1]

The evaluation of the integral in Eq. [8] still presents difficulties because the function that appears in

[1] Accounting for the contribution of unetched areas of the surface to the C-V product, a more approximate formula than Eq. [7] can be given. These areas, together with the bottom areas of the tunnels, may amount to about 6% of the C_tV product for the high voltage foil employed in this work. (In the low voltage foil this fraction is somewhat smaller).

the integrand is quite complex. A simple approximation would be to substitute the function $F(d/r)$ with a hyperbola function. Using the hyperbola shown in Fig. 1, the difference with the occupation factor is less than 5% in the interval $0 \leq d/r \leq 1.5$. For values of d/r between 1.5 and 1.633, the difference in ordinates might be greater than 5%, although the separation in abscissas is less than 3%. In any case, the approximations inherent to the model (step distribution, cylindrical tunnels, etc.) are larger than those introduced in the above mathematical approach.

In the Appendix we give the equation of the trial hyperbola as well as the details of the calculation of the occupation factor. However, from a practical point of view, it is more advisable to use the occupation function in a tabulated form (Table I) or in a graphical representation, such as that of Fig. 2. It can be appreciated from this figure that as the width δ of the distribution becomes larger, the occupation factor decreases more and more slowly with d/r. The occupation factor $F(d/r)$ given by Eq. [3] appears now as a particular case of $\Phi_\delta(d/r)$ for $\delta = 0$.

More general types of distributions.—The tunnels of the high voltage aluminum foil have a nearly cylindrical shape as a consequence of the chemical attack in HNO_3 undergone by the foil after the electrochemical etching (6). In addition, the distribution in radii is very narrow. Due to these facts, the approximation discussed in the preceding paragraph is good enough to adjust the experimental values of the C_tV product as we shall see in the next section. On the other hand, the foil for low voltage applications does not usually go through the chemical etch, resulting in tunnels with somewhat conical shape and a wide distribution in radii (5). As Morley and Campbell (1) have shown in this case, the distribution $D(r)$ is asymmetric and presents a tail in the region of large radii.

Given a general distribution like the one represented in Fig. 3, we can always make an approximation to it by means of several step distributions, as is schematically shown in the figure. In this case, the product C_tV will be given by

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi l[\bar{r}_1 N_1 \Phi_{\delta_1}(d/\bar{r}_1) + \bar{r}_2 N_2 \Phi_{\delta_2}(d/\bar{r}_2)] \quad [9]$$

with the total concentration of tunnels $N = N_1 + N_2$. We can write Eq. [9] in a more compact manner by putting $N_2/N_1 = \alpha$, and $\bar{r}_2/\bar{r}_1 = \beta$ ($\alpha = \Delta r_2/\Delta r_1$ when the two step distributions of Fig. 3 have the same height). Thus

$$C_tV = \frac{\epsilon_0\epsilon}{\kappa} 2\pi \bar{r}_{\text{eff}} N \bar{l} \Phi_{\text{eff}}(\delta_1\delta_2) \quad [10]$$

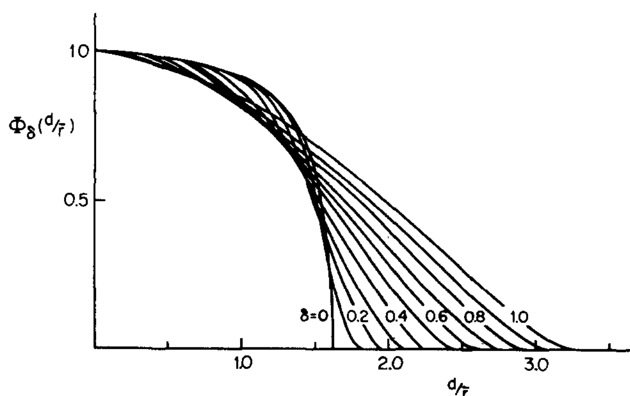

Fig. 2. Occupation factor $\Phi_\delta(d/\bar{r})$ of a step distribution in the radii of the tunnels for several relative widths of the distribution.

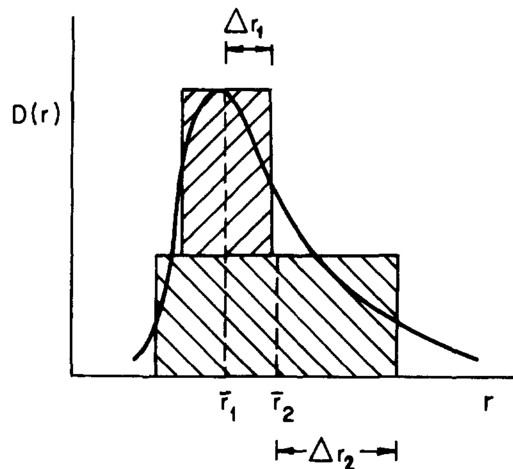

Fig. 3. Example of the approximation of a general distribution by two-step distribution functions.

where $\bar{r}_{eff}$ and $\Phi_{eff}(\delta_1\delta_2)$ are, respectively, the effective radius and the new occupation factor of the distribution, and are given by

$$\bar{r}_{eff} = \bar{r}_1 \frac{1 + \alpha\beta}{1 + \alpha} \quad [11]$$

$$\Phi_{eff}(\delta_1\delta_2) = \frac{\Phi_{\delta_1}(d/\bar{r}_1) + \alpha\beta\Phi_{\delta_2}(d/\beta\bar{r}_1)}{1 + \alpha\beta} \quad [12]$$

The new occupation factor $\Phi_{eff}(\delta_1\delta_2)$ has been normalized in such a way that it varies between 0 and 1, resulting in an effective radius r_{eff} within $\bar{r}_1$ and $\bar{r}_2$.

The case of a symmetric distribution function, a Gaussian, for example, can be handled by the above approximation making $\bar{r}_1 = \bar{r}_2$. The corresponding occupation factor Φ_{eff} takes values between $\Phi_{\delta 1}$ and $\Phi_{\delta 2}$, getting closer to $\Phi_{\delta 2}$ when δ_2 increases with respect to δ_1 (the converse is also true). In any case, the new occupation factor is quite similar to a step distribution with a width between δ_1 and δ_2. In this way, the step distribution approximation developed in the preceding paragraph is further justified. The observations that we have made for symmetric distributions do not apply in the case of asymmetric distributions treated in this paragraph. In this event, we have to add at least two occupation functions with different radii $\bar{r}_1$ and $\bar{r}_2$, resulting in a new function bounded by the above two.

Experimental Results

The interest of the occupation function resides in the fact that it helps to predict, in a simple manner, the dependence of the C_tV product of an etched aluminum foil as a function of the anodization voltage. To this end we have to know the parameters characterizing the shape and distribution of the tunnels which can be obtained in most cases by SEM. Figure 4 shows the variation of the C_tV product for commercial high and low voltage aluminum foils employed in the production of electrolytic capacitors. The aluminum foils were anodized in a typical electrolyte composed of an aqueous solution of boric acid, ammonium pentaborate, and glycol. The capacitance at 100 Hz of the foil has been measured in a boric acid solution (ρ = 100 Ω cm) with a Hewlett-Packard Model 4261A capacitance bridge.

The curve of the high voltage foil in Fig. 4 has been calculated employing a simple distribution of tunnels, as outlined in Eq. [7] and [8], assuming an anodization constant κ = 14 Å/V and a dielectric constant ϵ = 8.4 for aluminum oxide (7, 8)]. For this purpose, replicas of the tunnels were obtained by the technique of Dunn and Bolon (3) and observed under the scanning electron microscope (Fig. 5) both perpendicular and parallel to the original surface of the aluminum foil. From the microphotograph of Fig. 5 the following parameters characterizing the tunnels are observed: $\bar{r}$ = 0.5 μm; Δr = 0.2 μm; $\bar{l} \simeq$ 30 μm; and $N \simeq 17 \times 10^6$ cm^{-2}. As it can be appreciated, the concordance between the curve predicted by the model and the experimental results is quite good.

The curve corresponding to the low voltage foil in Fig. 4 cannot be adjusted with just one-step distribution in the radii of the tunnels. It is evident from the microphotograph of Fig. 6 that the distribution of radii

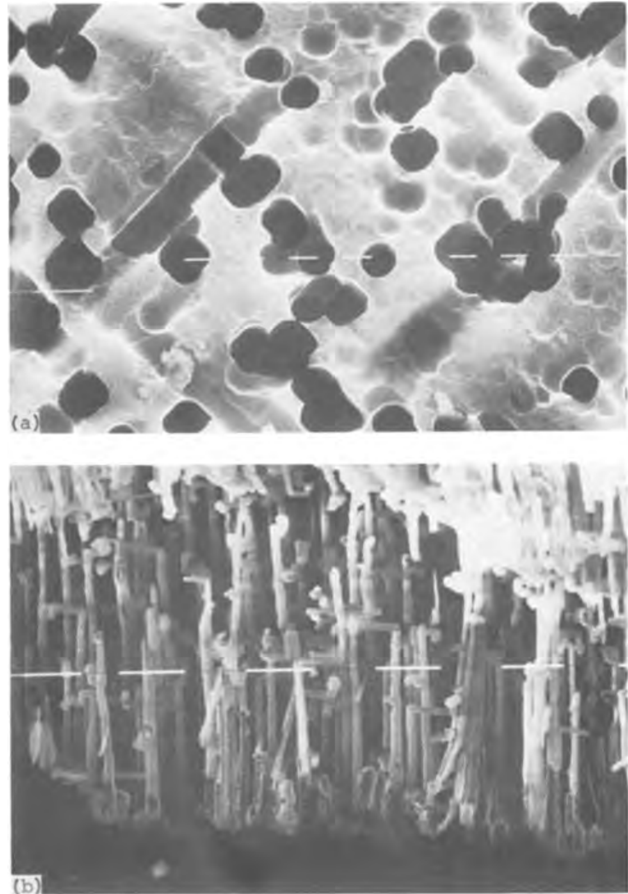

Fig. 5. (a) SEM micrograph of the surface of high voltage etched aluminum foil (reticule, 1 μm); (b) SEM micrograph of a cross section of the same foil obtained by the replica technique mentioned in the text (reticule, 10 μm).

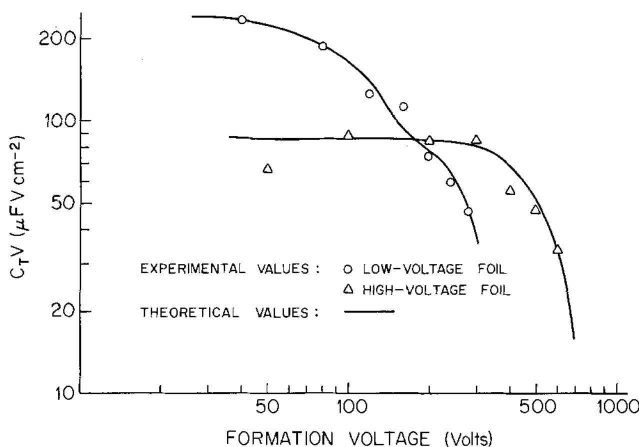

Fig. 4. Experimental values and computed curves for the C_tV product for high and low voltage aluminum foil.

Fig. 6. SEM micrograph of an oxide replica of the tunnels in low voltage etched aluminum foil.

is much wider than in the high voltage case, and also that the tunnels present a conical shape. Due to the difficulty in getting the parameters of the distribution, in this case we proceed in an inverse manner. This consists of adjusting the experimental points with an occupation function corresponding to an asymmetric distribution chosen in such a way that the error is the least possible one. By this procedure we obtain an effective radius $\bar{r}_{eff} = 0.10$ μm and a total tunnel length $N\bar{l} = 7.3 \times 10^9$ μm/cm², which compare well with typical values found in low voltage foil (4, 5). Now, it is not possible to separate the values of N and $\bar{l}$ unless we resort to precise measurements with the scanning electron microscope.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by the Universidad Autonoma de Madrid.

APPENDIX

The equation of the hyperbola resulting in the best fit for the occupation factor of Eq. [3] is given by

$$F(d/r) \simeq \frac{0.166}{(d/r) - 1.742} + 1.066$$

It can also be numerically shown that if a step distribution in the radii of the tunnels is used to adjust the values of the C_tV product given by Eq. [7] and [8] to the experimental points, it is practically immaterial to use either the function $F(d/r)$ or the hyperbola. When performing the integration in Eq. [8] it should be noted that the function $F(d/\rho\bar{r})$ does not contribute to the integral when $d/\rho\bar{r} > 1.633$, while the fitted hyperbola is different from zero in that interval. This difficulty can be overcome by computing the integral in two different intervals of the parameter $d/\bar{r}$. For values of the parameter up to $1.633\ (1 - \delta)$, where δ is the relative width of the distribution, the integrand is always positive and the calculation of the integral is quiet straightforward. In the interval $1.633\ (1 - \delta) \leq d/\bar{r} \leq 1.633\ (1 + \delta)$, the hyperbola is positive only when $\rho > (d/\bar{r})/1.633$. The negative values of the hyperbolic function can be eliminated if the lower limit of the integral is changed to $0.1624\ (d/\bar{r})$. The final result is the following:

(*i*) In the interval $0 < (d/\bar{r}) < 1.633\ (1 - \delta)$

$$\Phi_\delta(d/\bar{r}) = \frac{1}{2\delta}\int_{1-\delta}^{1+\delta} \rho \left[\frac{0.166}{(d/\rho\bar{r}) - 1.742} + 1.066\right] d\rho$$

$$= 1 - 0.0382(d/\bar{r}) - \frac{0.0110}{\delta}(d/\bar{r})^2 \ln\frac{1.742(1+\delta) - (d/\bar{r})}{1.742(1-\delta) - (d/\bar{r})}$$

(*ii*) In the interval $1.633\ (1 - \delta) < (d/\bar{r}) < 1.633\ (1 + \delta)$

$$\Phi_\delta(d/\bar{r}) = \frac{1}{2\delta}\int_{0.612(d/r)}^{1+\delta} \rho \left[\frac{0.116}{(d/\rho\bar{r}) - 1.742} + 1.066\right] d\rho$$

$$= \frac{(1+\delta)^2}{4\delta} - 0.0191\frac{(1+\delta)}{\delta}(d/\bar{r}) - \frac{0.082}{\delta}(d/\bar{r})^2 - \frac{0.011}{\delta}(d/\bar{r})^2 \ln\left[15\frac{1.742(1+\delta) - (d/\bar{r})}{(d/\bar{r})}\right]$$

Anodic Synthesis of Organic Carbonates

Divna Cipris* and Irving L. Mador

Allied Chemical Corporation, Corporate Research Center, Morristown, New Jersey 07960

ABSTRACT

Carbonic acid esters (carbonates) are produced by electrolysis of carbon monoxide and the corresponding alcohol in the presence of a halide electrolyte. The halide electrolyte plays a catalytic role in carbonate formation. The efficiency for the process depends, among other variables, on the starting alcohol. Both mono and 1,2-dihydric aliphatic alcohols form carbonates in high yields. Under our electrolytic conditions, without optimization, dimethyl carbonate from methanol and ethylene carbonate from ethylene glycol were formed with 80 and 45% current efficiencies, respectively. One mole of hydrogen is liberated per mole of carbonate. Organic carbonates represent a class of important industrial solvents. They are commercially produced via employment of phosgene; HCl is formed as a by-product. The electrochemical process obviates the use of phosgene and eliminates the hydrochloric acid disposal problem.

Interest in the electrochemical reactions of carbon monoxide, carbon dioxide, and other cheap, readily available raw materials has been renewed lately. The possibility of their use as building blocks for various commercially important chemicals is increasingly appealing. In this context, the demonstrated electro-

chemical reductive tetramerization of CO to squarate ion is most intriguing (1). A similar reaction with direct anodic oxidation of carbon monoxide has not been reported. Indirectly, carbomethoxylation of an aryl olefin[1] (2) and carbonylation of certain aromatic hydrocarbons (3) have been achieved. These appear to remain isolated cases of CO participation in anodic reactions from a synthetic point of view. The present paper describes the synthesis of carbonic esters (carbonates) by electrolysis of carbon monoxide in alcohols in the presence of a halide electrolyte, representing an additional example of an indirect anodic reaction.

The electrooxidation of methanol in aqueous solutions has been studied extensively in relation to fuel cell applications (4). In acid solutions, carbon dioxide is the principal product, with traces of formaldehyde and formic acid. In alkaline solutions, there is partial oxidation to formate. The anodic oxidation of absolute methanol has been studied to a limited degree, in spite of the fact that methanol has been widely used as a solvent for various electroorganic oxidations (5). Depending on the type of supporting electrolyte used, the following major products were obtained in the oxidation of methanol on platinum: dimethoxymethane ($NaClO_4$, tetrabutylammonium fluoride) (6), formaldehyde ($NaOCH_3$) (6-8), and methyl formate (NaI) (9). With sodium phenate electrolyte, no anodic reaction is reported to occur (8). The discharge of chlorine ion is the predominant reaction in the presence of lithium chloride. Some formate was detected (8). Addition of water (up to 10%) did not have a significant effect on the current efficiency for formaldehyde formation ($NaOCH_3$) (7); higher water content (or employment of KOH electrolyte) favored formate formation (8). The ethanol oxidation on platinum produced analogously diethoxyethane ($NaOCl_4$, TBAF), acetaldehyde ($NaOC_2H_5$) (6), and ethyl formate (NaI) (9).

Commercial production of carbonates involves the use of phosgene at elevated temperatures (10). The main advantage of the present process is in obviating the necessity for storage and handling of phosgene, and disposal of hydrochloric acid. Other chemical routes to carbonates are also described, but efficiencies of these reactions are not well established (11-13). Organic carbonates are used in many industrial applications, such as solvents for polymers and resins in processing operations, and in the synthesis of pharmaceuticals, rubber chemicals, textile finishing agents, and polycarbonate resins.

Experimental

Constant current electrolysis.—Preparative scale electrolyses were conducted at constant current using equipment described elsewhere (14). A stainless steel (T316 SS) high pressure electrolytic cell, equipped with a graphite liner and changeable cathodes and anodes, was employed in all runs. One electrode served as a container for the solution to be electrolyzed and had an approximate capacity of 300 ml. The second electrode was in the form of a rod (Fig. 1). The pressure bomb was supplied by Parr Instrument Company (pressure rating 2000 lb max, 300°C) and was in-house modified (head and liners) according to our specifications. A cation exchange membrane (Ionics 61/DYG 067) was used to separate cathodic from anodic chambers in some experiments.

In a representative experiment leading to high carbonate yields, 200 ml of alcohol and 4.0g (0.04 moles) of NH_4Br were charged into a stainless steel high pressure electrolytic cell and then pressurized with carbon monoxide to 100 atm. Commercial anhydrous alcohols were used without further purification or drying. Cosolvents were used where necessary. Graphite anodes and stainless steel cathodes were used

[1] An active intermediate, $Pt_x(CO)_y$, was formed via cathodic Pt dissolution, so this reaction is not solely anodic.

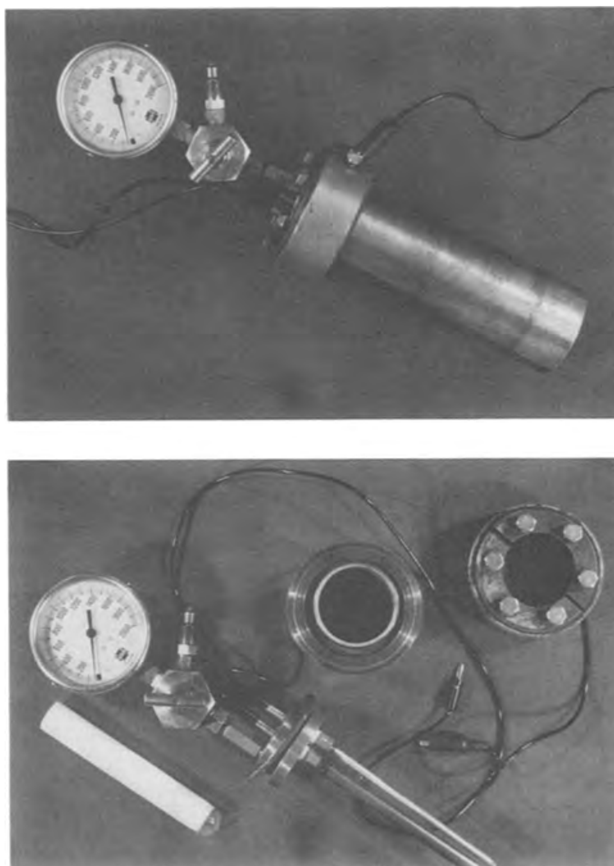

Fig. 1. High pressure electrolytic cell and electrodes. a, assembled; b, detailed view.

throughout the work. The reported results were obtained in a one-compartment cell. The electrolyses were conducted at constant current at varying anodic current densities (20-120 mA cm^{-2}) with equivalent results. A total of 0.45**F** was usually passed. The temperature was maintained at 20°-30°C by a cold water circulating coil.

Product analyses were performed by GC, GC-mass spectrometry, and *IR*. Isolation of various products was achieved using preparative GC techniques. GC analyses of methanol, ethanol, and ethylene glycol electrolysis products were carried out with a 5 ft × 1/8 in. stainless steel column packed with Poropak PS (70° → 230°C/8°/min). For analysis of aryl and alkaryl carbonates, a 2 ft × 1/4 in. glass column packed with OV 17 (150° → 250°C/10°/min) was used. A Finnigan Model 3300 gas chromatograph/mass spectrometer operated in a chemical ionization mode with methane as the reagent gas was used for analysis of liquid samples. Gas samples were analyzed by an AEI ms 902 Mass Spectrometer (ionizing voltage 70 eV).

Potentiodynamic measurements.—The equipment and cell used in these measurements were previously described (14). A graphite rod anode (~1 cm^2 geometric area) and platinum clad tantalum were working and auxiliary electrodes, respectively. Platinum and activated titanium anodes [home-made according to previously published procedure (15)] were also tested. Solutions were purged with argon prior to the recording.

Results

Dimethyl carbonate.—Effect of electrolyte and electrolyte concentration.—The electrolyte plays an essential role in determining the type of products formed. Besides dimethyl carbonate, methyl formate and dimethoxymethane are seen as the major products in various experiments. Some unidentified minor com-

ponents may also be present. With a bromide electrolyte, gas analysis showed the presence of CH_3Br, CO_2, and H_2 in the ratio 1:10:10. The data for various electrolytes shown in Table I were obtained after 0.45**F** (12 A-hr) with graphite anode at 100 atm carbon monoxide pressure. The value in parentheses represents the current efficiency (%) for dimethyl carbonate formation (based on a two-electron process).

Our experiments show that increase in the electrolyte concentration decreases the yields of dimethyl carbonate.

Effect of CO pressure and temperature.—The effect of carbon monoxide pressure on dimethyl carbonate formation is illustrated in Fig. 2. The scattering of results may be due to inadequate mass transfer (magnetic stirring bar employed). These data suggest that there is at least a 5% yield increase of dimethyl carbonate for each 6.8 atm (100 psi) increment of carbon monoxide. The reactions were conducted in the temperature range 20°-30°C. Our experimental facilities did not permit going above 100 atm.

No essential difference in dimethyl carbonate yields was observed when the reactions were carried out at 20°-30°C as compared to 50°-60°C. By-product formation (methyl formate, dimethoxymethane) is, however, somewhat increased at higher temperature.

Effect of current density, electrode materials, and cell configuration.—Electrolysis of CO in methanol conducted at 20 and 120 mA cm^{-2} (geometric area) on graphite gave identical current efficiencies for dimethyl carbonate formation. When a graphite anode was substituted by platinum (on tantalum), rapid dissolution of the anode took place at the higher current densities (Br^- electrolyte). Similar behavior was observed with activated titanium anodes (Ir + Se on Ti) in cyclic voltammetry experiments. A stainless steel cathode was used in all experiments described. The separation of anodic and cathodic compartments was essential only at low cathodic current densities, as can be seen from Table II. At higher cathodic current densities, dimethyl carbonate yields were not affected by elimination of separator.

Other carbonates.—Diethyl carbonate.—The synthesis of diethyl carbonate from ethanol and carbon monoxide was conducted under electrolytic conditions which

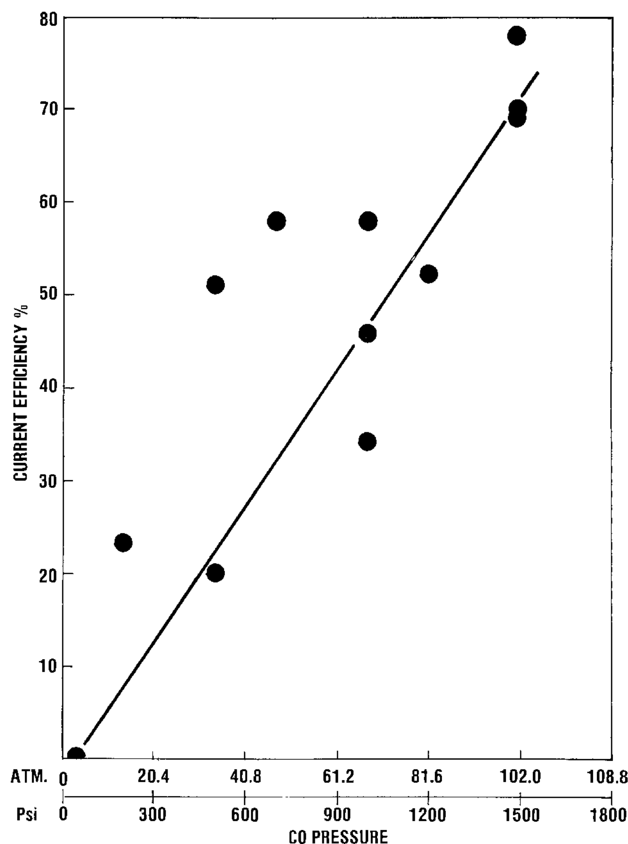

Fig. 2. Current efficiency dependence on carbon monoxide pressure in the synthesis of dimethyl carbonate.

led to the highest yield of dimethyl carbonate in this work (0.2M NH_4Br, 100 atm). Apart from diethyl carbonate (26% current efficiency, based on 2**F**/mole), ethyl formate was observed as the major by-product. Some unidentified products were also seen. The data for this and other carbonates are presented in Table III.

Table II. One- vs. two-compartment cell in dimethyl carbonate formation

Electrolyte	Cell	Cathode current density (mA cm^{-1})	Dimethyl carbonate, current efficiency (%)
LiBr 0.2M	Two-compartment (Cation exchange membrane)	20	70
	One-compartment	20	15
NH_4Br 0.2M	Two-compartment (Cation exchange membrane)	20	70
	One-compartment	120	70-80

Cyclohexanol	methanol	0.2M Bu_4NBr	none

* Conditions: 100 atm CO, 20°-30°C, graphite anode, 0.2-0.5F.

Ethylene carbonate.—Due to the lower conductivity of ethylene glycol/0.2M NH_4Br solution, the electrolysis of ethylene glycol and carbon monoxide was carried out with higher electrolyte concentration than in previous experiments (0.5M NH_4Br, 100 atm). Under these conditions, ethylene carbonate was formed with 5-10% current efficiency (2F/mole). Some unidentified products were detected. When methanol was used as cosolvent (ethylene glycol:methanol = 4:1), and the NH_4Br concentration was decreased to 0.2M, dimethyl carbonate and ethylene carbonate were the only products, with current efficiencies of 25 and 45%, respectively (Table III).

Diphenyl carbonate, dibenzyl carbonate, and dicyclohexyl carbonate.—Electrolyses of phenol, benzyl alcohol, and cyclohexanol, respectively, with carbon monoxide were conducted in the presence of methanol (1:1), in the usual way (0.2M NH_4Br, 100 atm). No evidence for formation of diphenyl, dibenzyl, or dicyclohexyl carbonate could be found. Interestingly enough, in methanol no trace of dimethyl carbonate could be detected with phenol present even in the relatively small smounts (~5 w/o).

Current-potential data.—Current-potential curves were recorded in methanol solutions with various electrolytes in the absence of carbon monoxide. Current-potential profiles of methanol with supporting electrolytes other than halides (5 w/o H_2SO_4 or 5 w/o NH_4NO_3) display current rises commencing at about 1.5V *vs.* SCE. This current may be due to the methanol or supporting electrolyte anion oxidation, along with oxidation of traces of water present in the solutions. When halide anions were added to any of these solutions, the current-potential profiles were changed, indicating halide ion oxidation. As expected, the oxidation potentials increase in the following order: $I^- < Br^- < Cl^-$. Figure 3 presents current-potential profiles for oxidation of iodide, bromide, and chloride ions on graphite electrodes in H_2SO_4/CH_3OH solution.

The current-potential curves in pure H_2SO_4/CH_3OH and with varying concentrations of added NH_4Br are shown in Fig. 4. The limited current for Br^- oxidation is proportional to the concentration, as expected (16, 17). Repetitive cycling of a 0.2M NH_4Br solution for 30 min did not alter the current-potential profile. Different results were obtained, however, when similar experiments were conducted in NH_4NO_3/CH_3OH solutions. Peaks representing bromide oxidation were ill defined (Fig. 5). On repetitive cycling a current decrease was observed.

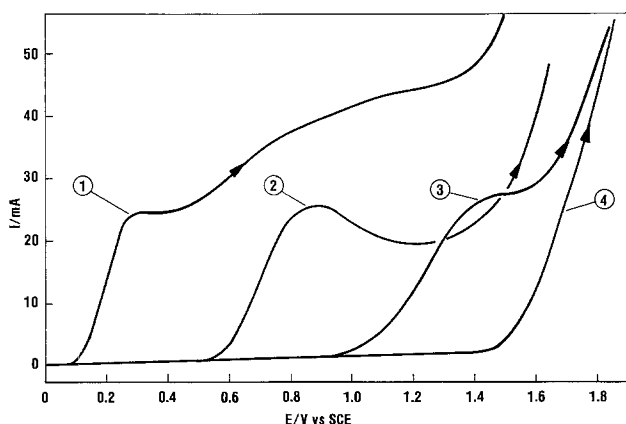

Fig. 3. Current-potential profile of halide ions oxidation in H_2SO_4/methanol solution. Graphite anode (~1 cm^2 geometric area); 25°C, sweep rate 50 mV sec^{-1}. 1, 2 × 10^{-1}M NaI; 2, 2 × 10^{-1}M NH_4Br; 3, 2 × 10^{-1}M NaCl; 4, pure 5 v/o H_2SO_4 in methanol.

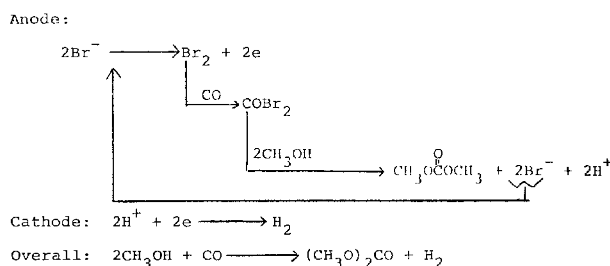
Discussion

Under our electrolytic conditions, electrolysis of methanol, in the presence of carbon monoxide but with electrolytes other than halides, produced methyl formate and/or dimethoxymethane (Table I), as previously observed (6, 9). Dimethyl carbonate was not detected until the addition of a halide ion.

Addition of a halide ion, or free halogen, to the nonhalide electrolytes resulted in dimethyl carbonate formation, along with the usually observed products. Under certain electrolytic conditions, dimethyl carbonate was the principal product with virtually no other products formed (Table I). The presence of free halogen, added or generated *in situ*, emerges thus as instrumental for carbonate formation. Dimethyl carbonate formation is therefore attributed to the indirect reaction, via carbonyl halide. A possible reaction sequence is as follows:

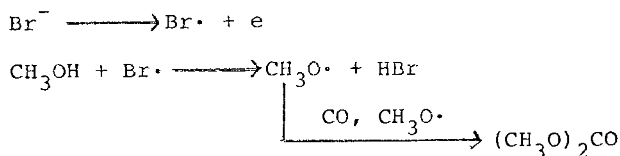
Scheme 1



The mechanism invoked in Scheme 1 can adequately account for experimental evidence obtained in this work.

The alternative anodic mechanism (Scheme 2), in analogy to a suggested mechanism operating to a certain degree in methanolic chloride solutions (8), was ruled out based on the fact that we did not detect any dimethyl carbonate in the solutions in which methoxy radicals are reported to be formed ($NaOCH_3$)[2]

Scheme 2



The best yields of dimethyl carbonate were generally obtained with bromide electrolytes. The lower yields obtained with chloride compared to bromide electrolytes are explained on the basis of low ΔE between chloride ion oxidation and direct methanol oxidation (see Fig. 3). Simultaneous oxidation of both may be thus possible under steady-state conditions. Direct methanol oxidation, even in the presence of CO, leads to products other than dimethyl carbonate as already seen. Formation of dimethoxymethane along with dimethyl carbonate is thus observed in the presence of chloride electrolyte. It should be emphasized, however, that all reported results were obtained with a graphite anode. It is conceivable that substantially different product distributions could be obtained with various activated titanium anodes, known for their catalytic effect on chlorine evolution (18). This remains to be determined. The lower yields obtained with iodide electrolytes are attributed to an apparently lower rate of CH_3OH/COI_2 interaction compared to rates of possible side reactions. The formation of several unidentified by-products is observed when CO was electrolyzed in methanol in the presence of iodide electrolyte (or upon addition of free I_2 to an inert auxiliary nonhalide electrolyte). Although not identified, these products are believed to be the result of direct iodination reactions.

The water content of methanol solutions in our work was generally below 0.5%. Higher water content can be tolerated with no, or only slightly, adverse effect on carbonate formation (2-3%). At 10 w/o water in methanol/NH_4Br solution, current efficiency for carbonate formation was substantially decreased. Increased water content in absolute alcohol reportedly leads to formate (with $NaOCH_3$ electrolyte) (8). No methyl formate was seen in our case, indicating that different mechanisms would be responsible for formate formation in these two media. Since no buildup of other products was observed, water discharge and/or methanol oxidation to carbon dioxide appears responsible for decreased efficiency in carbonate production.[3] An interesting dependence of methanol oxidation peak potential on water concentration was observed earlier (8), making such an explanation plausible.

As has been shown (Table II), high yields of dimethyl carbonate can be obtained in a one-compartment cell at comparatively high cathodic current densities. At low cathodic current densities, separation of anolyte and catholyte is required to secure high yields of dimethyl carbonate. This observation indicates that the anodic reaction products are decomposed at the cathode at low cathodic current densities. At high cathodic current densities, hydrogen evolution is, presumably, the predominant cathodic reaction and dimethyl carbonate yields are not affected.

[2] We agree with Reviewer II's comment that a more likely radical attack would be on the C—H bond. Scheme 2 is nevertheless included to show that, even if possible, it would not be applicable in our case.

[3] CO oxidation to CO_2 could not be excluded either.

Anodic current density has no effect on the product distribution within the range of the limiting current for bromine evolution. With bromide electrolyte, the choice of electrode materials appears limited to graphite. Neither platinum (on tantalum) nor activated titanium anodes could withstand bromine attack for a prolonged time. With a graphite anode, reproducible results can be obtained in most cases; however, attention should be paid to the choice of auxiliary electrolyte, if employed. Nitrate anion is found to reduce graphite activity with time for dimethyl carbonate formation. Current-potential curves showed that bromine evolution in this medium is not simply diffusion controlled. This aspect was not studied in detail.

Increase of carbon monoxide pressure favors dimethyl carbonate formation, as evidenced in Fig. 2. While the reaction was not examined at pressures higher than 100 atm, it is believed that reaction efficiency would further increase at higher pressures. An interesting feature is that while chemical formation of carbonates via phosgene is carried out at elevated temperatures, the electrochemical approach does not require high temperature for efficient reaction.

Electrolysis of ethanol and carbon monoxide was investigated under only one set of conditions, namely with NH_4Br electrolyte (0.2M) under 100 atm of CO. As indicated (Table III), diethyl carbonate was the principal product, but formation of ethyl formate was also observed along with a few minor components.

Ethylene glycol electrolysis in the presence of carbon monoxide (and bromide electrolyte) led to the formation of ethylene carbonate although in low yields (Table III). When methanol was used as cosolvent, simultaneous formation of dimethyl carbonate was observed without any additional by-products. This result suggests that ethylene carbonate can be synthesized with high current and material efficiencies when an inert cosolvent, rather than methanol, is employed. Ethylene carbonate itself could possibly be such a cosolvent. We did not attempt to optimize conditions for the synthesis of each particular carbonate, but rather contented ourselves with demonstrating the general validity of the concept for carbonates formation.

Based on our experimental evidence, the present electrochemical synthetic route to organic carbonates appears valid for aliphatic (mono- and 1, 2-dihydric) alcohols but not for alkyl-aryl or aryl. No evidence for formation of dibenzyl or diphenyl carbonate could be found in the few experiments conducted (Table III). This did not come entirely as a surprise for a number of reasons (apart from possible bromination on the ring), especially in the case of phenol electrolysis. Inhibition of bromine evolution upon addition of phenol has been previously observed (16). Also, no anodic reaction was observed when methanol was electrolyzed in the presence of sodium phenoxide (8). Adsorption of phenoxy radicals is credited for inhibition of bromine evolution. We believe that strong adsorption of phenoxy radicals and/or formation of an insulating organic film might be responsible for the total "passivation" of the anode observed in the second case. In addition to the absence of phenyl carbonate, no trace of dimethyl carbonate was observed with methanol as a cosolvent. This suggests that strong inhibition of bromine evolution was taking place, in this case, in agreement with previous observations. Electrolysis of benzyl alcohol and cyclohexanol with methanol as a cosolvent produced some dimethyl carbonate, but no other carbonates could be detected. This may be due to the different rates for aliphatic *vs.* alkyl-aromatic and alicyclic carbonates formation. Further studies will be conducted to assess whether the problems encountered above could be circumvented and anodic synthesis of aryl, alk-aryl, and alicyclic carbonates achieved.

The products of anodic methanol oxidation are highly electrolyte dependent, as already seen. Individual

mechanisms for some of these reactions have been suggested, but no effort has been made to explain the dramatic influence exercised by various electrolytes. Oxidation of methanol per se was not of primary interest, and it was not investigated in detail. Nevertheless, some observations are noteworthy. It is apparent from our results (Table I) that acetals can be preferentially formed in "acidic" (5 v/o conc. H_2SO_4) as well as in "neutral" ($LiClO_4$) electrolytes. The formation of methyl formate is favored by the presence of a halide electrolyte, in both "neutral" (Bu_4NBr) or "acidic" (10 v/o conc. HCl) media. The latter would speak in favor of the mechanism proposed recently, where methyl formate is formed via solution interaction with electrochemically generated free halogen in a fairly involved fashion (9). The only problem is, however, that our yields of methyl formate in 0.2M Bu_4NBr electrolyte (in the presence of CO) highly exceed theoretical yields based on proposed 4 **F**/mole (of ester) reaction. Participation of CO in the product formation, presumably via chemical reaction, should be considered. This result obviously deserves further attention.

Summary and Conclusions

Carbonic acid esters (carbonates) can be synthesized by electrolysis of carbon monoxide and corresponding alcohols in the presence of a halide electrolyte. The halide electrolyte is essential for carbonate formation. Based on our experimental evidence, a mechanism is proposed whereby carbonates are formed via interaction of an alcohol with an *in situ* generated carbonyl halide ($COCl_2$, $COBr_2$). Elevated carbon monoxide pressure is required to secure high yields. The efficiency of the process depends, among other variables, on the type of starting alcohols. Both mono and 1, 2-dihydric aliphatic alcohols form carbonates in high yields. No evidence for formation of diphenyl carbonate could be found when phenol was electrolyzed under carbon monoxide pressure in the presence of a bromide electrolyte. Inhibition of bromine evolution due to the preferential adsorption of the organic species on the electrode is believed responsible for the lack of carbonate formation. The failure to observe carbonates derived from benzyl alcohol and cyclohexanol is attributed to different causes.

Acknowledgment

Technical assistance of Mr. Arthur T. Walsh, who conducted the high pressure electrolyses, is greatly appreciated. The authors are also indebted to the Chemical Physics Department personnel for their invaluable contributions, especially Dr. D. E. Smith (GC-mass spectrometry), Mr. E. McCarthy (mass spectrometry), Mr. J. M. Hanrahan (preparative GC), and Dr. R. L. Lapinski (*IR* interpretation). One of the authors (D. C.) would like to thank Dr. F. Mares for useful discussions and encouragement during the early phases of this work. Thanks are also due to Ms. Marcy Daboul for her patience in typing various versions of this manuscript.

Manuscript submitted June 19, 1978; revised manuscript received July 24, 1978. This was Paper 559 presented at the Seattle, Washington, Meeting of the Society, May 21-26, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by Allied Chemical Corporation.

The Anodic Oxidation of Copper Amalgam and Polycrystalline Copper Electrodes in LiOH Solution

S. Fletcher,* R. G. Barradas,* and J. D. Porter**

Department of Chemistry, Carleton University, Ottawa, Ontario, Canada K1S 5B6

ABSTRACT

The anodic behavior of copper in lithium hydroxide solution was investigated at room temperature under controlled potential conditions. The electrodes were either saturated copper amalgams or small polycrystalline wires. Particular attention was focused on the copper (I) region. Two layer-planes of Cu_2O were formed at anodic overpotentials following the dissolution of copper (I) hydroxy complexes on the copper amalgam electrodes. Some novel data are reported concerning the nucleation of holes in these layers during the reverse reaction. Behavior analogous to that of the amalgam electrodes was observed on the polycrystalline electrodes, except that a thick layer of Cu_2O was also formed on top of the previously formed layer-planes. A model is proposed for the growth of this thick layer, and it is demonstrated that this model also describes the galvanostatic data acquired by earlier workers.

The corrosion of copper in alkaline solution is of interest in both chemical engineering and nuclear reactor applications. For this reason numerous experimental investigations have been performed on this system over the years (1-26). Prior to 1969 most work concentrated on the analysis of galvanostatic charging curves, which in general were poorly resolved (1-14). However two distinct solid phases were identified as being present at the electrode surface during the corrosion process: Cu_2O and $Cu(OH)_2$. Subsequent investigations afforded greater resolution of experimental data than had previously been possible, but the various interpretations of this data differ considerably (15-26).

Although there is general agreement regarding the nature of the phases formed (1-26), few unambiguous conclusions can be drawn from the literature regarding the electrode kinetics. We therefore suggest that a reappraisal of the behavior of copper in alkaline solution is in order. We have taken the first steps in this reappraisal by (*i*) considering the initial events which occur during the anodic oxidation of (dislocation-free) copper amalgam surfaces in LiOH solutions, and (*ii*) by presenting correlation of these data with data recorded on polycrystalline electrodes in the same solutions.

Experimental

Saturated amalgams [~5 mmoles Cu (27-32)] were prepared by direct combination of mercury (m5N8 Alfa Inorganics) and an excess of sheet copper (5N Koch-Light) under dry nitrogen for several weeks. The mercury was tapped from the interior of a reservoir; the copper was washed prior to use in dilute Aristar nitric acid and triply distilled water, then dried under a stream of nitrogen, and added to the mercury. Amalgam samples were tapped directly from the storage container into the syringe delivery system of the cell.

The base electrolyte was 0.1M LiOH and was prepared by dissolving the anhydrous alkali (Matheson, Coleman and Bell) in water distilled three times from alkaline permanganate solutions. Oxygen was purged from cell solutions using bottled nitrogen (Linde); traces of oxygen were removed from the gas in wash towers of aqueous vanadium (II, III) chlorides according to the method of Meites (33). The gas was finally passed through a tower containing the base electrolyte before entering the cell.

The reference half-cell used throughout the present work was Hg/HgO. The electrode was prepared in a manner similar to that recommended by Ives and Janz (34). Mercury was drawn from the interior of a reservoir and placed in the clean, dry electrode compartment, which was not treated in any way to produce hydrophobicity. A small quantity of the oxide (Fisher) was then placed on the mercury surface and the compartment flushed with dry nitrogen. Under the action of slight vibration the oxide rapidly spread over the exposed mercury to form a homogeneous "skin" on its surface. After assembly and preparation of the remainder of the cell, deoxygenated base electrolyte was allowed to fill the compartment slowly through the Luggin capillary. Electrodes prepared in this manner became stable quickly (1 hr) and exhibited very reproducible potentials.

The cell assembly is illustrated in Fig. 1. The working electrode was an amalgam drop (diameter = 1.47 mm, area = 0.0653 cm^2) supported on the end of an upturned capillary (ID = 0.551 mm). The capillary length was kept short (8 mm) to reduce ohmic resistance between the drop surface and the working electrode terminal H. The amalgam delivery system consisted of a gas-tight chromatographic syringe (C, Hamilton Company Model 1001) which incorporated a tight-fitting Teflon-tipped plunger. The syringe was secured in an aligned mount B, and the plunger travel was accurately controlled by means of a drum micrometer A (Moore and Wright Company). Zero levels were determined by microscopic observation of the capillary orifice using a cathetometer (The Precision Tool and Instrument Company). Reading and zero errors limited the theoretical surface area reproducibility to $\pm 0.8\%$ for the drop size employed in the present work. Prior to any measurements being made, the entire amalgam delivery system was washed with boiling triply distilled water and then immersed in mercury for several weeks to leach out any impurities possibly present in the Teflon. When in use, the delivery system could be refilled while assembled.

During an experiment, fresh surfaces were used for each measurement to eliminate the possibility of contamination of the electrode by any trace impurities in solution. Used drops were dislodged by streaming nitrogen through the inlet tube J. This procedure also served to agitate the cell solution between measurements.

Some experiments were also performed using polycrystalline copper wire working electrodes (25 mil, m5N Alfa Inorganics, geometric surfaces ~0.0250 cm^2)

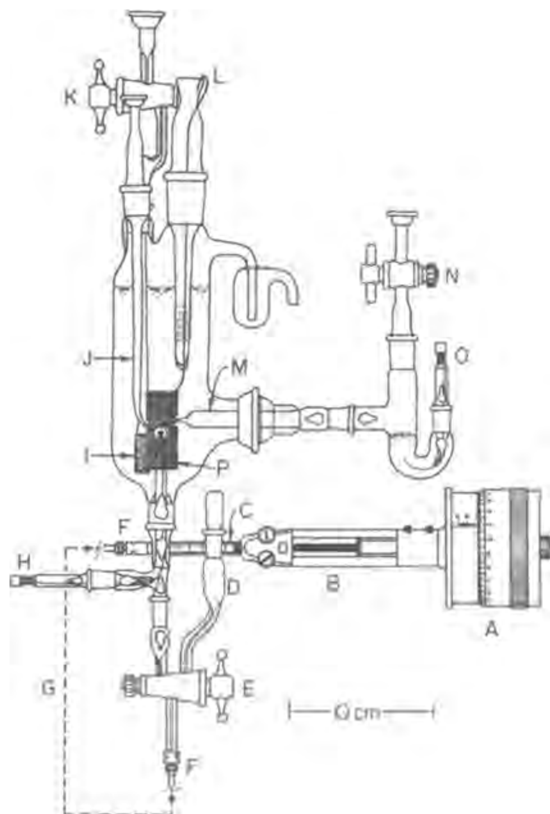

Fig. 1. The cell. (A) Micrometer, (B) syringe mount, (C) syringe, (D) amalgam reservoir, (E) inlet/outlet tap, (F) luer connector, (G) Teflon tubing, (H) working electrode terminal, (I) fritted bubbler, (J) N_2 inlet, (K) N_2 inlet tap, (L) counterelectrode terminal, (M) Luggin probe, (N) N_2 inlet tap, (O) reference electrode terminal, (P) counterelectrode.

sealed in Pyrex tubes which could replace the gas inlet tube J. Immediately subsequent to being sealed and cut to length, the electrodes were washed briefly in very dilute nitric acid, rinsed with degassed triply distilled water, and placed in the cell.

The reference electrode/probe assembly was designed to minimize internal resistances. The resistance between the tip of the Luggin probe M and the reference half-cell surface was kept as low as possible by constructing the probe for the most part out of large diameter (ID = 10 mm) tubing, by keeping the drawn-out portion of the probe short (<20 mm), by minimizing the distance from the probe tip to the Hg/HgO surface, and by avoiding the use of a sintered glass disk to separate the working and reference compartments. This type of construction minimized both noise and rise-time limitations in the potentiostat circuitry.

The iR drop between the tip of the reference probe and the surface of the working electrode was minimized by constructing the Luggin within a ball joint. This allowed the tip to be maneuvered close to the surface of the amalgam drop. The probe tip was drawn to a fine point (OD = 0.285 mm, ID = 0.241 mm), then carefully shaped and squared off using 600 mesh SiC paper under a dissecting microscope. In order to avoid shielding effects (35) the probe was positioned 2 tip diameters away from the drop surface during an experiment. Rough calculation of the expected resistance arising from this source (36) indicates that $R_{\Omega} < 0.01$ Ω cm^2 in this case.

Electric field homogeneity was maintained by using a cylindrical platinized platinum mesh counterelectrode (P, diameter = 20 mm, length = 50 mm) positioned coaxially with the capillary and symmetrically disposed about the amalgam drop. Small holes were cut in the mesh to allow the insertion of the gas inlet tube J and the Luggin probe M, and also to allow visual observation of the capillary orifice.

The cleaning procedure was designed to remove trace impurities possibly adsorbed on the interior surfaces of the glassware. Before each experiment the cell was dismantled and the all-Pyrex components placed in a covered 4 liter Pyrex beaker along with a Pyrex syphon assembly. The beaker was then filled with an aqua regia solution (10:1 HNO_3:35% HCl) and the components cleaned at elevated temperature (~90°C) for at least 24 hr. The contact assemblies and counterelectrode were cleaned in boiling HNO_3. Finally, all components were leached Soxhlet-fashion in boiling triply distilled water for 48 hr. All storage vessels and volumetric flasks were treated in the same manner.

Before assembly of the apparatus the amalgam-containing pieces were briefly oven dried at 150°C. The reference electrode was prepared as previously described; nitrogen was flushed continuously through tap N during this process. The amalgam delivery system was filled before the base electrolyte was admitted to the working compartment. Nitrogen was bubbled through the solution via the Luggin tip and the fritted bubbler for about 30 min before the reference compartment was filled. The working electrode was left at ~ −600 mV while the reference half-cell was allowed to stabilize. The entire apparatus was enclosed in a light-proof Faraday cage which was mounted on a vibration-damped platform.

The constant potential source was a PAR 170 Electrochemistry System. Potential profiles were generated on a PAR 175 Universal Programmer via a 10:1 potential divider. Potentials were recorded ±0.1 mV using a Hewlett Packard 3465A digital voltmeter in conjunction with a parallel-switched dummy cell circuit. The digital voltmeter was switched out of the potentiostatic circuit during the electrochemical measurements. Data were recorded either directly on a Honeywell 530 X-Y/Y-t pen recorder or digitally via a Biomation 805 Transient Recorder. The laboratory temperature was 22° ± 2°C.

Results and Discussion

Copper amalgam electrodes.—A typical linear potential scan of the copper amalgam electrode in 0.1M LiOH between the potential limits −700 and −200 mV is illustrated in Fig. 2. Four well-defined features are apparent on the forward scan. The region labeled A corresponds to the dissolution of Cu(I). At −380 mV a monolayer peak (B) stands clear from the dissolution. This is followed by a second monolayer peak (C) at somewhat more anodic potentials. The layers formed consist of Cu_2O (2-7). Finally, further inhibited dissolution of Cu(I) occurs in region D. On reversal of the potential scan the products of the anodic processes are reduced in one unresolved peak (E) which shows some evidence of fine structure.

The dissolution of Cu(I) was investigated by performing slow linear potential scans (5 mV sec^{-1}) into region A and observing the current as a function of potential. Exponential behavior was observed over more than a decade of current density (Fig. 3) with a reciprocal Tafel slope of 59 mV. This is the slope for the reaction

$$Cu \rightleftharpoons Cu^+ + e \quad [1]$$

$$Cu^+ + nOH^- \rightarrow Cu(OH)_n^{1-n} \quad [2]$$

Identical Tafel slopes were recorded in lithium hydroxide solutions between 0.1 and 2.0M. Although the position of the Tafel lines shifted along the potential axis toward more negative values with increasing LiOH concentration, reaction order measurements proved inconclusive. This was due to the incomplete dissociation of LiOH at the higher concentrations and the presence of migration effects which became important at concentrations below 0.1M.

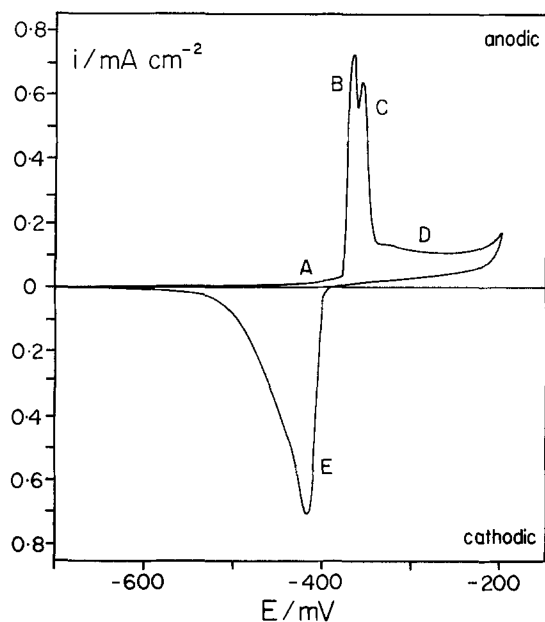

Fig. 2. LPS (ν = 20 mV sec^{-1}) of a saturated Cu amalgam electrode in 0.1M LiOH. (A) Dissolution of Cu(I), (B) formation of the first monolayer of Cu_2O, (C) formation of the second monolayer of Cu_2O, (D) inhibited dissolution of Cu(I), (E) reduction of the products formed on the forward scan.

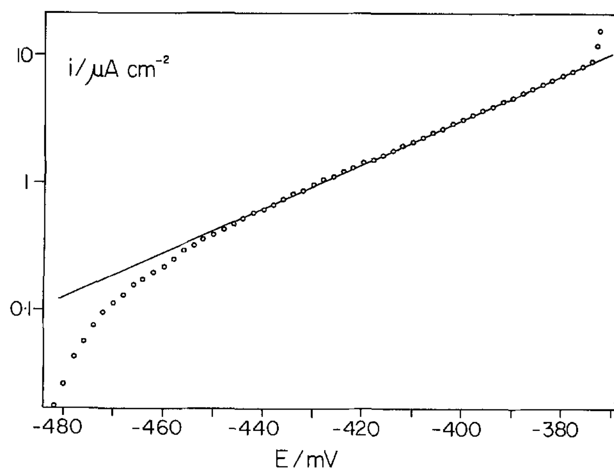

Fig. 3. Tafel plot of the Cu(I) dissolution region recorded using slow LPS (ν = 5 mV sec^{-1}) at a saturated Cu amalgam electrode in 0.1M LiOH. The reciprocal slope is 59 mV.

Reciprocal Tafel slopes of 59 mV were also obtained by the potential step technique. The $i(t)$ curves decreased monotonically as expected from Eq. [1] and [2] and were diffusion controlled at sufficiently long times. However, if the steps were carried out to potentials anodic to −380 mV in 0.1M LiOH (*i.e.*, into the potential region B associated with monolayer formation in Fig. 2) then results typified by Fig. 4 were obtained. Figure 4 shows the $i(t)$ response of a freshly generated copper amalgam surface following the application of a double potential step from −550.0 to −390.0 mV and finally to −377.4 mV. The double step allowed a large part of the double layer charging current and also a large part of the dissolution current to decay before switching to the final potential. This technique produced very clear and reproducible results. Four overlapping transients are observed which occur sequentially in time. Each corresponds to a separate process; the four are labeled A, B, C, and D, respectively (cf. Fig. 2). The first process exhibits a falling transient (A) and is the diffusion-controlled dissolution of Cu(I). The next two processes exhibit

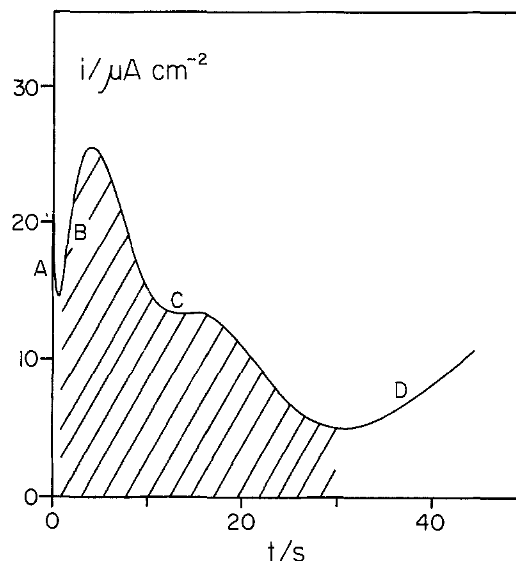

Fig. 4. Potentiostatic current transient recorded at −377.4 mV on a saturated Cu amalgam electrode in 0.1M LiOH. (A) Dissolution of Cu(I), (B) nucleation and growth of the first monolayer of Cu_2O, (C) nucleation and growth of the second monolayer of Cu_2O, (D) potential-independent reactivation of the electrode.

potential-dependent rising transients (B and C) and hence correspond to the nucleation and subsequent crystal growth of Cu_2O. The rate-determining steps for these processes must therefore occur at discrete reaction sites on the electrode surface, *i.e.*, at the peripheries of expanding nuclei of Cu_2O. Note also that the eventual falling sections of the transients B and C are due to the diminishing available periphery caused by the collision of nuclei. Finally, a potential-independent reactivation of the electrode surface can be observed at long times (D). The magnitude of this process depended strongly on the bulk concentration of OH^-.

The total charge passed during processes B and C was evaluated by integration of the transients as shown in Fig. 4 (hatched area). This charge (~360 μC cm^{-2}) was independent of the final step potential and as such was very strong evidence for monolayer formation. Attempts to better resolve the transients in order to compare individual sections with nucleation theory proved futile because a strong diffusion component became apparent in the experimental data at high overpotentials. The saturated copper amalgam was only about 5 mmoles in Cu and clearly the rate of mass transport of copper through the amalgam at higher current densities was inadequate to maintain the rate-determining step at the edges of the nuclei.

The effect of mass transport within the amalgam is illustrated quantitatively in Fig. 5, in which one of the transient maximum parameters (i_m) is plotted as a function of the final step potential for both the first and second monolayers. The first monolayer could not be resolved from the dissolution transient at potentials anodic to −375 mV. The diffusion component due to the dilute copper amalgam can be seen to be limiting in the second monolayer data at potentials anodic to −371 mV. The limiting gradient for the first layer is ~(4 mV)$^{-1}$ and that for the second layer ~(8 mV)$^{-1}$. These gradients are typical of nucleation and growth kinetics (37) but the accuracy of the values is obviously limited because of the experimental constraints.

The formation and reduction of the monolayers was best observed by the linear potential scan technique. The experimental results were quantified by investigating the potential scan rate (ν) dependence of the peak current (i_p). The data were analyzed in the form of log (i_p) *vs.* log (ν), which is appropriate for nucleation and growth kinetics (38). The gradient δ log

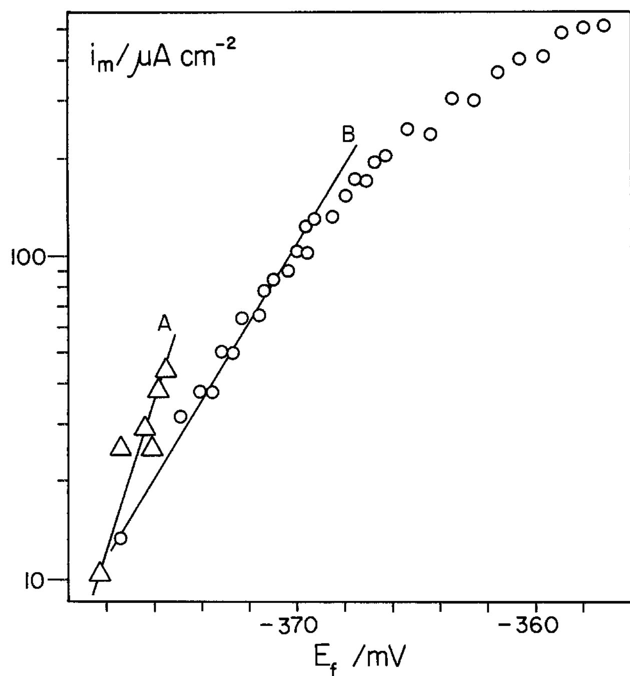

Fig. 5. The potentiostatic current transient maxima (i_m) for Cu_2O monolayer formation on a saturated Cu amalgam electrode in 0.1M LiOH *vs.* the final step potential (E_f). (A) First layer limiting dependence $\sim$(4 mV)$^{-1}$, (B) second layer limiting dependence $\sim$(8 mV)$^{-1}$. The curvature at large i_m is due to mass transport limitations.

$(i_p)/\delta \log (\nu)$ for the first monolayer was 0.57 and that for the second monolayer 0.59. These values should be compared with the value ½ which would be expected for a diffusion-controlled reaction (39). Clearly the kinetics of formation of the two monolayers were not determined by simple diffusion.

The high resolution of the monolayer peaks in linear potential scan measurements allowed a precise evaluation of the charge consumed in the formation of both layers. Over the three decades of scan rate investigated (0.1-100 mV sec^{-1}) the total charge was found to be constant and equal to 360 ± 10 μC cm^{-2}, in agreement with the potentiostatically derived value. Since the formation of a monolayer of the unit cell of Cu_2O [which has a cubic lattice (40)] would consume 352 μC cm^{-2}, we therefore suppose that each monolayer peak observed experimentally corresponded to the formation of a layer-plane of the unit cell and that layer-by-layer growth ceased when the unit cell structure was complete.

Because of the high resolution of the linear potential scan measurements, it was also possible to investigate the nucleation of holes during the reverse reaction. Such holes were found to be of two types depending on whether they penetrated only the first monolayer or both monolayers (Fig. 7b). We call the first type a "shallow" hole and the second type a "deep" hole. The appropriate experimental result is shown in Fig. 6, which illustrates the effect of varying the anodic potential scan limit on both the forward and reverse reactions.

On the forward scan, peak B is due to the formation of the first monolayer as described earlier. However, on the reverse scans, a new peak F is apparent which first increases and then decreases in size as the anodic potential scan limit is increased. At the same time, a peak at more cathodic potentials (G) is observed to increase steadily in size. The charges associated with peaks F and G are plotted against the anodic potential scan limit in Fig. 7a.

The results of Fig. 6 and 7a indicate that the initial process in the formation of the two layers is the nu-

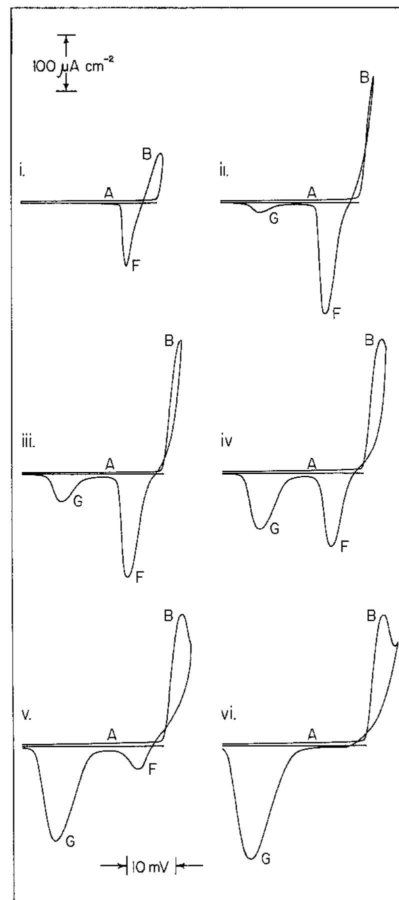

Fig. 6. LPS series at fresh saturated copper amalgam electrodes in 0.1M LiOH (ν = 5 mV sec^{-1}) illustrating the effect of varying the anodic potential scan limit. All scans begin at −407 mV. Anodic potential scan limits: *(i)* −374, *(ii)* −372, *(iii)* −371, *(iv)* −370, *(v)* −369, *(vi)* −363 mV. (A) Dissolution of Cu(I), (B) formation of the first Cu_2O monolayer, (F) reduction of the untransformed first Cu_2O monolayer, (G) simultaneous reduction of the unit cell bilayer.

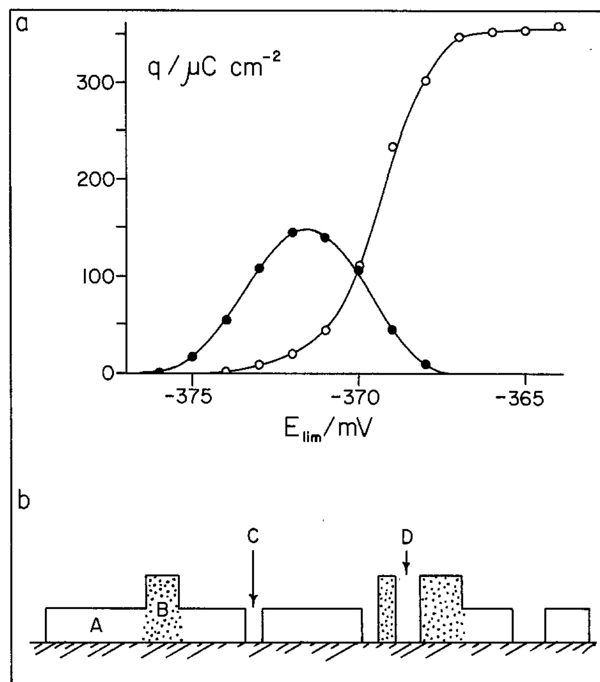

Fig. 7. (a) LPS reduction peak charge *vs.* the anodic potential scan limit for a saturated Cu amalgam electrode in 0.1M LiOH (ν = 5 mV sec^{-1}). (●) peak F, (○) peak G. cleation and subsequent growth of an unstable layer of Cu_2O of unknown structure. This unstable layer then rearranges (or is otherwise stabilized) concurrent with the growth of the second layer. In this way the unit cell structure is completed. Hence, peak F is due to the reduction of the unstable first layer by the nucleation and expansion of shallow holes, while peak G is due to the simultaneous reduction of both the transformed first layer and the second layer by the nucleation and expansion of deep holes. The situation is illustrated diagrammatically in Fig. 7b, which depicts an intermediate stage in the formation of the layers. Although the exact structure of the unstable first layer is unknown, Fig. 7a indicates that the maximum charge observed in this layer was about half that of the unit cell structure.

Further support for the above mechanism may be seen in the composite Fig. 8. The peak potential of peak F is seen to be approximately constant, independent of the charge under the peak. This is the result expected for the instantaneous nucleation of shallow holes in the patches of (unstable) first layer unaffected by second layer growth. Thus as the anodic potential scan limit was increased, all that changed was the area of untransformed first layer remaining on the electrode. Note that the nucleation of shallow holes was invariably instantaneous because the incomplete first layer was extensively intersected by small areas of uncovered electrode.

Peak G, on the other hand, does move as a function of the anodic potential scan limit but eventually reaches a limiting case. This scenario is also predicted by the model described above. At first the peak potential of G would be stationary because of the instantaneous nucleation of deep holes in the unit cell structure. Eventually, however, as the unit cell structure neared completion on the forward scan, a progressive nucleation mechanism would come into operation in order to create new deep holes since nearly all areas of electrode would be covered. Thus the peak potential of G would be expected to shift cathodically and eventually become constant as a function of the anodic potential scan limit, which is the observed situation.

Polycrystalline copper electrodes.—Cyclic voltammetry was performed at stationary polycrystalline electrodes in 0.1M LiOH solutions. Voltammograms recorded in this way exhibited a strong time dependence because of the repetitive dissolution and deposition of both Cu(I) and Cu(II) species. This served to roughen the electrode surface as a function of time. Eventually an "equilibrium" surface was obtained, for which a typical voltammogram is shown in Fig. 9. Although the experimental data could not be analyzed in a completely quantitative way because of this time-dependent surface roughening, the principal features of the system were clear and may be summarized as follows:

Region A in the diagram corresponds to the dissolution of Cu(I) as in Fig. 2, 4, and 8. The charge contained in peak B during the first sweep was $\sim$ 280 μC per apparent cm^2. Hence this peak is associated with the formation of a layer of less than unit cell dimensions in direct correspondence with the results obtained on the copper amalgam electrodes (cf. Fig. 2, 6, and 8). Assuming a charge of $\sim$ 175 $\mu C\ cm^{-2}$ for this layer, the initial surface roughness of the polycrystalline electrode in this case is calculated to be $\sim$ 1.6, and the roughness factor of the "equilibrium" electrode (*e.g.*, Fig. 9) is $\sim$ 3.7 [cf. factor $\sim$ 3.5 for polycrystalline copper electrodes obtained by Bockris and Conway (41)]. In region C there is evidence of second monolayer formation but this is not well resolved in this figure (see below). Peak H completes the Cu(I) region and corresponds to the nucleation and subsequent growth of a thick layer of Cu_2O as discussed with reference to part (C). Peaks I and J are the dissolution and nucleation of Cu(II) species, respectively (20). Progressive limit LPS experiments indicated that peak K is a reverse reaction associated with peak I (probably $Cu(II)_{aq} \rightarrow Cu(I)_{aq}$). Finally, on the reverse scan, region L corresponds to the reduction of the various species formed on the forward scan.

Some rate control of the processes of peaks I and J by the diffusion of OH^- was observed (Fig. 9). Indeed, increasing the LiOH concentration from 0.1 to 1M caused an approximately tenfold increase in the height of these peaks, but not in peak H. We therefore restricted further measurement to the Cu(I) region (~ -600 to ~ -300 mV).

Figure 10 illustrates successive linear potential scan measurements in 0.1M LiOH that were carried out into the copper (I) region at 50 mV sec^{-1}, increasing the anodic potential scan limit on each scan. The roughness factor in this instance was $\sim$3.6. As on the amalgam electrode (Fig. 6 and 8) a monolayer peak (B) was evident but at somewhat more cathodic po-

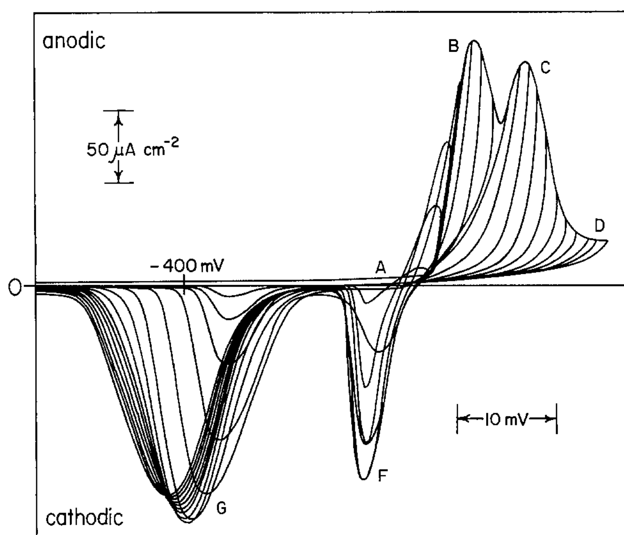

Fig. 8. Composite LPS (ν = 5 mV sec^{-1}) recorded on fresh saturated Cu amalgam electrodes in 0.1M LiOH illustrating the effect of varying the anodic potential scan limit. Fig. 10. Composite LPS (ν = 50 mV sec^{-1}) recorded on a polycrystalline copper electrode in 0.1M LiOH beginning at −970 mV, illustrating the effect of varying the anodic potential scan limit. The current density scale refers to the apparent geometric area of the electrode. (A) Cu(I) dissolution, (B) formation of the first Cu_2O monolayer, (C) formation of the second Cu_2O monolayer (F) reduction of the first Cu_2O monolayer formed in peak B, (G) reduction peak associated with the formation of the second monolayer in peak C, (H) formation of the thick Cu_2O layer, (M) reduction of the thick Cu_2O layer formed in peak H.

tentials. (Note: the difference between the potential of the first monolayer peak on the amalgam electrode and that on the polycrystalline electrode, both recorded at 20 mV sec^{-1}, was ~60 mV.) Clearly, monolayer formation proceeds more readily on the polycrystalline electrode. As the anodic potential scan limit was increased to potentials above −400 mV, evidence of second monolayer formation (as on the amalgam electrode) was observed (C) but this was more clearly seen in the reduction reaction (G).

Peak F corresponds to the reduction of the first monolayer and eventually shows some diminution as the anodic potential scan limit is increased. However the peak does not completely disappear, unlike on the amalgam, unless the potential is carried to extreme anodic limits. Consequently some uncertainty remains regarding the precise nature of peak G, although it is clearly related to the second monolayer formation (C).

The formation of a thick layer of Cu_2O can also be seen in Fig. 9 and 10 (peak H). Note that the monolayer reduction peak (F) persists even after extensive growth of this thick layer has occurred. Although the formation of the thick layer has been observed previously, the associated mechanism describing its formation has not been satisfactorily resolved (10, 15, 19, 20, 22, 24-26). We now discuss this mechanism in more detail.

Cu_2O multilayer growth on polycrystalline copper electrodes.—Figure 11 shows a typical current-time plot obtained following the application of a potential step into region H of Fig. 9 and 10. Rising transients were seen which exhibited at t^3 dependence of current density on time. This is the result which would be expected for the three-dimensional nucleation and growth of a thick layer of Cu_2O (42). The transients also exhibited well-defined maxima, after which the current decayed as approximately $t^{-1/2}$.

The sequence of events in the formation of the thick layer of Cu_2O can now be specified. Initially, three-dimensional nuclei emerge on top of the previously formed monolayers as a function of time. These nuclei clearly originate at macroscopic defects or dislocations which persist through the monolayers of Cu_2O from

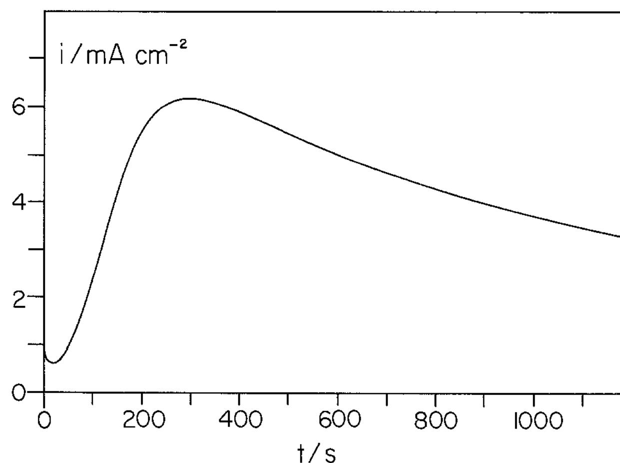

Fig. 11. Typical potentiostatic current transient recording the growth of the thick Cu_2O layer on a polycrystalline copper electrode in 0.1M LiOH at −400.0 mV. The current density scale refers to the apparent geometric area of the electrode.

the bulk metal underneath and are not associated with structural anomalies inherent in the Cu_2O monolayers themselves. This is shown by the fact that thick layer growth of Cu_2O is completely absent when smooth amalgam surfaces are used, despite the fact that the monolayers must incorporate similar misfits, defects, and crystallite boundaries in both cases.

The rising transients typified by Fig. 11 show that the rate-determining step for the thick layer growth occurs at the peripheries of individual nuclei. Under these circumstances the $i(t)$ response is described (42) by

$$i = (nFGM^2k_1^2k_2At^3/3\rho^2) \quad [3]$$

Here, G is a geometric constant (*e.g.*, $G = \pi$ for right circular cones), M is the gram formula weight of the deposit, ρ is its density, k_1 is a rate constant describing lateral growth of the nuclei, k_2 is a rate constant describing vertical growth of the nuclei, and A is a time-independent nucleation rate. The other symbols have their usual significance. Eventually the collision of expanding nuclei becomes important and at the same time the Cu_2O nuclei begin to dissolve into the bulk of solution as $Cu(OH)_n{}^{1-n}$ complexes because of the aggressive nature of the OH^- anion (15). The result of this dissolution process is that crudely hemispherical diffusion zones develop around individual nuclei. As the diffusion zones expand they eventually overlap to create a condition of semi-infinite linear diffusion. Then (43) at long times

$$i = nFD^{1/2}C_s(\pi t)^{-1/2} \quad [4]$$

where C_s represents the surface concentration of a given $Cu(OH)_n{}^{1-n}$ complex and D is its diffusion coefficient.

The reaction scheme outlined above is obviously best observed by the potential step method, because in this case the particular regions of interest (nucleation or diffusion) can be separated sequentially in time. Other techniques, for example galvanostatic steps (16, 24), will necessarily produce rather more complex results because of the potential dependences of the rate constants k_1, k_2, and A in Eq. [3]. However, because previous investigations of the formation of thick layers of Cu_2O have principally been of the galvanostatic type, it is useful to calculate the galvanostatic equivalent of Eq. [3] to see if the earlier data may be explained on the basis of this model.

The solution of this problem can be calculated for two distinct limiting cases. In the first case, the resulting galvanostatic transient exhibits only a small variation in potential (*e.g.*, a few millivolts) and the form of the nucleation law will thus be progressive in time

($N = At$). Alternatively, if the variation in potential is large, then the initial potential "spike" of the galvanostatic transient causes a very rapid nucleation of many nuclei, which thereafter remain virtually constant in number (44). Hence, after a small induction time in which the nucleation rate is greater than zero and nonsteady, the nucleation law will become $N = N_o$ = const. It is expected, on experimental grounds (24), that this latter route occurs in thick layer Cu_2O formation because the observed potential "spike" is large. Therefore, in order to proceed to the galvanostatic solution, Eq. [3] must be amended to take this "instantaneous" nucleation phenomenon into account. The result for the potentiostatic case is well known (42) and is given by

$$i(t) = n\mathrm{F}k_2[1 - \exp(-GM^2k_1^2N_ot^2/\rho^2)] [\exp(-GM^2k_1^2N_ot^2/\rho^2)] \quad [5]$$

where N_o is the number of nuclei that are nucleated at $t \to 0$ and the additional terms correct for the collision of nuclei in the absence of diffusion limitations. It should be stressed that Eq. [3] correctly describes the $i(t)$ transient observed under constant potential conditions, but that Eq. [5] is the appropriate basis for the potentiostatic-to-galvanostatic transformation.

Equation [5] may be rewritten

$$i(t) = 4i_m(S)(1 - S) \quad [6]$$

where i_m is the maximum of the potentiostatic current-time transient and S is the surface coverage function ($0 \leq S \leq 1$). If it is assumed that i_m and t_m are exponential functions of potential, then

$$i_m = (n\mathrm{F}k_2/4) = 10^{a_1E + b_1} \quad [7]$$

$$t_m = (\rho^2 \cdot \ln(2)/GM^2k_1^2N_o) = 10^{a_2E + b_2} \quad [8]$$

Equations [5]-[8] may be regarded as a set of differential equations specifying i as a function of t for various E in the case of three-dimensional instantaneous nucleation. The entire galvanostatic $E(t)$ response can be calculated by numerical solution (see below) or exact solutions can be calculated for certain limiting cases.

Equation [5] can be written as

$$i(t) = PQ^\lambda \exp(-kJ^2)[1 - \exp(-kJ^2)] \quad [9]$$

in which the terms J, Q, P, λ, and k are given (45) by

$$J = \int_0^t Q(t') \cdot dt' \quad [10]$$

$$Q = 10^{-a_2(E(t) - i(t) \cdot R)} \quad [11]$$

$$P = 4 \times 10^{b_1} \quad [12]$$

$$\lambda = -a_1/a_2 \quad [13]$$

$$k = \ln(2) \cdot 10^{-2b_2} \quad [14]$$

and where R is a fixed resistance which contributes to "iR drop" and $E(t)$ is the potential-time waveform. Setting $i(t) = i_g$ (the galvanostatically applied current density)

$$(i_g/P)^{1/\lambda} \cdot t = \int_0^J \exp(-kx^2/\lambda) [1 - \exp(-kx^2)]^{1/\lambda} \cdot dx \quad [15]$$

This equation demonstrates that as $J(t) \to \infty$, $t \to t_{ext}$, a finite "extinction" time at which $E \to \infty$. Thus experimental data may only be obtained over the interval $[0, t_{ext}]$. Defining the function

$$f(y) = y^{1/\lambda - 1}(1 - y)^{1/\lambda}(-\ln(y))^{-1/2} \quad [16]$$

considerably simplifies Eq. [15]. Upon substitution

$$2k^{1/2}(i_g/P)^{1/\lambda} \cdot t = \int_{e^{-kJ^2}}^1 f(y) \cdot dy \quad [17]$$

Replacing $i(t)$ in Eq. [6] by i_g demonstrates that E has a minimum (E_{min}) when $S = ½$. The time taken to achieve this minimum (t_{min}) is thus obtained trivially from Eq. [17]

$$2k^{1/2}(i_g/P)^{1/\lambda} \cdot t_{min} = \int_{1/2}^1 f(y) \cdot dy \quad [18]$$

In addition $Q^\lambda P/4 = i_g$ at $t = t_{min}$, from Eq. [9]. Combining this result with Eq. [9]-[12], after some rearrangement, gives

$$\log(i_g) = a_1(E_{min} - i_gR) + \text{const.} \quad [19]$$

Equation [19] thus allows the experimental determination of the constant a_1 defined in [7], provided R is known or the product i_gR tends to zero. The validity of this expression was confirmed by numerical integration of [15], and the numerical procedure also allowed the solution of the complete $E(t)$ response for a given i_g to be obtained. A typical result is illustrated in Fig. 12 where it is compared with some experimental data extracted from the paper of Ashworth and Fairhurst (24). There is excellent agreement, even to the extent of predicting the slight asymmetry of the transient. Thus, the model of three-dimensional nucleation and growth used to explain our potentiostatic results also describes the earlier galvanostatically acquired data (24).

The limiting behavior of the galvanostatic response at short and long times may also be obtained exactly. At short times as $t \to 0$, $J \to 0$, $Q \to \infty$, and $E \to \infty$ so that

$$i_g \sim PQ^\lambda kJ^2 \quad [20]$$

$$J \sim \text{const. } t^{\lambda(2+\lambda)} \quad [21]$$

$$Q \sim \text{const. } t^{-2/(2+\lambda)} \quad [22]$$

Hence, from [10]

$$E - i_gR \sim \frac{2}{2a_2 - a_1} \log(t/t_{ext}) + \text{const.}; \quad (t/t_{ext} << 1) \quad [23]$$

By similar reasoning, at long times

$$E - i_gR \sim \frac{-1}{a_2} \log\left(1 - \frac{t}{t_{ext}}\right); \quad \left(t/t_{ext} < 1, \left(1 - \frac{t}{t_{ext}}\right) << 1\right) \quad [24]$$

Equations [23] and [24] were also verified by numerical solution of [15].

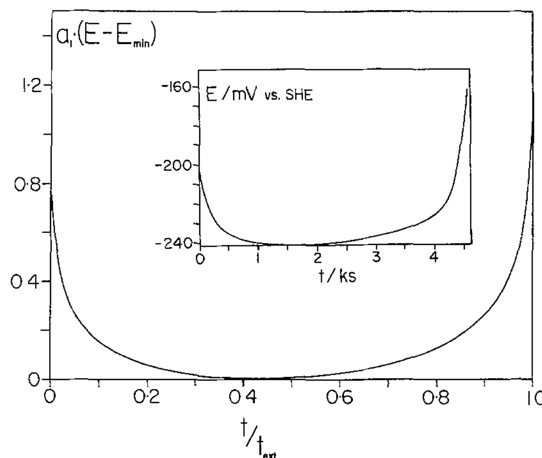

Fig. 12. Galvanostatic transient corresponding to the numerical solution of Eq. [5]-[8]. The constants were $\lambda = 3/5$, $i_g = 1.000$ mA cm^{-2}. The solution used 17,954 steps. Inset: Galvanostatic transient obtained by Ashworth and Fairhurst [from Fig. 12a of Ref. (24)] for polycrystalline copper in 0.1M NaOH at $i_g = 25$ μA per geometric cm^2.

Finally, when $t \to t_{ext}$, then $\exp(-kJ^2) \to 0$ so that [17] becomes

$$2k^{1/2}(i_g/P)^{1/\lambda} \cdot t_{ext} = \int_0^1 f(y) \cdot dy \quad [25]$$

showing that

$$i_g \cdot t_{ext}^{\lambda} = \text{const.} \quad [26]$$

This last result was also obtained as an empirical expression by Ashworth and Fairhurst (24), who determined λ galvanostatically ("instantaneous" nucleation conditions) to be 0.59, 0.44, and 0.54 for the formation of a thick layer of Cu_2O in 0.01, 0.1, and 1.0M NaOH, respectively. In this investigation, λ was determined potentiostatically (progressive nucleation conditions) to be 0.55 for Cu_2O thick layer formation on "equilibrium" polycrystalline copper in 0.1M LiOH.

Conclusion

The anodic behavior of copper amalgam and polycrystalline copper electrodes has been investigated in lithium hydroxide solutions. Certain features are shown to be common to both systems. These are (*i*) the dissolution of Cu(I) hydroxy complexes and (*ii*) the formation of two layer-planes of Cu_2O which complete a unit cell structure. The dissolution reaction exhibits a 59 mV reciprocal Tafel slope as expected for a reversible one-elecron transfer process followed by a slow chemical complexation reaction. The formation of the layer-planes occurs via the nucleation and subsequent growth of two-dimensional patches at the electrode surface. The first layer-plane which is deposited on the amalgam surface can be reduced via the instantaneous nucleation of "shallow" holes. A rearrangement or stabilization of the first layer is postulated to occur at the same time as the formation of the second layer-plane. Simultaneous reduction of both layer-planes at more negative potentials can then occur via the nucleation and subsequent expansion of "deep" holes. These "deep" holes are nucleated either instantaneously or progressively in time depending on the number of uncovered patches of electrode which intersect the unit cell layer.

A major difference between the behavior of the amalgam electrodes and the polycrystalline electrodes is the formation of a thick layer of Cu_2O in the latter case which emerges on top of the previously grown layer-planes. The mechanism of the formation of this layer is one of three-dimensional nucleation and growth. Nuclei originate at macroscopic features which persist through the unit cell layer. The equivalent galvanostatic response is also calculated. The results demonstrate that previous galvanostatic measurements of the formation of the thick layer of Cu_2O on polycrystalline copper in alkaline solution may be understood in terms of the described model.

Flatband Potential of Cadmium Sulfide (CdS) Photoanodes and Its Dependence on Surface Ion Effects

D. S. Ginley* and M. A. Butler*

Sandia Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

Results are presented which show that the flatband potential (V_{fb}) of a semiconducting cadmium sulfide (CdS) photoanode can be predicted from atomic electronegativity of its constituent atoms. This procedure, previously applied only to metal oxides, now appears generally applicable to any semiconductor-electrolyte system. The flatband potential was measured in a $CdS/S^{=}$, OH^{-}/Pt wet photovoltaic cell as a function of $S^{=}$ and OH^{-} concentrations. These measurements showed that the potential-determining species are HS^{-} and H^{+}. The condition for zero net adsorbed surface charge (PZZP) was also determined by change of solution $pS^{=}$ with added CdS powder and differential potentiometric titration experiments. This is found to occur at a unique $S^{=}$ ion concentration of 4×10^{-9}M. The measured flatband potential, corrected to the PZZP and for the difference between the Fermi level and the bottom of the conduction band, is in excellent agreement with the value predicted from the atomic electronegativities.

Two recent, closely related, developments have evoked considerable interest in the field of semiconductor electrochemistry. The first of these was the demonstration of the photoassisted electrolysis of water by Honda and co-workers in 1969 utilizing a titanium dioxide photoanode (1). The second was the demonstration of workable wet photovoltaic cells employing semiconducting anodes by a number of groups (2, 3). In general, the wet photovoltaic cell employs a redox couple of a potential such that electron transfer to the couple will predominate and no decomposition of the semiconductor will be observed. A prototypical cell in these latter systems has a CdS photoanode, an aqueous electrolyte containing dissolved sodium sulfide, sulfur, and sodium hydroxide, and a platinum or graphite cathode. In general the bulk cell chemistry is the oxidation of sulfide or polysulfide anions on the CdS and the reduction of sulfur (S°) or polysulfides (S_n^{2-}) on platinum. After a sufficient induction period a reasonably stable solution composition is achieved and no additional net chemistry is observed, though electrical power continues to be produced. Various n-type semiconductors have been tried, GaAs, CdSe, and CdTe in a variety of stabilizing electrolytes, alkaline aqueous selenide and telluride in particular (4), but in general the over-all behavior of these cells is illustrated by that of the CdS cell.

* Electrochemical Society Active Member.

Key words: cell, electrolyte, energy conversion, semiconductor.

Recent results have indicated that relatively high efficiencies can be produced in these cells equipped with polycrystalline electrodes (5). The ramifications of these results with respect to possible devices for the conversion of solar energy are obvious.

As a consequence of this we felt that an extension of some of our previous work (6) on the transition metal oxides with respect to the energy levels and chemistry in the cell would be of value in understanding the wet photovoltaic cells. One can illustrate the general schematic for the energy levels in the typical cell as is shown in Fig. 1, for a wet photovoltaic cell with a CdS anode and a metallic cathode. The Fermi level of the metallic cathode will equilibrate close to the level of the reductive half-reaction in which it is taking part. The potential drop determined by the current flowing and the load impedance will locate the Fermi level in the semiconductor. Consequently the extent of band bending at the surface of the semiconductor will depend on where the conduction band is initially pinned at the surface and the voltage drop across the load. The position at which the conduction band is pinned at the surface relative to the vacuum level is the electron affinity (*EA*) of the semiconductor. It can be related to solution measurements which are normally referenced to the standard calomel electrode (SCE), since this half-cell is at a fixed potential relative to the vacuum level (7). In electrochemistry the analogous quantity to electron affinity

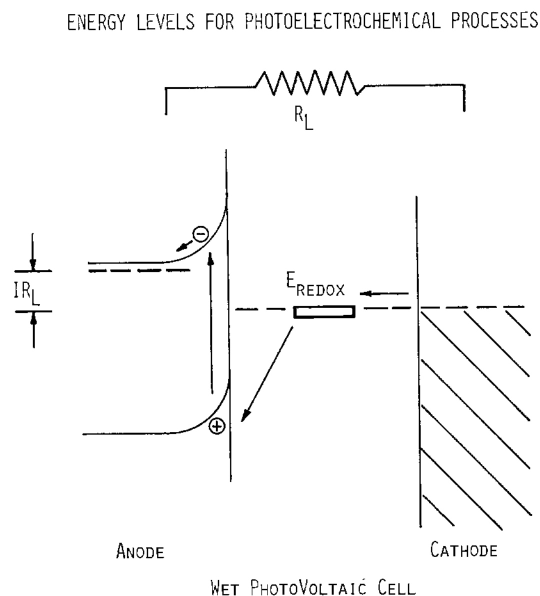

Fig. 1. Energy level diagram for a typical wet photovoltaic cell. Electrons are excited from the valence band to the conduction band by the absorbed photon. These electrons then flow through the load impedance R_L to the metallic cathode where the reductive half-reaction occurs. These reduced species migrate to the anode where they lose an electron to the trapped hole in the valence band. The position of the Fermi level in the semiconductor is determined by the potential drop across the load.

is the flatband potential (V_{fb}) which is a measure of the potential needed, *vs.* the SCE, to totally remove the band bending. The two can be related (6) as shown in Eq. [1]

$$EA = E_o + V_{fb} + \Delta_{fc} + \Delta_{pX} \quad [1]$$

where E_o is the energy difference between the SCE and the vacuum level (4.75) (7), Δ_{fc} is a correction term for the energy difference between the bottom of the conduction band and the doped Fermi level, and Δ_{pX} is a correction term due to the net surface charge of the adsorbed species on the electrode surface. Upon evaluation of the two correction factors one should be able to directly relate the electron affinity to the flatband potential. There is considerable interest in being able to predict flatband potentials since the maximum open-circuit voltage of the wet photovoltaic cell is the difference between the flatband potential and the redox potential measured with respect to the same reference electrode.

In this investigation we examine the properties of a $CdS/S^=$, OH^-/Pt cell and we demonstrate (*i*) that the atomic electronegativities of the constituent atoms of CdS can be used to arrive at its electron affinity, (*ii*) that simple chemical techniques can be used to evaluate Δ_{pX}, where X is an adsorbed species, and that Δ_{fc} can be readily evaluated. Thus, we can accurately calculate V_{fb} using Eq. [1]. We also illustrate how these results apply to the $CdS/S^=$, OH^-, S/Pt cell and show how they clarify certain questions as to the redox chemistry in these systems.

Experimental Procedures

Materials.—The CdS crystal was a 10 × 10 × 2 mm plate cut perpendicular to the c direction and was obtained from Harshaw Chemical. The CdS powder was obtained from Electronic Space Products, Incorporated and was 99.99% pure or better. $Na_2S \cdot 9H_2O$ was obtained from Mallinckrodt and KOH was obtained as a Baker analyzed reagent.

Solution and electrolyte preparation.—All solutions were prepared from deionized-distilled water stored in clear polyethylene containers. All glassware was washed in Alconox in an ultrasonic cleaner then rinsed a minimum of five times with distilled water. All the $Na_2S \cdot 9H_2O$ was rinsed with distilled H_2O then dried in a dessicator before weighing and use so as to remove any external impurities; primarily more highly dehydrated and oxidized sulfides. All sulfide solutions were standardized by potentiometric titrations with lead perchlorate. The experiments were run under an argon purge but solutions with sulfide concentrations from 10^{-4} molar and greater could be prepared in the air and then placed under argon purge. For solutions 10^{-5} molar and below, their preparation and all manipulations were carried out under an argon atmosphere. All sulfide solutions were used the day of their preparation and as rapidly as possible.

For the measurement of the PZZP of sulfide on CdS, a 0.1M KOH solution was prepared and allowed to thermally equilibrate. Then the desired Na_2S concentration was prepared by successive dilutions of a freshly prepared stock solution of 1M Na_2S in 0.1M KOH. The CdS powder employed has been previously washed 3-5 times with distilled water and then dried at 115°C in the air. It was ground as finely as possible, ~25 μm, in an agate mortar and pestle. For $pS^=$ drift measurements, a 600 ml, 0.1M KOH solution of the desired initial sulfide concentration was allowed to equilibrate while being stirred under a constant argon purge. The general schematic for the apparatus used is shown in Fig. 2. Equilibration was confirmed by the stabilization of the $pS^=$ measurements. At this point between 1 and 20g of the CdS powder was added to the solution. As long as the solution was stirred all of the CdS remained suspended. The $pS^=$ was continuously monitored and the reading normally stabilized in from 1 to 8 hr. For measurements of the PZZP by a differential potentiometric titration, Fig. 2, 600

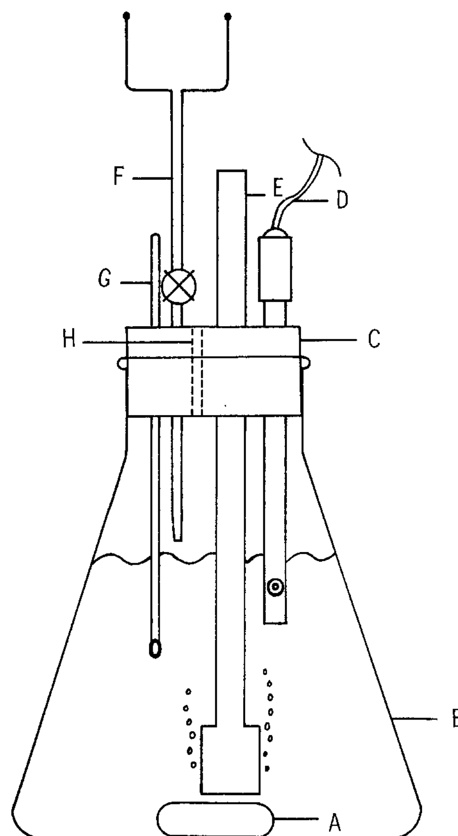

Fig. 2. This apparatus was used to determine the PZZP with respect to $S^=$ ion concentration, both by the drift and differential potentiometric titration methods. The parts of the apparatus are as follows: A, Teflon stir bar; B, 1 liter wide mouth Erlenmeyer flask; C, No. 11 rubber stopper; D, Orion sulfide ion selective ion electrode; E, argon bubbler; F, 5 ml microburette under constant Ar atmosphere; G, thermometer; H, vent hole.

ml of 0.1M KOH solution between 1 and 10g of suspended CdS powder was allowed to equilibrate under argon. The solution was then titrated, using a 5 ml microburette, with a 0.1M KOH solution of known Na_2S concentration. The titrant sulfide concentration was changed as needed during a run and the titrant and the solution being titrated were kept under argon. Nominally titrant was added in equal portions, usually 0.05-0.1 ml, and the solutions were allowed to equilibrate 2-5 min before readings were taken. Titrant volume could be read to ±0.002 ml.

The determinations of the flatband potential as a function of pH^+ or pNa_2S were all conducted by the successive dilutions of freshly prepared stock solutions of KOH and Na_2S.

CdS electrode preparation.—The CdS single crystal was cut perpendicular to the c axis and both sides were polished. A copper wire was soldered to one side using pure indium solder and a Fibra-Sonic, Incorporated ultrasonic soldering iron. Before each experimental run the CdS electrode was etched in warm, 30°C, 50% HCl solution for 1-5 min.

pH^+ and $pS^=$ measurements.—All pH^+ and $pS^=$ measurements were made with a Markson Electromark Analyzer, pH^+ and specific ion meter equipped with a Gralex digital panel meter. Measurements could be read to ±0.001 pH units or ±1 mV. pH^+ was measured with an Orion Model 91-02-00 combination pH electrode and $pS^=$ was measured with an Orion Model 94-16A solid-state sulfide electrode and an Orion Model 90-02-00 double junction reference electrode. The reference electrode outer junction was filled with 0.1M KOH. The sulfide electrode was polished before each run and was calibrated by titration with $Pb(ClO_4)_2$ solutions.

Electrochemical measurements.—All measurements were made with a PAR Model 173 potentiostat/galvanostat equipped with a PAR Model 179 digital coulometer and a PAR Model 175 universal programmer. Measurements were made using a standard 3-electrode setup, with a CdS anode, a smooth Pt cathode (30 cm^2), and a Corning Model 476015 standard calomel reference electrode. All solutions were argon purged but not actively stirred. The flatband potentials were determined from plots of the square of the photocurrent *vs.* potential. Extrapolation of the square of the photocurrent intercepts the potential axis at the flatband (8). This process avoids some of the pitfalls encountered when determining flatband potentials using Mott-Schottky plots. All flatbands were run using monochromatic light at 450 nm (~1.0 mW) from a Schoeffel 150W high pressure xenon arc lamp equipped with a Schoeffel grating monochromator. The reported flatbands were normally measured under d-c (maximum photocurrents 0.5 mA) conditions with light and dark currents measured every 0.05V *vs.* SCE. The a-c measurements agreed excellently with the d-c measurements. For sulfide concentrations of 10^{-4} molar and above no surface corrosion of the CdS electrode was observed. However, for 10^{-5} and 10^{-6} molar sulfide some slight corrosion was observed. As a consequence of this the flatbands for these solutions were measured with the light intensity reduced by a factor of 10 and 100, respectively. Under these conditions a microscopic investigation revealed no surface damage.

Results and Discussion

Calculation of the electron affinity.—Success has been achieved recently in calculating Fermi energies and photoelectric thresholds for several classes of compounds utilizing only the atomic electronegativities of the constituent atoms of the material (9, 10). We have recently applied this same technique to a number of transition metal oxide semiconducting electrodes in order to predict their flatband potentials (6, 11). We have chosen to utilize Mulliken electronegativities for our atomic electronegativities, since they provide an electronegativity scale with a simple physical interpretation based on physically measurable parameters. Mulliken defines the atomic electronegativity, $\chi(m)$, as being the arithmetic average of the first ionization potential (I_p) and the atomic electron affinity (EA) as in Eq. [2]

$$\chi(m) = \tfrac{1}{2}(I_p + EA) \qquad [2]$$

In a sense $\chi(m)$ may be thought of as representing the electrochemical potential of the electron in the neutral atom. When compounds are formed, these electrochemical potentials (electronegativities) are equalized by the flow of charge from atoms of smaller to atoms of larger electronegativity. Sanderson (12) and more recently Netherest (9), have postulated, based on bond length arguments, that the resulting bulk electronegativity of a compound is the geometric mean of the electronegativities of the constituent atoms. This hypothesis appears to be correct for a large number of compounds (6). By analogy with the atomic case, the bulk electronegativity of a solid is just the arithmetic mean of the highest filled state (top of the valence band) and the lowest empty state (bottom of the conduction band). This corresponds to the undoped Fermi level or the electrochemical potential of the electron in the intrinsic semiconductor. The electron affinity for CdS will simply be given by

$$EA(\text{CdS}) = [\chi(\text{Cd})\chi(\text{S})]^{1/2} - \frac{1}{2}E_g(\text{CdS}) \qquad [3]$$

where E_g is the bandgap of cadmium sulfide. The electronegativity of sulfur is determined using Eq. [2], the appropriate ionization potential (13), and the atomic electron affinity (14) to be 6.2 eV. The atomic electron affinity for cadmium is unknown, thus we cannot use Eq. [2] to determine the atomic electronegativity of Cd. However, Mulliken's definition tells us that the electronegativity is identical to the work function of a metal. Thus for cadmium (13) we have an electronegativity of 4.1 eV. The bandgap (15) of CdS is 2.4 eV. Therefore, we find for the electron affinity of CdS a value of 3.8 eV. Having calculated EA we can return to Eq. [1] and if we can evaluate the correction factors, we can determine accurately the flatband potential.

The evaluation of Δ_{fc}.—Since flatband potentials refer to the electrochemical potential of electrons in the semiconductor (Fermi level) and the electron affinity of the semiconductor refers to the bottom of the conduction band, a correction term exists in Eq. [1], Δ_{fc}, which accounts for the different reference points in these two types of measurements. This difference can be measured using conventional solid-state techniques such as the Seebeck effect (16). The Seebeck coefficient for our CdS electrode was found to be 0.54 mV/°K. From this number and the information in Kröger, Vink, and Volgers' paper (17) a carrier concentration of ~10^{17} was found. Using the standard treatment as outlined in Kittel (16), Δ_{fc} was then estimated to be 0.1V. This number of approximately a tenth of a volt for Δ_{fc} is typical of the highly doped semiconductors employed in photoelectrolysis and the wet photovoltaic cells.

Evaluation of Δ_{pX} and the PZZP.—Any electrode material immersed in an electrolyte will interact with the potential-determining species in solution. Since the electrolyte is in equilibrium with the electrode surface under the conditions of interest, the electrochemical potential of the adsorbed species ($\bar{\mu}_{ad}$) will be equal to that of the same species in the electrolyte ($\bar{\mu}_{sol}$)

$$\bar{\mu}_{ad} = \bar{\mu}_{sol} \qquad [4]$$

Depending on the concentration of the potential-determining ions in the electrolyte and the intrinsic pK_a of the material with respect to those ions, differing numbers of anions and cations will be adsorbed

on the surface. The difference between the number of positive and negative charges adsorbed on the semiconductor surface gives rise to a potential drop across the Helmholtz double layer which is measured as part of the flatband potential. This is the correction term Δ_{pX} in Eq. [1]. There is also a small potential across the Helmholtz double layer due to the ordering of the neutral water molecules (18) but this effect is quite small and will be ignored. Obviously Δ_{pX} is a function of the difference in the number of adsorbed anions and cations and therefore the activity of these ions in solution. Thus, most of the flatband potentials measured will show a dependence on the relative activity of the potential-determining ions in solution. For each material there exists a unique point, which is a function of its intrinsic affinities for the potential-determining ions, where the number of adsorbed anions and cations is equal and the potential drop across the Helmholtz layer is consequently zero. This point is called the point of zero zeta potential (PZZP) and is the only point at which truly meaningful flatband measurements can be made, and it is these flatbands to which the calculated electron affinities should be compared.

Since we hoped to show that our model previously developed for the transition metal oxides (6) could be extended to the nonoxides and the wet photovoltaic cells, we picked a cell configuration close to that employed in the normal CdS wet photovoltaic cell. Recent results by Minoura, Okada, and Tsuiki (19) illustrate that our prototype cell will evolve in time to the typical $CdS/S^{=}$, S, OH^{-}/Pt wet photovoltaic cell. They also discuss the dependence of cell performance on sulfur concentration. Our cell configuration is a CdS single crystal anode with a platinum cathode in an electrolyte composed of 0.1M KOH and various concentrations of Na_2S.

Historically, the determination of PZZP has had important ramifications in the area of flotation processes (20). As a consequence it has been primarily colloidal chemists who have measured the PZZP's for various materials, primarily oxides. They have, in general, employed two techniques to measure the PZZP. The first technique involves measurement of fast adsorption isotherms for solutions with different concentrations of an indifferent electrolyte and the second technique measures the *p*H change on addition of metal oxide powder. In the former, a potentiometric titration is performed with either acid or base on a metal oxide suspension in solutions of known specific ionic strength. Since the ions added must go either to changing the *p*H of the solution or being adsorbed on the metal oxide surface, it is possible to determine the surface charge density as a function of *p*H for several concentrations of the supporting electrolyte. The point at which these curves intersect will be the PZZP. In the latter, metal oxide powders are added to aqueous solutions of a known *p*H with no other adsorbable species present. The *p*H of the solution will drift on addition of the powder toward the PZZP. At the PZZP, the *p*H of the solution is independent of the amount of metal oxide added.

We have developed a modification of the first technique whereby all that is needed is to perform a differential potentiometric titration of a suspension of the material of interest with a solution of the ion of interest. Since the solid acts to buffer the solution everywhere but at the PZZP, a peak in the rate of change of *p*X with titrant added *vs.* *p*X curve should be observed. We have employed the *p*X drift and differential potentiometric titration techniques to elucidate the PZZP for the various sulfide species on CdS as is shown in Fig. 3.

For the drift experiments degassed 0.1M KOH solutions of known sulfide concentrations (as Na_2S) were equilibrated under argon with known amounts of finely powdered CdS. The solution makeup was monitored by following $pS^{=}$ with a specific ion electrode.

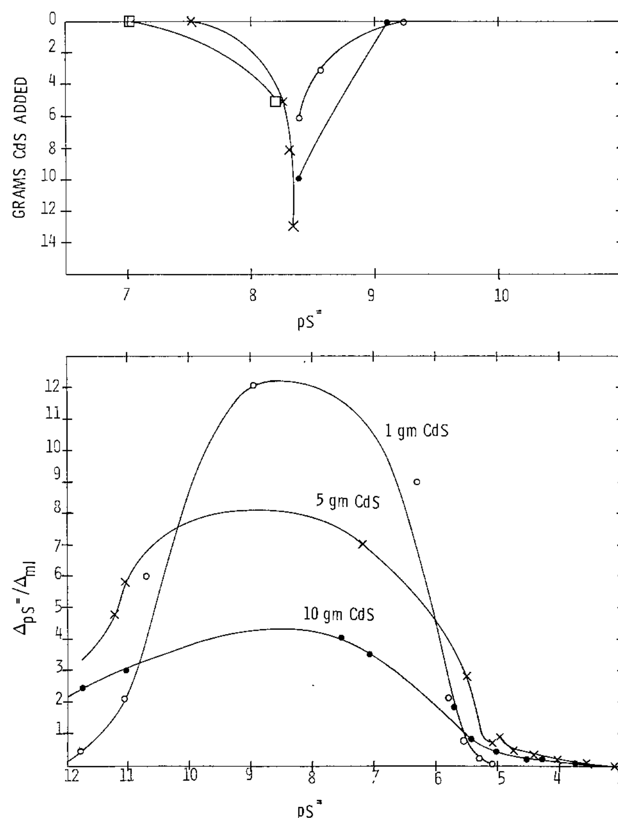

Fig. 3. Determination of the $S^{=}$ concentration at the PZZP of the CdS anode. The top half of the figure represents data taken by the *p*X drift technique. In particular we plot grams of CdS added to a 600 ml sulfide solution of known initial $pS^{=}$ and 0.1M KOH *vs.* measured $pS^{=}$. Points on continuous lines represent successive additions to the same solution. The lower half of the figure consists of three differential potentiometric titrations of a suspended amount of CdS 1, 5, 10g in 600 ml 0.1M KOH with Na_2S solution. The rate of change of $pS^{=}$ with added titrant $\partial pS^{=}/\partial S$ is plotted *vs.* $pS^{=}$. It is of note that the same peak for the PZZP is observed in both curves and that $\partial pS^{=}/\partial X$ scales inversely with the amount of added CdS.

The top half of Fig. 3 illustrates the drift data as a plot of grams of CdS powder added *vs.* the $pS^{=}$. Convergence on the PZZP is observed from both directions and the PZZP lies at a $pS^{=}$ of 8.4. This number does not reflect which of the sulfide species is the potential-determining species but just that a unique sulfide anion concentration exists at the PZZP and is 4×10^{-9}M $S^{=}$. The sulfide equilibria in solution (21) are illustrated in Eq. [5] and [6]

$$H_2S \rightleftarrows H^+(aq) + HS^-(aq); \quad K = 1.00 \times 10^{-7} \quad [5]$$

$$HS^- \rightleftarrows H^+(aq) + S^=(aq); \quad K = 7.08 \times 10^{-14} \quad [6]$$

The lower half of Fig. 3 illustrates some curves from differential potentiometric titrations of CdS suspensions. Two observations are important here: (*i*) the peak in the rate of change curve matches that of the drift measurements quite well, and (*ii*) the relative magnitude of the peak scales inversely with the amount of the material added. This is expected since the suspended CdS essentially acts as a buffering agent in the solution and the larger the amount of CdS the smaller $\Delta pS^{=}/\Delta ml$.

Flatband potential as a function of [Na_2S] *and* [H^+]. —In an attempt to determine which sulfide ions are the potential-determining species as well as to define the dependence of V_{fb} on pNa_2S and pH^+, a series of experiments were conducted using a single crystal CdS electrode in various sulfide, hydroxide electrolytes.

To derive full benefit from the flatband measurements the accurate composition of the solution must

Table I. Flatband dependence on Na_2S concentration

Nominal solution	Actual solution	pH	$[H_2S]$	$[HS^-]$	$[S^=]$	V_{fb} *vs.* SCE
10^0M Na_2S, 0.1M KOH	8.97×10^{-1}M Na_2S, 0.052M KOH	13.95	1.36×10^{-8}	1.22×10^{-1}	7.75×10^{-1}	−1.32

be known. This is relatively simple since we can rewrite Eq. [5] and [6] as

$$[H_2S] = \frac{[HS^-]10^{-pH}}{1 \times 10^{-7}} \quad [7]$$

$$[S^=] = \frac{7.08 \times 10^{-14}[HS^-]}{10^{-pH}} \quad [8]$$

and we know that

$$M_s = [S^=] + [HS^-] + [H_2S] \quad [9]$$

where M_s is the net moles of sulfide as original Na_2S added. M_s is known since all the stock Na_2S solutions were standardized with lead perchlorate (22). Since pH and $pS^=$ are known, the concentration of all of the relevant species in solution may be readily ascertained.

Table I illustrates the dependence of flatband on the bulk Na_2S concentration in argon purged 0.052M KOH solutions. The variation of flatband potential with concentration of a particular ion is due to changes in the potential across the Helmholtz layer due to adsorbed species Δ_{pX}. Starting from Eq. [4] we can write the potential across the Helmholtz layer due to an absorbed species as

$$ze\Delta_{pX} = \mu_{sol} - \mu_{ad} \quad [10]$$

where ze is the charge on the ion of concern and μ the relevant chemical potential. Taking into account the dependence of chemical potential on activity of the species, we have

$$ze\Delta_{pX} = {}^{\circ}\mu_{sol} - {}^{\circ}\mu_{ad} + RT \ln\left[\left(\frac{C_{sol}}{{}^{\circ}C_{sol}}\frac{{}^{\circ}\Gamma_{ad}}{\Gamma_{ad}}\right)\right] \quad [11]$$

where we have assumed the solution is close to ideal and the activities can be replaced by concentrations, C, and Γ is the surface concentration of adsorbed species. Thus if one plots the flatband potential *vs.* the log of the concentration, one expects the typical Nernstian slope (0.0592 V/pX/z). Figure 4 shows a plot of flatband potential *vs.* the log of the bulk Na_2S concentrations. The data is very linear with a slope of 0.060 ± 0.003 V/pNa_2S unit, very close to that predicted for a monovalent anion. This data is highly significant in two ways. First it allows us to extrapolate the flatband potential back to the PZZP to test our model. Second, the fact that it has a slope expected for a monovalent ion limits the number of possible sulfide ions that are potential determining.[1]

Extrapolating the flatband potential to our PZZP of 8×10^{-9}M Na_2S gives us an experimental flatband potential of −0.84V *vs.* SCE. We know

$$V_{fb} = EA - E_o - \Delta_{fc} - \Delta_{pX} \quad [12]$$

We have shown that EA = 3.8 eV, E_o = 4.75 eV, Δ_{fc} ~ 0.1 eV, and at the PZZP, $\Delta_{pX} = 0$. Thus, we calculate a flatband potential of −0.83V (SCE) for CdS which is in excellent agreement with the experimental value above.

An examination of Table I indicates that at Na_2S concentrations below 10^{-2} molar the ratios of the H_2S, HS^-, and $S^=$ concentrations are relatively constant, a consequence of the pH being almost constant. Since all ionic species present in the electrolyte are known and HS^- is the only monovalent ion present that will adsorb [OH^- does not adsorb on CdS (24)] the slope of the V_{fb} *vs.* p_{Na_2S} indicates that HS^- must be a potential-determining ion.

To investigate the dependence of V_{fb} on the solution pH, a number of solutions were made up with the compositions illustrated in Table II. Here a constant bulk Na_2S concentration is maintained and various KOH concentrations were employed. Of consequence is that the relative concentrations of the various sulfide species remains essentially constant with the HS^- ion being the predominant species. Since the HS^- ion is the negatively charged potential-determining species and its concentration remains essentially constant, variations in the flatband potential must be due to the changes in pH^+. Figure 5 illustrates the dependence of the flatband potential on pH^+ and once again the slope corresponds to that expected from the Nernst equation for a monovalent cation (0.056 ± 0.009 V/pH). Therefore, the proton must be the other potential-determining ion in the CdS cell. These data may

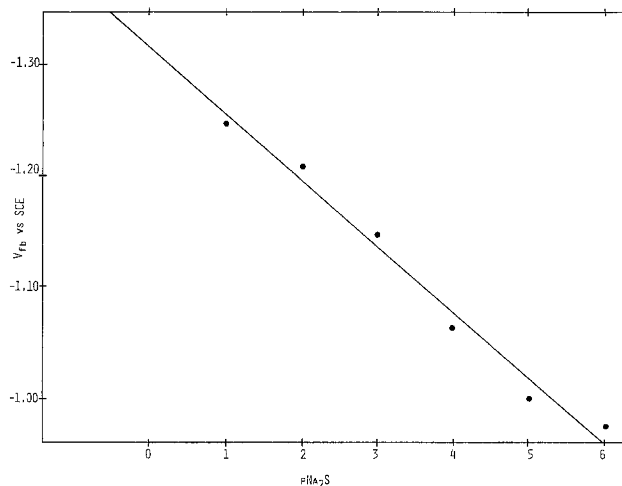

Fig. 4. Dependence of V_{fb} on bulk Na_2S concentration. The data shown are the same as those in Table I and are for a $CdS/S^=$, 0.052M KOH/Pt cell. The slope of the line is 0.060 ± 0.003 V/pNa_2S unit very close to the Nernstian slope for a monovalent ion (0.059 V/pX) indicating that the HS^- ion is a potential-determining species.

[1] The same Nernstian behavior of the flatband potential of CdS has been observed using bulk sulfide solutions by Minoura *et al.* (23). However, their conclusion that the $S^=$ ion adsorbs on the CdS electrode is incorrect since the Nernstian slope they observe is characteristic of a monovalent ion.

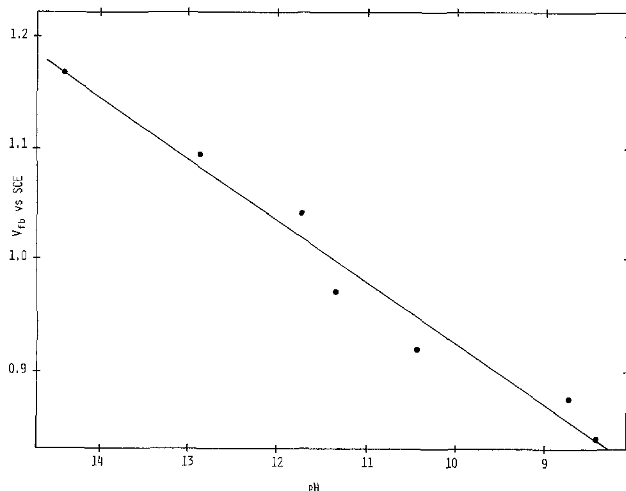

Fig. 5. Dependence of V_{fb} on pH. The data shown are the same as those in Table II and are for a CdS/9.44 × 10^{-4}M $S^=$, KOH/Pt cell. The slope of the line is 0.055V ± 0.009/pH unit which is close to Nernstian as is expected if the proton is one of the potential-determining species.

appear to be in conflict with results of Watanabe, Fujishima and Honda (24), however, their experiments were done in significantly different electrolytes and involved different sample pretreatments. The close agreement between their flatband of −0.87 (SCE) and that observed by Minoura, Watanabe, Oki, and Tsuiki for the Cd surface of CdS −0.85 (SCE) suggests that they have exposed the Cd surface. On this surface one would not expect adsorption of positive potential-determining ions such as H^+. This is consistent with their flatband being close to our PZZP. The determination of the pH^+ dependence requires significant sulfide concentrations since an equilibrium situation would not exist otherwise.

The PZZP measurements suggested that a unique $S^=$ ion activity exists when the adsorbed surface charge is zero (PZZP) even though we believe that HS^- and H^+ are the potentially determining species. How is this possible? If we return again to Eq [4] we can write the electrochemical potential equilibria for each potential-determining species. Subtracting these two equations we have

$$\bar{\mu}_{ad}^{H^+} - \bar{\mu}_{ad}^{HS^-} = \bar{\mu}_{sol}^{H^+} - \bar{\mu}_{sol}^{HS^-} \quad [13]$$

where the right side of the equation is in solution and the left side is the adsorbed phase. At the PZZP the number of H^+ and HS^- ions in the adsorbed phase are equal. If we then explicitly display the concentration dependences of the electrochemical potentials, we have

$$^\circ\bar{\mu}_{ad}^{H^+} - {}^\circ\bar{\mu}_{ad}^{HS^-} = {}^\circ\bar{\mu}_{sol}^{H^+} - {}^\circ\bar{\mu}_{sol}^{HS^-} + RT \ln a_{H^+,sol} - RT \ln a_{HS^-,sol} \quad [14]$$

where the activities refer to those at the PZZP. The activity of HS^- ions may be expressed in terms of the activities of H^+ and $S^=$ ions by using Eq. [6]. If we also use the fact that $2.303pX = -\ln C_X$, we find

$$^\circ\bar{\mu}_{ad}^{H^+} - {}^\circ\bar{\mu}_{ad}^{HS^-} = {}^\circ\bar{\mu}_{sol}^{H^+} - {}^\circ\bar{\mu}_{sol}^{HS^-} - 2.303RT\,pH^+ + 2.303RT\left\{pH^+ + pS^= + \frac{\ln K}{2.303}\right\} \quad [15]$$

where $K = 7.08 \times 10^{-14}$. Thus the dependence on pH^+ cancels and a unique value of $pS^=$ exists at the PZZP given by

$$^\circ\bar{\mu}_{ad}^{H^+} - {}^\circ\bar{\mu}_{ad}^{HS^-} = {}^\circ\bar{\mu}_{sol}^{H^+} - {}^\circ\bar{\mu}_{sol}^{HS^-} + 2.303RT\left\{\frac{\ln K}{2.303} + pS^=\right\} \quad [16]$$

Conclusions

In summary, we have shown that the techniques we had previously developed for oxide photoanodes are equally applicable to nonoxides and various redox chemistries. In particular, we have shown that for the case of the cadmium sulfide wet photovoltaic cell, we can predict the flatband potential of the CdS anode from the atomic electronegativities of the constituent atoms. This prediction may be compared with experiments if corrected for the potential across the Helmholtz layer due to specific ion adsorption Δ_{pX}. This correction factor can be simply evaluated using well-established procedures. Excellent agreement is found between the calculated value (−0.83 *vs.* SCE) and the experimentally measured value that has been corrected to the PZZP (−0.84V *vs.* SCE). We have also demonstrated how, by examining the behavior of the flatband with pNa_2S and pH^+, we can positively identify the potential-determining species on the cadmium sulfide electrode. These turn out to be HS^- and H^+. $S^=$ which was previously thought to be important seems to play no direct role.

Finally, the importance of considering the influence of the adsorbed ions cannot be underplayed. If flatband measurements in these systems are not referenced to the appropriate PZZP, the magnitude of Δ_{pX} remains unknown and the value of the intrinsic flatband cannot be determined. Further, by being able to determine which ions in solution are the potential-determining ones, the ability to intelligently modify the chemistry of the system becomes a possibility.

The Conductance, Cyclic Voltammetric, and Infrared Spectral Studies of Electrolytes in Dimethyl Sulfoxide

H. V. Venkatasetty* and D. J. Saathoff

Honeywell Corporate Material Sciences Center, Bloomington, Minnesota 55420

ABSTRACT

The conductance, cyclic voltammetry, and infrared spectra of $LiAsF_6$, $LiPF_6$, and $LiBF_4$ in dimethyl sulfoxide have been measured. From conductance data, information on optimum concentration of the electrolyte for maximum conductance as well as the formation of ion pairs and triple ions has been obtained. The cyclic voltammograms of these solutions have been used to establish their electrochemical stability and to study the electrochemical behavior of trace amounts of water in these solutions. The infrared spectra of dimethyl sulfoxide and the solutions of $LiAsF_6$, $LiPF_6$, and $LiBF_4$ in dimethyl sulfoxide have been obtained. The changes observed in the spectra of electrolyte solutions have been interpreted in terms of ion-solvent interactions.

Dimethyl sulfoxide (DMSO) is a dipolar aprotic solvent with excellent solvent properties for inorganic and organic materials. It is resistant to oxidation and reduction (1). It has fairly high dielectric constant of 46.6 at 25°C and its viscosity is 1.96 cp at 25°C (2). It is a potentially promising solvent for use in high energy density electrochemical power sources. The conductance behavior of dilute solutions of several uni-univalent electrolytes was studied in DMSO at 25°C and the limiting equivalent conductances were obtained (3). Activity coefficients, conductivities, viscosities, and nuclear magnetic resonance (nmr) spectral measurements were made on lithium chloride solutions in DMSO and the observed anomalies in the activity coefficients were attributed to ion-pair formation (4). Conductance measurements on dilute solutions of quaternary ammonium salts were made in DMSO, and information on single ion conductivities and association to ion-pairs was obtained (5). The conductance of several sodium salts and an alkyl ammonium salt was measured and ion conductivities were determined (6). It was found that in sodium salts, the association to ion pairs was evident in salts containing large anions as well as in alkyl ammonium salt (6).

As more concentrated solutions of electrolytes (~1M) are usually employed in battery systems to minimize *IR* drop, it is expected that there will be strong ion-ion and ion-solvent interactions in these solutions of aprotic solvents. It is known that the structural, thermodynamic, and transport properties of electrolyte solutions depend on the nature and the range of such interactions. The mass transport properties of electrolytes in solutions and the electrolyte solution electrode interactions can limit the efficiency and performance of the battery. It has been shown that in lithium cupric fluoride battery using 1M $LiClO_4$ in propylene carbonate, the severe performance limitations noticed during discharge at medium to high rates can be attributed to mass transport limitations in the electrolytes (7). The redox behavior of sulfur in 1M $LiClO_4$ in DMSO has been studied with a view to develop an ambient temperature nonaqueous electrolyte Li/S secondary battery (8). Therefore, there is a need to develop an understanding of ion-ion and ion-solvent interactions in concentrated solutions of electrolytes in nonaqueous aprotic solvents of interest to battery technology. There are relatively few studies on the transport properties and structure of solutions of lithium salts in DMSO useful to lithium battery technology.

The present investigations were undertaken to measure conductance of the solutions of $LiAsF_6$, $LiPF_6$, and $LiBF_4$ in DMSO over a wide concentration range to study their electrochemical stability by cyclic voltammetry, and their structures by infrared spectroscopy. From conductance data such information as equivalent conductance at infinite dilution (Λ_o), ion-pair dissociation constant (*Kd*) and information on triple ion conductance (Λ_{o3}), and dissociation constant (*K*) have been obtained. From cyclic voltammograms, the electrochemical stability and the electrochemical behavior of small amounts of water have been studied. The observed changes in the characteristic infrared frequency of the solvent and the polyatomic anions have been interpreted in terms of ion-solvent interactions.

Experimental

Dimethyl sulfoxide "distilled in glass" obtained from Burdick and Jackson Laboratories, Incorporated, was examined for water content by Karl Fischer titration, and the water content was found to be ~50 ppm. The electrolytes $LiAsF_6$, $LiPF_6$, and $LiBF_4$ were obtained from Foote Mineral Company and were dried under vacuum before use. $LiPF_6$ was quoted by the manufacturer as 99.1% pure and the impurity was the solvent methylformate or benzene. The other salts $LiAsF_6$ and $LiBF_4$ also had solvent impurity which

* Electrochemical Society Active Member.
Key words: dimethyl sulfoxide, electrolytes, conductance, cyclic voltammetry, infrared spectra.

was removed on drying. $LiAsF_6$ obtained from U.S. Steel was also used. All solutions were prepared in a dry box under a positive pressure of dry nitrogen, and lithium electrodes were prepared under dry argon. Jones- and Bollinger-type conductance cells with bright platinum disk electrodes were fabricated. The cell constant varied from 0.3264 to 5.5794 cm^{-1}, and these were used after calibration. The cell constants of the conductance cells were determined with standard 0.1 and 0.01D KCl solutions (9). All conductance measurements were made in a bath of mineral oil maintained at 25° ± 0.05°C. The conductance data are accurate to 2%. The specific conductance of dimethyl sulfoxide is 2-3 × 10^{-8} mho cm^{-1} (2) and the most dilute solution used has specific conductance of 1.9293 × 10^{-5} mho cm^{-1}, and therefore solvent correction is necessary. A Jones and Josephs-type bridge in combination with a Wavetek sweep generator and oscilloscope was used to measure the resistances of solutions. Cyclic voltammetric studies were carried out using Princeton Applied Research Corporation Model 173 potentiostat/galvanostat with a Model 175 Universal programmer. A three-electrode cell with compartments being separated by a medium porosity fritted disk was used. Most commonly used electrode materials in experiments on electrochemical stability are graphite and platinum (10). Platinum electrodes have been used by various workers (10) and in this work a smooth platinum disk electrode was used. The counterelectrode was a large platinum spiral, and the reference electrode was lithium foil immersed in lithium salt solution in DMSO. The voltammetric studies were carried out in less than 15 min, and the platinum electrode on examination did not show any change in appearance. The infrared spectra were obtained using a Digilab Fourier Transform Spectrometer. A KBr beam splitter was used in the 4000-400 cm^{-1} spectral range, and a 6 μm Mylar beam splitter was used in the 400-120 cm^{-1} range. The resolution was 8 cm^{-1} in the 4000-400 cm^{-1} range and 4 cm^{-1} in the 400-120 cm^{-1} range. Two types of cells were used due to the limited spectral range of the window materials. A sealed cell with KBr windows was used for the 4000-400 cm^{-1} range. A similar type sealed cell with polyethylene windows was used to cover the 500-150 cm^{-1} range. The cells were filled in a dry box with a positive pressure of dry nitrogen.

Results and Discussion

The conductance measurements were made on $LiAsF_6$, $LiPF_6$, and $LiBF_4$ in DMSO over a wide range of concentrations (Fig. 1, Table I). The addition of a known quantity of water to the solutions of $LiAsF_6$ shows a decrease in the conductance (Fig. 2), indicating preferential solvation of the Li^+ cation by the water molecules. The conductance data for dilute solutions of these electrolytes were analyzed by an equation of a form similar to that of Fuoss-Shedlovsky (11), except for the function $S(Z)$. The equation is

$$\frac{1}{\Lambda} = \frac{1}{\Lambda_0} + \frac{c\Lambda}{Kd(\Lambda_0)^2}$$

where Λ_0 is the limiting equivalent conductance and Kd is the dissociation constant. The derived values of Λ_0 and Kd for $LiAsF_6$ and $LiPF_6$ indicate similar behavior for these electrolytes, whereas these values

Table II. Equivalent conductance at infinite dilution and dissociation constants for ion pairs and triple ions at 25°C in DMSO

	Λ_0	$Kd \times 10^3$	$k/\Lambda_{03} \times 10^5$
$LiAsF_6$	55.5	4.8	1.9
$LiPF_6$	56.8	4.6	1.7
$LiBF_4$	52.9	13.9	1.2

are different for $LiBF_4$ due to ion-solvent interactions (Table II). The equation describing the equilibrium for triple ions (12, 13) is given by

$$\Lambda = \sqrt{\frac{Kd}{C}}\,\Lambda_0 + \frac{\sqrt{KdC}}{K}\,\Lambda_{03}$$

where Kd and K are the equilibrium constants for ion pairs and triple ions and Λ_0 and Λ_{03} have their usual significance (12, 13). The information on triple ions is given in Table II. Because of the scatter in the experimental data, these values are considered as approximate. The limiting equivalent conductance (Λ_0) for $LiAsF_6$ is 71.5 in methylformate, and it is 22.2 in propylene carbonate. For $LiBF_4$ it is 9.1 in methyl formate (14). These differences have been explained in terms of the viscosity of the solvents and the ion-solvent interactions.

Infrared spectroscopy.—In dimethyl sulfoxide both oxygen and sulfur atoms are rich electron sources and therefore can interact with electrolytes. The electronic structure of DMSO may be represented as a resonance hybrid of the structures

If interaction occurs through oxygen, S—O bond will weaken, resulting in a decrease in S—O stretching frequency. If interaction occurs through sulfur, it will result in an increase of S—O stretching frequency (15, 16). The characteristic frequencies most likely to be affected by ion-solvent interactions are the S—O stretching mode occurring at 1060 cm^{-1}, the CH_3 rocking mode at 955 cm^{-1}, and the asymmetric C—S stretching mode at 675 cm^{-1} in the pure solvent (15, 16). The observed changes in the spectra of these solutions are shown in Table III. The shift in S—O stretching frequency is minimal for solution of $LiAsF_6$ and more pronounced for solutions of $LiPF_6$ and $LiBF_4$, indicating relative magnitude of interaction.

The anions AsF_6^- and PF_6^- with octahedral symmetry (O_h) and low polarizability (17) should have six normal modes of vibrations of which only ν_3 and ν_4 are infrared active (18). The appearance of strong bands at 700 and 400 cm^{-1} can be attributed to ν_3 and ν_4 of AsF_6^- (Table III). The infrared spectrum of the compound $LiSbF_6$ shows a strong band ν_3 at 669 cm^{-1} and a medium ν_4 band at 350 cm^{-1} (19, 20). In the case of $LiPF_6$ a strong band appearing at 840 cm^{-1} and a medium-intensity band appearing at 555 cm^{-1} can be assigned to the ν_3 and ν_4 modes of PF_6^-, respectively. The third band of medium intensity appearing at 425 cm^{-1} can be attributed to ν_5 to PF_6^- due to lowering of symmetry as a result of ion-solvent interaction (Table III). The infrared spectrum of KPF_6 has been obtained and a strong band ν_3 at 830 cm^{-1} and a medium intensity band at 558 cm^{-1} have been attributed to the ν_3 and ν_4 mode, respectively (19, 20). The anion BF_4^- of $LiBF_4$ with tetrahedral symmetry (T_d) has only two infrared active vibrational modes, ν_3 and ν_4, and these are triply degenerate (20, 21). The appearance of a shoulder at 500 cm^{-1} can be attributed to the ν_4 mode of BF_4^- (Table III). A broad band of medium intensity appearing at 420 cm^{-1} can be attributed to the ν_2 mode which has become infrared active due to lowering of the symmetry as a result of ion-solvent interaction.

Cyclic voltammetry.—The cyclic voltammetric studies of electrolyte solutions in dimethyl sulfoxide show that the solutions are electrochemically stable from about +0.5 to +3.5V *vs.* Li/Li^+. The voltammogram of 0.6M $LiAsF_6$ in DMSO shows a main peak around +1.75V and small peaks around +2.3, +1.4, and +1.1V *vs.* Li/Li^+ (Fig. 3). On adding excess water (2500 ppm) to the solution, the voltammogram obtained shows that the main peak around +1.75V has increased in amplitude, whereas the other peaks show very slight increase. A voltammogram of 0.6M

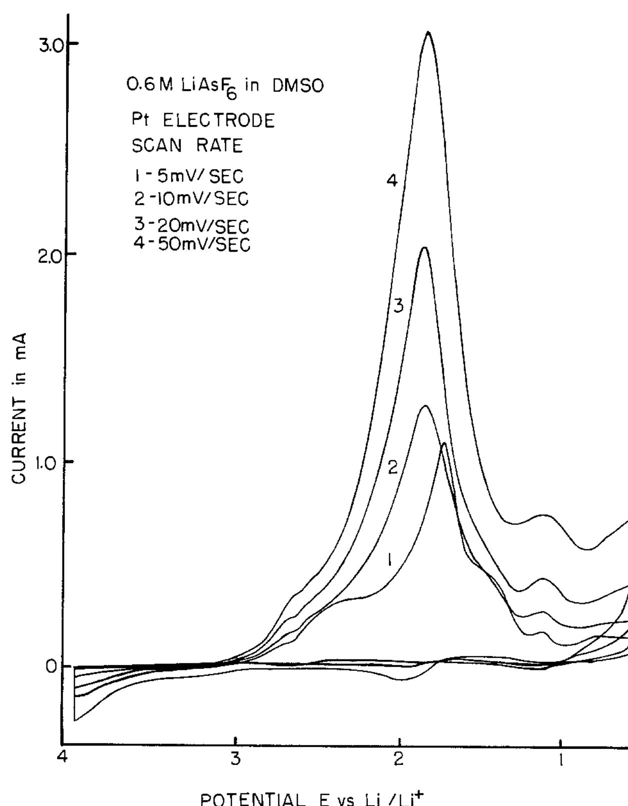

Fig. 3. Cyclic voltammogram of $LiAsF_6$ in dimethyl sulfoxide as a function of scan rate.

$LiAsF_6$ in tetrahydrofuran also shows one main peak and three small peaks (22). The main peak occurring around +1.75V *vs.* Li/Li$^+$ can be attributed to the reduction of water. A reduction peak at +1.4V *vs.* Li/Li$^+$ was observed in 1M $LiClO_4$ in propylene carbonate, and it was attributed to the reduction of water (23). At this time, it is not possible to attribute the peaks at 2.3 and 1.1V to any particular reduction reaction. The peak current corresponding to the main water reduction peak around +1.75V was found to increase with scanning rate. The relationship between peak current and voltage scan rate under linear diffusion condition is given by (24)

$$i_p = AD^{1/2}CV^{1/2}$$

where i_p is the peak current, D is the diffusion coefficient, C is the bulk concentration of the electroactive species, V is the scanning voltage, and A is a constant for the particular system. The ratio of $i_p/V^{1/2}$ was found to be constant at constant concentration within the range of potential scan (5-200 mV/sec). The voltammograms of the solutions of 0.6M $LiPF_6$ and 0.6M $LiBF_4$ in DMSO are similar to that of 0.6M $LiAsF_6$ in DMSO.

Conclusions

The maximum conductance for the electrolytes $LiAsF_6$ and $LiPF_6$ occurs at 0.6M and for $LiBF_4$ at 0.7M. These electrolytes form ion pairs and triple ions in DMSO. These solutions are electrochemically stable from +0.5 to +3.5V *vs.* Li/Li$^+$.

An Impedance Interpretation of Small Amplitude Cyclic Voltammetry

II. Theoretical Analysis of Systems that Exhibit Pseudoinductive Behavior

Digby D. Macdonald*

SRI International, Materials Research Center, Menlo Park, California 94025

ABSTRACT

Transform analysis is used to derive the small amplitude cyclic voltammetric (SACV) response of an equivalent circuit for an interface that exhibits pseudoinductive behavior. The predicted response contains both transient and steady-state contributions. The steady-state contribution exhibits hysteresis, and the hysteresis current is predicted to change sign with increasing voltage sweep rate as the reactive behavior becomes dominated by the parallel capacitance. Numerical analysis is used to illustrate the dependence of the steady-state response on the voltage sweep rate, and the calculated SACV response is compared with the behavior of the circuit in the complex impedance plane.

Small amplitude cyclic voltammetry (SACV) is used extensively for determining the polarization resistance $(\partial E/\partial I)$ of metal-solution interfaces, particularly during corrosion research. In this case, it is necessary to estimate $(\partial E/\partial I)$ at the corrosion potential in order to calculate the corrosion current, and

* Electrochemical Society Active Member.
Key words: linear polarization, corrosion, electrode kinetics.

hence the weight loss, using the Stern-Geary relationship (1). However, the SACV response current frequently exhibits hysteresis, and furthermore, the value obtained for the polarization resistance under dynamic control will in general be less than the desired d-c value. Hysteresis in the SACV current response arises from nonresistive (*i.e.*, inductive or capacitive) elements in the equivalent electrical circuit for the interface. In principle, the observed hysteresis can be used to delineate the contributions from the various interfacial components. Also, theoretical analysis of the SACV response provides the functional dependence of polarization "resistance" on frequency (or voltage sweep rate). These functions may then be used to extrapolate experimental data to zero frequency (or voltage sweep rate) in order to extract the desired d-c polarization resistance.

In Part I of this series (2), a rigorous analysis was presented of the SACV response of a simple resistive-capacitive equivalent circuit. Transform analysis was used to derive analytical expressions for the current-time (and hence current-potential) response, and the feasibility of extracting useful impedance data from the SACV technique was demonstrated. In this study, the analysis presented in Part I is extended to systems that exhibit inductive behavior at low frequency. A number of systems of practical interest, including passivating iron in inhibited and uninhibited sulfuric acid, have been found to exhibit low frequency inductive semicircles in the complex impedance plane (3-6). Definition of the theoretical behavior of these systems under SACV conditions could make it possible to identify inductive behavior during aquisition of polarization resistance data, and to estimate the impedance parameters of the components of the equivalent circuit (Fig. 1).

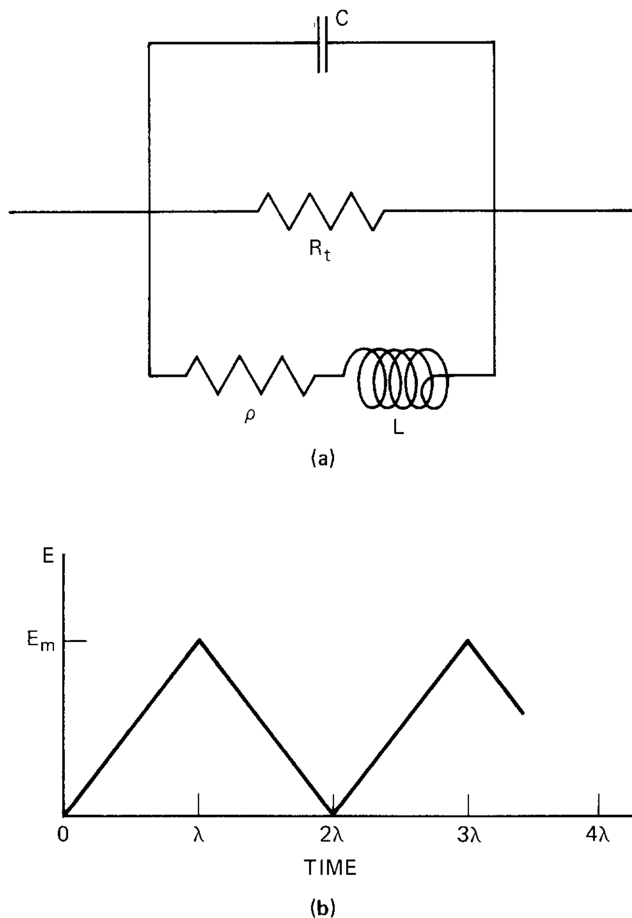

Fig. 1. (a) Equivalent electrical circuit for systems that exhibit pseudoinductance; and (b) SACV excitation voltage.

Theoretical Analysis

A typical a-c impedance complex plane diagram for the systems of interest in this work is shown in the upper right-hand corner of Fig. 2. The complex plane behavior is dominated by two semicircles; a high frequency resistive-capacitive semicircle that gives rise to positive values for the reactance, and a low frequency resistive-inductive semicircle that is characterized by a negative reactance (7). According to Epelboin and co-workers (3-6) and others (8), this type of behavior in the complex plane can be adequately described by the equivalent circuit shown in Fig. 1b provided the magnitude of the excitation voltage is sufficiently small that the components are effectively linear.

The admittance, $Y(p)$, of this circuit can be written in terms of the impedance operator, p, as follows (2)

$$Y(p) = 1/(\rho + pL) + 1/R_t + pC \qquad [1]$$

where $p = d/dt$ and $1/p = \int dt$. Thus, the response of the circuit to any time-dependent excitation voltage is given in Laplace space as

$$\overline{I}(s) = Y(s) \cdot \overline{E}(s) \qquad [2]$$

where $\overline{E}(s)$ is the Laplace transform of excitation function, and the admittance function in Laplace space, $Y(s)$, has the same algebraic form as Eq. [1] with $p \equiv s$. The Laplace transform of the excitation voltage used for SACV is given previously (2) as

$$\overline{E}(s) = E_m(1 - e^{-\lambda s})/\lambda s^2(1 + e^{-\lambda s}) \qquad [3]$$

Thus, substitution of Eq. [1] and [3] into Eq. [2] yields the following expression for the Laplace transform of the current

$$\overline{I}(s) = (E_m C/\lambda)[(1 - e^{-\lambda s})/s(1 + e^{-\lambda s})]$$
$$+ (E_m/\lambda)(1/R_t + 1/\rho) \times [(1 - e^{-\lambda s})/s^2(1 + e^{-\lambda s})]$$
$$- (E_m/\lambda\rho)[(1 - e^{-\lambda s})/s(1 + e^{-\lambda s})(s + \rho/L)] \qquad [4]$$

The inverse transformations of the first two terms for $\lambda > 0$ and $\mathrm{Re}(s) > 0$ is straightforward to yield [see Roberts and Kaufman (9)]

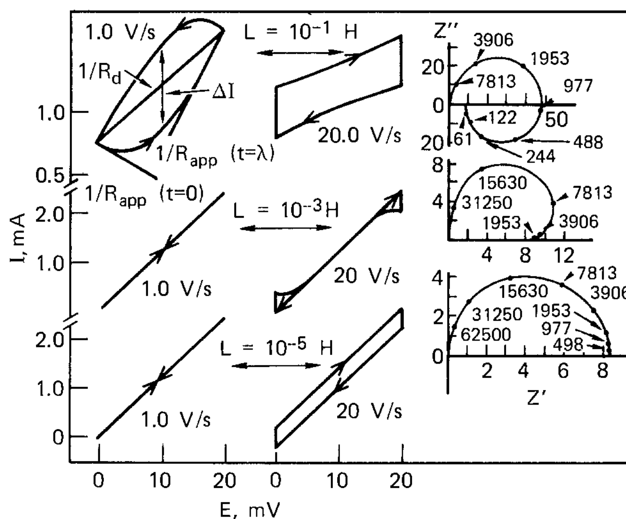

Fig. 2. Current-voltage curves for the SACV response and complex impedance plane diagrams for the equivalent circuit shown in Fig. 1. $C = 10^{-5}$F; $\rho = 10\Omega$; $R_t = 50\Omega$; $E_m = 0.020$V. Upper three curves, $L = 10^{-1}$H; middle three curves, $L = 10^{-3}$H; lower three curves, $L = 10^{-5}$H. The numbers next to the data points in the complex plane diagrams refer to frequencies in rad/sec. Z′ and Z″ have units of ohms.

$$I_1 + I_2 = \begin{cases} (E_mC/\lambda) + (E_m/\lambda)(1/R_t + 1/\rho)(t - 2n\lambda) \\ \qquad \text{for } 2n\lambda < t < (2n+1)\lambda \quad [5a] \\ -(E_mC/\lambda) + (E_m/\lambda)(1/R_t + 1/\rho) \times \\ \quad [2(n+1)\lambda - t] \quad \text{for } (2n+1)\lambda < t \\ \qquad < (2n+2)\lambda \quad [5b] \end{cases}$$

in which Eq. [5a] and [5b] hold for the forward and reverse sweeps, respectively, for the nth cycle ($n = 0, 1, 2, \ldots.$). The third term on the right-hand side of Eq. [4] can be inversely transformed by use of the convolution formula

$$I_3 = -(E_m/\lambda\rho)\int_o^t \mathbf{F}(x)G(t-x)dx \qquad [6]$$

where $\mathbf{F}(t)$ and $G(t)$ are the inverse transforms (9) of $(1 - e^{-\lambda s})/s(1 + e^{-\lambda s})$ and $1/(s + \rho/L)$, respectively. That is

$$\mathbf{F}(x) = \begin{cases} +1 \quad \text{for} \quad 2n\lambda < x < (2n+1)\lambda \\ \qquad \text{(forward sweep)} \quad [7a] \\ -1 \quad \text{for} \quad (2n+1)\lambda < x < (2n+2)\lambda \\ \qquad \text{(reverse sweep)} \quad [7b] \end{cases}$$

and

$$G(t-x) = e^{-\rho(t-x)/L}(t > x) \qquad [8]$$

Integrating over successive forward and reverse cycles therefore yields

$$I_3 = -(E_mL/\lambda\rho^2)\left\{2e^{-\rho(t-\lambda)/L}\left[\sum_{m=0}^{2n-1}(-1)^m e^{m\lambda\rho/L}\right] - e^{-\rho t/L} + 1\right\} \qquad [9a]$$

$$I_3' = -(E_mL/\lambda\rho^2)\left\{2e^{-\rho(t-\lambda)/L}\left[\sum_{m=0}^{2n}(-1)^m e^{m\lambda\rho/L}\right] - e^{-\rho t/L} - 1\right\} \qquad [9b]$$

for the forward and reverse sweeps, respectively, for the nth cycle. Addition of Eq. [5] and [9] and using the general expression for the sum of a geometrical series therefore yields the currents for the forward $[2n\lambda < t < (2n+1)\lambda]$ and reverse $[(2n+1)\lambda < t < (2n+2)\lambda]$ sweeps as

$$I^f(t) = (E_m/\lambda)\left\{C + (1/R_t + 1/\rho)(t - 2n\lambda) - (L/\rho^2)\left[2e^{-(t-\lambda)\rho/L}.\frac{(1 - e^{2n\lambda\rho/L})}{(1 + e^{\lambda\rho/L})} - e^{-\rho t/L} + 1\right]\right\} \qquad [10]$$

$$I^r(t) = -(E_m/\lambda)\left\{C - (1/R_t + 1/\rho) \times [2(n+1)\lambda - t] + (L/\rho^2) \times \left[2e^{-(t-\lambda)\rho/L}.\frac{(1 + e^{(2n+1)\lambda\rho/L}}{(1 + e^{\lambda\rho/L})} - e^{-\rho t/L} - 1\right]\right\} \qquad [11]$$

respectively. Equations [12] and [11] may be transformed into more convenient forms by redefining the time scales as follows (2)

$$t = t' + 2n\lambda \quad \text{(forward sweep)} \qquad [12]$$

$$t = t'' + (2n+1)\lambda \quad \text{(reverse sweep)} \qquad [13]$$

where t' and t'' are the times from the start of the forward and reverse sweeps, respectively. Transformation of the time scales therefore yields

$$I^f(t) = (E_m/\lambda)\{C + (1/R_t + 1/\rho)t' - (Le^{-t'\rho/L}/\rho^2) \times [2(e^{-2n\lambda\rho/L} - 1)/(1 + e^{-\lambda\rho/L}) - e^{-2n\lambda\rho/L}] - L/\rho^2\} \qquad [14]$$

$$I^r(t) = -(E_m/\lambda)\{C - (1/R + 1/\rho)(\lambda - t'') + (Le^{-t''\rho/L}/\rho^2)[2(e^{-2n\lambda\rho/L} + e^{\lambda\rho/L})/(1 + e^{\lambda\rho/L}) - e^{-(2n+1)\lambda\rho/L}] - L/\rho^2\} \qquad [15]$$

Equations [14] and [15] demonstrate that the predicted response of the equivalent circuit to the triangular excitation voltage consists of a steady-state contribution, which is independent of the cycle number n, and a transient contribution that decays with successive cycles.

From a practical viewpoint, the steady-state behavior is of greatest significance, since this state is the most easily examined experimentally. The steady state is achieved when $\exp(-2n\lambda\rho/L)$ and $\exp[-(2n+1)\lambda\rho/L] \to 0$, that is when $n \to \infty$. Thus, from Eq. [14] and [15], the forward sweep and reverse sweep steady-state responses are given by

$$I_{ss}^f = (E_m/\lambda)\{C + (1/R_t + 1/\rho)t' + [2Le^{-t'\rho/L}/\rho^2(1 + e^{-\lambda\rho/L})] - L/\rho^2\} \qquad [16]$$

and

$$I_{ss}^r = -(E_m/\lambda)\{C - (1/R_t + 1/\rho)(\lambda - t'') + [2Le^{-t''\rho/L}/\rho^2(1 + e^{-\lambda\rho/L})] - L/\rho^2\} \qquad [17]$$

respectively. Examination of Eq. [16] and [17] shows that the steady-state response consists of constant (but opposite in sign) contributions from the capacitance and the series combination of resistance ρ and inductance L, a linear contribution due to the transfer resistance, R_t, and exponential decay contributions that are of greatest significance at small times (t' and t''). For the case where $\rho \to \infty$, the response reduces to that for a simple parallel R-C circuit. In this instance, no exponential decay contributions are present; a result that is also valid for the case were $L \to 0$. A simple parallel R-C circuit in series with a resistance also exhibits exponential decay at short times (2). We will show later that this case is easily distinguished from pseudoinductance behavior by the sign of the hysteresis current.

Numerical Analysis

Because of the complexity of Eq. [16] and [17], it is convenient to resort to numerical analysis to illustrate the type of SACV response that might be shown by systems that exhibit pseudoinductance. The numerical analysis is best carried out by defining the following quantities

$$1/R_{app}(t = 0) = (\partial I_{ss}^f/\partial t')_{t'=0}/v = -(\partial I_{ss}^r/\partial t'')_{t''=0}/v \qquad [18]$$

$$1/R_{app}(t = \lambda) = (\partial I_{ss}^f/\partial t')_{t'=\lambda}/v = -(\partial I_{ss}^f/\partial t'')_{t''=\lambda}/v \qquad [19]$$

$$1/R_d = [I_{ss}^f(t' = \lambda) - I_{ss}^r(t'' = \lambda)]/E_m \qquad [20]$$

$$\Delta I = I_{ss}^f(t' = \lambda/2) - I_{ss}^r(t'' = \lambda/2) \qquad [21]$$

where R_{app} is the apparent resistance at $t = 0$ or λ, R_d is the diagonal resistance, ΔI is the hysteresis current, and V is the voltage sweep rate. These quantities are defined graphically in Fig. 2.

Substitution of Eq. [16] and [17] into Eq. [18]-[21], therefore, yields the following expressions for the characteristic quantities defined above

$$1/R_{app}(t = 0) = (1/R_t + 1/\rho) - 2/\rho(1 + e^{-\rho\lambda/L}) \qquad [22]$$

$$1/R_{app}(t = \lambda) = (1/R_t + 1/\rho) - 2e^{-\rho\lambda/L}/\rho(1 + e^{-\rho\lambda/L}) \qquad [23]$$

$$1/R_d = (1/R_t + 1/\rho) + (2/E_m) \times \{C - L/\rho^2 + 2Le^{-\rho\lambda/L}/\rho^2(1 + e^{-\rho\lambda/L})\}v \quad [24]$$

$$\Delta I = \{2(C - L/\rho^2) + 4Le^{-\rho\lambda/2L}/\rho^2(1 + e^{-\rho\lambda/L})\}v \quad [25]$$

Examination of Eq. [25] shows that the sign of the hysteresis current for $\rho\lambda/L \rightarrow \infty$ depends on the relative values of the two reactive components; that is, on the sign of $C - L/\rho^2$. In carrying out the numerical analysis, therefore, we have chosen values for C, L, and ρ that satisfy the following three states: $C < L/\rho^2$, $C = L/\rho^2$, and $C > L/\rho^2$.

Current-voltage curves for the three states defined above are shown in Fig. 2 for voltage sweep rates of 1.0 and 20.0 V/sec. Also plotted in this figure are complex plane impedance diagrams for the equivalent circuit with the appropriate values for the parameters C, L, ρ, and R_t. For the case where $C < L/\rho^2$, the contribution from the inductance dominates the reactive component of the impedance at low frequencies, as shown by the fourth quadrant semicircle in the complex plane. At higher frequencies, the imaginary component of the impedance changes sign and the system exhibits normal, noninductive, first quadrant behavior. This change in behavior is reflected in the SACV response of the circuit as a reversal in the direction of rotation of the current-voltage response from counterclockwise for low voltage sweep rates to clockwise for high sweep rates (Fig. 2). This phenomenon is shown in greater detail in Fig. 3, in which the variation of ΔI, as well as $1/R_{app}(t = 0)$, $1/R_{app}(t = \lambda)$, and $1/R_d$, is plotted as a function of sweep rate over the range 0-20.0 V/sec. The data show that for the values chosen for the components of the equivalent circuit, ΔI first shifts sharply to negative values with sweep rate, then passes through an extremum before becoming positive. The sweep rate at which $\Delta I = 0$, therefore, defines the point at which the system changes from inductive to capacitive in its reactive behavior. Furthermore, the sweep rate at which the ΔI *vs.* v plot passes through the extremum corresponds to that at which the second term in Eq. [25] begins to dominate the SACV response.

Intermediate inductive/capacitive behavior is shown by the curves plotted in the second row in Fig. 1. In this case, a value for L was chosen so that $C = L/\rho^2$. As expected, the hysteresis current as defined by Eq. [21] and [25] is zero because of the equal but opposite contributions from the two parallel reactive components. The exponential decay contributions at short times are still evident, however, particularly at high voltage sweep rates. In the complex plane, this pseudoresistive case exhibits a first quadrant distorted semicircle.

The variation of $1/R_{app}(t = 0)$, $1/R_{app}(t = \lambda)$, $1/Rd$, and ΔI with voltage sweep-rate for this case is shown in Fig. 4. The three conductance terms are nearly invariant with v because of the very low value selected for ρ/L. However, the hysteresis current begins to increase at $v > 10$ V/sec for the circuit parameters chosen.

For the third case selected, $C > L/\rho^2$, and the inductance is not expected to make a large contribution to the SACV response. This is shown in Fig. 2 by a lack of exponential decay at short times and by the appearance of a single, undistorted, semicircle in the complex plane. Furthermore, both ΔI and $1/R_d$ are predicted to increase in a roughly linear manner with v, whereas $1/R_{app}(t = 0)$ and $1/R_{app}(t = \lambda)$ are found to be independent of the voltage sweep rate (Fig. 5).

Equations [22] and [23] show that for all cases in the limit of an infinitely low voltage sweep rate (or $\lambda \rightarrow \infty$), $1/R_{app}(t = 0)$ and $1/R_{app}(t = \lambda)$ approach $(1/R_t - 1/\rho)$ and $(1/R_t + 1/\rho)$, respectively, as indicated in Fig. 3-5. This latter value is precisely the same limit toward which the real component of the complex impedance tends as the frequency of the excitation function is reduced to zero in the classical a-c impedance technique. Furthermore, the diagonal conductance, $1/R_d$, also approaches the upper limit of $(1/R_t + 1/\rho)$. However, the data plotted in Fig. 3,

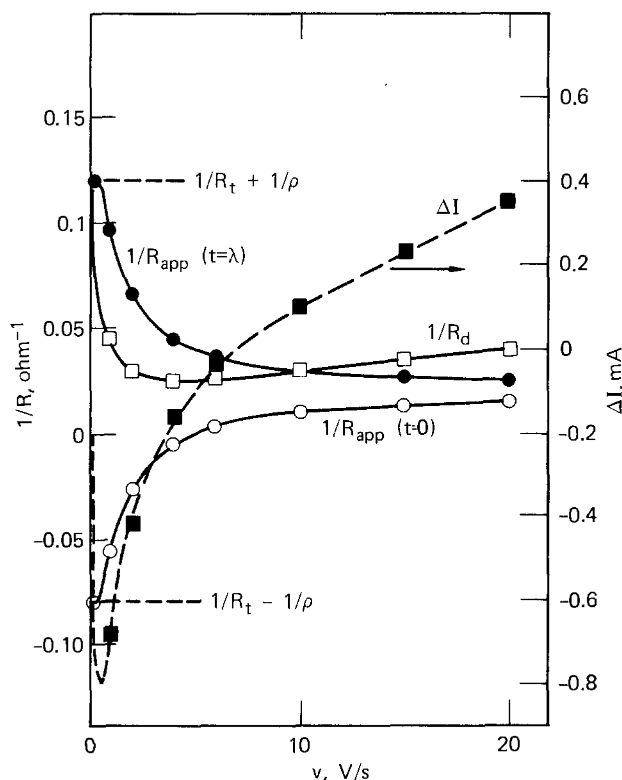

Fig. 3. Dependence of the SACV response of the equivalent circuit shown in Fig. 1 on voltage sweep rate. $C = 10^{-5}$F; $L = 10^{-1}$H; $\rho = 10\Omega$; $R_t = 50\Omega$.

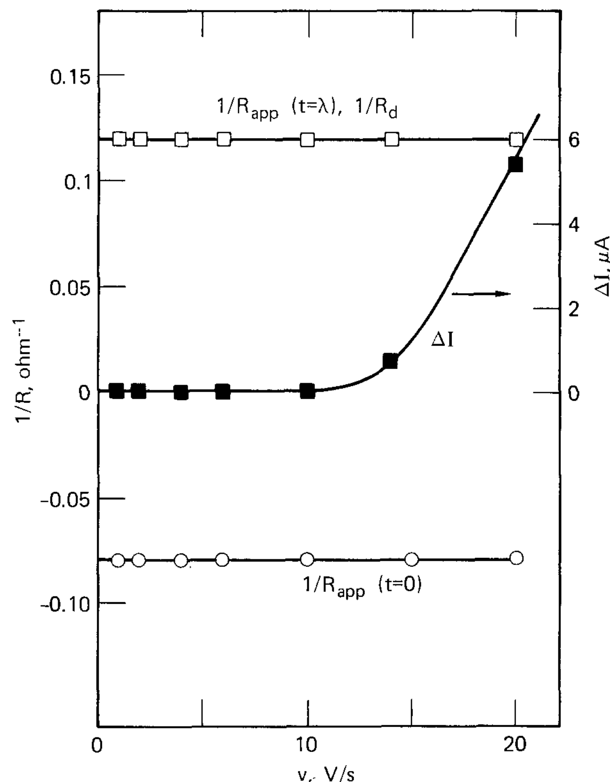

Fig. 4. Dependence of the SACV response of the equivalent circuit shown in Fig. 1 on voltage sweep rate. $C = 10^{-5}$F; $L = 10^{-3}$H; $\rho = 10\Omega$, $R_t = 50\Omega$.

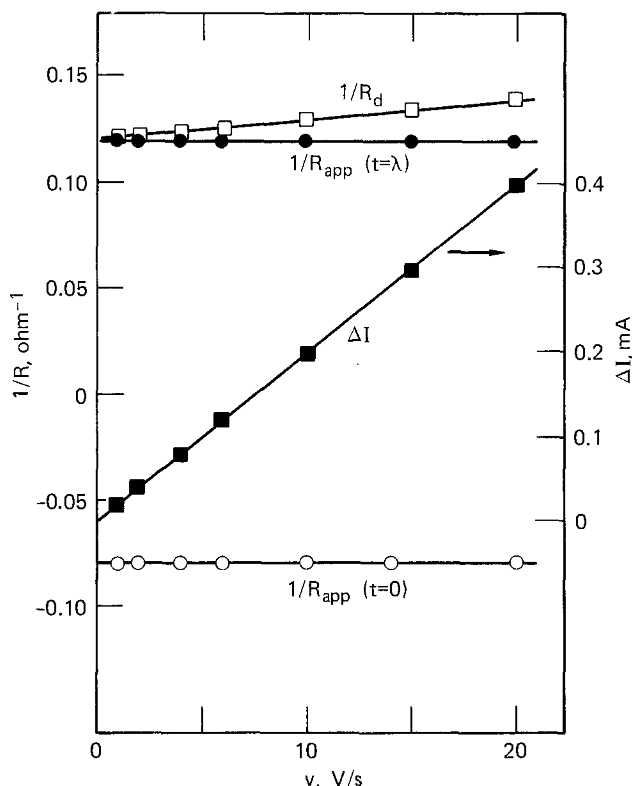

Fig. 5. Dependence of the SACV response of the equivalent circuit shown in Fig. 1 on voltage sweep rate. $C = 10^{-5}$F; $L = 10^{-5}$H, $\rho = 10\Omega$, $R_t = 50\Omega$.

in particular, indicate that the diagonal conductance is much more sensitive to voltage sweep rate than is the term $1/R_{app}(t = \lambda)$. This analytical disadvantage of the diagonal conductance for determining polarization resistance is offset by the fact that $1/R_d$ is much easier to measure experimentally than either of the tangential functions $1/R_{app}(t = 0)$ and $1/R_{app}(t = \lambda)$.

ABSTRACT

A method of numerical calculation is developed for predicting two-dimensional shape changes at a cathode during electrodeposition. The calculation uses finite element methods to obtain the secondary potential field distribution in an electrolysis cell. The cathode shape initially consists of parallel metal strips which are separated by, and coplanar with, insulating strips; the anode is at a fixed distance from the cathode. Transient numerical calculations provide a complete time history of cathode shape during deposition. Results are obtained in order to compile dimensionless shape change dependence on coulombs passed, polarization parameter, applied potential, and initial cathode shape.

The processes of electrochemical deposition or dissolution of metal inexorably lead to modification of surface shape. In turn, the reaction rate distribution along an electrode surface often depends critically on electrode geometry. Therefore, in order to predict shape change by electrolysis, it is necessary to determine how the reaction distribution changes during the evolution of shape. This theoretical study investigates the utility of finite element numerical methods for calculating electrochemical shape change phenomena.

Numerous factors govern the shape dependence of current and potential distributions within electrolysis cells. At low current densities, for example, the potential field within a cell depends on the electrolyte conductivity and the processes which accompany charge transfer at the electrode surface: crystallization, adsorption, homogeneous chemical reactions, etc.

Key words: shape change, current distribution, potential distribution, finite element, mathematical model, electrodeposition.

At high current densities, the concentration distribution within the cell depends on diffusion, convection, and migration, all of which are influenced by electrode shape. Owing to these complexities, it is, therefore, not surprising that quantitative treatments of shape change phenomena have been slow to develop.

A large number of industrial examples could be cited where shape changes play an important role. Leveling of deposits is reviewed by Kardos (1) who mentions the need for more quantitative methods of approach. Quality control in electrodeposition is often adversely affected by shape change as, for example, by nonuniform deposits in patterned wiring boards and in plated through-holes. Dendrite formation, electromachining, electropolishing, and electroforming are other fields where timewise variation of electrode shape is an integral part of the electrochemical process. The initiation of corrosion often depends critically on shape change processes which give birth to occluded cells and, thereby, to intensely accelerated localized corrosion. It is abundantly clear that a large number of industrially important electrochemical systems are influenced by the occurrence of shape change and that improved quantitative understanding would be beneficial.

In one of the few existing quantitative studies on two-dimensional shape change in an electrochemical process, Riggs (2) investigated electromachining of an initially flat workpiece with a cylindrically symmetric toolpiece. Laplace's equation is used to predict the potential field in the gap region, with allowance for temperature and gas evolution effects on electrolyte conductivity. Various overpotential relationships are used to describe charge transfer at both electrodes; the local current efficiency for the two anodic reactions is assumed to be constant. By modeling the entire electrolysis cell, this work achieves a high level of sophistication.

The method of solution used by Riggs involves breaking the region between tool- and workpiece into various subregions; a finite difference discretization is used in each subregion and the resulting equations are solved by an overrelaxation scheme. The over-all numerical procedure used the finite difference solution at successive time steps to predict evolution of workpiece shape during tool advance. By this method, they obtained numerical results which, after certain adjustments, compared very favorably with experimental observations.

Finite difference methods, as used in (2), have certain inherent difficulties in coping with shape change problems in a cost-effective manner. By contrast, recent advances in finite element methods of calculation have led to favorable results in predicting highly nonuniform field distributions in regions of nonuniform and timewise varying shape. Applications have recently been made in fields of structural mechanics of deformable bodies (3), heat transfer to surfaces undergoing phase change (4), groundwater seepage problems (5), and deformation and stability of fluid-fluid surfaces (6). Recent progress made in the area of heat transfer is of particular relevance; the method has been used to treat inhomogeneous materials, variable conductivity, nonlinear boundary conditions, and irregularly shaped boundaries.

Preference for finite element over finite difference formulations in handling problems involving nonuniformities results from two basic differences between the two methods. A comparatively loose set of restrictions on the finite element nodal structure allows nodes to be concentrated in regions of high activity and spread thin over more uniform regions, thus weighting areas in proportion to the associated difficulty of approximating the variable of interest. Further, finite element methods are able nonlinearly to interpolate both dependent and independent variables between nodes, so that both the variable of interest and the region in which it is defined may be more accurately modeled. A brief survey which describes in more detail the particulars of finite element methods as well as some strengths and weaknesses in comparison to other techniques is available (7, 8). Recent texts provide engineering (9) and mathematical (10) viewpoints and strategies.

The purpose of this investigation is to apply finite element methods to an electrochemical shape change problem. The geometry chosen for study purposefully includes a singularity in order to investigate the stability of the transient calculation. Computational details are reported in order to assess the accuracy and cost-effectiveness. Dimensionless results are reported for the particular problem at hand in order to compile results over a wide range of parameter space.

Theoretical Formulation

The electrochemical problem.—The two-dimensional cell to be investigated is shown in Fig. 1. The electrode of primary interest, the cathode, is initially coplanar with the lower insulating plane. The vertical side walls represent either insulating surfaces or else planes of symmetry in an array of parallel, evenly spaced cathodes. Between the electrodes is an electrolytic solution of uniform composition. Electrodeposition of metal at the cathode occurs under constant cell voltage.

During shape change, the two-dimensional secondary current distribution is calculated according to the following assumptions: (*i*) The electrolyte is of uniform composition, (*ii*) a single cathodic reaction occurs which obeys the Butler-Volmer rate equation, (*iii*) the anode is unpolarized and does not change shape during electrolysis, (*iv*) transport and kinetic parameters do not vary in space or time, and (*v*) transient shape change is slow with respect to establishment of the electrical double layer. The problem is an example of a secondary current distribution.

In the electrolytic solution, the potential field obeys the equation of Laplace

$$\nabla^2\phi = 0 \qquad [1]$$

At the cathode surface, the reaction rate obeys both Ohm's law and the Butler-Volmer kinetic rate equation

$$-\kappa\nabla\phi \cdot \underline{n} = i_o \left(e^{\frac{\alpha_A n\mathbf{F}}{RT}\phi} - e^{\frac{-\alpha_C n\mathbf{F}}{RT}\phi} \right) \qquad [2]$$

Since the anode is unpolarized, the potential in the

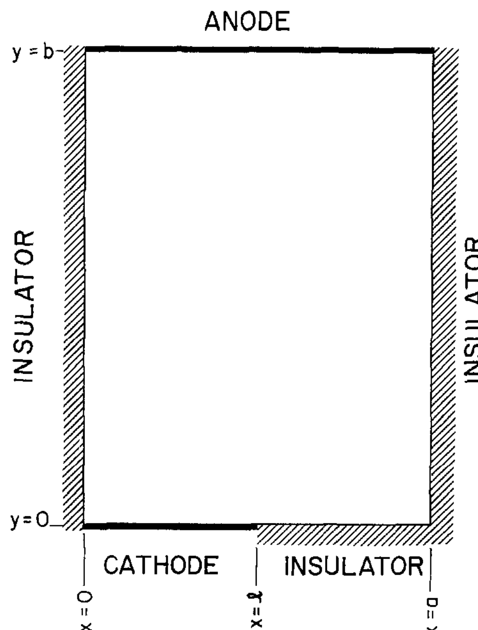

Fig. 1. Electrodeposition cell geometry prior to shape change at cathode.

solution is uniform along its surface

$$\phi = \phi_A \quad [3]$$

On the insulating surfaces and planes of symmetry, the normal potential gradient is zero

$$\nabla\phi \cdot \underline{n} = 0 \quad [4]$$

Equations [1]-[4] provide the current and potential distribution within the cell for any particular surface shape. At any instant in time, the local growth rate of the cathode surface is given by Faraday's law

$$\frac{dh}{dt} = -\left(\frac{M}{n\rho\mathbf{F}}\right)i = -\left(\frac{M\,i_o}{n\rho\mathbf{F}}\right)\left[e^{\frac{\alpha_A n\mathbf{F}}{RT}\phi} - e^{\frac{-\alpha_C n\mathbf{F}}{RT}\phi}\right] \quad [5]$$

By defining

$$\Phi = \frac{n\mathbf{F}}{RT}\phi,\quad X = \frac{x}{l},\quad Y = \frac{y}{l},\quad H = \frac{h}{l},\quad T = \frac{M\kappa RT}{l^2n^2\mathbf{F}^2\rho}t \quad [6]$$

the model equations become

$$\frac{\partial^2\Phi}{\partial X^2} + \frac{\partial^2\Phi}{\partial Y^2} = 0 \quad \text{in } \Omega \quad [7]$$

$$\nabla\Phi \cdot \underline{n} = -\xi[e^{\alpha_A\Phi} - e^{-\alpha_C\Phi}] \quad \text{on } \partial\Omega_C \quad [8]$$

$$\nabla\Phi \cdot \underline{n} = 0 \quad \text{on } \partial\Omega_i \quad [9]$$

$$\Phi = \Phi_A \quad \text{on } \partial\Omega_A \quad [10]$$

$$\frac{dH}{dt} = -\xi[e^{\alpha_A\Phi} - e^{-\alpha_C\Phi}] \quad \text{for } T > 0 \quad [11]$$

$$H(T = 0) = 0 \quad \text{on } \partial\Omega_C \quad [12]$$

where

$$\xi = \frac{i_0 l n\mathbf{F}}{\kappa RT} \quad [13a]$$

$$B = \frac{b}{l} \quad [13b]$$

$$A = \frac{a}{l} \quad [13c]$$

Equations [7]-[12] constitute the system to be solved in order to determine evolution of cathode shape with time.

Readers who do not seek additional mathematical details should proceed directly to the Results and Discussion section below.

The finite element representation of the electrochemical problem.—Rather than solve Eq. [7] and associated boundary conditions directly, a finite element technique is used to construct an approximate solution represented by a linearly independent set of basis functions which are defined within the region (electrolyte phase) as well as on its boundaries (electrode and insulating surfaces). Galerkin's method is used to generate a discretized version of the continuum characterization of the system. Weighted averages of the resulting Laplacian (with respect to members of a set of weighting functions chosen from the same basis used to represent the approximate solution) are required to vanish, thus satisfying a weak form of Eq. [8]. A discussion of Galerkin's method, as well as the broader class of weighted residual methods to which it belongs, is given by Finlayson (11, 12).

Accuracy depends ultimately on both the ability of the postulated approximation to simulate reality correctly and the ability of the weighting functions to weight the solution over the region in a proper manner. These two determining factors depend entirely on the choice of basis functions. In general, polynomials are chosen; in this investigation, second-order piecewise continuous polynomials were used. Important advantages which accrue from the use of piecewise polynomials include acquisition of banded matrices in the final discretized formulation and relative ease and accuracy in approximation of irregularly shaped boundaries.

Let the piecewise polynomial basis functions be represented by $\Gamma_i(X, Y)$ where the set of functions is continuous over the domain Ω and has the property

$$\Gamma_i(X_j, Y_j) = \delta_{ij} \quad [14]$$

where (X_j, Y_j) are the coordinates of node j and δ_{ij} a Kronecker delta function which is 1 if $i = j$ and 0 otherwise. That is, the basis functions are centered over a set of distinct nodes within the region and in fact are Lagrangian interpolation functions. As a result of this property, the potential distribution within the region can be approximated in terms of values of potentials at the nodes

$$\Phi(X, Y) = \sum_{i=1}^{M_w} \Phi_i\,\Gamma_i(X, Y) \quad [15]$$

In terms of the basis functions, the Galerkin equations are

$$\sum_{j=1}^{M_w} \Phi_j\left\{-\int_\Omega \nabla\Gamma_i \cdot \Delta\Gamma_j dA + \int_{\partial\Omega}\Gamma_i n \cdot \nabla\Gamma_j dS\right\} = 0 \quad [16]$$

for $i = 1, \ldots, M_w$.

Integration of the area integrals by parts, and substitution of appropriate boundary conditions into the resulting surface integral, yields

$$\sum_{j=1}^{M_w} \Phi_j \int\int_\Omega \nabla\Gamma_i \cdot \nabla\Gamma_j dA - \xi\int_{\partial\Omega_c}\Gamma_i\left(e^{\alpha_A \sum_k \Phi_k\Gamma_k} - e^{-\alpha_C \sum_k \Phi_k\Gamma_k}\right)dS = 0 \quad [17]$$

for $i = 1, \ldots, M_w$ and for k contained in the set of integers corresponding to those nodes located on the cathode.

The equivalent matrix formulation of the foregoing problem can be cast in the form

$$\underline{\underline{A}}\,\underline{\Phi} = \underline{f}\,(\underline{\Phi}) \quad [18]$$

where $\underline{\underline{A}}$ is a positive definite, symmetric $(M_w \times M_w)$ matrix with elements

$$a_{ij} = a_{ji} = \int\int_\Omega \nabla\Gamma_i \cdot \nabla\Gamma_j dA, \quad i,j = 1, 2, \ldots M_w \quad [19]$$

and where $\underline{f}\,(\underline{\Phi})$ is a nonlinear vector with components

$$f_i\,(\Phi) = \xi\int_{\partial\Omega_c}\Gamma_i\left(e^{\alpha_A \sum_k \Phi_k\Gamma_k} - e^{-\alpha_C \sum_k \Phi_k\Gamma_k}\right)dS - \sum_{j=N+1}^{M_w}\Phi_j\int\int \nabla\Gamma_i \cdot \nabla\Gamma_j\,dA \quad [20]$$

Here the nodes numbered $(N + 1)$ to M_w are located on the anode, a surface on which the potential Φ is specified. Inversion of the above system of matrix equations gives values of potential at the free nodes which may be used in Eq. [15] to approximate the potential distribution in the region as well as on its boundaries.

Method of solution.—The over-all numerical procedure used the finite element solution of Eq. [7]-[10] at successive time steps to compute shape change via a forward Euler solution of Eq. [11]. Second-order polynomials, piecewise continuous, were used as approximating functions on all surface and interior elements. The sequence of steps outlined below is more fully described in Ref. (13).

1. Establish a suitable nodal structure; Fig. 2 illustrates the general form chosen for the problem at hand.
2. Guess an initial potential distribution within the region.
3. Calculate components of $\underline{\underline{A}}$ and $\underline{f}(\Phi)$ along with the other quantities needed for the solution of Eq. [18].
4. Obtain an improved approximation of the potential distribution. In order to take advantage of the symmetry, positive definiteness, and bandedness of $\underline{\underline{A}}$, a banded solver utilizing Cholesky decomposition was used. With use of Newton's method to improve successive guesses of the potential distribution, repeat steps 3 and 4 until convergence on the nonlinear problem is achieved. The convergence criterion used in this study was that the difference in potential at each location between successive iterations was less than 10^{-6}. Typically, three to four iterations were needed to achieve convergence.
5. Calculate the current distribution along the cathode and, thence, the local growth rate normal to the cathodic surface.
6. Choose a time increment and, with the local normal growth rate from step 5, determine the new cathode shape expected at the end of the time increment.
7. Relocate nodes as needed to conform to the new cathode shape, and recalculate the integrals only for those elements with nodes which have been relocated. Grid construction was performed automatically after each time step. After $T = 0$ the elements along the electrode will have distorted bottom surfaces which correspond to the electrode shape.
8. With the potential distribution from the previous time step in hand, return to step 3 and repeat the entire procedure for each successive time step.

Normals to the cathodic surface were computed only on Gauss points on the sides of those elements contiguous with the cathodic surface, where the polynomials were continuous; that is, normals were not calculated at interelement boundaries.

Results and Discussion

Since the finite element method of calculation has not previously been employed in electrochemical potential distribution problems, the following results are divided into two sections. In the first, computational details are presented in order to assess the strengths and weaknesses of the finite element method for solving the particular electrochemical problem at hand. In the second, dimensionless results are compiled for electrochemical behavior over a range of parameter space including applied potential, polarization parameter, initial cell geometry, and time.

Assessment of numerical results.—Let us first examine how accurately the finite element method approximates the solution of Eq. [7] in the region of interest. In Fig. 2, the numbering of elements follows a precedent ordering of column (index J) and row (index I). Thus element 1 corresponds to $(I, J) = (1, 1)$; element 2 corresponds to $(I, J) = (1, 2)$; etc. Table I provides values of the Laplacian for the 63-element structure depicted in Fig. 2. The values of the Laplacian shown

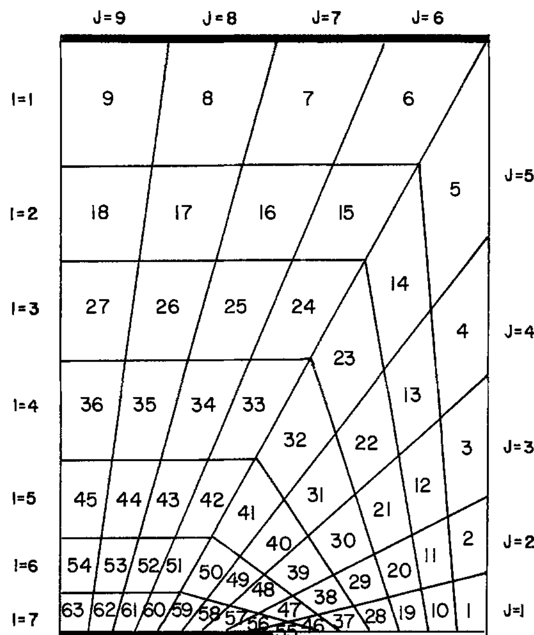

Fig. 2. Diagram of node structure showing element numbering scheme (not drawn to scale).

in Table I are unweighted integral averages over the particular element as determined from a four-point Gaussian quadrature scheme. Equation [7] indicates that an exact solution would exhibit values of zero far all entries in Table I.

In general, the values given in Table I tend to be largest near the cathode, particularly near the singularity at the cathode edge (elements 55 and 56) where potential field variations are at a maximum. Absolute values range from 10^{-6} to 10^{0}; the average value over the entire region is 10^{-3}. By comparison, the value of the potential and its first derivative will generally be of order unity. That is, on the average, the 63-element (222-node) structure is accurate to within 0.1%, but the local accuracy may stray widely at specific element locations.

Like all other numerical methods, finite element methods experience difficulty in simulating accurate potential distributions with piecewise quadratic polynomials when the potential variations are highly localized. Thus, despite the Galerkin requirement that various weighted averages of the Laplacian vanish in such regions, the Laplacian values may stray far from zero at specific points within the region. As a result, unweighted averages such as the ones tabulated in Table I may be large in localized regions. Since, however, finite element methods are particularly able to

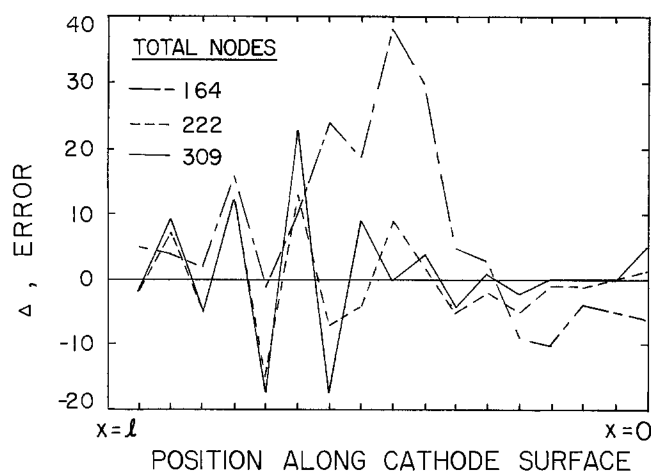

Fig. 3. Difference between cathodic current distribution calculated by Butler-Volmer and by Ohm's law equations. Results are shown for several nodal densities.

cope with singularities, an initial cell geometry was purposefully chosen with a singularity at the cathode edge.

Next, consider the current distribution along the cathode surface. The Butler-Volmer kinetic expression is used explicitly in the finite element formulation and yields a smooth and reliable current distribution along the cathode. A measure of accuracy of the potential field near the cathode is gained by comparing the first derivative (Ohm's law) with the current given by the Butler-Volmer equation. Figure 3 illustrates results for several different nodal densities. The abscissa gives the location along the cathode surface; the ordinate gives the difference, Δ, between the current calculated by the Butler-Volmer equation and by Ohm's law. Typical of finite element solutions is the variation in Δ about an average value which is very nearly exact zero. For the 222-node calculation, the maximum difference, Δ, was less than 1% of the absolute magnitude of current. The percentage error decreased to considerably less than 1% after the initial moment, when the singularity disappeared from the cathode edge. It is seen that results are not greatly dependent on nodal density.

At insulated boundaries and planes of symmetry, the normal current should be zero for an exact solution. For the 222-node structure shown in Fig. 2, the computed values of normal and tangential currents at the insulating edges are given in Table II. Normal values are generally two to three orders of magnitude smaller than tangential values except near the singularity (element 55). After the first time step, the singularity disappears and the normal current dropped to two orders of magnitude less than the tangential current.

63	−0.001	1.0

Finally, let us comment on the choice of time step between successive finite element calculations. Time steps ranging between 0.0075 and 0.18 dimensionless units were studied with the expectation that a characteristic cathode shape would be asymptotically approached on decreasing the step size. Such was not the case. For the entire range of step sizes, the system variables agreed to within 2-5%. We, therefore, conclude that within this range of time step, the choice of step size is not crucial in the present problem.

Compilation of electrochemical behavior.—Calculations were carried out to determine electrochemical behavior for the systems summarized in Table III. The dimensionless parameters which were varied include ξ, the polarization parameter; Φ_A, the applied potential; A, the ratio of cell width to cathode width; and Λ, the total coulombs passed during electrolysis. The parameters are defined by

$$\xi = \frac{i_0 \ln \mathbf{F}}{\kappa RT} \quad [21a]$$

$$\Phi_A = \frac{n\mathbf{F}}{RT} \phi_A \quad [21b]$$

$$A = \frac{a}{l} \quad [21c]$$

$$\Lambda = \frac{1}{A^2} \int_0^{X_{out}} Y dX \quad [21d]$$

The ranges of these parameters investigated in the present study are

$$0.1 \leq \xi \leq 3.0$$

$$1.2 \leq \Phi_A \leq 10.1$$

$$1.43 \leq A \leq 3.33$$

$$0 \leq \Lambda \leq 0.13$$

Certain parameters were arbitrarily fixed since they seemed less interesting; included among these were the transfer coefficients and the anode position. For all calculations reported here

$$\alpha_A = 0.5 \quad [22a]$$

$$\alpha_C = 0.5 \quad [22b]$$

$$\frac{B}{A} = 5.0 \quad [22c]$$

* All runs were made on a CDC 175 Computer. Parameters which were held constant for all runs were: $\alpha_A = \alpha_C = 0.5$; $\beta/\alpha = 5.0$, and $\Lambda_{max} = 0.13$.

It was found that the anode position did not influence the current distribution along the cathode when $B/A = 5.0$ or larger.

Also shown in Table III are the number of nodal points used in each calculation, the number of time steps, and the total execution time. On the average, calculations at 222-node conditions required 0.824 sec per time step.

Figure 4 provides the time history for growth of a deposit in one particular system as specified in the figure caption. As cathode growth proceeds, new surface area is generated, and the current distribution along the cathode becomes more uniform. Thus the deposit thickness distribution becomes more uniform during these initial stages of growth. It is seen that the deposit grows not only upward (toward the anode) but also outward (covering the adjacent insulator surface). Figure 4 illustrates the quantities Y_{sym}, Y_{max}, and X_{out} which will be used below to compile characteristic features of deposit growth.

Figure 5 illustrates the effect of variations in ξ in the absence of other changes in the system. The parameter ξ is a linear polarization parameter and is thereby an indicator of reaction uniformity. For values less than unity, surface charge-transfer processes are sluggish and the cathodic current distribution will tend to be uniform. For values greater than unity, conduction effects control the potential field and the current distribution will be nonuniform. The effect of ξ on the final shape of a deposit is shown in Fig. 5; the same number of coulombs have been deposited for each curve. It is seen that highly nonuniform deposit shapes are encountered when ξ has a large value.

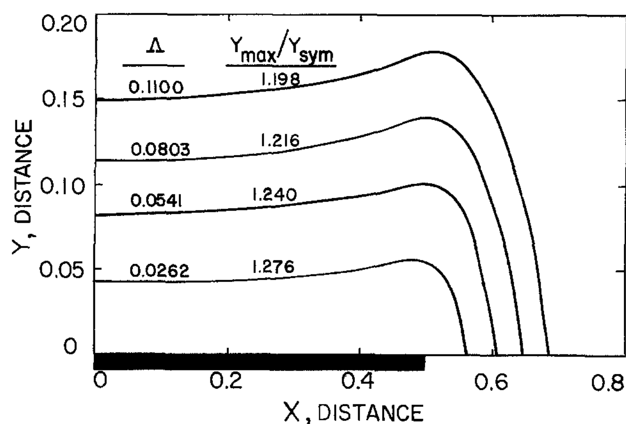

Fig. 4. Dependence of cathode shape with number of coulombs deposited; original shape shown along abscissa. ($\Phi_A = 3.87$, $\xi = 1.0$, $A = 2.0$.)

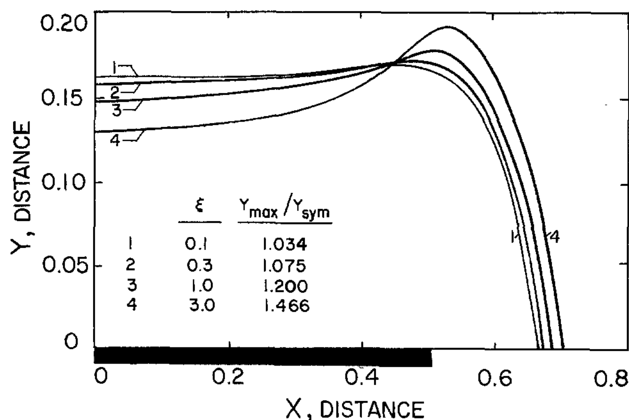

Fig. 5. Dependence of cathode shape on linear polarization parameter, the same number of coulombs has been deposited for each curve. Original cathode shape shown along abscissa. ($\Phi_A = 3.87$, $\xi = 0.11$, $A = 2.0$.)

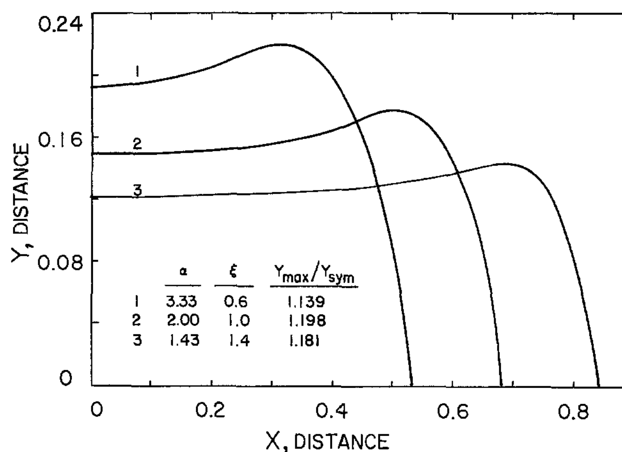

Fig. 6. Dependence of shape on initial cathode width; the same number of coulombs has been deposited for each curve. ($\Phi_A = 3.87$, $\Lambda = 0.11$.)

Figure 6 gives final deposit shapes following deposition of the same number of coulombs onto cathodes of three different widths. The cathode width, l, enters into both parameters ξ and A. Small values of l correspond to small values of ξ for which the current distribution would tend to be uniform. Values of $l/a \rightarrow 1$ correspond to cathodes which occupy the entire lower surface, thus achieving a uniform current distribution. The current distribution will be the most nonuniform for intermediate values of l. The middle curve in Fig. 6 ($A = 2$) exhibits a more nonuniform deposit than either of the other curves ($A = 1.43$ and 3.33).

There are two distance ratios which are particularly characteristic of the cathode shapes encountered in this study. Y_{max}/Y_{sym} is the ratio of maximum cathode height to the cathode height at the plane of symmetry, $X = 0$. X_{out}/Y_{max} is the ratio of outward growth along the adjacent conductor to the maximum cathode height. The next two figures illustrate how deposit shape is influenced by the parameters of the system.

Figure 7 shows how the ratio Y_{max}/Y_{sym} depends on the polarization parameter and the number of coulombs deposited. The ratio Y_{max}/Y_{sym} is a measure of deposit uniformity along the upper side of the deposit which faces the anode. Deposits are more nonuniform

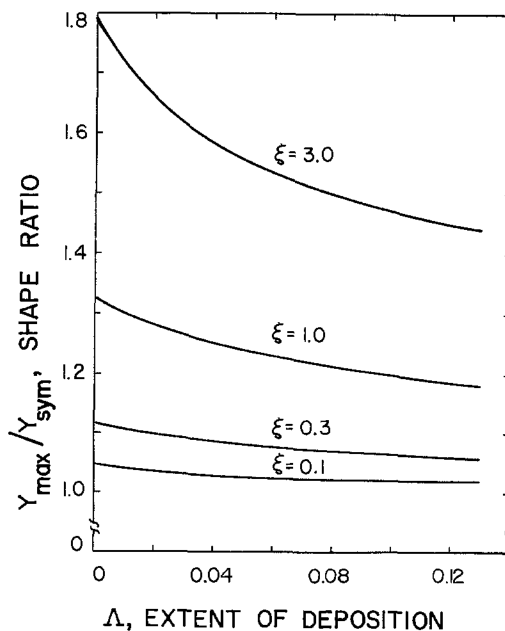

Fig. 7. Dependence of characteristic cathode shape ratio on linear polarization parameter and dimensionless number of coulombs deposited. ($\Phi_A = 1.16$.)

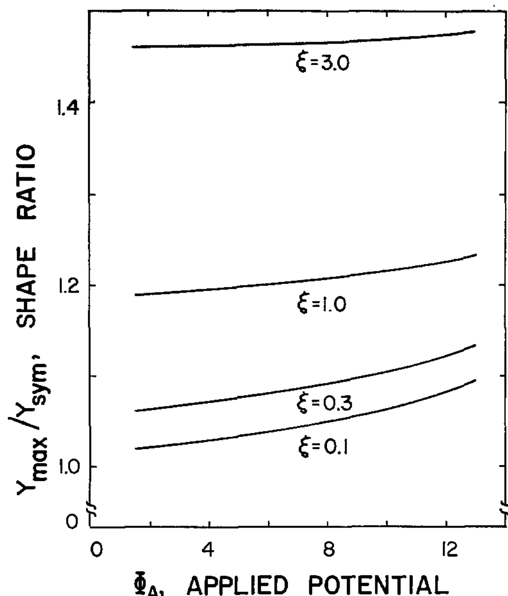

Fig. 8. Dependence of characteristic cathode shape ratio on linear polarization parameter and dimensionless applied voltage. ($\Lambda = 0.11$.)

with large values of ξ but become increasingly uniform as deposition continues. Figure 8 illustrates how the ratio Y_{max}/Y_{sym} varies with applied potential. It is seen that higher applied potentials yield more nonuniform deposits, owing to the nonlinear nature of the Butler-Volmer kinetic equation.

The ratio X_{out}/Y_{max} was compiled for all cases listed in Table III in order to characterize the outward growth of the deposit covering the adjacent insulating surface (see Fig. 5). For all cases examined in Table III, it was found that X_{out}/Y_{max} was always within 10% of unity. Therefore, within reasonable approximation, the edge of the deposit is cylindrical in shape.

Summary and Conclusions

The finite element method has been used to calculate the shape change of a cathode during electrodeposition. To our knowledge, finite element calculations have not previously been applied to electrochemical potential field calculations involving shape change. Calculation details have, therefore, been included in discussion of results. Problems involving electrode shape change appear to be particularly amenable to finite element methods of calculation since piecewise polynomials can be used with great accuracy to describe curved bounding surfaces.

Two difficulties arise in handling singularities. The first is the calculation of the potential field itself in the vicinity of a singularity. There is, however, growing attention to the development of special elements for use at singular points. It is, therefore, reasonable to anticipate rapid improvement in computational strategies for accurate treatment of such singularities. The second difficulty, encountered in the initial time step of shape change, is in approximating outward growth at the singularity. That is, the normal vector is undefined at a singular point. The choice used in this study (upward growth only) could perhaps be improved on.

The streamlining of any numerical procedure involves optimizing tradeoffs between accuracy and cost. It is likely that improved accuracy could be obtained in the procedures used here, especially in the integration schemes for evaluating area and surface integrals needed for solution of the system of equations resulting from the finite element formulation. These improvements will not be made without loss of computational speed. In many cases, however, the benefit of calculating an accurate current distribution does not depend so much on the cost effectiveness of the calculation itself but of the entire research endeavor.

Although the present study has purposefully been limited to a relatively simple secondary potential distribution, the general method of finite element calculations is exceedingly powerful and flexible. There would be no fundamental difficulty in embracing additional phenomena within this method of analysis. Multiple reactions could be incorporated to clarify effects of gassing, alloy deposition, and corrosion, among others. More complex kinetic rate equations could be introduced, including active/passive phenomena characteristic of many corrosion systems. Effects of diffusion and laminar convection have previously been studied by finite element methods in the chemical engineering literature and could be incorporated into electrochemical treatments. Heat transfer effects could be superimposed onto current distribution problems. The analysis of axisymmetric two-dimensional problems can be done with only minor modification of the integrals used in this study. The analysis of fully three-dimensional problems has been carried out for non-electrochemical situations. For these reasons, it seems worthwhile to pursue the application of finite element methods further in order that their inherent advantages be brought to bear on the analysis of complex electrochemical systems.

LIST OF SYMBOLS

English characters

A	dimensionless area
$\underline{A}$	dimensionless cathode length
$\underline{\underline{A}}$	matrix resulting from finite element formulation
a	anode length, m
a_{ij}	component of $\underline{\underline{A}}$ corresponding to i^{th} row and j^{th} column
B	dimensionless vertical separation between anode and cathode
b	vertical separation between anode and cathode, m
$\mathbf{F}$	Faraday's constant, 96,500 C/g equiv.
$\underline{f}$	nonlinear vector resulting from finite element formulation
f_i	i^{th} component of $\underline{f}$
H	dimensionless growth outward from cathode in normal direction
h	growth outward from cathode in normal direction, m
i	current density, A/m^2
i_o	exchange current density, A/m^2
l	cathode length, m
M_w	total number of set and free nodes in system
M	molecular weight, g/mole
N	number of free nodes in system
n	number of electrons involved in cathodic reaction, g equiv./gmole
$\underline{n}$	unit normal at system boundary
$\bar{R}$	gas constant, 8.314 J/gmole-deg
T	temperature, °K
t	time, sec
X	dimensionless spatial coordinate
X_{out}	dimensionless growth in horizontal direction from cathode edge

x spatial coordinate, m
Y dimensionless spatial coordinate
Y_{max} maximum height of cathode, dimensionless
Y_{sym} height of cathode at center symmetry line, dimensionless
y spatial coordinate, m

Greek characters
α_A anodic kinetic parameter
α_C cathodic kinetic parameter
Γ_i basis function centered over node i
$\Gamma^{(k)}$ portion of Γ_i lying in element k
Δ difference between Butler-Volmer and Ohm's law calculations
δ Tafel polarization parameter
κ conductivity of electrolyte, $\Omega^{-1}m^{-1}$
Λ dimensionless number of coulombs passed
ξ linear polarization parameter
ρ density of deposit, g/m^3
T dimensionless time
Φ dimensionless potential
Φ_A dimensionless applied potential
Φ_i dimensionless potential at node i
ϕ potential, V
ϕ_A applied potential, V
Ω region of applicability of the differential equation
$\partial\Omega$ boundary of Ω
$\partial\Omega_A$ portion of $\partial\Omega$ coinciding with anode
$\partial\Omega_C$ portion of $\partial\Omega$ coinciding with cathode
$\partial\Omega_i$ portion of $\partial\Omega$ coinciding with insulated surfaces and symmetry lines

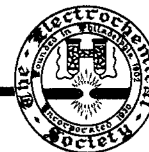
DISCUSSION SECTION



This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 124, No. 7 and 9, July and September, 1977, and Vol. 125, No. 2, February 1978.

Evaluation of Corrosion Rates from Nonlinear Polarization Data

R. L. LeRoy (pp. 1006-1012, Vol. 124, No. 7)

G. Palombarini,[1] **G. P. Cammarota,**[1] and **L. Felloni:**[2] This interesting paper by LeRoy has suggested to us a few considerations. First of all, the simultaneous determination of the corrosion current i_{corr} and the Tafel slopes β_a and β_c from polarization data requires the knowledge of at least three experimental pairs (ϵ, i), so as to attempt the resolution of three equations in the three unknowns. It is clear, however, that the reliability of the estimates increases together with the number of experimental pairs utilized. From this point of view, the method suggested by LeRoy for evaluating corrosion rates from polarization measurements in the vicinity of the corrosion potential constitutes a variation of the three-point method proposed by Barnartt[3] several years ago. Both methods, in fact, require the solution of a quadratic equation the coefficients of which are obtainable from the three measured pairs (ϵ, i), while the roots allow computation of the β values and then of the corrosion current. In practice, however, both the quoted authors have averaged the results of several calculations to minimize the risks of utilizing only three experimental points. Owing to their similarity, these methods are subject to the same limitations, especially with reference to the striking influence on the results that is exerted from the accuracy of each experimental value introduced in the resolutive equations. This disadvantage is serious just when the corroding samples are polarized to potentials ϵ near the corrosion potential. A higher uncertainty exists on low values of potentials and currents because of the complexity of the systems under examination and the inherent limits of the up-to-now available techniques.

Table I. Analysis of data recorded in the Table II of the paper under discussion by means of the three-point method

Selected ϵ (mV)	From experimental data β_a (mV)	β_c (mV)	i_{corr} (μA/cm^2)	From calculated data β_a (mV)	β_c (mV)	i_{corr} (μA/cm^2)
+5	No real solution			29.5	∞[4]	48.6
−5	No real solution			29.7	∞	49.4
+10	20.4	69.1	21.2	30.0	∞	50.5
−10	24.7	167.0	33.5	30.2	∞	51.3

[4] Very high but finite values of β_c have been assumed equal to infinity.

To confirm this, we have applied the three-point method at first to experimental and then to calculated data recorded in the Table II of the paper under discussion, obtaining our Table I. The above-reported calculations clearly show the extent to which the values of the polarization parameters are sensitive to the precision of experimental measurements. Few pairs (ϵ, i) in the vicinity of the corrosion potential seem, therefore, to be unable to determine these parameters correctly. In his note on the Tafel slopes for iron corroding in acidic solutions, Barnartt[5] has overcome the difficulty by operating at relatively high potentials ($|\epsilon| \geqq 20$ mV) with the aid of a galvanostatic pulse technique. Under these conditions,

[1] Institute of Metallurgy, University of Bologna, Italy.
[2] Institute of Chemistry, Center of Corrosion A.DACCO', University of Ferrara, Italy.

[5] S. Barnartt, *Corrosion*, **27**, 467 (1971).

lower relative errors may be expected. In the paper under discussion and with reference to the analysis of the data for the corrosion of zinc in 3% sodium sulfate solutions, instead, the difficulty has been avoided by utilizing anticipated but reasonable values of the Tafel slopes and then calculating i_{corr} with the contribution of all the available experimental points. From this procedure, the degree of fitting of all the experimental data recorded in the Table II of the paper under discussion amounts to

$$f = (1/n) \cdot \sum_{j=1}^{n} (i_j - i_{calc})^2 = 16.6 (\mu A/cm^2)^2$$

On the other hand, from a computer analysis of the same data we have obtained the values of $\beta_a = 22.4$ mV, $\beta_c = 105.5$ mV, and $i_{corr} = 26.4\ \mu A/cm^2$, which do not contradict the preceding three-point estimates and lead moreover to a much better quality of fitting, being this time $f = 2.5\ (\mu A/cm^2)^2$.

In conclusion, LeRoy has analyzed some polarization points of zinc in sodium sulfate solutions with the aid of independent estimates of the Tafel slopes. The same experimental data, however, would lead to quite different results when referred to a system lacking in preassignable parameters. Incidentally, we have also linearized LeRoy's experimental points ranging from −10 to +10 mV, finding an approximate value of the polarization conductance $(\partial i/\partial \epsilon)_{\epsilon=0} = 3.75\ \mu A/cm^2 \cdot mV$. Hence, by anticipating $\beta_a = 30$ mV and β_c = infinity and being therefore $B = \beta_a\beta_c/\ln 10 \cdot (\beta_a + \beta_c) = 30/\ln 10$ mV, one can calculate a value of $i_{corr} = B \cdot (\partial i/\partial \epsilon)_{\epsilon=0} = 48.8\ \mu A/cm^2$ about 3% lower than the value determined by LeRoy through Eq. [3] of his paper.

Further comments are necessary concerning the capability of several curves, corresponding to very different values of β_a, β_c, and i_{corr}, of reproducing the same points with comparable accuracy (see Fig. 8 and 9 in the paper under discussion). Clearly, a graphic comparison between experimental points and calculated curves is unreliable, as the appearance greatly depends on the scales adopted for ϵ and i. The simplest solution would seem to consist of evaluating the fitting quality, for example, through the already defined quantity f. In reality, by analyzing several curves of pure iron polarized in 1*N* H_2SO_4 and in 1*N* HCl in the vicinity of the corrosion potential, we have found[6] that not only the whole anodic and cathodic branches, but also each part of a polarization curve (*e.g.*, the part going from 0 to 5 mV, or from 5 to 10 mV, and so on) leads to very different values of β_a, β_c, and i_{corr} as well as LeRoy's data on zinc corrosion seem to do when analyzed with the three-point method.

Whether an insufficient precision of experimental measurements, the treating of β values as Tafel slopes linkable with certain reaction mechanisms rather than values simply compatible with the examined part of the polarization curve, or any other factor accounts for this behavior, it remains that the compliance between a measured polarization curve and its theoretical equation is very critical, and the problem of simultaneously determining the electrochemical parameters and the corrosion rate appears to be still unresolved.

The Pb/Pb^{+2} Exchange Reaction in Perchlorate Acidic Solution

A. S. Gioda, M. C. Giordano, and V. A. Macagno
(pp. 1324-1329, Vol. 124, No. 9)

S. B. Estevez[7] and D. J. Schiffrin:[8] Usually, great care has to be taken in the study of the anodic dissolution of a metal having a large exchange current, in particular, regarding the experimental conditions under which the true activated anodic current is measured, and in order to establish a dissolution mechanism, the surface concentration of the metal ion must be known. It appears that this precaution was not taken into account in the paper under discussion.

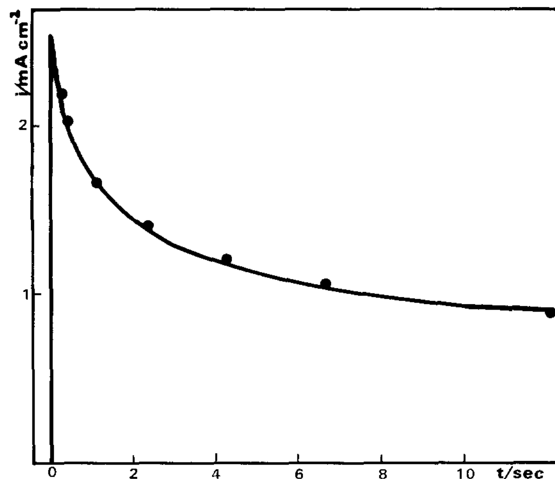

Fig. 1. —— Current-time transient for the anodic dissolution of Pb in 0.2M $NaClO_4$; pH = 2.5; T = 25°C; potential = −0.460V vs. NCE. ● Values fitted using Eq. [5].

For the Pb system, the anodic current for unstirred solutions are time dependent,[9] as would be expected for reactions with a large i_0 and in a potential range close to the standard potential of the metal/metal ion couple. Figure 1 shows a typical current-time transient[9,10] where the influence of the buildup of the Pb^{++} ion concentration during electrolysis is clearly seen. This type of transient behavior occurs in all the potential range which has been studied in the paper. The diffusional problem for the reaction

$$Pb \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Pb^{++} + 2e^- \quad [1]$$

can easily be solved using Ficks' diffusion differential equation with the conditions

$$C(x, 0) = C^b(Pb^{++}) \quad [2]$$

$$\left(\frac{\partial C}{\partial x}\right)_{x=0,t=0} = 0 \quad [3]$$

and

$$\frac{i}{2\mathbf{F}} = \{k_1 - C^{6}(Pb^{++})k_{-1}\} \quad [4]$$

where i is the current density, $C^b(Pb^{++})$ and $C^\sigma(Pb^{++})$ are the bulk and surface concentration of Pb^{++} ions, respectively, **F** is the Faraday constant, k_1 and k_{-1} are the corresponding electrochemical rate constants. This leads to

$$i = 2\mathbf{F}\{k_1 - C^b(Pb^{++})k_{-1}\}\exp\left\{\frac{k_{-1}^2}{D_{Pb^{++}}}t \right.$$

$$\left. \text{erfc}\ \frac{k_{-1}}{D_{Pb^{++}}{}^{1/2}}t^{1/2}\right\} \quad [5]$$

A typical current-time transient is shown in Fig. 1 and good agreement is observed over a wide range of time of electrolysis between the observed current and the values predicted from Eq. [5], indicating the correctness of the treatment outlined above. Equation [5] predicts the usual $t^{1/2}$ and $t^{-1/2}$ current dependence

at short and long times of electrolysis, respectively, and the Pb system in ClO_4^- solutions follows these relationships.[9,10] The anodic current due solely to the metal dissolution process (*i.e.*, $2Fk_1$ when $C^b(Pb^{++}) = 0$) can be obtained by extrapolation to $t \to 0$ from an i *vs.* $t^{1/2}$ plot.[9] The correct values obtained in this way differ widely from the steady-state measurements. When the measurements are performed in the way described in this paper, where natural convection conditions are established, the physical meaning of the observed currents can be obtained using the diffusion layer concept. This leads to

$$i \simeq \frac{2FD_{Pb^{++}}}{\delta} \left\{ \frac{k_1}{k_{-1}} - C^b(Pb^{++}) \right\} \quad [6]$$

where δ is the diffusion layer thickness. The equivalent equation derived from Eq. [5] for long times of electrolysis is

$$i = \frac{2FD_{Pb^{++}}^{1/2}}{\pi^{1/2}t^{1/2}} \left\{ \frac{k_1}{k_{-1}} - C^b(Pb^{++}) \right\} \quad [7]$$

Both Eq. [6] and [7] lead to a similar current-potential relationship which does not give direct information on the anodic process. When $k_1/k_{-1} >> C^b(Pb^{++})$, a situation which occurs in the potential range where an apparent good Tafel behavior was observed; the "Tafel" slope measured in the steady state is simply an indication of the reversible behavior of this system. Hence, no kinetic information on the anodic behavior can be obtained from steady-state experiments, as is wrongly assumed in the paper under discussion.

The term k_1/k_{-1} represents in this case the surface concentration of Pb^{++} ions, as defined by the Nernst equation. This is the reason why in Fig. 2 of the paper under discussion, the 30 mV slope (really a Nerstian slope for a 2 electron process) is observed for more anodic potentials as the bulk Pb^{++} ion concentration in solution is increased.

It is also our opinion that due to the incorrect way in which the anodic experiment has been performed, an incorrect order with respect to the ClO_4^- ion has been found. There is a finite order with respect to ClO_4^{-3}, as is discussed elsewhere.[10]

For the above reasons, the results presented in Table I of the paper and the mechanism proposed have to be considered dubious.

A. S. Gioda, M. C. Giordano, and V. A. Macagno:[11] As the authors have already answered practically the same arguments presented by Dr. Schiffrin in a rebuttal to S. D. Kapusta, they refer the reader to that discussion.[12]

Efficiencies of Cycling Lithium on a Lithium Substrate in Propylene Carbonate

R. D. Rauh, T. F. Reise, and S. B. Brummer
(pp. 186-189, Vol. 125, No. 2)

M. Garreau, J. Thévenin, and D. Warin:[13] We entirely agree with Brummer and co-workers when they consider that the determination of lithium cycling efficiency must be investigated, using not a foreign but a dense lithium substrate despite the inherent difficulties of this technique according to the determinant influence of the substrate on the properties of the electrodeposited lithium.[14] However, when faced with the same difficulties as those encountered by the authors, we have studied the cycling behavior of the lithium electrode in a different way. The results we have obtained lead us to interpretations somewhat different from those given in the paper under consideration. It appears of interest (*i*) To compare those two methods used to study the deterioration of the electrode properties; and (*ii*) to give some precise data on the main causes of the cycling inefficiencies described in the case of the propylene carbonate (PC) solutions.

(*i*) In the aprotic solvent-based electrolyte used with lithium where the ohmic drop RI generally composes the major part of the electrode potential V, we have considered it was convenient to measure the free ohmic drop potential $\eta = V - RI$ (overpotential) to be able to describe with accuracy the polarization state of the lithium electrode. Unlike Rauh *et al.*, we have thus studied the evolution in the time, not of the potential V but of the overpotential η during cycling operations carried out galvanostatically, in the experimental conditions: Solution, PC, 1M $LiClO_4$; $t = 25°C$; residual water content, 10 ppm; substrate, dense lithium; motionless electrode, $s = 0.2$ cm²; cell, cylindrical symmetry around the working electrode; cycling, current density $J = 1$-2.5-5-10 mA/cm² and charge density $Q = 1$-2-5-10 C/cm².

In conditions similar to those used by the authors in the paper under consideration, the stripping curves $\eta = \eta(t)$ do not show distinct components to which the removal of the deposit and of the substrate would be respectively ascribed. When the cycles are operated under conditions involving only weak overpotentials ($J \leq 2.5$ mA/cm² and $Q \leq 2$ C/cm²), an increase of the stripping overpotential up to a stationary value is only observed, with a weaker slope at each cycle. When other conditions are used ($J \geq 5$ mA/cm², $Q \geq 5$ C/cm²), the high involved overpotentials increase regularly up to an end value which rises slowly all along the cycling. In these cases, it is possible to observe on the curve $V = V(t)$ the two components of the electrode potential described (Fig. 3, p. 188) by Rauh *et al.*, the presence of these two components being due to a discontinued evolution of the interface resistance R. For example, Fig. 1 shows the typical evolution of the ohmic drop RI during the 5th stripping obtained with $J = 10$ mA/cm² and $Q = 10$ C/cm².

These results raise the following question: Is it really adequate to attribute the two components of the electrode potential V to two distinct intrinsic polarization levels required for the removal of the accessible portions of deposit and the complementary portion of substrate, accordingly: (*i*) To the ohmic origin of the separation of these two components; (*ii*) to the regular evolution of the end stripping overpotential during the cycling operation?

(*ii*) To find an indisputable test to detect the end of the deposit stripping, we have preferred to charac-

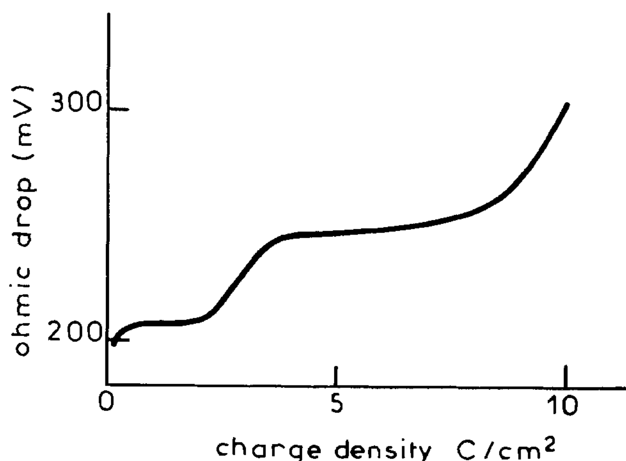

Fig. 1. Ohmic drop (*RI*)-charge density curve for stripping Li on an Li-dense substrate: 5th cycle; $i_s = 10$ mA/cm²; $Q_s = 10$ C/cm²; electrolyte = 1M $LiClO_4$ in PC.

terize the gradual degradation of the lithium electrode by the correlative decrease of the current density during cycling operations carried out with anodic and cathodic overpotentials maintained at a constant value.[14,15] This allowed us to point out the determinant importance of some experimental conditions which had not been considered in the paper under discussion. Thus we have observed that it is possible to obtain a great number of cycles without noticeable loss of the electrode activity when the experimental conditions are compatible with: (*i*) the formation of a homogeneous deposit without formation of large dendrites; and (*ii*) a regular dissolution of the metal without production of anodic passivating layers.[16] The main parameter responsible for these two causes of degradation of the electrode appears to be the overpotential which, during the whole cycle, must not exceed a critical value (about 50 mV with our PC, $LiClO_4$ solution). For example, we have obtained 500 consecutive cycles within the range of overpotential ± 25 mV under conditions defined by $J = 1$ mA/cm^2 and $Q = 1$ C/cm^2. The rapid deterioration of the electrode properties which intervenes with the experimental conditions indicated in the paper under consideration ($J = 2.5$ mA/cm^2; $Q = 10$ C/cm^2) is linked to an overstepping of the critical overpotential value of the solution used.

This interpretation raises other questions: (*i*) Would it not be possible to ascribe the best performances obtained with the AsF_6Li/PC solutions to a favorable shift of the overpotential critical value; (*ii*) can Rauh *et al.* link this eventual shift of the critical value to the different adsorbability of AsF_6^- compared to those of ClO_4^-, mentioned in the paper under consideration?

R. D. Rauh:[17] Clearly the processes contributing to the polarization of the secondary Li electrode are not well understood, although Garreau *et al.* are making some valuable contributions in this area. Our assumption that the break in the Li stripping curve represented the single cycle efficiency was based on the following observations: (*i*) The single cycle efficiencies obtained in this way agreed quite well with the average efficiencies calculated from the number of cycles required to deplete the Li initially present as the substrate; (*ii*) Two component stripping curves are not obtained under the same conditions on a Ni substrate; (*iii*) Two component stripping curves are not obtained on stripping Li foil under the same conditions. Both $LiAsF_6$ and (probably) low current densities impose a more compact, lower surface area morphology on the electrodeposit, which could explain the results of Garreau *et al.* and the absence of two plateaus in the initial cycles of our best PC/$LiAsF_6$ preparations (paper under discussion, Fig. 5). Low current densities also, of course, compress the *IR* scale.

Regarding the positive effects of $LiAsF_6$, they have been observed in tetrahydrofuran, propylene carbonate, and methyl acetate.[18] Recent work by Koch and Young,[19] also of our laboratory, indicate that the general success observed for this salt may result from AsF_3 impurities. We have shown previously that certain Li-reactive film-forming additives to these nonaqueous electrolytes actually improve the Li cycling efficiency.[20]

The idea put forth by Garreau *et al.* that high rate stripping can give rise to accumulation of reaction products on the Li electrode is an intriguing one. It would be extremely valuable for these authors to demonstrate the effects of controlled potential stripping on Li cycling efficiency and cycle life to supplement their results on the evolution of the overpotential.

The Theory of Light-Induced Evolution of Hydrogen at Semiconductor Electrodes

J. O'M Bockris and K. Uosaki (pp. 223-227, Vol. 125, No. 2)

L. Handley and J. F. McCann:[21] The authors have proposed a novel approach to the interpretation of semiconductor photoelectrochemistry.[22-27] It is, however, our view that their model is deficient in several respects and is not easily accommodated by the available experimental evidence.

At the outset, the authors consider that charge transfer by a quantum mechanical tunneling mechanism is rate limiting. They produce no evidence to support this contention and we would suggest that it is in fact inappropriate to make such an assertion since the high quantum efficiencies consistently measured for many semiconductors,[28-33] including p-GaP[34] do not support tunneling as the rate-determining step (rds) in the saturated photocurrent region of the photocurrent *vs.* voltage (i_p *vs.* V) curve. Also, Butler[35] has shown that the relationship $i_p{}^2 \alpha V$ and $(i_p h\nu)^{1/2} \alpha h\nu$ for WO_3 are consistent with a model where solid-state transport is the rds. An inspection of the authors' data shows that the relationship $i_p{}^2 \alpha V$ also holds for p-GaP and therefore supports a solid-state transport model. The authors of the paper have not considered these correlations and they are neither predicted nor explained by their model.

The solid-state treatment used in the proposed model would appear to be somewhat unconventional. Normally the continuity equation is solved for a given set of boundary conditions.[32,33,35-40] However, it is not clear how Eq. [7] used by these authors to describe solid-state transport was derived.[22-27] Moreover, the equation as written is mathematically imprecise since there is no integral sign in the exponent. (The value of the exponential $\exp\left(-\frac{1}{L(x)}dx\right)$ is 1 since

dx is normally defined as an infinitesimally small increment of x). Perhaps the authors meant to use x instead of dx in the exponential. But dx has been used repeatedly in their treatment.[22-27]

In evaluating the drift length l_E (Eq. [10]), the authors have used an electric field $V'(x)$ applicable under dark conditions only. The illuminated electric field equation is[36]

$$V'(x) = \pm \sqrt{\frac{8\pi kT}{\epsilon}[-(N_D - N_A)y + (p_o + \Delta p)(e^{-y} - 1) + (n_o + \Delta n)(e^{y} - 1)]} \quad [1]$$

where $y = e_o(V_x - V_b)/kT$, and the symbols are defined by Myamlin and Pleskov,[36] with Δp and Δn being the photogenerated hole and electron densities, respectively. No reasons were presented for not using this latter expression. If quantum mechanical tunneling is rate determining as they have assumed, then there will be an accumulation of photogenerated minority carriers in the space charge region. The calculations of Δp and Δn for space charge accumulation, which would be required, are complicated. The authors have not considered these problems.

The reasoning used by the authors to show that all electrons have been deactivated to the bottom of the conduction band before reaching the surface is not convincing. Even if an argument of the type presented by the authors were to be accepted, the frequency dependence of the absorption coefficient should be considered, *i.e.*, $\alpha \approx 10^4$ cm^{-1} for 4500Å light and $\alpha \approx 4.5 \times 10^5$ cm^{-1} for 3500Å light.[39,41] Taking the above factors into account electrons excited by 3500Å light would have a mean energy of 1.20 eV above the conduction band while those excited by 4500Å light would be deactivated to the bottom of the conduction band on reaching the semiconductor surface. Since the transmission coefficient is dependent upon electron energy[42] one concludes from the authors' model for electron deactivation and the conclusion that the critical potential is not frequency dependent that quantum mechanical tunneling is not the rate-determining step. On the other hand, the solid-state model,[32,35,36,38,40] predicts the frequency independence of the critical potential.

The validity of the method used to obtain the energy level of an electron in the ground state of the H_3O^+ ion is questionable. First, Fig. 2 is given without explanation. The experimental correlation is poor particularly for 1*N* H_2SO_4. Secondly, from footnote[43] Fig. 2 is an experimental check of the equation

$$\left(V_{fb} - \frac{E_g}{F}\right) = (V_{crit} - V_{fb}) + \text{constant}$$

If this were so then the absolute value of the slope should be 1 (*cf.* ~ 2 for 1*N* NaOH and ~1.5 for 1*N* H_2SO_4).

For p-GaP in 1*N* NaOH at 0V on the NHE scale the authors report in footnote 27 that about 50% of the electrons activated by light reach the surface. Since at 0V their experimental quantum efficiency for 3500Å light is 0.2, it follows that the transmission coefficient must be larger than 0.4. The WKB approximation is inaccurate in this region and will yield transmission coefficients at least 50% higher than the solution of the exact parabolic barrier.[42] Therefore an even greater discrepancy between the calculated and experimental results should be seen.

The critical photopotentials for the experimental i_p *vs.* V curves of p-GaP in Fig. 1 (1*N* H_2SO_4) and Fig. 4 (1*N* NaOH) are the same, which is inconsistent with the -0.059 mV/pH change in the flatband potential for p-GaP.[44] This is also inconsistent with the authors' flatband potential data reported in Fig. 2.

In discussing the discrepancies between the experimental and theoretical results, the present authors have stated that it may be possible for electrons to be transferred to hydronium ions directly attached to the electrode surface, therefore yielding higher quantum efficiencies. If this were the case, the barrier thickness would be reduced from 2.1Å to a much smaller value and not only would higher quantum efficiencies be calculated, but the assumption that charge transfer is the rate-determining step would be in doubt.

The Theory of Light-Induced Evolution of Hydrogen at Semiconductor Electrodes

J. O'M. Bockris and K. Uosaki (pp. 223-227, Vol. 125, No. 2)

Wm. E. Pinson:[45] I wish to discuss Fig. 4 of the above-mentioned paper.

The caption of Fig. 4 says the electrolyte is 1*N* NaOH.

The threshold of the experimental quantum efficiency is shown = +0.25V *vs.* NHE. In Fig. 1 of the same paper in 1*N* H_2SO_4 the threshold of the experimental quantum efficiency is also shown = +0.25V *vs.* NHE.

It would appear that the Fig. 4 caption is in error, based on the information supplied in another article by Bockris and Uosaki.[46] Figure 4 in this latter paper shows the p-GaP threshold quantum efficiency in 1*N* NaOH beginning at = −0.46V *vs.* NHE; in 1*N* H_2SO_4 at +0.14V *vs.* NHE, close to the +0.25V *vs.* NHE threshold of the paper under discussion.

The same error appears in the volume "Semiconductor Liquid-Junction Solar Cells."[47]

Significance of Effect of High Pressure on Kinetics of Electrode Reactions

I. Applications to Transition State in Hydrogen Evolution Reaction Mechanisms

B. E. Conway and J. C. Currie (pp. 252-257, Vol. 125, No. 2)

C. M. Marschoff:[48] In this article the authors show that observed negative and small positive values of the volume of activation for the hydrogen evolution reaction (her) may be explained on the basis of kinetic (reaction route and rate-determining steps) and electrocatalytic (electrode coverage by atomic hydrogen) considerations. It is also suggested that the particular behavior of the her with respect to $\Delta V^{\neq}$ values could be accounted for if the transition state for classical proton transfer arises by reorganization of the $H_9O_4^+$ ion,[49] resulting in the localization of the proton on one of the H_2O groups in the ion.

However, this view allows only a secondary role to specific properties of the electrode material, making it difficult to explain the above-mentioned kinetic and electrocatalytic effects. The lack of consideration of the specific properties of the metal has also been

pointed out[50,51] as a drawback of solvent-reorganization theories with respect to activation energy calculations for the her.

On these grounds, an alternative explanation to the abnormally low values of $\Delta V^{\ddagger}$ may be advanced in terms of an adiabatic proton transfer occurring with simultaneous charge delocalization.[50] According to this model, the charge on the transferring proton builds up from its initial value to a final $-e_0$ during the activation process. Hence, further electrostriction could occur on the H_2O (or H_8O_4) group, thus accounting for the observed $\Delta V^{\ddagger}$.

Mixed Conductivity in $LiFe_5O_8$

G. J. Dudley* and B. C. H. Steele*

Department of Metallurgy and Materials Science, Imperial College of Science and Technology, London, SW7 2AZ England

ABSTRACT

The lithium ion and electronic conductivities of lithium ferrite spinel, $LiFe_5O_8$, have been investigated by four-point d-c techniques. The ionic conductivity is relatively low, less than 10^{-5} Ω^{-1} cm^{-1} at 300°C. Transients observed in two-point d-c electronic conductivity measurements carried out in oxygen appear to be due to a surface oxidation process rather than to the ionic component of the total conductivity.

In the Rb_2O-Fe_2O_3, K_2O-Fe_2O_3, and Na_2O-K_2O-Fe_2O systems, analogues of the β-alumina structure can be prepared directly and have been shown to be good ionic as well as electronic conductors [*e.g.*, (1, 2)]. On the other hand, direct synthesis of the lithium analogue has not been reported, and under similar conditions an inverse spinel, $Fe_2^{3+}[Li^+Fe_3^{3+}]O_8$ results instead. In a recent paper (3) it was reported that despite its essentially close-packed structure, there were indications that a significant ionic conductivity was present in this compound at temperatures around 300°C. This led to a brief investigation by the present authors because the possibility of obtaining moderate values of ionic conductivity in this large class of compounds would be of considerable interest both theoretically and technologically.

Experimental

Two samples of lithium ferrite were used. Sample A was prepared by heating together the stoichiometric proportions of iron-III oxide (99.999%) and lithium carbonate ("Analar" grade) to 1000°C for 10 hr in a closed alumina crucible. The resulting powder was ground thoroughly, pressed into pellets, wrapped in platinum foil, and hot pressed in alumina powder in an alumina die in an oxygen atmosphere for 4 hr at 1170°C and a pressure of 500 kg cm^{-2}. The resulting density of the ceramic was 99.3% theoretical and powder x-ray photographs showed it to be predominantly in the β-form in which lithium and iron atoms are statistically distributed over the octahedral sites in the close-packed oxygen sublattice (4). Lines due to the ordered α-form were just visible. Sample B was flux-grown single crystal material, in the α-form (4).

Electronic conductivity measurements were carried out by two four-point d-c methods. The first employed samples 5 mm square by 0.5 mm thick, contacted on four sides by sprung tungsten wires, and used the analysis due to Van der Pauw (5). The second used a bar sample (6 × 1.5 × 1.5 mm) with platinum wire voltage probes at distances of one third and two thirds along its length and platinum foil current contacts at the ends which had previously been coated with evaporated gold.

Electronic Conductivity Results

Conductivity results are shown in Fig. 1. The conductivity of sample A as prepared and measured in an argon atmosphere (c, closed circle) was close to the value obtained for similar high density hot-pressed material by West and Blankenship (6) (c, open circle), and somewhat higher than that observed by Matsui and Wagner in argon (dashed line, d). In order to oxidize Fe^{++} to Fe^{+++} and produce the low electronic conductivity form reported by previous authors (3, 6-8), in which transients due to ionic conductivity would be most readily observable, sample A was annealed in oxygen at 850°C for 15 hr, 700°C for 15 hr, and slowly cooled to room temperature. X-ray powder photographs showed the sample to have converted to the α-modification. Van der Pauw conductivity measurements gave curve a (solid circles), still higher than curve d, and much greater than that observed by Matsui and Wagner in an oxygen atmosphere (e) and by Blankenship (h). After the oxygen anneal our measurements were carried out in an argon atmosphere. To examine whether the sample had been rapidly reduced in argon, oxygen was let into the apparatus while the temperature was held at 300°C. No appreciable change in conductivity took place. This sample, together with an A-type bar sample, was reannealed in oxygen, this time at 1000°C for 10 hr, 700°C for 24 hr, followed by a slow cool. Ferrite powder was placed around the samples to reduce the risk of lithium loss. The conductivity of the Van der Pauw specimen, measured at 250°C, had decreased only slightly (denoted by square in Fig. 1). Four-point conductivity measurements on the bar sample carried out as a function of temperature in oxygen coincided with curve a (open circles). However, if the voltage between the current contacts was used to calculate the conductivity, as in a two-point measurement, a much lower value was obtained, for example, g at 300°C and g′ at 492°C. At this latter temperature it was decided to monitor the potential differences between the current contacts V_{cc} and between the voltage probes V_{vp} as a function of time at constant temperature and current. Results are shown in Fig. 2. While V_{vp} remained almost constant, V_{cc} doubled in 50 hr. We thus conclude that the changes were caused by gradual buildup of a surface insulating layer (most of which had already formed during the anneal). This had no effect on V_{vp} since these probes were passing currents of less than 1 pA. This change in the "two-point" conductivity is shown by the line g′-f and is close to curve e for reported two-point measurements in oxygen (3).

Four-point bar conductivity data (crosses) for the single crystal material (B) is shown in Fig. 1, curve b. This sample was not annealed beforehand and was

heated during the measurements to 730°C, left at this temperature for 3 days, then cooled. Nevertheless results on cooling were in good agreement with those for heating, showing that no bulk oxidation had occurred. Again, however, the current contacts required ever-increasing voltages to maintain constant current.

Direct Ionic Conductivity Measurements

The high four-point electronic conductivities observed in this work make it difficult to detect transient effects due to ionic conductivity since the ionic transport number is likely to be much less than 0.01. We therefore resorted to direct four-point partial ionic conductivity measurements of the type previously reported for potassium ferrite (2). The principle of the method is illustrated diagramatically in Fig. 3. It is the ionic analogue of a four-point electronic conductivity measurement. An ionic flux is passed down the bar specimen by means of a suitable source and "sink" of the mobile ions contacting the ends of the bar via thin pieces of electrolyte to prevent electronic conduction. The source and sink can often be (as in the present case) pieces of the same mixed conductor as the specimen. The voltage probes are made up of pointed pieces of electrolyte in contact with a suitable material, providing a reference activity of the metal corresponding to the mobile cations. Since only voltage differences between these probes are required and an insignificant current is passed through them, the reference material can also be pieces of the mixed conductor under study, which is often experimentally much more convenient than using the parent metal. As in the electronic case, the technique avoids difficulties due to uncertain voltage drops at the current contacts, a particularly severe problem in the case of solid electrolyte-solid electrode interfaces simply pressed together. It also enables measurements to be made of the chemical diffusion coefficient $\tilde{D}$ associated with mobile ions and electrons, from the bar length L and the characteristic time τ of the slow transient behavior of the voltage between the ionic voltage probes when a constant current is switched on or off. $\tilde{D}$ is given by $\tilde{D} = L^2/\pi^2\tau$ (9) so that short bars are desirable to minimize the duration of the experiment. The theory and technique are described in detail in Ref. (2).

The lithium electrolyte used in this work was a 40% lithium phosphate-60% lithium silicate solid solution (10). The lithium source and sink were further pieces of lithium ferrite and the lithium reference electrodes were pointed pieces of the electrolyte contacted by more pieces of the lithium ferrite. In order that the apparatus could be used in an oxidizing atmosphere

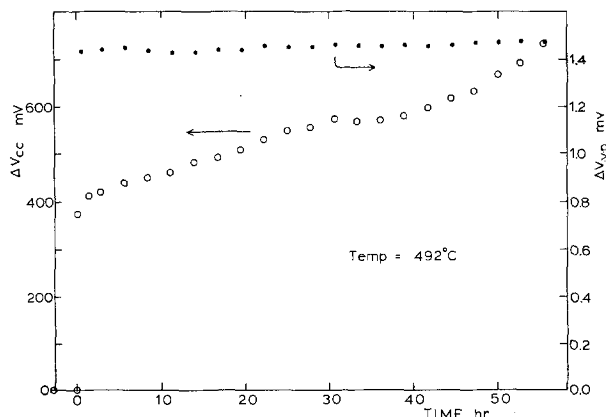

Fig. 2. Variations with time of current contact voltage difference (ΔV_{cc}) and voltage probe voltage difference (ΔV_{vp}) for bar sample at 492°C.

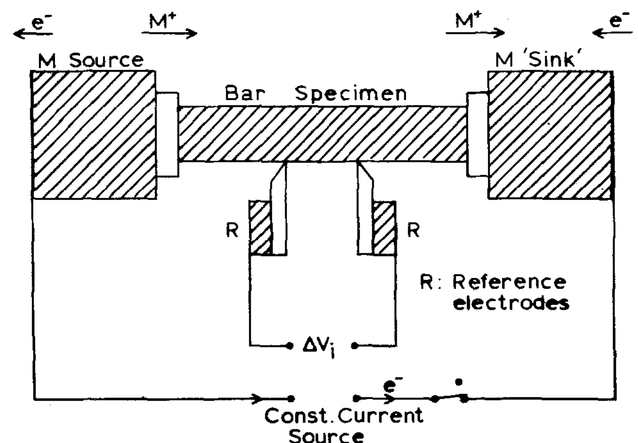

Fig. 3. Schematic of four-point ionic conductivity experiment. Shaded regions are mixed ionic-electronic conductor materials. Unshaded material is only ionically conducting (electrolyte).

the tungsten electronic voltage probes were replaced by platinum-10% rhodium. The tungsten springs and stainless steel jig were found to be satisfactory in oxygen up to at least 450°C.

The A-type sample used had not been annealed and was thus in the β-form. Interfaces between the current contacts and electrolyte were wetted with a trace of molten lithium nitrate in order to improve the ionic contact. The behavior of the ionic voltage probes on switching on and off lithium ion currents is shown in Fig. 4. The current required was so small (60 nA) as to be difficult to measure accurately, but an ionic conductivity of $6 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ at 295°C is indicated. Analysis of the switching on and off transients shows a chemical diffusion coefficient of $3 \times 10^{-5}\ cm^2\ sec^{-1}$.

In the case of sample B the use of lithium nitrate as an interface wetting agent was avoided in order to eliminate any chance of "ionic shorts" across the bar. The results are shown in Fig. 5. At 452°C $\sigma_i \sim 6 \times 10^{-6}$ and $\tilde{D} \sim 3 \times 10^{-4}$. This very high $\tilde{D}$ value requires that the gradient of lithium ion activity with concentration ("thermodynamic factor") must be very high. The currents used were so small, and the output impedance of the voltage probes so high, that these values can only be regarded as representing an upper limit to the ionic conductivity in the material. For comparison, a-c conductivity measurements on 84% dense polycrystalline samples of isostructural lithium gallate, which is not an electronic conductor gave a conductivity of about $3 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$ at 300°C (11). The four-point ionic conductivity values are included in Fig. 1 and denoted by i (sample A at 295°C) and j (sample B at 452°C).

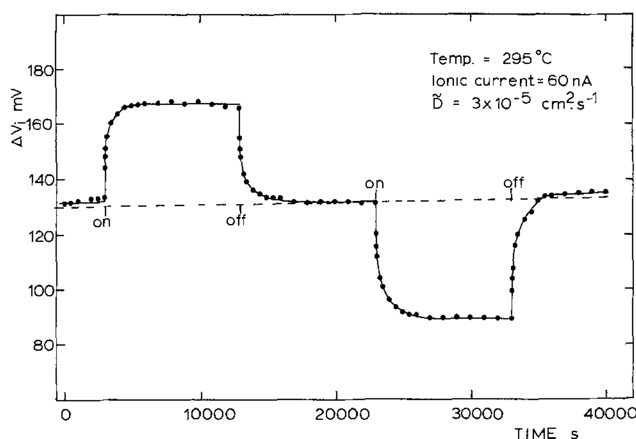

Fig. 4. Ionic voltage probe voltage difference vs. time for specimen A. Baseline is not at 0 mV because reference electrode materials were different for the two probes.

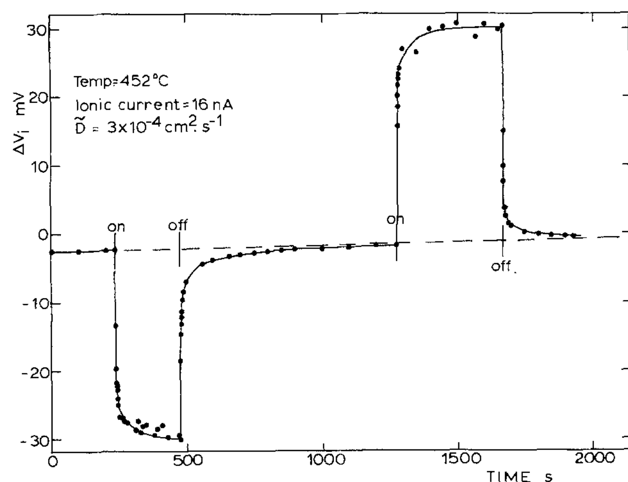

Fig. 5. Ionic voltage probe voltage difference vs. time for specimen B.

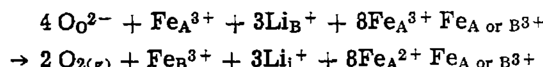
Discussion

Tretyakov and Rapp (12), in a study of the oxygen partial pressure in equilibrium with lithium ferrite, showed that their thermodynamic data were consistent with the following reaction for the reduction of the stoichiometric compound



$$4\,O_O^{2-} + Fe_A^{3+} + 3Li_B^{+} + 8Fe_A^{3+}\,Fe_{A\ or\ B}^{3+}$$
$$\rightarrow 2\,O_{2(g)} + Fe_B^{3+} + 3Li_i^{+} + 8Fe_A^{2+}\,Fe_{A\ or\ B}^{3+}$$

where A and B denote tetrahedral and octahedral sites, respectively. It has been assumed that lithium ion interstitials are formed in preference to iron interstitials though this was not conclusively proven. This results in the formula

$$[Fe_2^{3+}]_A[Li_{1-5\delta}\,Fe_{3-11\delta}^{3+}\,Fe_{16\delta}^{2+}]_B\,[Li_{6\delta}]_iO_8$$

where for convenience the Fe^{2+} ions have been assigned to the octahedral sites. Furthermore they showed that for a sample in equilibrium with air at 900°C δ would be in the region of 5×10^{-4}. This would probably approximate the stoichiometry of our sample A as prepared. On placing nonporous samples in contact with oxygen at 400°C the oxidation reaction would take place at the surface, and penetrate the bulk only very slowly due to the very low rate of oxygen diffusion expected at this temperature. However, the ionic conductivity experiments indicate that the chemical diffusion of lithium ions and electrons is fast and thus both could diffuse to the surface to be converted to Li_2O. Note however that there are 16 Fe^{2+} ions to 6 interstitial lithium ions so that when all interstitial lithium had moved to the surface Fe^{2+} ions would remain, maintaining a high bulk electronic conductivity. Diffusion of lithium in normal sites would be expected to be much slower and hence further oxidation would be inhibited except at the surface where direct reaction with oxygen could occur. We suggest this model could explain the relatively high electronic conductivity values measured by four-point techniques and the time-dependent lower conductivities calculated from the voltages observed at the current contacts corresponding to a two-point conductivity measurement. The smaller two-point conductivity values and voltage transients at constant current associated with the introduction of oxygen can thus be explained by the slow formation of a surface layer containing a depleted concentration of Fe^{2+} ions. It should be emphasized that all previously reported conductivity values known to us have involved only two-point measurements and their interpretation can produce erroneous conclusions about bulk conductivity. In particular the relatively high values of ionic conductivity inferred by Matsui and Wagner (3) are orders of magnitude too large. At 452°C for example, the partial ionic conductivity has a value of $6 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ corresponding to an ionic transport number of approx. 5×10^{-6}. The low ionic conductivity reflects the low concentration of interstitial lithium. The high chemical diffusion coefficient indicates a large thermodynamic factor consistent with a compound close to stoichiometry.

Conclusions

The results are consistent with a model in which a low concentration of interstitial lithium ions is responsible for a small ionic conductivity while the presence of Fe^{2+} ions gives rise to n-type electronic conductivity. Observed transients in two-point electronic conductivity measurements ascribed to high ionic conductivity appear instead to be due to surface oxidation leading to high resistance layers under the contacts. The effect of different initial iron to lithium ratios has not been studied and consequently the possibility that considerably different behavior might be observed at different stoichiometries cannot be excluded.

Thermal Oxidation of Arsenic-Diffused Silicon

Shinji Ohkawa and Yoshio Nakajima

Fujitsu Laboratories Limited, Kamikodanaka 1015, Nakahara, Kawasaki 211, Japan

ABSTRACT

Thermal oxidation of arsenic-diffused silicon was investigated in wet (95°C water) oxygen ambient over the relatively low temperature range of 650°-850°C. Arsenic was diffused into boron-doped silicon from an elemental source in an evacuated quartz capsule. The surface concentration of total arsenic was 2.5×10^{20}-2.2×10^{21} cm^{-3} while that of electrically active arsenic was 1.9×10^{20}-2.8×10^{20} cm^{-3}. The rate constant in the linear regime of oxidation seemed to increase proportionally to the total arsenic concentration. This suggests that the surface reaction rate of oxidation is proportional to the total arsenic concentration in higher concentration region than a certain value which may lie in the range of 3.4×10^{19}-7.6×10^{19} cm^{-3}. For this case, the equation which gives the relation between oxide thickness and oxidation time was derived. Calculated values from this equation agreed well with experimental results. The increase in the surface reaction rate is considered to be caused by catalyst function of arsenic in reaction of oxidant OH with silicon.

A thermal oxidation process by which thin film of silicon dioxide is formed on silicon wafers is of great technological importance for fabrication of silicon devices. For such devices as planar and MOS transistors, oxidation is essential and precise control of oxide thickness is needed to obtain good device performances.

Oxide thickness for short oxidation time and/or low oxidation temperature is proportional to the time and to the square root of the oxidation time for long time and/or high temperature. The rate constant in the former case (linear rate constant) is limited by the surface reaction rate for oxidation and the rate constant in the latter case (parabolic rate constant) is limited by the diffusion rate of oxidant in the oxide film (1). It was reported that these rate constants depend on the impurity concentration in silicon as well as the temperature and oxidizing ambient. Deal and Sklar (2) and Pliskin (3) investigated the oxidation rate of boron-doped silicon and phosphorus-doped silicon. Pliskin reported that the linear rate constant of heavily phosphorus-doped silicon with the doping level of 4.9×10^{20} cm^{-3} was 2.03 μm/hr, which was about twice of the rate constant of high resistivity silicon for steam-oxidation at 978°C. Since his result was obtained for only one doping level, the impurity concentration dependence of the oxidation rate could not be determined. Deal and Sklar described oxide thickness of phosphorus-doped silicon and of boron-doped silicon as a function of the oxidation time and the oxidation temperature. Two doping levels were employed in their investigation: 3.7×10^{19} and 1.5×10^{20} cm^{-3} for phosphorus-doped silicon and 1.0×10^{20} and 2.5×10^{20} cm^{-3} for boron-doped silicon. Therefore the concentration dependence of the oxidation rate is expected to be derived. Indeed they reported the oxidation rate as a function of the impurity concentration. Their results were obtained on the assumption that oxide thickness was proportional to the square root of the oxidation time. For a higher oxidation temperature than about 1100°C in wet ambient where the assumption was valid, oxide thickness of heavily doped silicon agreed with that of high resistivity silicon. On the other hand, the higher phosphorus concentration resulted in a thicker oxide for an oxidation temperature lower than 1000°C. In this temperature range, the relation between the oxide thickness and the oxidation time is no longer expressed by the parabolic law but by the combination of linear and parabolic terms. From the analysis of their results considering these two terms, however, no reasonable value was obtained for the oxidation rates. Hence the concentration dependence could not be determined.

We have investigated the thermal oxidation of arsenic-diffused silicon in wet ambient with temperatures 650°-850°C. This paper reports the oxidation rate of arsenic-diffused silicon and its dependence on the arsenic concentration.

Key words: silicon oxide, arsenic diffusion, thermal oxidation.

Oxidation Rate

For thermal oxidation in wet ambient, an oxide thickness x_o is given by solving the following differential equation (1)

$$\frac{N_1}{C^*}\frac{dx_o}{dt} = \left(\frac{1}{k_s} + \frac{1}{h} + \frac{x_o}{D}\right)^{-1} \quad [1]$$

where k_s is the chemical surface-reaction rate constant for oxidation, h is the gas-phase mass-transport coefficient, C^* is the equilibrium concentration of oxidant in the oxide, N_1 is the number of oxidant molecules incorporated into a unit volume of the oxide film, and D is the diffusion coefficient of oxidant in the oxide film. Under the initial condition of $x_o = 0$ at $t = 0$, the solution of Eq. [1] is expressed by

$$x_o^2 + Ax_o = Bt \quad [2]$$

$$\frac{B}{A} = \frac{C^*}{N_1}\left(\frac{1}{k_s} + \frac{1}{h}\right)^{-1} \quad [3]$$

$$B = \frac{2DC^*}{N_1} \quad [4]$$

From Eq. [2], it is easily found that B/A and B are the rate constants in the linear regime and in the parabolic regime of the oxidation, respectively. Equation [3] shows that the linear rate constant B/A is proportional to the chemical surface reaction rate constant because h is estimated to be about 1000 k_s on the basis of boundary layer theory, and Eq. [4] shows that the parabolic rate constant B is proportional to the diffusion coefficient of oxidant in the oxide film. These constants depend on such oxidation conditions as ambient, temperature, and crystal orientation. For wet ambient and (111)-oriented silicon, the constants have been presented as a function of the oxidation temperature T (1).

$$B/A = 7.8 \times 10^7 \exp(-1.96/kT)\mu\text{m/hr} \quad [5]$$

$$B = 2.0 \times 10^2 \exp(-0.71/kT)\mu\text{m}^2\text{/hr} \quad [6]$$

Experimental

Silicon wafers used in this investigation were cut parallel to the (111) plane and polished mechanically and chemically to 250 μm thick. All wafers were doped with boron and had a resistivity of 2 Ω-cm which corresponded to a hole concentration of 7×10^{15} cm^{-3} (4).

The procedure of arsenic diffusion was similar to that previously reported (5). The diffusion was carried out in an evacuated quartz capsule containing silicon wafers and elemental arsenic. The purity of elemental arsenic used as a diffusion source was 99.999%. The vapor pressure of arsenic in the capsule was calculated from the volume of the capsule and the amount of arsenic on the assumption that arsenic vapor consisted of an As_4 molecule at the diffusion temperature. Surface concentration of the arsenic-diffused layer was determined by the differential conductance method and by the backscattering method using helium ions of 1.5 MeV. The former method gives the concentration of electrically active arsenic atom while the latter method gives the total concentration of electrically active arsenic and inactive arsenic atoms.

Thermal oxidation of the silicon wafers was done in wet ambient which consisted of oxygen-bubbled deionized water at 95°C. The oxidation temperature was in the range of 650°-850°C which was much lower than the diffusion temperature of arsenic in order to avoid a change in the arsenic concentration during the thermal oxidation. In each oxidation, an undiffused but heat-treated silicon wafer was used as a standard. The heat-treatment of the silicon wafer was done in an evacuated quartz capsule containing no diffusion source at the same temperature to the arsenic diffusion.

After oxidation, approximated thickness of the oxide film was estimated from interference color of the film which could give oxide thickness within an error of ±100Å. The oxide film on half the wafer surface was masked by wax and then the film on the remaining half was dissolved in buffered hydrofluoric acid of which etching rate for the oxide film was about 1000 Å/min. Considering that the etching rate possibly lowered near the oxide/silicon interface, we decided to add 30 sec to the etching time which was required from the approximated thickness and the etching rate. Etching of arsenic-diffused silicon by hydrofluoric acid was hardly observed in the arsenic concentration range used in this experiment. The wax was dissolved in organic solvent and silver was evaporated onto the whole wafer surface. The oxide thickness was measured using multiple-beam interferometric technique. Accuracy of this measuring method is estimated to be ±40Å.

Results and Discussion

Arsenic-diffused silicon.—Oxide thickness of the arsenic-diffused silicon wafers are shown in Fig. 1 (a),

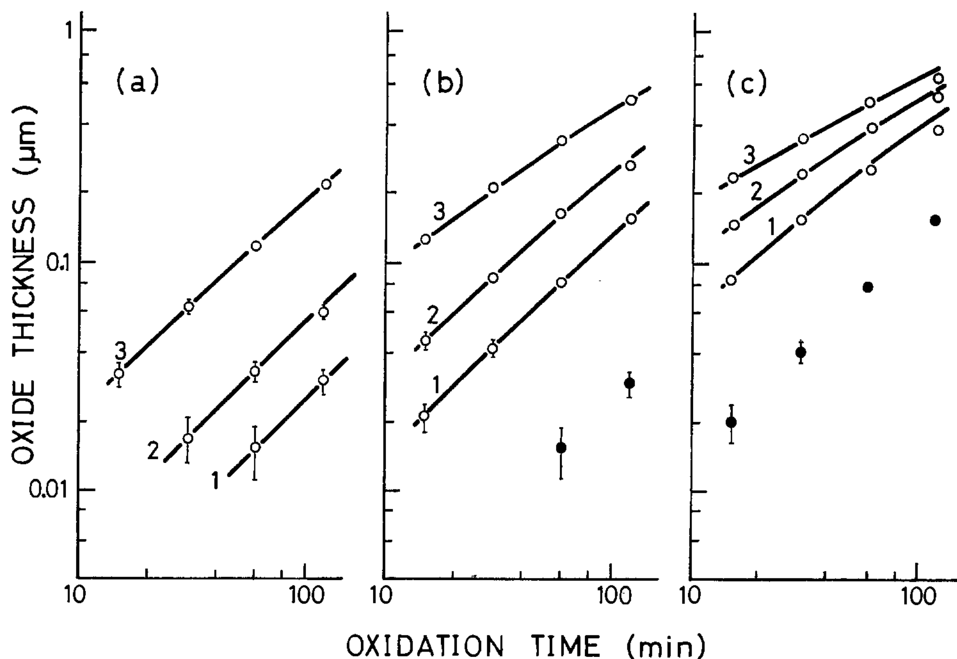

Fig. 1. Oxide thickness vs. oxidation time at (a) 650; (b) 750; and (c) 850°C. Curves 1, 2, and 3 are calculated values for surface concentration C_s of 2.5×10^{20}, 5.5×10^{20}, and 2.2×10^{21} cm^{-3}, respectively. Experimental values: ○, arsenic-diffused; ●, undiffused silicon.

(b), and (c) as a function of the oxidation time with a parameter of the surface concentration. Arsenic diffusion was carried out at 1000°C for 4 hr. The surface concentrations of total arsenic C_s were 2.5×10^{20}, 5.5×10^{20}, and 2.2×10^{21} cm^{-3} for the arsenic vapor pressures of 2, 20, and 200 Torr, respectively, while the surface concentrations of electrically active arsenic C_{se} were 1.9×10^{20}, 2.5×10^{20}, and 2.8×10^{20} cm^{-3}. The result of undiffused silicon was not presented in Fig. 1(a) because the oxide film of the undiffused silicon wafer oxidized at 650°C was too thin to determine oxide thickness.

The linear rate constant B/A and the parabolic rate constant B were obtained by applying Eq. [2] to the results shown in Fig. 1 using the least squares method. Thickness of the film used in this procedure was the mean value of experimental results obtained by five times measurements. The mean values are presented by open and closed circles in Fig. 1. In Fig. 2 and 3, B/A are shown as a function of reciprocal oxidation temperature and of the surface concentration of total arsenic C_s, respectively. As shown in Fig. 1(a) and (b), oxide thickness of the arsenic-diffused silicon wafers with the surface concentration C_s of 2.5×10^{20} and 5.5×10^{20} cm^{-3} is almost proportional to the oxidation time up to 120 min at 650° and 750°C. Therefore the parabolic rate constant B was obtained for only the wafer with the highest surface concentration and is shown in Fig. 4 as a function of the reciprocal oxidation temperature.

Oxidation rate of arsenic-diffused silicon.—In Fig. 3, it seems that the linear rate constant is proportional to the surface concentration of total arsenic C_s for oxidation at 650° and 750°C. As described above, the linear rate constant is a function of k_s, C^*, and N_1.

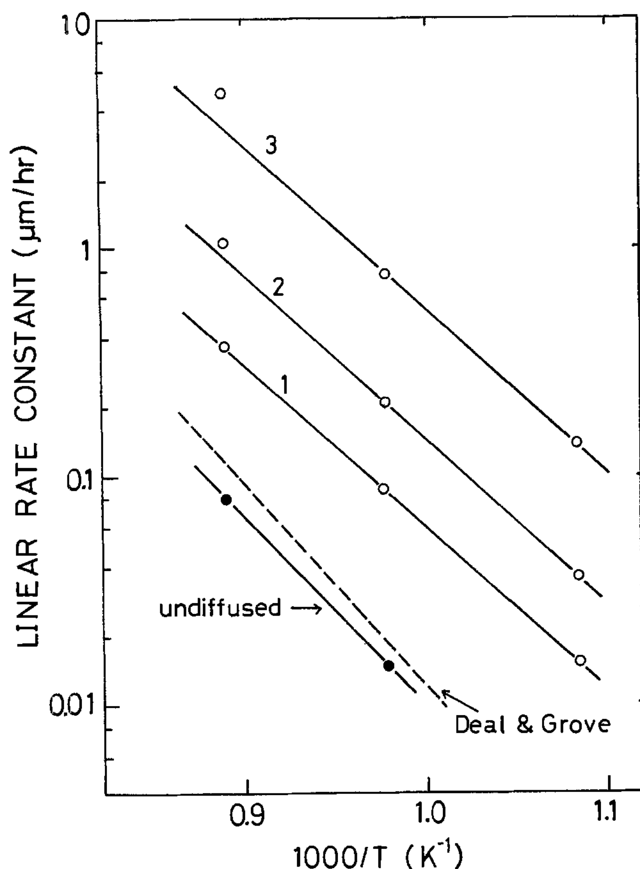

Fig. 2. Linear rate constant vs. reciprocal oxidation temperature. Lines 1, 2, and 3 are for surface concentration C_s of 2.5×10^{20}, 5.5×10^{20}, and 2.2×10^{21} cm^{-3}, respectively. Broken line is Deal and Grove's result. Experimental values: ○, arsenic-diffused; ●, undiffused silicon.

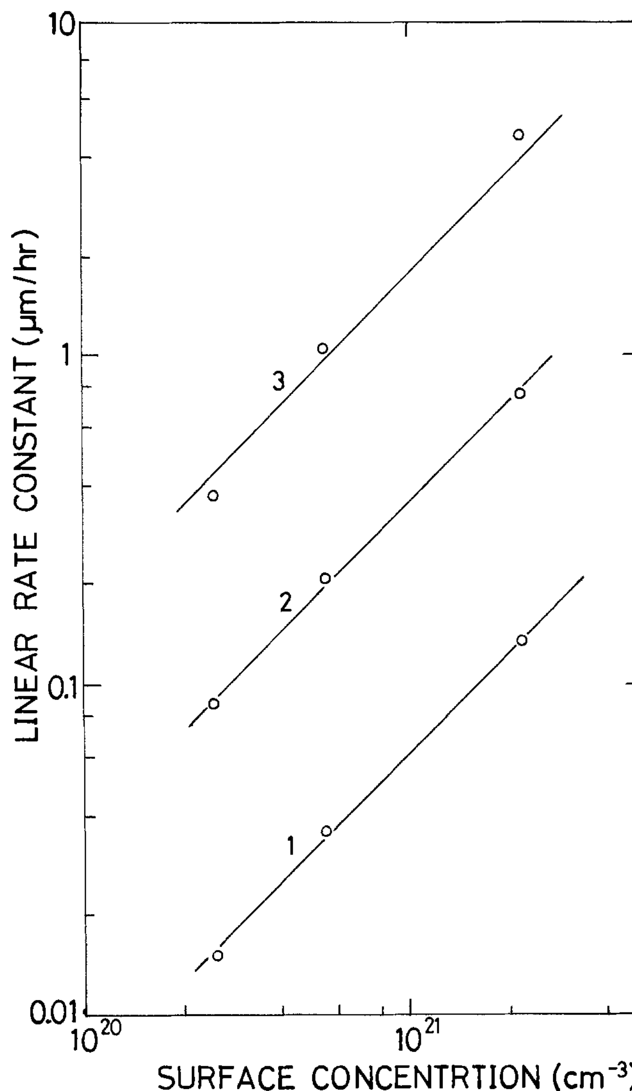

Fig. 3. Linear rate constant vs. surface concentration. Lines 1, 2, and 3 are for 650°, 750°, and 850°C oxidation, respectively.

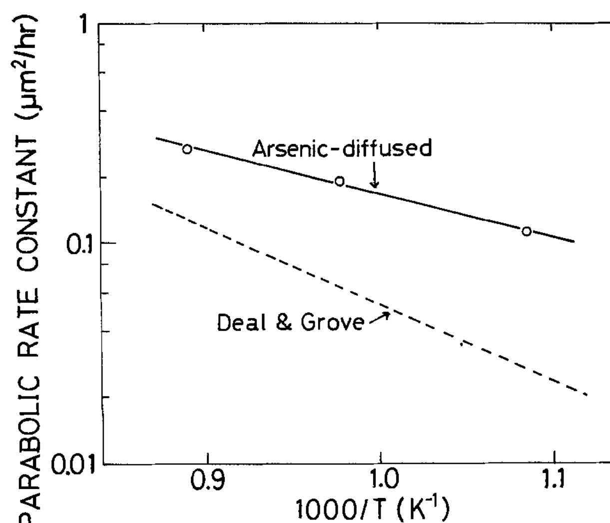

Fig. 4. Parabolic rate constant vs. reciprocal oxidation temperature. Solid line is experimental result for arsenic-diffused silicon with surface concentration C_s of 2.2×10^{21} cm^{-3} and broken line is Deal and Grove's result.

Since the values of C^* and N_1 are considered to be the same for both arsenic-diffused and undiffused silicon, the increase in B/A is attributed to the enhancement of the surface reaction rate constant k_s. When k_s de-

pends on the arsenic concentration in silicon, k_s in Eq. [1] is not constant but a function of oxide thickness for the arsenic-diffused wafer in which the arsenic concentration depends on a distance from the surface of the wafer. Therefore, Eq. [2] is no longer valid to arsenic-diffused silicon.

Assuming that k_s is proportional to the arsenic concentration, we derived the relation between oxide thickness and oxidation time. From the assumption, k_s is expressed by

$$k_s = k_o C \quad [7]$$

where C is the arsenic concentration. Equation [1], therefore, is described as

$$\frac{N_1}{C^*}\frac{dx_o}{dt} = \left(\frac{1}{k_o C} + \frac{1}{h} + \frac{x_o}{D}\right)^{-1} \quad [8]$$

Since C in arsenic-diffused silicon depends on the distance from the surface x, that is, $C = C(x)$, it is necessary to know the function $C(x)$ in order to solve Eq. [8]. In high concentration region, the diffusion coefficient of arsenic is proportional to the arsenic concentration (6). $C(x)$ is given as the solution of the following diffusion equation

$$\frac{dC_o}{dt_o} = \frac{d}{dx}\left(D_s C_o \frac{dC_o}{dx}\right) \quad [9]$$

$$D_s = 2C_s D_i / n_i \quad [10]$$

where C_o is the arsenic concentration normalized by the surface concentration C_s, D_s and D_i are the diffusion coefficients of arsenic at the surface and in low concentration region, respectively, t_o is the diffusion time, and n_i is the intrinsic carrier concentration at the diffusion temperature. We have reported that the solution of Eq. [9] is approximated well by a simple quadratic Eq. [7]

$$C_o = C/C_s = 0.999 - 0.872Y - 0.45Y^2 \quad [11]$$

$$Y = \frac{x}{2\sqrt{D_s t_o}} = \frac{x}{2\sqrt{2C_s D_i t_o / n_i}} \quad [12]$$

For growth of silicon dioxide with thickness of x_o, the silicon layer of $0.45x_o$ thick is consumed. Hence Eq. [12] is written as

$$Y = \frac{0.45x_o}{2\sqrt{2C_s D_i t_o / n_i}} \quad [13]$$

Equation [7] becomes

$$k_s = k_o C_s (0.999 - 0.872Y - 0.45Y^2)$$

$$= k_o C_s \left(0.999 - \frac{0.39x_o}{2\sqrt{2C_s D_i t_o/n_i}} - \frac{0.09x_o^2}{8C_s D_i t_o / n_i}\right)$$

$$\equiv k_o C_s (a - bx_o - cx_o^2) \quad [14]$$

Using Eq. [14], Eq. [8] is reduced to

$$\frac{N_1}{C^*}\frac{dx_o}{dt} = \left\{\frac{1}{k_o C_s (a - bx_o - cx_o^2)} + \frac{1}{h} + \frac{x_o}{D}\right\}^{-1} \quad [15]$$

The solution of Eq. [15] can be obtained as

$$\frac{C^*}{N_1} t = \frac{x_o^2}{2D} + \frac{x_o}{h} + \frac{2\sqrt{2C_s D_i t_o / n_i}}{0.72 k_o C_s} \log\left[\frac{1 + \dfrac{x_o}{12.2\sqrt{2C_s D_i t_o/n_i}}}{1 - \dfrac{x_o}{3.60\sqrt{2C_s D_i t_o/n_i}}}\right] \quad [16]$$

under the initial condition of

$$x_o = 0 \text{ at } t = 0$$

At the arsenic diffusion temperature of 1000°C, D_i and n_i are 8.14×10^{-4} μm^2/hr and 5.7×10^{18} cm^{-3}, respectively (8, 9). N_1 for the wet ambient where water is the main oxidizing species is 4.5×10^{22} cm^{-3}, and h is about 10^8 μm/hr. C^* and k_o depend on the oxidation temperature. C^* is obtained from the parabolic rate constant B which is $2DC^*/N_1$ as described above using Deal's results (1). The coefficient k_o of Eq. [7] is determined from Fig. 3 on the assumption that B/A in Fig. 3 is equal to $k_o C_s C^*/N_1$. D also depends on the oxidation temperature and possibly depends on the arsenic concentration. However the concentration dependence of D was not obtained because D was determined for only one concentration. The calculation of Eq. [16] is carried out using the values of D shown in Fig. 4 and the concentration dependence is assumed to be negligible. The values of C^*, k_o, and D employed here are listed in Table I. The calculated results shown in Fig. 1 by solid lines agree with the experimental values except for the oxidation at 850°C for 120 min. In the deriving process of Eq. [16], we did not take the impurity redistribution during the thermal oxidation into account. The discrepancy between calculated and experimental values may indicate the fact that the redistribution of arsenic cannot be neglected in this oxidation condition.

Although impurity such as arsenic or phosphorus seems to facilitate the reaction of oxidant to silicon, the role of this impurity is not clear. As another impurity affecting oxidation rate of silicon, sodium has been reported. Revesz and Evans have studied the effect of sodium which was introduced during oxidation (10). They have reported that sodium increases the linear rate constant for oxidation in wet ambient. It is attributed to the facility of the entrance of OH through autocatalytic reaction in the presence of sodium. Devereux *et al.* have investigated the oxidation of polycrystalline silicon wafer coated with sodium carbonate in wet (water vapor pressure of 24 Torr) ambient (11). They have reported that initial oxidation follows cubic kinetic behavior and have explained this behavior by the following mechanism; in the presence of high concentration sodium oxide, the main oxidant is the oxide ion which is consumed by formation of silicate ion; thus the surface reaction rate will decrease with time. Arsenic in high concentration region may have a function of catalyst similar to sodium. As described above, sodium was introduced from the outside of the oxide film. On the other hand, arsenic in the oxide film was provided from silicon in this experiment. Therefore the number of arsenic atoms acting as catalysts is proportional to the arsenic concentration at the interface between oxide film and silicon.

Arsenic-diffused and step-etched silicon.—Modified Eq. [16] is applied to the oxidation of the arsenic-diffused silicon wafer, of which surface layer is etched off after the diffusion. Arsenic diffusion was carried out at 950°C for 60 min under the arsenic vapor pressure of 30 Torr. Surface concentration of total arsenic was 3.5×10^{20} cm^{-3}. The arsenic-diffused layer was step-etched by anodic oxidation technique using potassium nitrate and tetrahydrofurfuryl alcohol. The number of etched steps was four and the depth of each step was 600Å. As a standard, an undiffused silicon wafer which had been heat-treated at 950°C for 60 min in vacuum was also step etched. Oxidation was carried out at 850°C for 30 min on both the arsenic-diffused and step-etched wafer and the heat-treated

Table I. Coefficient k_o of proportional Eq. [7], diffusion coefficient of oxidant D, and equilibrium concentration C^*

°C	k_o ($\mu m/hr \cdot cm^{-3}$)	D (μm^2/hr)	C^* (cm^{-3})
650	6.68×10^{-20}	63.2	4.04×10^{19}
750	4.24×10^{-19}	125	3.64×10^{19}
850	2.50×10^{-18}	185	3.21×10^{19}

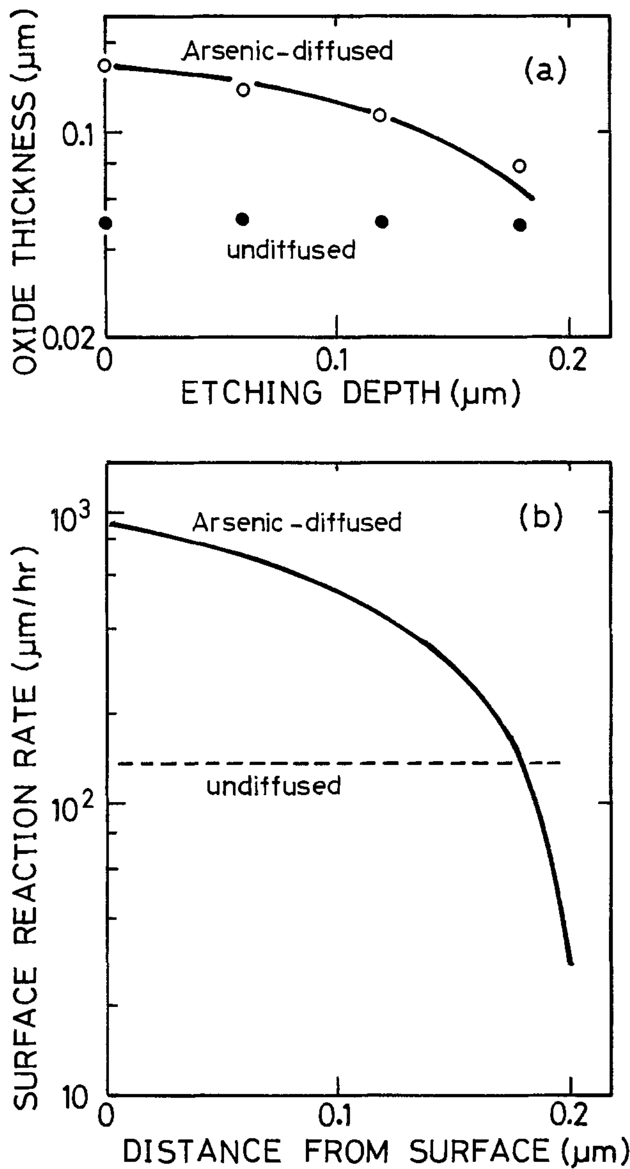

Fig. 5. (a) Oxide thickness vs. depth of step etching. Solid line is the calculated value of arsenic-diffused silicon. Experimental values: ○, arsenic-diffused; ●, undiffused silicon. (b) Surface reaction rate vs. distance from the surface. Solid line and broken line are for arsenic-diffused and undiffused silicon, respectively.

and step-etched wafer. Oxide thickness is shown in Fig. 5(a) as a function of thickness of the etched silicon layer. As thickness of the etched layer increases, that is, as the surface concentration decreases, oxide thickness is observed to decrease. On the other hand, the oxide film of undiffused silicon has a constant thickness of about 500Å. This indicates that the heat-treatment and the etching by anodic oxidation did not have an effect on the oxidation rate.

In this case, the arsenic concentration is expressed by

$$\frac{C}{C_s} = 0.999 - \frac{0.872(x+s)}{2\sqrt{D_s t_o}} - \frac{0.45(x+s)^2}{4D_s t_o}$$
$$= 0.999 - \frac{0.872s}{2\sqrt{D_s t_o}} - \frac{0.45s^2}{4D_s t_o} - \left(\frac{0.872}{2\sqrt{D_s t_o}} + \frac{0.09s}{4D_s t_o}\right)x - \frac{0.45x^2}{4D_s t_o} \quad [17]$$

where s is etching depth and x is $0.45x_o$. Hence the equation which gives the relation between oxide thickness and oxidation time is obtained by the same way as deriving Eq. [16] and is expressed by

$$\frac{C^*}{N_1}t = \frac{x_o^2}{2D} + \frac{x_o}{h} + \frac{2\sqrt{2C_sD_it_o/n_i}}{0.72k_oC_s} \log\left[\frac{1+\dfrac{x_o}{12.2\sqrt{2C_sD_it_o/n_i}+2.22s}}{1-\dfrac{x_o}{3.60\sqrt{2C_sD_it_o/n_i}-2.22s}}\right] \quad [18]$$

The experimental values agree with the theoretical curve shown in Fig. 5(a) by solid line except for the point at 1800Å. Under the oxidation condition of 850°C, 30 min, and wet ambient, oxide thickness of undiffused silicon is proportional to the oxidation time as shown in Fig. 1 and the thickness of 500Å corresponds to the surface reaction rate k_s of 140 μm/hr. For arsenic-diffused silicon, k_s is assumed to be proportional to the total arsenic concentration, namely $k_s = k_oC$, and the coefficient k_o is given as 2.1×10^{-18} μm/hr · cm^{-3} at 850°C from Fig. 1. As shown in Fig. 5(b), k_s of arsenic-diffused silicon is calculated to be smaller than that of undiffused silicon for larger x than 1900Å. However k_s of arsenic-diffused silicon must not be smaller than that of undiffused silicon for any arsenic concentration. The assumption that k_s is proportional to the arsenic concentration, therefore, is no longer valid in lower concentration region. This may be the cause of the discrepancy beween the theoretical and the experimental values of the oxide thickness at $s = 1800$Å.

The concentration dependence of k_s may be expressed by a function which approaches k_s of high resistivity silicon in the low concentration region and is proportional to the impurity concentration in the high concentration region. As shown in Fig. 5(a), the experimental values agree with the theoretical curve for the smaller s than 1200Å while the discrepancy takes place at s of 1800Å. Oxide thickness for s of 1200Å is 1150Å, which corresponds to the thickness of the consumed silicon layer of about 500Å for oxide. The arsenic concentration at the distance of 1700Å (= 1200 + 500Å) from the surface is 7.6×10^{19} cm^{-3}. Therefore, for higher concentration than this value, the assumption that k_s is proportional to the total arsenic concentration is considered to be valid. On the other hand, for larger values of x than 1900Å where the arsenic concentration is 3.4×10^{19} cm^{-3}, the assumption is not valid as described above. Thus the lower limiting concentration for the validity of the assumption may lay in the region of 3.4×10^{19}-7.6×10^{19} cm^{-3}.

Summary and Conclusions

Oxidation of arsenic-diffused silicon has been investigated at 650°-850°C in wet ambient. The oxidation rate of silicon with higher surface concentration than 2.5×10^{20} cm^{-3} has been found to be much larger than that of high resistivity silicon. The larger oxidation rate is mainly attributed to the increase in the linear rate constant under the oxidation condition in this experiment. The linear rate constant and the surface reaction rate seem proportional to the surface concentration of total arsenic when the oxide film is thin. The increase in the surface reaction rate is considered to be caused by catalyst function of arsenic in reaction to the oxidant OH with silicon.

The approximated equation which gives the relation betwen oxide thickness and oxidation time is derived for arsenic-diffused silicon on the assumption that the surface reaction rate is proportional to the total arsenic concentration. The equation is applied to arsenic-diffused silicon, of which the surface layer is step-etched. Comparison of calculated values with experimental results indicates that the lower limiting concentration for the validity of the assumption may lay between 3.4×10^{19} and 7.6×10^{19} cm^{-3}.

Development of a Gentle Accelerated Corrosion Test

S. P. Sharma,* J. H. Thomas III,*[1] and F. E. Bader

Bell Laboratories, Incorporated, Columbus, Ohio 43213

ABSTRACT

A gentle accelerated corrosion test has been devised using a kinetic rate equation for contact materials to establish approximate acceleration factors due to relative humidity and thermal effects. The duration of the test can be suitably chosen depending on the application and has been taken to be one year. The test consists of a high/low relative humidity cycle and a high/low temperature cycle which will sample the ambient over a one year period and which will be equivalent to 25°C/35-40% RH for 53 years (a typical total equivalent lifetime for a gold-based contact).

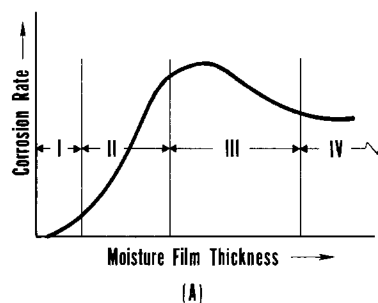
High reliability applications in the electronic industry require that electrical connections function satisfactorily for a substantial time (as much as 40 years in a telephone industry). As a consequence, there is considerable interest in developing meaningful accelerated corrosion tests (corrosive environmental tests, etc.) to aid in assessing contact material systems and connector designs. It is known that atmospheric pollutants (such as SO_2, H_2S, nitrogen oxides, Cl_2, HCl, etc.) combined with humidity cause corrosion and tarnishing of materials. To develop a meaningful accelerated test procedure, pertinent failure mechanisms must be accelerated. It is also important that failure mechanisms which do not occur in service not be introduced.

Two approaches are presently employed in testing contact material systems: (*i*) field exposure tests (1, 2), and (*ii*) laboratory accelerated tests (3, 4).

Field exposure tests are time consuming but tend to be realistic, that is, atmospheric pollutants at field exposure sites are employed in the test. Laboratory tests are rapid (~2 weeks) but employ large concentrations of corrosive gases (and hence large acceleration factors) which may introduce unrealistic failure mechanisms. These tests are generally considered severe. It is therefore of considerable interest to develop a test procedure which is both realistic and reasonable in duration. This paper describes a gentle accelerated aging test which may be used to evaluate the performance and predict the expected end of life of a material system.

Corrosion Rate—Effects of Relative Humidity

It is generally believed that most contact materials degrade through the mechanism of moist atmospheric corrosion and tarnishing. The rate of atmospheric corrosion, shown in Fig. 1, is related to the amount of moisture on a surface (generally a thin invisible film which acts as an electrolyte in a corrosive environment). At low relative humidity (RH), when the moisture film is less than a monolayer thick or discontinuous, corrosion proceeds by dry corrosion proc-



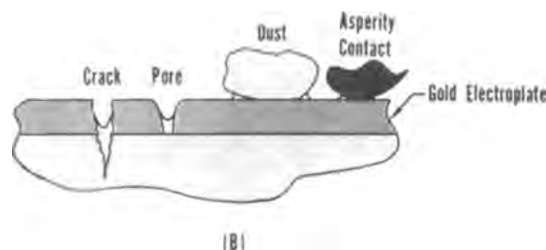


Fig. 1. (A) Qualitatively the dependence of corrosion rate on relative humidity is shown. (B) Capillary-like corrosion sites are shown diagramatically.

Key words: accelerated test, environmental test, atmospheric corrosion, corrosion of electrical contacts.

esses, such as oxidation (see Fig. 1A region I) according to Tomashov (5, 6). At higher RH, the moisture film increases in thickness forming a continuous layer and assumes the role of an electrolyte. In this case the corrosion rate increases (region II). At higher RH, the film becomes visible (region III and IV) and the mechanism again changes (5).

In service, exposed base metals used in electrical contacts corrode by the mechanism of electrochemical corrosion (region II Fig. 1A). The amount of moisture (water) on a surface depends on the material system and varies with relative humidity. Relative humidity therefore plays a significant role in determining the corrosion rate. In addition to physical adsorption of water on a surface, capillary-like sites also increase the condensation rate. For example, (see Fig. 1B) condensation can take place in crevices, capillaries, and under particulate matter (dust) at lower RH than surface adsorption (7). Corrosion products can also enhance this effect (capillarity under particles or hygroscopicity). The presence of salts can further enhance moisture accumulation (water of hydration) (5).

Corrosion Rate—Acceleration Factor

Generally, it is only possible to semiquantitatively derive a set of test conditions because of a general lack of information required to estimate acceleration factors. However, we describe an attempt to estimate the acceleration factor based on a first-order approximation of the rate equation (6, 8). The kinetic rate equais assumed as follows

$$\text{rate} = K\left[\exp\left(\frac{-\Delta E}{kT}\right)\right][H_2O]^w[SO_2]^x[H_2S]^y\ldots(A)^z \quad [1]$$

where K is the rate constant, $[m]$ is the concentration of m; w, x, y, z are reaction constants, (A) is the air velocity, ΔE is the activation energy, k is Boltzmann's constant, and T is absolute temperature. $[H_2O]$ is the amount of water adsorbed on the surface and is a function of relative humidity. This equation assumes that the individual gas reactions proceed independently. The rate constant, K, depends on the material system being considered including, among other things, the porosity and history of prior exposure. Estimates of an acceleration factor based on such simplification must be viewed with caution and establish only qualitatively the effects of various variables on acceleration factors. If the pollutant level is held constant for a given material, (*i.e.*, the test utilizes the polluted air from an industrial area) the important parameters remaining are $[H_2O]$ and temperature. By manipulating the relative humidity, which determines $[H_2O]$, and temperature, a gentle accelerated aging test can be devised.

Thomas and Sharma (9) have measured the amount of water on gold surfaces as a function of relative humidity and temperature. Both adsorption and desorption branches of the weight-RH curves were fitted to the BET model (10). The desorption isotherm was used in this analysis since the pores which are filled (in adsorption) release the capillary water at lesser relative humidity in desorption. The desorption isotherm is therefore a more realistic approximation to real situations. The amount of water on a porous gold surface can be estimated from the following

$$[H_2O] = \frac{CX_mRH}{[1 + C(C-1)RH][1 - RH]} \quad [2]$$

where C is related to the heat of desorption, X_m is the monolayer capacity, and RH is the relative humidity. In the case of desorption [from Ref. (9)], X_m is 0.25 μg/cm^2 and the heat of desorption is 0.1 eV ($C = 50$).

In Eq. [1], the order of the rate with respect to water, w, is not known for porous gold on copper. Experimentally, w can be determined by performing weight gain measurements at various relative humidities which are directly related to the amount of water on the porous gold surface [see Eq. [2] and Ref. (3)]. Krumbein's (11) experiments of pore corrosion of the porous gold on copper system in SO_2 at various humidities can be used to estimate the corrosion rate and hence w. If the number of corrosion spots exceeding a certain size is proportional to the corrosion rate, a rough estimate of $w = 2$ can be made. The value of w obtained from Krumbein's data (11) is the same as Lorenzen (8) found for atmospheric corrosion of silver. Therefore, we assumed $w = 2$ in designing the gentle accelerated corrosion test. This assumption is justified by the fact that the predictions based on this assumption compare favorably with the experimental measurements as reported in an accompanying paper (12).

Figure 2 shows the effect of relative humidity on corrosion rate assuming $w = 2$, at constant temperature using Eq. [2], that is, $R \propto [H_2O]^2$ where $[H_2O]$ is given by Eq. [2]. The corrosion rate is observed to increase at relative humidities above 65-75%. This range of relative humidity has been termed "the critical humidity" in corrosion literature.

The temperature can also significantly affect corrosion rate (holding other parameters constant in Eq. [1]). An estimate of the activation energy, ΔE in Eq. [1], can be made from experiments performed by Clarke and Sansum (13). They have shown that corrosion of copper, silver, and nickel plated with gold in 10% SO_2 at a controlled relative humidity is accelerated by a factor of 12 if temperature is increased from 25° to 60°C. Thus, ΔE is $\sim$ 0.6 eV. We use this activation energy, 0.6 eV, to determine the thermal acceleration factor. Schwartz (14) has shown that for electrochemical corrosion, ΔE generally falls in this range.

Contacts must meet life requirements (as much as 40 years for the telephone industry), in addition to production, storage, and shipping. In an air-conditioned telephone office, the long-term operating temperature and relative humidity were taken as 25°C and 40% RH, respectively. During air-conditioning equipment failures, maintenance, etc., the relative humidity can approach 80% for as much as 15 days per year. In addition, more severe environments are encountered in manufacture, storage, and shipping. To normalize the time spent in these various environments to an equivalent time at 25°C and 35-40% RH, Eq. [1] (excluding pollutant concentrations and air velocity effects) has been used assuming $w = 2$, $\Delta E =$ 0.6 eV, and the desorption relation (Eq. [2]). Table I summarizes the results of this calculation. In certain applications the temperatures in actual field service can be higher than 25°C but the relative humidity near

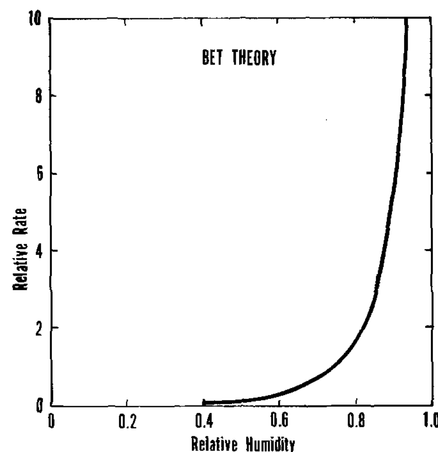

Fig. 2. Corrosion rate ($\propto [H_2O]^2$) is plotted as a function of relative humidity using desorption data of Thomas and Sharma.

Table I.

Environment	Temperature (°C)	Humidity (%)	Time	Equiv. time (year)
Manufacturing	35	80*	1 month	1
Storage	35	80*	2 months	3
Shipping	35	85*	1 month	2.5
Field service:				
Long term	25	35-40	39 years	39
Short term	25	75-80	1 year	8
		Total	~40 years	~53

* Assume worst case.

the contact region will be lower for the same absolute humidity (see psychometric chart). The decrease in relative humidity compensates the increase in temperature from the corrosion point of view. From these calculations it is observed that contact material systems (for 40 years life) should be designed to last at least 53 years at 25°C and 35-40% RH.

The Gentle Accelerated Corrosion Test

Ambient atmosphere at increased relative humidity and temperature supplies the corrosive environment which should approximate a real service environment. That is, as mentioned earlier, increased humidity and temperature will be used to accelerate corrosion. Due to seasonal variations in atmospheric pollutant concentrations, the over-all test was designed to operate over a one year period. In the case of mated contacts, mechanical motion caused by thermal variations may be important. These effects may be included by thermally cycling the test. The effects of dry corrosion (tarnish and oxidation) which may affect corrosion rates are taken into account qualitatively by humidity cycling. In summary, the test consists of a high/low RH cycle and a high/low temperature cycle which samples the ambient over approximately a one year period and which will be equivalent to 25°C/35-40% RH for 53 years. One such sequence is as follows: 12 hr at 80% RH, 65°C; 12 hr at 35-40% RH, 65°C; and 12 hr at 35-40% RH, 25°C.

Thus the cycle will be based on a 36 hr period. Since 36 hr is not synchronous with daily fluctuations of the ambient environment, fluctuation effects should be averaged out over a reasonable test duration.

The objective of this test is to simulate corrosion due to 53 years at 25°C/35-40% RH. The test at 65°C/80% RH for 4 months is equivalent to 53 years at 25°C at 35-40% RH from Fig. 2, and assuming $\Delta E = 0.6$ eV using the simplified Eq. [1]. Thus by cycling the test as shown above, the materials being tested will be exposed for one year; 4 months at low RH/low temperature; 4 months at high RH/high temperature; and 4 months at low RH/high temperature. During the one year period, the system undergoes 243 mechanical (thermal) cycles to simulate micromotion in service. Effectively, the material will have been thermally aged at 65°C for 5850 hr (8 months). In terms of substrate diffusion to the gold surface, copper film thickness can be predicted from Ref. (15 and 16).

The acceleration factors derived from this test for Cu, Ni, and Ag by comparing the film growth in the field environment to the film growth in the test will be described in other papers (12, 17). It is sufficient to say that the test works well for Cu and Ni with large acceleration factors, but is not a suitable test for Ag (12) because the acceleration factor is too small for Ag. The contact resistance changes on real connector systems will be described in another paper (17).

Conclusions

A one year accelerated corrosion test has been devised by using the kinetic rate equation to establish approximate acceleration factors due to relative humidity and thermal effects. From an analysis of Clarke and Sansum's thermal data, the thermal activation energy for corrosion was ~0.6 eV. The corrosion reaction order from Krumbein's data was approximated as 2, and the amount of moisture is found from a BET analysis of Thomas and Sharma's results. An acceleration factor of 154 is obtained for 65°C/80% RH with respect to 25°C/35-40% RH using the kinetic rate equation which is in close agreement with the required acceleration factor of 159 (53 × 3, see Table I) for a 4 month test. The acceleration factor and the test conditions derived on such simplified models as presented in this report will be modified as our knowledge concerning the activation energy, ΔE, and the reaction order w is improved.

It is believed that by using the typical ambient found in field locations and by manipulating temperature and relative humidity, a meaningful realistic corrosion test is possible. A first attempt on one such test has been described above. The results on contact resistance changes (of the connectors) and the measurement of acceleration factors on Cu and Ni show that this is a realistic environmental test (12, 17) for these materials.

Atmospheric Corrosion of Silver, Copper, and Nickel—Environmental Test

S. P. Sharma*

Bell Laboratories, Incorporated, Columbus, Ohio 43213

ABSTRACT

The corrosion growth kinetics for Cu, Ni, and Ag in an air-conditioned telephone office and a nonair-conditioned telephone office basement have been obtained by measuring the film thicknesses on coupons exposed for various times. The film constituents and thicknesses on these materials were obtained by AES and cathodic reduction. Over a two year period, Ag tarnishes linearly and the major film constituents are sulfur and chlorine. Copper and nickel corrosion data have been fitted to parabolic growth rate kinetics and the film thicknesses have been extrapolated to 40 years. The major film constituents on Cu and Ni are oxygen, chlorine, and sulfur. The film constituents and thicknesses have also been obtained by exposing the same materials in the One Year environmental test. The constituents are similar to the films grown in the field. Acceleration factors for the One Year test for these materials have been derived by comparing film thicknesses to those developed in the field. It is concluded that the One Year test is a suitable test for Cu and Ni but not for Ag.

Many applications require that electrical connectors and other material systems used in telephone offices perform satisfactorily for as much as 40 years. Therefore, the development of a meaningful accelerated corrosion test for materials is of prime interest. In an accompanying paper, Sharma *et al.* (1) described an accelerated corrosion test lasting one year. The test was derived semiquantitatively based on a kinetic rate equation. Because of general lack of scientific information about various parameters and constants (activation energy, reaction rate constants, etc.) in the rate equation, engineering judgements were made in designing such a test. The test was based on the measurement of the amount of water adsorbed on a gold surface as a function of relative humidity by Thomas and Sharma (2). A rate constant of 2 and an activation energy of 0.6 eV were assumed in the test. The decrease in solubility of gases in adsorbed H_2O at the surface with increase in temperature was not taken into consideration and this may have resulted in overestimation of acceleration factors in test design. The test consists of a high/low relative humidity and temperature cycle, asynchronous with daily fluctuations in ambient environment, to simulate the service life of a connector in a one year period. The sequence of the test is as follows: 12 hr at 80% RH, 65°C; 12 hr at 35-40% RH, 65°C; and 12 hr at 35-40% RH, 25°C.

The test was conducted in the basement of a telephone central office in Cleveland. This office is located in an industrial area having, according to Environmental Protection Agency data, one of the highest mean concentrations of SO_2 in the country as well as high concentrations of other pollutants and particulates.

This paper reports the acceleration factors derived experimentally from this test for Ag, Cu, and Ni. The acceleration factors are derived by comparing the thicknesses of corrosion films on these materials from the test chamber to the thicknesses on similar materials from the field chambers at the same location. There are two field chambers in this office, one in the air-conditioned central office (no special humidity control is employed in this central office) on the third floor of the building and the other in the nonair-conditioned basement. The test chamber is located near the field chamber in the basement. Film thicknesses were measured by sputter back profiling in an Auger electron spectrometer. Silver tarnishes linearly and provides an acceleration factor of ~4.0, which compares with the theoretical value of 3.74, but is too low to make this a practical test. Copper corrosion has been fitted to a parabolic growth rate model, and utilizing this model, an acceleration factor of ~20 is obtained with respect to Cu coupons exposed in the basement environment. With respect to an air-conditioned central office environment, an acceleration factor greater than 100 is achieved. For nickel coupons an acceleration greater than 100 is achieved for the central office environment while the basement environment provides an acceleration of ~27.

Experimental

The test was conducted in a 10 ft^3 capacity Tenney TTRS environmental chamber, custom designed to provide the sequence of test conditions. It is equipped with a purge system to change the air within the chamber at a rate of 4 times/hr. The air velocity is about 400 ft/min. It has an extended time cycle, *i.e.*, the programmable cam-operated controller regulated the first 24 hr period of the test cycle and a separate programmable timer provided the additional 12 hr period. The humidity is determined by the difference of dry and wet bulb temperatures (measured by platinum resistance sensing elements of a bridge controlled circuit). Humidity is increased by introducing water vapor and decreased by introducing drier air into the chamber. The temperature is controlled by a heater or a refrigeration system. The test chamber is located in a central office basement. There is no air conditioning or filtration of the room air, and a window is frequently open to the outside air.

The field chambers are modified five drawer file cabinets. The bottom of each file drawer was replaced by metal mesh to permit free flow of air. The cabinets are louvered at the bottom and equipped with several small fans (blower unit) mounted at the top behind a furnace filter. The same type of furnace filter was used in the test chamber. The blower unit provides a linear air flow of about 250 ft/min. The chambers are equipped with a hygrothermograph to record the temperature and humidity.

The materials exposed were 1½ in. square coupons and were abraded using metallographic papers to a 400 grit random finish and liquid honed to a fine uniform finish. The coupons were cleaned according to procedures outlined in Ref. (3) prior to installation in the field and the test chamber.

Key words: Auger, accelerated test, corrosion of electrical contacts, corrosion.

The corrosion films were analyzed for the elements present on a Physical Electronics Scanning Auger System Film Analyzer, *i.e.*, Auger electron spectrometer (AES). This system is equipped with a single pass CMA, coaxial electron gun, and a Varian rastered ion gun. The thickness and distribution of elements into the film were determined by depth profiling using ion sputtering in conjunction with AES. Normal operating conditions were 3 kV electron gun voltage, 1200V electron multiplier voltage, 1 eV/sec sweep rate, 0.3/sec time constant on the lock-in amplifier, 3 eV modulation amplitude, and 1.6 mA emission current. For sputtering, the argon pressure was 5×10^{-5} Torr and the ion beam voltage was 1 kV. By means of a multiplexer system, peaks corresponding to various elements in the corrosion film were analyzed. Film thickness was determined by knowing the sputter rate and the time to sputter through the film. The time to sputter through the film is determined by measuring the time required for the substrate Auger signal to reach 70% of its maximum signal amplitude and/or by measuring the time for the last constituent of the corrosive film to reach 30% of its maximum signal amplitude. It is assumed that the sputter rate of the corrosion film is the same as of the substrate material. This assumption is not critical, since we are only interested in the relative thickness. The thickness values are therefore not absolute. In addition to AES, the film thicknesses of Ag and Cu were also determined by cathodic reduction in some cases.

Results and Discussion

Silver.—Figure 1 shows a typical depth profile obtained from a silver sample exposed in the basement field chamber. A depth profile from a Ag coupon subjected to the test conditions for 3 months in the test chamber is shown in Fig. 2. Similar spectra have been obtained from all the field-exposed samples (basement as well as third floor central office up to a period of 2 years) and all the samples in the One Year test. It is seen that the constituents of the films developed in the test chamber are similar to those in the field-exposed chambers. Table I presents the constituents of the film developed in order of decreasing peak heights as a function of time. The composition of the film developed in field chamber is not constant, *i.e.*, the ratio of Ag to Cl and Ag to S is not constant for coupons exposed to different time periods. This could be a time effect, coupon effect, or due to surface variability. In addition, the composition of the film changes along the thickness of the film. The only conclusion about the chemistry of the film is that each sample contains some AgCl and some Ag_2S, and the relative amount of these varies from sample to sample. The conclusion of the film being a mixture of Ag_2S and AgCl is substantiated by the fact that in cathodic reduction the reduction potentials match with those of AgCl and Ag_2S. The film thicknesses of the basement coupons are plotted as a function of time in Fig. 3. Table II pre-

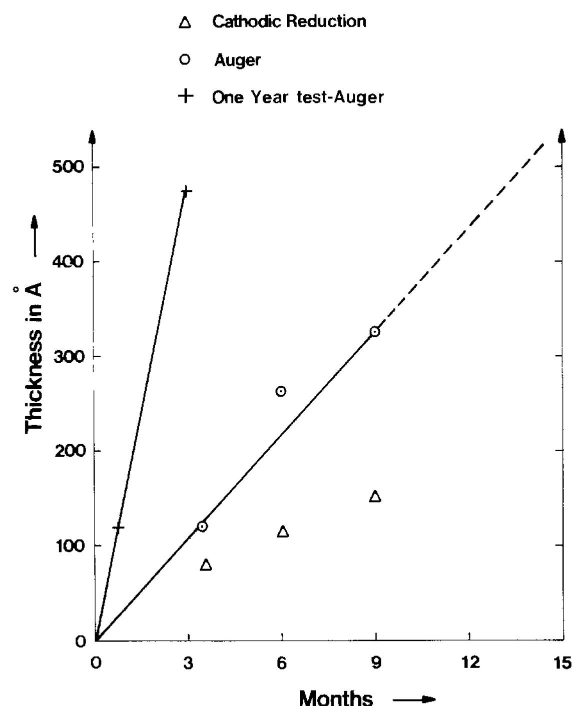

Fig. 3. Film thickness-time curve for Ag exposed in the basement field chamber and in One Year test.

sents the thicknesses of films obtained by cathodic reduction and by AES. It is seen that within the experimental errors the film thicknesses obtained by two different methods (AES and cathodic reduction) do not differ greatly. Silver corrodes linearly at a rate of 30-35 Å/month in the basement. Also shown in Fig. 3 is a plot of film thicknesses as a function of time, from the test chamber samples. By comparing the slopes of two curves, an acceleration factor of ~4 is calculated for Ag. This is a small but not an entirely unexpected acceleration factor for Ag as discussed further. SEM analysis of the corrosion products reveals that the morphology of the corrosion products is similar for the test samples and the samples from the field chamber. No significant roughness difference in the morphology of the corrosion products is seen.

It is known (4-6) that there is no significant change in the rate of corrosion of Ag with respect to temperature in the range 30°-55°C (and possibly up to 65°C) for relative humidities up to 85% and for modest concentrations (up to 1 ppm) of H_2S, SO_2, and Cl_2. There are various possible explanations for this lack of temperature dependence of silver tarnishing. One possible explanation is that the solubility (concentration) of gases dissolved in the adsorbed water film on Ag surface decreases with increasing temperature[1] (7). The

[1] Solubility of Cl_2 in H_2O (7) at 65°C is 0.47 times the solubility of Cl_2 at 25°C and the solubility SO_2 in H_2O at 65°C is 0.36 times its solubility at 25°C.

Table II. Thickness of films on silver

24	Basement	—	513
1	Test chamber	120	121
3	Test chamber	480	267
12	Test chamber	—	1200

other factor may be that the activation energy may be small resulting in a smaller temperature coefficient for acceleration. In addition, the amount of H_2O adsorbed at the surface could also decrease with increasing temperature. Whatever the reason, the temperature has little effect on the acceleration of corrosion in the temperature range of the One Year test and the only accelerating factor for Ag is the relative humidity.

The equation which describes (4) the rate dependence of silver tarnishing on relative humidity with other variables held constant is

$$\text{rate} = K_w\,[H_2O]^2_{Ad} \quad [1]$$

where K_w is the frequency factor and H_2O is the amount of water adsorbed on silver surface at a given relative humidity.

Utilizing the water adsorption isotherm on Ag obtained by Bowden and Throssell (8), the amount of H_2O adsorbed as a function of relative humidity (RH) is

$$[H_2O]_{Ad} = \frac{3.95\,\text{RH}}{(1 - \text{RH})\,(1 + 7.8\,\text{RH})} \quad [2]$$

Since the average relative humidity in the basement is approximately 40-45%, the acceleration factor (AF) can be calculated by

$$\text{AF} = \frac{\text{rate of corrosion at 80\% RH}}{\text{rate of corrosion at 45\% RH}} \times \frac{1}{3} + \frac{2}{3} = 3.74$$

since the chamber is at 80% of RH for 1/3 of the time. Therefore, theoretically the One Year test should provide an acceleration factor of 3.74. Experimentally an acceleration factor of ~4 is obtained.

These results can be compared to studies of Wagar (9), Abbott (5), and Crossland and Knight (6) on silver tarnishing. Abbott (5) has reported linear tarnish rates for Ag for S_8 mixtures and for mixed gases with low levels of H_2S in which other oxidizing agents such as NO_2 and/or Cl_2 are present. While Crossland and Knight (6) and Abbott (5) have shown that H_2S-O_2-H_2O mixtures produce nonlinear kinetics.

Since the One Year test in its present form provides a very small acceleration factor for Ag, it is not a practical test for Ag, although it is the only test known to produce the mixed sulfide/chloride films found at all our field sites. The test could be modified or another test (like flowers of sulfur) should be used for Ag.

Copper.—Figures 4 and 5 show typical depth profiles from field-exposed samples in the basement and central office. Figure 6 shows the depth profile of the one month old coupon from One Year test. The principal constituents in all the films are oxygen, chlorine, and carbon (not shown), and, of course, copper. In the central office environment the film also contains small amounts of sulfur. Table I presents the constituents of the film in order of decreasing peak heights. Figure 7 shows thicknesses calculated from the Auger depth profiles for the copper coupons exposed in the basement as a function of time (also see Table III). Also shown in Fig. 7 are the film thicknesses measured by cathodic reduction (10). These thicknesses are generally smaller since cathodic reduction only measured the oxides of copper.

The corrosion of copper can be fitted to a parabolic growth rate (11)

$$x^2 = kt \quad [3]$$

where k = parabolic rate constant, x = thickness, and t = time.

From the experimental curve 1 in Fig. 7, we derive a value for $k = 2 \times 10^{-12}$ cm²/month (or 0.78×10^{-18} cm²/sec). This rate constant would predict that in 40 years approximately 3100Å of film will develop on copper. In comparison, Wagar (9) has given the film thicknesses developed in telephone central office en-

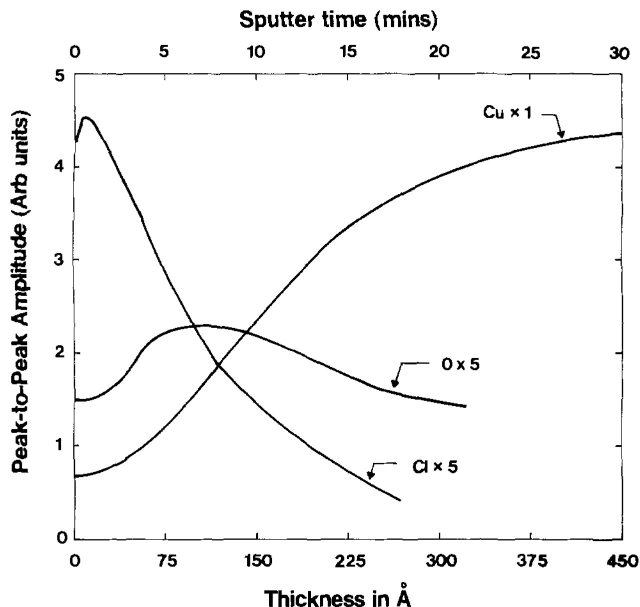

Fig. 4. Auger depth profile of the film on Cu coupon exposed to 3 months in basement field chamber.

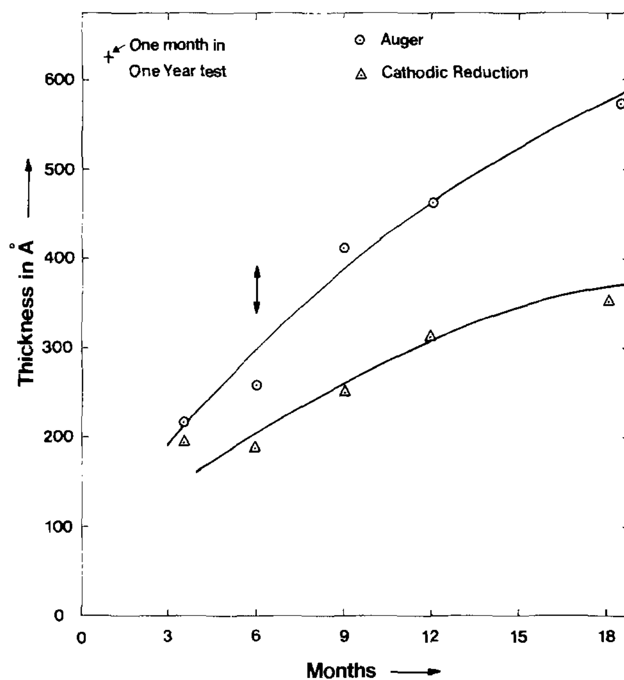

Fig. 7. Film thickness plotted as a function of time for copper corrosion in basement.

vironments up to 10 years. His data can also be fitted to a parabolic growth rate model. His measurements provide a k value of 5×10^{-12} cm^2/month and would predict 4900Å thick film on Cu in 40 years. Wagar's (9) data are believed to be typical of telephone central office environments of 1930-1940 period when there was no central air conditioning in the central offices. These environments are therefore comparable to Cleveland basement environment as regards the humidity and temperature excursions. The calculated values of film thicknesses compare favorably with these results. These predicted thicknesses also compare favorably with other results on copper corrosion in central office environments of 1920-1930 period.

Cathodic reduction measurements can also be fitted to a parabolic growth rate model with $k = 0.9 \times 10^{-12}$ cm^2/month ($\sim 0.35 \times 10^{-18}$ cm^2/sec) and would predict an oxide thickness of only 2100Å in 40 years. The total film thickness calculated earlier was 3100Å in 40 years. The remaining film is mostly chloride.

From the One Year test we get a film thickness of 625Å in one month and $\sim$1100Å in 3 months. This provides a corrosion rate constant of $\sim 40 \times 10^{-12}$ cm^2/month. From the field measurements in the basement environment $k = 2 \times 10^{-12}$ cm^2/month. Therefore, the acceleration factor is approximately 20 for copper exposed in the basement. In the design of the test, it was anticipated that the acceleration factor would be greater than 40. The low value of acceleration achieved in the real test may be due to several reasons. The test is based on water adsorption on gold and not copper. The high relative humidity is employed to achieve corrosion reactions with certain constituents of air (like sulfur, chlorine). However, the oxidation rate

* Number in parenthesis represents measurements on another part of the coupon.

of copper decreases with increasing relative humidity as shown by Campbell and Thomas (12) and the net effect may be a slower increase in film thickness at high relative humidity. In addition, the solubilities of pollutant gases decrease with increasing temperature as explained earlier. Lack of information about the activation energy of the complex corrosion reaction in real field environments is another factor. Consequently, the acceleration factor obtained in the test is lower than anticipated.

Figure 8 shows the thickness of the film on copper coupons exposed in the air-conditioned central office environment. The thickness of the films is considerably smaller than in the basement. Also shown in this figure are the thicknesses measured on the copper coupons exposed in other central office environments for 12 months. Film thickness on copper in most central office environments varies between 150-250Å in one year. Chiarenzelli (13) has observed that in a New York City office building the total film thickness in 13.6 months is ~280Å, which compares favorably with our results. The corrosion of copper in an air-conditioned central office environment proceeds slowly with a rate constant k between 0.3×10^{-12}-0.5×10^{-12} cm^2/month. The film thickness on a copper coupon in central office environment would be 1200-1550Å in 40 years. The acceleration factor for copper in a central office environment can be derived in a similar manner and is about 100.

Various investigators (5, 9, 14) have studied the natural films developed on copper in real field environments. Our studies indicate that the corrosion film contains oxides, chlorides, and small amounts of sulfides. The predominant constituents are the oxides (Cu_2O and CuO) and chlorides and not Cu_2S. In cathodic reduction, the reduction potential of the reducing film matches with that of Cu_2O, substantiating the conclusion that most of the film is Cu_2O. Environmental tests, which mainly produce Cu_2S, are not representative of telephone central office environments and may not be suitable laboratory tests for copper. The peak-to-peak intensity ratio of Cu to oxygen in Cu_2O is approximately measured to be 2.6 (15). In the field-exposed samples and also in the One Year test, the ratio of Cu to O (peak-to-peak heights) is not constant and is generally different (larger) than 2.6. Some of the Cu in the film is bound to chlorine. The film is a mixture of copper chloride and copper oxides, the relative amount varying from film to film. Carbon is also present as a surface specie. When S and Cl Auger peak heights are corrected for their sensitivities relative to that for the O-peak (16) and the corrected peak heights of Cl and S are added to the O-peak height, the ratio of Cu-peak height to the peak height sum of anions ($O^=$, Cl^-, and $S^=$) is found to be much less than 2.6. This points out that the copper is in a higher oxidation state (cupric) than Cu_2O as observed by Frankenthal and Thompson (15) in their experiments on Cu_2O exposed to flowers of sulfur. The copper chloride, therefore, may be $CuCl_2$ and the oxide may partly be CuO.

Nickel.—Figures 9 and 10 show typical depth profiles for samples exposed in the basement and third floor central office. Similar spectra have been obtained on other samples exposed to various times. The constituents of the films are oxygen, chlorine, sulfur, and carbon as shown in Table I. The thickness of the film developed on Ni exposed in the central office is plotted as a function of time in Fig. 11 (also see Table IV). In 2 years of exposure, a film 32Å thick is obtained. This is a thinner film than on copper. The major constituent of the film is oxygen. Nickel oxidation has been

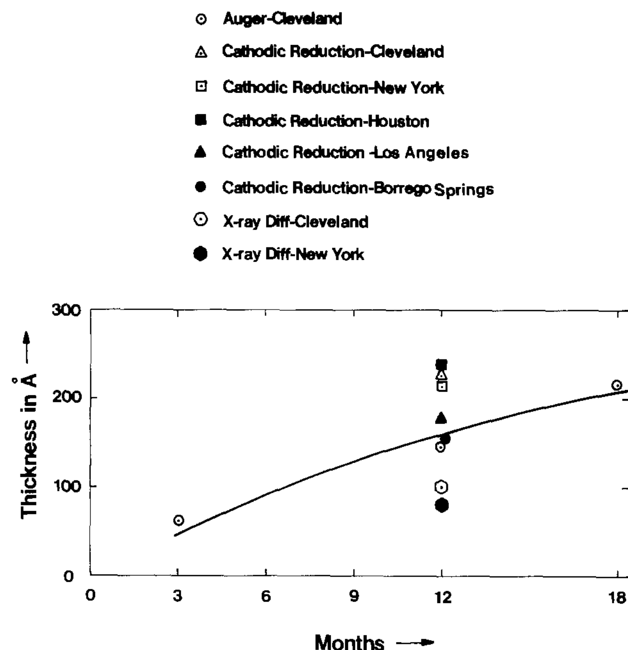

Fig. 8. Film thickness developed on copper in various central offices.

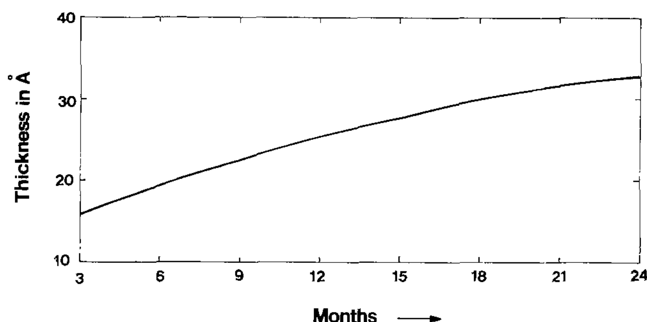

Fig. 11. Film thickness on Ni plotted as a function of time for Ni corrosion in the central office environment.

studied at low temperatures by various investigators. Nickel does not undergo appreciable oxidation at temperatures below 300°C. Kulpa and Frankenthal (17) reported a limiting thickness of 15Å at 200°C in dry air, which was found in good agreement with the value of ~17Å at 200°C reported by Graham and Cohen (18). Graham and Cohen (18) also reported a limiting thickness of about 10Å at room temperature while Kulpa and Frankenthal (17) reported a thickness of about 4-5Å. In the central office environment we measured a thickness of about ~16Å in 3 months which increased to ~32Å in 2 years. Chiarenzelli (13) also observed that the films on nickel developed in the field are very thin and highly insulating and coherent. Our observations are in agreement with his results. It is well known that in the absence of water vapor the oxidation of nickel is self-limiting and ceases after one to two monolayers of the oxide (17). NiO is a p-type semiconductor and oxide grows by the diffusion of cation vacancies (11, 17, 18). As the relative humidity increases the thickness of the oxide increases, probably because of adsorbed water on the surface causing an increase in the cation vacancy concentration at the surface (19). Air-conditioned central office environments have an average relative humidity of ~40%. The oxide growth on Ni in the central office is, therefore, rather slow. In addition to oxide, the other constituents in the film are sulfur, chlorine, and carbon. The total film thickness is slightly larger than if only an oxide grows on the surface in the drier air.

The corrosion of nickel has been fitted to a parabolic growth rate model. This model provides conservative acceleration factors. The parabolic growth rate constant for Ni corrosion in central office environment is approximately 5×10^{-15} cm²/month. The One Year test develops a film 80Å thick (Fig. 12) in one month and ~140Å thick film in 3 months with no further significant increase in film thickness with time. The test, therefore, provides an acceleration factor greater than 100 with respect to the central office environment. Since the film probably approaches a limiting thickness in the field (asymptotic film growth rate) and also in the test as a function of time, the acceleration factor calculated is only approximate. As mentioned earlier, a parabolic growth rate model has been used in this study, since the acceleration factors so obtained are conservative.

The ratio of nickel to oxygen in the film varies from 0.71 to 0.88. Theoretically, Kulpa and Frankenthal (17) had shown that the ratio of I_{Ni}/I_O should be less than these numbers if the film which grew on nickel was only NiO (*e.g.*, $I_{Ni}/I_O = 0.66$ at 30Å). The remaining Ni in the film is associated with Cl and S. Wootton and Birks (20) have studied the oxidation of nickel in atmospheres containing SO_2 (oxygen partial pressure

Table IV. Thickness of films on nickel

24	Basement	195
1	Test chamber	80
3	Test chamber	140
12	Test chamber	140

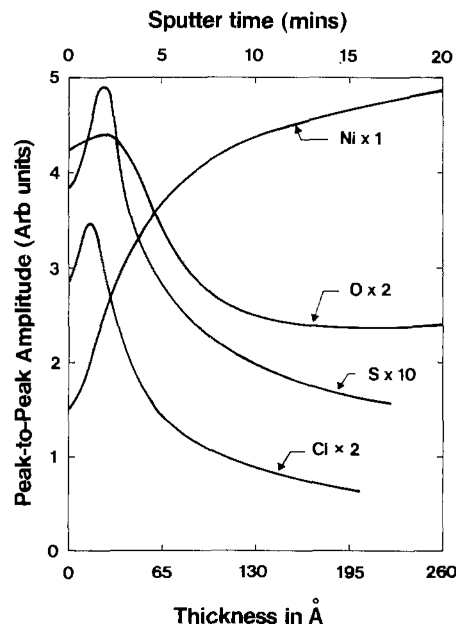

Fig. 12. Auger depth profile of the film developed on Ni exposed for one month in One Year test.

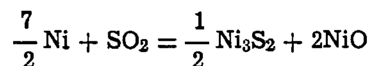
<10^{-6} atm) at higher temperatures. They have concluded that the composition of the film in SO_2 environment is NiO and Ni_3S_2



$$\frac{7}{2} Ni + SO_2 = \frac{1}{2} Ni_3S_2 + 2NiO$$

They also reported that preoxidation of Ni reduces the sensitivity of Ni to SO_2 attack. In the real life environment (air) the amount of oxygen available is more than SO_2. We therefore expect that the major constituent of the film would be NiO plus small amounts of Ni_3S_2.

The films developed on Ni exposed in the basement are harder to analyze because a few samples contain excessive amounts of carbon. The carbon layer is thick and may arise from several sources. It is possible that some of these samples became dirty due to improper handling. But the 6 and 12 month coupons do not contain excessive carbon and have been analyzed further. Since the films developed are thin (unlike copper), a small amount of contamination will cause the results to be misleading. An interesting but not surprising observation is that the films which contain large amounts of carbon also show high contact resistance.

Table IV provides the film thicknesses for various samples. Assuming a parabolic growth rate, these two coupons can be utilized to extrapolate the film thicknesses and derive the acceleration factors. An average parabolic growth rate constant k from these two coupons is $\sim 2.4 \times 10^{-14}$ cm²/month. Comparing it with the coupons in the One Year test chamber, an acceleration factor ~27 is obtained for the basement nonair-conditioned environment. This low acceleration factor may again be due to the fact that the adsorption isotherms used were for gold and not for nickel and that the solubilities of gases decrease with increasing temperature.

Conclusions

The growth kinetics of Ag, Ni, and Cu in an air-conditioned telephone central office environment and nonair-conditioned environment (in the Cleveland central office basement) have been obtained. The constituents and film thickness on these materials were primarily obtained by AES. In first 2 years silver tarnishes linearly, the basement growth rate being 30-35 Å/month. The major constituents of films on Ag are Cl and S. Copper corrosion has been fitted to a parabolic growth rate model and provides a rate constant of $\sim 2 \times 10^{-12}$ cm²/month in the basement and 0.3×10^{-12} cm²/month in the central office environment. The extrapolated value of corrosion film thickness on copper in a period of 40 years is ~3100Å in the basement and 1200-1550Å in the central office environment. The major constituents of the corrosion film on Cu in the field are oxygen and chlorine. Nickel tarnish rates are much slower and films only 32Å thick are obtained in 2 years in the central office and ~60Å thick film in the basement in 12 months. The major film constituents are oxygen, chlorine, and sulfur. These observations on Cu, Ni, and Ag are consistent with the published literature.

The coupons exposed in the chamber (One Year test) have also been analyzed for their constituents and film thicknesses. The constituents are similar to films grown in the field. Film thicknesses on these coupons have been used to calculate the acceleration factors for the One Year test. For the basement environment the OneYear test provides an acceleration factor of ~4.0 for Ag, 20 for Cu, and 27 for Ni. The test is not a practical test for Ag. For the central office environment, the acceleration factors for Cu and Ni are greater than 100. Since the test provides a suitable balance between air-conditioned and non-air-conditioned environment, it is an excellent accelerated test for the atmosphere corrosion of Cu and Ni.

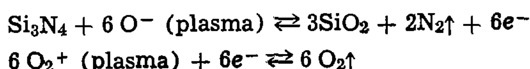
ABSTRACT

A process of conversion of oxide/nitride into a single layer oxide using plasma oxidation at moderate temperature (≤800°C) is discussed. Physical parameters, refractive index, etch rate, etc. of this plasma-converted oxide are found to be similar to that of thermal SiO_2. In addition, dielectric strength and charge level in such insulator are also comparable to thermally grown SiO_2. Metal oxide semiconductor (MOS) structures as well as MOSFET device characteristics indicate its excellent feasibility as a gate dielectric in MOS technology.

Silicon nitride is used in the gate dielectric because of high dielectric strength and dielectric constant, the ability to mask against diffusion and oxidation, and resistance to penetration by positively charged ions. However, these MNOS IGFET's suffer from threshold voltage (V_T) degradation when stressed at elevated temperatures. This shift is due primarily to charge trapping at the oxide/nitride interface and, as such, presents a reliability concern. In certain IGFET technology, it is advantageous to use oxide/nitride structure in areas other than the gate regions in order to take advantage of nitride passivation characteristics during device fabrication. In such applications, the effect of trapping could be minimized if oxide/nitride gate dielectric is replaced by single-layer oxide dielectric without major change in MNOS device process. This work discusses a process of conversion of oxide/nitride into a single layer gate dielectric using plasma oxidation at moderate temperature (≤800°C). Characteristics of this plasma-converted oxide with respect to (*i*) fixed charge incorporation due to plasma exposure; (*ii*) insulator integrity or breakdown strength; (*iii*) refractive index; and (*iv*) etch rate are investigated. Bias-temperature stress aging of MOS capacitors is studied to investigate flatband voltage stability. Hot electron trapping is characterized by avalanche injection of MOS capacitors and stress aging of MOSFET devices.

Experimental Details

Preparation of the plasma-oxidized nitride films.—Thin silicon nitride films may be converted to SiO_2 at moderately low temperature through plasma-enhanced oxidation reaction of nitride. The nature of this anodization process is believed to be as follows



$$Si_3N_4 + 6\,O^- \text{ (plasma)} \rightleftarrows 3SiO_2 + 2N_2\uparrow + 6e^-$$

$$6\,O_2^+ \text{ (plasma)} + 6e^- \rightleftarrows 6\,O_2\uparrow$$

The processing sequence of obtaining plasma-oxidized nitride films consists of:

(*i*) Standard wafer cleaning; (*ii*) Thermal oxidation in dry oxygen in system prepurged with HCl to minimize contamination and charge level. Oxide thus fabricated showed refractive index of 1.47 and dielectric constant of 3.9; (*iii*) Chemical vapor deposition of thin nitride film. Nitride films had refractive index of 2.0 and dielectric constant of 7.0; (*iv*) Plasma oxidation of overlayer nitride in a plasma reactor in an ambient of dry O_2 and argon. (A schematic of the reactor is shown in Fig. 1. A typical processing condition is shown in Table I.) Converted insulator exhibited refractive index of 1.47 and dielectric constant of 3.9-4.0; (*v*) Postanodization anneal to minimize charge level.

Device fabrication.—Silicon substrates used in this study were of p-type and of resistivity either 2 or 0.05 Ω cm. Metal oxide semiconductor (MOS) capacitors consisting of this plasma-oxidized insulator were fabricated by evaporating aluminum dots as field plates. Aluminum was also deposited on the back side and annealed in forming gas at 400°C for about 20 min. Mobile charge levels were checked by the *I-V* loop technique (1) after biasing the capacitors at 200°C and $+2.0 \times 10^6$ V/cm for 10 min. Mobile ion contamination (N_I) in all runs under investigation was consistently below 10^{10} cm^{-2} level while fixed charge levels were below 1×10^{11} cm^{-2}. Film thickness was measured with an ellipsometer. Experimental MOSFET devices were also fabricated. First source and drain regions were formed using an arsenosilicate glass source as a dopant. After cleaning, the gate dielectric was grown as described above. Aluminum was used as the gate metal. After aluminum evaporation, the device wafers were also treated in a forming gas anneal at 400°C for about 20 min. Conventional photolithography was used throughout. Conversion of standard dual dielectric MNOSFET into a single layer dielectric plasma-converted oxide MOSFET is illustrated in Fig. 2. Devices thus fabricated had a threshold voltage range of approximately +1.3V for ~70 nm of converted SiO_2 gate dielectric of 2 Ω cm p-silicon wafers using initial oxide/nitride thickness of 38/15 nm. Standard fixed charge density, N_{SS}, breakdown, bias-temperature stress aging, and avalanche injection measurements were carried out to characterize the quality of the plasma-converted insulator layer for stability and charge trapping. Standard MNOS and MOS structures were used as reference for comparison.

Results and Discussion

Table II summarizes the physical characteristics of this plasma-anodized insulator layer. It is seen that the refractive index and etch rate are quite comparable to thermal SiO_2.

Charge level and effect of anneal.—Experiments were designed to study the effect of annealing on charge level and flatband voltage. Three types of annealing ambients were investigated: forming gas, N_2, and a mixture of N_2 with 2 m/o (mole percent) O_2. Details of the annealing conditions are summarized in Table III. It may be noted that the net positive charge density is low for all samples on plasma exposure. Either a N_2 anneal at higher temperature (1075°C) or a forming gas anneal at lower temperature (850°C) resulted in almost charge-free insulator. As shown in the table, an anneal in a mixture of O_2 and N_2 at 1000°C did not reduce fixed charge level in the insulator when compared to annealing in N_2 at the same temperature. This observation may support the postulate that the plasma-converted insulator may not be oxygen deficient and, therefore, fixed charges in such insulators may not be associated with incomplete oxidation.

Breakdown strength.—Figure 3 shows the breakdown distribution of the plasma-oxidized insulator layer compared with thermal SiO_2 MOS data. As is seen from Fig. 3, the lower mode of breakdown distribution around 2-4 × 10^6 V/cm observed in thermal SiO_2 is not observed in plasma MOS structures. Breakdown distribution ranges from 6.5 × 10^6 to 9 × 10^6 V/cm and compares favorably with thermal SiO_2.

Flatband voltage stability.—MOS capacitors were stressed at 190°C and +2 × 10^6 V/cm for 18 hr to determine the stability of the flatband voltage. The data obtained is tabulated in Table IV. It is clear that the shift data of flatband voltage are quite compatible to the PSG-MOS and better than composite films of Si_3N_4/SiO_2 MOS capacitors.

Trapping characteristics.—Electron trapping characteristics were studied by avalanche injection of MOS capacitors, after Nicollian and co-workers (2). The technique is more completely described by Gdula (3). Typical results are shown in Fig. 4 where trapped charge density $\Delta Q/q$ is plotted against injected electron density N_{inj}. The latter was computed from simultaneous gate current measurements. Trapping behavior of these plasma-oxidzed films is compared with that of PSG/SiO_2 and of a composite of Si_3N_4/SiO_2 and of thermal SiO_2. It is seen that traps in plasma-oxidized insulator are comparable to CVD PSG/SiO_2 films. Trap density of such films is significantly lower when compared with Si_3N_4/SiO_2 composite films. However, thermal SiO_2 films exhibit minimum density of traps. For PSG-oxide and plasma-oxidized insulators, a change in slope is observed at $N_{inj} \simeq 10^{14}$ cm^{-2}, indicative of another kind of a trap center. The associated initial $\Delta Q/q \simeq 10^{11}$ cm^{-2} is due to the large cross section traps associated with fixed oxide charge (4). It is known that this fixed oxide charge could be minimized by extended annealing

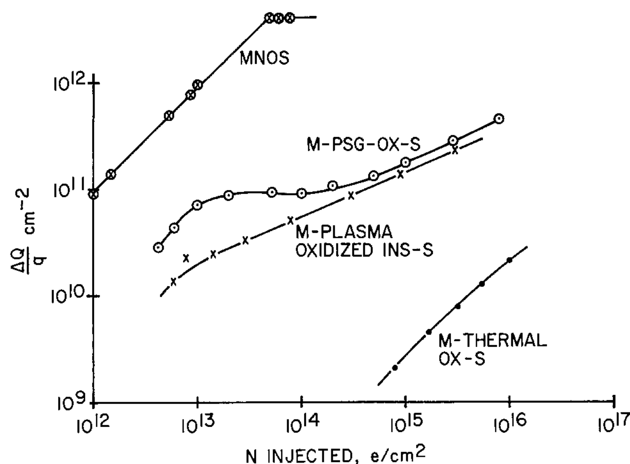

Fig. 4. Charge-trapping characteristics of plasma-oxidized insulator.

time. The relationship between insulator trapping characteristics and hot electron-induced threshold voltage shift and subsequent design margin and reliability has been discussed by Abbas and Dockerty (5). Such hot-electron design relief is obviously greater in oxide (MOS) than in oxide-nitride (MNOS), where nitride offers more trapping sites. Hot electron relief over MNOS structures as observed from capacitor data is further confirmed by stress aging MNOSFET and plasma-oxidized gate dielectric MOSFET devices. Figure 5 shows the threshold voltage shift data obtained, with the stress conditions shown in the notes of the figure. The data indeed confirms that the plasma-oxidized gate insulator does trap less than the composite nitride/oxide gate dielectric, thereby offering design ability of an FET circuit at a drain voltage of 2.75V higher than the corresponding circuit with MNOS FET devices.

Conclusions

Plasma-converted oxide from oxide/nitride dual dielectric layer demonstrates characteristics similar to thermally grown oxide in refractive index, etch rate, effective charge, and breakdown strength. Low N_{SS}, N_I has also been demonstrated. Bias-temperature stress data of plasma-converted oxide shows better stability compared with that of oxide/nitride and of oxide/PSG structures.

Avalanche injection data indicates that trapping characteristics are comparable to PSG/SiO_2 structures and are midway between thermal SiO_2 and oxide/nitride composite dielectric structures.

An Estimation of the Quantum Yield in the Candoluminescence Process by Low Energy H^+ Ion Bombardment

I. S. T. Tsong, Andres Corredor, and William B. White*

and N. H. Tolk and J. S. Kraus

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The luminescent quantum yields for $Zn_2SiO_4:Mn^{2+}$ and $Y_2O_3:Eu^{3+}$ phosphors under hydrogen ion beam excitation have been determined at 300°K as a function of beam energy in the range 1-8 keV. The dependence of the yields on the energy of the H^+ bombarding ions follows an exponential relation and the yields extrapolated to zero ion energy are $\eta_o = 4.0 \times 10^{-6}$ for $Zn_2SiO_4:Mn^{2+}$ and $\eta_o = 2.7 \times 10^{-4}$ for $Y_2O_3:Eu^{3+}$.

Candoluminescence is usually defined as a process of light emission from solids under flame excitation, in excess of thermal radiation. The candoluminescence phenomenon has been recently reviewed by Ivey (1). Flame excitation of phosphor materials at relatively low temperatures, *i.e.*, room temperature to a few hundred degrees, has been observed by a number of workers and it has also been found that similar luminescence can be excited in the absence of a flame by generating active species of hydrogen or nitrogen in an arc or microwave plasma (2-5). This flameless excitation phenomenon has given rise to the term "radical-recombination luminescence" (RRL) and its physical process is considered to be similar to candoluminescence.

Despite its obvious importance, there have been remarkably few measurements of the quantum yield of the candoluminescence or RRL process. The difficulty no doubt lies in the fact that one cannot easily count the number of recombinations or impacts of particles (radicals, ions, etc.) on the phosphor surface when one is using a flame or an rf discharge as the excitation source. A knowledge of the quantum yield would allow us to assess the applicability of candoluminescence to lighting device development.

In previous determinations of quantum yield of RRL (6-8), calorimetric techniques were employed where the number of recombinations was estimated by the heat output caused by the recombination of the hydrogen or nitrogen atoms on the phosphor surface. A typical value of the quantum yield, *i.e.*, number of photons per recombination, is of the order of 10^{-4}. One disadvantage of the technique is that the rise of temperature recorded may be due to processes, *e.g.*, collision with the surface, other than recombination alone. Moreover, it is not at all certain that the luminescence is caused by just one particular species of the gas atoms since there is no mass separation involved and the vacuum in the apparatus is generally poor.

In the present work, we attempt to measure the quantum yield by using an entirely new approach. The surfaces of two candoluminescent materials, $Zn_2SiO_4:Mn^{2+}$ and $Y_2O_3:Eu^{3+}$ were bombarded with a low energy H^+ ion beam at room temperature. In this way we can measure the number of H^+ arriving at the surface since we can measure the ion current, and the photon output is measured by single-photon counting. The quantum yield is therefore a simple ratio of the two. We chose to examine the above two materials because of their different luminescence characteristics. $Zn_2SiO_4:Mn^{2+}$ is a broad-band emitter, whereas $Y_2O_3:Eu^{3+}$ is a line emitter. Moreover, the quantum yield of $Zn_2SiO_4:Mn^{2+}$ has been measured by Sommermeyer (6) and Styrov *et al.* (8), and we can make a comparison between our results and theirs.

Experimental

Figure 1 shows the schematic diagram of the experimental apparatus. The ion beam unit consists of a Colutron ion source. The ion mass is selected by a velocity filter. The energy of the ion beam can be varied from 10 eV to 10 keV. The H^+ ion current was $\sim 1 \times 10^{-6}$A at 8 keV but decreased to $\sim 1 \times 10^{-8}$A at 1 keV. This could not be avoided as this was the characteristic of the ion beam extraction and acceleration systems. It is considered to be a difficult problem in present-day ion beam technology to produce a well-focused, mass-analyzed, as well as high flux ion beam at energies below 1 keV. The production of such ion or atomic beams are subjects of specialized research (9, 10). The ion beam and the optical axis of the monochromater (0.3m McPherson) are at right angles to each other, while the incident-beam makes an angle of 50° with the target normal. Single photon counting is used to measure the light output. Such experimental setup had been used to observe optical emis-

Key words: luminescence, quantum theory, ion exchange.

sion from sputtered particles during heavy ion bombardment (11). However, in the present experiment the sputtering effect caused by H^+ ion was negligible and the observed emission was entirely due to luminescence from the bulk of the solid.

The original powder samples were compacted into solid disks by using a binder solution commonly used in scanning electron microscopy. The two samples were mounted on the same holder, one above the other. Bombardment of the sample was accomplished by sliding each sample into the beam path at each energy setting of the beam. The beam spot on the target surface was 3 mm in diameter. There was no heating stage in the target holder and the samples remained at room temperature during bombardment.

The ion current was measured by a picoammeter when the target holder was positioned in such a way as to allow the entire ion beam to strike the exposed metal parts of the target holder in between the two samples. This ion current was found to be virtually unchanged when the ion beam was incident on the insulating phosphor targets. This interesting observation suggests the possibility that a small voltage (say $\sim +10V$) buildup may have occurred between the phosphor and the metal target-holder, and the $\sim 10^4$ V cm^{-1} field thus created pulls electrons from the metal into the phosphor, giving rise to an observed current on the picoammeter. This 10^4 V cm^{-1} is uniform and is small compared to fields encountered in electroluminescence, and these electrons therefore generate no luminescence themselves. A tungsten filament was positioned close to the target surface and when this was turned on to flood the surface with electrons, no change in the luminescence intensity was observed. From this it was concluded that the sample surface did not charge up during ion bombardment.

The vacuum in the target chamber during bombardment was $\sim 10^{-7}$ Torr. The intensities at 525 nm for $Zn_2SiO_4:Mn^{2+}$ (Sylvania Type 161) and 613.5 nm for $Y_2O_3:Eu^{3+}$ (Sylvania Type 1130) were measured as a function of ion energy. The slit width of the monochromater was 500μ. The detection sensitivity of the optical system was determined by means of calibration against a standard tungsten lamp. The quantum efficiency of the optical detection, *i.e.* the number of photons detected per emitted photon, at the wavelength of interest was thus determined and this was used to correct the measured intensities. The calibration of the optical system is a standard procedure and has been described in detail by other workers, see, *e.g.*, Andersen *et al.* (12), and will not be repeated here.

To test whether any deterioration of the phosphor had taken place during the H^+ bombardment, the luminescence was first measured as a function of decreasing ion energy unti the signal becomes comparable to noise, and then the steps were repeated as a function of increasing ion energy. The reproducibility of the data indicated there was little or no deterioration of the phosphor targets during our experiment. This absence of deterioration is probably due to negligible sputtering effect by the H^+ ions.

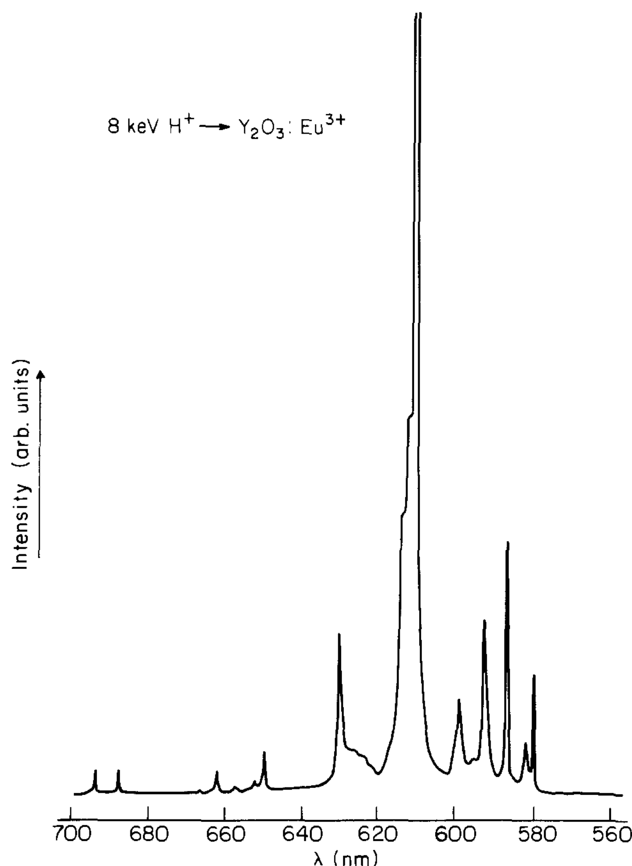

Fig. 3. Emission spectrum of $Y_2O_3:Eu^{3+}$ under 8 keV H^+ bombardment.

Results

The luminescence spectra of $Zn_2SiO_4:Mn^{2+}$ and $Y_2O_3:Eu^{3+}$ bombarded by H^+ ions are shown in Fig. 2 and 3. The variation of the quantum yield of the two samples as a function of the H^+ ion energy is shown in Fig. 4 and 5. The quantum yield is defined as the number of photon counts per incident ion. The number of photons counted experimentally per second before correcting for the quantum efficiency of the optical detection system was of the order of 10^6 for both samples at 8 keV. This number decreased to $\sim 10^2$ at 1 keV, comparable to the background radiation detected. The background counts were due to scattered light from the heated ion source filament. It was hoped at the onset of the experiment to extend the luminescent intensity measurement to an H^+ ion energy of 10 eV, the lower limit of the Colutron ion beam system. However, no further data were taken below 1 keV since the signal was comparable to the background noise.

The straight lines drawn through the data points in the log-linear plots shown in Fig. 4 and 5 show that the quantum yield dependence on energy can be represented by the expression

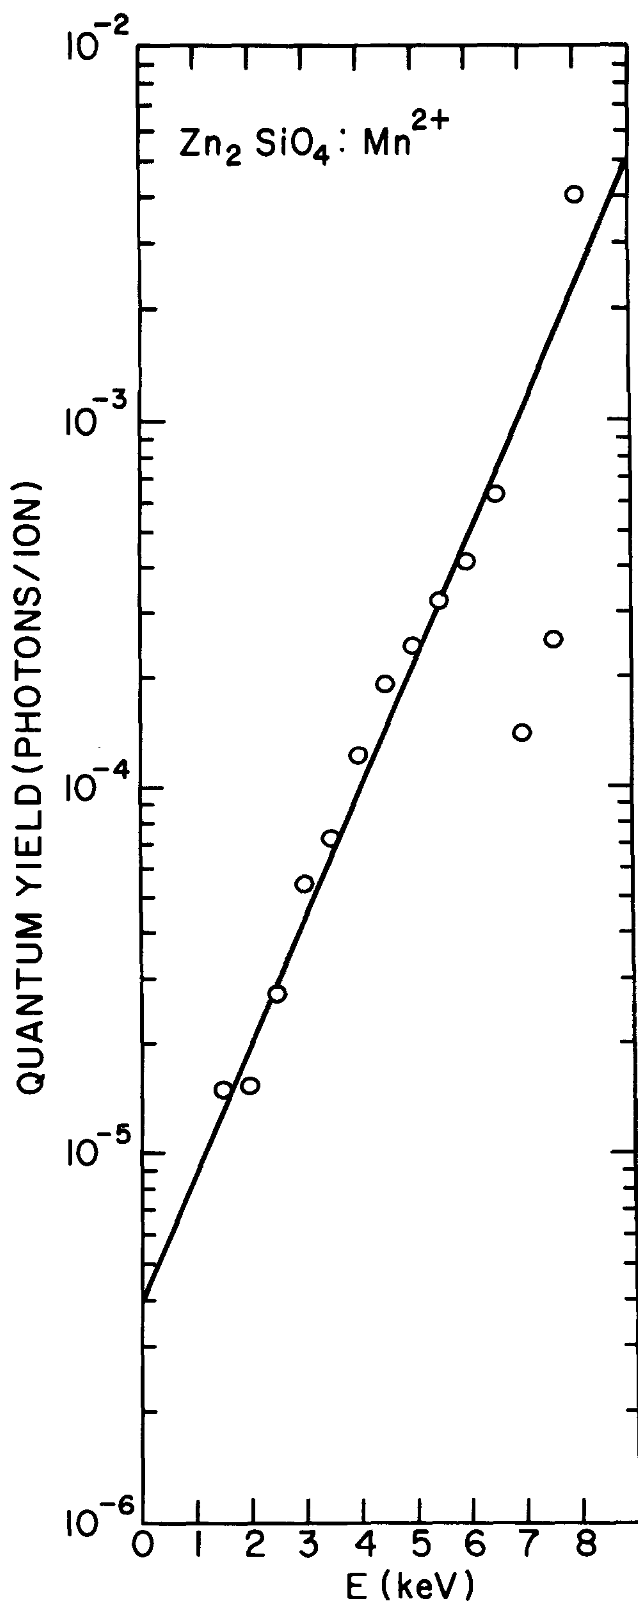

Fig. 4. Dependence of quantum yield of Zn_2SiO_4:Mn^{2+} on H^+ ion energy.

$$\eta = \eta_o \exp(aE) \qquad [1]$$

where η_o and a are constants. If the plots are extrapolated to zero energy, then we obtain

$$\eta_o = 4.0 \times 10^{-6} \text{ for } Zn_2SiO_4:Mn^{2+} \qquad [2]$$

$$\eta_o = 2.7 \times 10^{-4} \text{ for } Y_2O_3:Eu^{3+} \qquad [3]$$

Discussion

The quantum yield at room temperature, $\eta = 4.0 \times 10^{-6}$ for Zn_2SiO_4:Mn^{2+} when extrapolated to zero energy, is remarkably similar to the η value, 8.2×10^{-6}, given by Styrov *et al.* (8) and 5×10^{-6} by Sommermeyer (6) for the RRL process measured by the calorimetric method. There is no corresponding η value determined for Y_2O_3:Eu^{3+}. However, a quantum yield of 5.8×10^{-2} for cathodoluminescence was quoted by Garlich (13), which compares favorably with the η values obtained at ion energies above 4 keV in the present work (see Fig. 5).

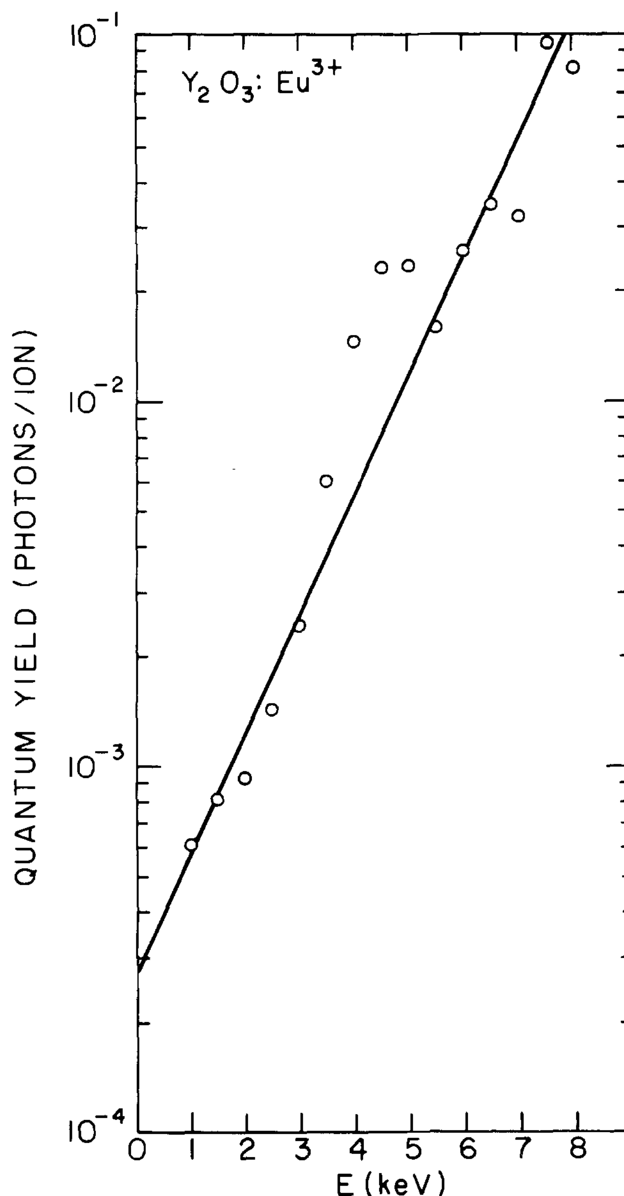

Fig. 5. Dependence of quantum yield of Y_2O_3:Eu^{3+} on H^+ ion energy.

Eve and Duckworth (14) have reported the observation of luminescence from Zn_2SiO_4:Mn^{2+} when bombarded by heavy ions at high energies (6-25 keV). An intensity-energy relationship of the type

$$I \sim (E - E_o)^n \qquad [4]$$

was reported, where n has a range of values between 1.29 and 1.83 for bombardment by various heavy ions except hydrogen. Heavy ion bombardment can cause sputter-induced optical emission (11) which Eve and Duckworth probably were not aware of at the time. Since no wavelength selector was used by them to isolate the luminescence from other emission from the Zn_2SiO_4:Mn^{2+} sample, it is not certain how their final results would be affected. Moreover, sputtering by heavy ion bombardment could cause rapid deterioration of the phosphor. Clearly, the results of the

present work in the lower energy range (1-8 keV) indicate a different intensity-energy relationship from Eq. [4]; and the intensity is shown to fall off much more rapidly with decreasing energy.

Our procedure of extrapolation to zero energy may not be justified on the grounds that it is not known whether the quantum yield values at energies below 1 keV would follow the same exponential behavior as those at higher energies. Measurable light signals at energies <1 keV would be feasible if a high flux ion beam is available (we have already discussed the problems associated with high flux and low energy ion beams in the Experimental Section), so that quantum yield data can be extended to energies of only a few electron volts. The luminescence observed in the present work is caused by the kinetic energy transfer of the bombarding ions to the electrons in the solid (15), whereas in RRL, it is postulated that the potential energy of the recombining atoms is involved in exciting the phosphor. The question remains whether, in addition to the kinetic energy of the H^+, the 13.5 eV available in potential energy from capturing an electron by the incoming H^+ ion

$$H^+ + e^- \rightarrow H, \quad \Delta E = -13.5 \text{ eV} \quad [5]$$

can also be utilized. We can picture, for instance, the incident proton capturing an electron from some valence band ~13 eV deep by a resonance-transfer process, whereupon the hole created is ultimately captured on the Mn^{2+}. An electron drawn in from the metal base of the target holder is then captured also, producing Mn^{2+*} which emits. Another possibility would be the Auger neutralization (16) of the incoming H^+ ion by a valence electron tunneling through the potential barrier, creating a hole in the valence band. The excess energy of this neutralization process then excites a second electron into the conduction band. The electron-hole pair then recombines at the activation center Mn^{2+}, resulting in emission.

Some such chain of events [see for example Ref. (1)], though of course not identical with those described above, is implied by Styrov *et al.* (8) and Sommermeyer (6) when they link their observed Mn^{2+} emission to the potential energy available from the recombination of adsorbed H atoms

$$H + H \rightarrow H_2, \quad \Delta E = -4.55 \text{ eV} \quad [6]$$

We find it surprising that our η_o, obtained by simple extrapolation to 0V as if the potential energy contribution is an additive constant and representing the efficiency of the conversion of this potential energy into Mn^{2+} emission, is so close to the quantum yield values given by Styrov and Sommermeyer. It is surprising that two H atoms combine and transfer their potential energy to the Mn^{2+} center with the same efficiency as one H^+ is neutralized by creating a hole which ultimately leads to Mn^{2+} excitation and emission. This suggests that both mechanisms of radical recombination and charge neutralization may be responsible for the candoluminescence process, since both radicals and ions (17) are present in the flame acting as the source of excitation.

Luminescence from $Zn_2SiO_4:Mn^{2+}$, $Y_2O_3:Eu^{3+}$, and other phosphors when bombarded by N_2^+ and other heavy ions at very low energies (~ 40 eV) have been recently reported by Kramer (18). By comparison with luminescence from a ZnO sample, Kramer estimated quantum yield values as high as 1 photon per 40 N_2^+ ions. However, the experimental situation was complicated by the presence of an electron beam (~ 20 eV) which also bombarded the sample surfaces. We do not understand the high yields reported by Kramer, three orders higher than the η_o values reported here, except perhaps that the 20 eV electrons may interact with the positive ions in some very advantageous manner to transfer the energy to the Mn^{2+} and Eu^{3+} centers.

Kramer also observed characteristic blue-green luminescence from ZnO bombarded by low energy heavy ions only (19). Once again very high quantum yield was reported compared to the value 7×10^{-6} for ZnO reported by Styrov *et al.* (8) for RRL, and the process was attributed to the creation of electron-hole pairs in the phosphor due to the Auger neutralization of the incoming ions (16).

The quantum yields quoted apply to a temperature of 300 K and are not necessarily the maximum yield attainable. Both candoluminescence and RRL exhibit a characteristic bell-shaped dependence of intensity on temperature. For both $Zn_2SiO_4:Mn^{2+}$ and $Y_2O_3:Eu^{3+}$ the luminescent intensity is low at room temperature, increases as the temperature increases, reaches a maximum at some intermediate temperature, and then decreases to low values as the temperature is further increased. The temperature at which maximum brightness occurs is a function of activator, phosphor host, and recombining species (20, 21). The peak brightness occurs in $Zn_2SiO_4:Mn^{2+}$ at 40°C for H_2 radical recombination, and at 178°C in the hydrogen flame. The corresponding value for the flame excitation of $Y_2O_3:Eu^{3+}$ is 210°C. It has been argued (22) that in RRL the number of recombinations depends on the competition between the rate of adsorption of the atoms arriving on the surface and the rate of desorption of the same atoms. Then the maximum in the brightness-temperature curve can be explained on the basis of the variation of the relative rates of desorption of recombined neutral species as contrasted with the desorption of freshly adsorbed active species at different temperatures. It is therefore expected that the effective quantum yield would also be a sensitive function of temperature. However, in the present experiment, if the luminescence is the direct result of electronic excitation in the solid by the bombarding ions, then the observed quantum yields would probably not increase with increasing target temperature. It would be most interesting to carry out similar experiments at target temperatures above room temperature in order to understand the full implication of the similarity between the quantum yields determined by low energy H^+ ion bombardment and those determined by calorimetric method.

Conclusions

The trend of our quantum yield measurements of the luminescence of $Zn_2SiO_4:Mn^{2+}$ and $Y_2O_3:Eu^{3+}$ caused by H^+ ion bombardment in the 1-8 keV range indicates that at ion energies close to zero, the quantum yield is not too different from that in RRL where excitation is assumed to be the result of potential energy transfer. It would be desirable to extend the measurements to energies ~ 10 eV if and when a high flux ion beam at such low energies becomes available. Measurements of quantum yield at elevated target temperatures would also be useful.

Direct Observation of Dislocations in $Ga_{1-x}Al_xAs$-GaAs Grown by the LPE Method

Satoshi Komiya and Tsuyoshi Kotani

Fujitsu Laboratories Limited, 1015 Kamikodanaka Nakahara-ku, Kawasaki, Japan

ABSTRACT

Transmission x-ray topographs of thick LPE $Ga_{1-x}Al_xAs$ layers grown on (001) GaAs substrates were obtained by a double crystal Lang technique using monochromatic divergent radiation and compared with the etch pit pattern revealed by molten KOH. It was observed that most threading dislocations bend abruptly at the interface. Although the substrate parts of these dislocations were of various types, the epitaxial parts were clearly classified as either [001] oriented, β-, or arc-like dislocations. Nonequivalent behavior of threading dislocations between the two <110> directions was observed. Some effects due to melt-back of the substrate prior to the epitaxial growth are discussed.

It has been ascertained that the rapid degradation of $Ga_{1-x}Al_xAs$-GaAs double heterostructure lasers was due to the appearance of a nonluminescent area, called a dark line defect (DLD). The DLD oriented to the <100> or <110> direction has been observed by photoluminescence (1) and scanning electron microscopy (2). Petroff and Hartman have shown that the <100> DLD was associated with a dislocation network originating from a threading dislocation in the epitaxial layers (3). Some growth mechanisms from a threading dislocation to a dislocation dipole have already been proposed and discussed (4-7). It seems that these mechanisms are closely related to properties of threading dislocations.

Ishii *et al.* have observed dislocations in thin GaAs epitaxial layers by using molten KOH (8). Most dislocations propagate from the substrate to the epitaxial layers but some of them disappear in the epitaxial layers. Kumar and Takagi recently studied dislocations in a thick homoepitaxial layer on a GaAs (111) As face substrate by using x-ray topography (9). It was observed that some new dislocations are generated during the growth in addition to normal threading dislocations. Dislocations in a thick epitaxial $Ga_{1-x}Al_xAs$ layer have been rarely studied by x-ray topography because a wafer with a thick epitaxial layer is bent due to the lattice mismatch between the substrate and epitaxial layer. In this report, transmission x-ray topographs of (001) GaAs wafers with thick heteroepitaxial $Ga_{1-x}Al_xAs$ layers were obtained by a double crystal Lang technique with a curved monochromater crystal (10), and then compared with the etch pit pattern on the epitaxial layer produced by molten KOH.

Key words: liquid phase epitaxy, III-V compound, dislocation, x-ray topography, etch pit.

Experiments and Results

An epitaxial $Ga_{1-x}Al_xAs$ layer has been grown on a (001) GaAs substrate by liquid phase epitaxy. The method of growth is similar to that reported by Blum and Shih (11). The characteristics of the samples are summarized in Table I, where melt-back of the substrate has been employed for sample II by a temperature rise of 3.8°C. X-ray topographs are obtained under conditions of anomalous transmission (μt = 12-14) by a double crystal Lang technique using monochromatic divergent radiation made by a curved (111) Ge crystal (10). Cu-Kα_1 radiation and Ilford L4 50 μm

Table I

	Sample	x	Carrier concentration (cm^{-3})		Thickness (μm)
Substrate	GaAs		Undoped	2×10^{16}	300
I	$Ga_{1-x}Al_xAs$	0.40-0.10*	Te	6.2×10^{17}	51
II	$Ga_{1-x}Al_xAs$	0.40-0.073*	Te	—	66

* The values decrease monotonously from the interface (x = 0.4) to the surface (x = 0.10 or 0.073).

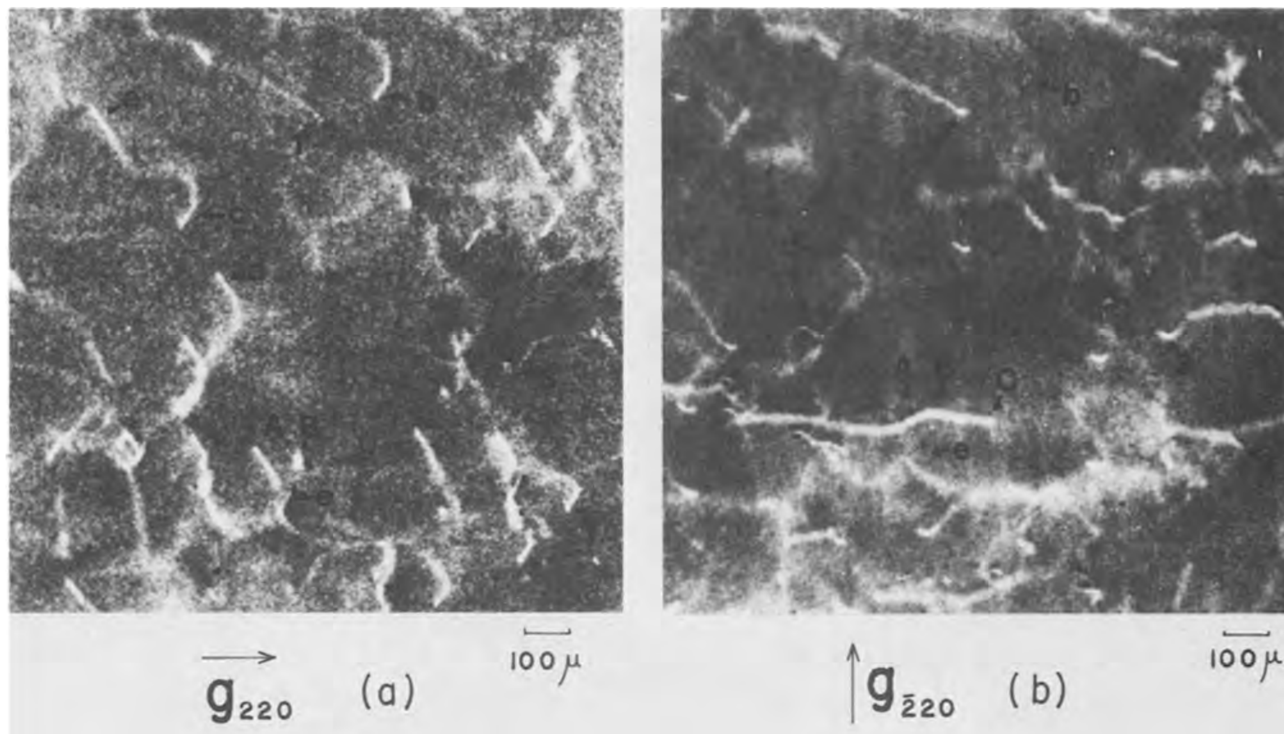

Fig. 1. Transmission x-ray topographs of the as-grown epitaxial wafer I. The epitaxial surface was toward the emulsion. The topographs are the projection on the (001) growth plane, and a sharp end point of a dislocation line in the photographs corresponds to the intersection at the epitaxial surface.

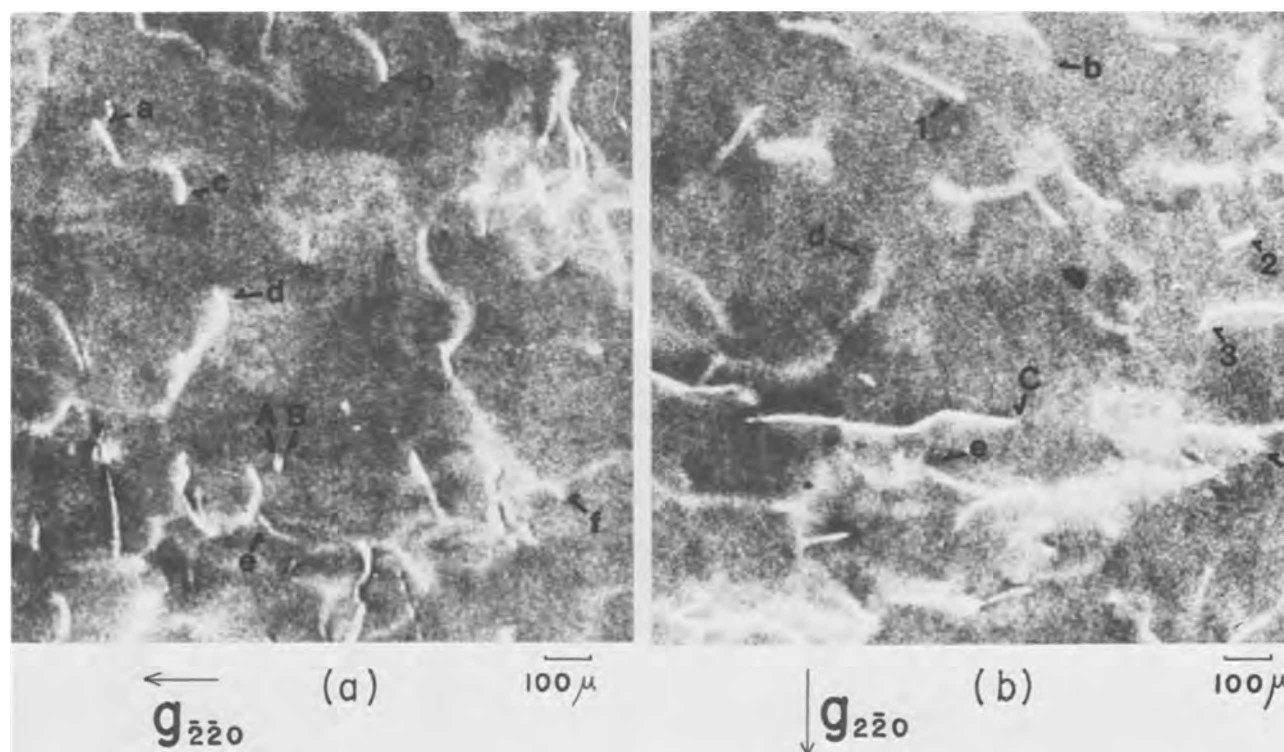

Fig. 2. Transmission x-ray topographs of the substrate of the sample I, from which the epitaxial layer has been removed by etching. The etched surface was toward the emulsion.

nuclear emulsions were employed. Transmission x-ray topographs of the as-grown wafer I and its substrate are shown in Fig. 1 and 2, respectively. The opposite diffraction vectors for the substrate were employed in order to study the effect of bending on the contrast of a dislocation image, but no conspicuous changes were observed. The epitaxial part of a dislocation image is identified by comparison between x-ray images of a dislocation in the two topographs [Fig. 1(a) and 2(a) or Fig. 1(b) and 2(b)], and how it propagates from the substrate to the epitaxial layer can be determined.

It has been reported that the etchant ($H_2O/H_2O_2/CH_3COOH/HF$) is a dislocation etchant for $Ga_{1-x}Al_xAs$ epitaxial layers (12). Molten KOH is a good dislocation etchant for (001) GaAs (13, 14). Molten KOH is also more effective for observation of

dislocation etch pits on the $Ga_{1-x}Al_xAs$ (001) face with only a small value of x ($\lesssim 0.25$) than the etchant ($H_2O/H_2O_2/CH_3COOH/HF$).[1] A gold crucible is employed for molten KOH instead of fused silicate glass or platinum because they are attacked by molten KOH. Temperature of the molten KOH is controlled at 360° ± 2°C by using an Al-Cr thermocouple inserted into a gold tube. The etch rate of the GaAs (001) face is 0.40 μm/min, and etch pits become observable after etching for 2-3 min. The etch pit pattern on the epitaxial layer of sample I is shown in Fig. 3. Similarly, transmission x-ray topographs of the as-grown wafer II and its etch pit pattern are shown in Fig. 4 and 5. There is good agreement between the etch pit patterns and the emergent end points of the dislocations observed on the x-ray topographs.

The two nonequivalent <110> directions in the (001) growth plane of a GaAs substrate have been distinguished with the diffraction technique of Bartels and Niyman (15) and compared with hexagonal etch pits. The result is shown schematically in Fig. 6.

Most dislocations in the epitaxial layer propagate from the substrate and can be classified into three types according to their x-ray images and shapes of etch pits, although the types of the sample I are not always equivalent to the types of the sample II. Many of the classified dislocations are marked with three kinds of symbols, *i.e.*, capital letters, small letters, and numbers. A dislocation is marked with the same symbol on the x-ray topographs and etch pit patterns.

A careful study of the etch pits and topographs as well as comparing the diffraction contrast for a given dislocation under different diffraction conditions has led to the identification of the following dislocation types: Type I-1, Dislocations associated with the large hexagonal etch pits A, B, and C in Fig. 3(a) are oriented along the [001] growth direction in the epitaxial layer. Dislocations A and B are parallel to the [001] direction in both substrate and layer. Dislocation C runs along the [110] direction in the substrate

[1] The dislocations of types I-3 and II-3 have not been revealed as etch pits by the etchant ($H_2O/H_2O_2/CH_3COOH/HF$).

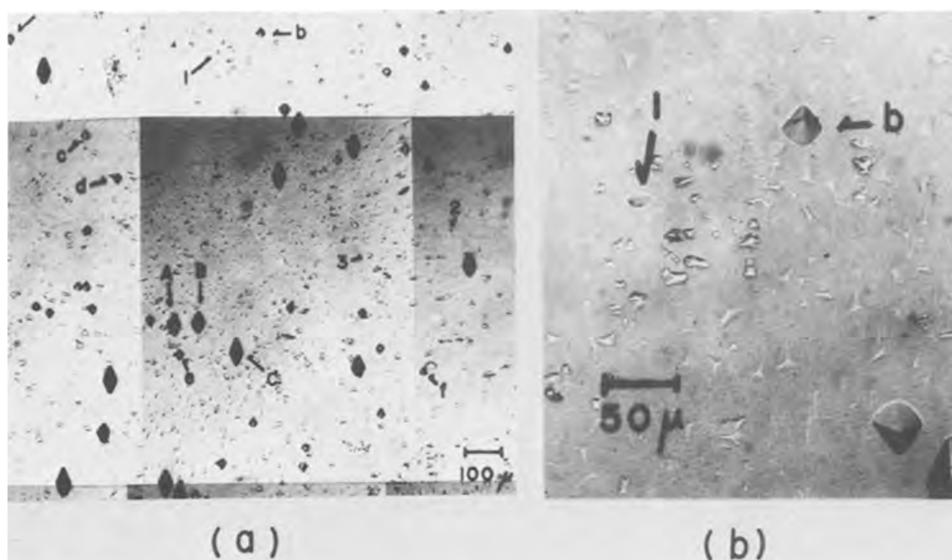

Fig. 3. Etch pit pattern revealed on the epitaxial surface of the sample I by molten KOH at 360°C ($x = 0.13$ on the etched surface).

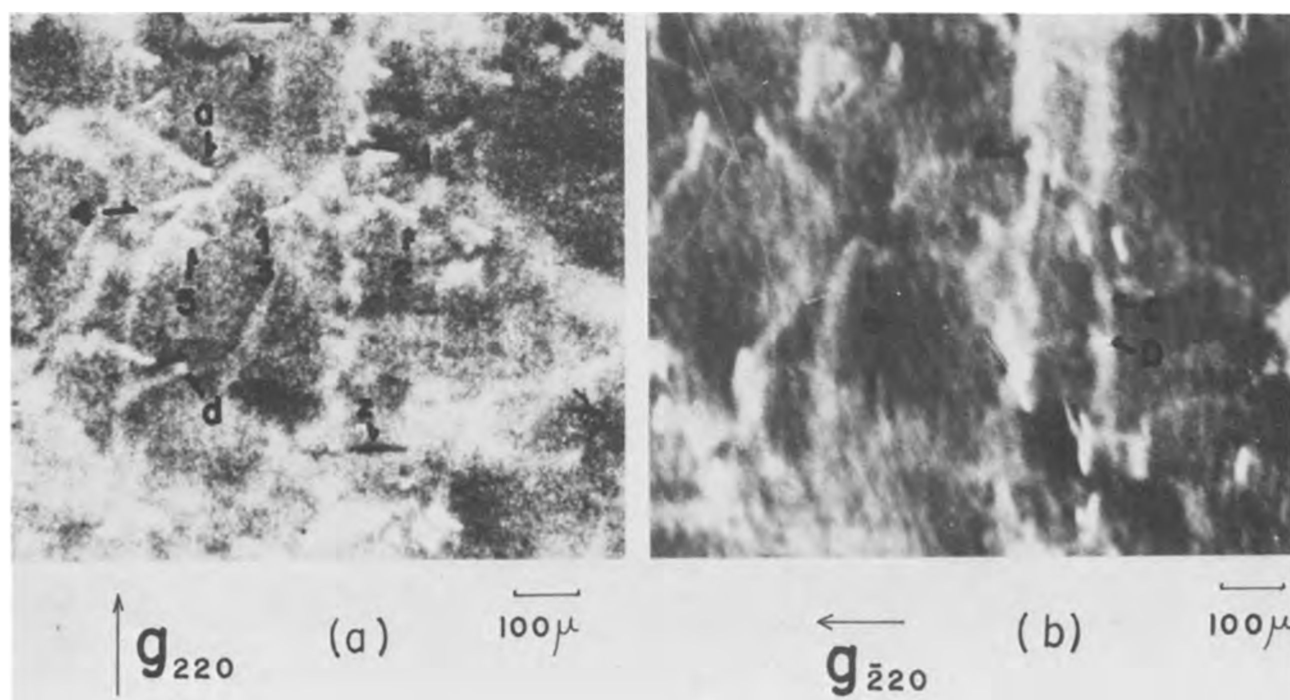

Fig. 4. Transmission x-ray topographs of the as-grown epitaxial wafer II. The conditions are similar to that of sample I

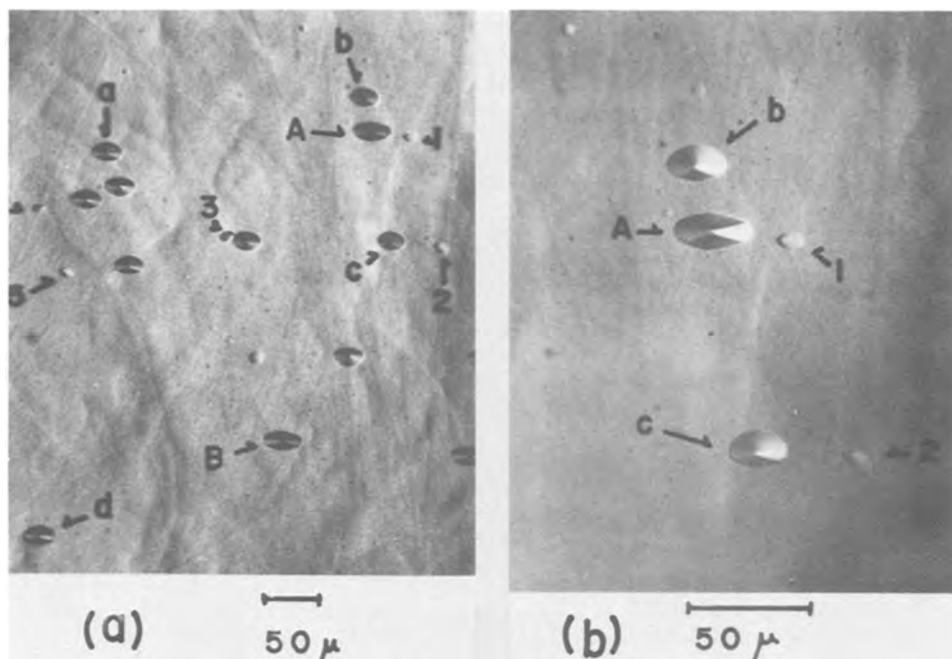

Fig. 5. Etch pit pattern revealed on the epitaxial surface of sample II by molten KOH at 360°C (x = 0.20 on the etched surface.

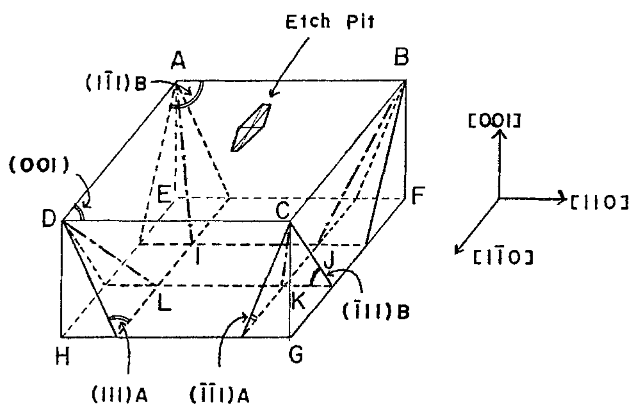

Fig. 6. The relation between x-ray polarity of {111} planes (A- and B-face) and the hexagonal etch pit is shown schematically, where the growth direction is denoted as <001>.

with $\pm a/2$ $[\bar{1}10]$ Burgers vector and abruptly bends to the [001] direction in the layer; Type I-2, The epitaxial part of the threading dislocations b and c in Fig. 1(a) and 2(a) are 60° dislocations oriented along the $[0\bar{1}1]$ direction ($\overline{LD}$ in Fig. 6) with $\pm a/2$ [110] Burgers vector. These dislocations correspond to the pyramidal etch pits b and c in Fig. 3; Type I-3, The small arc-like images denoted with numerals are epitaxial parts of threading dislocations with $\pm a/2$ $[\bar{1}10]$ Burgers vector and correspond to the small etch pits in Fig. 3.

In the case of sample II, stacking faults y and z are observed in the x-ray topograph shown in Fig. 4(a). However, stacking faults are not always associated with melt-back of the substrate and will not be discussed here. Type II-1, Dislocation associated with the large hexagonal etch pit A in Fig. 5(a) or 5(b) corresponds to the blurred point-like image with $\pm a/2$ $[\bar{1}10]$ Burgers vector in Fig. 4(b) and is identical with the type I-1; Type II-2, Etch pits a and d in Fig. 5(a) correspond to the similar point-like images, but are clearly distinguished from the etch pit A. The epitaxial parts of these dislocations a and d are nearly oriented to the [001] direction with $\pm a/2$ [110] Burgers vectors; Type II-3, Dislocations denoted with numerals correspond to the small etch pits in Fig. 5, and their epitaxial parts are oriented to various directions in Fig. 4.

Discussion

Etch pits on each epitaxial surface of samples I and II are clearly classified into three types from their shapes and sizes. Their sizes are mainly associated with the inclination of a dislocation so as to be supported from the results of the x-ray topographs. The dislocations of the type II-2 are nearly oriented to the [001] direction, and sizes of their etch pits are comparatively similar to that of the type II-1, but the shapes are similar to that of the type I-2 rather than the type II-1 or I-1. It has only rarely been reported that the shape of etch pits depends on the kind of a dislocation (16). The geometry of the hexagonal etch pit and polarity of {111} planes (A- or B-face) are schematically shown in Fig. 6. Furthermore, etch pits on the (001) GaAs, $Ga_{1-x}Al_xAs$, and $GaAs_{1-y}Sb_y$ by molten KOH under the same condition are shown in Fig. 7 and this result suggests that the shape of a hexagonal etch pit also depends on the component atoms. The shape of an etch pit depends on the etching properties of some specific planes, the arrangement of atoms on their lattice planes, and the kinds of their component atoms. Therefore, it seems that the dislocation of the type II-2 is clearly distinguished from one of the type II-1.

Ettenberg and Paff reported that there is a perfect lattice matching between AlAs and GaAs at about 900°C (17). Mismatch of this sample ($x = 0.40$ at the interface) is about 5×10^{-3}% at 850°C, which epitaxial growth stops, and about 0.056% at room temperature. Moreover, there is some mismatch due to the different doping level.[2] Dislocations of the substrate propagate in the epitaxial layer under this mismatch so that most of the substrate dislocations bend at the interface and propagate through the epitaxial layer as one of the three types. A few dislocations of the substrate which accidentally belong to some of the three types pierce straight through the epitaxial layer (A or a in Fig. 1). There are fewer dislocations of the type I-1 than of the type I-2 or I-3, since dis-

[2] A wafer with a thick Te-doped GaAs epitaxial layer ($\sim 10^{17}$ cm^{-3}) of about 100 μm on the Te-doped GaAs substrate ($\sim 10^{18}$ cm^{-3}) has been concave in the growth direction in contrast to samples I and II, and its radius is about 10 m.

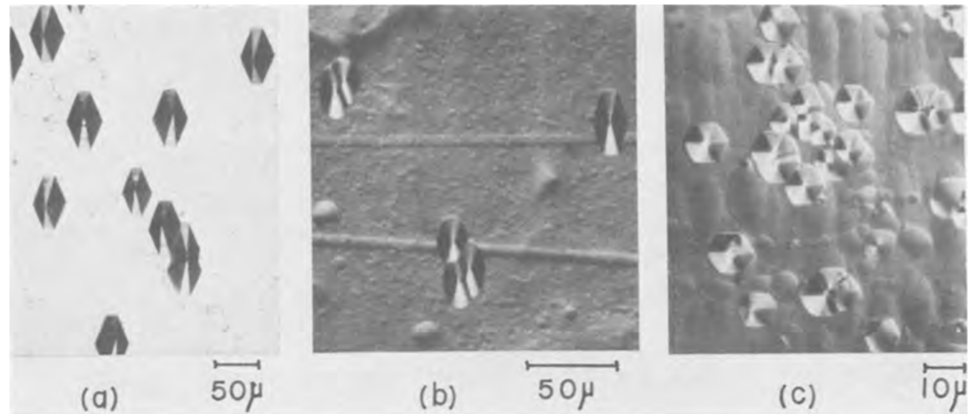

Fig. 7. Etch pit patterns (a), (b), and (c) revealed on the (001) face of the GaAs substrate, the $Ga_{0.83}Al_{0.17}As$ epitaxial layer, and the $GaAs_{0.93}Sb_{0.07}$ epitaxial layer by molten KOH at 360°C, respectively.

locations of the type I-1 are less effective in the relaxation of lattice mismatch. It seems that the difference between dislocations of the type I-2 and I-3 is associated with the two nonequivalent <110> directions in the (001) growth plane (16, 18, 19). Most 60° dislocations of the type I-2 have Burgers vector $\pm a/2$ [110] in the (001) plane and are oriented to either the $[\bar{1}01]$ or $[0\bar{1}1]$ direction (IA or LD in the Fig. 6). Since the extra (111) half-plane probably tends toward the substrate from the larger lattice constant of the GaAlAs, both of them are β-dislocations. They serve to relax the mismatch component of the $\pm$ [110] directions.

On the contrary, most dislocations of the type I-3 have Burgers vector $\pm a/2$ $[\bar{1}10]$ and are convex to the $\pm$ $[\bar{1}10]$ directions in Fig. 1(b). Therefore, it seems that these dislocations are half-loop-like dislocation rather than helical ones. They relax the mismatch component of the $\pm$ $[\bar{1}10]$ directions.

Other wafers with various epitaxial layers ($\gtrsim$ 8 μm in thickness, x = 0.05-0.3) have been studied only by the etching technique because of the low resolution of x-ray topography. For example, etch pits which were revealed on the $Ga_{0.95}Al_{0.05}As$ layer of a thickness of about 10 μm are also classified into three types from their sizes, though all etch pits are hexagonal due to the small Al concentration. Considering the shift of these etch pits by repetitive etching, the difference between sizes of these etch pits, and their crystallographically simple structures, dislocations of the types I-1 and I-2 probably exist in the $Ga_{1-x}Al_xAs$ epitaxial layers.

Since the difference intentionally added to the sample II is only a point of melt-back by a temperature rise of 3.8°C prior to the epitaxial growth, the difference between the results of the sample II and I is mainly caused by melt-back. Saul has reported the decrease of etch pit density in the epitaxial layer GaP owing to melt-back (20). He suggested the formation of half-loops or partial loops (21) due to the climb process by many vacancies or interstitials. In this case, all dislocations of the substrate which intersect to the interface propagate to the epitaxial layer. Comparing Fig. 1 with Fig. 4, some irregular distortions of lattice planes, especially the $(\bar{1}10)$ plane, are guessed from many uneven vertical stripes. It seems that the behavior of threading dislocations in sample II, therefore, is perturbed by local distortions, while the behavior in sample I is probably natural. However, it is not clear why only some types of dislocations of the substrate propagate to the epitaxial layer and whether this behavior of threading dislocations is the essential effect of melt-back, though melt-back is perhaps subject to making some localized stress.

Conclusion

Nearly all dislocations in the $Ga_{1-x}Al_xAs$ epitaxial layer originate from the substrate and few dislocations generate during the LPE growth except some stacking faults in sample II. Most of these threading dislocations bend at the interface. Their epitaxial parts are clearly classified into three kinds, though the corresponding substrate parts consist of various kinds. Most dislocations of the substrate with Burgers vector $\pm a/2$ [110] and $\pm a/2$ $[\bar{1}10]$ propagate through the epitaxial layer as β-dislocations and arc-like dislocations, respectively. For the sample of the substrate with melt-back prior to the epitaxial growth, most threading dislocations also bend at the interface and the dislocations oriented nearly to the [001] direction increase.

Acknowledgments

The authors wish to thank Mr. O. Ueda for helpful discussions and Mr. S. Isozumi for providing the samples.

ABSTRACT

Chlorine concentration profiles in thermal silicon oxides prepared in O_2/HCl and H_2O/HCl ambients at 900°-1100°C have been determined using secondary ion mass spectrometry (SIMS). The oxides represent various processing conditions, including 0-10 v/o HCl in the oxidizing ambient, 0.25-4.0 hr oxidation time, and 0.05-0.25 μm oxide thickness. For all O_2/HCl oxides, chlorine is found to be piled up in the oxide in a region less than 200Å from the Si-SiO_2 interface. The chlorine peak concentration increases with increasing HCl concentrations, oxidation temperatures, and oxidation times. Highest concentrations are observed at 1100°C, where values as measured in this investigation range up to 2.4×10^{21} cm^{-3} (3.5 a/o). No appreciable amount of chlorine is found in oxides prepared in H_2O/HCl ambients. These results are discussed in relationship to previous investigations involving chlorine profiles, oxidation kinetics, and passivation properties of chlorine oxides.

Recent work carried out in these laboratories has dealt with the kinetics of silicon oxidation at 900°-1100°C in oxygen and water ambients containing small amounts (1-10 v/o) of HCl (1-3). In these and other studies (4-6) it was found that the addition of HCl to the oxidizing ambient increases the oxidation rate for dry O_2, but does not for H_2O. It has been reported that for dry O_2 ambients some type of chlorine species remains in the oxide in a narrow region near the Si-SiO_2 interface (7-10). This may result from a reaction between O_2 and HCl, whose reaction products also are probably responsible for the increased oxidation rate. Oxidized silicon samples prepared for Ref. (1) and (3) were evaluated using secondary ion mass spectrometry (SIMS) analysis, and concentration profiles of chlorine in the oxides were obtained. The results of this brief investigation are reported, with special emphasis on process variable effects.

Experimental

Sample preparation.—As indicated above, the oxidized samples used in this evaluation were selected from those prepared in previous oxidation kinetic studies (1, 3). They involved for the most part 4-6 Ωcm (111) n-type silicon substrates with oxide thicknesses in the range 0.05-0.25 μm (the majority of oxide thicknesses were about 0.10 μm). Oxidation temperatures were 900°, 1000°, and 1100°C, and 1-10 v/o HCl was added to a dry O_2 or pyrogenic H_2O oxidizing ambient. Flow rates were controlled by calibrated flow meters. Other experimental conditions, procedures, and equipment were described previously (1, 3).

Key words: SIMS, oxidation, spectrometry.

Analysis technique.—The procedure and apparatus used for the SIMS analysis were similar to those reported earlier for determining cesium profiles in thermal oxides (11). Briefly, the sample being analyzed was sputter etched using 8 keV Ar^+ ions at a rate of 12-16 Å/min as determined by crater step measurements. Also, these rates have been verified by comparing the original oxide thickness measurement with the position of the $^{35}Cl^+$ and $^{16}O^+$ profiles. The extracted secondary ion beam was mass separated by a quadrupole spectrometer, and the ion current of the species being investigated was measured as a function of time. The measurements were performed at 2×10^{-7} Torr residual pressure while the argon partial pressure was 5×10^{-6} Torr. The depth resolution is estimated to be about 5% of the sputtered film thickness, or 50Å for the typical 1000Å oxide films. The secondary ion yields of Cl^+ in SiO_2 are less than a factor of 3 greater than in silicon, while the sputter rates in Si and SiO_2 differ by not more than 10% under these measurement conditions (12). No evidence for charging effects on the Cl species due to the sputter etch procedure was indicated.

The chlorine concentration was calibrated by implanting $^{35}Cl^+$ into a silicon substrate and obtaining a SIMS profile as described above. From the known implantation dose and the measured profile, the concentration of $^{35}Cl^+$ at the maximum of the distribution can be computed. An example of an implanted silicon sample used for calibration purposes is shown in Fig. 1. The solid curve is that obtained by SIMS profiling and the dashed curve is that calculated from the Cl^+ implantation conditions. The latter were 40 keV and 1×10^{15} cm^{-2} which results in a predicted peak concentration of 1.9×10^{20} cm^{-3}. The method of

calculating the curve distribution and fitting it to the experimental curve was that reported by Gibbons *et al.* (13) and also used previously (12). It can be observed from Fig. 1 that a reasonably good fit is obtained except at the silicon surface. If both the experimental and theoretical sources of errors are considered, it is predicted that depth errors due to curve broadening should not be more than ± 5%. The validity of this assumption is discussed in the Discussion Section.

Results

Dry O_2/HCl.—Typical chlorine concentration profiles are shown in Fig. 2. These results, also tabulated in terms of peak concentrations in Table I, are for oxides prepared in O_2/5% HCl mixtures at three temperatures. Also included in Fig. 2 is a chlorine profile for an oxide control prepared with no HCl addition. Oxidation times were selected so that oxide thicknesses would all be in the 0.10 μm range. The approximate position of the interface between the SiO_2 layer and the substrate is indicated in the figure by vertical lines. The determination of this interface is based on the known oxide thickness. The interface position was also verified in the SIMS profiles by monitoring the oxygen concentration. Such a plot of both Cl and O concentration profiles is included as an insert in Fig. 2. This helps confirm that the chlorine is essentiallly piled up in the oxide near the Si-SiO_2 interface. It is unlikely that any chlorine extends into the silicon, although it would be difficult to tell because of a ± 50Å uncertainty of the depth resolution in the measurement. The increasing chlorine peak concentration with oxidation temperature is obvious in both Fig. 2 and Table I.

The other trends relating chlorine peak concentrations to O_2/HCl oxidation variables are indicated in Tables II and III. A slight correlation of Cl concentration in the oxide with increasing HCl content in the oxidizing ambient at 1000°C is observed in Table II. A more severe increase in Cl concentration with HCl content is noted at 1100°C in the same table. Table III shows the effect on chlorine concentration at two temperatures due to increasing oxidation times (and oxide thicknesses). HCl concentration in O_2 was 5% at 1000°C and 3% at 1100°C. At both temperatures, the longer time, thicker oxide resulted in higher peak chlorine concentration, with the larger effect being observed at 1100°C. Two peak concentration values are listed for the 1 hr sample at 1100°C, due to a greater variation of this particular measurement.

Included in Tables I-III are the estimated widths of the chlorine peaks in the oxides. They are represented by chlorine peak half-widths. In all cases these thicknesses range from 100 to 200Å, with the majority being about 150Å.

One other comparison was made which was between (111) and (100) oriented silicon. Since only one (100) silicon oxide was profiled, the data are not tabulated. The results are surprising and must be repeated. Essentially, it was found that a (100) silicon oxide duplicating the conditions of the 1100°C, O_2/3% HCl, 1 hr (111) oxide tabulated in the last line of Table III has a peak chlorine concentration of 12.5 × 10^{20}/cm^3, less than either value obtained (15 and 23.7 × 10^{20}/cm^3) for the (111) oxide. Yet the oxide thick-

Oxides are approximately 1200Å thick, except for 1100°C oxide which is not all shown in figure. Profile of control oxide (no HCl) prepared at 1000°C is also included.

nesses are nearly the same and the chlorine peak half-widths are identical.

H_2O/HCl.—Chlorine concentration profiles were obtained for oxides prepared in pyrogenic H_2O/5% HCl mixtures of 900°, 1000°, and 1100°C. A control oxide with no HCl addition was included. Resulting profiles are shown in Fig. 3 and the data are tabulated in Table IV. The first fact apparent is that no real Cl peaks are evident in the profiles. Further, the chlorine concentrations across the oxide layers are nearly the same as the background in the control. The one exception is the 900°C oxide where the Cl concentration appears to increase at the oxide surface to 2.5×10^{20}/cm^3. It is believed that this exception is due to an impurity other than chlorine at the oxide surface (or some other artifact) and is similar to the 1000°C dry O_2 profile in Fig. 2. In any event, the H_2O oxides prepared under the above conditions apparently do not incorporate any significant amount of chlorine.

Discussion

Several trends may be noted regarding the dependence of the peak chlorine concentrations on process conditions used to prepare the thermal silicon oxides. First, the chlorine peak height increases with oxidation temperature. Also, a trend of increasing chlorine concentration with HCl content in the oxidizing ambient is evident. Finally, increasing oxidation time or oxide thickness results in increased peak heights at a given HCl percentage or oxidation temperature. In all these cases the greatest change occurs at 1100°C and under the more severe conditions of oxidation time or HCl concentration at this temperature. For oxidation in H_2O/HCl mixtures, the chlorine apparently does not enter into the oxidation process nor is any appreciable chlorine incorporated into the oxide for the conditions investigated. The relationship of these trends to the oxidation kinetics or to other properties of the oxide

1100	0.15	0.237	—	0.20
1000 (No HCl)	0.15	0.122	—	0.10

will be discussed below, along with the possible silicon orientation effect.

These chlorine concentration profiles in oxides prepared in O_2/HCl ambients can be compared with results reported by other investigators. Most of the previously reported profiles have been carried out using Rutherford backscattering of alpha particles, such as Meek (7), van der Meulen *et al.* (9), and Butler *et al.* (10). Kriegler *et al.* (8) have used the SIMS technique to determine Cl profiles at 1150°C as a function of percent HCl in O_2 (2.5-4.0%), although their chlorine concentrations in the oxide are reported only in arbitrary units. For the above backscattering analyses, the peak concentrations reported range from 2×10^{20}/cm^3 to 2×10^{21}/cm^3. If the exact oxide preparation procedures are considered, all these results are in reasonable agreement with those reported here. For instance, van der Meulen *et al.* (9) report chlorine concentrations for 0.1 μm oxides prepared at temperatures ranging from 900° to 1150°C which are similar to the present values, in that peak concentrations increase from $<3 \times 10^{19}$ to 8.4×10^{20}/cm^3 for 9 v/o HCl in O_2. All these profiles indicate a pileup of the chlorine in the oxide near the Si-SiO_2 interface, and of peak concentration half-widths of less than 200Å.

Even with the apparent agreement between these chlorine concentration and peak-width values and previous backscattering results, some caution must be exercised. As more sophisticated and accurate analytical techniques are being developed, thickness dimensions related to the Si-SiO_2 interface are found to be less than previously assumed (14). Also, the calibration of absolute concentrations such as reported here is very difficult. Therefore values reported for both Cl peak concentrations and widths must be considered as preliminary until more accurate measurements can be carried out. The relative values and their dependence on process variables can be considered significant, however.

The chlorine profile results obtained in this work may also be compared with oxidation kinetic effects and alkali passivation properties of chlorine-containing oxides. If the increased oxidation rates of silicon in O_2/HCl mixtures reported previously (1, 4) are considered, no direct correlation between chlorine incorporation in the oxide and oxidation rate constants can be observed. Rather the kinetic data in Fig. 4 and 5 of Ref. (1) would indicate a more direct relationship between the parabolic rate constant B and HCl content in the oxidation ambient. The linear rate constant at a given temperature is independent of HCl concentration above 1-3%. For H_2O/HCl oxidations (3) no increase in oxidation rate is observed and no significant chlorine incorporation in the oxide occurs over the temperature and HCl concentration ranges investigated. This is more of a negative correlation.

Unlike the oxidation kinetics, the alkali passivation properties appear to be related to the chlorine content as reported by Kriegler (15) and Rohatgi (16). Even so, while the ability of the chlorine to complex alkali ions depends on the peak chlorine concentration above a certain level, certain concentration regions are noted where passivation is not complete or even partially effective (16). On the other hand, the presence of any type of chlorine species in the oxidizing ambient, O_2 or H_2O, appears to provide cleaner, more stable oxides, while oxide fixed charge and interface state density are apparently not affected by even the highest chlorine concentrations (2-3). All of these findings lead to the conclusion that a better understanding of the chlorine passivating effect is needed.

One result obtained in this investigation is not understood and this concerns the differences in chlorine content between (111) and (100) silicon orientation. The data must be considered very preliminary since only one (100) oxide chlorine profile was evaluated. The fact that a greater peak chlorine concentration was observed for (111) silicon as (100) for the same

oxidation conditions is surprising.[2] This is especially true when it is considered that at 1100°C, where the orientation effect on chlorine concentration was noted, the oxidation process is nearly independent of silicon orientation. More comparisons will have to be made to verify if such an effect is real. If it is, some relationship between chlorine concentration and the linear oxidation rate constant and/or interface charges may exist. This would suggest a possible complexing of the chlorine species within the so-called SiO_x interface region, which has been found to depend on silicon orientation (17).

Summary

Chlorine concentration profiles in silicon oxides prepared in O_2/HCl and H_2O/HCl ambients have been obtained using secondary ion mass spectrometry (SIMS). The dependence of these profiles on process variables involved with the oxide preparation has been determined. These variables included oxidation temperature (900°-1100°C), oxidizing ambient (O_2 and H_2O), HCl content in ambient (0-10 v/o), oxidation time (0.25-4.0 hr), and silicon orientation [(111) and (100)]. Oxide thickness over these conditions ranged from 0.05 to 0.25 μm.

Results are in general agreement with those reported previously by other investigators using different analytical methods. Essentially, a chlorine species piles up in the oxide over a region about 150Å wide or less near the Si-SiO_2 interface in the case of O_2/HCl oxidations. The chlorine peak concentration, ranging from 2 to 20 $\times$ 10^{20}/cm^3 as measured in this investigation, increases with oxidation temperature, oxidation time, and HCl content in O_2. The effects are more severe at 1100°C. Little or no chlorine incorporation in the oxide is noted for H_2O/HCl oxidations up to 1100°C and 5% HCl. The chlorine profile results do not appear to correlate directly with oxidation kinetic data obtained for O_2/HCl mixtures, but some correlation is evident for alkali passivation properties reported by other investigators. An apparent dependence of chlorine incorporation in the oxide on silicon orientation has been observed, but the validity of this result must be verified.

Acknowledgments

The authors wish to thank Drs. J. M. Early and J. J. Barnes of Fairchild R&D for critically reviewing the manuscript. Also, thanks are due C. R. Helms and R. W. Barton of Stanford University for providing the Auger analysis mentioned in the paper.

[2] Similar HCl/O_2 oxides from this series were analyzed using Auger spectroscopy by C. R. Helms and R. W. Barton of Stanford University. Their results indicate a 1.5:1 ratio of peak chlorine concentration between (111) and (100) silicon. The half-peak widths, however, are less than 50Å. Also, these Auger results indicate somewhat lower peak concentration values.

Manuscript submitted May 2, 1978; revised manuscript received July 10, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by Fairchild Camera and Instrument Corporation.

Cathodic Deposition and Characterization of Metallic or Semiconducting Binary Alloys or Compounds

F. A. Kröger*

Department of Materials Science, University of Southern California, Los Angeles, California 90007

ABSTRACT

The conditions to be met to achieve cathodic deposition of compounds or alloys of well-defined stoichiometric composition are discussed. If the deposition rate constants of the components are of the same order, two classes of codeposition have to be distinguished, differing in whether the difference in electrode potential of the individual components is larger (class I) or smaller (class II) than the shift in electrode potential of either component as a result of compound or alloy formation. In the former case the potential of the deposit is determined by the less noble component over the entire composition range, the deposition potential shifting monotonically with composition. In the latter case the role of potential-determining species may shift from one component to the other at an intermediate composition, the deposition potential at this composition being more positive than that of either of the components when deposited individually. For class I, quasi rest potentials uniquely characterize the deposits. For class II different deposits may have the same quasi rest potential. Compounds are stable in electrolytes with large concentrations of the normal ions of one of the components in the absence of nonmetal complexes necessary to make cathodic deposition of the compounds possible. If the potential is not determined by adsorbed noncomponent species, the potentials are determined by the normal ions, the concentrations of which are linked by solubility products.

Cathodic codeposition of different elements with formation of metallic alloys or compounds from aqueous electrolytes has been known for a long time (1). Nonmetals such as S, Se, Te, and As and semimetals such as Sb and Bi can be deposited cathodically from solutions of complex ions or molecules (2) and cathodic codeposition of one of these elements and metallic elements with the formation of compounds may therefore also be possible. Examples are found in the formation of CdSe and Ag_2Se (3), Ni-P and Co-P alloys (4), and $Cu_{3-x}As$ (5).

Interactions between the components in the deposit usually shift the deposition potential of the deposit to values that are positive relative to the deposition potential of the less noble component (induced codeposition) (6). In some cases, *e.g.*, for Ni, Sn alloys (7), the deposition potential is positive even relative to that of the noble component, an effect that so far remained unexplained (8).

In this paper the thermodynamic basis of codeposition and the nature of the potential-determining species are considered and on this basis an explanation of the observed effects is arrived at. No attention is paid to the possibility of hydrogen discharge.

Theoretical

The electrode potentials at which codeposition is possible are equal to the quasi rest potentials (QRP) of the alloy or compound plus a polarization which increases with increasing current density. The QRP is defined as the potential of the deposit relative to the electrolyte with activities of potential-determining species as they are at the solid-electrolyte interface during deposition. The polarization is established with a relaxation time $\tau \leq 10^{-3}$ sec. Therefore the QRP can be determined experimentally by measuring the electrode potential $\approx 10^{-3}$ sec after interruption of the deposition current. Further changes of potential occur when the composition of the electrolyte at the interface changes back to the bulk value, a process with a relaxation time of seconds. Equilibration of the deposit with the electrolyte of bulk composition may and usually does cause a marked change in the surface composition of the deposit, changing the QRP to a rest potential. Quasi rest potentials are important for characterizing the bulk of the deposit. They arise as a result of the interplay of four factors: (*i*) the equilibrium potentials of the components (which may be widely different); (*ii*) the interaction of the components when forming the alloy or compound; this interaction changes the activity of the components in the deposit to an extent dependent on the exact composition of the deposit; (*iii*) the values of the activities of ionic species in the electrolyte at the interface solid-electrolyte during deposition (which may be markedly different from those in the body of the bath), and (*iv*) the relative magnitude of the exchange currents of the components in the deposit.

It will be assumed that the QRP is an equilibrium potential relative to an electrolyte of the composition as it is at the deposit-electrolyte interface during deposition. This is not completely correct, for there is no complete equilibrium immediately after interruption of the current, but it will give us some indications of what is to be expected. With this assumption, the first three factors can then be taken into account by expressing the electrode potentials of the components in terms of the activities of ionic or molecular species in the electrolyte at the interface and the activities of the components in the deposit. The former can often be approximated by the concentrations as they are at the interface, but the latter are usually very different from the concentrations.

Let us consider a compound M_rN_s for which deposition of component M involves m electrons, that of component N n electrons. The quasi-rest potentials of M and N then are

$$E_M = E_M{}^\circ + \frac{RT}{m\mathbf{F}} \ln (a_{M^{m+}}/a_M) \quad [1]$$

$$E_N = E_N{}^\circ + \frac{RT}{n\mathbf{F}} \ln (a_{N^{n+}}/a_N) \quad [2]$$

* Electrochemical Society Active Member.

Key words: cathodic deposition, alloy deposition, quasi rest potential, potential-determining species.

Here $a_{M^{m+}}$ and $a_{N^{n+}}$ are activities of the species M^{m+} and N^{n+} in the electrolyte at the interface during deposition and a_M and a_N are the activities of M and N in the deposit. Without loss of generality it may be assumed that M is less noble then N, *i.e.*, $E_N^o > E_M^o$.

The activities a_M and a_N of M and N in the deposit are related through

$$rM(s) + sN(s) = M_rN_s;\ G \quad [3]$$

where G is the Gibbs free energy increment of the reaction. In equilibrium

$$a_{M_rN_s}/a_M{}^r a_N{}^s = \exp(-G/RT) \quad [4]$$

or, since $a_{M_rN_s} \approx 1$

$$a_M{}^r a_N{}^s = \exp(G/RT) \quad [5]$$

A large a_M gives rise to a small a_N, and vice versa. Limiting values of a_M and a_N are determined by the corresponding activities in coexisting phases in the phase diagram. In the simplest case M_rN_s is the only compound in the system, M in coexistence with the compound is almost pure M, and N in coexistence with the compound is almost pure N.

At the two-phase boundaries we then have respectively $a_M = 1$, $a_N = \exp(G/sRT)$, and $a_N = 1$, $a_M = \exp(G/rRT)$.

The variation of a_M and a_N over the existence range of the compound gives rise to a corresponding variation in the quasi rest potentials of M and N, the total variations being, respectively

$$\Delta E_M = -G/rm\mathbf{F} \quad [6]$$

$$\Delta E_N = -G/sn\mathbf{F} \quad [7]$$

Since $G < 0$, these variations are such that the potentials of both components become more positive (*i.e.*, more noble) when their activity decreases.

A homogeneous deposit with two components at a given composition and the a_M and a_N corresponding to that composition can have only one potential. In the absence of potential determination by adsorption of noncomponents such as H^+, OH^-, SH^-, etc., this potential is the result of exchange processes between the electrode and the electrolyte involving the two components, the effects of the components individually depending on their relative contributions to the exchange current. These contributions in turn are equal to the product of characteristic rate constants and appropriate powers of the activities of the involved ionic or molecular species at the solid-electrolyte interface (9).

Two possibilities exist: The rate constants of the exchange currents for the two components are of the same order of magnitude, or these quantities are widely different. In the former case both species have equal weight in determining the potential and a change between their individual contributions can only occur as a result of a change of the activities of species in the electrolyte and the corresponding change in the deposit. In the latter case one of the components may be potential determining under all conditions. For an exact quantitative treatment of this problem it is necessary to have detailed knowledge of the kinetics of processes by which charge transfer for the various components takes place. In the absence of such knowledge it can be stated, however, that a species present at the interface at a concentration close to zero cannot be expected to play a major role in the establishment of the potential: It cannot be a potential-determining species.

Systems is Which the Rate Constants of the Exchange Currents of Individual Components Are of the Same Order of Magnitude

Since a deposit of one composition can have only one quasi rest potential, always

$$E_{M_rN_s} = E_M = E_N \quad [8]$$

This equality leads to a relation between the concentrations of M^{m+} and N^{n+} in the electrolyte at the interface electrolyte-deposit, and this in turn determines the ratio in which the various species contribute to the exchange current, *i.e.*, which is the main potential-determining species. Elimination of E_M and E_N from [1] and [2] with the aid of [8] gives

$$\frac{RT}{\mathbf{F}} \ln (a_{M^{m+}}{}^{1/m}/a_{N^{n+}}{}^{1/n}) = (E_N^o - E_M^o) + \frac{RT}{\mathbf{F}} \ln (a_M{}^{1/m}/a_N{}^{1/n}) \quad [9]$$

Or, at the M_rN_s-M phase boundary

$$\frac{RT}{\mathbf{F}} \ln (a_{M^{m+}}{}^{1/m}/a_{N^{n+}}{}^{1/n}) = (E_N^o - E_M^o) - \frac{G}{ns\mathbf{F}} \quad [10]$$

and at the M_rN_s-N phase boundary

$$\frac{RT}{\mathbf{F}} \ln (a_{M^{m+}}{}^{1/m}/a_{N^{n+}}{}^{1/n}) = (E_N^o - E_M^o) + \frac{G}{mr\mathbf{F}} \quad [11]$$

Since we assumed $(E_N^o - E_M^o) > 0$, while $G < 0$, [10] indicates that at the M boundary always $a_{M^{m+}} >> a_{N^{n+}}$, *i.e.*, the less noble component M is the potential-determining species. At the N boundary, however, [11] indicates that two cases have to be distinguished, dependent on whether $(E_N^o - E_M^o) >$ or $< G/mr\mathbf{F}$.

Class I. $(E_N^o - E_M^o) > |G/mr\mathbf{F}|$; $a_{M^{m+}} >> a_{N^{n+}}$, though the ratio $a_{M^{m+}}/a_{N^{n+}}$ is not as large as at the M boundary. M remains the potential-determining species over the entire deposition range.

Class II. $(E_N^o - E_M^o) < |G/mr\mathbf{F}|$; $a_{N^{n+}} >> a_{M^{m+}}$ and N is the potential-determining species. Evidently in this case the potential-determining species changes from M at the M side of the system to N at the N side, the cross-over occurring near the point where the contributions of M and N to the exchange current are of the same order; at and near this point both M and N are involved in determining the potential.

As mentioned earlier, the individual potentials become more positive when the activity of the species in the deposit decreases.

The variation of the potentials of M and N with a_M and a_N, calculated for constant values of $a_{M^{m+}}$ and $a_{N^{n+}}$ equal to one are shown in Fig. 1A and Fig. 2A for classes I and II, respectively. These figures do not represent the situation in the plating bath at the interface deposit-electrolyte during deposition but they indicate in what way differences in nobility of the two components are affected by their interaction in the deposit, show which species must be expected to be potential determining, and help us to compose an electrolyte from which codeposition will be possible.

Class I.—In the situation depicted in Fig. 1A, M is the potential-determining species for all possible compositions of M_rN_s. Codeposition of the noble N and the less noble M in the ratio $s:r$ is possible from one solution if this solution contains N species at a low concentration and M species at a large concentration, for only under such conditions is it possible to reduce the concentration of N^{n+} ions relative to that of M^{m+} ions at the interface as required by [10] and [11] and make codeposition of M and N possible. Application of a potential somewhat more positive than that which would be required to deposit pure M from the electrolyte in the absence of N species preferentially deposits N; owing to the interaction between N and M, each N that is deposited makes possible the deposition of r/s M. Deposition

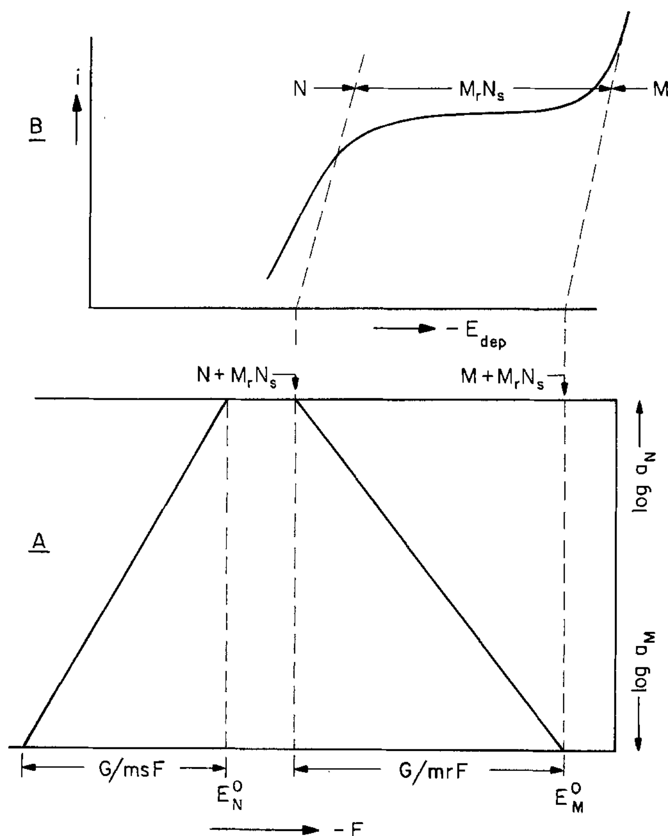

Fig. 1. Equilibrium potentials E of M and N as a function of the activities a_M and a_N relative to an electrolyte with $a_{M^{m+}} = a_{N^{n+}} = 1$ for class I (A) and the corresponding current-cathode potential curve for deposition of M_rN_s from an electrolyte with $a_{M^{m+}} \approx 1$, $a_{N^{n+}} << 1$ (B). The current value of the plateau is proportional to $a_{N^{n+}}$.

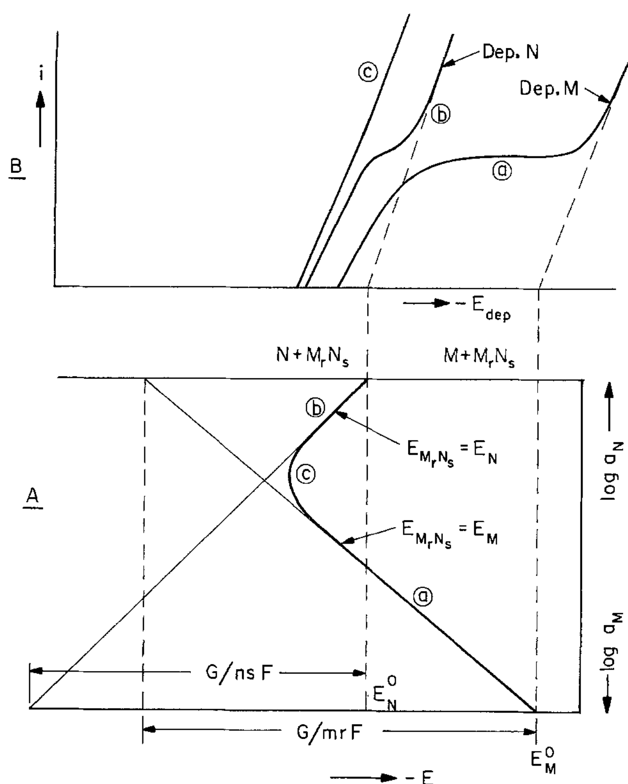

Fig. 2. Equilibrium potentials E of M and N as a function of a_M and a_N relative to an electrolyte with $a_{M^{m+}} = a_{N^{n+}} = 1$ for class II (A) and current-cathode potential curves for deposition of M_rN_s (B) from electrolytes with $a_{M^{m+}} = 1 << a_{N^{n+}}$ (a), $a_{M^{m+}} << a_{N^{n+}} \approx 1$ (b), and $a_{M^{m+}} \approx a_{N^{n+}} \approx 1$ (c).

of N exhausts the electrolyte at the interface from the species N^{n+} and creates a situation in which continuing deposition requires transport of N^{n+} from the bulk to the interface by diffusion through a thin electrolyte layer close to the interface, *i.e.*, the so-called diffusion layer, the thickness of which depends on agitation (stirring or convection). Deposition of M also tends to decrease the concentration of M^{m+} at the interface. However, since $a_{M^{m+}} >> a_{N^{n+}}$, this reduction is relatively unimportant, the M^{m+} concentration remaining practically the same as in the bulk. This means that the QRP of M_rN_s, determined by M^{m+}, remains given by [1] with $a_{M^{m+}}$ close to the value characterizing the bulk of the solution. The potential of N remains in line with [2] by the forced reduction of $a_{N^{n+}}$ at the interface to make $E_M = E_N$.

At a given bulk electrolyte composition, the exact value of the ratio r/s can be varied through current density and/or rate of stirring, an increase of current density increasing r/s, an increase of the rate of stirring (which makes the diffusion layer thinner) decreasing r/s. On the other hand, at given current density and stirring rate, increase of the M concentration in the electrolyte favors formation of M-rich deposits, increase of the N concentration in the electrolyte favors formation of N-rich deposits.

For a given electrolyte composition, the i-E_{dep} characteristic has the form schematically shown in Fig. 1B. After a gradual increase of i at low electrode potentials where the interface activity $a_{N^{n+}}$ is gradually reduced, a plateau is reached when the interface value of $a_{N^{n+}}$ is reduced to zero. A sharp increase of i occurs at a critical large potential where deposition of pure M becomes possible. Owing to the relatively large concentration of M^{m+} in the electrolyte, saturation of the M deposition by formation of a diffusion layer with $(a_{M^{m+}})_{interface} \approx 0$ will occur only at extremely large values of i and has not been included in the figure. If the concentration of M^{m+} in the electrolyte is ≈ 1 normal, the QRP's of the various possible products M_rN_s (with slightly varying values of r/s) are as shown in Fig. 1A, covering a potential range of width $G/mr\mathbf{F}$ at the positive side of $E_M°$. The corresponding deposition potentials are shifted to the negative side relative to the quasi rest potentials by the polarization which increases with increasing current density. The polarization has two components, the polarization proper of the deposit at the interface with the electrolyte and an iR drop in the current-carrying part of the circuit used to measure electrode potential. The iR drop is negligible for deposition of metals on a metallic electrode but may become appreciable for deposition of semiconducting compounds on a semiconducting electrode (*e.g.*, CdS on glass covered by SnO_2:Sb or In_2O_3:Sn). In that case $R = R_{base} + R_{deposit}$ with $R_{deposit}$ proportional to the thickness of the deposit. Since deposition of M_rN_s involves deposition of both M and N, interaction between M and N has made possible the deposition of component M at potentials that are more positive than that required to deposit pure M. N induces deposition of the less noble component [Brenner (6): induced codeposition]. Note that two-phase deposition of M + M_rN_s or N + M_rN_s occurs at specific potentials or current densities. Examples of class I alloys are CdS, CdSe, and CdTe, with Cd the potential-determining species; *e.g.*, for CdS, $E_{Cd}° = -0.403V$ *vs.* NHE, $E_S°$ (from H_2SO_3) = 0.449 *vs.* NHE, $-(G_{CdS})_{298} = 140.4$ kJ/mole (10). Hence $-G_{CdS}/2\mathbf{F} = 0.726V < (E_S° - E_{Cd}°) = 0.852V$. Similar considerations apply to CdTe (11).

Class II: The variation at standard values of $a_{M^{m+}}$ and $a_{N^{n+}}$ of the individual potentials of M and N with a_M and a_N corresponding to class II is shown in Fig. 2A. Interaction again shifts both potentials to more positive values, but now M has the most negative potential at large a_M, N has the most negative potential at small a_M (= large a_N), equality of

potentials (at standard values of $a_{M^{m+}}$ and $a_{N^{n+}}$) occurring somewhere in between. For electrolytes with different values of the ion activities the curves have to be shifted accordingly.

In the range where M has the most negative potential, Eq. [10] shows that under QRP conditions $a_{N^{n+}} \approx 0$, M being the potential-determining species. In the range where N has the most negative potential, [11] shows that $a_{M^{m+}} \approx 0$ and N is the potential-determining species. In this case deposition of M-rich products requires an electrolyte with $a_{M^{m+}} >> a_{N^{2+}}$ (as for class I) a change in deposition conditions (current density, rate of stirring) making possible the formation of deposits with different compositions, but all at the M-rich side of the system. Deposition of N-rich products, on the other hand, requires an electrolyte with $a_{N^{n+}} >> a_{M^{m+}}$, a change of conditions making possible formation of N-rich deposits over a limited composition range. Although $a_{M^{m+}}/a_{N^{n+}}, << 1$, this ratio cannot be as small as for class I. Care must be taken that M remains the most easily deposited species, for only then is it possible to achieve codeposition of M and N with the ratio r/s decreasing with increasing current density. Deposition of products with component activities in the range where both species are potential determining requires an electrolyte in which the two species have comparable activities. Now the change in composition of the deposit with current density or stirring rate will be extremely limited, since the deposition rate of both species will be affected in approximately the same way. If both $a_{M^{m+}}$ and $a_{N^{n+}}$ are chosen large, no appreciable exhaustion occurs. Schematical i-E_{dep} curves at activities of a_M corresponding to a, b, and c in Fig. 2A, with large values of $a_{M^{m+}}$ and $a_{N^{n+}}$ for c, are shown in Fig. 2B.

There are various systems in which such an effect has been observed, *e.g.*, NiSn (7), CoSn (12), and CoSb (13), but a satisfactory explanation has so far not been proposed (14). Let us consider the former case, where the metastable alloy NiSn is deposited from a solution containing chloride and fluoride ions (7). The standard potentials of Ni and Sn *vs.* NHE are $E_{Ni}^o = -0.250$V and $E_{Sn}^o = -0.136$V (2). The presence of fluoride ions makes the Ni potential ≈ 0.1V more negative but shifts the Sn potential more strongly in the same direction, making the standard potentials equal within 0.1V (Sn ending up slightly less noble than Ni); $-(G_{Ni_3Sn})_{298} = 157$ kJ/mole (10), $\Delta E_{Ni} = -G_{Ni_3Sn}/6F = 0.276$V and $\Delta E_{Sn} = -G_{Ni_3Sn}/2F = 0.812$V. For the metastable NiSn, $-(G_{NiSn})_{298} = 30$ kJ/mole, $\Delta E_{Ni} = \Delta E_{Sn} = -(G/NiSn)/2F = 0.31$V. Thus for both compounds the shift of the individual potentials due to compound formation are larger than $(E_{Ni}^o - E_{Sn}^o)_{F,Cl} \approx 0.1$V.[1] The situation corresponds to that at c in Fig. 2, with concentrations of Ni and Sn in the electrolyte that were of the same order. Deposition of alloys at potentials more positive than those of either Ni or Sn should therefore be expected and was indeed observed (7). That alloys of the composition NiSn were formed rather than alloys with higher Sn content may be due to the fact the rest-potential maximum is close to this composition; Sn-rich deposits are formed only at large current densities if the electrolyte contains more Sn than Ni (*e.g.*, 65% Sn, 35% Ni). In electrolytes as concentrated as the ones used, exhaustion of the electrolyte at the interface is not appreciable at low current density. Therefore the QRP should be close to the rest potential and thus to the equilibrium potential. The potential maximum near the composition NiSn therefore indicates that this alloy is more noble than either Ni or Sn, a fact that explains the observation that NiSn can be deposited on Sn by electroless plating (7). It should be emphasized, however, that the authors themselves explain the various effects by assuming the presence of a Ni-Sn-F complex in the electrolyte.

Nucleation problems.—Deposition of class I alloys occurs at potentials that are always more negative than that required to deposit the noble component. Therefore deposition can easily be initiated by discharge of this component, after which M-N interaction makes possible the deposition of the M component. The situation is different for class II alloys in the range where the deposition potential is more positive than that required to deposit either component separately, so that initial deposition of the noble component is not possible. In this case considerable nucleation problems are to be expected, deposition only being possible after fluctuations have formed an N, M, or M_rN_s nucleus. It is also possible that M, N complexes are present in the electrolyte which on discharge forms the required nuclei.

The quasi rest potential for deposits of M or N.—In the M and N phases in equilibrium with M_rN_s at the M-rich or N-rich end of the existence range of the compound both M and N must have the same activity as in the compound at the corresponding phase boundary. Therefore for these phases the species determining the QRP must be the same as for the coexisting compound. For class II this means that M is potential determining for the M phase and N for the N phase. For class I, however, M is the potential-determining species for both M and N. As far as N is concerned, this can only be the case if N contains some M in solid solution, to be expected for N coexisting with the compound. Only for N almost completely free of M will the QRP be determined by N itself.

The QRP of N follows a relation similar to [7] but with G replaced by the interaction free energy of M and N in almost pure N. Therefore, we expect the N potential to shift to more positive values with increasing M content leading again to a QRP maximum at the point where M takes over as the potential-determining species. Thus in principle there is always a maximum QRP. For class II it is inside the range where the compound is deposited; for class I it is in the range where N is deposited. The latter maximum, however, will be extremely small and can probably not be detected.

Binary systems with more than one compound.—Considerations similar to the ones presented above hold for binary systems with more than one compound. However, since the activities of the components vary in opposite directions monotonically over the system, there will be at most one compound in which the role of potential-determining species changes from one component to the other and for which, accordingly, a maximum in the QRP will occur. All other compounds have their potential determined by one of the components and their QRP's cover a range determined by the activity range of these components.

For compounds richer in N than the compound with the QRP maximum the potential-determining component is N; for compounds richer in M it is M. Similar considerations also apply to systems forming alloys of variable composition. Now the variation in a_M and a_N and the corresponding variation in the potentials of M and N have to be obtained by graphical integration of the Gibbs-Duhem equation

$$x_M d\mu_M + x_N d\mu_N = x_M d \ln a_M + x_N d \ln a_N = 0 \quad [12]$$

$$\ln a_M = -\int_{a_N=1}^{a_N=0} \frac{x_N}{x_M} d \ln a_N \quad [13]$$

with

$$x_N = n_N/(n_M + n_N) \text{ and } x_M = 1 - x_N = n_M/n_M = n_N$$

n indicating numbers of atoms.

[1] Formulas [1] and [2] for the quasi rest potentials hold also in the presence of complexing agents which shift the potential to more negative values by making the ion activities in the electrolyte much smaller than the corresponding concentrations. It is also possible, however, to use total ion concentrations rather than activities in [1] and [2], accounting for the effect of the complexing agents by a change in the standard potentials. This is the approach followed here.

Systems in Which the Rate Constants of the Exchange Currents of the Individual Components Are Widely Different

In such systems the component with the larger exchange rate constant is favored over the other one, and a change in the potential-determining species expected on the basis of activity and/or concentration effects may not occur at all or occurs at a different point.

Stability and Potentials in Electrolytes from Which Deposition is Not Possible

The arguments presented above relate to potentials and stability (or lack of stability) in electrolytes from which cathodic deposition was possible. It might be asked what can be said about these properties in electrolytes containing ionic species of the components, but of such a nature that cathodic deposition is not possible.

As an example let us consider CdX (X being S, Se, or Te) in an electrolyte containing Cd^{2+} ions but no X^{4+} complexes. In such a situation, a small amount of CdX will dissolve with formation of Cd^{2+} and X^{2-} ions until the solubility product

$$\pi_{CdX} = c_{Cd^{2+}} c_{X^{2-}} \approx a_{Cd^{2+}} a_{X^{2-}} \quad [14]$$

is reached; from then on CdX is stable and its potential is determined by Cd (Eq. [20] below).

CdX formed by cathodic deposition from an electrolyte containing X^{4+} complexes may have an excess of X at its surface as a result of electroless exchange of Cd and X. If such a sample is placed in an electrolyte containing Cd^{2+} ions but no X^{4+} complexes, the surface layer of X at the surface can be removed by cathodic deposition of Cd at a potential slightly more positive than required to deposit Cd at $a_{Cd} = 1$. Continuation of this process leads to a change in the bulk concentration (activity) of Cd. This method has been used to vary the stoichiometric composition of CdS (16). Since bulk diffusion is involved in this case, the method can only be used for thin films (thickness ≤ 1 μm).

The upper and lower boundaries of the CdX stability region in the Pourbaix diagram (*E vs.* pH) are determined by

$$CdX \rightarrow Cd^{2+} + X + 2e^- \quad [15]$$

and

$$CdX \rightarrow Cd + X^2 - 2e^- \quad [16]$$

Both are independent of pH

CdX is also stable in electrolytes rich in X^{2-} ions. Under such conditions the concentrations of Cd^{2+} and X^{4+} complexes are very small. The potential can be expressed either as an X potential according to

$$X^{2+} \rightleftarrows X + 2e^-; \quad 2FE_X^\circ \quad [17]$$

with

$$E_X = E_X^\circ - \frac{2.302RT}{2F} \log a_{X^{2-}}/a_X \quad [18]$$

or as a Cd potential according to

$$Cd \rightleftarrows Cd^{2+} + 2e^-; \quad 2FE_{Cd}^\circ \quad [19]$$

with

$$E_{Cd} = E_{Cd}^\circ + \frac{2.302RT}{2F} \log a_{Cd^{2+}}/a_{Cd} \quad [20]$$

Here $a_{Cd^{2+}}$ and $a_{X^{2-}}$ are activities of Cd^{2+} and X^{2-} in the electrolyte; a_{Cd} and a_X are the activities of Cd and X in CdX.

Elimination of Cd, X, and e^- from [17], [19], and [21]

$$Cd + X \rightleftarrows CdX; \quad G_{CdX}^\circ \quad [21]$$

$$a_{Cd} a_X = \exp G_{CdX}^\circ \quad [22]$$

gives

$$CdX \rightleftarrows Cd^{2+} + X^{2-}; \quad 2F(E_{Cd}^\circ - E_X^\circ) - G_{CdX}^\circ \quad [23]$$

$$\frac{2.302RT}{2F} \log \pi_{CdX} = (G_{CdX}^\circ/2F) + E_X^\circ - E_{Cd}^\circ \quad [24]$$

Introduction of [24] into [18] or [20] shows that $E_{Cd} \equiv E_X$. Evidently distinction between the components as potential-determining species is unnecessary when solubility products of the ionic species exist, which is the case when dissolution of the compound involves oppositely charged ions, so that no electrons are involved. Distinction between different potential-determining species is necessary if dissolution involves electrons, which is the case if the solid dissolves with formation of ions of the same charge. This is generally the case with metallic alloys and applies to the present substances when they are placed in electrolytes containing Cd^{2+} and X^{4+} complexes from which CdX can be made by cathodic deposition. In such cases the distinction between class I and class II materials applies.

In an electrolyte 1 molar in X^{2-}, the potentials at the boundaries of the stability range are shifted to more negative (less noble) values with respect to those of an electrolyte 1 molar in Cd^{2+} by

$$\Delta E = \frac{2.302}{2F} \log \pi_{CdX}$$

given by [24]. In both electrolytes the potential width of the stability range between CdX in equilibrium with Cd (*i.e.*, $a_{Cd} = 1$) or X ($a_{Cd} = \exp (G_{CdX}^\circ/RT)$ is given by

$$\Delta E_{stab} = |G_{CdX}^\circ|/2F \quad [25]$$

Values of the decomposition potentials of the chalcogenides of Cd and of Zn (to which the same considerations apply) under the two conditions are given in Table I. Figure 3 shows these potentials for CdS as a function of a_{Cd} and a_S under the same two conditions. By combining a change of electroyte composition with a change in the stoichiometry of CdX, a potential range of approximately 1V can be covered. However, in alkaline $S^=$ solutions the potential of CdS is not determined by these ions (or Cd^{2+}) but by SH^-; thus the lower curve is not valid (22). Table I also shows values of the solubility products calculated from [24]—an equation commonly used for this pur-

pose. Values reported by other authors are given for comparison.

Combination of [18] and [20] leads to

$$E_{Cd} = E_X = \frac{1}{2}(E_{Cd}^{o} + E_X^{o}) + \frac{2.302RT}{2F} \log (a_{Cd^{2+}} a_{X^{2-}} / a_{Cd} a_X) \quad [26]$$

an expression first derived by Sato (21). However, [18] and [20] are easier to handle.

Discussion

The quasi rest potentials as introduced in the present paper are characteristic for the deposited material in bulk and may be compared with equilibrium potentials valid for the case that equilibration of bulk as well as surface is possible (23).

An extensive discussion of equilibrium potentials of alloys first given by Reinders (24) is reproduced in the review article by Kremann and Müller (25). For random alloys Reinders' approach is similar to ours, the potential being determined by ions of the components, and in particular by those that are least noble. Compounds were believed to have a fixed composition. Distinction was made between compounds that can and those that cannot exist in equilibrium with an electrolyte containing the components in the same ratio as in the compound. The potential of the former were believed to be determined by the Nernst formula with ions of the lattice molecule $M_rN_s^{t+}$ the potential-determining species in the electrolyte. This complex ion was assumed to dissociate with formation of M^{m+} and N^{n+} ions. In electrolytes with different concentrations of these ions but $c_{M^{m+}} + c_{N^{n+}}$ = constant, $c_{complex}$ and therewith the electrode potential is found to have a maximum value when $c_{M^{m+}}/c_{N^{n+}} = r/s$. Since ions of the separate components are not potential determining, the compound potential maximum may have any values relative to the component potential which are believed to be determined by their ions. When, at the point where compound and electrolyte have the same composition, the potential of a solid solution of the less noble component in the noble component has a potential more positive (= noble) than the compound, the latter cannot exist in an electrolyte of its own composition.

The maximum in the potential of the compound that may coexist with an electrolyte of its own composition, though similar to that of our class II alloys in that it occurs for small differences of the standard potentials of the components, has a completely different reason: the change in concentration of the complex ion in the electrolyte.

In view of what is presently known about the existence of point defects and nonstoichiometry in compounds, it seems preferable to assume that no complex ions but the individual ions of the components determine the potential of the compound as they do that of the components—the assumption made in the present paper. Reinders' phase diagrams in which the compositions of coexisting solid and electrolyte phase are plotted as a function of potential can be adopted with that modification with only minor adjustments. Reinders' compounds that may coexist with electrolytes of the same composition are our class II compounds or alloys, with M the potential-determining species at the M side of the potential maximum, N the potential-determining species at the N side of the maximum. Compounds that cannot coexist with electrolytes of their own composition are our class I compounds.

The compositions of a compound in equilibrium with different electrolytes are not exactly the same: The compound has different deviations from stoichiometry and correspondingly different potentials.

Kremann and Müller (24), though reproducing Reinders' arguments, do not seem to fully subscribe to his conception of a compound with a variable potential: They ascribe a single potential to a compound, identifying it with the most noble potential it ever displays. This view—though incorrect—still has many adherents.

The idea of ions of the individual components as potential-determining species for compounds and alloys was used by Pourbaix (2) in the construction of his well-known atlas. It leads to fields rather than lines of stability in the potential-*p*H diagrams. It is also accepted by Sato (21) who derived on this basis a general expression for the potential of a compound as a function of the activities of atoms in compounds and of component ions in the electrolyte. Since in alloys and compounds the Gibbs free energy of interaction between the components is invariably negative, acceptance of the ions of the components as potential-determining species must lead to a situation in which the potentials of alloys and compounds are always more positive (= more noble) than those of the components, the ions of which dominate the potential. Various diagrams in Ref. (24) and (25), *e.g.*, Fig. 3 (BD) and Fig. 5 (AG and BK) in Ref. (24) and Fig. 71 (BG), Fig. 73, Fig. 79 (top curve), Fig. 81 (AD), and Fig. 84 (BG) in Ref. (25), are in conflict with this requirement. Absence of experimental proof for shifts toward less noble potentials under the conditions described may be considered proof for the individual ion model.

Summary

The cathodic deposition of binary alloys and compounds is discussed on the basis of deposit-electrolyte thermodynamics and the rate of transfer of the components, using the quasi rest potential (QRP), defined as deposition potential minus polarization of the solid, to characterize the deposit. The species with the larger value for the product of the discharge rate constant and the concentration of species in the electrolyte at the deposit-electrolyte interface is believed to be dominant in determining the potential.

In general, each component is potential determining at its side of the system, both potentials shifting to more positive values on alloy formation and thus

giving rise to a QRP maximum at the point where the change of potential-determining species occurs. If the shift in component potentials due to alloy or compound formation is large relative to the difference in the individual equilibrium potentials of the components (class II), the maximum of the QRP occurs at some intermediate composition. If the shift is small (class I), the maximum is expected to occur in the stability range of the nearly pure noble component and may be too small to be observed. Marked differences in the values of the exchange rate constants for the components extends the activity range in which a species dominates the QRP in favor of the species with the larger rate constant.

Compounds placed in electrolytes containing large concentrations of the normal ions of one of the components, but no complexes of the nonmetal component which are required for cathodic deposition of the compound, are stable, their potential being determined by the normal ions. For ions with concentrations linked by a solubility product, either species may be used to formulate the equilibrium potential.

ABSTRACT

Deep junction (4 μm) GaAlAs/GaAs heteroface solar cells were irradiated with 1 MeV electrons at fluences of 10^{13}, 10^{14}, 10^{15}, and 10^{16} electrons/cm^2. The short-circuit current degraded to 0.02 of its original value after a fluence of 10^{16} electrons/cm^2. Computer modeling of the spectral response before and after irradiation showed that, in addition to a decrease in the minority carrier diffusion length in p-GaAs from several micrometers to ½ μm, an increase in the recombination velocity at the GaAlAs/GaAs interface from 10^4 to 10^8 cm/sec was required to completely explain the observed change in the spectral response.

GaAs solar cells are of interest for generating electrical power in space on a solar power satellite or for a high temperature, near-sun science mission. With the achievement of 18.5% AMO efficiency (1) research is being directed toward optimization of the stability in the electron and proton environment of space. This

optimization requires a fundamental understanding of the interaction of radiation with solar cells. The efficient operation of solar cells depends on such parameters as minority carrier diffusion length, carrier mobility, and recombination rates. To determine the effect of 1 MeV electrons on these cell parameters, computer-generated spectral response curves have been compared to experimental spectral response data for 1 MeV electron irradiated, deep junction (4 μm) GaAlAs/GaAs heteroface solar cells. In this paper we describe: the cells developed to study radiation effects in the p-GaAs region, the measurements, the comparison between experimental and calculated results, and our conclusions.

Experimental

Heteroface p-GaAlAs/p-GaAs/n-GaAs solar cells were fabricated using the etch-back epitaxy process (1). The n-type GaAs substrates were Si doped to a carrier concentration of 2×10^{17} carriers/cm^3. The p-GaAlAs layer thickness was 0.3-0.5 μm. The p-GaAs layer was 4 μm thick giving a junction depth of 4 μm measured from the GaAlAs interface. Large area, vacuum-evaporated Sn-Ag contacts were used for electrical connection to the n-GaAs. Front finger contacts to the GaAlAs layer were deposited by sputtering a layer of Pd followed by a layer of Ag using an appropriate mask.

The cells, mounted on aluminum backing plates, were irradiated with 1 MeV electrons. Groups of cells were irradiated at fluences of 10^{13}, 10^{14}, 10^{15}, and 10^{16} electrons/cm^2. Electron irradiation rates were chosen such that the cells remained at ambient temperature during irradiation.

Short-circuit currents were measured both before (I_{sc0}) and after irradiation (I_{sc}). The cells mounted on metal headers were placed on the water-cooled stage of solar simulator. For all short-circuit current measurements, the intensity of the filtered xenon solar radiation was set to one air mass zero solar constant using a balloon-calibrated Si solar cell. The short-circuit current of the GaAlAs/GaAs cell was then obtained by measuring the voltage drop across a precision resistor. The relative spectral responses were obtained both before and after irradiation by mounting the cells in an intensity-calibrated spectrophotometer and measuring the short-circuit current as a function of wavelength.

Results and Discussion

The effect of radiation on the short-circuit current at AMO illumination is shown in Fig. 1. The curve is a plot of the averages of short-circuit current ratios *vs.* electron fluence. The short-circuit current degraded to 0.02 of its original value after a fluence of 10^{16} electrons/cm^2. Additional information about the degradation can be obtained from measurements of the spectral response of the short-circuit current. The spectral response typical of the cells used in this study is shown in Fig. 2 which consists of plots of the relative spectral response as a function of the incident wavelength, before and after irradiation. The points are the experimentally derived data and the curve is computed using the device equations for this cell configuration (2, 3).

The computed curve fits the experimental data for the unirradiated cell with the mobility of electrons in the p-GaAs region chosen to be 3300 cm^2/V-sec, the minority carrier diffusion length in the p-GaAs region 3.3 μm, and an interface recombination velocity of 10^4 cm/sec.

The spectral response after irradiating the cell with 10^{16} electrons/cm^2 is also shown in Fig. 2. It can be seen that the response in the blue region is reduced much more than the response near the bandedge. The device equations incorporate a number of material parameters which could be affected by the radiation and lead to reduced response. These material parameters for the p-GaAlAs, the p-GaAs, and the n-GaAs layers are the minority carrier diffusion lengths, the mobilities of minority carriers, the majority carrier densities, and the surface and interface recombination velocities.

Solar cells having deep junctions such as those used in this study proved advantageous since the reduction of the short-circuit current of the solar cells due to electron irradiation can be attributed to changes produced in the p-GaAs region only. Effects on short-circuit current produced by radiation damage in the base region can be neglected. This assumption was corroborated by the calculations.

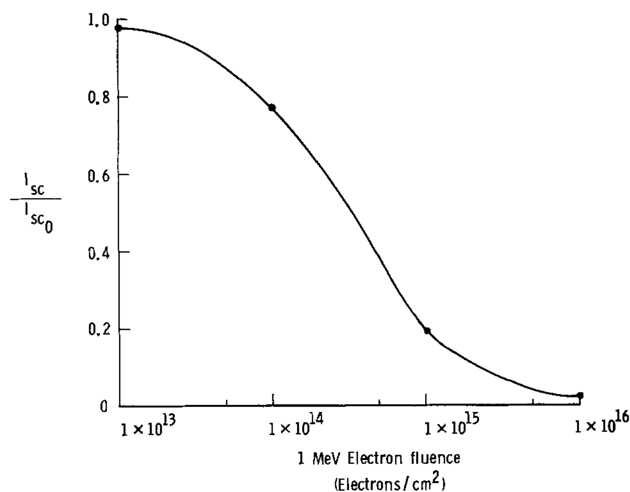

Fig. 1. Ratio of final short-circuit current to initial short-circuit current as a function of 1 MeV electron fluence for deep junction GaAlAs/GaAs heteroface solar cells.

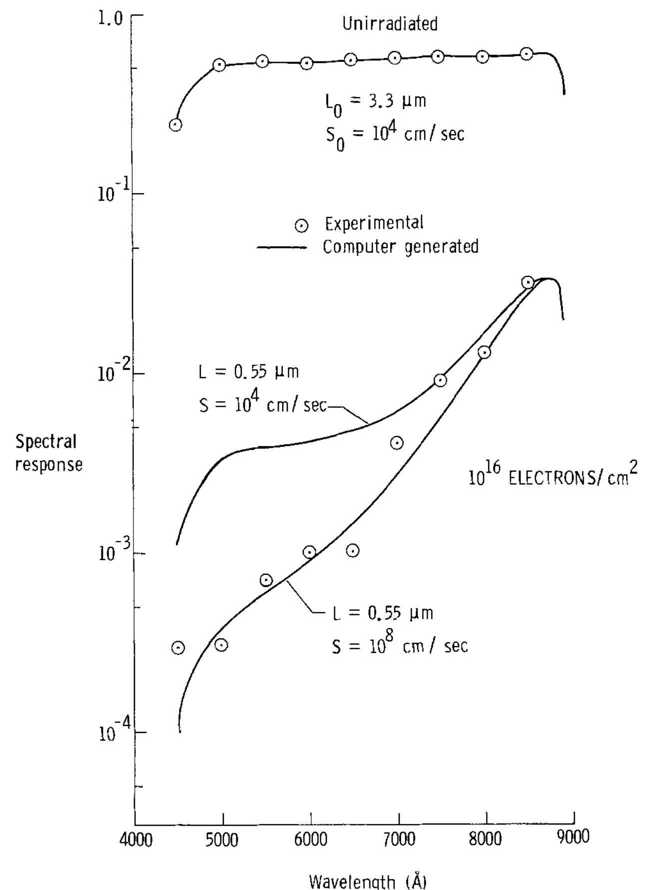

Fig. 2. Measured and computed spectral response of a deep junction GaAlAs/GaAs heteroface solar cell unirradiated and irradiated with 10^{16} 1 MeV electrons/cm^2.

Using the device equations, it was found that a reduction of the minority carrier diffusion length in the p-GaAs could explain the reduced spectral response in the red region (middle curve, Fig. 2), but a change in at least one additional parameter was needed to explain completely the reduction in the blue region. Calculations of spectral response were made by reducing the mobility from an initial value of 3300 to 5 cm^2/V-sec, with the diffusion length fixed at 0.55 μm. Slightly improved agreement in the blue region was achieved, but the assumed mobility reduction to 5 cm^2/V-sec was unreasonably large (4). Calculations indicated that the mobility change expected from ionized-center scattering due to radiation defects would be small.

Majority carrier trapping on radiation defects could account for a carrier density reduction of less than $10^{17}/cm^3$. However, this effect would be small since the density of holes in the p-GaAs is in excess of $10^{18}/cm^3$ and, further, this effect is not spectrally selective. Therefore, both the radiation-induced mobility change and the majority carrier trapping were eliminated as the cause of the reduced blue response.

The third material parameter in the model which could produce the reduced response is the recombination velocity (S) at the p-GaAlAs, p-GaAs interface. A computed spectral response curve using a value of S higher than that before irradiation reduced the blue response but did not affect the response in the red spectral region (bottom curve Fig. 2). Thus, the computed spectral response could be made to agree with the experimental data in the red region by reducing the minority carrier diffusion length to 0.55 μm, and in the blue region by increasing the interface recombination velocity to 10^8 cm/sec.

This use of an increase in surface recombination velocity to explain a significant reduction in blue response of the cell has been discussed so far only in terms of the correlations between experimental and calculated results. However, it is plausible that S would increase with irradiation.

The radiation-induced damage is expected to be uniform throughout the solar cells (5), both in the bulk and near the interface. This suggests that the changes in minority carrier diffusion lengths are related to changes in interface recombination velocity. Assuming that the reduction in minority carrier diffusion length is due to the introduction of recombination centers in the bulk, and that the same type of recombination centers near the interface cause an increase in the recombination velocity, then an expression can be derived relating the minority carrier diffusion lengths to the interface recombination velocities before and after irradiation. The minority carrier diffusion length L is related to the diffusion constant D, the capture probability density K, and the number density of bulk recombination centers N_B, by

$$L = \left(\frac{D}{KN_B} \right)^{1/2}$$

where it is assumed that the lifetime is determined by the recombination centers.

Using the Shockley-Read model for the surface recombination velocity, the following assumptions are made: (*i*) the capture cross section for holes and electrons are equal; and (*ii*) the thickness, t, of the interface region is constant. With these assumptions, the interface recombination velocity S is given as

$$S = K(N_I t) \frac{P}{n}$$

where the product ($N_I t$) gives the number density of recombination centers in the interface region, P is the bulk density of majority carrier, and n is the intrinsic carrier density. The ratio of the square of the diffusion length after irradiation to that before irradiation yields

$$\left(\frac{L}{L_0} \right)^2 = \frac{N_{B0}}{N_B} \qquad [1]$$

where the zero subscript indicates the parameter value before irradiation. The ratio of the interface recombination velocity before irradiation to that after irradiation leads to

$$\frac{S_0}{S} = \frac{N_{I0}}{N_I} \qquad [2]$$

After sufficient irradiation, the density of recombination sites in the bulk and at the interface is determined by the irradiation and, therefore, $N_B = N_I$. This leads to the expression

$$\frac{S}{S_0} = \left(\frac{L_0}{L} \right)^2 \cdot \frac{N_{B0}}{N_{I0}} \qquad [3]$$

Equation [3] gives qualitative results. It shows that an increase in surface recombination velocity can reasonably be expected from the irradiation that reduces minority carrier diffusion length.

In summary, deep junction GaAlAs/GaAs heteroface solar cells showed significant degradation when irradiated with 1 MeV electrons at fluences up to 10^{16} electrons/cm^2. Computer modeling of the spectral response indicated that both a decrease in the minority carrier diffusion length in the p-GaAs region, as well as an increase in the recombination velocity at the GaAlAs/GaAs interface, was required to fully explain the observed changes.

On the Diffusion of Excess Vacancies to Free Surfaces and Voids in Thin Films

J. R. Lloyd

Department of Materials and Metallurgical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030

and S. Nakahara*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Recent investigations have shown that resistivity decay in evaporated gold films originates, in part, from the annihilation of excess vacancies, trapped during film condensation, at a high density (10^{15}-10^{17}/cm^3) of small (<50Å) voids present within the film. This paper presents a theoretical treatment of vacancy diffusion to free surfaces and to voids. The treatment predicts both the observed void growth and resistivity decay in thin films.

It is well known that the resistivity of freshly deposited thin films changes continuously with time at room temperature (1-3). It has been generally accepted that resistivity decay in thin films takes place as a result of the diffusion of excess vacancies, quenched-in during film formation, to sinks such as free surfaces and grain boundaries (1, 3). Recent transmission-electron-microscope (TEM) studies of evaporated gold films have shown that thin films generally contain a high density ($\sim 10^{16}$/cm^3) of small voids (4, 5). The presence of such a high density of voids suggests that these voids may serve as potential sites for the annihilation of excess vacancies. Experimental evidence for this suggestion has been found in our recent observations that these voids grow at the expense of excess vacancies with aging time even at room temperature (6, 7). Assuming that voids are the only sinks for excess vacancies, Lloyd and Nakahara (6) were able to relate, semiquantitatively, the void growth to the resistivity decay in evaporated gold films. Although the effect of the surfaces was not considered, this treatment was in good agreement with experiments for long times following film deposition, but could not account for short-term resistivity decay. We have, therefore, treated our earlier problem by using a more rigorous mathematical framework which considers both surfaces and voids as potential sinks for excess vacancies.

Theoretical Model

Based upon our previous experimental results (5), several assumptions were made for determining the excess vacancy concentration and the rate of void growth in evaporated gold films. (*i*) The film was assumed to contain an initially uniform concentration of quenched-in excess vacancies; (*ii*) The pre-existing voids, which serve as vacancy sinks, are distributed uniformly throughout the film. The creation of new voids by vacancy clustering is ignored; (*iii*) The void distribution was approximated by a simple cubic lattice of equally sized voids in an otherwise defect-free film; (*iv*) The voids were treated as perfect sinks, *i.e.*, vacancies may be annihilated, but not created, at void sites. A schematic view of this theoretical model is shown in Fig. 1.

If voids were not present in the film, the vacancy concentration could be determined from a solution of the diffusion of vacancies out of a thin slab (8, 9). On the other hand, if voids were present, for example, in an infinitely thick film, one would solve the problem of vacancy diffusion to a periodic array of voids using the formulation similar to that used by Ham (10) for the case of the growth of precipitates from a supersaturated solid solution. In the present case, the film can be best approximated by a thin slab containing uniformly distributed vacancy absorbers (voids). This situation can, therefore, be described as the out-diffusion of vacancies from a thin slab with a simultaneous irreversible chemical reaction.

The irreversible chemical reaction is

$$(\text{Vacancy})_{\text{Lattice}} \xrightarrow[k]{} (\text{Vacancy})_{\text{Void}} \qquad [1]$$

The vacancy concentration (C_x) in the film can be represented by the solution to

$$\frac{\partial C_x}{\partial t} = D\frac{\partial^2 C_x}{\partial x^2} - kC_x \qquad [2]$$

where D is the vacancy diffusivity and t is time, sub-

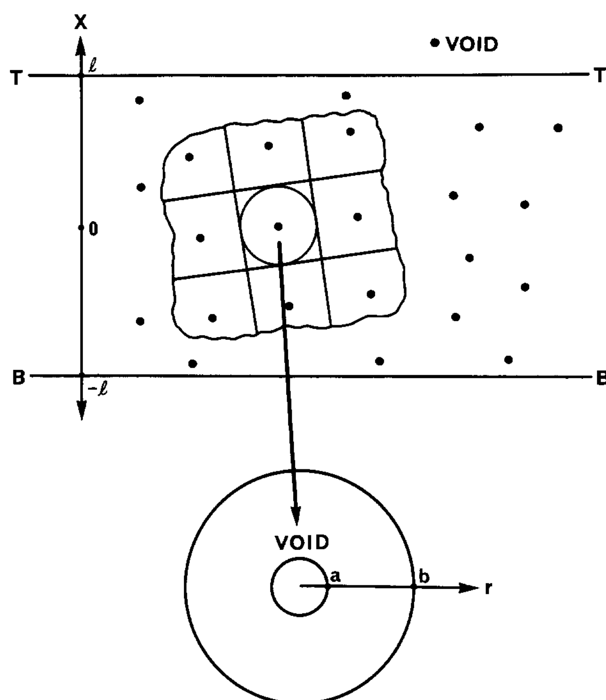

Fig. 1. Schematic view of the model showing a simple cubic lattice of voids in a thin slab of thickness 2*l* and a view of the Wigner-Seitz cell.

* Electrochemical Society Active Member.

Key words: diffusion, films, surfaces.

ject to the boundary conditions

$$C_x(\pm l, t) = 0$$
$$C_x(x, 0) = C_0 \quad [3]$$
$$\frac{\partial C_x}{\partial x}(0, t) = 0$$

where l is the half-thickness of the film (see Fig. 1) and C_0 is the initial vacancy concentration.

From Eq. [2] and [3], the vacancy concentration, $C_x(x, t)$, can be easily shown to be

$$C_x(x,t) = \frac{4C_0}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)} \cos(\theta_n x) \exp(-Q_n) \quad [4]$$

where

$$Q_n = \int_0^t (\theta_n^2 D + k)\, dt \quad [5]$$

and

$$\theta_n = \frac{(2n+1)\pi}{2l} \quad [6]$$

In the case of D and k being time-independent

$$Q_n = (\theta_n^2 D + k)t \quad [7]$$

Determination of k

The second term on the left-hand side of Eq. [2], kC_x, represents the rate of the vacancy annihilation, which takes place at preexisting voids. This relation can then be expressed as

$$kC_x = J_a 4\pi a^2 N_v \quad [8]$$

where J_a is the vacancy flux at a void surface, a the void radius, and N_v the void density. In order to obtain a value for k, J_a was determined from a solution of the problem of vacancy diffusion to a simple cubic (SC) lattice of voids. The use of the assumption that the voids lie on a SC lattice reduces the problem to that of diffusion in a single unit cell. By replacing the SC unit cell by the equivalent Wigner-Seitz cell, the problem can be further simplified to allow the use of spherical coordinates. The diffusion equation for this problem can be written

$$\frac{\partial C_r}{\partial t} = D\nabla^2 C_r \quad [9]$$

which is subject to the boundary conditions

$$C_r(a, t) = 0 \quad [10a]$$
$$C_r(r, 0) = C_0 \quad [10b]$$
$$\frac{\partial C_r}{\partial r}(b, t) = 0 \quad [10c]$$

where C_r is the vacancy concentration in the Wigner-Seitz cell. The radius of the equivalent Wigner-Seitz sphere, b, is calculated from

$$\frac{1}{N_v} = \frac{4}{3}\pi b^3 \quad [11]$$

The solution, C_r, is

$$C_r(r,t) = \sum_{n=1}^{\infty} \frac{2C_0 a}{\lambda_n} \phi_{na} \frac{\sin\lambda_n(r-a)}{r} \exp\left(-\lambda_n^2 \int_0^t D\,dt\right) \quad [12]$$

where

$$\phi_{na} = \frac{1 + b^2\lambda_n^2}{b^2\lambda_n^2(b-a) - a} \quad [13]$$

and the λ_n's are the nonzero roots to

$$\tan\{\lambda_n(b-a)\} = b\lambda_n \quad [14]$$

The vacancy flux at the surface of the void, J_a, is then

$$J_a = D\frac{\partial C_r}{\partial r}\bigg|_{r=a} = 2C_0 D \sum_{n=1}^{\infty} \phi_{na} \exp\left(-\lambda_n^2 \int_0^t D\,dt\right) \quad [15]$$

Substituting Eq. [15] into Eq. [8], we obtain

$$kC_x = 8\pi C_0 a^2 D N_v \sum_{n=1}^{\infty} \phi_{na} \exp\left(-\lambda^2 \int_0^t D\,dt\right) \quad [16]$$

It should be emphasized that C_r (the solution to Eq. [9]) and C_x (the solution to Eq. [2]) are not independent of each other, but are constrained by the requirement that the concentration from Eq. [2] averaged over the film thickness, $\overline{C_x}$, must be the same as the concentration from Eq. [9] averaged over the Wigner-Seitz cell at any given time. The initial condition Eq. [10b] must, therefore, be replaced by the time-dependent boundary condition

$$\frac{1}{V}\int_V C_r(r,t)\,dV = \overline{C_x} \quad [17]$$

where V is the volume of the Wigner-Seitz cell. It should be noted that the use of Eq. [17] makes the reaction constant, k, time dependent.

Equation [2] together with Eq. [15] and [16] can be integrated numerically over small increments of time, using an iteration method in a self-consistent manner with the aid of a digital computer.

The variation of k with time is shown in Fig. 2. We note a high initial value which rapidly decays to a minimum followed by a slow increase to an apparent saturation value. This behavior of k is reflected in Eq. [8], in which k is seen to be proportional to the vacancy flux into the void, J_a, as well as to the void surface area, $4\pi a^2$. The initial rapid drop in k with time is due to the relaxation of the concentration gradient at the boundary ($r = a$). In other words, the infinite gradient at the boundary gives an infinite vacancy flux into the void which results in an infinite value for k. In order to avoid this mathematical complication, the computation was initiated at $t = 0.1$ sec rather than at $t = 0$. At this time (0.1 sec), the series in Eq. [4] was found to converge satisfactorily in about 400 terms. After a few hours, a single term was found to be adequate. The minimum in the k *vs.* t curve (Fig. 2) demonstrates the relative contributions of both the concentration gradient and the void size. With further increase in time, the contribution of the void size to

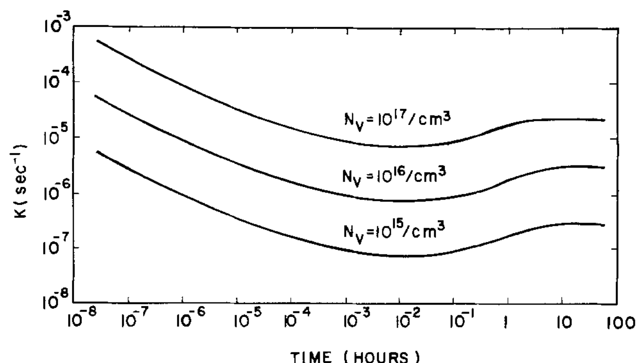

Fig. 2. Variation of the reaction constant, k, with time as a function of void density. Note that this plot and all succeeding plots are for a 1000Å-thick film, $C_0 = 0.5\%$, and $T = 298°K$ unless otherwise indicated.

the value of k becomes dominant until an apparent saturation point is reached. As the vacancy concentration reaches the equilibrium value, the reaction constant, k, will eventually approach zero, regardless of the void size.

The void size is obtained by numerical integration over the void growth rate given by

$$\frac{da}{dt} = J_a\Omega \qquad [18]$$

where Ω is the vacancy volume which is estimated to be half the atomic volume.

Theoretical Results

Figure 3 shows the effect of a void concentration ($5 \times 10^{16}/cm^3$) on the vacancy concentration profile. An examination of these profiles confirms our earlier conclusion that, after few hours, voids become the principal sinks for diffusing excess vacancies (6). The effect of void density on the average vacancy concentration as a function of time is shown in Fig. 4, where it is clearly seen that, for 1000Å-thick film, voids become important sinks at a void density higher than $1 \times 10^{16}/cm^3$.

As expected, with decreasing film thickness, the contribution of the surfaces becomes more important. The effect of the film thickness on the vacancy concentration is shown in Fig. 5. It should be pointed out, however, that for very thin films in which the mean intervoid distance is greater than the film thickness, this model for calculating the vacancy concentration and the void size is not physically realistic, but the computational method remains useful for the following reason. In very thin (<500 Å) thin films, where the periodic boundary condition is no longer appropriate, the effect of surfaces as vacancy sinks becomes so dominant that voids are no longer effective for the vacancy annihilation. On the other hand, as the film thickness is increased and, consequently, voids become more important as vacancy sinks, the periodic boundary condition becomes more valid. In fact, films that are greater than 1 μm in thickness, act as if they are infinitely thick with virtually all of the vacancies diffusing to voids.

Spontaneous changes in the vacancy concentration may be undesirable for many solid-state device applications, as they might contribute significantly to changes in physical properties such as the resistivity. Figure 6 shows the vacancy concentration as a function of time for different temperatures in a 1000Å-thick film. The important observation here is that, in order for a stable resistivity to be achieved, only a short-time anneal at a relatively modest temperature is required.

Void Growth

The diffusion of vacancies to voids results in void growth until all of the excess vacancies have been annihilated. The effect of the initial vacancy concentration, void density, and film thickness on void growth can be seen in Fig. 7, 8, and 9. As expected, a higher vacancy concentration produces larger voids. Furthermore, growth of larger voids can be seen in thicker films and in films with lower void densities.

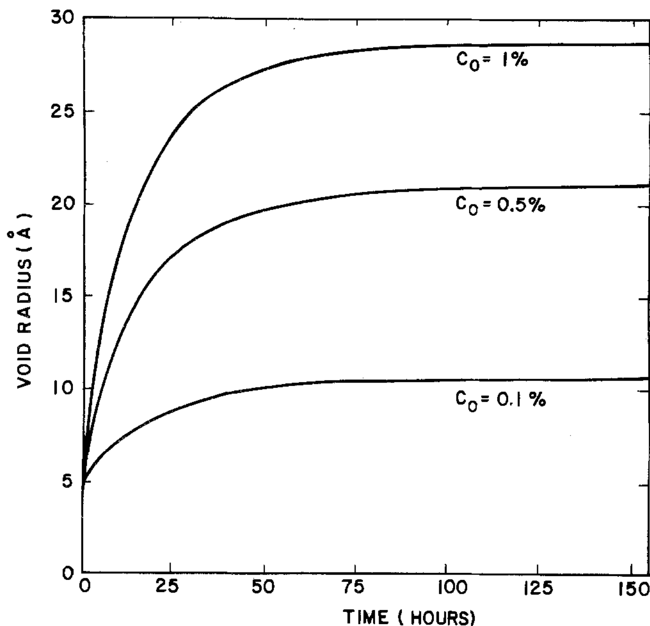

Fig. 7. Void size as a function of initial vacancy concentration. $N_v = 1 \times 10^{16}/cm^3$.

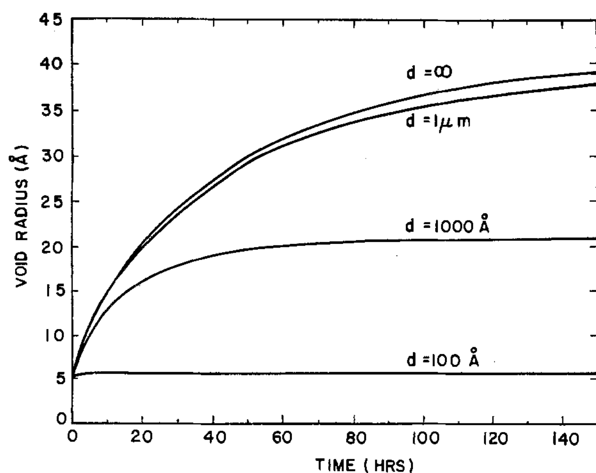

Fig. 8. Void size as a function of film thickness. $N_v = 1 \times 10^{16}/cm^3$.

Comparison with Experiment

Since the resistivity due to vacancies is linearly related to the excess vacancy concentration (8), the resistivity, ρ, can be expressed as

$$\rho = \rho_{xs} + \rho_0 \quad [19]$$

where ρ_0 is the the resistivity without vacancies, and

$$\rho_{xs} = \alpha C_v$$

where α is the vacancy resistivity and C_v the average vacancy concentration in the film.

The resistivity decay at room temperature will be directly proportional to the rate of the vacancy annihilation. The vacancy resistivity, α, was taken to be 1.9 $\mu\Omega$ cm, which is an average of several published values obtained from quenching experiments (11-13).

The film examined in this study was evaporated by resistance heating at a rate of 2-3 Å/sec onto a glass slide in an oilless vacuum of 1×10^{-6} Torr. During the evaporation, radiant heating raised the substrate from about 25° to 110°C. Immediately after the deposition, the sample was cooled to room temperature under vacuum, while the substrate temperature was recorded on a strip chart recorder with a Chromel-Alumel thermocouple in contact with the substrate. This temperature history was taken into account in our theoretical calculation. The activation energy for vacancy diffusion in gold and the initial vacancy concentration were chosen to be 0.87 eV and 0.25%, respectively. These values were found to produce results in good agreement not only with experiment, but also with those in the published literature (13, 14). The void density was determined from TEM examinations to be $5 \times 10^{16}/cm^3$. A TEM micrograph of this sample can be seen in Fig. 10.

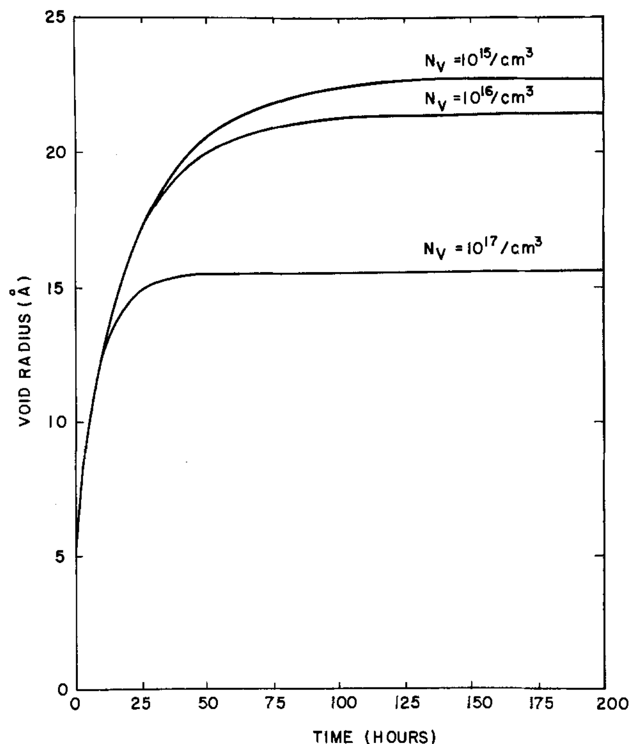

Fig. 9. Void size as a function of the void density

To compare the theoretical resistivity decay curve with experiment, a single experimental point (at 94 hr) was used as a reference and all other points were calculated from the vacancy resistivity and the theoretical vacancy concentration. This calculation was performed for a film containing the observed void density as well as for a void-free film. The results are shown in Fig. 11(a) and (b). It can be clearly seen that the calculation, which accounts for the presence

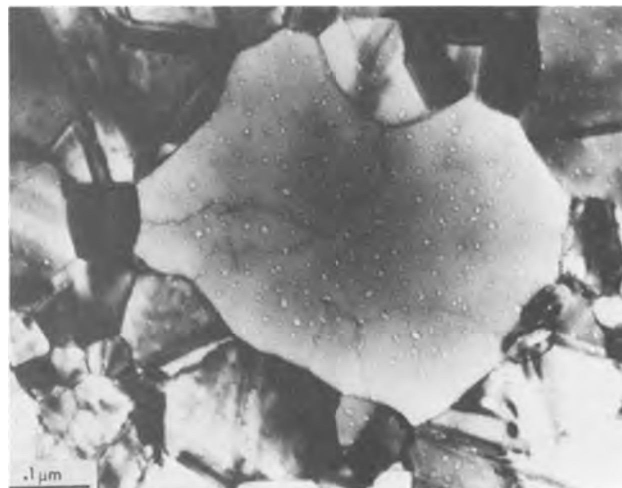

Fig. 10. TEM micrograph of voids in the sample studied here. Void density is measured to be $N_v = 5 \times 10^{16}/cm^3$. The film thickness is 1000Å.

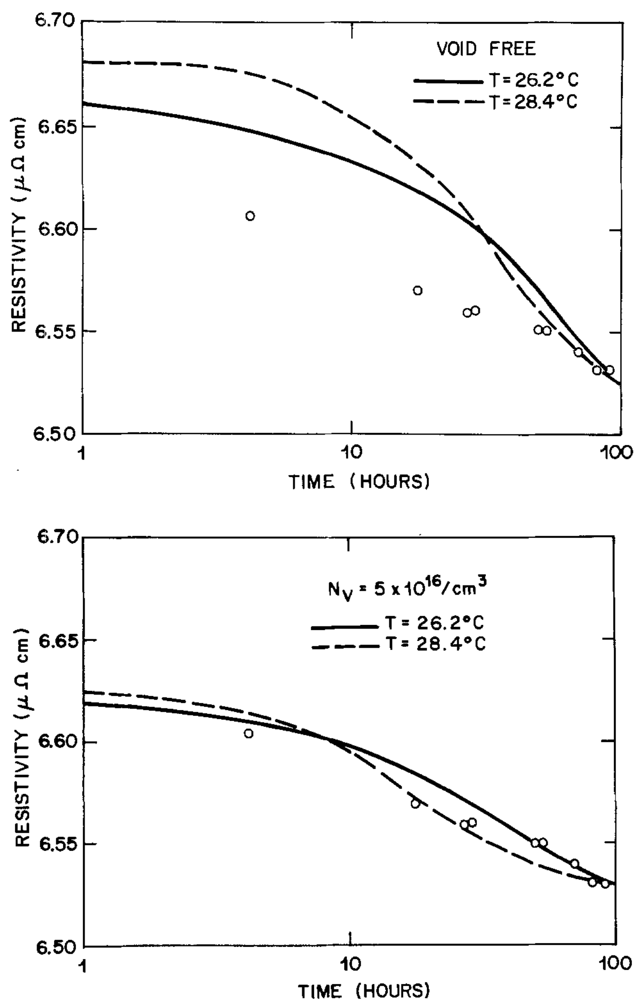

Fig. 11. Comparison of theoretical resistivity decay with experiment (a) for a void-free gold film; and (b) for a film containing the observed void density of $5 \times 10^{16}/cm^3$. $C_0 = 0.25\%$. The temperatures listed reflect the experimental uncertainty. The film thickness is 1000Å.

of voids, agrees much better with the experiment than that in which the voids are ignored.

Summary

Both the resistivity decay and the void growth due to quenched-in excess vacancies in thin evaporated gold films were analyzed by the use of a theoretical model in which the vacancy annihilation takes place primarily at film surfaces and preexisting voids. In this mathematical formulation, the vacancy concentration is determined from a solution to the problem of outdiffusion from a thin slab with a simultaneous first-order chemical reaction. This treatment gave excellent agreement with experimental measurements of resistivity decay and void growth. Furthermore, theoretical results have shown that the voids are important sinks for excess vacancies in thin films. Finally, it is suggested that the problem of the resistivity decay can be readily eliminated by annealing the film typically for less than an hour at 75°C.

Impurity Dopant Incorporation and Diffusion during Molecular Beam Epitaxial Growth of IV-VI Semiconductors

Donald L. Smith* **and Vincent Y. Pickhardt**

The Perkin-Elmer Corporation, Optical Group Research Department, Norwalk, Connecticut 06856

ABSTRACT

PbTe, $Pb_{0.78}Sn_{0.22}Te$, and $Pb_{0.91}Sn_{0.09}Se$ single crystal films were grown on $BaF_2(100)$ at 620°-720°K and 10^{-9} Torr by coevaporation of the stoichiometric binary compounds and the dopant elements from separate sources. Molecular incident fluxes measured with a quartz crystal monitor usually agreed with those calculated from vapor pressure data to within 20%. Unintentionally doped films had carrier concentrations in the 10^{16}-10^{17} cm^{-3} range. n and p doping were achievable by stoichiometry adjustment using coevaporated Pb and Te (or Se), respectively; but only $\approx$0.1% of each became incorporated: the remainder surface-segregated (Pb) or reevaporated (Te,Se). Conversely, $>\frac{1}{2}$ of incident Bi and Tl became incorporated as n and p dopant, respectively, to levels $>10^{19}$ cm^{-3}, most likely by substituting for Pb or Sn and displacing it to the growth surface; except that Bi in the selenide (and Sb in both) showed less incorporation as dopant at $>10^{18}$ cm^{-3}, most likely due to compensation. Bi_2Te_3 behaved as Bi in the telluride and was found to sublime molecularly according to $\log_{10} P(Bi_2Te_3, Torr) = (1.53 \times 10^4/T) + 16.4$. SIMS depth profiling of grown abrupt dopant steps showed high-concentration diffusion coefficients of Bi and Tl in (PbSn)Te at 650°K and of Tl in (PbSn)Se at 620°K to be 9, 4, and 0.9 $\times$ 10^{-15} cm^2/sec, respectively; but much faster diffusion ($>10^{-10}$ cm^2/sec) of Tl in the selenide occurred up to 3 $\times$ 10^{17} Tl/cm^3. Similar low-concentration fast diffusion caused carrier concentrations of undoped telluride films below layers doped with Bi or Bi_2Te_3 to be shifted by 3 $\times$ 10^{17} cm^{-3} toward n-type and 5 $\times$ 10^{17} cm^{-3} toward p-type, respectively; the latter and possibly also the former shift was due to equalization of dopant-perturbed stoichiometry deviation rather than to fast-diffusing Bi. Excellent junction profile control may be obtained with these impurity dopants provided that the fast-diffusing components are appropriately compensated for in junction design.

The IV-VI semiconductors, particularly the ternary alloys $Pb_{1-x}Sn_xVI$, where VI is S, Se, or Te, are valuable as photovoltaic infrared radiation detectors and as tunable diode lasers. This is because they have small direct bandgaps which are widely variable through the infrared photon energy range by both composition (x) and temperature tuning. Molecular beam epitaxial (MBE) growth of these compounds offers the following advantages: low temperature to minimize interdiffusion, precise definition of multilayer structures, and compositional uniformity over large areas.

Like other compound semiconductors, the IV-VI compounds are single phase over a range of stoichiometry deviation from metal-rich to metal-poor, and the resulting lattice vacancies (and sometimes interstitials) act as n-type and p-type dopants, respectively. Control of the stoichiometry deviation by various techniques has often been used to produce p/n junctions in these materials, but this procedure is limited in both the control and the level of doping achievable when MBE is used, as will be seen below. We have consequently employed instead the impurities Sb and Bi as n-type dopants and Tl as a p-type dopant. It has been suggested that these impurities are incorporated substitutionally on metal lattice sites (1), and this model is consistent with their doping behavior and their position relative to Pb and Sn on the Periodic Table. Bi and Tl have been demonstrated to be particularly well-behaved (in PbTe, at least) compared to Cu, Ag, In, As, and Sb in that the carrier concentration which they produce changes very little with stoichiometry deviation or with measurement temperature (1). It was the object of the present work to study the behavior of these impurities under MBE growth conditions, including rates of incorporation into the growing film, maximum doping levels achievable, and diffusion rates. The IV-VI compounds selected included PbTe and two ternary alloys which have bandgaps of 0.9 eV (14 μm photon) at 77°K; namely, $Pb_{0.78}Sn_{0.22}Te$ and $Pb_{0.91}Sn_{0.09}Se$. These ternary alloys will be referred to as (PbSn)Te and (PbSn)Se in the text below.

Experimental Procedures

The basic MBE apparatus has been described in detail previously (2). Briefly, film constituents are evaporated from isothermal Knudsen cell sources enclosed in individual liquid nitrogen-cooled shrouds, in an ultra-high vacuum system which operates at 10^{-9} Torr during film growth. Substrates are chemically polished $BaF_2(100)$ wafers which are heated and temperature controlled to ±1°K. Binary compound evaporation sources, *e.g.*, PbTe, are synthesized in-house by vacuum fusion of the 6-nines pure elements, which are weighed to within 10 ppm (2 $\times$ 10^{17} atoms/cm^3) of stoichiometric proportions. The binary compounds sublime almost entirely as molecules (3). Dopant materials are evaporated simultaneously from separate sources during film growth. In this work all dopants were evaporated from elemental sources, except that Bi in the form of commercially obtained Bi_2Te_3 was also used for comparison purposes.

Mass deposition fluxes of the various evaporated materials are measured by a room temperature resonant quartz crystal monitor swung into the substrate position. This technique as applied here is accurate to 5% or $\pm 10^{-9}$ g/cm^2 sec, whichever is greater. For calibration purposes, the deposition fluxes can be related to the vapor pressures of the evaporants in the

* Electrochemical Society Active Member.
Key words: Bi, Tl, Bi_2Te_3, vapor pressure, nonstoichiometry.

following manner. Evaporant effuses from a thin-walled orifice in a hemispherical pattern in which the flux at any position on the hemisphere is proportional to the cosine of the angle from the orifice normal. For this cosine-law distribution, the flux at the normal is twice the average flux over the hemisphere, so that by mass balance

$$2\pi r^2(W/2) = (\pi/4)D^2J \text{ or } W = (D^2/4r^2)J \quad [1]$$

where W = flux (molecules/cm^2 sec) incident on quartz crystal or on substrate positioned normal to the orifice, D = orifice diameter, r = radial distance of quartz crystal from orifice, and J = effusion flux. For true Knudsen cell operation, molecular flow through the orifice must be maintained by keeping cell pressure P low enough so that the molecular mean free path exceeds the orifice diameter, and vapor-solid equilibrium must be ensured by maintaining isothermal conditions and by keeping the orifice area well below evaporant surface area (here it is about 1/10). Under these conditions, which are maintained in this work

$$J \text{ (molecules/cm}^2\text{ sec)} = 3.51 \times 10^{22} P/(MT)^{1/2} \quad [2]$$

where P = vapor pressure in Torr of effusand at cell temperature T(°K) and M = molecular weight of effusand (4). In this work, T is accurate to $\pm\frac{1}{2}\%$. J as defined above also denotes the surface evaporation flux from a pure material, provided that the molecular species are the same in the vapor and in the condensed phase, so that Eq. [2] is also useful for estimating reevaporation rates from a growing film. In order to avoid confusion, surface evaporation flux will be denoted as J'. Vapor pressures calculated from quartz crystal data using Eq. [2] are almost always within a factor of two of those reported in the literature [for the elements see Ref. (5)] and are usually within 20%. In cases of discrepancy, the quartz crystal result has always been assumed to represent the true W here. The necessary assumption that all incident material condenses on the room temperature quartz crystal appears to be valid, for even in the case of the most volatile constituent encountered in this work, Se, the measured deposition rate was no less than that calculated from reported vapor pressure data, provided that a comparable amount of Pb or Sn was simultaneously incident to assist condensation. If significant reevaporation of Se had been taking place, the measured W would have been less than that calculated from P. In the cases of the dopant materials, W during film growth is typically two orders of magnitude below the level at which an accurate quartz crystal calibration can be made. In such cases, the quartz crystal calibration point has been extrapolated assuming the same P vs. T slope as reported in the literature for that material. Since these slopes depend only on the latent heat of evaporation, they are far less likely to be affected by experimental conditions than are the absolute values of P; and in fact, in several cases for which we have measured the slope, no discrepancy has been observed.

A quadrupole mass spectrometer is positioned in the path of the effusing beams to monitor evaporant composition and purity. The beams are mechanically chopped at 17 Hz, and the mass peak output is synchronously detected in order to distinguish the beam signal from the d-c background which tends to build up in the mass spectrometer in the cases of the more volatile species.

Film growth conditions for the selenide typically have been 1 μm/hr and 620°K (substrate temperature), and those for the telluride have been varied from 1 μm/hr and 650°K to 4 μm/hr and 720°K. The higher growth rate has been adopted to save time and necessitates a higher substrate temperature to maintain film quality. Growth under these conditions is initiated at 650°K for the first 0.1 μm to ensure uniform nucleation on the BaF_2. In general in MBE, best epitaxy is obtained at a substrate temperature not more than 50°-100°K below the point at which the reevaporation rate of the growing film begins to approach deposition rate; that is, before $J' \rightarrow W$.

Carrier concentrations and mobilities of the grown films were determined by resistivity and Hall voltage measurements using the van der Pauw method (6) at 77°K. Gold pressure contacts were adequate in most cases. The single-carrier expressions were used for calculation, assuming a unity Hall factor

$$n = 10^{-8} IH/deV \quad [3]$$

and

$$\mu = dV/10^{-8} IH\rho \quad [4]$$

where n = carrier concentration (cm^{-3}), I = sample current (amperes), H = magnetic field strength (G), d = film thickness (cm), e = electronic charge (coulombs), V = Hall voltage, μ = mobility (cm^2/V-sec), and ρ = resistivity (Ω-cm).

The dislocation etch pit density of PbTe on BaF_2(100) was measured for films 4-17 μm thick using the etch recommended by Harman (7) and was found to be $4(\pm1) \times 10^7$/cm^3, independent of thickness. This is about the same as the density reported for $Pb_{0.78}Sn_{0.22}Te$ on PbTe (8) despite the larger lattice mismatch of the former (3.7% vs. 0.51%).

Dopant diffusion studies were carried out on two-layer films consisting of an undoped layer covered by a layer highly doped with Tl or Bi. Between layers, growth was stopped with a shutter for about 2 min to allow dopant source equilibration at the appropriate temperature for evaporation. The resulting abrupt step in dopant concentration was thus exposed to the film growth temperature for the time required to grow the doped layer. The dopant profile was then determined by an outside laboratory by secondary ion mass spectroscopy (SIMS), which involves sputtering away the film with an ion beam while mass-analyzing the sputtered species. Actual spectra showed that the mass resolutions of the Cameca SIMS instruments used were sufficient in most cases to separate completely both the Tl and Bi peaks from the much larger Pb peak adjacent. In addition to these measurements, carrier concentration levels and uniformities in the undoped underlayers of these two-layer films were determined by etching just through the doped top layer using $Br_2/HBr/H_2O$ and then measuring the carrier concentration of the remaining film. Successive etches and electrical measurements on progressively thinner remainders of film were used to determine doping gradients in the undoped layer.

Dopant Incorporation

Results.—The incident flux calibration data necessary to calculate the degree of dopant incorporation were obtained as discussed above except in the case of Bi_2Te_3, for which vapor pressure and vapor composition were unavailable and had to be measured using the quartz crystal and the mass spectrometer. Figure 1 shows the mass spectrum of subliming Bi_2Te_3. Although the mass spectrometer has an upper mass/charge limit of 300, the triply-ionized species ($q = 3$) in all cases fall within range. The predominant species are Bi_2Te_3, Bi, and Te, with no evidence of BiTe, Bi_2, or other molecular fractions. An absolute calibration was obtained for the intensity of the Bi^+ peak in this spectrum by using the source of elemental Bi, which evaporates predominantly as the monatomic species. This source was in turn calibrated using the quartz crystal. The W_{Bi} represented by the Bi^+ peak height shown on Fig. 1 amounts to only 2% of the total W of Bi_2Te_3 as determined directly by the quartz crystal. Therefore, Bi_2Te_3 sublimes almost entirely undissociated, and its use consequently represents a significantly different doping situation from the use of elemental Bi. Even the small amount of dissociation

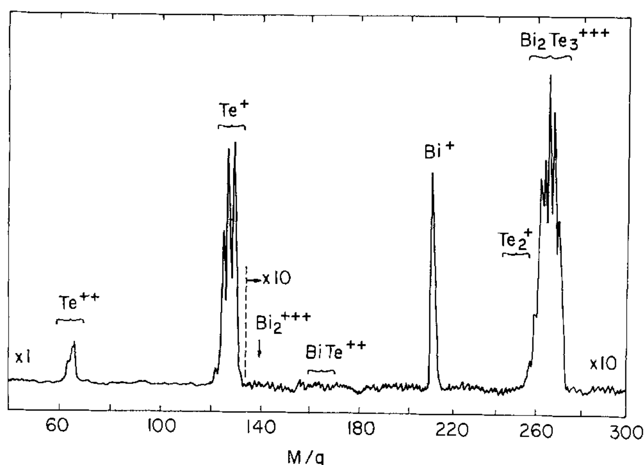

Fig. 1. Mass spectrum of sublimating Bi_2Te_3, showing Bi_2Te_3, Bi, and Te to be the major vapor species and Bi_2, BiTe, and Te_2 to be absent. Note the ×10 ordinate sensitivity increase above $M/q = 130$. M = molecular weight (amu) and q = ion charge.

which is observed could be occurring on electron impact in the ionization chamber of the mass spectrometer rather than on sublimation. It was observed, in addition, that the telluride is somewhat less "gassy" a source than the element, possibly because of a reduced tendency to oxidize on exposure to atmosphere. Vapor pressures of subliming Bi_2Te_3 calculated from quartz crystal data using Eq. [1] and [2] were fitted to within 10% over the range 2×10^{-2} to 1×10^{-4} Torr to the following equation of the standard Clausius-Clapeyron form

$$\log_{10} P(Bi_2Te_3, Torr) = (1.53 \times 10^4/T) + 16.4 \quad [5]$$

Equation [5] was extrapolated to obtain Bi_2Te_3 incident fluxes at doping levels. P of 2×10^{-2} Torr occurs just below the melting point of 846°K.

Dopant incorporation efficiency can be measured by comparing the actual change in carrier concentration produced by the dopant, $(n - n_o)$, with the change calculated assuming that all incident dopant is incorporated in active form, $(n_c - n_o)$. A doping coefficient γ is thus defined

$$\gamma = (n - n_o)/(n_c - n_o) \quad [6]$$

The carrier concentration (in cm^{-3}) for the doped (n) and undoped (n_o) films are found from Hall measurements using Eq. [3]. Typically, n_o is much larger than the intrinsic carrier concentration, presumably because of nonstoichiometry doping. n_o is in general expected to be a function of growth conditions, but within the range of conditions used here it was reproducible to within 20% for each of the three semiconductors and was 4×10^{16} n/cm^3 for PbTe, 6×10^{17} p/cm^3 for (PbSn)Te, and 2×10^{17} p/cm^3 for (PbSn)Se. $(n_c - n_o)$ is calculated from

$$(n_c - n_o) = \alpha_o (W_d/G_t) N_t \quad [7]$$

where α_o = theoretical number of charge carriers per dopant molecule, G = molecules/cm² sec incorporated into the growing film, N = density (molecules/cm³), subscript t denotes the sum of the major film species, *e.g.*, (PbTe + SnTe), and subscript d denotes a dopant species. α_o is −1 for Bi, +1 for Tl, and −2 for Sb_2 and Bi_2Te_3; W_d is calculated as discussed under "Experimental Procedures"; G_t is found from final film thickness and growth time; and $N_t = 1.5 \times 10^{22}$ molecules/cm³ for the tellurides and 1.7×10^{22} for the selenides.

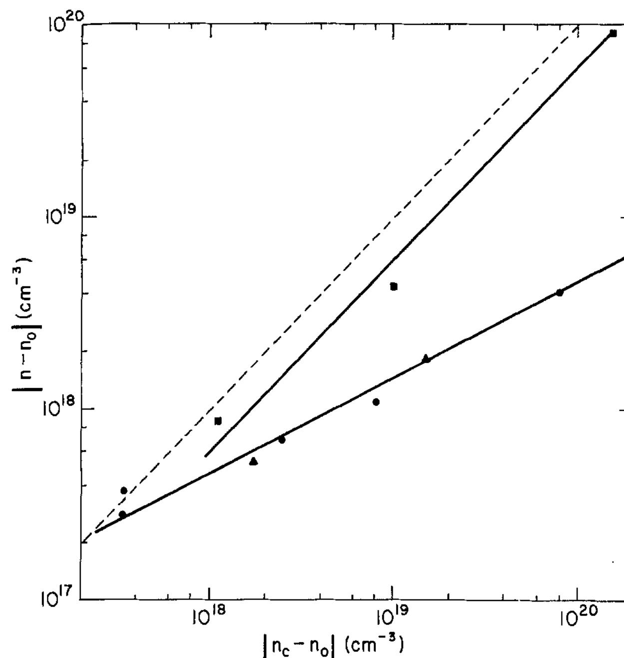

Fig. 2. Impurity dopant incorporation in $Pb_{0.91}Sn_{0.09}Se$ grown at 1 μm/hr and 620°K. – – = unity incorporation coefficient, ■ = Tl, ● = Bi, ▲ = Sb.

Doping incorporation data for Tl, Bi, and Sb in (PbSn)Se grown at 1 μm/hr and 620°K are plotted in Fig. 2. Tl is incorporated into the semiconductor with $\gamma = 0.6$ up to a doping level as high as 9×10^{19} cm^{-3}, whereas Bi and Sb exhibit a sublinear dependence of γ on doping level, such that the dependence in both cases fits the empirical equation

$$\gamma = 0.45(10^{18}/|n_c - n_o|)^{0.50} \quad [8]$$

Table I summarizes the doping coefficients calculated from plots such as Fig. 2 in this and previous work in our laboratory on the IV-VI semiconductors. These include the doping coefficients for the Group IV and

Table I. Doping coefficients for IV-VI semiconductors grown from stoichiometric binary compound sources

	Sb_2	0.46	$0.15(10^{18}/\|n_c - n_o\|)^{0.54}$	—	$0.45(10^{18}/\|n_c - n_o\|)^{0.50}$

[a] Se_5 is the major vapor species between 500° and 1000°K (10).
[b] Previously published data (11).
[c] Same at 4 μm/hr at 650°K.

Group VI elements themselves, which are added during film growth from separate elemental sources just as are the impurity dopants, rather than being obtained by using nonstoichiometric IV-VI compound sources. For the tellurides, note that Sb_2, but not Bi, exhibits a sublinear dependence on doping level of the form of Eq. [8].

In some cases γ was constant only up to some "saturation level" of doping, above which it dropped to zero. Table II summarizes the highest doping levels obtained thus far in this work, with those levels which represent saturation levels being so indicated. In the case of (PbSn)Te grown with W_{Pb} well above the saturation level, metallic droplets could be observed under the microscope on the grown films (11). For comparison, Table II also presents saturation level data reported by other workers on annealed ingots.

The effect on γ of adding a large excess flux of elemental Te_2 ($W_{Te} = 0.1 W_t$) during growth of impurity-doped film was also studied for a few selected cases, as outlined in Table III. For PbTe, excess Te_2 increased the γ of Sb_2 and of Bi, but that of Bi_2Te_3 was unchanged. In the Bi case, γ had begun to decrease from the constant value of 0.8 reported in Table I as saturation was approached, and the excess Te_2 brought it back up to 0.6. In the case of Tl incorporation in PbTe at levels above $10^{18}/cm^3$, excess Te is necessary to maintain good μ. A possible explanation for the very low μ otherwise obtained is that Tl is beginning to enter Te sites, where it would be likely to behave as a carrier trap. In the case of Bi-doped (PbSn)Te, the excess Te_2 actually reversed the carrier type.

Hall mobilities, μ, were independent of doping level up to a certain "knee" level, and were about 1×10^4 cm^2/V sec for all p-type material, 2×10^4 for n-type ternary alloys, and 3×10^4 for all n-type PbTe. Above the knee, μ decreased with increasing n so as to maintain resistivity, ρ, constant at

$$\rho = 1/ne\mu = 2 \times 10^{-4}\ \Omega\text{-cm} \quad [9]$$

for all three compounds, to within a factor of two.

Table II. Highest doping levels achieved for IV-VI semiconductors. Growth was from stoichiometric binary compound sources except as noted. Underlined data indicates "saturation level."

Discussion.—A simple model for the condensation and incorporation of a dopant during MBE will be developed here to allow a first-order calculation of γ to be made. The model will assume that all incident dopant becomes incorporated in electrically active form except that which reevaporates given the vapor pressure of the pure dopant. The way in which the experimental γ's differ from those found from this model will give some insight as to which of the other possible mechanisms are taking place, namely, surface segregation, increased or decreased evaporation rate due to molecular binding differences, or incorporation in inactive or compensating form.

To begin with, $(n_c - n_o)$ in Eq. [6] for γ is given by Eq. [7]. For $(n - n_o)$ in Eq. [6], we may write

$$(n - n_o) = (\alpha G_d/G_t) N_t \quad [10]$$

where α = actual number of charge carriers per dopant molecule, and other symbols are as defined previously. In the most general terms, G for any one of the film constituents may be expressed as

$$G = W - R - F - Lf' \quad [11]$$

where R = molecules /cm^2 sec reflected from the surface of the growing film immediately upon impact, F = molecules/cm^2 sec reevaporated from the surface, L = molecules/cm^2 in a monolayer, and f' = time derivative of fractional surface coverage f. Steady-state surface composition may be assumed under steady growth conditions (except near the start of growth), so that $f' = 0$. For the major species, growth temperature is always low enough so that $G_t \approx W_t$. (If G_t were less than W_t, by the way, it would be possible to obtain values of γ greater than unity.) We will also assume that the attraction of the dopant species to the surface is strong enough so that $R = 0$. Finally, we will assume that the dopant reevaporation rate F_d may be determined from the pure substance vapor pressure (Eq. [2]), certainly the most tenuous assumption of this simple model, and that it is also proportionately reduced by the fractional surface coverage f_d. This is equivalent to Raoult's law of ideal solutions

$$F_d = f_d J_d' \quad [12]$$

We will now define a surface segregation coefficient, β, as the excess of the dopant fractional surface coverage, f_d, over its fractional atomic incorporation rate

$$\beta = f_d/(z_d G_d/z_t G_t) \quad [13]$$

where z = atoms per molecule. This definition neglects the small differences in atomic volume amongst the elements involved. With these simplifications, we may combine Eq. [6], [7], and [10]-[13] into a form from which an estimate of γ may be calculated

$$\gamma = (\alpha/\alpha_o)/(1 + \beta z_d J_d'/z_t W_t) \quad [14]$$

Using Eq. [14] and [2] and available vapor pressure data, γ's have been calculated for the special case of complete dopant activation ($\alpha = \alpha_o$) and no surface segregation ($\beta = 1$) and for growth conditions of 1 μm/hr ($W_t = 4.5 \times 10^{14}$ molecules/cm^2 sec) and 650°K. These results are listed in Table I. Note that all of the metals and Bi_2Te_3 have low enough P's so that γ is near unity; whereas for Te_2 and Se_5, γ's are very low because most of the adsorbate is reevaporating. Agreement between calculated and experimental γ's is good for Tl, Bi, Bi_2Te_3, and Te_2 in the tellurides. For Pb in (PbSn)Te, on the other hand, γ is 10^3 smaller than expected. Considering the magnitude of the discrepancy, this is most likely due to surface

segregation ($\beta >> 1$) rather than to a lower α or higher J_d' than expected; for it is generally believed that most incorporated excess Pb does produce charge carriers ($\alpha \approx 1$), and the appearance of metal droplets on (PbSn)Te supersaturated with Pb proves that J_d' is not excessive. Why such extensive surface segregation ($\beta \approx 10^5$) should occur for a major constituent of the film even when composition is well away from the metal-rich phase boundary remains unexplained. For Se_5 in (PbSn)Se, γ is 1000 times larger than expected, and this can only be due to a J' which is much less than that given by Eq. [2], which means that Se is bonded much more strongly to the (PbSn)Se surface lattice than it is to itself.

The sublinear dependence on n of γ_{Sb} in PbTe and of γ_{Sb} and γ_{Bi} in (PbSn)Se could be due to an n dependence of either α or β in Eq. [14]. The fact that both p and n behavior has been observed for Sb in PbTe (1) depending on stoichiometry deviation is evidence of amphoteric behavior in this dopant, which would be expected to lead to a decreasing α with increasing n: As more metal lattice vacancies (n-type sites for Sb) were filled, more Sb would be forced into nonmetal (p-type) sites, thus compensating itself out. The threefold increase in γ_{Sb} in PbTe with the use of excess Te_2 during growth is consistent with this explanation: A larger fraction of the Sb is incorporated into the Pb vacancies thus created, rather than going into Te sites. Excess Te had the opposite effect on Bi-doped (PbSn)Te, however, actually changing it to p-type. The much higher solubility of metal vacancies in (PbSn)Te than in PbTe (18) probably caused the large amount of Te excess used ($W_{Te} = 0.1\ W_t$) to generate in (PbSn)Te a concentration of Pb vacancies larger than N_d, thus overcompensating it, whereas in PbTe this many metal vacancies could not be generated. Adjustment of W_{Te} to a lower value should avoid such compensation and accomplish the desired increase in γ, but it is preferable to use compound dopants such as Bi_2Te_3. The absence of influence of W_{Te} on the γ of Bi_2Te_3 in PbTe and the near-unity value of that γ suggest that the use of Bi in telluride form is forcing it into Pb sites without the need for excess Te. The following reaction for the incorporation of Bi_2Te_3 is proposed

$$Bi_2Te_3(g) \rightarrow 2BiTe^+(s) + 2e^- + \tfrac{1}{2}\,Te_2(g) \quad [15]$$

where (g) denotes a gaseous species, (s) a substitutional solid species, and e^- a conduction electron. Here $BiTe^+$ substitutes directly for PbTe or SnTe in the crystal lattice. The extra Te must be reevaporating rather than generating metal vacancies; otherwise, a lower γ of 0.5 would be observed due to compensation. It is likewise improbable that mechanisms involving dissociation of the $BiTe^+$ are involved, for the Te thus produced would also generate compensating metal vacancies and reduce γ substantially.

The "saturation levels" reported in Table II for both present and reported work are the maximum n's obtainable no matter how much dopant is used. These are presumably the solubility limits of the dopants. The highest doping levels achieved in the present work are about equal to the saturation levels reported for annealed ingots except in the case of Te_2, whose high volatility is the likely explanation for the lower saturation level observed in the present work. It should be noted that in most cases the highest levels observed in the present work have not yet been demonstrated to be the saturation levels, simply because higher doping levels were not attempted. The doping levels achieved here for Tl, Bi, and Bi_2Te_3 are high enough for most device applications.

The fact that Bi and Tl are incorporated into PbTe and (PbSn)Te with near-unity γ's up to the 10^{19} cm^{-3} level tells us something about their incorporation reaction mechanisms during film growth, as is shown by the following argument. Consider that in general, the metal dopants may be incorporated interstitially or substitutionally. Substitution may involve occupation of a metal vacancy, generation of a Te vacancy, or displacement of a metal atom; the displaced atom in turn is incorporated interstitially or precipitated at the growth surface. We neglect the possibility of dopant substitution on VI sites which was suggested above for Sb and for Bi in (PbSn)Se, because there is no evidence of such behavior for Bi or Tl in (PbSn)Te, and it can be avoided for Bi and Tl in PbTe by the use of excess Te. The various mechanisms described above may be expressed symbolically for Bi incorporation as

$$Bi(a) \rightarrow Bi^+(i) + e^- \quad [16]$$

$$Bi(a) + V_{Pb}^- + e^+ \rightarrow Bi^+(s) + e^- \quad [17]$$

$$Bi(a) \rightarrow Bi^+(s) + V_{Te}^+ + 2e^- \quad [18]$$

$$Bi(a) + Pb(s) \rightarrow Bi^+(s) + Pb^+(i) + 2e^- \quad [19]$$

$$Bi(a) + Pb(s) \rightarrow Bi^+(s) + Pb(a) + e^- \quad [20]$$

(a) denotes a species adsorbed at the surface, (i) an interstitial, (s) a substitutional, V a vacancy, and e^+ a hole or p-type charge carrier. Vacancies are written ionized as ($V_{Pb}^- + e^+$) and $V_{Te}^+ + e^-$) to indicate their recognized behavior as acceptors and donors, respectively. Of course, Sn as well as Pb may be involved in any of the above mechanisms.

Similarly, for Tl incorporation

$$Tl(a) \rightarrow Tl^+(i) + e^- \quad [21]$$

$$Tl(a) + V_{Pb}^- + e^+ \rightarrow Tl^-(s) + e^+ \quad [22]$$

$$Tl(a) \rightarrow Tl^-(s) + V_{Te}^+ + e^+ + e^- \quad [23]$$

$$Tl(a) + Pb(s) \rightarrow Tl^-(s) + Pb^+(i) + e^+ + e^- \quad [24]$$

$$Tl(a) + Pb(s) \rightarrow Tl^-(s) + Pb(a) + e^+ \quad [25]$$

Note that α varies from $+2$ to -1 among the above ten mechanisms. We will now argue that many of these mechanisms are highly unlikely. Metal interstitials generally behave as donors [Ref. (9), p. 17], but since Tl is experimentally an acceptor, Eq. [21] cannot be important. Among the substitutional mechanisms, Eq. [17] and [22] are ruled out because the supply of V_{Pb} is insufficient from material grown from stoichiometric sources. The solubility of V_{Te} in (PbSn)Te is not sufficient to support Eq. [18] or [23] (see Table II); furthermore, Eq. [18] would lead to $\alpha = 2$, while in fact $\alpha = 0.5$ for Bi, and Eq. [23] would lead to $\alpha = 0$, while in fact $\alpha = 0.8$ for Tl. Equations [19] and [24] involving the production of Pb(i) are highly unlikely because of the very high β of Pb, and because they predict γ's far different from those observed. Therefore, it is most likely that Bi and Tl incorporation proceed by Eq. [20] and [25] involving substitution and displacement of Pb (and Sn) to the growth surface, although interstitial Bi (Eq. [16]) cannot be ruled out either. Note that, in contrast to Eq. [20] and [25], Eq. [15] for Bi_2Te_3 involves the accumulation of no metal at the surface, but rather of Te_2, which is volatile.

Dopant Diffusion

Results.—The experiments described in this section are summarized in Table IV. Two-layer diffusion test films using Bi and Tl in (PbSn)Se and (PbSn)Te were grown and SIMS-profiled as described above under "Experimental Procedures." The actual doping profile for the Tl203 isotope in (PbSn)Se is shown in Fig. 3, for a film grown at 1 μm/hr and 620°K with the calculated doping profile shown by the dotted line. There is an abrupt drop at the edge of the doped region, as expected, but there remains a constant residual level of 3×10^{17} Tl/cm^3 throughout the undoped layer; finally, the Tl signal drops to the noise level of the instrument at the BaF_2 substrate surface. The Tl203 signal intensity has been converted to N_{Tl}

	Tl	No detectable shift in underlayer doping (<4 × 10^{16}/cm^3)	—

(atoms/cm^3) by assuming N_{Tl} at the surface to be the same as in a single-layer film grown under the same conditions as the top layer in Fig. 3. N_{Tl} of the single-layer film was calculated from Hall measurements assuming $\alpha = 1$ in Eq. [10]. Bi209 in (PbSn)Se could not be analyzed due to interference from Pb208. However, using a higher resolution instrument, both Tl and Bi in (PbSn)Te were analyzed, and similar profiles were obtained, except that tails were present on both signals which extended from the abrupt step all the way into the substrate, as illustrated qualitatively in Fig. 3. Such a tail is characteristic of the so-called "knock-on" effect, in which some material is pushed ahead into the film by the impinging SIMS ion beam. The problem could be avoided by growing the undoped layer on top of the doped layer, but that configuration presents the risk of a small amount of surface-segregated dopant continuing to incorporate into the undoped top layer as the latter is grown, producing a similarly artifactual tail. For a sufficiently large β, this effect could be as large as the "knock-on" effect.

In order to verify that the tails observed were in fact artifacts, Tl- and Bi-doped (PbSn)Te diffusion samples were also analyzed for n *vs.* depth by the progressive etching technique described above under "Experimental Procedures." The results for Bi are shown in Fig. 4. The dotted line shows the expected n in the Bi-doped layer and n_o in the undoped layer based on Hall measurements on single-layer films grown under the same conditions (1 μm/hr, 650°K). The horizontal bars show measured average n over the film thickness remaining after each of three etching steps. Note that n is the same, within experimental error, for all three film remainders, but that it is also significantly less p-type than that observed in an undoped single-layer film. This difference (3 × 10^{17}/cm^3) thus represents the effect of exposing an undoped layer to a highly Bi-doped layer for ½ hr at 650°K. The same experiment for Tl in (PbSn)Te showed that no measurable change (<4 × 10^{16}/cm^3) in n of the undoped layer was brought about by the presence of the highly doped (2 × 10^{19} Tl/cm^3) layer. The use of Bi_2Te_3 (5 × 10^{18} Bi/cm^3) as a Bi dopant in the etching sample resulted in an increase in the p-conductivity of the undoped layer, rather than a decrease as observed for Bi metal dopant. For successive etches of the undoped layer under the Bi_2Te_3-doped layer, n was constant at 1.1 ± 0.05 × 10^{18} p/cm^3, an increase of 5 × 10^{17}/cm^3 over the n_o of an undoped single-layer film.

Discussion.—SIMS profiles for Tl in (PbSn)Se and for Tl and Bi in (PbSn)Te and etching data for Tl, Bi, and Bi_2Te_3 in (PbSn)Te all show an abrupt (<0.2 μm wide) step in doping level at the position of the grown metallurgical junction, indicating diffusion rates slow enough for good junction profile control in device fabrication. Etching data demonstrated that the tails observed on the SIMS profiles of Tl and Bi in (PbSn)Te were indeed artifacts. However, it is observed from SIMS data in the case of Tl in (PbSn)Se and from etching data in the cases of Bi and Bi_2Te_3 in (PbSn)Te that there is also a much faster diffusion mechanism operable up to a certain intermediate N_d which significantly affects the carrier concentration of the entire underlying layer.

A rough estimate of the diffusion coefficient D for the slower diffusion may be obtained from the SIMS data by assuming that D is independent of N_d above the intermediate level, in which case the solution to the diffusion equation for an infinite medium with an initial ($t = 0$) diffusand concentration $N = N_o$ for $x < 0$ and $N = 0$ for $x > 0$, becomes [Ref. (9), p. 105]

$$N(x,t) = (N_o/2)[1 - \text{erf}(x/2\sqrt{Dt})] \qquad [26]$$

Since for all time t, $N = N_o/2$ at $x = 0$, the slope of

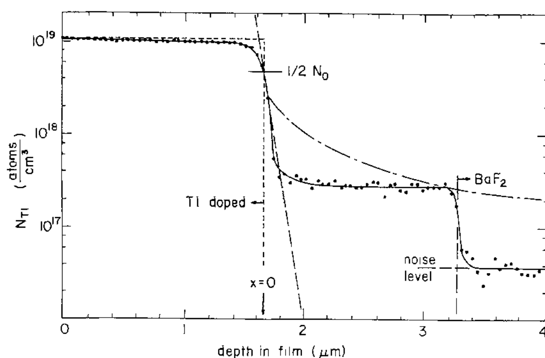

Fig. 3. Doping profile of Tl203 in $Pb_{0.91}Sn_{0.09}Se$ as determined by SIMS, showing very fast diffusion of Tl throughout the undoped layer up to a level of 3 × 10^{17} cm^{-3} and much slower diffusion at higher levels; 1 μm/hr and 620°K growth. --------- expected N_{Tl} profile with no diffusion, —— —— slope at ½ N_o used to calculate D, —·—·—·— "knock-on" tail obtained in (PbSn)Te (typical shape).

the concentration profile at $N_0/2$, as shown in Fig. 3, becomes a convenient measure of D. It follows from Eq. [26] that

$$d(\log_{10}N)/dx|_{x=0} = 0.434/(\pi Dt)^{1/2} \quad [27]$$

To the actual slope measured from Fig. 3, a correction must be applied for that part of the slope which is due to sputter-etch roughening of the SIMS sampled area. This contribution was determined by measuring the slope of the Pb208 signal at the BaF_2 surface and adjusting it to $x = 0$ by assuming that roughness increases linearly with sputter-etching depth. Similar calculations were made on SIMS data for Bi and Tl in (PbSn)Te, and the resulting D's are presented in Table V along with related diffusion data from the literature.

The fast diffusion coefficients observed below the intermediate N_d cannot be calculated in this way because the gradients in N_d in the undoped layers are not large enough to be measurable; but a lower limit on D may be obtained by observing that the change in N_d through the undoped region is less than $1 \times 10^{16}/cm^3$ and by applying this condition to Eq. [26]. These calculations have been done for the SIMS data on Tl in (PbSn)Se and for the etching data on Bi in (PbSn)Te, and the results are presented in Table V. Since etching data indicates insignificant fast diffusion using Tl in (PbSn)Te, no fast diffusion coefficient appears for that system.

Diffusion data of other workers presented in Table V were in most cases obtained over a range of T not extending down to the MBE growth T, so the standard expression

$$D = D_0 \exp(-Q/kT) \quad [28]$$

was used for extrapolation to obtain D's at that T, where Q = activation energy for diffusion. Three types of data are presented: self-diffusion, and junction and impurity diffusions. The first describes the motion of radioactive tracer through the otherwise homogeneous material, which motion may take place by an interstitial, a vacancy, or some more complex mechanism. Junction diffusion describes the motion of a p/n junction produced by a nonstoichiometry gradient. Junction motion may involve any of the self-diffusion mechanisms of either the Group IV or the Group VI elements, but may also be much faster than any of these. For example, if the junction moves by Pb vacancy diffusion, which takes place by exchange with neighboring Pb atoms, the vacancy may pass through the entire crystal while each Pb atom involved in the individual "hops" between neighbors only moves one atomic distance. Therefore, the vacancy may move much farther through the crystal in a given time than do any of the individual Pb atoms involved in its motion. The junction diffusion coefficient includes the motion of excess Pb and Te vacancies, while the self-diffusion or radioactive tracer diffusion coefficient measures only the motion of labeled atoms, not of vacancies. Since, in general, D is expected to be dependent on the degree of nonstoichiometry of the host material because of the role of vacancies, the carrier concentration of the material used is also listed when available. The case of Pb self-diffusion in PbTe (13) is particularly dramatic in this respect, D in low p-type material being 10^4 larger than in high p-type. The authors attributed the increase to a change in mechanism from vacancy to interstitial, which was consistent with the accompanying drop in Q which was also observed.

The slow D's measured above the intermediate level of N_d for Bi and Tl in (PbSn)Te in the present work compare well with reported D's for self-diffusion and Sb diffusion in low p-type tellurides: They are all of the order of 10^{-14} cm²/sec. The slow D for Tl in (PbSn)Se is about 10^2 higher than that of Sb or Pb in PbSe, and the fast D below the intermediate doping level is at least 10^4 higher than any D reported in the IV-VI compounds (junction D's excepted since these do not necessarily represent directly the transport of material, as explained above). While diffusion behavior such as that observed here for Tl in (PbSn)Se is unusual, a similar situation has been reported for In in GaAs (17), in which most of the In diffuses slowly in Ga-substitutional sites, but a small fraction enters interstitial sites and diffuses very rapidly. Lower solubility impurity components in general tend to have higher D's [Ref. (9), p. 90]. Therefore, the following is a likely mechanism for the D behavior of Tl in (PbSn)Se: most of the Tl enters metal-substitutional sites according to Eq. [25] and diffuses very slowly, but a small fraction enters interstitial sites according to Eq. [21] and diffuses much more rapidly.

A similar low-solubility, fast-diffusing interstitial component of Bi incorporated according to Eq. [16] would explain the $3 \times 10^{17}/cm^3$ drop in n observed in undoped (PbSn)Te underneath highly Bi-doped material. However, an equally reasonable alternate explanation could be based on the incorporation of a small fraction of the Bi according to Eq. [17], [18], or [19] in addition to the predominant incorporation according to Eq. [20]. The resulting reduction in V_{Pb} or increase in V_{Te} or Pb(i), respectively, would set up a nonstoichiometry gradient toward the undoped layer, the equalization of which would result in a reduction in the p-conductivity of the underlayer and would also

proceed by the relatively fast p/n junction diffusion mechanism. In fact, the lower limit of D measured for the fast-diffusing component is of the same order, 10^{-10} cm²/sec, as the average junction D reported for PbTe. If this latter mechanism were the correct one, the same effect would be expected to occur to at least a detectable extent for Tl as well, whereby Eq. [22]-[24] would cause a drop in p-conductivity in the underlayer. However, in view of the fact that such a drop is not observed below Tl-doped material, the fast diffusion mechanism in Bi-doped material is more likely to be that involving a fast-diffusing component of Bi itself.

In the case of the increase in p-conductivity of material under the Bi_2Te_3-doped layer, the extra Te atom has to be involved in the fast diffusion mechanism and the Bi itself must be diffusing much less quickly in order to explain such an increase. That is, in addition to the Eq. [15] mechanism for Bi_2Te_3 incorporation, which involves reevaporation of the extra Te atom, some of this Te must be incorporated into the film according to

$$Bi_2Te_3(g) \rightarrow 2BiTe^+(s) + Te^-(i) + 2e^- + e^+ \quad [29]$$

or

$$\rightarrow 2BiTe^+(s) + Te(s) + V_{Pb}^- + 2e^- + e^+ \quad [30]$$

followed by nonstoichiometry equalization by Te(i) or V_{Pb} diffusion as discussed above. Reported junction diffusion coefficients (Table V) are large enough to account for the observed doping shift under the conditions existing. The replacement of Bi by Bi_2Te_3 as an n-dopant has not eliminated effects on the underlayer, but has merely changed the nature of the problem. Nevertheless, the effects in both cases are small enough so that they can be canceled by appropriate compensation without degrading the material appreciably, since μ does not begin to decrease until above 10^{18} N/cm³ or so.

Conclusions

It has been demonstrated above for MBE growth of IV-VI semiconductors that accurate and reproducible n control up to the 10^{19}/cm³ level may be obtained in most cases by using Bi and Tl as n-type and p-type impurity dopants and by calibrating W with a quartz crystal monitor. This approach is preferable to n control by stoichiometry deviation adjustment, which usually cannot achieve as high an n and which also involves extensive surface segregation in the case of excess metal and extensive reevaporation in the case of excess nonmetal. The latter is expected to lead to an exponential dependence of γ on growth temperature, which would make control difficult. Nearly all Bi and Tl are actively incorporated into both the tellurides and the selenides except for Bi in (PbSn)Se. The latter situation could probably be improved by using Bi_2Se_3 as a Bi source, if it were found to evaporate molecularly as was Bi_2Te_3.

Most Bi and Tl appears to be incorporated substitutionally on metal sites by displacing metal to the growth surface, and the D's of these dopants are low enough so that very abrupt (<0.2 μm) junctions may be grown. However, in most cases, a small fraction of dopant is also incorporated in such a way as to lead to much faster diffusion of metal interstitials or nonmetal vacancies up to a certain intermediate level of doping. This leads to a shift in the n of adjacent epitaxial layers, which must be accounted for in junction device growth. In view of the likely role in these processes of interstitials and vacancies of the Group IV and VI elements themselves, the extent of n shift as well as the fast D values are expected to be dependent on n_o, which in turn depends on the specific growth conditions for the material. Therefore, the numerical values reported here can only be regarded as typical. The D values might also be driven either up or down by the use of material with a lower dislocation density. Finally, although the most likely diffusion mechanisms were postulated above based on the available evidence, unique mechanisms cannot be identified without studying the profiles across a junction of both N_d and n as a function of n_o and preferably also as a function of T.

Theory and Direct Measurement of Boron Segregation in SiO_2 during Dry, Near Dry, and Wet O_2 Oxidation

Richard B. Fair* and J. C. C. Tsai

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

A theory of B segregation is developed which accounts for the differences in m observed in, for example, diffusion from a highly doped B_2O_3 source as compared to oxidation of B-doped Si in wet and dry oxidizing ambients. We have found that most dry O_2 oxidations are really only partially dry and that the presence of as little as ~20 ppm H_2O results in an m essentially the same as oxidation in 100% steam, *i.e.*, $m = 0.58$ at 1200°C with an "effective" activation energy of 0.64 eV. However, in a truly dry oxidation, the B segregation coefficient at 1200°C is ~1 with an effective activation energy of 0.33 eV. We propose that these differences as well as the $m > 2$ observed in high concentration B_2O_3 diffusion source oxidations are determined by the formation thermodynamics of the B compounds that are created during segregation. Quantitative agreement with m values obtained from directly measured B distributions across the SiO_2/Si interface are obtained (SIMS measurements with oxygen leak). Also, through-oxide B implants were observed to have segregation coefficients equal to the pure dry O_2 case even though the subsequent oxidations were performed in O_2 ambients with trace amounts of H_2O. Examples are presented which illustrate the effect of trace amounts of H_2O on B diffusion during oxidation.

During the growth of an oxide layer on silicon containing a Group III or V impurity, unequal distribution of the impurity will occur between the two Si phases. For the case of B in Si it has been presumed that B_2O_3 glass is formed during the segregation reaction at the interface (1, 2). Since this oxide is very stable, B will be "gettered" into the growing SiO_2 films. Since the diffusivity of B is large in Si compared with the SiO_2 growth rate, a significant depletion of B can occur in the Si near the SiO_2/Si interface.

Many studies of B segregation in SiO_2 have been reported in the literature. A review of these studies through 1975 is given by Murarka (3). More recent work has been reported in Ref. (4-10). Most of these studies have relied on various mathematical models using boundary conditions imposed by surface oxidation, some of which are too approximate or are incorrect. Also, using these models to extract segregation coefficients, m, from measurements of sheet resistance and junction depth can be risky due to the large sensitivity of m on R_S. As a result, reported segregation coefficients cover a wide range and show conflicting dependence on temperature. More recent studies in which direct measurements have been made also show an orientation dependence (6).

It is the purpose of this paper to present a theory of boron segregation in SiO_2 as a basis for evaluating the extensive published data. Orientation dependence and concentration dependence as well as ambient dependence are considered. In addition, new data are presented which were obtained from secondary ion mass spectrometry utilizing an oxygen leak for continuous measurement through the SiO_2/Si interface. It is shown, that in pure dry O_2 ambients, B segregates in SiO_2 as glassy B_2O_3 and elemental B with $m = C_{Si}/C_{SiO_2} = 1$ at 1200°C and with an "effective" activation energy of 0.33 eV. With as little as 20 ppm H_2O in the ambient, it is proposed that B segregates as crystalline HBO_2 and elemental B with $m = 0.58$ at 1200°C and with an "effective" activation energy of 0.64 eV. The results with 100% steam are the same as "dry" O_2 with trace amounts of H_2O.

To begin, the experimental procedure used in this study is presented along with experimental results. Based on the apparent equilibrium nature of boron segregation (11) the theory of this phenomenon is discussed.

Experimental

Sample preparation.—Silicon wafers, n-type, 1-2 Ω-cm with <100> and <111> orientations were used in this study. These wafers were Syton polished on one side and chemical etched on the other side. They were given a standard cleaning process which includes H_2O_2 + HCl and H_2O_2 + NH_4OH. Silicon wafers oxidized in a wet ambient were processed with nitrogen gas passing through water at 98°C, and those oxidized in "dry" oxygen were processed with plant oxygen which contains ~16 ppm of methane. Since methane

Key words: ion implantation, diffusion, oxidation, segregation, boron.

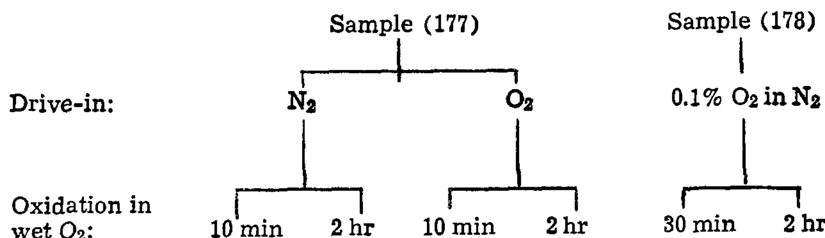
combusts to water at high temperature, these wafers were not oxidized in purely dry oxygen. Earlier direct measurements of moisture content in a typical B-drive-in furnace in our facility as a function of position in the tube showed 15-30 ppm H_2O in the flow of oxygen (12). The effect of moisture on the experimental results are discussed in a later section.

Conditions of treatment and sample identification.—The following is a list of all the experimental information on the samples in this paper:

1. The first group of wafers were oxidized to a thickness close to 2150Å in either "dry" oxygen or wet oxygen. Two of these wafers were <111> oriented and the rest were <100> oriented. Boron was implanted at 50 keV to a dose of 1×10^{15} cm^{-2} into these wafers through the oxide. The boron profile had its peak concentration near the oxide-silicon interface. These wafers were then diffused at 1150°C for 60 min in 1% O_2 + 99% N_2 or in 100% O_2. Another wafer was divided into four quarters and three of them were diffused in 1% O_2 + 99% N_2 at 1100°, 1050°, and 1000°C for 120, 240, and 480 min, respectively.

2. The second group of silicon wafers, <100> oriented, were boron implanted at 50 keV with doses ranging from 1×10^{14} to 1×10^{16} cm^{-2} and diffused at 1150°C for 55 min in 0.1% O_2 + 99.9% N_2. After diffusion these wafers were oxidized and the oxidation conditions are given in Table I.

3. Two <100> oriented wafers were boron implanted at 50 keV to a dose of 5×10^{14} cm^{-2}. One of these wafers (177) was cut into two halves. They were driven-in at 1150°C for 55 min in N_2 (177A) and O_2 (177B), respectively. The other wafer (178) was diffused at 1150°C for 55 min in 0.1% O_2. Subsequent wafer division and processing are shown below:



4. Four Si wafers (2 Ω-cm, <100> orientation) were boron implanted at 30 keV to a dose of 5×10^{14} cm^{-2} and diffused at 1150°C for 55 min in 0.1% O_2 + 99.9% N_2. Each wafer was divided into four quarters and three of them from each wafer were oxidized at 1200°C (No. 1 wafer), 1150°C (No. 2 wafer), and 1050°C (No. 3 wafer) for 2, 5, and 10 min; and at 950°C (No. 4 wafer) for 5, 10, and 20 min in oxygen. The sample identifications are given in Table II. The oxide thicknesses were measured with an ellipsometer. Since the samples were small in comparison with the light beam, a few samples did not give good ellipsometric readings. The measured oxide thicknesses are also given in Table II and these results reasonably agreed with the SIMS data.

Table I. Sample identification and processing

Sample	Dose	Temp (°C)	Time (min)	Ambient
104	1E14	1050	60	Dry O_2
60	1E16	1050	60	Dry O_2
308A	5E15	900	30	Wet O_2
307A	5E15	1050	10	Wet O_2
307B	5E15	1050	30	Wet O_2

950-20	950	20	190

Ion implant—Ion implantations were done in either an AI machine or an Extrion-Varian 200-1000 ion implant system. B^{11} ions were extracted at 30 keV, mass analyzed, and accelerated for energies greater than 30 keV. Both machines provided uniform implantations at comparable ion energies. No special cleaning was performed on the experimental samples after implantation prior to heat-treatment.

SIMS analysis.—The boron profiles near the SiO_2/Si interface were measured by the SIMS technique (secondary ion mass spectrometry) in a CAMECA IMS-300 system which has been modified with an oxygen leak in the target chamber.[1] Blanchard has made this improvement on his system and reported the advantages of such an arrangement (13).

Since a clean silicon surface is chemically active and it can be oxidized in a very short time, the presence of sufficient oxygen near the silicon surface will convert it to oxide readily. The needed oxygen is introduced onto the sample surface through a controlled oxygen leak valve. The primary ion beam is sputtering off SiO_2 instead of Si for the entire measurement. Thus, when measuring the secondary Si signal across a SiO_2-Si interface, no abnormal changes of the signal are recorded, which means there is no change of the secondary ion yield near an interface. When measuring the secondary ion signal from an impurity near an interface, any discontinuity of the signal would represent the segregation phenomenon.

IR reflectance and ESCA analysis.—The chemical state of B implanted into SiO_2 and segregated into SiO_2 was studied using electron spectroscopy for chemical analysis (ESCA).[2] Also, infrared reflectance spectra were obtained at room temperature on a Perkins-Elmer 621 grating *IR* spectrophotometer.[3]

Experimental Results

Implantation through SiO_2.—The measured profiles of B implanted through 2150Å of SiO_2 at 50 keV are shown in Fig. 1. Excellent continuity of measured B concentration is obtained across the SiO_2/Si interfaces. The result obtained when the 1×10^{15} cm^{-2} implant was annealed at 1150°C for 60 min in 100% O_2 (<100> Si) is shown in Fig. 2a. During the oxidation drive-in, 650Å of SiO_2 was grown in addition to the existing oxide. It can be seen that the B segregation coefficient is ~1 at the SiO_2/Si interface since the B concentration on the SiO_2 side is equal to the B concentration on the Si side. A similar result (m = 0.8) was obtained for a <111> sample oxidized at 1050°C for 60 min in 100% O_2.

The resulting profile when the drive-in is performed in 1% O_2 is shown in Fig. 2b. Some redistribution of

[1] These profiles were measured under contract by B. Blanchard, Centre D'Etudes Nucleaires De Grenoble, Commissariat A L'Enegie Atomique, France, Grenoble.
[2] The ESCA work was performed by G. P. Schwartz, Bell Laboratories.
[3] The infrared spectra were obtained by G. A. Baldauf, Bell Laboratories.

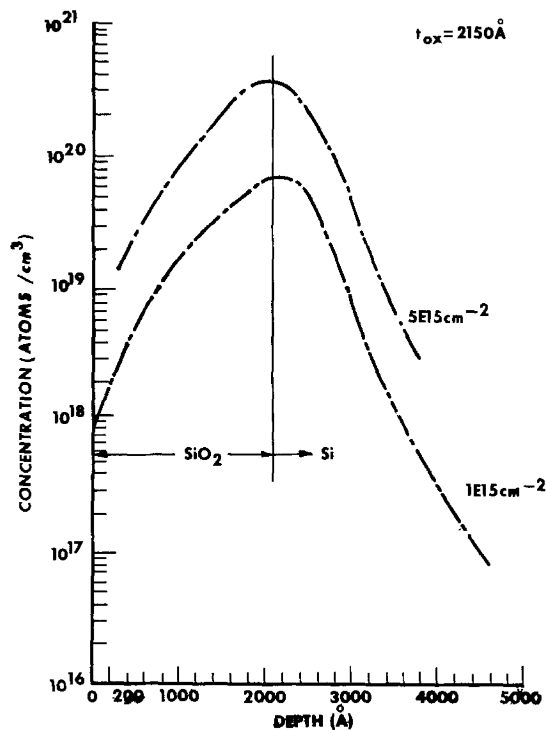

Fig. 1. SIMS profiles of two 50 keV B implants through the Si/SiO_2 interface.

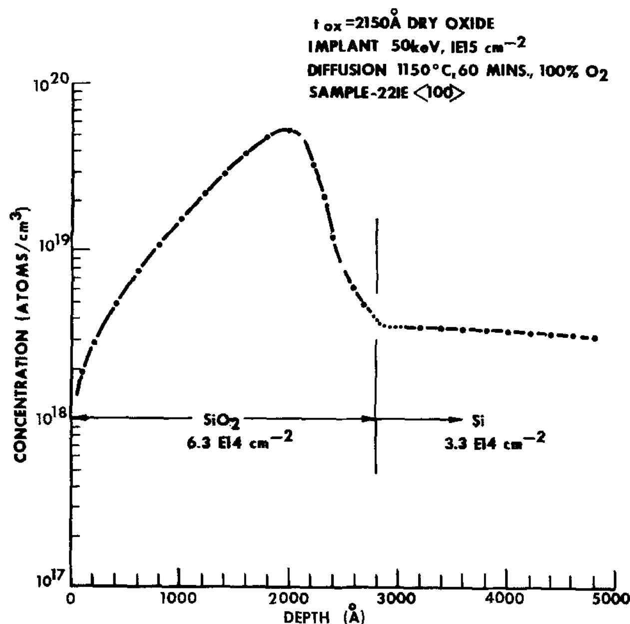

Fig. 2a. SIMS profile of the diffusion and segregation of a through-oxide B implant in near dry O_2.

B has occurred on the SiO_2 side of the interface to accommodate the boundary condition $m = 1$ for the thin oxide growth. For this case, the oxide layer acts much like a blocking boundary since little segregation occurs. The surface concentration was observed to decrease with time, t, according to the expression

$$C_S = K\left(\frac{Q_T{}^2 n_i}{D_i t}\right)^{1/3} \quad [1]$$

where $K = 0.53$ is an empirical constant, Q_T is the implant dose, n_i is the intrinsic electron concentration, and D_i is the intrinsic B diffusion coefficient. A similar result has been obtained for implanted As diffusion in Si (14).

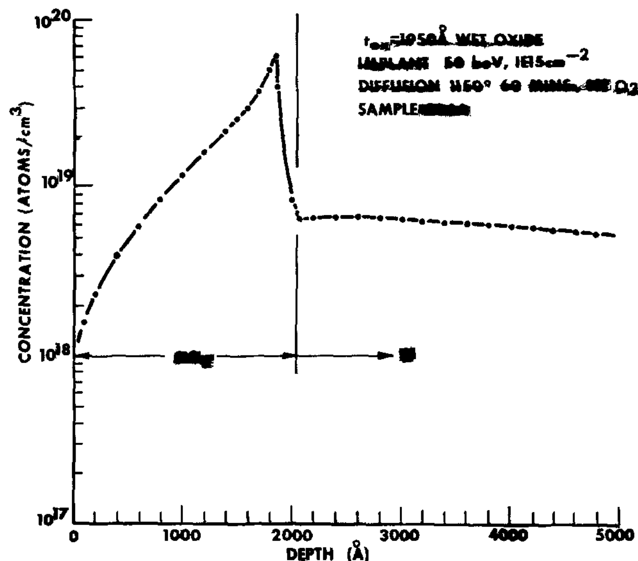

Fig. 2b. SIMS profile of a through-oxide implant diffused in 1% O_2.

Oxidation of B-implanted Si.—Typical results of the effect of Si oxidation on the segregation of B implanted and diffused into bare <100> Si are shown in Fig. 3a and b. Sample 104 was oxidized in "dry" O_2 for 60 min at 1050°C and sample 307B was oxidized for 30 min in wet O_2. For both cases the segregation coefficient is ~0.33. The results for this phase of the study are summarized in Fig. 4 where the measured segregation coefficient data are plotted *vs.* B concentration at the Si side of the SiO_2/Si interface. It can be seen that regardless of the time of oxidation, ambient, preoxidation treatment, and surface concentration, the B segregation coefficient is $m = 0.33 \pm 0.03$ at 1050°C.

The time dependence of the segregation coefficient at four oxidation temperatures is shown in Fig. 5. It can be seen that m is independent of time. Thus, it would appear that B segregation can be treated as an equilibrium phenomenon as proposed by Thurmond (11).

Chemical state of boron.—The results of using ESCA to determine the chemical state of B near the SiO_2/Si

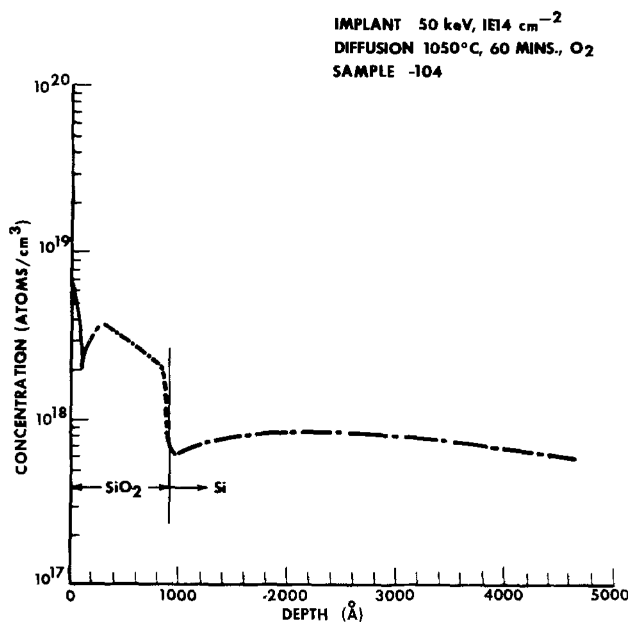

Fig. 3a. SIMS profile of the diffusion and segregation of B implanted into Si and annealed in near dry O_2.

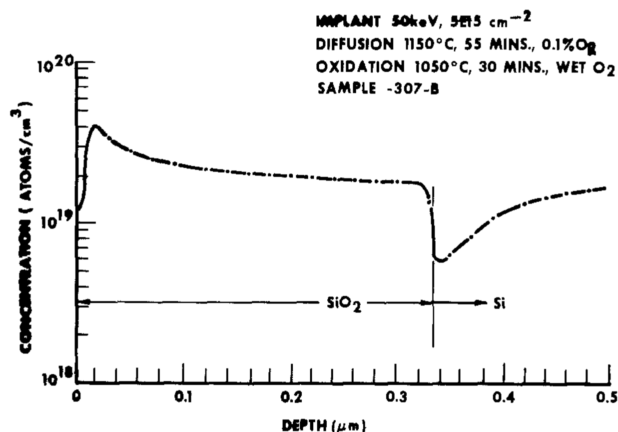

Fig. 3b. SIMS profile of the diffusion and segregation of B implanted into Si and annealed in wet O_2.

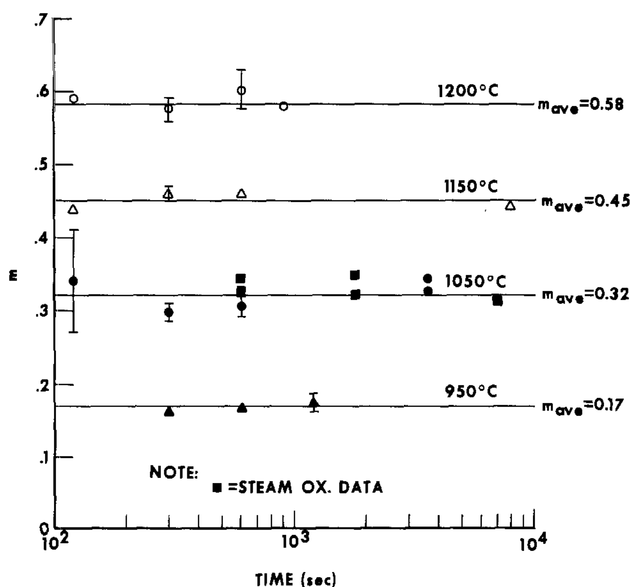

Fig. 5. Time dependence of B segregation coefficient for near dry oxidation of <100> Si.

interface indicated that in both the as-implanted samples (B into SiO_2/Si) and the heat-treated in "dry" O_2 samples, boron exists in the B^{+3} state. Since this is the naturally occurring state for boron, it is expected that typical B compounds (oxides, oxoacids, etc.) can potentially form in the SiO_2 film.

Infrared reflectance measurements of samples 1050-10 and 1150-10 (SiO_2 grown in "dry" O_2 over B implanted-diffused Si) showed a slight, but detectable B-OH peak at 8.4 μm and no B-O peak at 7 μm. Higher dose B implants (1×10^{16} cm^{-2}) into 2150Å of SiO_2 with subsequent O_2 annealing at 1150°C for 1 hr showed a significant 8.4 μm satellite peak on the broad 9.2 μm Si-O band. Again, no 7 μm B-O peak was observed.

The 8.4 μm B-OH band was observed by Arai *et al.* (15) following an 800°C, 5 min wet oxygen heat-treatment of an insoluble Si-B compound produced at a B_2O_3/Si interface. The above results indicate that any B_2O_3 formed during the oxidation treatments in our experiments may have reacted with the trace amounts of water in our system to form a compound such as B_2O_3-H_2O (or $2HBO_2$). The effects of small amounts of water vapor on the vapor pressure of HBO_2 and B_2O_3 over B sources such as BBr_3 and BN indicate that in the 800°-1200°C temperature range the vapor pressure of HBO_2 is several orders of magnitude higher than that of B_2O_3 with 0.04 atm H_2O (16). Also, molecular ion detection in a SIMS apparatus has shown that at the interface between a CVD borosilicate film and Si, BO_2^- ions were detected (17). It is not clear whether the detected ions were $HB^{10}O_2^-$ (mass 43) or $B^{11}O_2^-$ (mass 43). Nevertheless, they were only detected at the interface.

These observations support our hypothesis that some B-OH compound is formed in B-doped SiO_2 during near dry and wet O_2 oxidation. At this point it is appropriate to develop a theory of B segregation in order to see if our results are consistent with the concept of thermodynamical equilibrium at the SiO_2/Si interface.

Theory of Boron Segregation in SiO_2

Dry O_2 oxidation.—Following the arguments of Thurmond (11) it is possible to estimate the equilibrium segregation coefficient of B from basic thermodynamics. A proposed reaction occurring at the SiO_2/Si interface during pure dry O_2 oxidation is

$$BO_{3/2} + 3/4\ Si = B + 3/4\ SiO_2 \quad [2]$$

The reaction free-energy *vs.* temperature curve of [2] and other reactions to be discussed are shown in Fig. 6 (18). Reaction [2] involves the oxide B_2O_3. However, since the B^{+3} ion is randomly arrayed in cation positions in a dilute solution, X_{gl} will be the mole fraction of B^{+3} in the glass. The oxide can then be conveniently written $BO_{3/2}$.

Assuming thermodynamic equilibrium exists, an equilibrium constant for the above reaction can be written as

$$K_1(T) = \frac{\gamma_s X_s}{\gamma_{gl} X_{gl}} \quad [3]$$

where X_s and X_{gl} are the mole fractions of B in the Si and the glassy $BO_{3/2}$ phase, respectively. The activity coefficients are γ_s and γ_{gl}. $K_1(T)$ can be calculated from the free energy of $BO_{3/2}$ formation through the expression

$$\Delta G^\circ = -RT \ln K_1(T) \quad [4]$$

The segregation coefficient m is defined as

$$m \equiv \frac{X_s}{X_{gl}} \quad [5]$$

$$= \left(\frac{\gamma_{gl}}{\gamma_s}\right) \exp\left(\frac{-\Delta G^\circ}{RT}\right) \quad [6]$$

from Eq. [3] and [4].

The condition of equilibrium requires that the chemical potential of a particular component be the same in each phase. Thus, for a liquid phase

$$\gamma_s X_s = \gamma_l X_l \quad [7]$$

where γ_l and X_l refer to the activity and mole fraction of B in a liquid phase. Equation [6] can now be written in terms of the binary distribution coefficient $k_l = X_s/X_l$ which is empirically known to be 0.7 for B

in Si at the melting temperature of Si (19). Thus

$$m = k_1 \frac{\gamma_{gl}}{\gamma_l} \exp\left(\frac{-\Delta G^\circ}{RT}\right) \quad [8]$$

At the melting point of Si ($T = 1415°C$), ΔG° of reaction [2] is -5.73 kcal/mole (18). Assuming that $\gamma_{gl} \simeq \gamma_l$ gives $m = 4.1$. The assumption of equal activities can be made, but it is not known if B has the same charge state in the Si melt as in the SiO_2 glass. Also, the effect of oxygen in the Si melt on γ_l is not known.

In order to investigate the temperature dependence of m, use will be made of Weiser's (20) expression for the binary distribution coefficient given as

$$k_l = \frac{X_s}{X_l} = \gamma_l \exp\left[\frac{\Delta H_f - \Delta \overline{H}^s}{RT} - \frac{\Delta H_f}{RT_{mB}}\right] \quad [9]$$

In this equation ΔH_f is the heat of fusion of B (5.3 kcal/mole), $\Delta \overline{H}^s$ is the differential heat of solution of B in the Si crystal, and $T_{mB} = 2030°C$ is the melting point of B. The last term in the brackets is the entropy of B fusion. The $\Delta \overline{H}^s$ term is a function of the bonding energy of B in Si, the strain energy associated with the misfit of B in Si, and the heat of sublimation of B to a monatomic gas. This term is calculated in the Appendix.

The activity coefficient of B in the Si melt becomes constant as the melting point of Si is approached (20). If it is assumed that $\gamma_{gl} = \gamma_l$, this implies that all of the B segregated into the SiO_2 is in a glassy (or liquid) form such as B_2O_3. However, Inoue *et al* (21) have been able to resolve unoxidized B in SiO_2. Therefore, B_2O_3 can be reduced to elemental B in the SiO_2 lattice. Thermodynamically, Si can reduce B_2O_3. Chu *et al.* (22) have, in fact, shown that thin SiO_2 films are Si rich. Most of the excess Si exists within 2-4 monolayers of the interface at concentrations of $\sim 1 \times 10^{16}$ cm^{-2}, independent of temperature. More recent measurements by Feldman *et al.* (23) indicate that elemental Si exists within ~3Å of the SiO_2/Si interface at concentrations of $\sim 10^{15}$ cm^{-2}.

What this all means is that the free energy of the B segregation reaction at the interface will depend on how much B_2O_3 is formed. Also, the activity coefficient of B in the glassy form, γ_{gl}, will change. For this situation the new activity coefficient, γ_{gl}', can be written as (at $T = 1415°C$)

$$\gamma_{gl}' = \frac{\gamma_{gl} X_{gl}}{X_{gl}'} \frac{a_{gl}'}{a_{gl}} = \gamma_l \left(\frac{X_s}{X_{gl}'}\right)\left(\frac{X_{gl}}{X_s}\right) \exp\left(\frac{-\Delta G_{gl}^\circ}{RT}\right) \quad [10]$$

In this expression a_{gl} denotes the activity of B in the glassy phase, and ΔG_{gl}° is the difference in free energies between the cases where X_{gl} and X_{gl}' mole fractions of B_2O_3 are formed during segregation. It has already been shown that $X_s/X_{gl} = m$ and $X_s/X_{gl}' = m'$.

Following the calculations of Weiser (20) in the Appendix it is shown that $\Delta \overline{H}^s = 22.4$ kcal/mole for B in Si. Using $\Delta H_f = 5.3$/mole (24) and substituting Eq. [9] and [10] into the expression for segregation coefficient, m finally becomes

$$m = \left[\gamma_l \left(\frac{m'}{m}\right) \exp\left(\frac{-\Delta G_{gl}^\circ}{RT}\right)\right]\Bigg|_{T = T_{mp\,Si}} \exp\left[\frac{-17{,}100 - \Delta G^\circ}{RT} - 1.151\right] \quad [11]$$

Numerous reactions were investigated involving the segregation of B, including reaction [2]. These reactions were evaluated on the basis of Eq. [11] which requires that ΔG° be compatible with the temperature dependence of experimental data, and the preexponential term including ΔG_{gl}° at $T = 1415°C$ combine to yield the correct value. Only one other reaction besides [2] was found to satisfy these criteria. It is proposed here that the following reactions can occur at the SiO_2/Si interface in 100% dry O_2

$$\tfrac{1}{2}\,Si + \tfrac{1}{2}\,O_2(g) = \tfrac{1}{2}\,SiO_2(gl) \quad [12a]$$

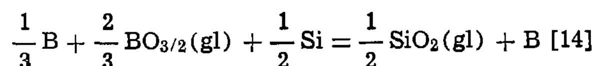
$$\tfrac{1}{2}\,B_2O_2(g) = B + \tfrac{1}{2}\,O_2(g) \quad [12b]$$

$$\tfrac{1}{2}\,B_2O_2(g) + \tfrac{1}{2}\,Si = \tfrac{1}{2}\,SiO_2(gl) + B \quad [12c]$$

The ΔG° *vs.* T curve for [12c] is shown in Fig. 6. The gas B_2O_2 represents the partial oxidation of B and exists as a vapor in the 1000°-1300°C range (25). It can be formed by the reduction of B_2O_3 by B according to the reaction (26) (see Fig. 6)

$$\frac{1}{3}B + \frac{1}{3}B_2O_3(gl) = \frac{1}{2}B_2O_2(g) \quad [13]$$

Adding reactions [12c] and [13] together gives the result



$$\frac{1}{3}B + \frac{2}{3}BO_{3/2}(gl) + \frac{1}{2}Si = \frac{1}{2}SiO_2(gl) + B \quad [14]$$

Reaction [14] is similar to reaction [2] except its free energy is 2/3 ΔG° for [2] ($\Delta G^\circ = -5.73$ kcal/mole at the melting temperature of Si). Referring to Eq. [10] the difference in reaction free energies, ΔG_{gl}°, is 1.9 kcal/mole. Using $m = 4.1$ at $T = 1415°C$ for reaction [2] and extrapolating the measured segregation coefficient data in Fig. 7 to 1415°C yields $m' = 1.4$ for reaction [14]. Thus

$$\gamma_{gl}' = \gamma_l \frac{(1.4)}{(4.1)} \exp\left(\frac{-1900}{RT}\right) = 0.2\gamma_l \quad [15]$$

From Eq. [8] the activity coefficient, γ_l, can be determined and is found to be ≈ 350. Substituting these numbers into Eq. [11] yields

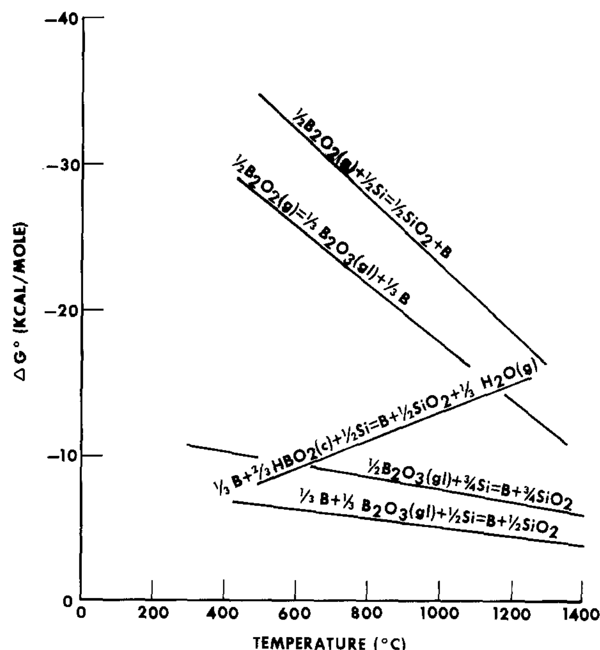


Fig. 6. Reaction free energies of B at the Si/SiO_2 oxidizing interface.

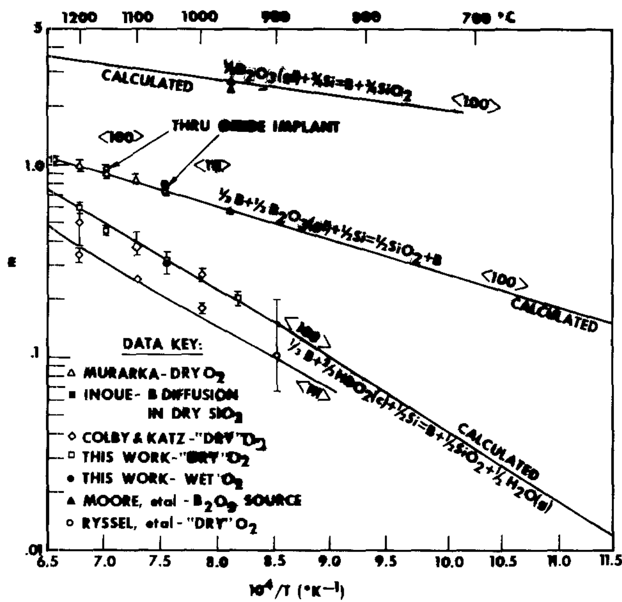

Fig. 7. Boron segregation coefficients at the Si/SiO_2 oxidizing interface.

$$m = 70 \exp\left(\frac{-17{,}100 - \Delta G^\circ}{RT}\right) \qquad [16]$$

with the ΔG° data for reaction [14] (see Fig. 6).

This equation is plotted in Fig. 7 along with the result obtained when only B_2O_3 is formed (reaction [2]). Several interesting observations can be made at this point:

1. Equation [16] gives excellent agreement with the dry O_2 data of Murarka (3) (<100> B implanted Si), with the data of Inoue *et al.* (21) (BN diffusion into SiO_2 on <100> Si), and with the through-oxide implantation of B and subsequent O_2 oxidation performed in this study (<100> sample 221E in Fig. 2a and the <111> sample diffused at 1050°C). The reasoning behind why these data represent pure dry oxidations are presented in the Discussion section.

2. Even though the free energy, ΔG°, for reaction [14] changes with temperature, an "effective" activation energy for Eq. [16] can be obtained by approximation with a van't Hoff-type expression. Thus for dry O_2 oxidation

$$m_{\text{eff}} = 13.4 \exp\left(\frac{-0.33 \text{ eV}}{kT}\right) \qquad [17]$$

The 0.33 eV activation energy is physically meaningless and only is useful in determining the approximate slope of the m *vs.* $1/T$ curve.

3. The calculation of m for reaction [2] indicates that values of $m > 2$ are possible for the case of pure B_2O_3 in SiO_2 on Si. The predicted curve agrees well with the Auger measurements of Moore *et al.* (8) who deposited a boron glass on <100> Si at 957°C in an oxidizing ambient. The two data points on the B_2O_3 curve in Fig. 7 correspond to 5 and 20 min depositions. After ~40 min deposition the resulting glass was ~1800Å thick and the measured segregation coefficient had dropped from ~2.6 to ~0.6. The latter value falls on the curve described by Eq. [16].

By considering the Auger spectra obtained by Moore *et al.* and the B concentrations and B diffusivity in their samples, it is apparent from the B_2O_3-SiO_2 phase diagram that at 957°C a liquid B-doped glass existed at the interface with the Si. Brown and Kennicott (2) also observed this in SiO_2 films doped greater than ~30%/B_2O_3. Consequently, one might expect that the conditions described by reaction [2] would obtain as long as the molten glass was in contact with the Si surface. However, as deposition time proceeded it is evident that dilution of the molten glass occurred at the interface. As the concentration of B_2O_3 dropped below ~30% the boundary condition changed to segregation from a B-doped SiO_2 solid according to reaction [14] with $m \simeq 0.6$.

4. The absolute value of the preexponential factor in Eq. [16] was calibrated by using the measured B binary distribution coefficient $k_l = 0.7$. This value of k_l was obtained for <111> Si. No information could be found on k_l for B in <100> Si. However, Trumbore *et al.* (27) found that the distribution coefficient for antimony in Si did not depend on crystal orientation. Therefore, as expected from equilibrium thermodynamics, the theory as presented does not explain the reported orientation dependence of B segregation (4, 6, 9).

Steam oxidation (or trace water vapor in "dry" O_2).—During the oxidation of Si in a wet oxygen ambient, H_2O becomes the primary oxidant source. Irene and Ghez (28) have shown that the parabolic oxidation rate constant increases abruptly even at trace H_2O concentrations on the order of 25 ppm H_2O in O_2. In their experiments, elaborate methods were required to obtain O_2 ambients with 1 ppm H_2O since the dry O_2 itself contained ~17 ppm methane which combusts to form H_2O. A similar amount of methane was measured in our O_2 gas. The O_2 ambient in the dry oxidation experiments of Beckmann and Harrick (29) contained ~60 ppm H_2O. A recent review by Revesz (30) shows that in numerous experiments performed in "dry" O_2 ambients, Si-OH and Si-H absorption peaks have been found in *IR* spectroscope data, even when Si oxidation tubes were used.

In view of the fact that the B-OH infrared reflectance peak was observed in our "dry" O_2 samples, numerous reactions were investigated involving $H_2O(g)$, B, and $SiO_2(gl)$. Equation [11] was used to evaluate acceptable reaction free energies against the measured segregation data.

For the case where H_2O is the primary oxidant it is proposed that at the SiO_2/Si interface B is initially segregated as $B(OH)_2$ (boron dihydroxide gas). Thus

$$\tfrac{1}{2}\,Si + H_2O(g) = \tfrac{1}{2}\,SiO_2 + H_2(g) \qquad [18a]$$

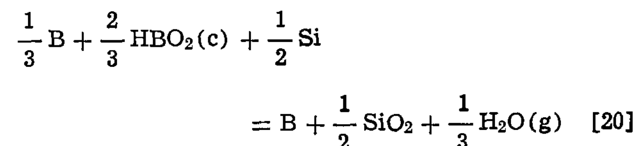
$$H_2(g) + B(OH)_2(g) = B + 2H_2O(g) \qquad [18b]$$

$$\tfrac{1}{2}\,Si + B(OH)_2(g) = B + H_2O(g) + \tfrac{1}{2}\,SiO_2 \qquad [18c]$$

The reaction free energy for [18c] at 1300°K is $\Delta G^\circ = -41.64$ kcal/mole (18). The $B(OH)_2$ gas immediately forms elemental B and a crystalline form of HBO_2 (metaboric acid) according to the reaction

$$\frac{2}{3}H_2O + \frac{2}{3}HBO_2(c) + \frac{1}{3}B = B(OH)_2(g) \qquad [19]$$

with $\Delta G^\circ = 28.21$ kcal/mole at 1300°K (18). The sum of the interface reactions is



$$\frac{1}{3}B + \frac{2}{3}HBO_2(c) + \frac{1}{2}Si = B + \frac{1}{2}SiO_2 + \frac{1}{3}H_2O(g) \qquad [20]$$

The free energy for this reaction is plotted in Fig. 6.

Metaboric acid, HBO_2 or $\tfrac{1}{2}(B_2O_3 \cdot H_2O)$ is stable above 100°C. Holt (31) found that no known acid contains less water than metaboric acid. Thus, it can be formed in trace amounts of H_2O. HBO_2 also has a O-B-OH structure (32) as predicted by *IR* spectroscopic measurements.

For reaction [20] the segregation coefficient for B is

$$m = \gamma_{gl}' \exp\left(\frac{-17{,}100 - \Delta G^\circ}{RT} - 1.151\right) \qquad [21]$$

Since HBO_2 in the oxide is assumed to be crystalline, γ_{gl}' should be near unity. The assumption of crystalline HBO_2 is based entirely on ΔG° *vs.* T data and the comparison of Eq. [21] with measured segregation coefficient *vs.* T data for <100> Si. Referring to Eq. [10] for γ_{gl}' and using the extrapolated m data for <100> Si at $T = 1415°C$ ($m \simeq 1.2$) and with $\Delta G_{gl}^\circ \simeq 11$ kcal/mole, $\gamma_{gl}' \simeq 3.9$. Thus, for reaction [20], Eq. [21] for <100> Si in nearly dry and wet O_2 ambients is

$$m_{100} = 1.23 \exp\left(\frac{-17{,}100 - \Delta G^\circ}{RT}\right) \quad [22]$$

with the ΔG° *vs* T data for reaction [20] shown in Fig. 6.

Equation [22] is plotted in Fig. 7 and compared with the measured <100> data of Colby and Katz (6) and of this work. Excellent agreement is obtained with the temperature dependence of these data. Several observations can be made.

1. Reaction [20] is similar to reaction [14] in that elemental B is created in the interface reactions. However, the mass-action expression for reaction [20] shows that at most, only ~0.4% of the B in the SiO_2 is in elemental form.

2. Equation [22] was empirically adjusted in absolute value to agree with the <100> data in Fig. 7. By adjusting the preexponential factor, γ_{gl}', in Eq. [21] so that agreements with <111> data is obtained (6, 10), the expression for B segregation in <111> Si in wet or near dry O_2 is

$$m_{111} = 0.8 \exp\left(\frac{-17{,}100 - \Delta G^\circ}{RT}\right) \quad [23]$$

The reason why γ_{gl}' in SiO_2 on <100> Si is ~1.5 times larger than γ_{gl}' for <111> Si is not known at this time.

3. In terms of "effective" activation energies, Eq. [22] and [23] can be written for near dry and wet O_2 oxidations as

$$m_{100(\text{eff.})} = 104.0 \exp\left(\frac{-0.66\text{ eV}}{kT}\right) \quad [24]$$

$$m_{111(\text{eff.})} = 65.2 \exp\left(\frac{-0.66\text{ eV}}{kT}\right) \quad [25]$$

Discussion

Effects of trace amounts of H_2O.—The implications in the data and theory presented so far are that 15-30 ppm water in a "dry" O_2 oxidation furnace can reduce the boron segregation coefficient by as much as a factor of three (at 900°C) and change the Si oxidation rate (28). The condition under which pure dry O_2 oxidation occurs was apparently achieved in Murarka's work (3, 33). He used a dedicated dry O_2 laboratory drive-in furnace which had an O_2 gas dryer on it. The dry O_2 samples used by Colby and Katz (6) were oxidized in a general production processing area. It is unlikely that any special precautions were made to eliminate methane or moisture from the O_2 gas stream (34). For the case where B is implanted or diffused into an SiO_2 layer and O_2 oxidation is then performed, it is believed that the B in the SiO_2 ties up water diffusing through the oxide. Thus, the diffusing water will not reach the oxidizing interface. The evidence for this lies in the fact that a large B-OH infrared reflectance peak was observed in through-oxide B implants following our "dry" O_2 oxidation process.

We know that the remaining oxidations performed in our study were done in O_2 furnaces with 15-30 ppm H_2O measured in them. It can be seen in Fig. 4 that at 1050°C, these "dry" O_2 oxidations yielded the same B segregation coefficient as the wet O_2 oxidations.

Although the proposed models give consistent explanations of the experimental results, additional data are needed to establish the existence of HBO_2 in the SiO_2. Also, additional experiments are needed in dry O_2 ambients with <1 ppm of water.

Computer modeling of B diffusion and segregation.—If the values of B segregation coefficient obtained by indirect means such as mathematical modeling (3-5, 7-9) are plotted *vs.* $1/T$, the result is a scatter plot. In this approach the segregation coefficient is determined from measured sheet resistances and junction depths or from measured B profiles in the Si. A small error or uncertainty in these measurements may cause the calculated m to change significantly. An example is shown in Fig. 8 where the profiles are plotted for calculated sheet resistances of 124 and 140 Ω/□ and $m = 0.9$ and 0.45, respectively. The measured sheet resistance for this sample was 132 Ω/□. The profile was obtained by SIMS. The sample had been implanted to 7×10^{14} cm^{-2} at 50 keV and diffused in a near dry O_2 ambient at 1150°C for 60 min. The calculations were done using a stored modeling program which includes orientation- and concentration-dependent diffusion effects as well as the appropriate boundary conditions for an oxidizing Si surface (3). Also, Wagner's (35) mobility data were used in the sheet resistance calculation. The use of Thurber's more recent mobility data (36) led to an overestimation of R_s for the profile shown in Fig. 8.

It can be seen that the $m = 0.45$ curve gives the better fit to the measured B profile. However, a value of m between 0.45 and 0.9 would result in a profile whose sheet resistance matched the measured value of 132 Ω/□. The discrepancy between the measured and calculated sheet resistances is ~6% but this could lead to an overestimation of the true m by ~50%. Some improvement in the accuracy of segregation coefficient estimation is possible using a differential sheet resistance method (9). However, the m values reported in Ref. (9) have not been supported by direct measurement.

It can be seen in Fig. 8 that the effect of diffusing B in Si during oxidation in 100% dry O_2 as opposed to O_2 with ~20 ppm H_2O or more is to change the surface region profile the most. This is further demonstrated in Fig. 9 at four different temperatures. The calculated curves represent oxidations of 1×10^{15} cm^{-2}, 50 keV B implants which were preannealed in N_2 at 1050°C for 1 hr. All calculations were performed to simulate 1 hr diffusions at the temperatures shown in dry O_2 (dashed curves) and near dry O_2 (solid curves). As the B segregation coefficient curves in Fig. 7 indicate, the largest difference in the surface region profiles occurs at the lowest temperatures. At

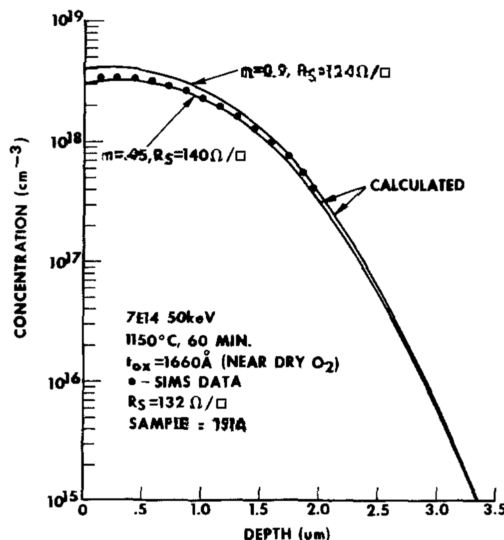


Fig. 8. Comparison between measured and calculated B profiles in Si for two values of segregation coefficient.

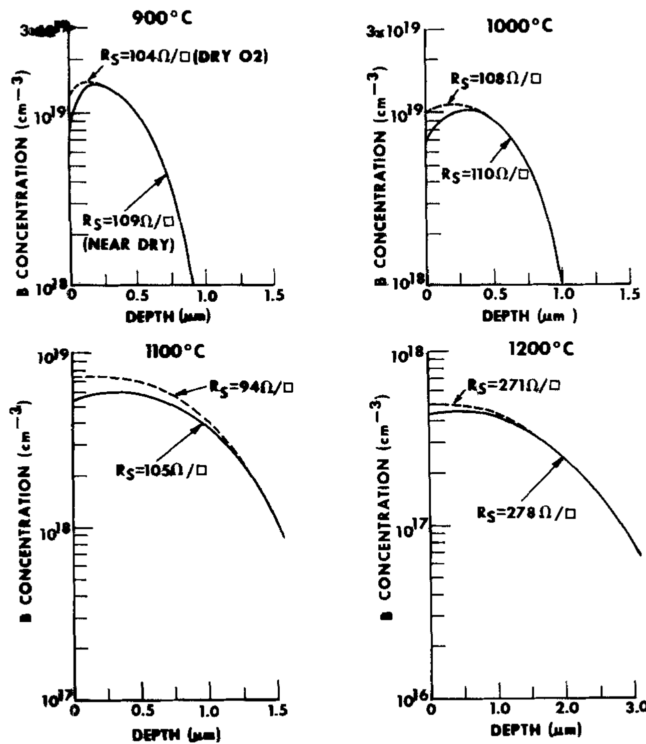

Fig. 9. Calculated B profiles after dry and near dry O_2 oxidations of $\langle 100 \rangle$ Si. B implant is 1×10^{15} cm^{-2}, 50 keV diffused at 1050°C for 1 hr in N_2 plus 1 hr at temperatures shown above.

900°C the surface concentrations differ by a factor of two. However, the sheet resistances differ by only 5%. As the temperature is raised, the difference between the profiles occurs over a larger fraction of the junction depth.

Summary and Conclusions

The theory of B segregation in SiO_2 has been presented and refined to the point that semiquantitative agreement with pure dry O_2 segregation data has been obtained. For the case of B segregation during near dry or wet O_2 oxidation of B-doped Si, quantitative agreement with the temperature dependence of m has been achieved. However, the absolute values of m show an orientation dependence in the activity coefficient of B (HBO_2) in SiO_2 which is not explainable at this time. Specific conclusions are as follows:

1. Segregation coefficients greater than 2 can be obtained for the special case where concentrations of $B_2O_3 \gtrsim 30\%$ in SiO_2 are deposited on Si in an oxidizing ambient (8). This condition will continue as long as the liquid B-doped glass is in contact with the Si surface. As oxidation proceeds dilution of the glass may occur so that a solid solution of B in SiO_2 is formed. Segregation will then proceed according to reaction [14] with $m \leq 1$.

2. It is possible to achieve a unity B segregation coefficient at 1200°C if one of the following conditions is fulfilled: (*i*) Oxidation of B-doped Si is performed in very dry O_2. It is not known what concentration of H_2O can be tolerated. However, 15-30 ppm H_2O in O_2 at the oxidation temperature is too high. (*ii*) Oxidation of a through-oxide B implanted SiO_2/Si structure is performed in dry or near dry O_2. (*iii*) Diffusion of B occurs through an SiO_2 layer on Si in a dry or near dry O_2 ambient (21) with $\lesssim 30\%$ B_2O_3 doping (2). The effective segregation coefficient obtained under these conditions (apparently independent of Si orientation) is

$$m_{\text{eff.}} = 13.4 \exp\left(\frac{-0.33\ \text{eV}}{kT}\right) \quad [17]$$

3. The oxidation of B-doped Si in near dry or wet O_2 ambients produces B and crystalline HBO_2 in the growing oxide. In $\langle 111 \rangle$ Si, the effective segregation coefficient in near dry or wet O_2 is

$$m_{111(\text{eff.})} = 65.2 \exp\left(\frac{-0.66\ \text{eV}}{kT}\right) \quad [25]$$

and in $\langle 100 \rangle$ Si it is

$$m_{100(\text{eff.})} = 104.0 \exp\left(\frac{-0.66\ \text{eV}}{kT}\right) \quad [24]$$

4. It has been shown that trying to extract segregation coefficients from models requiring measurements of sheet resistance and junction depth as the only inputs can be risky.

5. Computer simulations using the directly measured m values give excellent agreement with measured B profiles.

APPENDIX

The relative partial molar enthalpy (or differential heat of solution) $\Delta\overline{H}^s$ is the energy necessary to transfer the B atom from its own lattice to that of the host Si crystal. Weiser postulated that the total energy for this process is (20)

$$\Delta\overline{H}^s = 4\epsilon_{Si} - H_{Si}^s + H_B^s - H_{B\text{-}Si} \quad [A\text{-}1]$$

where ϵ_{Si} is the bond energy of the Si crystal with each atom surrounded by four neighbors, H_{Si}^s is the heat of sublimation of Si (monatomic gas), H_B^s is the heat of sublimation of B, and $H_{B\text{-}Si}$ is the energy released by the impurity atom on condensation in a vacancy. Weiser has shown that Eq. [A-1] may be simplified to (20)

$$\Delta\overline{H}^s = \frac{(H_{Si}^s - H_B^s)^2}{H_{Si}^s + H_B^s} + E^{st} \quad [A\text{-}2]$$

where E^{st} is the strain energy that must be supplied if the impurity atom differs in size from the host atom. Thus

$$E^{st} = 22 \times 10^{20}(r_{Si} - r_B)^2 (\text{cal/g atom}) \quad [A\text{-}3]$$

Using the covalent radii of Pauling (37) ($r_{Si} = 1.17$Å and $r_B = 0.88$Å)

$$E^{st} = 18.5\ \text{kcal/g atom}$$

Also, using $H_{Si}^s = 105$ kcal/mole and $H_B^s = 136.5$ kcal/mole (24) yields

$$\Delta\overline{H}^s = 22.6\ \text{kcal/mole}$$

The temperatrue for which $\Delta\overline{H}^s$ is calculated is not very important since the difference in $\Delta\overline{H}^s$ at T_1 and T_2 is at most given by $\int_{T_1}^{T_2} \Delta C_p dT$. The ΔC_p is the difference in heat capacity between the host crystal and the impurity crystal. For B and Si ΔC_p is $\simeq 0$ (18).

ABSTRACT

The growth of semi-insulating LPE GaAs layers requires that the donors and acceptors be highly self-compensated and that Cr be used to form deep acceptor levels. The high compensation can be achieved by systematic bakeouts of the Ga melt, between growths, at a critical temperature which depends on the materials used in the growth system. The optimum bakeout temperatures for SiO_2-C-H_2, SiO_2-BN(C)-H_2, and SiO_2-BN-H_2 systems were found to be 775°, 700°, and 675°C, respectively. By this method, we are able to grow undoped layers having carrier densities in the low 10^{13} cm^{-3} range. By adding 0.5 m/o Cr to the melt under the same conditions, we have grown semi-insulating GaAs layers with resistivities in the 10^6 Ω-cm range.

High resistivity buffer layers are often used for GaAs field-effect transistors (FET) to isolate the active layers from impurities and defects in the Cr-doped substrates (1, 2). It has been found that the growth of such high resistance liquid-phase epitaxial (LPE) GaAs layers requires close compensation of shallow donors and acceptors arising from residual impurities in the source materials and from chemical reactions between the growth system components. Once near compensation is attained, semi-insulating LPE GaAs is obtained by adding Cr to form deep acceptor levels (3). We report here on the effects of (*i*) the growth system components on background impurities in LPE GaAs layers; (*ii*) the bakeout temperature of As-saturated Ga melts on the compensation of donor and acceptor impurities; and (*iii*) the optimum growth conditions for growing semi-insulating LPE GaAs.

Crystal Growth

The dominant background impurities in LPE GaAs are silicon, carbon, and oxygen (4). The sources of these impurities appear to be related to chemical reactions between the growth system components (3). To study these chemical reactions and their effect on the electrical properties of the grown layers, the growth system components, the bakeout temperature of the As-saturated Ga melt, and the saturation temperature were varied. It was found that the system components and the bakeout temperature made the most significant change in the electrical properties of the epitaxial layers. Saturation temperatures below

800°C have a small effect on the electrical properties of the grown layers, since they are essentially equivalent to a short-term bakeout (3).

Three different horizontal tilt LPE growth systems were used in this study. These growth systems all consisted of a fused-quartz reactor tube (General Electric Grade 204), a temperature-gradient growth cell (5), and a purified hydrogen atmosphere. The differences in this study were the materials used for the growth cell: high purity graphite (Ultra Carbon) [C], pyrolytic boron nitride (Union Carbide) with a graphite cradle [BN(C)], and pyrolytic boron nitride with a fused-quartz cradle [BN]. The components corresponding to each of these growth cells are referred to as the SiO_2-C-H_2, SiO_2-BN(C)-H_2, and SiO_2-BN-H_2 systems, respectively.

The quartz reactor tube and cradle were cleaned in organic solvents and aqua regia, rinsed in DI water and methanol, dried, and outgassed in an H_2 atmosphere at 900°C for 24 hr. The graphite boat was outgassed under a high vacuum at $\sim$ 1300°C. For each series of growth, the system was baked out in an H_2 atmosphere at 900°C for 15 hr before loading the new melt. The starting materials for the growth were 6-9's purity Ga (Cominco American, Incorporated) and high purity polycrystalline GaAs (Asarco) As-source. Pellets of 5-9's purity (Electronic Space Products, Incorporated) were used for Cr doping. Chromium-doped semi-insulating GaAs, obtained from Laser Diode Laboratories or Crystal Specialties, was employed for substrates. All substrates were oriented to the (100) crystallographic plane and had resistivities greater than 10^6 Ω-cm. They were chemmechanically polished with 20% NaOCl solution. Immediately before each growth, the substrate was degreased with organic solvents, boiled in concentrated HCl to remove any surface oxide film, and then was displacive rinsed with methanol and boiled in isopropyl alcohol. After draining off the hot isopropyl alcohol, the substrate was loaded immediately into the growth cell. The system was purged with H_2 for at least 2 hr before the growth cycle was started.

For a particular system, the electrical properties of the epitaxial GaAs layers appear to be determined principally by the bakeout of the As-saturated Ga melt in the growth system. As described in more detail elsewhere (3), the Ga melt and the GaAs source were baked together before each growth at a prescribed temperature, in the 600°-850°C range, for 15 hr without the substrate in the growth system. After the substrate was loaded into the system the melt was saturated at 700°C for 30 min, after which the furnace was tipped to start the growth while cooling at a rate of 4.5°C/min. For most of the growths, the hydrogen flow rate was kept at 0.61/min during both the bakeout and the growth steps. The epitaxial layer thicknesses were approximately 15 μm.

The bakeout temperature has the most dramatic effect on the free-carrier density, as shown in Fig. 1. Low bakeout temperatures provide n-type layers while high bakeout temperatures give p-type layers. At a critical intermediate bakeout temperature unique to each particular growth system, high resistivity layers with low carrier densities and N_A/N_D ratios close to 1 are obtained. The transition bakeout temperatures for the SiO_2-C-H_2, SiO_2-BN(C)-H_2, and SiO_2-BN-H_2 systems were found to be 775°, 700°, and 675°C, respectively. As the bakeout temperature approaches this transition temperature from either the low or the high temperature side, the carrier density decreases. Highly compensated epitaxial GaAs layers grown in each of these systems, without deep level impurity doping, had room-temperature free carrier densities of 2×10^{14}, 9×10^{13}, and 3×10^{13} cm^{-3}, respectively.

The change in the electrically active donor and acceptor impurities as a function of total accumulated bakeout time at different bakeout temperatures in the

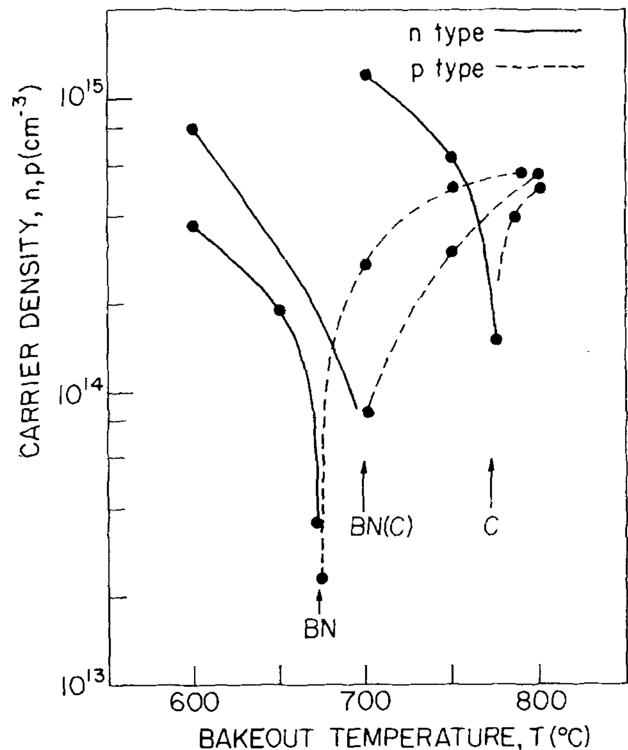

Fig. 1. Carrier concentration vs. bakeout temperature for three different growth systems. C: SiO_2-C-H_2 system; BN(C): SiO_2-BN(C)-H_2 system; and BN: SiO_2-BN-H_2 system.

SiO_2-BN-H_2 system, Fig. 2, shows that the impurities decrease during the first 60 hr of accumulated bakeout. Similar phenomena were also observed in the SiO_2-C-H_2 and SiO_2-BN(C)-H_2 systems. After about 60 hr of accumulated bakeout whereas subsequently grown layers had reproducible electrical properties, both donor and acceptor concentration leveled off and the N_A/N_D ratio reached constant values at each bakeout temperature. The N_A/N_D ratio increased with bakeout temperature, *e.g.*, $N_A/N_D \simeq 0.5$ at 650°C and $\simeq 0.9$ at 675°C. Above 700°C, N_A/N_D exceeds 1 and the epitaxial layer becomes p-type. However, the donor concentrations, after both 650° and 675°C bakeouts, remained constant at about 4.5×10^{14} cm^{-3} for layers grown from these stabilized melts in the SiO_2-BN-H_2 system.

These results suggest several possibilities that can be related to the bakeout: (*i*) the removal of volatile impurities from the melt, such as oxygen and sulfur, by their extraction and volatization from the Ga melt into the H_2 stream during the bakeout; and (*ii*) the introduction of acceptor impurities into the melt, such as Si and C, which are products of chemical reactions between the growth system components. Subsequently, some of these impurities are incorporated into the layer during growth. Since oxygen is the dominant shallow donor impurity while Si and C are the dominant acceptor impurities (6, 7), the N_A/N_D ratio and the conductivity type of the epitaxial layer are controlled by their relative concentration in the Ga melt and thus depend on the bakeout temperature. In each growth system, the bakeout transition temperature occurs at a temperature where the incremental acceptor concentration incorporated into the layer, due to the increase of acceptor impurities in the melt by bakeout, equals the net background donor concentration ($N_D - N_A$). It appears that the net background donor concentration remains nearly constant at 5×10^{15}, 6×10^{14}, and 1×10^{14} cm^{-3} for the SiO_2-C-H_2, SiO_2-BN(C)-H_2, and SiO_2-BN-H_2 systems, respectively. The chemical reactions in the three systems are different due to the location or absence of the graphite. However, in each case, the rate-limiting reaction is

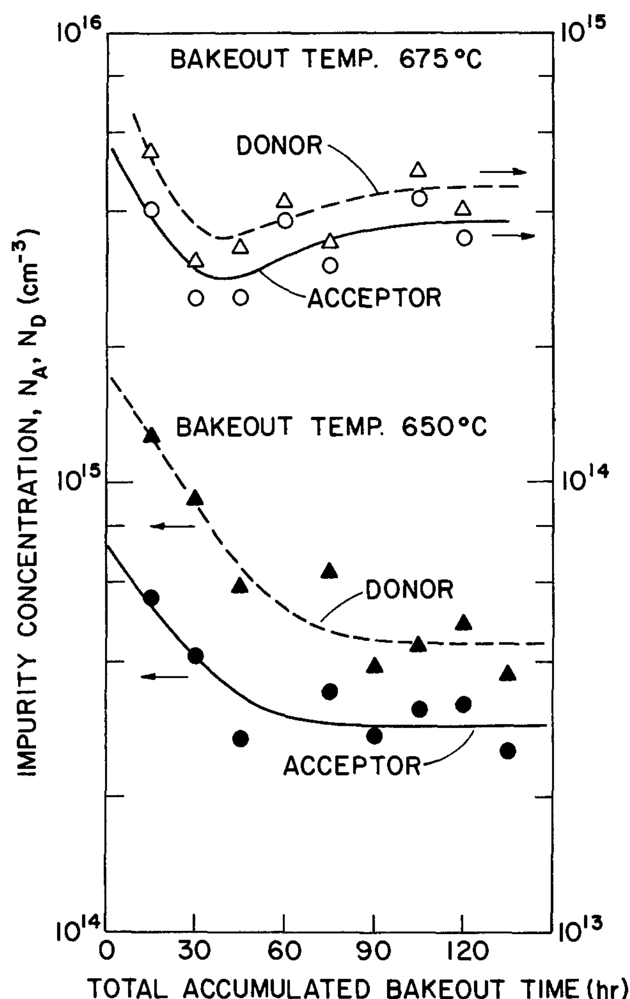

Fig. 2. Dependence of background donor and acceptor impurities on accumulated bakeout time and bakeout temperature in the SiO_2-BN-H_2 system.

due to the reduction of fused quartz by hydrogen (6). The increase in acceptor concentration with bakeout appears to be about the same order of magnitude as that obtained from thermodynamic calculations. Therefore, the differences in the bakeout transition temperatures appear to be due to the net background ionized donor concentration in these systems. The concentration of background impurities in the graphite cell system is about an order of magnitude higher than that in the BN cell system. This is probably due to the fact that graphite increases the oxygen contamination.

For the Cr-doping studies, 0.5-0.7 m/o Cr was added to the stabilized melt (after 50-100 hr of bakeout). Initially, doped growths had a very high carrier density ($\simeq 10^{17}$ cm^{-3}) at low bakeout temperatures (3). This is believed to be due to shallow donor impurities contained in the Cr source which are removed after a few hours of bakeout at 800°C. Following this initial 800°C bakeout, regular bakeout and growth procedures were carried out on the Cr-doped melt. We found that Cr doping had very little effect on the electrical properties of the epitaxial GaAs layers grown from Cr-doped melts baked out at temperatures on either side of the transition temperature where the net ionized shallow impurity concentrations are high. It appears that the Cr concentration in such layers is too low to compensate the shallow impurities. However, when Cr-doped melts were baked out near the transition temperature for the three growth systems, the carrier concentration decreased sharply and the resistivity reached a peak value. When 0.7 m/o Cr was added to the melt and baked out at 775°C in the SiO_2-C-H_2 system, moderately high resistivity (300 Ω-cm) epitaxial layers were obtained. When the SiO_2-BN(C)-H_2 and SiO_2-BN-H_2 systems with 0.5 m/o Cr were baked out at their corresponding transition temperatures, the grown layers were semi-insulating with resistivities higher than 10^6 and 10^3 Ω-cm, respectively. These semi-insulating layers show good uniformity in resistivity and excellent surface morphology over the 1×1.5 cm^2 sample area. However, when more than 1.5 m/o Cr was added in the melt, the grown layers showed rough surfaces and contained inclusions. This is probably because the solubility of Cr in the Ga melt is lower than 1.5 m/o at this growth temperature (700°C).

The segregation coefficient of Cr in GaAs is very small, about 3×10^{-7} for LPE growth (8). It is estimated that the active Cr concentration in the epitaxial layer must be in the range of 1×10^{14} cm^{-3} when 0.5 m/o Cr is added to the melt. Therefore, in order for Cr deep acceptors to control the resistivity and yield semi-insulating LPE GaAs, the background free-carrier concentration must be reduced to less than 10^{14} cm^{-3}. For the SiO_2-C-H_2 system, the background free-carrier density of the layers grown from a melt baked at the transition temperature was higher than this value, and only a moderately high resistance layer was obtained. Although the SiO_2-BN-H_2 system produced the lowest background-free carrier density (3×10^{13} cm^{-3}), the addition of Cr did not yield layers with resistivities as high as that of the SiO_2-BN(C)-H_2 system. It appears that the formation of deep levels is limited by fewer deep level impurities at the relatively low bakeout temperature (insufficient to compensate the shallow impurities).

Electrical and Optical Properties

The electrical properties of Cr-doped semi-insulating LPE layers were evaluated by differential van der Pauw techniques to avoid the shunting effect of the Cr-doped semi-insulating substrate. The measurements were made while the semi-insulating layers were contained in a stainless steel dewar under vacuum ($\gtrsim 10^{-4}$ Torr) and initially baked at 480°K. The room temperature electrical properties of two semi-insulating layers grown in the SiO_2-BN(C)-H_2 system, samples No. 1315 and 1320, are listed in Table I. Conductivity *vs.* reciprocal temperature plots between 350° and 480°K, as shown in Fig. 3, yield a thermal activation energy in the 0.7 eV range. The photoluminescent spectrum at 6°K for sample No. 1315, Fig. 4, shows a dominant peak at 0.83 eV. Recent studies by Kocot and Pearson (9) indicate that this photoluminescent peak is due to intra-impurity transitions between the Cr^{2+} ($^5T_2$) ground level and its ^5E excited state. The thermal activation energy (0.7 eV) corresponds to the separation between the Cr^{2+} ground level and the bottom of the conduction band. It has been reported that the ^5E level lies about 0.1 eV above the bottom of the conduction band (10).

In conclusion, we have shown that the growth of semi-insulating LPE GaAs can be achieved after systematic bakeouts of the As-saturated Ga melt at the transition bakeout temperature in a SiO_2-BN(C)-H_2 system. Under these conditions, the shallow donors and acceptors are very closely compensated and yield high resistivity LPE layers. Further improvements were obtained by the addition of Cr to the melt, which

A Method for Estimating Impedance Parameters for Electrochemical Systems That Exhibit Pseudoinductance

Digby D. Macdonald*

SRI International, Materials Research Center, Menlo Park, California 94025

ABSTRACT

A simple algebraic method is presented for estimating impedance parameters for electrochemical systems that exhibit pseudoinductance. The method, which makes use of four characteristic points from the complex plane diagram, is illustrated by calculating impedance parameters for transpassive chromium in sulfuric acid. The quantitative nature of the method renders it particularly useful for estimating impedance parameters for those systems that exhibit single capacitive and inductive semicircles in the complex plane.

A number of electrochemical systems exhibit pseudoinductive behavior which is characterized by the existence of a negative reactance loop upon plotting the impedance data in the complex plane (1-9). For instance, Epelboin, Keddam, and Takenouti (1) found that corroding iron in sulfuric acid, particularly in the presence of propargylic alcohol, exhibits pseudoinductance at frequencies less than about 1.0 Hz. Armstrong and Henderson (2) have also observed this behavior for chromium in the transpassive region in sulfuric acid. Theoretical analyses (1, 3) show that the inductive behavior at low frequency arises from relaxation of the coverages of intermediates on the electrode surface. At high frequencies, kinetic limitations prevent the surface coverages from following the sinusoidal excitation function so that the reactance becomes dominated by a parallel capacitance.

In corrosion research, it is frequently necessary to estimate the rate of corrosion from polarization data. Accordingly, it is commonly assumed that the quantity that should be substituted into the Stern-Geary relationship is the polarization resistance which is equal to the interfacial impedance in the limit of zero frequency. This assumption appears to be well justified for systems that exhibit resistive/capacitive behavior in the complex plane as shown, for example, by the recent work by Macdonald *et al.* (10). However, Epelboin *et al.* (1) claim that the transfer resistance, R_t, is a more appropriate quantity than the polarization resistance for calculating the corrosion rate in systems that exhibit pseudoinductance.

The problem of extracting a numerical value for the transfer resistance from experimental impedance data for pseudoinductive systems does not appear to have been considered in detail. It is possible that the required value could be generated by the nonlinear least squares data fitting procedures recently described by Macdonald and Garber (8). However, these techniques are cumbersome and do not appear to be well suited to regular application in corrosion research. In this paper a simple algebraic method is presented for estimating the impedance parameters, including the transfer resistance, for electrochemical systems that exhibit pseudoinductance. The technique is illustrated by analyzing impedance data for transpassive chromium (2) taken from the literature.

Computational Method

A simple electrical equivalent circuit that satisfactorily accounts for the observed impedance behavior of a large number of systems which exhibit pseudoinductance is shown in Fig. 1. This circuit gives rise to a resistive/capacitive semicircle at high frequencies, and a resistive/inductive semicircle at low frequencies (Fig. 2). Note that this equivalent circuit is capable of yielding only a single inductive loop, and is therefore valid only for those cases where a single surface coverage gives rise to inductive relaxation. Multiple inductive relaxations are observed in a number of systems, for example in the electro-

* Electrochemical Society Active Member.

Key words: electrochemical impedance, pseudoinductance, corrosion, electrode kinetics, impedance parameters.

deposition of zinc (3). These more complex cases are not covered by the computational method presented here.

The admittance function for the equivalent circuit shown in Fig. 1 is given by

$$Y(p) = 1/R_t + pC + 1/(\rho + pL) \quad [1]$$

where p is the impedance operator and R_t is the transfer resistance. The other components are as shown in Fig. 1. The steady-state impedance is given by the reciprocal of Eq. [1] with the parameter p replaced by $j\omega$, where ω is the angular frequency of the excitation function, and $j = \sqrt{-1}$. Thus

$$Z(j\omega) = Z' - jZ'' \quad [2]$$

with

$$Z' = \frac{\rho^2 R_t + R_t^2 \rho + \omega^2 L^2 R_t}{[\rho + R_t - \omega^2 R_t CL]^2 + \omega^2 [L + \rho R_t C]^2} \quad [3]$$

and

$$Z'' = \frac{\omega [R_t^2 \rho^2 C - L R_t^2 + \omega^2 L^2 R_t^2 C]}{[\rho + R_t - \omega^2 R_t CL]^2 + \omega^2 [L + \rho R_t C]^2} \quad [4]$$

The reactance, Z'', is zero at the following three frequencies:

(*i*) $\omega = \infty$. In this case the real component is zero due to the infinite conductance of the capacitance (Fig. 2). This case is trivial, and will not be considered further.

(*ii*) $\omega = 0$. The intercept on the real axis in this instance is equal to the polarization resistance, R_p; that is

$$R_p = \rho R_t / (\rho + R_t) \quad [5]$$

(*iii*) The third root of Eq. [4] is obtained by equating the quantity in square brackets to zero. This yields

$$\omega^2 = (L - \rho^2 C)/L^2 C \quad [6]$$

which gives real values for ω only if $L > \rho^2 C$. If this condition is not met, the inductive semicircle in the fourth quadrant is no longer observed. Instead, a first quadrant distorted semicircle is obtained (12). For the case where $L > \rho^2 C$, substitution of $\omega = (L - \rho^2 C)^{1/2} / LC^{1/2}$ into Eq. [3] yields the following expression for the real component of the impedance at which the reactive behavior changes from capacitive to inductive

$$R_0 = R_t L / (L + R_t \rho C) \quad [7]$$

Equations [5] and [7] represent two independent expressions that may be used to estimate the impedance components. However, the equivalent circuit contains four components so that two additional relationships are required to completely define the system. One of the required expressions is generated by assuming that to a first approximation the reactance in the first quadrant in the region of maximum Z'' at the frequency ω_C (Fig. 2) is independent of the inductance, L. The second expression can be derived using a similar assumption regarding the low frequency reactance in the region of ω_L, *i.e.*, at this frequency the fourth quadrant reactance is independent of the capacitance. The frequencies ω_C and ω_L at which the first quadrant and fourth quadrant reactances are at a maximum, respectively, are therefore given by

$$(\partial Z''/\partial \omega)_{L \to \infty} = 0 \quad [8]$$

$$(\partial Z''/\partial \omega)_{C \to 0} = 0 \quad [9]$$

which yield

$$\omega_C = 1/R_t C \quad [10]$$

$$\omega_L = (R_t + \rho)/L \quad [11]$$

Equations [5], [7], [10], and [11] may be solved simultaneously to yield expressions for R_t, C, ρ, and L in terms of the experimentally observed quantities, R_p, R_0, ω_C, and ω_L (Fig. 2). The expressions obtained are as follows

$$R_t = \{R_0 + [R_0^2 + 4(\omega_L/\omega_C) R_p R_0]^{1/2}\}/2 \quad [12]$$

$$\rho = R_p R_t / (R_t - R_0) \quad [13]$$

$$L = (R_t + \rho / \omega_L) \quad [14]$$

$$C = 1/\omega_C R_t \quad [15]$$

Discussion

The application of Eq. [12]-[15] in the analysis of impedance data for systems that exhibit pseudoinductance is best illustrated by example. For this purpose we have chosen to analyze the data of Armstrong and Henderson (2) for transpassive chromium in 0.5M sulfuric acid at 25°C. The complex plane diagram for this system is reproduced in Fig. 3, and yields the following values for the experimental parameters: $R_p = 3.7\Omega$, $R_0 = 8.3\Omega$, $\omega_C = 3142$ rad/sec (500 Hz), and $\omega_L = 132$ rad/sec (21 Hz). Substitution of these values in Eq. [12]-[15] therefore gives the following numerical data for the impedance parameters: $R_t = 8.4\Omega$, $C = 37.9\ \mu F$, $\rho = 6.5\Omega$, and $L = 0.11H$.

The value obtained above for the transfer resistance, R_t, is slightly greater than the value for R_0, but is much greater than that for the polarization resistance, R_p. Use of this latter quantity, rather than R_t, in the Stern-Geary relationship would clearly lead to serious error in the calculated corrosion rate, as found experimentally by Epelboin *et al.* (1) for the corrosion of iron in inhibited sulfuric acid. The calculated capacitance of 37.9 μF, that is 190 $\mu F/cm^2$, is higher than expected for the electrical double layer (normally 20-50 $\mu F/cm^2$). However, the presence of at least one adsorbed species on the metal surface is indicated by the presence of the inductive loop, and it is possible that other adsorbed species gives rise to pseudocapacitance. The large capacitance may also reflect a very high roughness factor for the electrode surface.

A sensitive test of the method developed here for estimating the impedance parameters is to calculate the impedance spectrum over a wide range of frequency, and then to compare the calculated spectrum with the experimentally determined data. This test is shown in Fig. 3, in which the open points were calculated using Eq. [3] and [4] and the values for R_t, C, ρ, and L given above. The locus of calculated

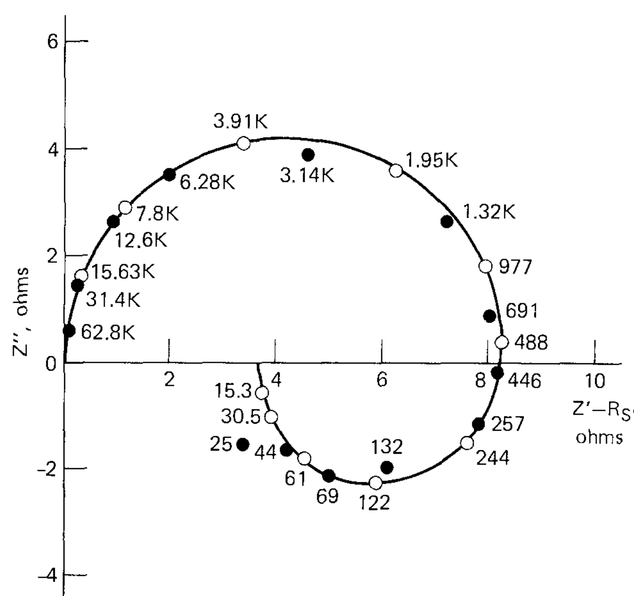

Fig. 3. Complex plane diagram for transpassive chromium in 0.5M H_2SO_4. Open points, calculated data; closed points, experimental data according to Armstrong and Henderson (2). The number next to each point is the frequency of the excitation function in Hz. Electrode area ≐ 0.2 cm^2. R_S = solution resistance.

points is given as the solid line, and it is seen that excellent agreement exists between the calculated values and the experimental data over the entire frequency range considered.

The accuracy of the computational method is clearly limited by the validity of the assumption that the first and fourth quadrant subspectra are independent of one another in the neighborhood of the maxima in the reactance. However, it is believed that this approximation is sufficiently accurate to yield precise corrosion data (R_t, C) for most systems of interest. In those cases where the above assumption is not valid, the method may still be used to estimate initial values for the impedance parameters which can then be refined using the more sophisticated nonlinear least squares techniques (11).

Thermodynamic and Kinetic Aspects of Bromine Lamp Chemistry

Suresh K. Gupta

General Electric Company, Lamp Phenomena Research Laboratory, Nela Park, Cleveland, Ohio 44112

ABSTRACT

The thermodynamic approach to bromine regenerative chemistry has been found inadequate in explaining a number of observed lamp phenomena. The basic shortcoming of these treatments has been attributed to the questionable assumption of thermodynamic equilibrium which may not prevail, especially, with respect to atomic hydrogen and carbon monoxide on the lamp walls. This has led to the consideration of a kinetic model which is based on rates of various processes and mass flow within the lamp. Calculations of tungsten mass flow, based on a simple diffusion model, have demonstrated the importance of gas phase and wall reactions. For instance, the gas phase reactive reduction of the tungsten atom flux at the wall of a typical bromine lamp is significant only when the first-order reaction rate constant exceeds the value of 1 sec^{-1}. The role of atomic species has been considered since these are produced at the filament. Hydrogen atoms recombination rates have strong dependence on fill pressure; these are also found to be slower than their diffusion rates to wall. Doubtful validity of the equilibrium assumption at the walls is clearly demonstrated by these calculations. Atomic hydrogen concentrations at the wall, however, are expected to be extremely low when H:Br $<$ 1. Application of this kinetic model to lamp chemistry is limited due to lack of appropriate kinetic data on wall reactions. Comparison of the two models indicates that thermodynamic calculations, if performed correctly, can give valuable insight into transport processes occurring near the filament. However, kinetic considerations are believed to be far more important in understanding the chemistry near the bulb wall.

Tungsten halogen lamps are compact light sources which utilize regenerative actions of halogens to prevent tungsten deposition on lamp walls as well as to sustain long life for the filament Understanding of the regenerative lamp chemistry has been approached primarily from thermodynamic considerations which, for the bromine lamp, were initially restricted to the W-H-Br system (1, 5, 6). However, since most of these lamps are generally made with bromomethanes such as CH_3Br, CH_2Br_2, $CHBr_3$, etc., and usually contain some residual oxygen, these calculations have been extended to the more complex W-O-C-H-Br system (2-4, 6). Complexity of these systems requires careful analysis of condensed phases in these calculations as has been pointed out earlier (3). Recently, the role of carbon in these lamps and its effect on thermodynamic equilibrium computations has been explored in some detail (7, 8).

Key words: thermodynamics, kinetics, bromine lamp.

Generally, however, these thermodynamic approaches to explain lamp behavior have been rather unsuccessful (4). Yannopoulos and Pebler have, for example, attempted to explain observed discrepancies in terms of evolution of water from quartz (4). Prevalent temperatures and pressures in an operating lamp warrant localized thermodynamic equilibria (LTE) near the filament. Multiple collisions due to high operating pressure ($\sim$15 atm) may be expected to lead the system toward rapid equilibration. However, it is questionable to assume that reaction rates are fast enough to attain equilibria near the wall.

Since hydrogen atoms are produced at the filament, kinetics of reactions, such as

$$H + H + Ar = Ar + H_2 \quad [1]$$

may be quite important, more so in view of their high mobility. Possible occurrence of slow heterogeneous wall reactions such as

$$2\tfrac{1}{2}\,W(s) + CO(g) = W_2C(s) + \tfrac{1}{2}\,WO_2(s) \quad [2]$$

and

$$1\tfrac{1}{2}\,W(s) + CO(g) = WC(s) + \tfrac{1}{2}\,WO_2(s) \quad [3]$$

may also contribute to the system's deviation from equilibrium. In fact, CO, due to its extreme kinetic stability resists disproportionation at lower temperatures as required by thermodynamic arguments.

These limitations of thermodynamic arguments have been summarized and a modified lamp model based primarily on kinetic considerations has been proposed. Calculations have been performed to investigate the migration of tungsten atoms assuming a simple diffusion model. Under this approach one aspect of the lamp model, *e.g.*, the blackening criterion, assumes a different form and depends on the gas phase and wall tungsten atoms reaction rates. There are limitations to this simplified model since convective and thermal diffusion flows are also prevalent in an operating lamp. However, it is believed that this modified approach will provide a better understanding of the regenerative lamp chemistry and stimulate further experimental and theoretical work.

A recent publication describes a mass transfer model for the lamp based on diffusion of participating species across the boundary layer (9). The model has been applied to the W-O-Br system in establishing blackening conditions based on initial levels of lamp additives.

Thermodynamic Model

Formulation.—In the thermodynamic model, as depicted by an idealized situation in Fig. 1, the lamp operation is primarily controlled by localized thermodynamic equilibria at the filament and the bulb wall (10). Partial pressures of tungsten-bearing gaseous species, computed for the desired system, *e.g.*, W-O-C-H-Br in the bromine lamp, are analyzed to discern the direction of the transport. As illustrated in Fig. 1, the ΣP_{Wi}, *i.e.*, sum of all W-bearing gaseous species at the filament and wall are primary quantities, and the condition for tungsten deposition on the wall, *i.e.*, blackening is defined as

$$[\Sigma P_{Wi}]_{fil} > [\Sigma P_{Wi}]_{wall} \quad [I\text{-}a]$$

Since earlier thermochemical calculations indicate that the major species at the filament and bulb wall are W atoms and WO_2Br_2, respectively, (3) this relation can be simplified as

$$P_W(T_F) > P_{WO_2Br_2}(T_B) \quad [I\text{-}b]$$

where T_F and T_B are the corresponding temperatures. Thus, an ideal quartzline lamp, without any temperature gradients along the filament and wall, would stay clean at the balance of these two quantities. Any imbalance would result in either wall darkening or a nonuniform tungsten deposition on the filament which are both undesirable for a designed long-life lamp.

Limitations.—Comparative test results of lamps containing carefully controlled levels of C, H, Br, and O, along with thermodynamic calculations for these systems have been reported (4). The lamp results, however, fail to follow predictions of the calculations. For example, more blackening occurred in the $CHBr_3$ lamps compared to the CH_2Br_2 group, even though the latter group contained far higher H/Br ratios. Lamps made with HBr, CBr_4 + CH_4 (1:1), and CH_2Br_2 behaved differently in spite of same, *i.e.*, 1:1 H/Br ratio. Variable levels of H_2O released from quartz wall of these lamps have been proposed to be the primary reason for these discrepancies (4). These calculations also suggest that lamps made with CH_3Br and low levels of oxygen, such as 0.01%, should darken if the controlling wall temperature is below 800°K. However, contrary to these predictions, such lamps have been found to stay clean (4).

Apparent failure of the thermodynamic approach may be due to a number of reasons, such as incomplete and/or incorrect thermodynamic treatment of the lamp system by exclusion of important yet unknown species and inclusion of nonexistent phases, lack of well-defined data, lamp geometry effects, and filament impurities. But perhaps, the most important factor may be the questionable assumption of LTE under steady-state operating conditions, especially near the bulb walls.

Prevalence of chemical equilibria implies that at the filament and wall, reaction rates are fast enough to establish equilibria with migrated gaseous species (10). Flow of species occurs via radial and thermal diffusion and convection. Extent of each mode of flow will depend on lamp geometry, temperature profiles, and pressures. At the filament temperatures ~3000°K, reaction rates are likely to be fast enough to attain instant equilibrium; however, the same could not be assumed *a priori* at lamp walls where temperatures are ~1000°K.

In this regard, the role of two important lamp constituents, H_2 and CO, deserves special consideration. Hydrogen, because of its extreme mobility, and CO, due to its extraordinary kinetic stability, are likely to contribute heavily toward any deviation of the system from equilibrium. H atoms recombination reaction rate calculations, which are discussed in a later section, suggest an important role for hydrogen.

There is enough evidence to suggest that CO may also play a major role in creating nonequilibrium conditions. Very slow rates of carbon transport observed with the reaction

$$C(s) + CO_2(g) = 2CO(g) \quad [4]$$

have been explained in terms of slow reaction rates with CO (10). Reactions such as [5] and [6]

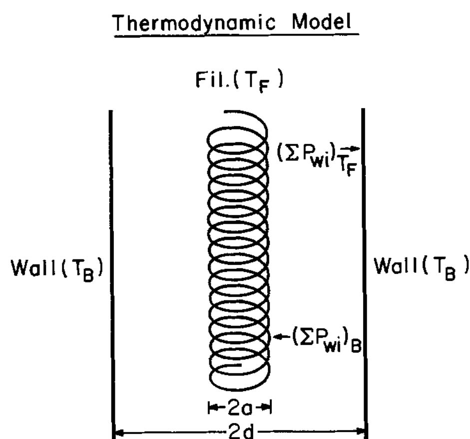

Fig. 1. Comparative formulations of the thermodynamic and kinetic blackening criteria for bromine lamp.

$$W(s) + 2CO_2(g) = WO_2(s) + 2CO(g) \quad [5]$$

$$2W(s) + 2CO(g) = W_2C(s) + CO_2(g) \quad [6]$$

may be quite slow. For example, flash desorption of CO from tungsten surface at ~1000°K does not yield any reaction products which are thermodynamically possible (11).

Since temperatures in most parts of an operating lamp are over 1000°K, CO is the major oxygen bearing gaseous species. At the walls, where temperatures are lower, CO reaction such as [4] essential for providing WO_2Br_2 at the bulb walls, may play a decisive role in the darkening of lamps. Thus, if this reaction is kinetically slow, blackening is likely to result. This, of course, assumes the necessity of oxygen in tungsten removal from the wall. Kinetic studies suggest formation of primarily the WO_2Br_2 species at the wall conditions (12). Binary bromides are known to form in W-Br reactions at bromine pressures at least an order of magnitude higher than those normally prevalent in a typical lamp (13). Available thermodynamic data also discount significant binary bromide formation at bulb walls (14). Thus, the role of CO is considered quite important in wall reactions such as [4] and in creating nonequilibrium conditions at lamp walls.

Kinetic Model

Formulation.—The thermodynamic approach and its limitations in explaining observed lamp phenomena have been discussed in the preceding section. Whether drawbacks of the approach are due to failure of the lamp system at the wall to attain equilibrium with regard to atomic hydrogen and CO cannot be substantiated until relevant kinetic data are available. Hence, the kinetic approach has been explored. In this consideration, important parameters are rates of various processes in the lamp, *e.g.*, reactions at the filament, bulb wall, and gaseous interphase as well as species diffusion.

For the regenerative lamp, three primary rate processes to consider are: (*i*) W atoms evaporation at the filament, (*ii*) W atoms removal by chemical reactions in the gas phase between the filament and wall, and (*iii*) W atoms reaction on the lamp wall. The blackening criterion as discussed earlier is, now, defined as

$$J(W) > [R]_B \quad [II]$$

Here, $J(W)$ is defined as the W atoms flux reaching the wall; it thus depends on the filament temperature T_F and gas phase reaction rates. $[R]_B$, the wall reaction rate, is controlled by wall temperature, T_B, and reactant concentrations.

Calculations.—Flux values can be calculated by solving steady-state diffusion equation (15)

$$D \nabla^2 C - kC = 0 \quad [III]$$

which for cylindrical coordinates becomes

$$D \frac{d}{dr}\left[r \cdot \frac{dC_W(r)}{dr}\right] - k \cdot C_W(r) = 0 \quad [IV\text{-}a]$$

The angular and axial dependence are ignored as the major mass transfer occurs radially. The symbols are defined as follows: D is the mean diffusion constant of W atoms in argon; $C_W(r)$ is tungsten atoms concentration at distance, r, from the filament axis; k is assumed first-order W atoms gas phase reaction rate constant defined as

$$\frac{-dC_W(r)}{dt} = kC_W(r) \quad [V\text{-}a]$$

$$= k'[C_{Br}(r)]^x C_W(r) \quad [V\text{-}b]$$

$$= k''[C_O(r)]^y C_W(r) \quad [V\text{-}c]$$

where k' and k'' are modified rate constants; x and y are the dependence orders; and brackets indicate concentrations of particular species. The kinetic expressions [V-b] and [V-c] would be applicable to reactions such as

$$W(g) + Br(g) = WBr(g) \quad [7]$$

and

$$W(g) + O(g) = WO(g) \quad [8]$$

Similar expressions may be formulated for other possible reactions with H_2O, CO, and O_2 molecules depending on the specific lamp system.

Solution of the relation presented in detail in Appendix I, is

$$[J(W)]_{k=0} = \frac{D \cdot C_W(a)}{d \ln (d/a)} \text{ g-atoms/cm}^2\text{sec} \quad [VI\text{-}a]$$

and

$$[J(W)]_{k>0} = \frac{D \cdot C_W(a)}{d} \frac{1}{\Xi + \frac{\alpha}{\beta^2}\Omega} \text{ g-atoms/cm}^2\text{ sec} \quad [VII]$$

where a and d are defined in Fig. 1 and $C_W(a)$ is the W atoms concentration at the filament. α and β^2 are defined as $\alpha = k/D$ and $\beta^2 = k_s/D$, where k_s is the reaction rate constant on the wall (see Appendix I). The parameters Ξ and Ω are composed of the modified Bessel functions of the first and second kind (16). The tungsten flux relation [VI-a] is modified when the inner bulb diameter is larger than Langmuir film diameter, $2b$. The modified relation is

$$[J(W)]_{k=0} = \frac{D\text{-}C_W(a)}{d \ln (b/a)} \text{ g-atoms/cm}^2\text{ sec} \quad [VI\text{-}b]$$

Using a recent formulation (17), Langmuir film diameter for a typical 500W T3 lamp filled with 2500 Torr of argon and filament at 3000°K, was calculated to be 0.48 cm compared to the bulb diameter of 0.8 cm. Since chemical reactions are not considered limited to only outside of the Langmuir film, the flux calculations for one filament and two different bulb diameters presented in Fig. 2 are based on relations [VI-a] and [VII]. Dramatic reduction in the W atoms flux is caused by gas phase reaction rate constant values $k > 1 \text{ sec}^{-1}$.

The reaction rate constant for W atom loss in relation [IV-a] based on kinetic theory is first order in the limiting case of surface reaction. The volume reactions for species, such as atomic oxygen, have also been found to be first order (18) and hence this assumption is considered quite valid. The relations [V-a], [V-b], and [V-c] imply that $C_{Br}(r)$ and $C_O(r)$

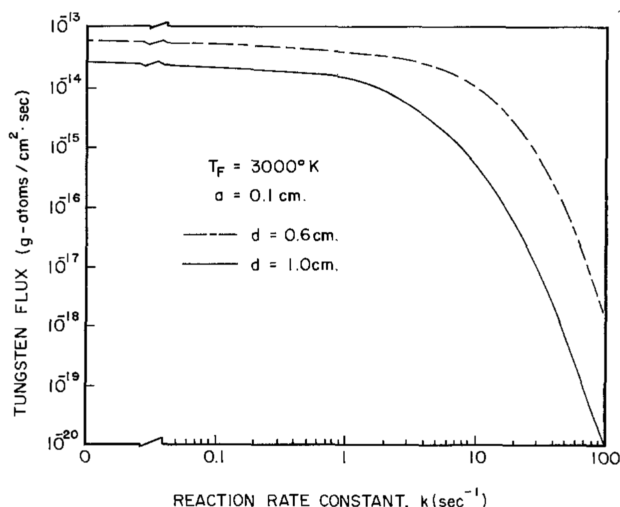

Fig. 2. Effect of gas phase reaction rate constants on the tungsten atoms flux reaching the bulb wall.

are invarient in r. While this is not strictly true due to gas phase loss, proportionately large values of C_{Br} or C_O compared to $C_W(r)$ (see Appendix II) clearly justify these kinetic formulations. Reactions involving radicals and atomic species occur with activation energies $E \approx 0$. The dissociation reaction, *e.g.*, the reverse of reactions [7] or [8] would undoubtedly involve significant activation as these processes are thermodynamically quite unfavorable under the lamp prevalent conditions under present considerations.

A probable range for the values of k has been estimated using collision kinetic theory. Details of these calculations are given in Appendix II. The k values, of course, depend on the postulated reactions. For example, at 1500°K, k values are 6×10^3 and 6×10^4 sec^{-1}, respectively, for reactions [7] and [8] rewritten with Ar as a collision stabilizer

$$W(g) + O(g) + Ar = WO(g) + Ar \qquad [9]$$

and

$$W(g) + Br(g) + Ar = WBr(g) + Ar \qquad [10]$$

These may be regarded as intermediary steps leading to further reactions as products approach lamp wall. Difference in magnitudes of k for the two postulated reactions, obviously, lies in relative reactant concentrations. Thus, increased reactant levels should further reduce W atom flux $J(W)$. The flux, due to its linear dependence on W vapor pressure, increases with filament temperature. The reaction rates, then, must be correspondingly higher to prevent wall blackening.

Lack of experimental kinetic data for tungsten reactions at wall temperatures under lamp environment does not permit any verification of the kinetic model.

Limitations.—The simplified diffusion model only points out the nature of the treatments involved. In reality, however, the lamp phenomena are much more complicated. Convective and thermal diffusion mass flows are also very important as has been pointed out by Fisher *et al.* (19). In fact, at lamp operating pressures, convection becomes the dominating mode of mass and heat transfer. However, chemical reactions have not been considered by them. Availability of the relevant reaction kinetic data is important so that the current approach, even in its present approximate form, can be utilized to increase understanding of the lamp behavior.

Role of Atomic Species

Atomic species such as H, Br, and O are produced at the hot filament. These will react and recombine during their diffusion toward the bulb wall. Rates of these reactions are obviously important in establishing equilibrium conditions in the lamp. Among these, the role of hydrogen atoms, which is the most mobile species, can be investigated to some degree, since reasonably well-established kinetic data are available (20).

Hydrogen is added to the lamp generally as bromomethanes or HBr. Amount of atomic species H and Br at the filament temperature of 3000°K calculated for two typical lamp conditions assuming chemical equilibrium are given in Table I. Movement of these species would occur primarily via diffusion and convection, and in the process the species would undergo reactions such as

$$H + H + Ar = H_2 + Ar \qquad [1]$$

Table I. Equilibrium distribution of species at 3000°K

System	Cold fill pressure (Torr)	P_H (atm)	P_{H_2} (atm)	P_{HBr} (atm)	P_{Br} (atm)
H_2 + HBR (1:1)	6	2.8×10^{-3}	3.1×10^{-2}	5.1×10^{-3}	2.7×10^{-2}
HBr	3	1.4×10^{-2}	7.6×10^{-3}	2.7×10^{-3}	2.9×10^{-2}

$$Br + H + Ar = HBr + Ar \qquad [11]$$

and

$$Br + Br + Ar = Br_2 + Ar \qquad [12]$$

due to fairly high (~14 atm) inert gas pressures. Inert gas atoms of Ar act as third body stabilizers in the collision processes (20). These reactions, although written as termolecular are really composed of two bimolecular collision steps. Available kinetic data have enabled calculations of rates of these reactions.

Since the loss of H atoms occurs primarily by two concurrent reactions, namely [1] and [11], the rate expression may be formulated as

$$-\frac{dC_H}{dt} = 2\frac{dC_{H_2}}{dt} + \frac{dC_{HBr}}{dt} \qquad [VIII\text{-}a]$$

Based on known reaction rate constants, k_1 and k_{11}, respectively, for reactions [1] and [11], the rate equation is

$$-\frac{dC_H}{dt} = \left[\frac{2k_1}{C_{Ar}}\right] \cdot (C_H)^2 \cdot C_{Ar} + \left[\frac{k_{11}}{C_{Ar}}\right] \cdot C_H \cdot C_{Br} \cdot C_{Ar} \qquad [VIII\text{-}b]$$

For the simple case where initial concentrations of H and Br atomic species are about equal, such as for H_2 + HBr system calculated in Table I, the above relation is simplified to give

$$\frac{1}{C_H} - \frac{1}{C_H^\circ} = \left[\left\{\frac{2k_1}{C_{Ar}}\right\} C_{Ar}\right] \cdot \tau_D + \left[\left\{\frac{k_{11}}{C_{Ar}}\right\} C_{Ar}\right] \cdot \tau_D \qquad [VIII\text{-}c]$$

and the unreacted atom fraction

$$\frac{C_H}{C_H^\circ} = \frac{1}{1 + (k_1' + k_{11}')\tau_D C_H^\circ} \qquad [VIII\text{-}d]$$

where k_1' and k_{11}' refer to the bracketed quantities for the particular argon concentration, C_H is the H atom concentration at $t = \tau_D$, and C_H° is the initial concentration. τ_D is the mean H atom diffusion time between the filament and wall given by

$$\tau_D = \frac{(d - a)^2}{D} \qquad [IX]$$

based on simple diffusion model where D is the mean diffusion constant and $(d - a)$ is the diffusion distance (15). Temperature-dependent rate constants, available from shock tube studies, are

$$\frac{k_1}{C_{Ar}} = 2.3 \times 10^{14}\left(\frac{T}{2870}\right)^{-1.2} \frac{cm^6}{mole^2\,sec} \qquad [X]$$

and

$$\frac{k_{11}}{C_{Ar}} = 5.8 \times 10^{14}\left(\frac{T}{3000}\right)^{-2} \frac{cm^6}{mole^2\,sec} \qquad [XI]$$

Appropriate values of C_{Ar} can be used to derive k_1' and k_{11}' for calculating the concentration of H atoms reaching the bulb wall. Reaction [12] is not considered important in affecting Br atom concentration since bromine is expected to be nearly fully dissociated at the prevailing wall temperatures. Furthermore, Br atom diffusion is much slower compared to that of H atom, but it is obvious that the uncombined H atom concentration is primarily governed by the extent of reaction occurring during the mean diffusion time of atomic hydrogen, τ_D. Therefore, the computed C_H/C_H° values are based on this assumption.

In cases such as computed in Table I or others where atomic concentrations of hydrogen and bromine at the filament are not equal, the solution of rate equation [VIII-b] becomes

$$\frac{1}{C_H} - \frac{1}{C_H{}^\circ} = k_I{}'t + k_{II}{}'\left[\frac{C_{Br}}{C_H}\right]t \quad \text{[VIII-e]}$$

Numerical methods are required to evaluate $C_H/C_H{}^\circ$ for such systems. In the case of HBr filled lamps (see Table I) when the bromine atom concentration is about double that of H atoms, the dominant second term in [VIII-e] controls $C_H/C_H{}^\circ$. Therefore, consideration of only reaction [11] is considered satisfactory for calculating values of $C_H/C_H{}^\circ$ in view of the fact that the reaction rate constants themselves are not very well established (20). Since numerical values of $k_I{}'$ and $k_{II}{}'$ at the prevalent lamp conditions are about equal and $C_{Br}{}^\circ = 2C_H{}^\circ$, the expression [VIII-d] without further modification also yields the estimates of unreacted H atom fractions for the particular case of HBr filled system.

The proportion of unreacted hydrogen atoms which reach the lamp wall is a function of total fill pressure, the mean reaction temperature, and the diffusing distance, *i.e.*, the distance between the wall and filament. This is well illustrated in Fig. 3 for the simpler case of H_2 + HBr system where equal amounts of atomic H and Br species prevail at the filament (see Table I). Argon pressures in operating lamps were taken as 4 times the cold fill values. These operating pressures were then used to evaluate $k_I{}'$ and $k_{II}{}'$ and finally $C_H/C_H{}^\circ$ at different reaction temperatures. The diffusion constant, D, was calculated using the formula given in Appendix I. Figure 3 clearly demonstrates the dramatic effect of cold fill pressure, reaction temperature, and path length on the extent of H atoms recombination.

Most regenerative lamps are filled at 2000-3000 Torr. The mean lamp temperature is ~1300°K and filament to wall distance ~0.5 cm. Thus, $C_H/C_H{}^\circ$ would be in the range 2×10^{-4} to 7×10^{-5} which, under steady-state conditions, corresponds to H atom pressures at the wall of ~4×10^{-6} to 1×10^{-6} atm.

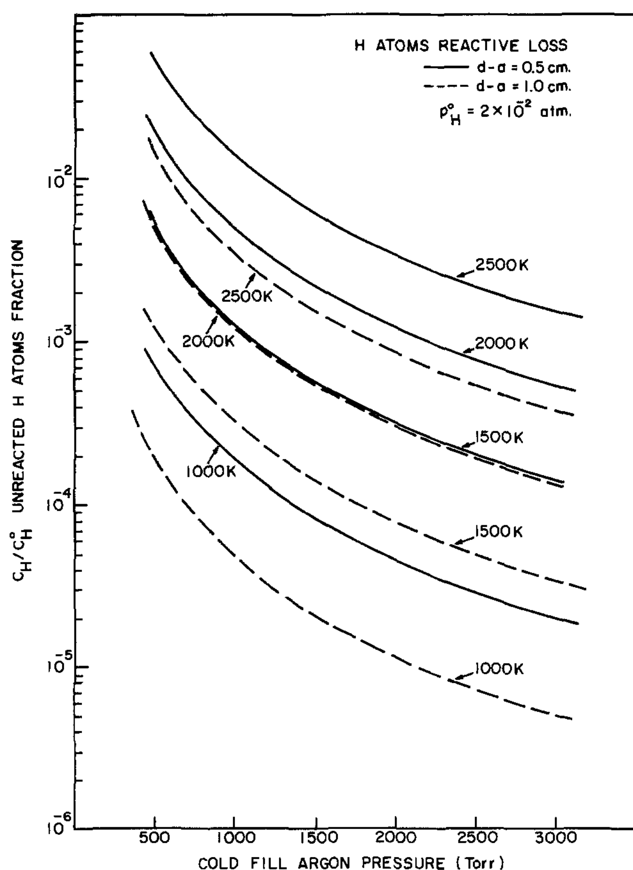

Fig. 3. Lamp fill pressure and temperature dependence of H atoms recombination for two different path lengths.

Table II. Diffusion and reaction times of H and Br atoms

Reaction	τ_r (sec)	τ_D (sec)	T°K
H + Br + Ar = HBr + Ar	0.54	0.36	1500
H + H + Ar = H_2 + Ar	0.2	0.9	1500

Lamp parameters: Cold fill Ar P = 2500 Torr
Filament temp. = 3000°K
H_2 + HBr (1:1) cold filled P = 6 Torr
Fil.-wall distance = 0.5 cm

This is also the range for the specific case of lamps filled with 6 Torr of H_2 + HBr(1:1) as shown in Table I. In the other case of HBr filled lamps at 3 Torr, the calculated H atom wall pressure range of 3×10^{-6} to 1×10^{-6} is not much different from that in the H_2 + HBr case. The effect of increasing the diffusive path length from 0.5 to 1.0 cm is evident from Fig. 3. A minimum diffusion distance of 1.1 cm is required for reaction [1] to reach equilibrium at the wall. The mean diffusion times τ_D and reaction times to reach equilibrium are listed in Table II for both reactions. This suggests that under conditions such as when the filament to wall distances in lamps are large, the entire system can be treated on LTE basis.

Unreacted H atoms reaching the wall, besides being capable of reducing tungsten oxide, will also undergo surface recombination. Published data, however, suggest that recombination reactions on fused silica surfaces are quite slow and strongly dependent on the surface conditions (21). For example, at 900°K, the recombination coefficient is ~3×10^{-2}, which implies only three successful collisions out of 100. The surface recombination coefficient appears to increase with temperature (21). At these low surface reaction rates and low H atom pressure, silica reduction reaction

$$SiO_2(s) + 2H = SiO(g) + H_2O(g) \quad [13]$$

is not believed to be significant. This immediately suggests that tungsten oxide reduction may be a far more efficient process than reaction [13]. There are no experimental data to verify this conclusion.

Limitations of these calculations should also be pointed out. A simplified approach has been adopted in the present calculations rather than use a highly involved solution of diffusion equation with second order dependence on concentration as demanded by relation [III]. The results, thus, may not be rigorous, but certainly represent the general effects of temperature and pressure. The rate constants used are not exactly valid over the adopted temperature and pressure range. Only the diffusion mode of mass transfer was considered in the evaluation of τ_D, even though convection and thermal diffusion due to temperature gradients are quite important, especially at high operating pressures (19).

APPENDIX I

Solution of Diffusion Eq. [IV-a]

Diffusion Eq. [IV-a] can be written as

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{dC(r)}{dr}\right) - \alpha^2 C(r) = 0 \quad \text{[IV-b]}$$

which has the following solution (22)

$$C(r) = AI_0(\alpha r) + BK_0(\alpha r) \quad \text{[XII-a]}$$

where I_0 and K_0 are the modified Bessel functions of the first and second kind, respectively (16). The constants A and B are evaluated using the following boundary conditions: (*i*) At $r = a + \lambda/2$, $C(r = a + \lambda/2) = C(a)$, where $C(a)$ is the tungsten atom concentration at the filament and λ is the mean free path. (*ii*) At $r = d - \lambda/2$, $D\, dC(r)/dr = -k_s[C(r) - C(d)]$, which implies that the flux at $d - \lambda/2$, *i.e.*, half a mean free path from the wall, is equal to the rate of impingement. $C(d)$ is the tungsten atom concentration at $d - \lambda/2$ distance and k_s is defined as $k_s = 1/4 \cdot \bar{v} \times$ condensation (or reaction) coefficient on the wall where $\bar{v}$, is the mean velocity. Since vapor pressure of tungsten at wall temperatures is negligible, $[C(r) - C(d)] \simeq C(r)$.

Application of the boundary conditions yields

$$C(a) = AI_0(\alpha a) + BK_0(\alpha a) \quad \text{[XIII]}$$

and

$$\beta^2[C(r) - C(d)] = -A \cdot \alpha I_0'(\alpha r) - B \cdot \alpha K_0'(\alpha r) \quad \text{[XIV]}$$

which for $r = d$ gives

$$\beta^2 C(d) = A \cdot \Phi(\alpha d) + B \cdot \psi(\alpha d) \quad \text{[XV]}$$

where

$$\Phi(\alpha d) = \alpha I_0'(\alpha d) + \beta^2 I_0(\alpha d) \quad \text{[XIV]}$$

and

$$\psi(\alpha d) = \alpha K_0'(\alpha d) + \beta^2 K_0(\alpha d) \quad \text{[XVI]}$$

Solution of A and B gives an expression for $C(r)$ (16)

$$C(r) = -\frac{C}{\eta} \cdot \psi(\alpha d) \cdot I_0(\alpha r) + \frac{C_a \Phi(\alpha d)}{\eta} \cdot K_0(\alpha r) \quad \text{[XII-b]}$$

where

$$\eta = K_0(\alpha a) \cdot \Phi(\alpha d) - I_0(\alpha a) \cdot \psi(\alpha d) \quad \text{[XVII]}$$

Under steady-state condition, the flux is given by (22)

$$\text{flux,} \quad J = -2\pi r \cdot D \cdot \frac{dC(r)}{dr} \quad \text{[XVIII]}$$

Differentiation of the expression for $C(r)$ and appropriate use of Bessel function relations yields (16)

$$(J)_{r=d} = \frac{D}{d} C(a) \frac{1}{\Xi + \frac{\alpha}{\beta^2}\Omega} \text{ g-atoms/cm}^2\text{ sec} \quad \text{[VII]}$$

where

$$\Xi = K_0(\alpha a) \cdot I_0(\alpha d) - I_0(\alpha a) \cdot K_0(\alpha d) \quad \text{[XIX]}$$

and

$$\Omega = K_0(\alpha a) \cdot I_1(\alpha d) + I_0(\alpha a) \cdot K_1(\alpha d) \quad \text{[XX]}$$

These combinations of Bessel functions can be solved using available expressions (16). Diffusion constant, D, was taken as the average of the values at 1200° and 3000°K. Calculations of D were done by using the following simplified relation (16)

$$D = \frac{2.63 \times 10^{-3}}{P_T \cdot (\alpha_{12})^2} (T)^{3/2} \left[\frac{M_1 + M_2}{M_1 \cdot M_2} \right]^{1/2} \quad \text{[XXI]}$$

where M_1 and M_2 are the respective atomic weights of the two species. T is the absolute temperature, P_T is the total pressure taken as 15 atm here, and α_{12} is the mean atomic diameter of the two diffusing species in angstroms. D values for W-Ar system at 1200° and 3000°K are evaluated as 0.085 and 0.336 cm²/sec, respectively. β^2 is calculated as follows

$$\beta^2 = \frac{k_s}{D} = \frac{1/4\, \bar{v}}{D} \times \text{condensation (or reaction) coefficient} \quad \text{[XXII]}$$

where $\bar{v} = \sqrt{8\kappa T/\pi\mu} = 3.39 \times 10^3$ cm/sec. D is evaluated to be 0.07 cm²/sec at 1000°K and condensation (or reaction) coefficient is approximated as 0.1. κ and μ are the Boltzmann constant and the reduced mass, respectively.

The expression for diffusion without any chemical reaction has been well known (17)

$$(J)_{\substack{r=d \\ k=0}} = \frac{DC(a)}{d \cdot \ln(d/a)} \text{ g-atoms/cm}^2\text{ sec} \quad \text{[VI-a]}$$

When the Langmuir sheath diameter, $2b$, is smaller than the bulb diameter, $2d$, the modified relation is

$$(J)_{\substack{r=d \\ k=0}} = \frac{DC(a)}{d \cdot \ln(b/a)} \text{ g-atoms/cm}^2\text{ sec} \quad \text{[VI-b]}$$

APPENDIX II

Estimation of k

The diffusion expression [IV-a] contains a reaction term for the first-order rate of loss of tungsten atoms in gas phase reactions, defined as

$$\frac{-dC(r)}{dt} = k \cdot C(r) \quad \text{[V-a]}$$

Two postulated reactions are [9] and [10]

$$W(g) + O(g) + Ar = WO(g) + Ar \quad [9]$$

and

$$W(g) + Br(g) + Ar = WBr(g) + Ar \quad [10]$$

for which no experimental values of k are available. Collision theory can be used to estimate values of k which may be expressed for both reactions as follows

$$\frac{-dC_W(r)}{dt} = kC_W(r) = k'C_W(r) \cdot C_O \cdot C_{Ar} \quad \text{[XXIII-a]}$$

$$= k''C_W(r) \cdot C_{Br} \cdot C_{Ar} \quad \text{[XXIII-b]}$$

The ternary collision expressions really involve two consecutive binary collisions in which the third body, Ar, acts as the collision stabilizer. Details of treatment of ternary collision gas kinetics are given elsewhere and, thus, only outlines will be given (23). The rate of reaction [9] for example, can be expressed as

$$\frac{-dC_W(r)}{dt} = P \cdot Z_3^\circ \exp(-E/RT) \cdot C_W(r) \cdot C_O \cdot C_{Ar} \quad \text{[XXIV]}$$

where P is the probability factor, E is the activation energy and the number of ternary collisions, Z_3, is defined as

$$Z_3 = Z_3^\circ C_W(r) C_O C_{Ar} \quad \text{[XXV-a]}$$

A simplified and approximate version of the expression for Z_3° is

$$Z_3^\circ = 54 \cdot \sqrt{3} \cdot R \cdot T \cdot M^{-1} \cdot \tau \cdot d^4 \quad \text{[XXV-b]}$$

where M is the mean molecular weight, d is the mean molecular diameter, and τ is mean lifetime of the binary complex defined as: $\tau = d/v$ where v is the mean relative velocity of the complex at T°K.

In the present considerations of the two reactions, activation energy, E, is taken as zero as is the case for radical-type reactions. The reaction rate expressions are defined, respectively, as

$$\frac{-dC_W(r)}{dt} = kC_W(r) = Z_3^\circ \cdot P \cdot C_W(r) \cdot C_O \cdot C_{Ar} \quad \text{[XXIII-c]}$$

and

$$= Z_3^\circ \cdot P \cdot C_W(r) \cdot C_{Br} \cdot C_{Ar} \quad \text{[XXIII-d]}$$

which yield for k the following

$$k_9 = Z_3^\circ \cdot P \cdot C_O \cdot C_{Ar} \text{ sec}^{-1} \quad \text{[XXVI-a]}$$

and

$$k_{10} = Z_3^\circ \cdot P \cdot C_{Br} \cdot C_{Ar} \text{ sec}^{-1} \quad \text{[XXVI-b]}$$

Substitution of appropriate quantities yields the following for Z_3°

$$Z_3^\circ = 4 \times 10^{-35} \cdot T \frac{\text{cm}^6}{(\text{molecule})^3} \cdot \frac{1}{\text{sec}}$$

$$= 1.5 \times 10^{13} \cdot T \frac{\text{cm}^6}{(\text{mole})^3 \text{ sec}} \quad \text{[XXV-c]}$$

Mean reaction temperature for lamp gas phase is

assumed to be 1500°K. A typical lamp has Ar, Br, and O atom concentrations $\sim 10^{20}$ ($\sim$15 atm), 10^{17} ($\sim 10^{-2}$ atm), and 10^{16} ($\sim 10^{-3}$ atm) atoms/cm^3, respectively. If the reaction probability, P, is assumed 0.1, reaction rate constants, k_9 and k_{10}, respectively, are 6×10^3 and 6×10^4 sec^{-1}.

and G. E. McGuire*

Texas Instruments, Dallas, Texas 75222

ABSTRACT

Methods are described to extract the grain boundary diffusion coefficient from experimental measurements of surface concentration of a diffusing species. For Type C kinetics, where bulk transport is negligible, easily used exact analytical solutions are available for infinite source and zero or infinite sink boundary conditions. For infinite or finite source and finite sink boundary conditions, the surface concentration is described by an exponential curve if the surface capacity is larger than the grain boundary capacity. The finite sink analysis has been applied to chromium diffusing in platinum, and D_b was found to equal 1.1×10^{-3} exp ($-31{,}700/RT$). For Type B kinetics, where bulk transport is not negligible, equations developed by Wuttig and Birnbaum may be used with a general criterion for approximating the bulk lattice flux developed in the present work. These solutions are available for infinite and finite source and infinite and zero boundary conditions. For an infinite source and sink condition, D_b was calculated for gold in platinum by a "time-of-penetration" measurement and was shown to equal 0.018 exp ($-38{,}000/RT$).

Electron and ion spectroscopies are being widely used in analysis of low temperature diffusion accelerated by defects such as grain boundaries (1, 2). The diffusion phenomena can be characterized by either measuring concentration *vs.* depth in the solid (sputter profiling), or by measuring surface concentration on a finite thickness film as a function of time and temperature (permeation analysis) (1). Permeation analysis is often preferred because of sputtering artifacts (3, 4) and efficiency in the collection data, but proper analysis of the data is not always straightforward.

Hwang and Balluffi (5, 6) have given exact analytic expressions for material concentration in the grain boundary or on the surface as a function of time and temperature for finite or infinite source and finite sink boundary conditions. Their treatment assumes the leakage of material from grain boundary can be neglected. Harrison (7) has developed a terminology useful in designating the general effects of bulk diffusion on grain boundary diffusion. When the amount of material lost from the boundary is negligible, Harrison designates this Type C kinetics. When the loss of material from the boundary to the bulk is significant but the diffusion fields from grain boundaries do not overlap, the kinetics are Type B. Type A kinetics occur when the diffusion fields overlap. In the terminology developed by Harrison (7), Hwang and Balluffi's analysis is applicable to Type C kinetics. However their exact solution is complex, requiring numerical solutions of a transcendental equation, therefore it is not easily used.

Similarly, Gilmer and Farrell (8, 9) have derived exact analytical expressions for material concentration *vs.* distance in thin films for infinite source and zero or infinite sink boundary conditions. With some manipulation, their expressions can describe surface concentration *vs.* time and temperature. Their derivation is applicable to the temperature regime where

* Electrochemical Society Active Member.

loss of material to the grain is significant, *i.e.*, what Harrison (7) calls Type B kinetics, but the solution also involves a transcendental equation, which is very inconvenient since such equations must usually be solved on a digital computer.

It is desirable to find solutions or simplifying assumptions to make it easier to extract grain boundary diffusion coefficients. For Type C kinetics Hwang and Balluffi (5, 6), Nelson *et al.* (1, 10), and Hall and Morabito (11) have described simplifying assumptions for finite and infinite sink boundary conditions. The resulting solutions will be described and Hwang and Balluffi's solutions compared to literature data for chrominum diffusing in platinum (12).

For Type B kinetics, Wuttig and Birnbaum (13) have solved the diffusion equations using an approximate value for the grain boundary leakage flux, but Holloway *et al.* (1) experienced difficulty in using their approximation because the leakage flux was underestimated. It will be shown that a methodology can be developed to select this flux by determining the total amount of material lost from the boundary during the course of an experiment. Calculations based on Wuttig and Birnbaum's treatment will be compared to earlier numerical calculations (1). With this general criterion to approximate grain boundary leakage flux, the boundary diffusion coefficient can be calculated from a time of penetration measurement corrected for bulk diffusion as will be shown for gold diffusing in platinum (14).

Model for Grain Boundary Diffusion

The grain boundary diffusion geometry originally proposed by Fisher (15) and extended by several others (16-18) is used. It is shown schematically in Fig. 1. The grain boundary is a region 2δ wide with a concentration C_b and diffusivity, D_b. The region, $\delta < y < d/2$, is the bulk of the grain with a concentration C_g and diffusion coefficient D_g for the diffusant. The geometry in Fig. 1 departs from that of Fisher and others in that finite thickness films are considered, therefore boundary conditions at the sink are extremely important. The source and sink may be high diffusivity regions with widths ϵ and γ, respectively, and characterized by a concentration C_s and a diffusion coefficient, D_s.

Let the concentration of the diffusing species be a function of x, y, time (t), and temperature (T). Then by Fick's second law (9)

$$\frac{\partial C_g}{\partial t} = D_g\left(\frac{\partial^2 C_g}{\partial x^2} + \frac{\partial^2 C_g}{\partial y^2}\right) \quad \text{for } y > \delta,\ 0 < x < L \quad [1]$$

Requiring that the flux and concentrations be continuous at $y = \delta$ and that C_b is an even function in y, Whipple (16) showed that

$$\frac{\partial C_g}{\partial t} = D_b \frac{\partial^2 C_g}{\partial x^2} + \frac{D_g}{K\delta}\frac{\partial C_g}{\partial y} \quad \text{for } y = \delta,\ 0 < x < L \quad [2]$$

was the single homogeneous boundary condition. The flow into the grain is given by the usual flux condition

$$q_g = -D_g \left.\frac{\partial C_g}{\partial y}\right|_{y=\delta} \quad [3]$$

These equations are generally solved for an infinite source condition expressed by

$$C(0,y,t) = K\alpha_0 \quad [4]$$

or a finite source condition expressed by

$$C(x,y,0) = \nu\delta(x) = \int_0^\infty \int_0^L C(x,y,t)\,dx\,dy \quad [5]$$

where α_0 is the bulk terminal solid solubility of the solute in the solvent, K is the grain boundary segregation factor, $\delta(x)$ is the Dirac delta function, and ν is the surface density of the solute. The conditions expressed by Eq. [4] and [5] are met both in the boundary and grain and are referred to extensively throughout this paper as infinite and finite source conditions, respectively. The common sink boundary conditions are zero flux, expressed by

$$\left.\frac{\partial C(x,y,t)}{\partial x}\right|_{x=L} = 0 \quad [6]$$

or an infinite sink expressed by

$$C(L,y,t) = 0 \quad [7]$$

As for the source conditions, these sink conditions expressed by Eq. [6] and [7] are met both in the boundary and in the grain and are extensively referred to as zero and infinite sink conditions, respectively. Even though the surface concentration is pinned at zero at $x = L$ for an infinite sink, diffusant can still accumulate on the surface. This is possible at short times by rapid surface diffusion away from the boundaries. At longer times, the diffusant exiting from the grain boundaries must be removed for an infinite sink condition. Nelson and Holloway (10) have shown that oxidation can effectively remove material from the boundary and allow it to accumulate on the surface while maintaining an infinite sink boundary condition.

Another boundary condition often encountered is that of a finite sink, *e.g.*, when a submonolayer of material builds up on the surface of a solid as defined mathematically below. This often occurs since the free energy of mixing lowers the system free energy thereby causing diffusion, but without a heat of chemical reaction or strain energy term, the system free energy is not reduced by multilayer accumulation. Thus the surface is often saturated at approximately a monolayer. A finite boundary condition is difficult to treat rigorously because of coupling between bulk, grain boundary, and surface diffusion. For Type C kinetics, only grain boundary and surface diffusion coupling must be considered, and Hwang and Balluffi (5, 6) have done so by writing equations like Eq. [2] for both the grain boundary and the surface regions [but with $D_b/\delta^{-1}(\partial C_g/\partial y) = 0$]. The boundary conditions for a finite sink are

$$C_b(L,t) = C_s(0,t), \quad \delta D_b \frac{\partial C_b(x,t)}{\partial x} = \gamma D_s \frac{\partial C_s(y,t)}{\partial y} \quad [8]$$

for $x = L$, $y = 0$ and

$$\left.\frac{\partial C_s(y,t)}{\partial y}\right|_{y=d/2} = 0 \quad [9]$$

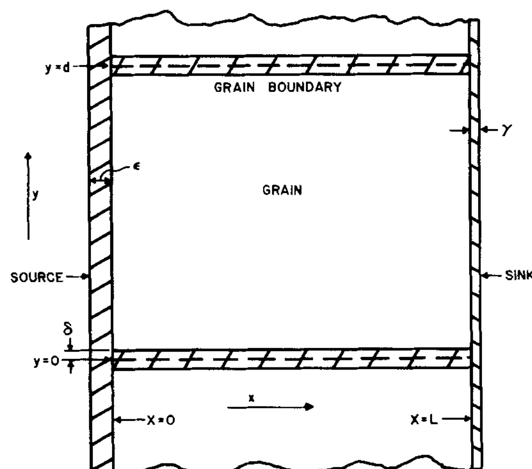

Fig. 1. Schematic representation of a thin film with grain boundaries.

The finite sink boundary condition has not been solved for Type B kinetics. At times a zero sink may be a good approximation to a finite sink boundary condition, as will be discussed. Finally, all of the above treatments assume that for both the boundary and grain

$$C(x,y,t) = 0, \text{ for } 0 < x < L, \ 0 < y < d/2, \ t = 0 \quad [10]$$

Nonzero initial concentration profiles have not been treated, even with approximate solutions. A nonzero initial concentration can easily occur during sample preparation and can have significant impact on data analysis, as will be discussed.

Type C Kinetics

Type C kinetics, where bulk transport is negligible, is the simplest case for data analysis, and experimental conditions should meet this criterion when possible. Solutions for infinite source and zero or infinite sink boundary conditions can both be adapted from solutions given by Crank (20) for diffusion in a plane sheet. For

$$\left.\frac{\partial C_b(x,y,t)}{\partial x}\right|_{x=L} = 0$$

i.e., a zero sink boundary condition, Crank gives

$$\frac{C_b(L,0,t)}{K\alpha_0} = 1 - \frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)} \exp\left(-\frac{D_b(2n+1)^2\pi^2}{L^2}t\right) \quad [11]$$

The shape of Eq. [11] is shown in Fig. 2 (plot C), which can normally be determined by evaluating only ~5 terms in the summation. To get the average concentration at $x = L$, the concentration, C_b, must be multiplied by the fractional cross-sectional area of the grain boundaries at $x = L$.

Crank (20) also gives the total surface concentration of material at $x = L$, Q, for an infinite sink as

$$\frac{Q}{K\alpha_0 L} = \frac{D_b t}{L^2} - \frac{1}{6} - \frac{2}{\pi^2}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^2} \exp\left(-\frac{D_b n^2\pi^2}{L^2}t\right) \quad [12]$$

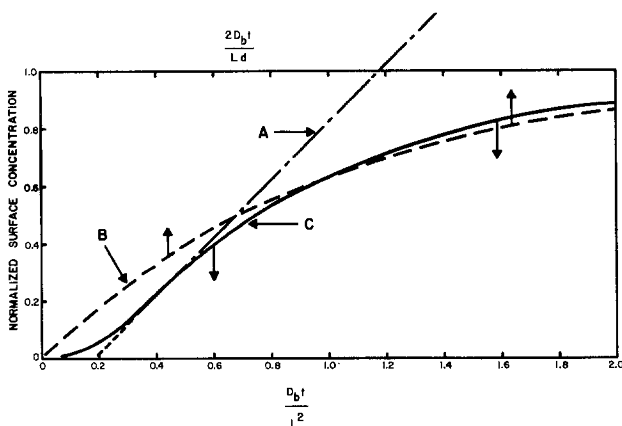

Fig. 2. Surface concentration of material *vs.* dimensionless time parameters. A, Plot for infinite source-infinite sink boundary conditions as discussed for Eq. [12]. B, Plot for infinite source-finite sink boundary conditions as discussed for Eq. [17]. C, Plot for infinite source-zero sink boundary conditions as discussed for Eq. [11].

where Q is the total amount of material transported to the sink surface region. Nelson and Holloway (10) have applied Eq. [12] to the diffusion of Cr in Au and have shown that a time-of-penetration test may be used to determine D_b. For $t >> L^2/\pi^2 D_b$, Eq. [12] has an intercept (for $Q = 0$) on the time axis, t_I, of

$$t_I = \frac{L^2}{6D_b} \quad [13]$$

and by simple rearrangement, D_b can be calculated from such an intercept. Equation [13] applies only to Type C kinetics; as is shown below, such an approach can also be used for Type B kinetics with corrections for grain boundary leakage. For an infinite sink boundary condition at $x = L$, the accumulated surface concentration increases linearly with time, as shown in Fig. 2, and the slope can also be used to determine D_b. It should be noted, however, that if a surface analytical technique with a limited detection depth is used, the detected surface concentration may appear to saturate when the thickness of diffusant at the sink becomes greater than the detection depth, even though an infinite sink boundary condition is appropriate. Care must be taken in that the apparent saturation should not be confused with the real saturation effect for zero sink, finite sink, or finite source boundary conditions.

For the case of a finite sink with a finite or infinite source boundary conditions, the solution of Hwang and Balluffi (5,6) must be used. For an infinite source boundary condition, they show that the concentration on the surface at $x = L$ is given by

$$C_s(L,y,t) = K_s\alpha_0\left[1 - 2\sum_{n=1}^{\infty}\exp\left(-\frac{\alpha_n^2 D_b t}{L^2}\right)\frac{HF\cos\{\alpha_n F(1-2y/d)\}}{\alpha_n\{(1+H)F\sin(\alpha_n)\cos(\alpha_n F) + (1+HF^2)\cos(\alpha_n)\sin(\alpha_n F)\}}\right] \quad [14]$$

where K_s is the surface segregation coefficient and

$$H = \frac{2K_b\delta L}{K_s\gamma d}, \quad F = \frac{D_b d^2}{4L^2 D_s} \quad [15]$$

and α_n are the roots of

$$HF\cos\alpha\cos(\alpha F) - \sin\alpha\sin(\alpha F) = 0 \quad [16]$$

Equation [16] is difficult to solve therefore Hwang and Balluffi simplified Eq. [14]. Their derivation is complicated, therefore, it will be sufficient to note that by assuming rapid surface diffusion (*i.e.*, $D_s t >> d^2/4$) and a greater surface capacity (γd) than grain boundary capacity ($2\delta L$, *i.e.*, $H << 1$), Eq. [14] becomes

$$C_s(L,t) = K_s\alpha_0\left(1 - \exp\left[-\frac{2D_b t}{dL}\right]\right) \quad [17]$$

where it is assumed that $2\delta = \gamma$ and $K_b = K_s$. This curve is shown in Fig. 2 and the difference in shape is not large between zero and finite sink boundary conditions. The most distinguishable feature lies in the fact that for $H \gtrsim 1$, Eq. [11], [12], and [14] predict an initial period where the concentration at the surface $x = L$ is near zero. As the surface capacity becomes large compared to the grain boundary capacity this delay becomes much less prominent and is not noticeable for $H << 1$. The delay in the surface appearance of the diffusing species results from the time required to establish a "steady-state" concentration profile through the film when the initial distribution is zero ($C(x,y,0) = 0$). If the initial distribution is instead

$$C_b(x,y,0) = 1 - x/L \quad [18]$$

the initial transient for curves A and C in Fig. 2 will not be observed and the data will be described well

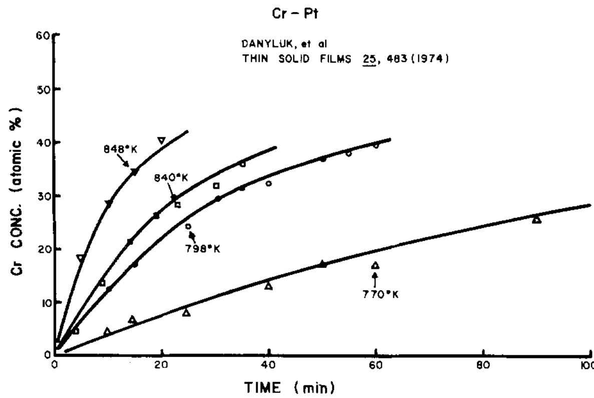

Fig. 3. Chromium surface concentration *vs.* time at various temperatures. The solid lines are fitted exponential curves with characteristic times reported in Table I.

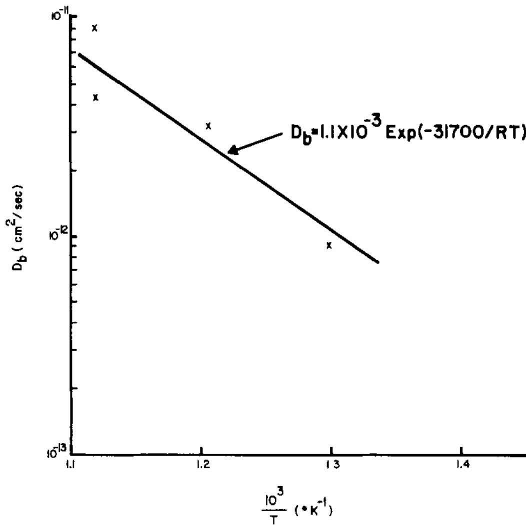

Fig. 4. Grain boundary diffusion coefficient *vs.* reciprocal temperature for chromium in platinum.

by an exponential curve like Eq. [17]. Therefore, care must be taken to identify the proper sink boundary condition and the proper analysis.

Equation [17] can be applied to data for chromium diffusing in platinum as reported by Danyluk *et al.* (12). In this case, the authors report a grain size of ≈1000A, therefore $H \approx 2$ and it is questionable if Eq. [17] should apply. However no chromium was detected on the surface at zero time and no time delay was observed in the appearance of chromium on the surface, which suggests Eq. [17] is applicable. Data for each temperature were fitted to an exponential curve with a characteristic time, τ_o, as shown in Fig. 3. Table I shows the D_b calculated using Eq. [17]. These coefficients are plotted *vs.* T^{-1} in Fig. 4 and the best fit data are

$$D_b = 1.1 \times 10^{-3} \exp(-31{,}700/RT)$$

and

$$\delta D_b = 2.8 \times 10^{-11} \exp(-31{,}700/RT) \qquad [19]$$

where δ is assumed to be 2.5A in Eq. [19]. This pre-

Table I. Time constant and calculated grain boundary diffusion coefficients for Cr in Pt

T(°K)	τ_o(min)	D_b(cm²/sec)	δD_b* (cm³/sec)
848	11	9.1×10^{-12}	2.28×10^{-19}
840	23	4.3×10^{-12}	1.08×10^{-19}

* δ = 2.5A.

exponential factor is a factor of 10 lower, and the activation energy is lower (32 *vs.* 38 kcal/mole) than reported by Danyluk *et al.*, based on a percent diffusion test. Numerical calculations by Hwang and Balluffi have shown that Eq. [17] deviates from Eq. [14] for $H \gtrsim 1$, therefore the coefficient in Eq. [19] may be low by a factor of 2. However in the limit of $H >> 1$, Eq. [17] approaches Eq. [11] which is controlled by an exponential with an argument of D_bt/L^2 rather than $2D_bt/Ld$ in Eq. [17]. For the experimental data under discussion, the variation from L^2 to $Ld/2$ results only in a factor of 4 difference, therefore Eq. [19] must be less than a factor of 4 in error.

Type B Kinetics

Type B kinetics are much more difficult to describe due to leakage of material from the grain boundary and surface to the bulk. As pointed out earlier, Gilmer and Farrell (8,9) have described exact solutions for an infinite source and zero or infinite sink boundary conditions but their exact solution is difficult to use. Wuttig and Birnbaum (13) have given solutions for Type B kinetics using Eq. [2] and [3] where Eq. [3] was approximated by

$$\left.\frac{\partial C_g(x,y,t)}{\partial y}\right|_{y=\delta} = \frac{C_g(x,y_m) - C_g(x,\delta,t)}{y_m - \delta} \qquad [20]$$

Wuttig and Birnbaum (13) chose $y_m = d/2$ and $C(x,y_m) = 0$ for their analysis, but Holloway *et al.* (1) found that this approximation caused such low grain boundary leakage that it reduced to Type C kinetics. Selecting y_m based on the product of D_g and t_o (the maximum experimental time) yielded curves closer to experimental data, but no general scheme was developed to select y_m. It is possible to methodically select y_m, as shown below.

To generally select y_m, the amount of material lost from the boundary to the grain is first determined by integrating over y, then the total amount of material lost to the bulk is determined by integrating the flux, defined by Eq. [20], over time. Since these two quantities must be equal, they are equated to determine y_m. Assume that the concentration in the bulk is given by a complementary error function (20), *i.e.*

$$C_g(x,y,t) = \alpha_o \operatorname{erfc}([y - \delta]/2\sqrt{D_gt}) \quad \text{for } y > \delta \qquad [21]$$

where $C_b(x,\delta,t)$ has been replaced with a time independent concentration, α_o. The total amount of material lost to the bulk at time t is given by

$$Q = \int_\delta^{y_m} \alpha_o \operatorname{erfc}([y - \delta]/2\sqrt{D_gt})\,dy$$

$$\simeq \int_0^\infty \alpha_o \operatorname{erfc}(y/2\sqrt{D_gt})\,dy \qquad [22]$$

since in Type B kinetics, the diffusion fields from adjacent grain boundaries do not overlap. During an experiment of length, t_o

$$Q = 2\alpha_o\left(\frac{D_gt_o}{\pi}\right)^{1/2} \qquad [23]$$

is lost to the bulk. From Eq. [20] the amount lost to the bulk can also be determined by integrating the flux, $-D_g(\partial C_g/\partial y)$, over time

$$Q = \int_0^{t_o} D_g\left[\frac{C_g(x,\delta,t) - C_g(x,y_m)}{y_m - \delta}\right]dt \qquad [24]$$

and if it is assumed that $C_g(x,\delta,t)$ is α_o independent of time[1] and $C_g(x,y_m) = 0$, then

[1] Setting $C_g(x,\delta,t) \sim \alpha_o$ is not as severe an assumption as it might appear. This overestimates the amount of material lost to the bulk in both the integration over y (Eq. [23]) and over time (Eq. [25]). These overestimates tend to cancel one another yielding a good value for y_m.

$$Q = D_g \left(\frac{\alpha_o}{y_m - \delta} \right) t_o \qquad [25]$$

Equating Eq. [23] and [25] yields

$$y_m = \left(\frac{\pi D_g t_o}{4} \right)^{1/2} + \delta \qquad [26]$$

which may be applied to Wuttig and Birnbaum's expressions for various source and sink boundary conditions.

To check the validity of this value for y_m, it is used to calculate the surface concentration from Wuttig and Birnbaum's expression for an infinite source and sink

$$\frac{Q}{K\alpha_o L} = \frac{k/n}{\sinh (k/\eta)} \left[\eta^2 t + \eta^2/2k^2 - \eta/2k \coth (k/\eta) + \frac{2\pi^2\eta}{k} \sinh (k/\eta) \sum_{j=1}^{\infty} \frac{(-1)^{j-1} j^2}{\xi_j^2} \exp (-\xi_j \eta^2 t) \right] \qquad [27]$$

where

$$k^2 = \frac{D_g}{y_m\delta}, \quad \eta^2 = \frac{D_b}{L^2}, \quad \xi_j = (j^2\pi^2 + k^2/\eta^2) \qquad [28]$$

Equation (27) is compared to experimental data for chromium diffusing in gold (1, 10) in Fig. 5. The dashed line is for $D_g = 0$, *i.e.*, Type C kinetics, whereas the solid and dot-dash line were calculated using Eq. [26] and [27]. Since the calculated curves agree well with the experimental data, the approximation for y_m is considered satisfactory.

With this expression for y_m, the Wuttig and Birnbaum expressions may be applied to Type B kinetics. Generally only about five terms in the summation in Eq. [27] need be evaluated, thus it can be solved without a digital computer. In addition, the transition between Type B and C kinetics can be investigated with this formalism, and it was found that Type B kinetics apply for $y_m > 2\delta$.

Equation [26] can also be used to develop a time of penetration test to determine D_b, even for Type B kinetics. For $t >> \eta^{-2}$, Eq. [27] reduces to

$$\frac{Q}{K\alpha_o L} = \frac{k/\eta}{\sinh (k/\eta)} \left[\eta^2 t + \eta^2/2K^2 - \frac{\eta}{2K} \coth (k/\eta) \right] \qquad [29]$$

which has a time axis intercept, t_I, for $Q = 0$ of

$$t_I = \frac{\coth (k/\eta)}{2k\eta} - \frac{1}{2k^2} \qquad [30]$$

Equation [30] can therefore be used to calculate D_b from a time of penetration test. However, Eq. [30] can be simplified in some cases by noting that for $k/\eta < \pi/4$, $\coth (k/\eta)$ is given by

$$\coth (k/\eta) = \left[\frac{k}{\eta} - 1/2(k/\eta)^3 + 2/5(k/\eta)^5 \ldots \right]^{-1} \qquad [31]$$

and neglecting terms higher than cubic, Eq. [26], [28], and [30] may be combined to yield

$$D_b = \frac{L^2}{6t_I} + \frac{D_g L^2}{3y_m\delta} \qquad [32]$$

Equation [32] may be applied to literature data reported by McGuire *et al.* (14) for gold diffusing through platinum. The ratios of the gold 2111 eV to the platinum 1967 eV derivative Auger peak heights are shown in Fig. 6 *vs.* time. In this case, 0.55 μm of platinum was electroplated on 0.25 mm of gold, therefore the source was infinite. Sputter profiling showed a heavy concentration of gold on the platinum surface, therefore the boundary condition at the sink, $x = L$, will be taken as infinite. The time intercepts for $Q = 0$ are shown in Fig. 6 and tabulated in Table II. The value for lattice diffusion of gold in platinum reported by Bolk (21) is used in Eq. [32] ($D_g = 0.33 \exp [-63{,}000/RT]$). The values of D_b are tabulated in Table II and plotted *vs.* T^{-1} in Fig. 7. A best fit to the data yields

$$D_b = 0.018\, e^{-38{,}000/RT} \quad \text{or} \quad \delta D_b = 4.5 \times 10^{-9}\, e^{-38{,}000/RT} \qquad [33]$$

where $\delta = 2.5$Å. With this value of D_b, $k/\eta \sim 0.5$ which satisfies the approximation made to write Eq. [31] and [32]. The activation energy of 38 kcal/mole is higher than that reported by Change and Quintana (22) for the appearance of gold on the platinum surface. The difference in activation energy has been explained by the presence of antimony and potassium in the films studied by McGuire *et al.* (14). McGuire showed that antimony segregated to the surface. therefore it almost certainly also segregated to the grain boundaries and probably changed the kinetics of transport. This is discussed further in Ref. (14).

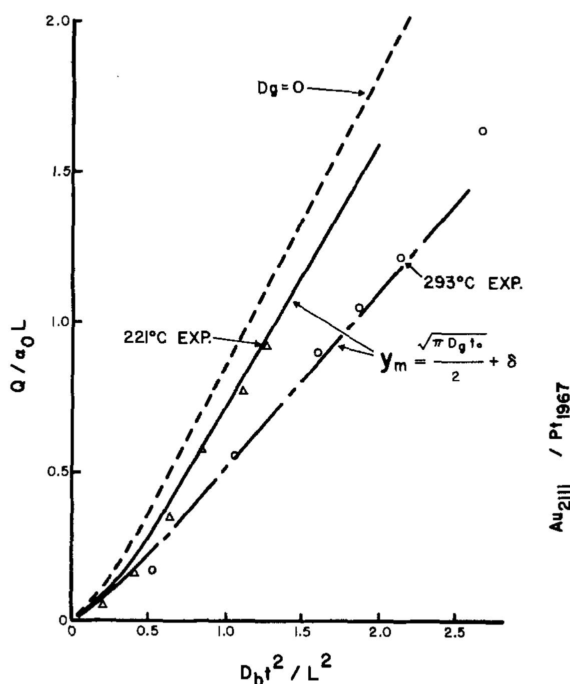

Fig. 5. Dimensionless parameter plot of the accumulation of chromium on gold surface [see Ref. (1) and (10) for experimental details]. Note that grain boundary leakage causes the data to deviate from the Type C kinetic curve (designated by $D_g = 0$), but by calculating y_m from Eq. [26], Eq. [27] can be corrected for the grain boundary leakage effect.

Summary and Conclusion

Although grain boundary diffusion to the surface of solids is complicated by coupling between grain boundary, surface, and bulk transport, numerical exact analytic, and approximate analytic solutions can now describe the variations in concentration of diffusing species. Because numerical and exact analytic solutions are not always easy to use, approximate solutions have been developed which involve, at the most, evaluating the first few terms of an infinite sum. For Type C kinetics where bulk transport may be neglected, easily manipulated exact solutions exist for infinite source and zero or infinite sink boundary conditions. A good approximate solution exists for an infinite or finite source and finite sink boundary conditions, where the capacity of the grain boundary is much less than that of the surface. This solution was used to show that D_b for chromium in platinum is given by $1.1 \times 10^{-3} \exp(-31{,}700/RT)$.

For Type B kinetics where bulk transport is significant, a general method for approximating the flux of material into the grain was developed. With this flux approximation, good expressions are available to describe the concentration both for infinite or finite source and for zero or infinite sink boundary conditions. A method for determining D_b from a time-of-penetration test was developed for Type B kinetics, and was applied to gold diffusing in platinum. For this system, D_b was found to equal $0.018 \exp(-38{,}000/RT)$.

X-Ray Diffraction Topography and Crystal Characterization of GaN Epitaxial Layers for Light-Emitting Diodes

A. Shintani,* Y. Takano, S. Minagawa,* and M. Maki

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

Gallium nitride is a wide bandgap semiconductor which permits realization and performance of light-emitting diodes (LED's) generating green (1, 2), blue (3-6), yellow (4, 5, 7), red (8), and violet (9) light. To date, these GaN LED crystals grown on sapphire substrates have been electrically characterized by estimation of their free electron concentrations and Hall mobilities (10). The crystals have also been optically evaluated from near gap emissions in their photoluminescences (11-13) and in their cathodoluminescences (14). Crystallographical evaluation using hot phosphoric acid was recently studied for undoped and LED crystals (15, 16). However, the etching technique has the essential disadvantage that it destroys the subject crystal.

Here, x-ray diffraction topography and the rocking-curve technique were applied to evaluation of GaN crystal layers. As a result, undoped and LED GaN crystals could be characterized by these x-ray diffraction techniques.

Epitaxial GaN crystals employed in the study were grown on {0001} and {$1\bar{1}02$} oriented sapphire substrates using a conventional chemical vapor deposition technique (4, 15). The LED crystals consisted of undoped (50-80 μm in thickness) and Zn-doped layers (10 μm). The x-ray diffraction topography utilized was the oscillation method using monochromatic divergent beams proposed by Kohra and Takano (17). In the present study, Cu Kα x-ray beams monochromatized by a curved Si single crystal were used. Distribution of x-ray diffraction intensity (rocking curve) was also measured to examine crystalline quality using a (0006) diffraction plane. Furthermore the crystal surface morphology was microscopically observed to investigate the correlation between the topographs and crystal growth patterns.

Generally, undoped GaN layers are higher than 10^{18} cm^{-3} in carrier concentration with n-type conducting characteristics due to native donors. Here, crystalline qualities were compared for undoped crystals (10-80 μm in thickness) with carrier concentrations of 10^{18} and 10^{20} cm^{-3}. In the case of crystals with carrier concentrations of 10^{19}-10^{20} cm^{-3}, their crystal defects are higher than 10^6 cm^{-2} in density at the crystal surfaces (15). An x-ray topograph of this high carrier concentration crystal showed no distinct pattern, as shown in Fig. 1, even when the

* Electrochemical Society Active Member.

Key words: crystalline quality, carrier concentrations, surface morphology.

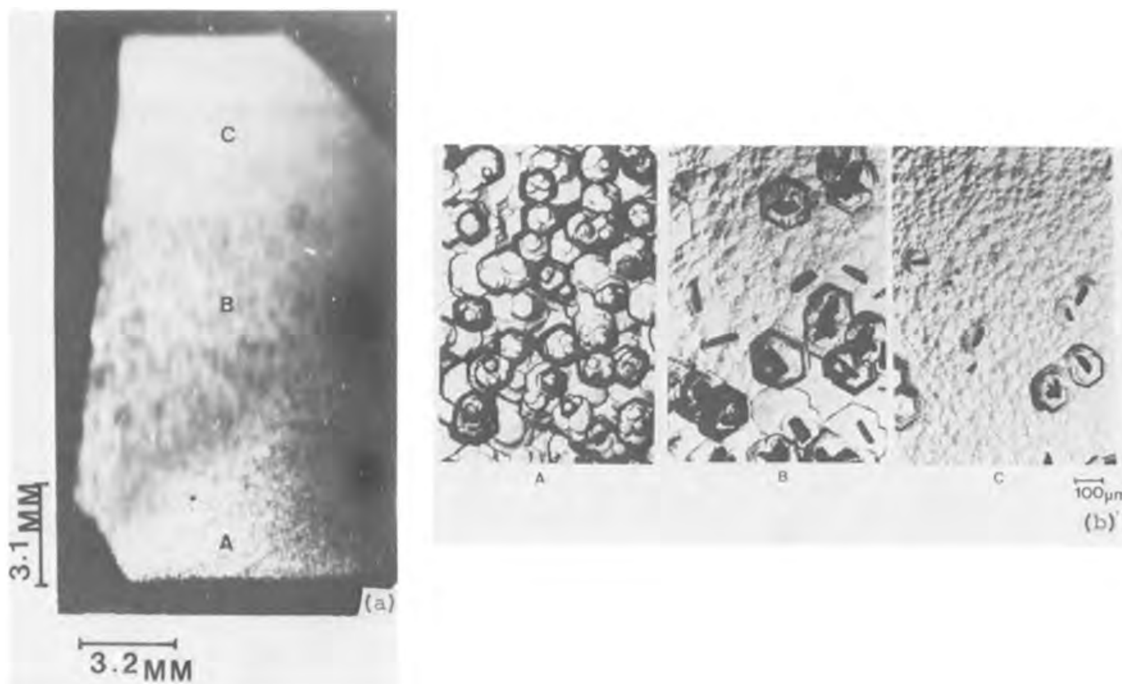

Fig. 1. X-ray diffraction topograph of an undoped GaN {0001} crystal with a carrier concentration of 7×10^{19} cm^{-3} (left) and crystal surface morphologies (right). Photographs A, B, and C of Fig. 1(b) correspond to the A, B, and C regions in the topograph, respectively.

resolution of the apparatus was improved. Careful observation of the topograph notes that the partial region, designated by A in Fig. 1(a), shows a relatively distinct diffraction pattern rather than the other regions marked by B and C. Differences in surface morphology were observed among A, B, and C regions. The relatively good quality regions showed significant hexagonal growth hillocks, as indicated in Fig. 1(b), which reflected the crystal symmetry of GaN. In the other regions, most of the hillocks become smaller in size and vaguer in shape in the order of B and C. Some bar-type crystals were deposited at apexes of some growth hillocks in the B and C regions. On the other hand, undoped crystal with a carrier concentration of 10^{18} cm^{-3} showed a little more distinct patterns in the x-ray topograph, as indicated in Fig. 2(a). The surface of this crystal consists of scale-like and/or spiral hillocks as seen in Fig. 2(b). The spiral hillock found in the figure corresponds to the dark spot indicated by arrow B in Fig. 2(a). The spiral step height was found to be 3000Å. In the case of crystals whose surfaces consist of many large spiral hillocks [see Fig. 4 in Ref. (15)], the step heights were around 300Å.

The difference in crystalline quality described above was more distinct in the x-ray rocking curves (Fig. 3). In the case of the crystal shown in Fig. 1, the peak height of the curve obtained for A region of the crystal was more intense than that for B region. The half-width of the curve for A region is estimated at 32′, while that for B region is done at 48′. These results are consistent with the topograph shown previously. On the other hand, the rocking curve half-width of the crystal shown in Fig. 2 is smaller, around 26′, though there were some crack lines in the crystal as marked by A in Fig. 2(a).

In Fig. 3, the rocking curve obtained for {0001} oriented LED crystal was also compiled. The curves in the figure indicate that the LED crystal is superior in crystalline quality to undoped crystals. The rocking curve for this LED crystal was much narrower, around 12′, in the half-width. This result, however, was apparently inconsistent with the etching results that the doped crystals are poorer in crystalline quality than undoped ones with carrier concentrations of 10^{18} cm^{-3} (15). This difference would be due to the greater sensitivity of hot phosphoric acid etching to Zn precipitates in GaN crystal surface.

{0001} oriented LED crystals showed relatively distinct x-ray topographs, as shown in Fig. 4(a). In the topograph, some hillock-like patterns indicated by arrows B and C were observed. Corresponding to these diffraction patterns, a group of small circularly formed crystals or large unclearly shaped crystals were found on the Zn-doped layer surface. Regular Zn-doped layer surfaces show many large hexagonal pyramids or dishes (15). Comparing with this topograph, the $\{11\bar{2}0\}$ oriented LED crystal showed more

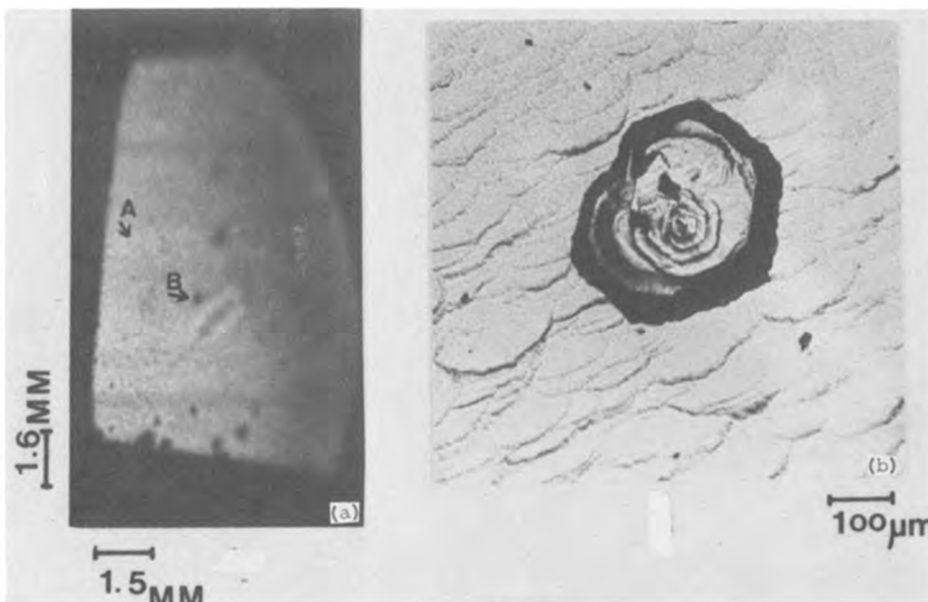

Fig. 2. X-ray diffraction topograph of an undoped GaN {0001} crystal with a carrier concentration of 3×10^{18} cm^{-3} [A, Fig. 2(a)] and crystal surface morphology [B, Fig. 2(b)].

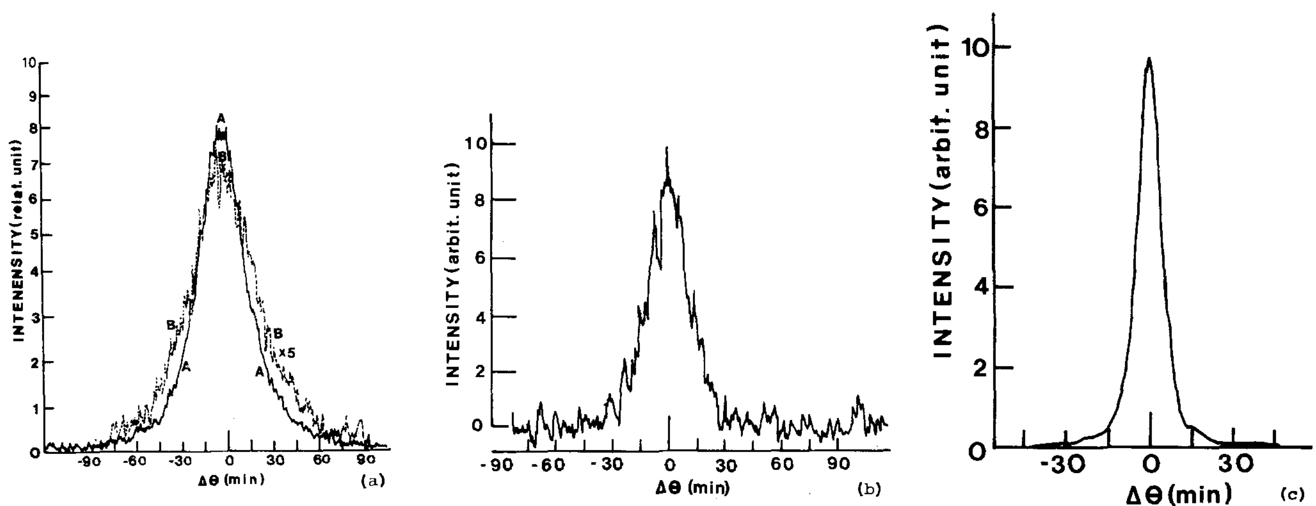

Fig. 3. Rocking curves obtained for the crystals shown in Fig. 1(b) and Fig. 2(b) and a {0001} LED crystal [Fig. 3(c)]. The letters A and B in the Fig. 3(a) curves correspond to A and B regions in the topograph shown in Fig. 1.

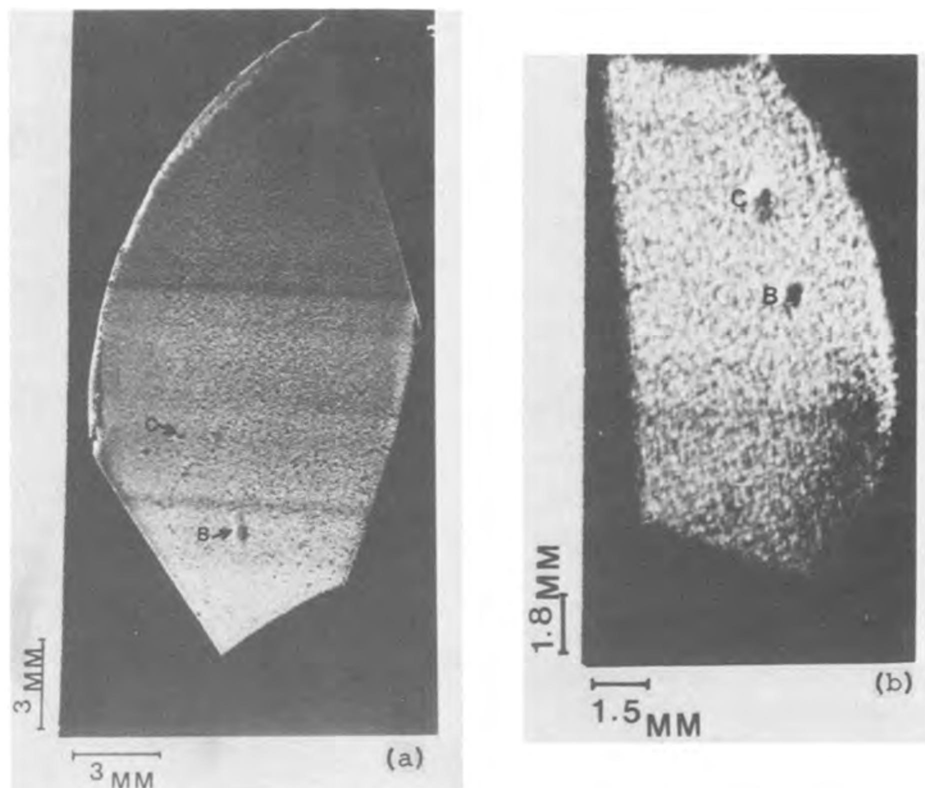

Fig. 4. X-ray diffraction topographs obtained for: (a) {0001} LED crystal; (a) and (b) a {11$\bar{2}$0} LED crystal.

diffuse x-ray diffraction topographs, as indicated in Fig. 4(b). The pattern is considered to be due to poorer crystalline quality than the {0001} LED crystal. In this topograph, two large hillock-like patterns are observed, similarly to the topograph for the {0001} LED crystal [designated by B and C in Fig. 4(b)]. However, this crystal surface morphology is different from the case of the {0001} LED crystal described previously. A lack of crystal growth or crystal misalignment was found in the crystal region showing the hillock patterns.

In summary, the x-ray diffraction topography and rocking curve technique are found useful for characterization of undoped and LED GaN crystals. With respect to undoped crystals, the crystals with the surfaces of scale-like and/or spiral hillocks are better in crystal quality than those with other surfaces, hexagonal and irregular hillocks. Comparing {0001} oriented LED crystals with {11$\bar{2}$0} ones, {0001} LED crystals are apt to grow in better crystalline quality than the other. From the crystallographical viewpoint, {0001} oriented crystals would be preferable for LED's than the other.

Study of Crystal Perfection of CVD-Grown α-Al_2O_3 Single Crystals by Transmission X-Ray Diffraction Topography

Krishan Lal and Vijay Kumar

National Physical Laboratory, New Delhi-110012, India

α-Al_2O_3 crystals have been of great importance in modern as well as classical technologies. Because of this, consistent efforts have been made to improve the quality of single crystals of this material. More recent applications in the field of lasers and microelectronic devices utilizing single crystal α-Al_2O_3 substrates have laid great emphasis on the perfection of these crystals. The flame-fusion method (1, 2), Czochralski method (2, 3), flux method (1-3), growth from the vapor phase (1, 3), chemical vapor deposition (CVD) (4), gradient furnace technique (5), and edge-defined film-fed growth (6) are the principal techniques for the growth of these crystals. Detailed investigations of perfection of crystals grown by a number of these techniques have been made by using the etch pit method (7-9), decoration method (10), electron microscopy (11-13), LEED (14), and x-ray diffraction topography (8, 15-19).

In this paper we describe results of the study of perfection of CVD-grown α-Al_2O_3 crystals using transmission x-ray diffraction topography. To compare the perfection of these crystals with the crystals grown by other techniques, a few wafers of crystals grown by Czochralski method were also investigated.

The CVD-grown α-Al_2O_3 crystals used in this investigation were grown in Lexington Laboratories, Lexington, Massachusetts, and were kindly provided by Dr. J. J. Cuomo of IBM Thomas J. Watson Research Center, Yorktown Heights, New York. These wafers were cut perpendicular to [0001] and polished to 1 μ In. finish by Insaco Corporation, Quakertown, Pennsylvania. Special care was taken to ensure that there was no surface damage left on these wafers. Residual surface damage gives strong contrast in topographs. The residual surface damage, if present, is removed by etching in hot orthophosphoric acid until sharp diffraction curves and topographs free of damage marks are obtained. The Czochralski grown wafers were also cut perpendicular to [0001]. The wafers were kindly provided by Dr. P. Thoma of the Physikalisch-Technische Bundensautalt, Braunschweig and Berlin, West Germany. The x-ray diffraction topography camera used in this investigation is similar to a conventional Lang Camera (20) and has been developed in our laboratory (21). A microfocus x-ray generator developed in our laboratory (22) was used as a source of x-rays. In most of these investigations line focus source has been used. Divergence of the exploring x-ray beam in the horizontal plane was about 50 sec of arc and divergence in the vertical plane is 4.5 min of arc for a specimen having vertical dimensions of 1 mm. $CuK\alpha_1$, $MoK\alpha_1$, and $AgK\alpha_1$ radiations have been used. Most of the topographs have been recorded on Ilford L4 nuclear emulsion plates having 50 μm thick emulsion. Kodak Periapical dental x-ray films have been used for preliminary work.

The CVD-grown crystals used in these investigations can be broadly divided into two categories: (*i*) Wafers in which a part of seed is also present. These were particularly chosen to see the perfection of the seed-crystal interface. For convenience we call these type A crystals; and (*ii*) Wafers which were cut away from the seed and had no part of seed contained in their body. For convenience we call these crystals type B crystals. In the following we shall describe separately the results for crystals of type A and B, as well as for crystals grown by the Czochralski method.

As is well known, a good idea about the state of perfection of a crystal wafer can be had from the shape of its diffraction curve (23, 24). The diffraction curves are recorded by observing the diffracted intensity as a function of the angular position of the crystal as it is rotated across the Bragg peak. The detector has a 5 mm wide open window, which is at a distance of 200 mm from the specimen crystal. Before recording a topograph we always recorded a diffraction curve for that reflection.

Key words: crystallography, CVD, x-rays.

Perfection of the CVD-Grown Crystals of Type A

Most of these crystals having a part of the seed in them were found to contain low angle boundaries. Figure 1 shows a typical projection topograph of a crystal of this type. A small nearly circular portion in the center is the part of the seed. As can be seen, the crystal is highly strained. The strain is very large at the crystal-seed interface. Due to strain the topograph of whole of the wafer could not be recorded in one scan. To record this picture we divided the crystal into 3 approximately equal portions which slightly overlapped each other. Topographs recorded for these three regions were put together to get the composite picture shown in Fig. 1.

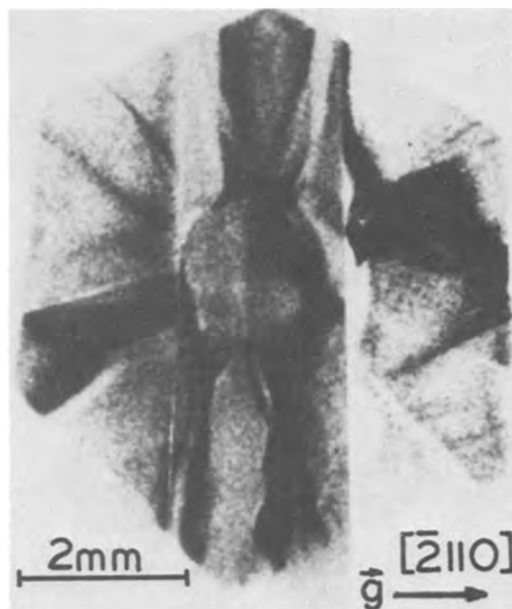

Fig. 1. A typical projection topograph of a CVD-grown α-Al_2O_3 crystal of type A. The flat faces of the wafer were cut parallel to the basal plane (0001). $AgK\alpha$ radiation and a [$\bar{2}$110] diffraction vector are used. The topograph was recorded in three parts, as the crystal was highly strained.

As can be seen, a number of low angle boundaries were present in these crystals. To get more quantitative information about low angle boundaries, diffraction curves were recorded at different regions of the wafer. Figure 2b shows a typical diffraction curve recorded for a region close to the right-hand side of the crystal as in the topograph shown in Fig. 1. In Fig. 2b we see several peaks separated from each other by a few minutes of arc. This is a diffraction curve typical of crystals containing low angle boundaries. For comparison, Fig. 3 shows a typical diffraction curve of a dislocation-free Si single crystal showing well-resolved peaks due to $K\alpha_1$ and $K\alpha_2$ radiations (25). The crystals were aligned for different peaks in Fig. 2b and projection topographs were recorded by scanning the crystals for about 1 mm each time. Figure 2a shows these topographs. It is seen that different regions of the crystal diffract when the alignment is changed from one peak position to another. This shows conclusively the presence of low angle boundaries in this type of wafers. The angle of mis-set between the adjoining grains is of a few minutes of arc. It was futile to look for isolated dislocations in these crystals.

Perfection of CVD-Grown Crystals of Type B

In contrast to the crystals of type A, the crystals of type B were invariably found to be nearly perfect. Figure 4 shows a typical diffraction curve of one of the crystals of this type. Two well-resolved peaks due to $K\alpha_1$ and $K\alpha_2$ components of the characteristic radiations are observed. This can be compared with the diffraction curve of the perfect Si single crystal.

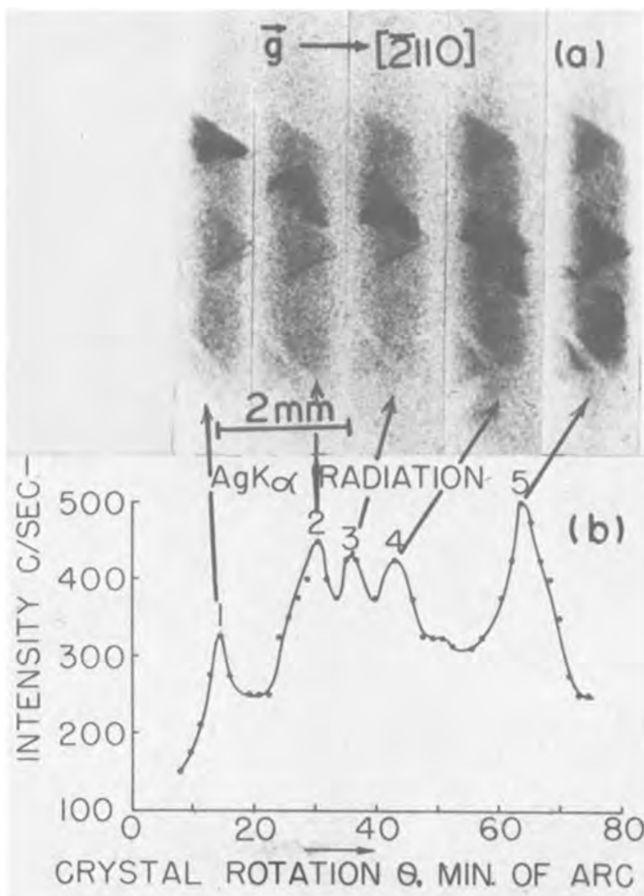

Fig. 2. (a) A typical set of projection topographs of the same CVD-grown single crystal whose topograph is shown in Fig. 1. A [2̄110] diffraction vector and AgKα radiation were used. These topographs correspond to a small region of the crystal whose topograph also appears on the extreme right-hand side in Fig. 1; (b) A typical diffraction curve of this crystal corresponding to Fig. 2a.

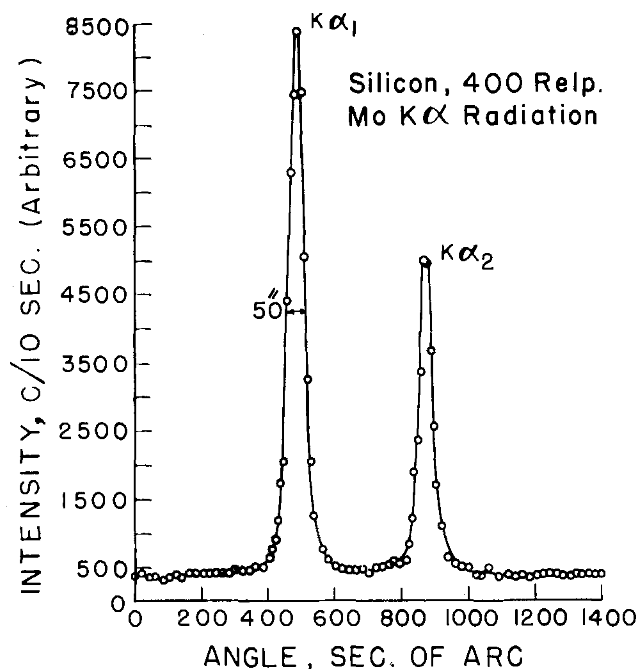

Fig. 3. A typical diffraction curve of a dislocation-free Si single crystal recorded using 400 reflection with MoKα radiation.

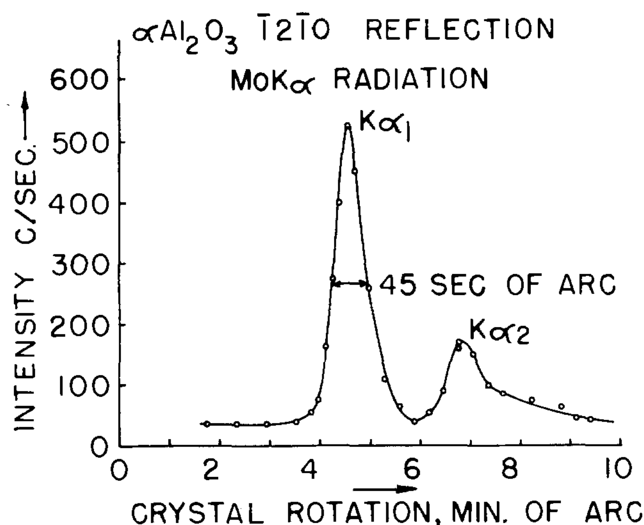

Fig. 4. A typical diffraction curve of a CVD-grown (0001) α-Al_2O_3 single crystal wafer of type B recorded using 1̄21̄0 reflection with MoKα radiation.

None of these crystals were found to contain low angle boundaries. This result is supported by the topographs recorded for these crystals.

Figure 5 shows a few typical topographs of one of the crystals of type B. Except for some regions near the edges, a large portion of the wafers is practically free from crystalline defects. In Fig. 5a we see in the central region several straight lines parallel to [011̄0]. This topograph was recorded with $\vec{g}$ parallel to [2̄110]. To investigate the nature of these lines several topographs were recorded with different diffraction vectors. Figures 5b and 5c show topographs recorded with diffraction vector $\vec{g}$ parallel to [1̄21̄0] and [112̄0], respectively. Using the $\vec{g}\cdot\vec{b}$ analysis criterion we say that the dislocations observed parallel to [011̄0] are of edge type. Their Burgers vector is parallel to <2̄110>. These dislocations vanish in topograph recording using diffraction vectors parallel to [011̄0]. Similarly, some of

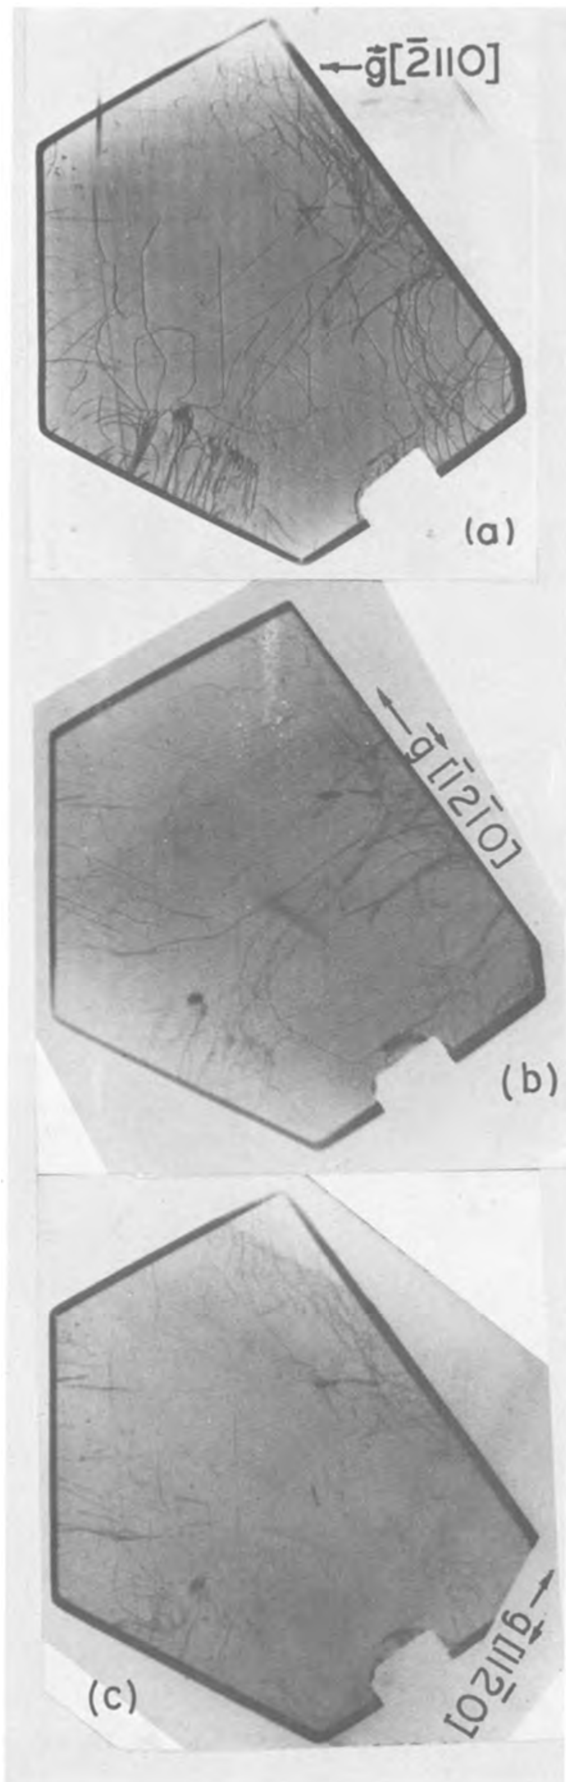

Fig. 5. Projection topographs of a CVD-grown (0001) α-Al_2O_3 single crystal wafer of type B recorded with $MoK\alpha_1$ radiation. Diffraction vectors were parallel to [2̄110], [1̄21̄0], and [112̄0] in (a), (b), and (c), respectively. A typical diffraction curve of this crystal is shown in Fig. 4 for this class of reflections.

the symmetrically equivalent dislocations have been characterized. <2̄110> is known to be a prominent slip direction from the earlier work on slip system of this material (17). Another very important feature of these pictures is that a large area of these crystals is free of dislocations. As we will show subsequently, these crystals can be treated as nearly perfect crystals.

If we look carefully at the dislocation lines in Fig. 5a we see a white halo running along the length of the dislocations. These topographs have been recorded using $MoK\alpha_1$ radiation for which the value of μt is approximately 0.34. A white halo around an edge dislocation can be understood in the following manner. As has been shown in earlier work (26-28), if the diffracting planes are slightly curved, enhancement in diffracted intensity will be observed when the radius of curvature of the diffracting planes $\vec{r}$ points along the direction of diffraction vector $\vec{g}$. When $\vec{g}$ is antiparallel to $\vec{r}$ a reduction in intensity is to be expected. Indeed this criterion has been used to determine the nature of dislocation loops in gadolinium gallium garnet crystals (28). If we use this criterion in the present case we find that the straight dislocations in this case are of vacancy type. Possibly these may have formed just after growth due to condensation of vacancies.

The observed white halo around edge dislocations has been explained on the basis of dynamical contrast due to curvature of lattice planes around the edge dislocations in Fig. 5a. If we use harder radiations, like $AgK\alpha_1$, it should be possible to reduce the value of μt substantially and, therefore, remove the possibility of any dynamical effect. We have recorded topographs with $AgK\alpha_1$ radiation. No dynamical contrast was observed in these topographs.

Another way of testing whether these crystals are nearly perfect is to see whether one can record topographs with predominant dynamical contrast. Such topographs depend predominantly upon dynamic diffraction of x-rays, so that in the crystal the wavefields of the direct and the diffracted x-ray beams are coupled with each other. A defect in the lattice of nearly perfect crystal is expected to break this coupling between the incident and diffracted wave fields in the region surrounding it. Therefore, in this case defects appear as white on black background. We have succeeded in recording transmission topographs of these wafers with dynamical contrast also. In this case we have used $CuK\alpha_1$ radiations so that $\mu t = 3.15$. Figure 6 shows a tyical topograph that was recorded on the

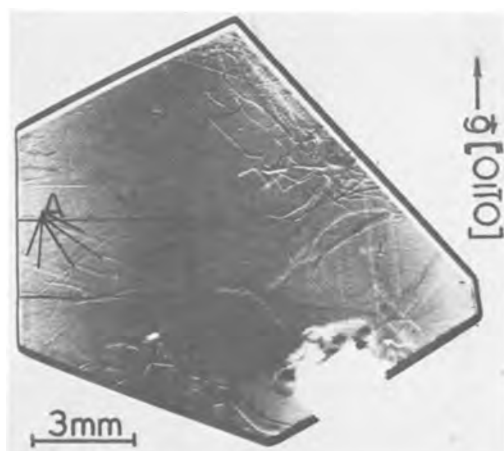

Fig. 6. A typical projection topograph of a CVD-grown α-Al_2O_3 single crystal recorded with $CuK\alpha_1$ radiation and [01̄1̄0] as diffraction vector.

same wafer whose topographs are shown in Fig. 5. This topograph was recorded with $\vec{g}$ parallel to [01$\bar{1}$0]. Here we see dislocation lines appearing as white on a black background. This result supports our conviction that these crystals are nearly perfect crystals. Another interesting feature of this topograph is a few lines observed in the area marked as A. These lines are observed in Fig. 5b also. However, from Fig. 5b one would be tempted to conclude that these are screw dislocations lying in the plane of the wafer, *i.e.*, in the basal plane. However, an examination of these lines in Fig. 6 shows that they do not lie in the plane of wafer but intersect it at an oblique angle. From the observed length of these lines and thickness of the wafers we have estimated the angle between the line vector of these dislocations and the surface of the wafer. It is found to be about 7°, suggesting that these lines lie on a high index plane. This result also shows that the sensitivity of topographs with predominant dynamical contrast is higher than the sensitivity of the normal kinematic topographs.

Study of Crystal Perfection of Czochralski-Grown Crystals

As mentioned earlier, in order to compare the perfection of CVD-grown crystals with that of the crystals grown by other techniques we chose Czochralski-grown crystals. Perfection of Czochralski-grown crystals has been studied earlier (8, 9, 17, 18). Czochralski-grown wafers that we have investigated were in general not as perfect as CVD-grown crystals of type B. Their perfection was generally comparable to that of the CVD-grown crystals of type A. Figure 7 shows a typical diffraction curve of a Czochralski-grown crystal. The presence of several peaks separated by a few minutes of arc from each other is evidence of the presence of low angle boundaries in these crystals. A typical topograph of these crystals is shown in Fig. 8. The crystal was fairly imperfect and, therefore, one full topograph could not be recorded in one scan. The topograph shown in Fig. 8 is in fact the topograph composed of 3 different topographs. The presence of low angle boundaries is very obvious even from this topograph. The upper region of this crystal is not diffracting. However, by suitably tilting the crystal this portion can be made to diffract. These results are similar to those reported earlier (8, 15, 16). Some details of this aspect are reported elsewhere (29).

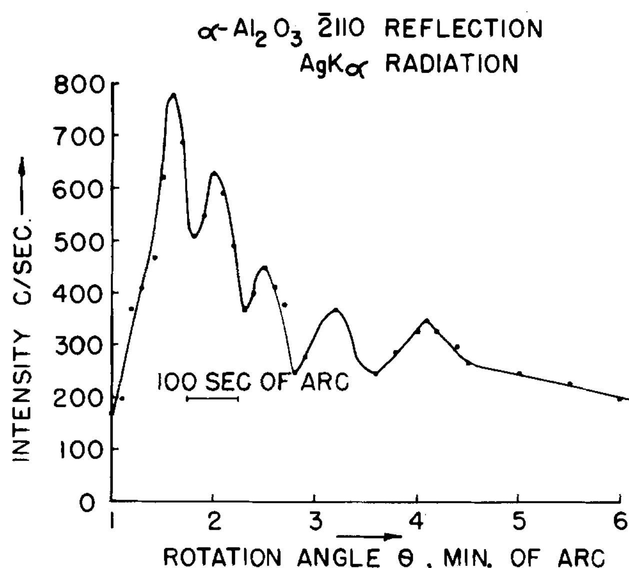

Fig. 7. A typical diffraction curve of a Czochralski-grown (0001)α-Al_2O_3 single crystal wafer recorded using $\bar{2}$110 reflection with AgKα radiation.

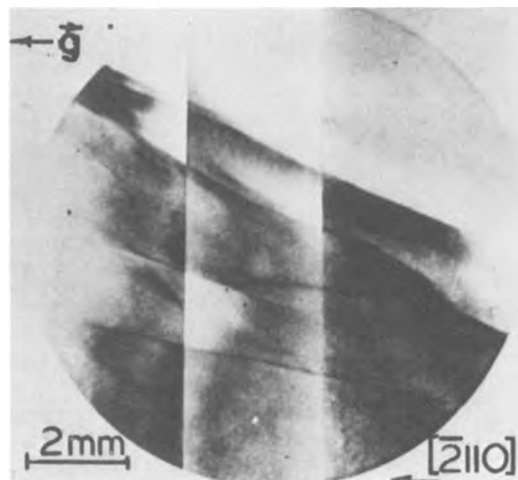

Fig. 8. A typical projection topograph of a Czochralski-grown (0001)α-Al_2O_3 single crystal wafer. [$\bar{2}$110] diffraction vector and AgKα radiation were used. Figure 7 shows a diffraction curve of this crystal.

The present investigation has shown that CVD-grown crystals of α-Al_2O_3 are nearly perfect crystals in which large areas are practically free of dislocations. The perfection is so high that we have observed dislocations with predominant dynamical contrast. These results are consistent with the earlier work that Czochralski- and flame fusion-grown crystals are not very perfect (8, 9, 15-18, 29). In fact, in a study on growth of niobium films on sapphire crystals (30) it has been shown that CVD-grown crystals have much better perfection as compared to perfection of Czochralski- and Verneuil-grown sapphire crystals. This is consistent with the present results. The dislocations near some of the edges apparently are due to instabilities during growth.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 125, No. 2 and 3, February and March 1978.

Kinetics of the Thermal Oxidation of Silicon in O_2/H_2O and O_2/Cl_2 Mixtures

B. E. Deal, D. W. Hess, J. D. Plummer, and C. P. Ho
(pp. 339-346, Vol. 125, No. 2)

J. Monkowski,[1] R. E. Tressler,[2] and J. Stach:[1] In their paper, Deal *et al.* point out that the predominant reaction governing the gaseous composition of H-Cl-O ambients is

$$4HCl + O_2 \rightleftarrows 2H_2O + 2Cl_2 \quad [1]$$

They further state that the exact equilibrium conditions are not known, but based upon empirical evidence the complete dissociation of HCl occurs at temperatures above 1100°C.

However, thermodynamic data are available in the literature,[3] and calculations of the equilibrium compositions of $HCl/O_2/H_2O$ mixtures have been carried out for various oxidation temperatures.[4] Moreover, the reaction of HCl with O_2 does not "go to completion" anywhere in the range of typical oxidation temperatures (700°-1300°C). Above 1100°C, the HCl concentration (volume percent) is greater than 4 times the Cl_2 concentration when HCl/O_2 mixtures are introduced into the furnace.

The significance of these thermodynamic calculations was demonstrated quite clearly by Tressler *et al.*,[4] who showed that both the enhanced parabolic growth rate and the passivation of ionic sodium correlate well with the partial pressure of Cl_2 (P_{Cl_2}) calculated to be present within the oxidation furnace under equilibrium conditions. They showed that, at 1150°C, the parabolic growth rate is a smoothly increasing function of P_{Cl_2}, regardless of whether HCl/O_2 or Cl_2/O_2 mixtures are introduced into the furnace. In this manner, they showed that HCl and H_2O play insignificant roles in the growth rate enhancement. The amount of Cl_2 was also shown to be the determining factor in the realization of passivation. This was done by comparing passivation data of oxides grown in HCl/O_2 mixtures with data from oxides grown in $HCl/O_2/H_2O$ mixtures. The two sets of data were consistent only when put in terms of P_{Cl_2}.

Deal *et al.* based their conclusions concerning Eq. [1] primarily upon two experiments. In the first, they compared the parabolic growth rates obtained in HCl with those obtained in H_2O. At 1100°C the growth rates of oxides grown in HCl/O_2 mixtures approached those grown in H_2O/O_2 mixtures when the HCl/H_2O ratio (volume fraction introduced into the furnace) was 2. From this correlation, they concluded that the dissociation of HCl increases as the temperature is raised, and reaches completion at temperatures above 1100°C.

In the second experiment, two oxides were grown. For one, a 4% HCl/96% O_2 mixture was introduced into the furnace; for the other, a 2% Cl_2/2% H_2O/96% O_2 mixture was used. Both oxides were found to possess similar growth rate constants. From this fact, Deal *et al.* concluded that Eq. [1] does indeed describe the predominant reaction occurring within the furnace; the HCl does react with the O_2 to produce Cl_2 and H_2O.

Based upon the work of Tressler *et al.*, the correlations seen in the first experiment can be shown to be fortuitous, and the conclusion of the second experiment can be shown to lack substantiation by the data.

Comparing an oxide grown in a particular volume fraction of HCl with an oxide grown in half that volume fraction of H_2O is irrelevant in view of the thermodynamic data calculated by Tressler *et al.* Since the HCl dissociates very little, the comparison should be made for oxides grown in much lower amounts of H_2O.

The data can be rationalized by looking at the temperature dependence of the growth rate enhancement for Cl_2 as well as H_2O. Comparison of Fig. 3 of Deal *et al.* with their Tables I and II shows that at 1000 C H_2O has a much larger effect on the rate constant than Cl_2. However, at 1100°C, Cl_2 has the dominant effect. Therefore, for HCl/O_2 oxidations at 1000°C and below, the growth rate enhancement is due primarily to the small amount of H_2O present

[4] R. E. Tressler, J. Stach, and D. M. Metz, *This Journal*, **124**, 607 (1977).

within the furnace. At 1100°C and above, the small amount of Cl_2 present in the furnace has a disproportionately large effect, such that an oxide grown in 10 v/o HCl is nearly as thick as one grown in 5 v/o H_2O (Fig. 9 of paper). The experimental data cited by Tressler *et al.* was obtained at 1100° and 1150°C, where Cl_2 is the dominant species.

For the second experiment, one can only conclude that regardless of whether HCl or a mixture of Cl_2 and H_2O is introduced into the furnace, the equilibrium composition, whatever it may be, is attained. No conclusion can be made concerning the amounts of the gases present or even the types of gases present. The gases HCl, Cl_2, and H_2O may, in principle, not even exist within the furnace in significant quantities. Additional information, such as a thermodynamic analysis, is required to determine the ambient composition.

In fact, the data of Deal *et al.* indicate that equilibrium is not completely atttained. The $Cl_2/H_2O/O_2$ mixture yielded a slightly higher parabolic growth rate than the other mixture. This is understandable due to the effectiveness of Cl_2 and H_2O, as compared to HCl, in enhancing the growth rate. If equilibrium were not attained, the $Cl_2/H_2O/O_2$ mixture would contain more Cl_2 and H_2O than the HCl/O_2 mixture.

Deal *et al.* also noted that introduction of 2% Cl_2 into a 2% H_2O/98% O_2 mixture resulted in the growth of significantly thinner oxides. With the realization that Cl_2 suppresses the amount of H_2O, this result is also reasonable.

In view of the suppression of P_{Cl_2} by H_2O, Deal *et al.* stated that for HCl/O_2 mixtures, an increase in the HCl content would increase the H_2O content, thus suppressing the Cl_2 content. This is not the case; the amount of Cl_2 must equal the amount of H_2O (Eq. [1]), and, in addition, if the HCl/O_2 ratio (volume percent at equilibrium in the furnace) is relatively small, the HCl/Cl_2 ratio remains unchanged regardless of the amount of HCl introduced into the furnace. This can be shown from the equilibrium constant for Eq. [1]

$$K_P = \frac{(P_{Cl_2})^2 (P_{H_2O})^2}{(P_{O_2})(P_{HCl})^4} \qquad [2]$$

Since $P_{Cl_2} = P_{H_2O}$

$$K_P = \frac{1}{P_{O_2}} \left(\frac{P_{Cl_2}}{P_{HCl}}\right)^4 \qquad [3]$$

As long as P_{O_2} remains close to 1 atm, the ratio Cl_2/HCl will not change significantly. This is confirmed in the work of Tressler *et al.* where the ratio Cl_2/HCl is very similar for both 2 and 20 v/o HCl introduced into the furnace.

Over-all, the approach of Deal *et al.* could prove quite fruitful in sorting out the contributions of the various gaseous species present during oxidation. If the oxidation furnace were constructed such that the gases were heated long enough to ensure the attainment of equilibrium, then the thermodynamic analysis of Tressler *et al.* could be used to ascertain the composition of the ambient. In this manner, a direct comparison could be made between the growth of an oxide and the conditions present during its formation.

On Thermally Stimulated Space-Charge Decay in Sn^{2+}-doped Sodium Chloride and Potassium Chloride Crystals

Ah Mee Hor and P. W. M. Jacobs (pp. 430-432, Vol. 125, No. 3)

A. Kessler:[5] The investigation of the "dielectric chaos" should, no doubt, give a clue to the understanding of the space-charge formation, the discharge of ions at the electrodes, etc. But the reproducibility is bad, the peaks are overlapping, and the multitude of processes which might eventually be the cause of the DC are understood only modestly or not at all. Hence only very few papers are found which are devoted exclusively to this problem. Rather, relevant results are found scattered in investigations concerning other questions. Thus, they easily escape one's attention.

Inverted peaks, for instance, are found in CdF_2,[6] spontaneous peaks in Teflon,[7] and in NH_4Cl.[8] In the latter case the cause is roughly understood. It shows, among other things, that the peak can be classified as extrinsic and dependent on the history of the sample. It can be avoided in consequence. But the four peaks observed besides the impurity complex peaks in CdF_2, for instance, are of an intrinsic nature. The two which occur below room temperature are obviously caused by an accumulation of point defects.[9,10] The other two, which occur eventually above the polarization temperature, are attributed to a dissociation of complexes,[10] that is to a similar process as assumed by the authors.

Performance of Synthetical n-$MoSe_2$ in Electrochemical Solar Cells

J. Gobrecht, H. Tributsch, and H. Gerischer*

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Faradayweg 4-6, D-1000 Berlin 33, Germany

The general ability of transition metal dichalcogenides like n-$MoSe_2$ for application as photoanodes or p-WSe_2 as photocathodes in electrochemical solar cells has been demonstrated earlier (1 to 4). In most cases the photocurrent-potential behaviour was rather unsatisfying with respect to the characteristics required for photoelectrochemical energy conversion: The photocurrent increases steadily over a wide potential range without reaching a saturation value. The result is a poor current-voltage output characteristic with low fillfactors in the region of 0.2 to 0.25.

We wish to report new results obtained with synthetic n-type $MoSe_2$ crystals grown by a bromine gas transport technique which exhibit significantly improved behaviour.

The current-potential curve in the dark shows a very asymmetrical shape (Fig. 1) which implies good rectifying properties of the interface. At potentials more positive than 0.55 V vs. SCE a photocurrent starts to flow in base electrolytes such as KCl or H_2SO_4 which causes electrode corrosion by forming Mo(VI) and selenic acid:

$$MoSe_2+6H_2O+14h^+ \xrightarrow{h\cdot\nu} Mo^{6+}+2SeO_3^{2-}+12H^+$$

This photocurrent reaches a saturation at potentials above 0.9 V vs. SCE.

Flatband potentials were obtained from Mott-Schottky-plots. In base electrolyte it is situated at 0 V vs. SCE. Interestingly, there are redox couples such as I^-/I_2 which shift the flatband-potential to more negative values, probably due to a strong interaction of the I^- ions with the $MoSe_2$ surface. For the investigated system the shift is 300 mV. This is the reason why a photovoltage greater than 0.5 V is obtained with an n-$MoSe_2$/(I^-/I_2)/Pt photocell although the redox potential of the couple is 0.28 V vs. SCE. The decrease of the saturation photocurrent in the redox system I^-/I_2, compare Fig. 1, is caused by the light absorption of the iodine.

The power output characteristic shows a satisfying rectangular shape with a fillfactor of 0.67 (Fig. 2). This indicates that the number of recombination centers in the surface and the space charge layer of the selected samples of $MoSe_2$ is small and therefore a small internal field strength is sufficient to separate the generated electron-hole-pairs. The optimum efficiency for sunlight (85 mW/cm^2, AM1) is around 3.5%. It should be pointed out here, that both, the crystal properties and the light-intensity can critically influence the fillfactor. Crystals with less ideal properties exhibit a less steep increase of the photocurrent with potential and reach the saturation at higher voltages. They also show greater anodic dark currents. At high illumination levels of several hundred mW/cm^2 like in 2) and 4) transport processes towards and from the interfaces become the rate limiting factor.

The current-voltage curve (Fig. 1) shows, that the I^- oxidation is kinetically so much more favourable than the decomposition reaction that electrode corrosion is avoided. This has been shown by operating a longterm experiment with an n-$MoSe_2$/(I^-/I_2)/Pt solar cell for 9 months at a photocurrent density of 10 mA/cm^2 (2).

Similar results have been obtained with n-MoS_2 but the flatband potential is 100 to 200 mV more positive and therefore a smaller output voltage is reached. Also, the photocurrent is

* Electrochem. Soc. Active Member

somewhat lower due to the 0.4 V larger bandgap of MoS_2 (1.7 eV).

We conclude that liquid junction solar cells based on transition metal dichalcogenides can reach similar conversion efficiencies as the other intensively investigated systems such as the CdS or CdSe based cells in the redox systems S^{2-}/S_2^{2-} or Se^{2-}/Se_2^{2-} (5,6) but are easier stabilized against photodecomposition.

ACKNOWLEDGEMENT

We thank Dr. F. Lévy (EPF Lausanne, Switzerland) for supplying us with excellent crystal samples.

RN

The invention of the transistor (1, 2) in late 1947 and its later embodiment in junction form (3) marked the beginning of a profound change in electronics. Not only did the receiving tube basically become obsolete, but many new device functions emerged, and ultimately unbelievable size reductions and enormous packing densities resulted. As is well known, it became possible to build an entire functional system in a single conducting block of material. Also, new forms of power devices, based on the transistor effect, became possible.

With the invention of the transistor the study of electrical conduction in solids took on new importance, and similarly the growth and study of semiconductor crystals, at first, Ge (4). Since Ge is a much more tractable material than other elemental semiconductors, it was natural that the transistor began with Ge, and that in turn the transistor (and p-n junctions) motivated the growth and study of single crystal Ge of great purity (4, 5). In fact, Ge and its successor Si, because of the transistor, have been purified to such high levels and have been grown with such perfection that Si now even serves as the standard for determination of Avogadro's number (6).

The original transistor pioneers were quite aware that beyond their initial experimental material (Ge), Si offered a large potential (7). The real emergence of Si as a transistor material probably came in late 1954 and early 1955 when, at Bell Laboratories, Si-diffused-impurity devices were first constructed. Based on his considerable understanding of switching devices and the need for low off-stage leakage current, John Moll above all others urged the development of diffused-impurity Si devices; for this purpose, in his own group Au-Sb and Al metallization of Si were developed (8), as well as certain forms of transistor devices (9). The most important form of diffused-impurity p-n junctions came from Carl Frosch (and L. Derick) (10), including oxide masking and with it the teaching to leave the oxide on Si for protection of the device (11). These developments were sufficient for Moll and his colleagues to be able to convince Jack Morton (spring of 1955) to switch transistor development from Ge to Si. The rest is history, and now where Si "can do the job," there is little interest on the part of device researchers to attempt to displace it with another material. No other material has been as extensively developed, nor offers a natural oxide affording so many processing and device advantages.

As useful as Ge and, more so, Si have proven to be in semiconductor devices, they possess also certain limitations. Their bandgaps are indirect and are fixed at $E_g(\text{Ge}) \approx 0.68$ eV and $E_g(\text{Si}) \approx 1.1$ eV. Hence, they are not useful as light emitters, not even in the infrared where they emit, but poorly. The energy band structure (indirect) is not suitable for transferred electron devices (Gunn oscillators) (12). As a solar energy converter, Si is good (technologically) but has too small of an energy gap for optimum efficiency and for some applications has too small of an absorption coefficient. Both Ge and Si can readily be fabricated into homojunctions (13) but so far have not proved to be very valuable for use in heterojunctions. Clearly, Si may be the most valuable semiconductor, but it is not by any means a universal semiconductor material, thus the basis for our interest in compound semiconductors and their capability for extending electronic functions.

Here we are concerned mainly with III-V compounds because these materials, first of all, are amenable to formation into p-n homo- and heterojunctions and thus have a practical basis for use in electronics (14). Besides the fact that they can be grown conveniently in the form of heterojunctions, which is of growing importance, III-V compounds can be prepared with direct energy gaps ranging from the infrared (InSb) to the yellow-green ($In_{1-x}Ga_xP$, $x \sim 0.73$). This is, of course, what makes these materials useful as lasers (15-18) and light emitters (17). In the mixed crystal systems $Al_xGa_{1-x}As$, $GaAs_{1-x}P_x$, $In_{1-x}Ga_xP$, $Al_xGa_{1-x}As_{1-y}P_y$, and $In_{1-x}Ga_xP_{1-z}As_z$ the band structure can be varied continuously from direct to indirect energy gaps by varying the crystal composition. This property obviously does not exist in binary III-V's nor in Ge or Si. In the direct range of energy gaps, *e.g.*, binaries such as GaAs and InP and ternaries such as $GaAs_{1-x}P_x$, the band structure (see Fig. 1) is such that electrons can be transferred from a low mass, high mobility direct valley (Γ) to various indirect high mass, low mobility minima (L or X), thus permitting Gunn oscillations (12). Because of the small electron mass and high mobility that some of these compounds possess, they (*e.g.*, GaAs) are also useful for high speed field effect transistor applications (19).

In general, it is a special property of a given III-V material that permits a particular application, and it is only as these applications have developed that III-V semiconductors have become important. In fact, device studies, as much as anything, have resulted in the preparation of high purity materials and have uncovered the fundamental properties of III-V semiconductors. A good example is the Gunn oscillator (12), which has resulted in the extension of transport studies in solids into new areas (20) and has

* Electrochemical Society Life Member.

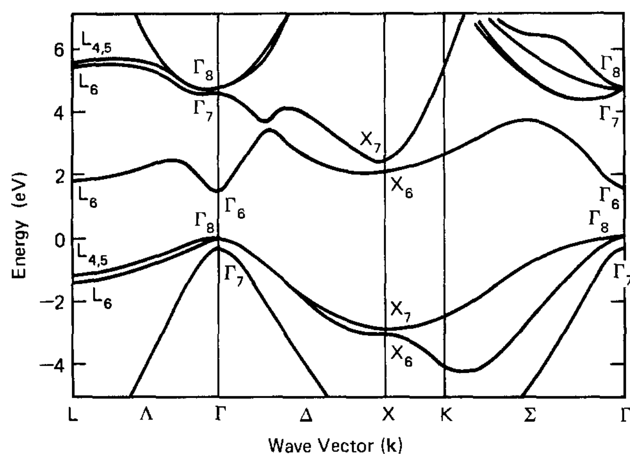

Fig. 1. Energy band structure of GaAs

supplied, moreover, the motivation to develop high purity, high mobility GaAs (21) and InP (22). In any case, in this survey we take the point of view that various applications (that Si cannot match) have been the driving force for the study and development of the III-V semiconductors. Below we discuss the more important of these materials and their capabilities in the context of various applications.

Crystal Growth

The search for improved methods to grow semiconductor crystals is an ongoing problem. The most used III-V bulk and substrate materials are GaAs, GaP, and InP; these materials continue to be heavily studied (23). The first, GaAs, is frequently synthesized and grown as a single crystal in a horizontal furnace in a quartz ampul subjected to a collapsing or moving temperature gradient. The crystal can be doped n-type or p-type, or be made semi-insulating with Cr doping. Besides being important as a substrate to support measurement samples (of separately prepared epitaxial layers), semi-insulating GaAs (also semi-insulating InP) is becoming increasingly important in device use (19), *e.g.*, making possible an interconnected array of devices (IC) on "insulating" substrates. Because of the high P pressure at the melting points of GaP and InP, these crystals are grown in pressurized systems by the liquid encapsulation (LEC) method (24), which can be used also to grow GaAs. Other methods are used to grow mixed crystal systems and to prepare homo- and heterojunctions. These are discussed below.

Vapor phase epitaxy (VPE).—In 1960 Marinace (25) described the VPE growth of Ge on GaAs substrates, thus leading to the first high performance heterojunctions. This VPE crystal growth process, which occurred in a closed-tube held in a small temperature gradient, employed iodine as the transport agent (VPE by halide transport and chemical disproportionation). Marinace's process could be inverted, making possible the VPE growth of GaAs on Ge substrates (26). In addition, the closed-tube VPE-crystal-growth process could be generalized to employ other halide transport agents and to grow also mixed III-V crystal systems. Thus, closed-tube VPE was used (in 1960) to grow GaAs on Ge heterojunctions, GaAs on GaAs tunnel junctions, and GaP on GaP junctions, and to synthesize and grow (VPE) $GaAs_{1-x}P_x$ and $GaAs_{1-x}P_x$-$GaAs_{1-y}P_y$ heterojunctions (26).

The demonstration of the work of Ref. (26) to Ruehrwein (27) (and to F. V. Williams, fall, 1960, Syracuse, New York) led to today's most widely used open-tube VPE system (Fig. 2) for the large-scale growth of $GaAs_{1-x}P_x$ ($x = 0$ GaAs, $x = 1$ GaP) (28-31). In this process of crystal growth, HCl is used to transport the column III constituents (Ga or In

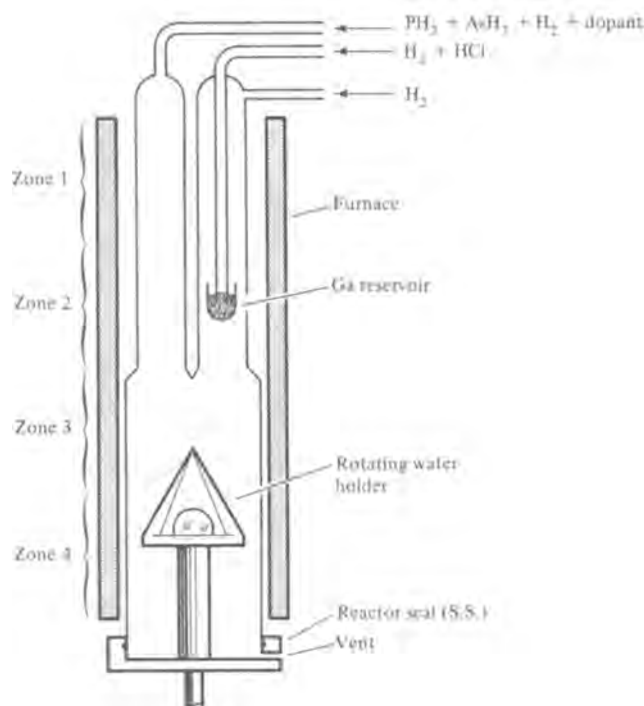

Fig. 2. Schematic diagram of reactors used for commercial growth of $GaAs_{1-x}P_x$, GaAs ($x=0$), and GaP ($x=1$) using the hydride VPE process [after Ref. (31)].

metal), and AsH_3 and PH_3 are the source of the As and P for the VPE crystal. It is an easy matter to add NH_3 to the crystal growth reactor in order to introduce N doping, an isoelectronic trap, in the VPE layers. Epitaxial layer growth rates are ~1 μm/min. The details of this process for the growth of GaAs, GaP, and $GaAs_{1-x}P_x$ are described elsewhere [Ref. (28-31)]. It is worth mentioning, however, that since the AsH_3-PH_3 system of VPE crystal growth is the highest volume, most widely used one in the LED industry, it is under constant study in order to effect improvements in crystal quality, freedom from defects, and improved doping. Also, it is worth mentioning that this crystal growth process, as well as the VPE process of the next paragraph, is capable of growing epitaxial layers of low doping level ($N_d - N_a < 10^{15}/cm^3$) and high mobility (~8800 cm^2/Vsec for GaAs).

At the time (1963) of the discovery of transferred electron oscillations (Gunn effect) (12, 32) the best available GaAs had total impurity concentrations in the 10^{16} cm^{-3} range. Although material of this quality could be compensated to produce lower electron concentrations, it became apparent that the purity of GaAs would have to be improved to obtain useful devices. To overcome some of the problems associated with closed-tube VPE, a number of open-tube methods were investigated. In 1965 the feasibility of obtaining higher purity GaAs by an epitaxial technique was demonstrated by Knight *et al.* (33) with the $AsCl_3$-Ga-H_2 open-tube VPE system. Since that time this VPE method has been developed to a high state of reliability by a number of workers. The contributions of many of these workers and the details of the chloride-transport VPE system are reviewed in Ref. (34). Because of the ease with which high purity, controlled doping, precise thicknesses, and mirror-smooth surfaces can be obtained with this technique, the $AsCl_3$-Ga-H_2 VPE process is the most commonly used method of growing epitaxial GaAs for a variety of applications. It is mainly due to the development of this epitaxial growth process that GaAs is currently taking over a substantial part of the work, formerly performed by Si, in high speed integrated circuits.

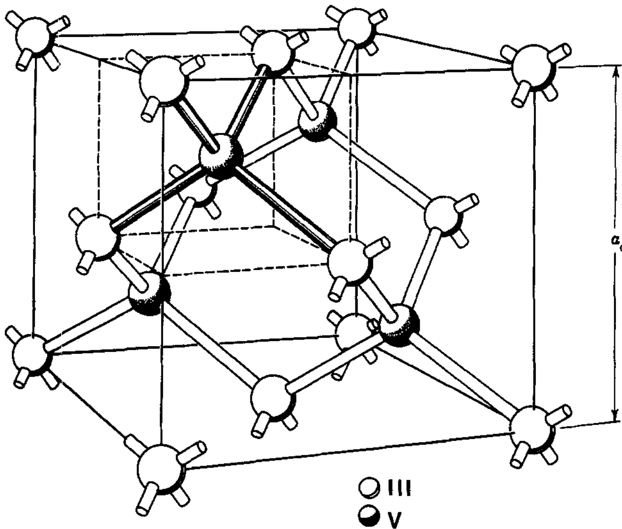

Fig. 3. Sphalerite crystal structure of III-V compound semiconductors [after Ref. (21)].

In III-V crystal systems containing Ga (Ga occupying column III latttice sites, Fig. 3), Al will substitute for Ga with only a small change in the crystal lattice constant. Until recently, however, Al has not been an easy or even manageable component to handle in a VPE crystal growth reactor because of its highly reactive nature. This problem has been overcome by Dupuis and co-workers, who have employed metallorganic chemical vapor deposition (MO-CVD, a form of VPE) to grow a wide range of high performance $Al_xGa_{1-x}As$-GaAs heterojunction devices (35-41). In the MO-CVD crystal growth process (35-37), the metal alkyls, trimethylgallium (TMGa) and trimethylaluminum (TMAl), are used as sources of the group III elements Ga and Al. The hydride AsH_3 is used as the source of the group V element As, and PH_3 for P. H_2Se is used as a source of Se for n-type doping and diethylzinc (DEZn) is used as a source of Zn for p-type doping. The various layers of a heterostructure are grown sequentially at 750°C on {100} GaAs substrates, or on Ge or GaAsP substrates, using growth rates of ~0.25 μm/min.

As an example of the high quality heterostructures that have been grown by MO-CVD, foremost are $Al_xGa_{1-x}As$-GaAs-$Al_xGa_{1-x}As$ DH laser diodes that operate at current thresholds as low or lower than any made by other methods (41). This has led to easily realizable room temperature continuous laser operation (40), which previously has been possible only with DH diodes grown by liquid phase epitaxy (LPE) and, less successfully, with molecular beam epitaxy (MBE). [See Ref. (42) for an extensive discussion and complete list of references.] In addition, MO-CVD $Al_xGa_{1-x}As$-GaAs-$Al_xGa_{1-x}As$ quantum-well heterostructures (200Å GaAs active layers) have been grown that operate as laser diodes at relatively low thresholds (38) and that photopumped exhibit stimulated emission on confined-particle transitions well into the visible-red (39).

The nature of these results, taken with the many other advantages of VPE processes, make it likely that the MO-CVD growth of GaAs and $Al_xGa_{1-x}As$, and possibly $GaAs_{1-y}P_y$ and $Al_xGa_{1-x}As_{1-y}P_y$ (43), and heterostructures based on these crystal systems, will gain wide acceptance. The advantages of the MO-CVD process for the growth of $Al_xGa_{1-x}As$ and GaAs include: (*i*) capability for large scale operations (large substrate areas); (*ii*) convenient growth rates with excellent control of layer thicknesses (from $\lesssim$ 50Å to over 1 μm); (*iii*) highly reproducible layer thicknesses and capability for multiple layer growth, including quantum-well structures; (*iv*) easily controlled doping levels from $N_d - N_a \lesssim 10^{15}/cm^3$ to degeneracy; (*v*) excellent composition control; (*vi*) good lattice match; (*vii*) superior surfaces with no problems with melt wipe-off or contact with foreign bodies; and (*viii*) no problems with halide etching or attack of surfaces.

In concluding this brief discussion of VPE, we mention that because of the broad nature of Ref. (27), it covers quite generally the open-tube VPE growth (via AsH_3, PH_3, etc.) of a large number of compound semiconductors, including $In_{1-x}Ga_xP_{1-z}As_z$. This quaternary system has recently become important for laser and detector diodes in the wavelength range $\lambda \gtrsim 1$ μm at which optical fiber transmission is optimum. Besides LPE, VPE can be used for the growth of double heterojunctions employing $In_{1-x}Ga_xP_{1-z}As_z$ (44); this is not an extensively developed or practiced art yet but potentially could become important.

Liquid phase epitaxy (LPE).—A significant number of III-V semiconductor devices that have been successfuly developed in the last 10 years have depended upon LPE crystal growth, *e.g.*, $Al_xGa_{1-x}As$-GaAs-$Al_xGa_{1-x}As$ double heterojunctions (45, 46), red GaP:Zn-O and green GaP:N light emitters (47, 48), InP-$In_{1-x}Ga_xP_{1-z}As_z$-InP DH lasers (λ = 1-1.7 μm) (49), and visible-spectrum $In_{1-x'}Ga_{x'}P$-$In_{1-x}Ga_xP_{1-z}As_z$-$In_{1-x'}Ga_{x'}P$ DH lasers (50). The prototype for this system of crystal growth, particularly to form p-n junctions, is the method of Nelson (51), which was first used to grow LPE GaAs homojunctions. As initially demonstrated, a Ga melt (or solution) is first saturated with GaAs, a substrate crystal (GaAs) is moved under the melt (nowadays by means of a graphite slider boat), and simultaneously the temperature is lowered to cause supersaturation and growth of GaAs from the melt on the substrate. If a small amount of Al is introduced into the Ga melt, the epitaxial layer that is grown is $Al_xGa_{1-x}As$ (52), and a heterojunction with GaAs results. Until the recent success of the MO-CVD process, this had been the most successful process (LPE) for the growth of $Al_xGa_{1-x}As$-GaAs heterojunctions. Problems with the difficult oxides of Al are avoided by the simple fact that it is possible to slide a substrate wafer into contact with the "clean" portion of a liquid. An extensive discussion of this technology appears in Ref. (42).

In one way or another most LPE III-V crystal- and junction-growth processes are similar or related, and will not be discussed in detail [see Ref. (42)]. Because of the importance of green LED's and the fact that so far LPE GaP:N has proved to give the highest (green) performance (48), no doubt this system will receive further attention. Red GaP: Zn-O, because of the low solubility of the isoelectronic complex Zn-O, probably will receive limited attention. [Red-orange VPE $GaAs_{1-x}P_x$:N is a more viable system (31).] Of the systems having reason to be grown by LPE, that receiving most attention in the long run will probably be $In_{1-x}Ga_xP_{1-z}As_z$, simply because so far LPE has been the most successful method for growing this alloy and most likely its importance for optical fiber communications will increase.

Compared to VPE, LPE suffers certain disadvantages such as lesser control of layer thickness, poorer control of crystal composition, and problems with melt wipe-off, growth terraces, and meniscus lines. There are certain advantages of LPE processes, however, and doubtless this method of crystal and heterojunction growth will be developed further. Its low cost makes it ideal for laboratory-scale experiments, and it is capable of certain results that have not been obtained by other methods. As an example, the amphoteric dopants Ge and Si act as donors in GaAs that is grown near stoichiometric conditions; but, in the LPE growth process (due to relatively fewer As atoms and hence As vacancies), Ge or Si can occupy column V lattice sites (see Fig. 3) and act as acceptors. This form of

doping has been useful in DH lasers (42). Also, Si-doped LPE GaAs homojunctions have become a standard high efficiency LED in optoelectronic applications. During the LPE growth cycle the Si dopant first acts as a donor but later in the growth cycle tends to occupy As sites (Fig. 3) and thus switches its behavior to an acceptor, in fact, introducing the usual shallow and also a deeper acceptor (53). Electron-hole recombination involving the deeper acceptor results in reduced photon energy and in recombination radiation that does not suffer much absorption, thus making possible a higher efficiency LED. In this case LPE accomplishes a unique result.

A further matter concerning III-V semiconductors should be mentioned in concluding this section. III-V materials are by no means simple; nevertheless, in many cases they have proven to be sufficiently manageable to make it possible to determine their phase behavior and construct their phase diagrams [see Casey and Panish, Ref. (42)]. Obviously it is a matter of considerable importance, for example, in determining how impurities are incorporated, whether a III-V semiconductor is grown under conditions of excess column III or excess column V atoms. This applies also to the behavior of impurities diffused into III-V crystals. For example, Zn diffusion in GaAs (or GaAsP) behaves much differently under conditions of excess As as compared to excess Ga. How this process proceeds is governed to a large extent by the Ga-As-Zn phase diagram of the system (42). Although the phase diagrams of many III-V's and their more common dopant impurities are known, this area of work is far from complete. Perhaps the most complete discussion of this topic appears in Ref. (42).

Molecular beam epitaxy (MBE).—One more system of III-V crystal and heterojunction growth should be mentioned; molecular beam epitaxy (MBE). An extensive description of this process appears in Ref. (54). Basically MBE consists of growing a crystal in a vacuum by letting controlled "beams" of the requisite atoms strike a hot substrate (GaAs, etc.) and form the crystal. The beams of atoms are provided by small effusion-cell ovens that deliver, by evaporation, streams of atoms. The cells are shuttered, in a time sequence pattern, to change epitaxial layer compositions or to switch from the growth of one type of layer (GaAs) to another ($Al_xGa_{1-x}As$ or AlAs).

Various heterostructures have been constructed by MBE, perhaps the most unique being multilayers of $Al_xGa_{1-x}As$ and GaAs that are thin enough to exhibit quantum size effects (QSE) (55) and also artificial materials consisting of a certain number of monolayers of one crystal (GaAs) interleaved with a certain number of monolayers of a second crystal (AlAs) (56). This last form of MBE crystal is a type of material not formed naturally. For the example stated, it is an ordered form of $Al_xGa_{1-x}As$ since the Al atoms appear on a well-defined set of planes (similarly the Ga atoms). In the usual case (VPE, LPE, or MBE) the Al and Ga atoms are uniformly distributed in density, but in a disordered arrangement. The ordered form of $Al_xGa_{1-x}As$ (and possibly other III-V alloy systems), and the many forms of ordered doping arrangements that can be imagined may well be the most important feature of MBE and its capability for growing epitaxial layers monolayer by monolayer. This is also one of its limitations, its low growth rate and its inherent small mass transport and thus resulting limited crystal-size capability.

Optical Devices

In the early phase of transistor development it was imagined that III-V compounds, with their high mobilities, would make possible higher speed transistors. This judgment now has validity, but it did not when it was first made. There is little doubt that it was the light-emission capability of the III-V's that finally encouraged their large-scale development. This was particularly true after the report of efficient spontaneous emission from GaAs p-n junctions (57), and the subsequent demonstration of infrared (15, 16, 18) and visible-red (17) stimulated emission from III-V p-n junctions. This work made it evident that practical LED's in the range from the infrared to the red could be developed.

Laser diodes.—There is ample evidence showing that the light-emission process in a direct-gap crystal is much stronger than in an indirect-gap material. For example, when the pressure on (direct-gap) $GaAs_{1-x}P_x$ (58) or $In_{1-x}Ga_xP_{1-z}As_z$ (59) laser diodes is increased, the X indirect band minima and the Γ direct minimum (Fig. 1) shift and approach one another; as $E_\Gamma \rightarrow E_X$, electrons transfer from Γ to X and laser operation quenches. In the latter case band-to-band recombination (X electrons and Γ holes) and the light emitted are weak. Direct-gap crystal is essential for laser diodes and is advantageous also in LED's.

Although homojunction laser diodes were the first to be constructed (15-18), nowadays essentially all study and further development of these devices is concentrated on DH diodes. The two systems receiving most attention are $Al_xGa_{1-x}As$-GaAs-$Al_xGa_{1-x}As$ and InP-$In_{1-x}Ga_xP_{1-z}As_z$-InP. The former is extensively discussed in Ref. (42). Relative to further progress, the most important recent development is that these devices (AlGaAs-GaAs) have been constructed by MO-CVD and have operated CW (300°K) (40) and, in addition, have operated at thresholds as low or lower (41) than LPE DH laser diodes. If these diodes prove to exhibit high reliability, then MO-CVD will be capable of delivering large quantities of $Al_xGa_{1-x}As$-GaAs-$Al_xGa_{1-x}As$ DH laser diodes at very low cost. (This will be an interesting development to watch in succeeding years since MO-CVD has implications also for a number of other devices.)

Several features make InP-$In_{1-x}Ga_xP_{1-z}As_z$-InP DH diodes important. The first is that the direct-gap center active region can be "tuned" in composition to the wavelengths at which optical fibers exhibit optimum transmission characteristics (49). Another is that the heat sinking of these devices is accomplished via InP, which is a considerably better heat conductor than AlGaAs. In spite of their early state of development, quaternary DH laser diodes exhibit extremely low low temperature threshold current densities (60), which suggests that the room temperature thresholds can eventually be made much lower. Lower thresholds, if realizable, could result in simpler, cheaper, and more reliable laser diodes.

It is interesting that direct-gap $In_{1-x}Ga_xP_{1-z}As_z$ is useful also for visible-spectrum DH laser diodes (50). In this spectral region, however, the quaternary is much more difficult to grow (61) than at smaller energy gaps (62) (~800° *vs.* ~650°C). For this reason and because of the possible effect of substrate ($GaAs_{1-y}P_y$) defects, visible-spectrum quaternary DH diodes have not yet matched the performance obtained at smaller energy gaps ($\lambda > 1$ μm).

Light-emitting diodes (direct-gap).—Not all direct-gap diodes, or even the largest number, involve stimulated emission (for many optoelectronic applications, *e.g.*, coupled pairs, spontaneous emission suffices). In the infrared by far the most widely used material is GaAs. Homojunction diodes prepared by Zn diffusion into n-type GaAs substrates are well developed (63) and widely used. The external quantum efficiency of these diodes (uncoated) is typically ~0.3% (50 mA). For higher efficiency (~1.5%, 20 mA), Si-doped junctions grown by LPE are employed. For still higher efficiencies (as high as 40% (64) but at still greater expense) LPE $Al_xGa_{1-x}As$-GaAs-$Al_xGa_{1-x}As$ DH diodes have been developed. The successful (large-area) construction of this type of diode (DH) by MO-CVD (40), a large-area growth process, raises the interesting possibility that high performance *IR* LED's will become available even-

tually at very low cost. Also, MO-CVD makes very practical a new form of light emitter, a quantum-well LED (38, 65). Depending upon current, these devices emit over a wide spectral range, including into the visible-red (38, 39).

Beyond GaAs there is no binary III-V with a higher energy direct bandgap. Hence, to achieve higher energy direct gaps it is necessary to resort to alloys or mixed III-V systems. One of these systems, $GaAs_{1-x}P_x$ ($x \sim 0.40$) (17) for various reasons has become the industry-wide standard red LED material. By VPE it is possible to prepare $GaAs_{1-x}P_x$ of reasonable quality, cheaply, and in large quantities (28). Then with the same type of simple Zn-diffusion process used for GaAs (63), red-emitting p-n junctions are prepared in the alloy. This results in a cheap, relatively high performance red LED. Because it is already known that $Al_zGa_{1-z}As_{1-x}P_x$-$GaAs_{1-x}P_x$ heterojunctions can be grown (43), it is likely that MO-CVD (35) can be extended and be used to make (at low cost) a much higher performance visible heterojunction LED based on light emission from $GaAs_{1-x}P_x$.

Light-emitting diodes (indirect-gap).—Although $In_{1-x}Ga_xP$ does not become indirect until $x \sim 0.73$ (59) and presumably could be used for a direct-gap LED extending to the yellow-green, this alloy system is not well developed. Compared to $GaAs_{1-x}P_x$, $In_{1-x}Ga_xP$ is not simple to grow nor to prepare into good p-n junctions and has been largely ignored. For $x > 0.4$ $GaAs_{1-x}P_x$ (*i.e.*, beyond the direct-indirect transition, $x \equiv x_c \approx 0.48$) the LED brightness decreases (in the orange, yellow, and green) as shown by the dotted curve of Fig. 4 (66). The solution to this problem (solid curve of Fig. 4) is to introduce N doping in $GaAs_{1-x}P_x$ to maintain LED brightness from the red to the yellow (67), and to the green ($x = 1$, GaP:N) (68).

Nitrogen in GaP and in $GaAs_{1-x}P_x$ is a short-range isoelectronic trap with a shallow binding energy. If carriers are confined spatially, then in k space they are spread out ($\Delta k \Delta x \sim 1$). When electrons are excited (injected) into the X indirect minima, which is the lowest conduction band minima of Fig. 5, the N trap captures the carriers and, as shown by the shaded region representing $\psi_N(\vec{k})$, introduces a considerable probability for the electron to appear at $\vec{k} = [000]$, or Γ, and thus recombine with a Γ hole. As the alloy composition is shifted from $x = 1$ (GaP) toward $x = 0$ (GaAs) and the Γ conduction band minimum approaches E_N (the trap level), this effect, known as band structure enhancement, increases the oscillator strength for electron-hole recombination at the N trap (69). Thus, although the eye sensitivity decreases toward the red, the recombination radiation is enhanced and the brightness of $GaAs_{1-x}P_x$:N LED's is reasonably flat (Fig. 4) from the red to the green, *i.e.*, from $x \sim 0.4$ to $x = 1$.

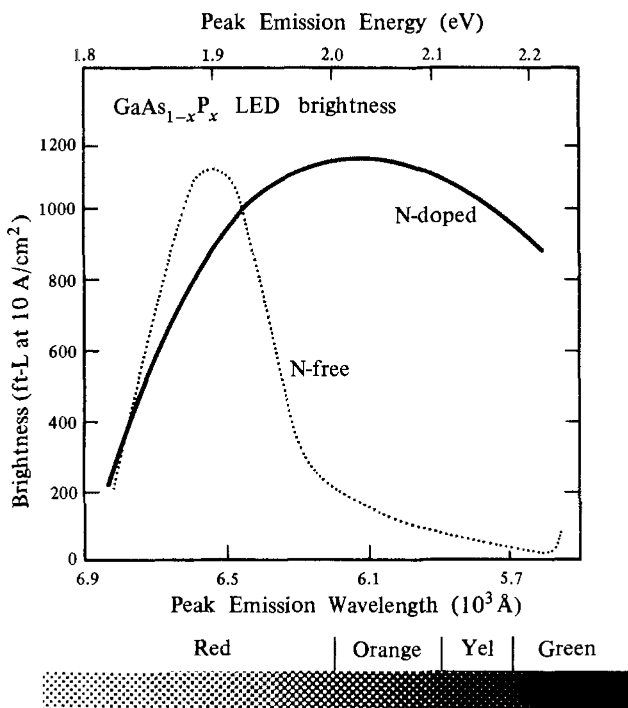

Fig. 4. Brightness as a function of alloy composition for $GaAs_{1-x}P_x$ diodes with and without nitrogen doping. The brightness is measured in foot-Lamberts with a drive current of 10 mA or 10 A/cm², corresponding to a device area of 10^{-3} cm² (after Ref. (31)).

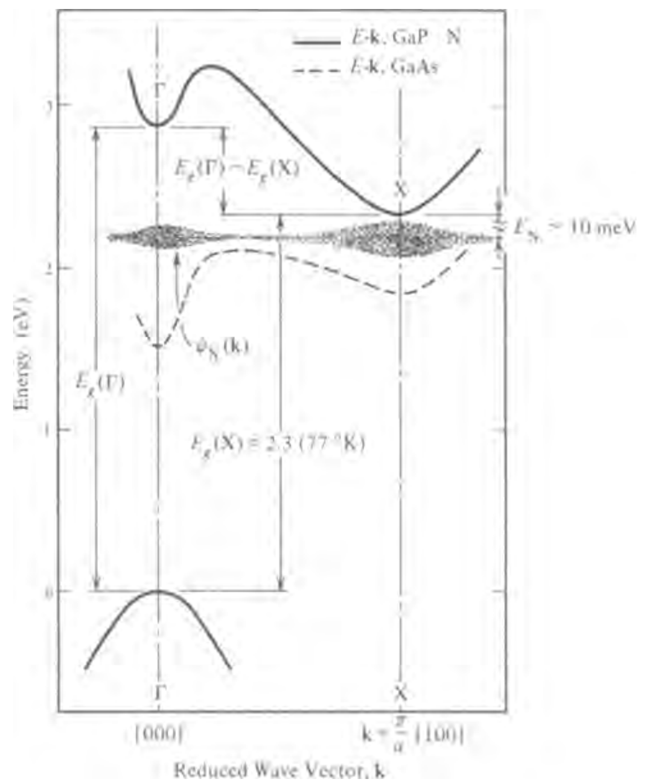

Fig. 5. *E-k* diagram of GaP:N with GaAs shown dotted for reference. The N isoelectronic trap lies ~10 meV below the X minima, and $|\psi_N(k=0)|^2 > 0$. As the crystal composition, x, of the $GaAs_{1-x}P_x$ alloy is varied and E_Γ approaches E_X, $|\psi_N(k=0)|^2$ increases and attains a maximum when E_Γ is adjusted to coincide with the N trap energy [after Ref. (31)].

The theory of the behavior of N in $GaAs_{1-x}P_x$ continues to be improved (70), but, as usual, improvement in LED brightness depends more upon improvement in crystal growth, doping, and junction quality. Progress in this area is now largely evolutionary (66). It is interesting to speculate, however, that when MO-CVD is extended in this direction (*i.e.*, toward AlGaAsP, GaAsP, and AlGaAsP-GaAsP heterojunctions, N doping included) major further progress will be realized in LED development.

Detectors.—p-n junctions and heterojunctions in III-V materials, in addition to serving as efficient light emitters, also serve as efficient light detectors. In this respect they have several advantages over an elemental semiconductor, one being their high absorption coefficients (direct-gap crystal) and another the fact that essentially a continuous range of energy gaps is possible from the *IR* to the visible by the utilization of alloys. In addition, they can be conveniently fabricated into heterojunctions, which is important for wide bandwidth applications. Other compound semi-

conductors are also very important in detector applications, particularly at wavelengths longer than about 5.5 μm, the long wavelength limit of InSb at 77°K and the long wavelength limit of practical intrinsic detectors in III-V materials. Even at shorter wavelengths, however, compound semiconductor detectors such as PbSe and PbS are very important, but since these detectors are typically polycrystalline thin-film devices formed by either vacuum evaporation or chemical deposition of some type, they will not be discussed further here. At the longer wavelengths, $Hg_{1-x}Cd_xTe$ and the PbSn chalcogenides $Pb_{1-x}Sn_xTe$ and $Pb_{1-x}Sn_xSe$ are highly developed single crystal compound semiconductor alloys that are very useful for intrinsic photoconductors and photodiodes. Detectors in these materials systems have recently been reviewed in some detail (71, 72) and will not be discussed further in spite of their considerable importance for detectors in the 5-14 μm wavelength range.

Most of the important detector applications of III-V compounds occur in the near infrared spectral region, but there are two important exceptions that are useful for far infrared detectors. The first is the InSb "free electron bolometer." The absorption mechanism in this detector is the free carrier absorption of radiation, which has a λ^2 dependence for "short" wavelengths and is constant at long wavelengths. For InSb, the λ^2 dependence is approximately true for $\lambda < 1$ mm. In most semiconductors, free carrier absorption simply contributes slightly to increasing the temperature of the sample. However, in InSb at very low temperatures ($T \lesssim 4.2$°K), a different effect occurs. InSb has a very low electron effective mass and high electron mobility at low temperature, and the electron coupling to the lattice is very weak. In addition, the electron mobility is energy dependent, so that absorption of far infrared radiation via the free carrier absorption mechanism can produce a significant increase in the average electron energy and thus a change in the average electron mobility. The resulting change in conductivity can be detected in the same manner as ordinary photoconductivity, and since the effect is electronic rather than thermal, this detector is capable of fast response. These detectors have been described in detail by Putley (73), and are widely used in far infrared and submillimeter research for wavelengths $\gtrsim$ 200 μm.

The other III-V compound far-infrared detector is the GaAs extrinsic photoconductor (21). All of the shallow donor impurities in GaAs are very nearly hydrogenic, with ionization energies of about 5.86 meV and Bohr radii for the ground state of about 100Å, so that very pure material is required for the observation of isolated impurity levels. Because of the large effort expended in developing high purity GaAs, mainly for Gunn-effect applications, such material is now readily available. The ionization energy of 5.86 meV corresponds to a photoionization threshold wavelength of about 212 μm, but because the impurity levels are so shallow, the dominant response of these detectors at 4.2°K corresponds to the wavelength or photon energy for excitation of a bound electron from the ground state to the first excited state of a hydrogenic donor (21). The photoconductivity from this absorption results because of subsequent thermal ionization of the excited electron into the conduction band. This photothermal ionization mechanism produces a photoconductivity spectrum with a dominant peak at 282 μm, considerably beyond the 120 μm long-wavelength threshold for Ge extrinsic photoconductive detectors. Since this type of GaAs detector is fast and its peak response falls between the long wavelength cut-off of Ge detectors and the longer wavelengths where the InSb free electron bolometers have their optimum response, they are a very useful addition to the small assortment of fast detectors in the far infrared spectral region (21).

The III-V compound semiconductor detectors in the near infrared spectral region are not in general very highly developed. One notable exception is InSb, which has a long wavelength threshold of about 7 μm at room temperature and about 5.5 μm at liquid nitrogen temperature. Photoconductor and photoelectromagnetic InSb detectors have been developed and have recently been reviewed by Kruse (74). Photovoltaic InSb devices have also been developed to some degree (75). In addition, InSb avalanche photodiodes have been reported (76), but these devices have not been studied extensively. Photodiodes utilizing InAs are available commercially; these devices have a long wavelength threshold of about 3.5 μm when operated at room temperature.

Most of the other III-V compounds have larger bandgaps, and because of the ready availability of photomultiplier tubes and Si p-i-n and avalanche photodiodes, there has been little incentive to develop III-V photodetectors for the same spectral region. The absorption coefficients for the more common binary III-V compound semiconductors are shown in Fig. 6, along with the absorption coefficients of Ge and Si for comparison (77). Except for GaP, all of the III-V materials shown have a direct bandgap and therefore a very steep absorption edge. The differences between the absorption for direct and indirect energy gaps is quite distinct when the direct absorption edges of III-V compounds are compared to Si—the absorption coefficient of Si does not extend as high as for the direct bandgap III-V compounds until the photon energy is over twice the bandgap energy. (The reason for the more rapid increase in the absorption coefficient for the indirect-gap materials Ge and GaP than for Si is that higher energy direct conduction band minima dominate the absorption in these semiconductors at energies only slightly above the indirect energy gap).

Because of the relatively low absorption coefficient of Si at wavelengths longer than about 0.8 μm, there is a trade-off between the quantum efficiency and frequency response in these devices that becomes important in wide band-width applications; the depletion width of the device must be wide enough to absorb a significant fraction of the incident radiation, but the wide depletion width can impose a transit-time limit on the frequency response. At 1.06 μm, Si p-i-n detectors capable of a baseband response of 10 MHz are limited to an internal quantum efficiency of about 85%, while a base bandwidth of 100 MHz limits the internal quantum efficiency to about 20% (77). Thus, Si is not suitable as a material for high quantum

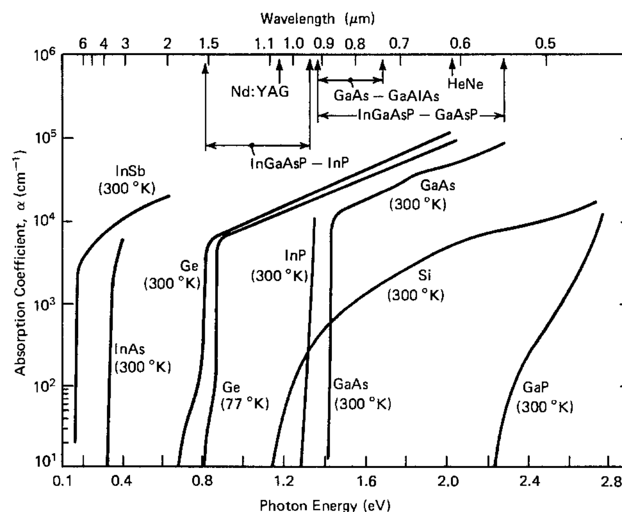

Fig. 6. Absorption coefficient of important III-V compound semiconductors. The absorption coefficients of Si and Ge are shown for comparison. The wavelengths of some important laser and LED sources are indicated for comparison [after Ref. (77)].

efficiency, wide-bandwidth detectors at wavelengths longer than 1.06 μm.

Even for wavelengths shorter than 1.06 μm, there is interest in III-V materials for wide bandwidth detectors; for example, uniform high gain, low noise GaAs Schottky-barrier avalanche photodiodes have been reported (78). High external quantum efficiencies ($\gtrsim$ 50% without antireflection coating) and short response times (~175 psec) at 1.06 μm have been achieved with $In_xGa_{1-x}As$ Schottky barrier avalanche photodiodes (79). These devices are also capable of uniform, high avalanche gains ($\gtrsim$ 250). Even higher external quantum efficiencies (~95% with antireflection coating) but smaller avalanche gains (~10) at 1.06 μm have been obtained with $GaAs_{1-x}Sb_x$ p-n junction detectors (80). The low device yield of $In_xGa_{1-x}As$ detectors with high avalanche gain and the difficulty in obtaining uniform high avalanche gain devices with $GaAs_{1-x}Sb_x$ are probably related to the lattice mismatch between the GaAs substrate and the alloy active layer, although in both cases grading or buffer layers have been employed to reduce the number of misfit dislocations. The crystal mismatch is even more important when longer wavelength detectors (~1.27 μm) for the optimum fiber optic wavelength are considered, although uniform avalanche gains up to 15, pulse rise time of less than 100 psec, and quantum efficiencies of 60% at 1.06 μm and 45% at 1.27 μm for mismatched GaAlSb-GaSb 1.0 to 1.4 μm avalanche photodiodes have recently been reported (81). It is possible that microplasmas related to lattice mismatch limit the performance of these devices.

For longer wavelengths especially, but also for wavelengths close to 1.0 μm, the quaternary $In_{1-x}Ga_xP_{1-z}As_z$ lattice matched to InP substrates is of interest for the same reasons discussed for lasers and LED's. This material is currently being investigated in many laboratories for applications as avalanche photodiodes. There have been several preliminary reports of promising results using this alloy (82-85).

Another "detector" application of III-V compound semiconductors that must be mentioned is that of negative electron affinity (NEA) photocathodes. Negative electron affinity is obtained in compound semiconductors by treating the surface so that an electron at the bottom of the conduction band in the "bulk" of the semiconductor has an energy greater than the zero energy level of an electron in vacuum. In this situation, then, an electron excited into the conduction band can be "emitted" into the vacuum if it travels (diffuses) to the surface without first "thermalizing" or recombining. Negative electron affinity in GaAs and other III-V compounds is obtained using a thin coating of CsO (~8Å thick for GaAs) on degenerate p-type [111]-B oriented material. Quantum efficiencies greater than 20% have been obtained with these GaAs devices.

Equally important or perhaps even more important (than the GaAs NEA photocathodes) is the extension of photoemissive devices further into the infrared, beyond the long-wavelength limit of the familiar S-1 photocathode. The alloys InGaAs, InAsP, and InGaAsP and others have been studied for this application; a very complete review of this work as well as a general review of the GaAs NEA work and of classical photoemissive surfaces has recently been given by Zwicker (86). The quantum efficiency curves for several alloy NEA photocathodes are given in Fig. 7. The quantum efficiency curve for the usual S-1 photocathode is also shown for comparison; it can be seen that much higher quantum efficiencies can be obtained in the near infrared using NEA photocathodes. These curves show also, however, that as the long-wavelength threshold is extended towards longer wavelengths, the resulting quantum efficiency is decreased over the rest of the spectral range. This rather disappointing result is presumably due to a barrier which limits the emission probability of lower energy electrons.

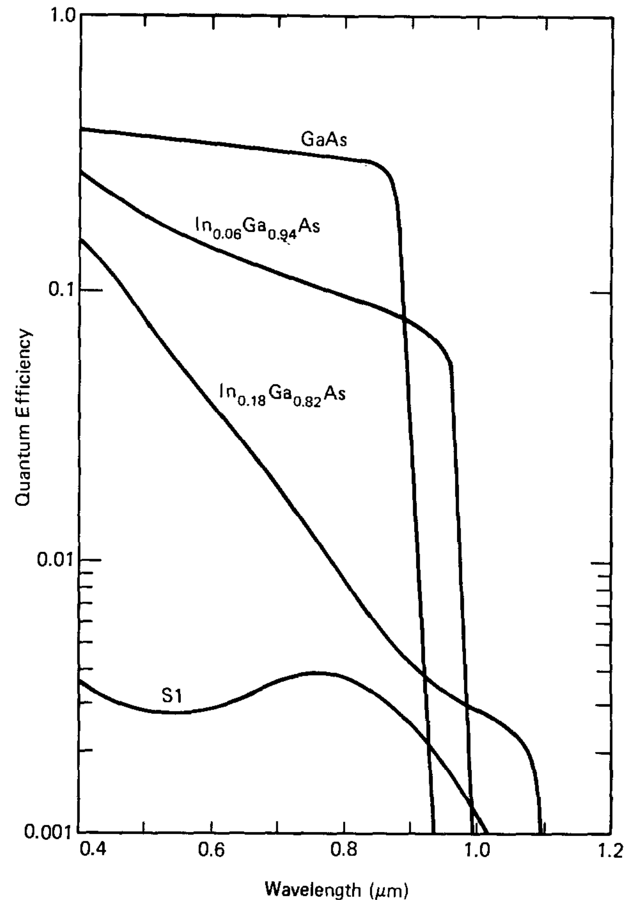

Fig. 7. Variation in quantum efficiency with wavelength for several NEA photocathodes. The quantum efficiency of the S1 photocathode is shown for comparison [after Ref. (86)].

Further extension of the long wavelength threshold of NEA photocathodes will probably require the development of a coating material other than CsO, a material which does not have the limiting barrier that causes the decrease in quantum efficiency with increasing long-wavelength threshold shown in Fig. 7. Nevertheless, these NEA photocathodes incorporated in sophisticated photomultiplier structures, including the dynamic crossed field photomultiplier structure (87), provide the most sensitive infrared detectors, and these devices are available commercially.

Solar cells.—Because of the magnitude of the problem of solar energy generation, one form of light or radiation detector deserves special mention, the solar cell. Silicon is the most generally used material in these applications (88), but it is by no means ideal. Its energy gap is too small (relative to the solar spectrum), its absorption coefficient also is too small (thus requiring a rather thick layer of crystal to absorb fully the incident radiation), and it is not easily or conveniently formed into heterojunctions. In respect to all of these, GaAs is a better although more expensive material.

The most important form of III-V solar cell is the $Al_xGa_{1-x}As$-GaAs heterojunction (89, 90), which is capable of efficiencies >20% (91,92) for air mass one (AM1). The main terrestrial application of this type of solar cell will be in systems utilizing solar concentration (91). GaAs solar cells are much better suited to this application than Si solar cells because of better high temperature performance. In solar concentrators, the cost of the cell is not the major cost of the system; thus it is economically feasible to develop the highest efficiency cell possible since the major cost is the con-

centrating system itself (93). More complicated graded-bandgap solar cells with higher concentrator efficiencies are being developed (94, 95); *e.g.*, calculations indicate that if energy concentrations greater than 1000 suns can be used, systems with expensive, high performance solar cells will be economically viable (96). Although the single crystal $Al_xGa_{1-x}As$-GaAs heterojunction is the most important III-V solar cell at present, in the future polycrystalline thin-film GaAs devices may become even more important for terrestrial applications. This possibility arises because of the steep absorption edge of GaAs, due as discussed previously to the direct bandgap, and the relaxed requirements on cell thickness and minority carrier lifetimes and diffusion lengths compared to indirect crystals. Because of the reduced thickness requirements (the GaAs films need only be 1-2 μm thick for ~10% efficiency while Si cells require layers 10-20 μm thick), the amount of GaAs material required for these polycrystalline cells could be considerably less than the amount of Si required for equal output. In addition, the actual cost per unit weight for the GaAs material required could be less than for the comparable Si needed since the material requirements on Si (longer diffusion length and lifetime) will probably be more stringent than on the GaAs (93). The development of polycrystalline solar cells, of either Si or GaAs, that are economical will of course depend on the development of suitable polycrystalline films on very inexpensive substrates.

Microwave Devices

In addition to applications in optical devices, III-V compounds are of interest for use in three types of microwave devices. These are Gunn effect or transferred electron devices, impact-avalanche-transit-time (IMPATT) devices, and field effect transistors (FET's). There are special bandstructure properties of compound semiconductors such as GaAs and InP that make Gunn effect devices possible. These result in transport effects not present in Si. In addition, there are other properties of III-V crystals such as GaAs and InP that make possible higher performance IMPATT's and FET's compared to similar Si devices. These devices and the particular features of compound semiconductors relevant to them are discussed in this section.

Gunn effect devices.—After the discovery of the tunnel diode, there was considerable interest in finding other effects in homogeneous semiconductors that could provide greater ranges of negative resistance and even faster response times. In 1962, two theoretical papers were published that predicted such a possibility. These two papers were based on the transfer of electrons from a high mobility, low effective-mass band to a low mobility, high effective-mass band as a function of electric field (97, 98). In the second of these papers, it was actually predicted that GaAs would be a suitable although not ideal material. About two years later, J. B. Gunn observed microwave current oscillations in GaAs pulsed to high electric fields (12, 32); Kroemer (99) pointed out that Gunn's observations could be explained by the theoretical papers of Ridley and Watkins (97) and Hilsum (98). The current pulses observed by Gunn, the "Gunn effect," were due to transit-time oscillations of domains formed because of a negative resistance characteristic (100). These results spurred a large development effort in many different laboratories; much of this effort has been devoted to developing techniques for the preparation of high purity GaAs (21, 34). With the availability of higher purity, more uniform material, higher power and higher efficiency devices have been obtained. In particular, Copeland observed a new nontransit-time limited mode of operation, which he termed the LSA (limited space charge-accumulation) mode (101). This work and the results obtained have been reviewed by Copeland (102) and by Bulman *et al.* (103).

The early theoretical work on GaAs was based on the transfer of electrons from the direct conduction band minimum at the center of the Brillouin zone to the six equivalent conduction band minima in the [100]-directions of the Brillouin zone. These minima were believed to be closest in energy to the direct conduction band minimum, with the eight equivalent conduction band minima in the [111] direction somewhat higher in energy. Subsequent measurements have shown that the energy band structure is that shown in Fig. 1, where the L conduction band minima are closest in energy to the Γ minimum and with the X minima slightly higher in energy (104, 105). Most of the ideas in the early theoretical papers are correct, although the quantitative results presented may not be reliable. Even in recent calculations of the electron relaxation process in GaAs, only a two-band model, Γ-X, is considered because of the stronger Γ-X intervalley scattering (106). In 1970, however, before these corrections to the GaAs band structure were known, Hilsum and Rees (107) proposed that electron transfer should be much more complete in InP than in GaAs, because the L conduction band minima (in InP) are closer to Γ and should have a small Γ-L coupling coefficient while the X minima are higher in energy but have a large Γ-X coupling coefficient. It was also proposed that these differences in the electron transfer involving the three conduction band minima should lead to higher peak-to-valley velocity ratios and consequently higher efficiency transferred-electron microwave devices, along with higher frequency operation. The possibility of higher device performance in InP devices spurred nearly as large a development effort in the preparation of high purity InP material as that for GaAs resulting from the initial discovery of the Gunn effect. After several years of controversy, it now appears that in InP the Γ-L deformation potential coupling coefficient, $\Xi_{\Gamma L}$, is much larger than originally anticipated from comparison with Ge; therefore the behavior of InP can be adequately explained for most purposes also in terms of a two-band model (108). The large amount of development effort expended on InP has confirmed, however, that there are significant differences between the transferred electron effects in GaAs and InP, and that InP transferred electron oscillators should be capable of higher efficiency (~40% theoretical, compared to ~25% for GaAs) and higher frequency operation ($\gtrsim$ 60 GHz for InP compared to $\gtrsim$ 40 GHz for GaAs) (109, 110). Further development of the technology of InP material will probably result in applications of this material in many different microwave devices. At present GaAs transferred electron oscillators are readily available commercially and find applications in doppler radar systems, burglar alarm systems, radar altimeters, and related systems. Devices are generally available from X band through K_a band (~8-40 GHz) for CW operation at 25-500 mW, with much higher pulsed power outputs possible. Besides these standard products, some companies also provide custom components tailored to particular center frequencies, tuning ranges, packages, etc.

Impatt devices.—The Gunn effect or transferred electron devices described above depend for their operation on particular features of the conduction band that can best be obtained in III-V compound semiconductors. Impact-avalanche-transit-time (IMPATT) devices, on the other hand, depend on impact ionization or avalanche breakdown that can occur in all semiconductors. However, the source of the negative resistance is not as clear as it is in the case of transferred electron devices. The operation of IMPATT or "Read" diodes was first described theoretically in 1958 (111), and microwave IMPATT oscillations were first reported in 1965 in work utilizing silicon

diodes that had been fabricated some 10 years earlier (112). The negative resistance in this type of device results from a 180° phase delay between the applied voltage and the current through the device. 90% of the phase shift occurs because of the avalanche injection mechanism and the other 90° occurs because of the drift of the injected charge through a high field region. Most IMPATT devices are still made of Si, which has higher thermal conductivity than the III-V compounds and which also provides devices that have good reliability. However, Si IMPATT devices are also very noisy, as is expected for any avalanche device; on the other hand, GaAs IMPATT devices appear to be capable of lower noise and higher efficiency performance than Si IMPATT's. The reasons for this are not well understood, but are certainly related to the higher peak drift velocity for electrons in GaAs and to the differences in the impact ionization coefficients for electrons and holes for Si and GaAs. For the operating fields and temperatures present in IMPATT diodes, it is probable that the electron and hole impact ionization coefficients in GaAs are nearly equal. This results in a narrower avalanche zone and higher efficiency for GaAs compared to Si. To date, the highest powers, highest efficiencies, and lowest noise measured for IMPATT diodes have been obtained with GaAs (113). The development of GaAs IMPATT devices continues to be an active area of device research, and special doping profiles (low-high-low, double-drift, etc.) are utilized to increase the efficiency; annular diodes are used to reduce the thermal resistance and compensate for the lower thermal conductivity of GaAs (114).

Microwave transistors.—Transistors, not to be forgotten, offer another possibility for the generation and amplification of microwave signals. It was realized as early as 1958 that GaAs could have significant advantages as a high frequency, high temperature transistor material because of its high mobility and wide bandgap. However, bipolar GaAs transistors have fallen far short of the performance expected (115). This failure is due primarily to the presence of minority carrier trapping states in the base regions of these transistors. The great improvements in the quality of GaAs material over the past few years may lead to a future reconsideration of GaAs bipolar or heterojunction bipolar transistors, but now the most important GaAs transistor and probably the most important high frequency transistor of any type is the GaAs field effect transistor (FET). At present, GaAs FET's have higher gain and lower noise than any other device in the frequency range from 4 to 20 GHz. At frequencies higher than about 6 GHz, GaAs FET's are also capable of greater power output than Si bipolar transistors.

There are three types of FET's in use: (*i*) the junction-FET (JFET); (*ii*) the metal-oxide-semiconductor-FET (MOSFET), which is also sometimes referred to as the insulated-gate-FET (IGFET); and (*iii*) the metal-semiconductor-FET (MESFET) or Schottky-gate-FET. Of these three types, it is the GaAs MESFET that is most important for microwave applications. It has often been pointed out that Schottky-barrier gates are very useful in (compound) semiconductors where (in many cases) it is difficult to form p-n junctions, and that the operation of a Schottky-barrier gate FET (MESFET) is the same as the operation of a depletion-mode JFET. However, there is an additional advantage in the use of a Schottky-barrier gate for microwave applications. In the Schottky-barrier gate the current is carried by majority carriers, and thus the frequency response is not limited by minority carrier recombination and minority carrier traps as it is in p-n junction devices. This is especially important for compound semiconductor devices.

A schematic diagram of a GaAs MESFET structure is shown in Fig. 8. The active GaAs material consists

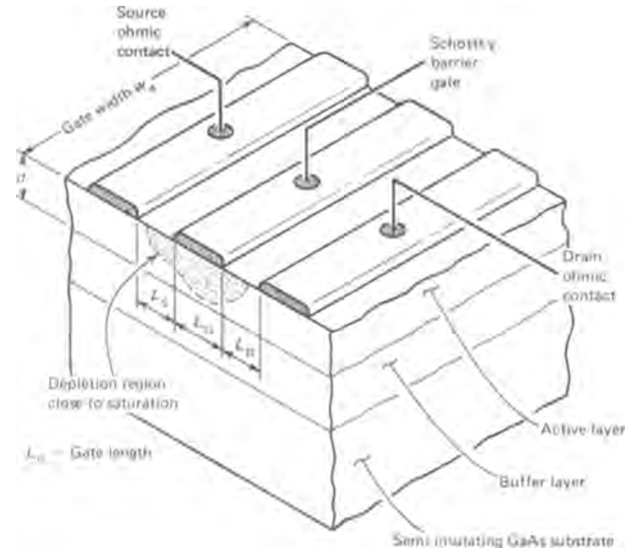

Fig. 8. Schematic cross section of a GaAs MESFET structure

of a thin ($d \approx 0.3$-0.7 μm) epitaxial layer with a net donor concentration in the 4×10^{16} cm^{-3}-2.5×10^{17} cm^{-3} range. The mobility and/or the saturated drift velocity of the electrons in this epitaxial layer is important, because for short gate devices, the cut-off frequency is directly proportional to the drift velocity. In order to grow thin epitaxial layers with the highest mobility, it is necessary to grow high resistivity buffer layers. The buffer layer is more important, however, for low noise performance than it is for high frequency response. This is presumably due to excess noise from traps in the semi-insulating substrate that is minimized when high purity buffer layers with trap concentrations much lower than in the substrate are used. These buffer layers, as well as the active layer, are usually grown using the H_2-Ga-$AsCl_3$ VPE growth technique described previously, but modified (116) to permit easy control of the resistivity of the grown layers by using the $AsCl_3$ mole fraction effect for reducing the residual background doping level in the buffer layer (117). The high resistivity buffer layers are obtained in this technique through compensation by out-diffusion of acceptor impurities from the semi-insulating substrate during growth.

The other factor that strongly influences the frequency response of the MESFET is the effective gate length. For low noise microwave FET's, the current state-of-the-art gate length is about 0.5 μm, which is obtained using 10:1 reduction optical projection photolithography. The layout and a SEM photograph of the gate structure of a low noise GaAs MESFET fabricated at Bell Laboratories are shown in Fig. 9 (118). The device consists of two 250 μm wide, 0.6-0.8 μm long Al Schottky-barrier gates. The source-drain spacing is about 3 μm. The structure of high power MESFET's is similar, except that the gate lengths are not so short (typically $\sim$2 μm) and the total gate width, which varies from 1 to about 15 mm, is obtained with multiple gates about 250 μm wide. Other laboratories or companies utilize similar structures. Buffer layers are almost always used in low noise microwave devices utilizing vapor phase epitaxial active layers, but not necessarily for high power devices. However, the use of buffer layers in power devices eliminates the "looping" often observed in d-c current-voltage characteristics, presumably because of fewer traps in the active layer when buffer layers are used. Very good low noise results have also been obtained by several laboratories (Avantek, Hughes, and Rockwell) with MESFET's fabricated from bulk semi-insulating GaAs in which the conducting channels have been formed by direct ion implanation (sulfur for example) into "specially qual-

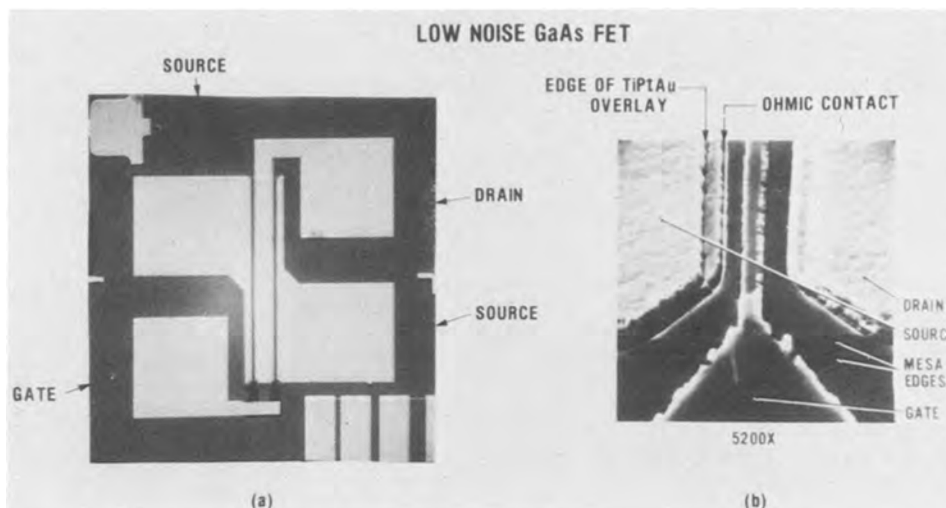

Fig. 9. Layout and high magnification SEM photograph of the gate structure of a low noise GaAs MESFET fabricated at Bell Laboratories (provided by J. V. DiLorenzo).

ified" Cr-doped wafers. This would clearly be a desirable way of fabricating MESFET's, and much work is in progress to develop reliable Cr-doped bulk semi-insulating material. MBE is another obvious crystal growth method that is particularly well suited to the preparation of thin epitaxial layers as required for GaAs MESFET's, but noise figure results so far indicate the MBE material is inferior to both VPE and ion-implanted material.

Since the short gate microwave MESFET's are really hot electron devices, and since the cut-off frequency of these devices for a given geometry is usually determined by the drift velocity, there is the possibility that InP might be an even more suitable microwave FET material than GaAs. The peak carrier velocity for InP is about 25% greater than for GaAs, even at the doping levels ($n \approx 10^{17}$ cm^{-3}) used for FET channels. There have been some preliminary results on InP MESFET's (119) which indicated a cut-off frequency about 1.5 times higher than GaAs, but other properties (noise figure, gate-drain capacitance) were inferior to GaAs MESFET's. There is a considerable effort in many different laboratories to develop higher quality InP material and low noise microwave InP FET's. Other even less well developed materials, such as particular compositions of the quaternary InGaAsP (120), may be even more suitable for high frequency FET's because of the possibility of still higher peak drift velocities. There is currently considerable work on this quaternary semiconductor to develop the required materials technology.

New Developments

The recent improvement in GaAs, GaAlAs, and InP materials preparation has been both produced by the needs of the laser, LED, Gunn effect, IMPATT, and FET device applications discussed and has in turn been responsible for the advances in performance of these devices. Although it is still not possible to prepare GaAs material as uniform over large areas or as cheap as Si, the rapid advances that have been made in III-V crystal growth make it possible to consider new applications that were previously unreasonable.

One of the most exciting and potentially most important of these applications is in digital integrated circuits (121) that employ the high speed GaAs MESFET's described above. In these circuits, the high electron mobility and majority carrier operation have made possible switching speeds of less than 100 psec and, equally important, these switching speeds have been obtained at very low power levels, as low as 0.5 mW/gate. Equally low power requirements have also been obtained using enhancement-mode GaAs JFET's or MESFET's (122), although the experimental switching speeds obtained with this approach have not been quite as good.

For compatibility with large scale integrated (LSI) digital circuits, it is important that the MESFET threshold voltage be very uniform, and that different active regions can be fabricated and isolated on the same chip as is done in Si LSI circuits. Both of these requirements have been met using ion-implantation into insulating GaAs substrates (123). In developing GaAs digital integrated circuits that are compatible with LSI, workers at Rockwell have utilized Schottky diode-FET logic, which employs very small, low capacitance Schottky diodes for most logic functions. Where inversion and/or gain is required, GaAs MESFET's are used. The use of diode logic is desirable for LSI, because diodes are very small and require only a fraction of the chip area necessary for MESFET's. The ion-implantation fabrication process developed by Rockwell utilizes two different types of implants—one optimized for the Schottky barrier logic diodes, and the other optimized for the GaAs MESFET channels. The ion implantation masks used for these integrated circuits are arranged so that the source and drain contacts of the MESFET's, and similarly the cathode contacts of the logic diodes, receive both implants, thus yielding maximum doping in these areas. Schottky diode MESFET ring oscillators have been built with propagation delays as low as 82 psec and with speed-power products in the 200-250 fJ range. These preliminary results indicate the potential of LSI GaAs technology in high speed processor or computer applications that cannot be satisfied by higher power and/or lower speed Si digital circuits. There will undoubtedly be many rapid advances in this technology.

Another successful Si "device" that has not been feasible previously in GaAs because of material limitations, but now shows promise, is the charge coupled device or CCD (124). Silicon CCD's are finding wide applications in semiconductor memories and in imaging applications. The maximum clocking frequency in CCD's must be low enough to accomplish complete charge transfer between adjacent wells within one clock period. Since the electric field between the potential wells is small, the carrier transfer is limited by the low field electron mobility rather than the saturated drift velocity. Thus the higher electron mobility of GaAs and other III-V compounds should make higher speed CCD devices possible. Clock frequencies as high as several hundred MHz are used for Si CCD's; cooled Si CCD's, with higher electron mobility, have been operated at frequencies approaching 1 GHz (125). For CCD's to be useful, however, high frequency FET amplifiers on the same substrate are essential. The highly developed Si-integrated circuit technology has contributed greatly to the success of CCD's, but the relatively low cutoff frequency of Si FET's also limits the upper frequency of practical Si CCD's to about 100 MHz. The capability

of fabricating high frequency GaAs MESFET's and the high electron mobility of GaAs should make GaAs CCD's with multi-GHz clocking frequencies possible. In fact, recently a Schottky-barrier gate, buried-channel GaAs CCD has been demonstrated (126). It is certain there will be further developments in this area, and, in general, in the use of GaAs in LSI.

The rate at which "new developments" in III-V materials and devices are occurring is high and gives no hint of slowing down. No attempt will be made here to predict the wide range of future developments that are apt to occur; to some extent these have already been suggested in the material presented in this review. Just to recall several examples, MBE gives promise of making possible new classes of materials, and thus devices, that are assembled monolayer by monolayer. Within certain limits this will make possible not only thin layers but ordered rather than disordered crystals, at least in one dimension. Similarly, MO-CVD, which can probably be extended beyond GaAs and AlGaAs, is capable of producing rather amazing layered heterostructures, with individual layers well under 50Å thick. Besides being a practical way to fabricate LED devices that exhibit quantum size effects, as well as high quantum efficiencies even at low currents (0.6%, 1 mA) (38), MO-CVD has already made possible a Bragg-reflector AlGaAs-GaAs laser diode, with 28 reflecting layers on one side and 28 on the other side of the GaAs active layer, which emits a narrow beam (127). The MO-CVD crystal growth process, even in this early state of development, gives promise of leading to a large family of devices.

From the few examples cited here and the more extensive presentation above it is clear that III-V materials are already very important in electronics, and give every promise of growing further in use and importance.

There are, of course, other compound materials that are important in various applications. As explained in the beginning of this article, these materials are not considered in this review. The reader is referred to the literature, for example, Ref. (128), for examples of other compound materials that are of interest in research studies. It will be obvious that the style and character of much of this work follows what is now standard practice with III-V materials.

Acknowledgments

We are grateful to a number of our colleagues for their help in assembling this material. We wish to mention: M. G. Craford, D. L. Keune, J. A. Rossi (Monsanto Company), J. J. Coleman, J. V. DiLorenzo (Bell Laboratories), R. D. Dupuis, P. D. Dapkus (Rockwell International), and Y. S. Moroz. Also, we thank John Bardeen for some early Si history [Ref. (7)]. We wish to thank also the following agencies for support: National Science Foundation, Advanced Research Projects Agency (DoD), the Office of Naval Research, and Air Force Office of Scientific Research.
