mesitylene was employed as the solvent even at the highest sweep rates studied, showing that the iodine formed during the anodic sweep disappeared rapidly due to a chemical reaction. The anodic peak current $i_p(a)$ was proportional to the concentration of KI in all four solvents.

The unusual behavior of o-xylene can be seen further in Fig. 5 in which the cathodic peak current $i_p(c)$ is plotted against the sweep rate on a log-log scale for different concentrations of KI. As the concentration of KI increases the plots resemble more and more those obtained in benzene or ethyl benzene,

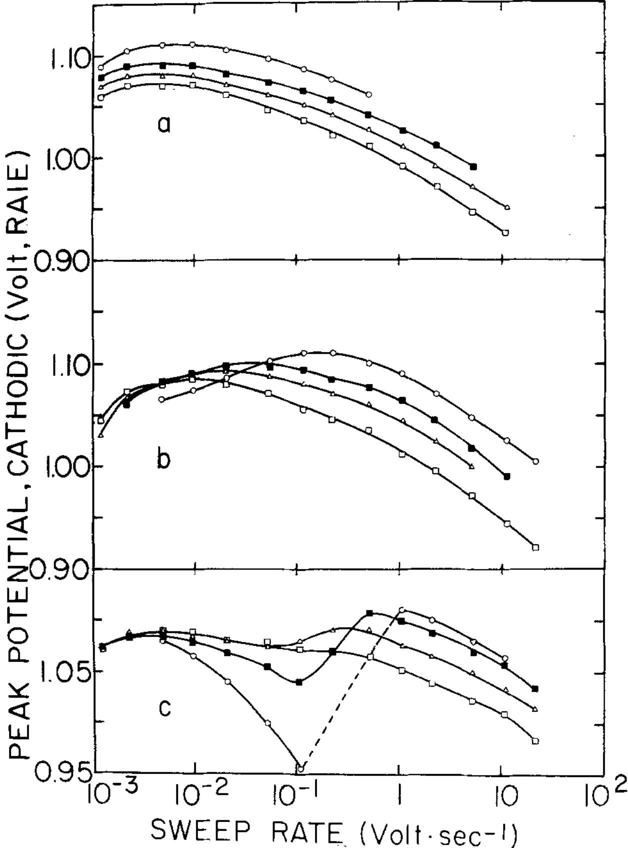

Fig. 4. The peak potential on the cathodic sweep, E_p (c), as a function of log v for: a, benzene; b, ethyl benzene; c, o-xylene. Concentrations of KI as in Fig. 3.

which are also given in the same figure for comparison.

Steady-state measurements.—Tafel plots determined at different concentrations of KI in ethyl benzene are shown in Fig. 6.[1] It can be seen that the lines are very closely parallel. The average value of the Tafel slope (based on measurements at eight concentrations of KI in ethyl benzene) was 34 ± 1 mV. The effect of the solvent on the slope is shown in Fig. 7. The Tafel slopes and reaction orders obtained in three solvents are given in Table I. All kinetic parameters were determined in the range of $i \leq 0.05 i_L$ under essentially pure activation control. In the limiting current region the reaction order was unity in all the solvents studied.

The over-all reaction.—Early experiments in cyclic voltammetry have already indicated that only part of the iodine produced during the anodic sweep was available for reduction in the following cathodic sweep, the rest being consumed in a chemical reaction. If this chemical reaction leads to regeneration of I^-,[2] one should observe an increase in the apparent value of n, the number of electrons taking part in the over-all reaction. This quantity was determined by setting the potential to a value in the limiting current region and following the decrease of current with time. Since the limiting current is proportional to the concentration, it is easy to show (25) that the current will decrease with time following the equation

$$I(t) = I^\circ \exp(-I^\circ/nFC^\circ V)t \quad [1]$$

where V is the volume of the solution, C° the initial concentration, and I° the total current extrapolated back to zero time. The parameter n is determined from the slope of a plot of log I vs. t. Such plots are shown in Fig. 8 for benzene and ethyl benzene as the

[1] For the sake of clarity only one out of three experimental points are shown in this figure.
[2] It will be shown below that this is indeed the case.

solvent. In both solvents $n > 1$ and increases with time, as would be expected for a catalytic process following charge transfer, in which the reactant is regenerated. The calculated values of n at different intervals of time after electrolysis was started are shown in Table II. When mesitylene was employed as the solvent, the apparent value of n approached infinity, *i.e.*, the current did not decrease with time.

2-17	77-69	Ethyl benzene	1.6
25-250	67-50	Ethyl benzene	8.1

chemical oxidation of I^- was a bulk reaction in which molecular iodine took place or a reaction requiring an electrochemically formed intermediate, which could only occur at the electrode surface. For this purpose a solution of I_2 in the pure solvent was added to another solution containing 1.0M Al_2Br_6 and 0.80M KBr in the same solvent, and the change of concentration of iodine with time was followed by standard analytical methods. In a typical experiment the initial concentration of I_2 was 28 mmoles. After four days at room temperature it decreased to 19 mmoles in benzene and to 5 mmoles in mesitylene. These experiments were performed in a cell which had no electrodes in it, confirming that the chemical reaction in which iodine is consumed can occur in the bulk. The possibility that it can occur faster on the electrode surface in the presence of electrochemically formed intermediate cannot be excluded, however.

Discussion

General.—The results presented above show that iodine formed electrochemically or introduced into a solution containing Al_2Br_6 and KBr in an aromatic hydrocarbon undergoes a chemical reaction. The rate of this reaction increases with increasing rate of bromination of the hydrocarbon (21, 24). This is best seen in Fig. 2, where the ratio of cathodic to anodic peak currents decreases as the initial potential for bromine evolution becomes less anodic.[3] The fact that the apparent value of n, the number of electrons taking part in the over-all reaction, is larger than unity shows that I^- is regenerated in this chemical reaction. Direct iodination of the aromatic hydrocarbon in a reaction of the type

$$I_2 + ArH \rightarrow ArI + H^+ + I^- \quad [2]$$

could fit these experimental observations. However, it is well known that iodination of aromatic hydrocarbons does not occur under the conditions of the present experiment. It is more likely that bromination will take place in a reaction sequence such as

$$2I^- \rightleftharpoons I_2 + 2e \quad [3]$$

$$2Br^- + I_2 \rightleftharpoons 2I^- + Br_2 \quad [4]$$

$$Br_2 + ArH \rightarrow ArBr + H^+ + Br^- \quad [5]$$

In aqueous solutions this reaction sequence could not proceed since it implies that Br^- is oxidized by I_2 although the oxidation potential for the Br^-/Br_2 couple is about half a volt higher than that of the I^-/I_2 couple. In the present system, however, the reversible potentials for different redox couples were shown to be much closer (17, 18, 23). Thus the initial potentials of I_2 and Br_2 evolution[4] are 1.15 and 1.45V (RAlE), respectively, if benzene is used as the solvent. In mesitylene the corresponding values are 1.11 and 1.21V (RAlE). Moreover, the reaction sequence given above could be substituted by

$$2I^- \rightleftharpoons I_2 + 2e \quad [3]$$

$$I_2 + Br^- \rightleftharpoons IBr + I^- \quad [6]$$

$$IBr + ArH \rightarrow ArBr + H^+ + I^- \quad [7]$$

Iodobromine is formed at a potential lower than that required for the formation of Br_2 (26, 27). Thus steps [4] and [6] will not be shifted completely to the left in the present system and bromination of the hydrocarbon may be expected to occur at a significant rate. It may be noted that free Br^- and I^- ions do not exist in this system (22, 23) and more complex equilibria of the type

$$Al_2Br_6 + I_2 \rightleftharpoons Al_2Br_5I + IBr \quad [8]$$

or

$$Al_2Br_7^- + I_2 \rightleftharpoons Al_2Br_6I^- + IBr \quad [9]$$

are probably involved. Since the exact nature of the negative ion is not important for the subsequent arguments, nor is it exactly known, the simple ions will be written in all further equations for brevity.

It may be concluded that electrochemical oxidation of iodide in the presence of a large excess of bromide is followed by formation of IBr or Br_2 and regeneration of I^-, along with bromination of the hydrocarbon. If mesitylene is used as the solvent the bromination reaction is so fast that all of the iodine formed is rapidly reduced back to I^-. As a result a cathodic peak cannot be observed on the voltammogram even at high sweep rates, and the apparent value of n tends to infinity. The bromination of benzene occurs several orders of magnitude more slowly. Therefore, the ratio of cathodic to anodic peak currents approaches unity at high sweep rates and n is only slightly higher than unity at short electrolysis times. The behavior of other hydrocarbons such as ethyl benzene and o-xylene falls between these two extremes.

Analysis of the cyclic voltammograms.—A detailed mathematical analysis of the shape of the voltammograms for reversible and irreversible electrochemical reactions, preceded or followed by chemical reactions, was given by Nicholson and Shain (28). One of the diagnostic criteria proposed by these authors is a plot of the "current function" $i_p(a)/C^\circ v^{1/2}$ against the sweep rate v.[5] This is shown in Fig. 9 for the four solvents studied. For a simple charge transfer process this function should be independent of sweep rate. The behavior shown in Fig. 9 is consistent, according to Nicholson and Shain (28), with either reversible or irreversible charge transfer followed by an irreversible chemical reaction which regenerated the reactant, according to the formal scheme

$$R \rightleftharpoons Ox + ne \quad [10]$$

[3] It was shown in a previous publication (21) that the initial potential for bromine evolution decreases with increasing rate constant for bromination of the hydrocarbon.

[4] The initial potentials are used here instead of the half-wave potentials or the formal potentials which were not determined. It is reasonable to assume that the difference in the initial potentials of the two redox couples is close enough to the difference in their half-wave potentials for the purpose of the qualitative argument given above.

[5] In the original paper the current function is defined as $i_p/nFC^\circ v^{1/2}D^{1/2}$. For a given system this only differs from the function employed here by a constant factor.

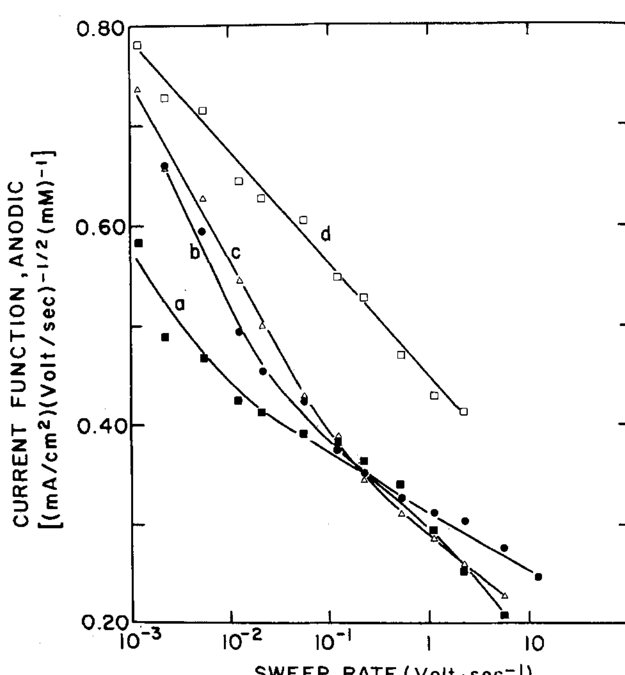

Fig. 9. Plots of the "current function," $i_p(a)/v^{1/2} C^\circ$, against log v in four solvents at C_{KI} = 7.9 mmoles. Curve a, benzene; curve b, ethyl benzene; curve c, o-xylene; curve d, mesitylene.

$$Ox + Z \rightarrow R \quad [11]$$

In the present system this would correspond to step [3] followed by steps [4] and [5] (or [6] and [7]) combined.[6]

A similar case in which charge transfer is preceded by adsorption of the reactant was also treated mathematically (29). It was shown that the "current function" should increase with increasing rate constant of the chemical step following charge transfer. It can be seen in Fig. 9 that the "current function" is highest for mesitylene and lowest for benzene, which is to be expected if bromination of the solvent is involved in the chemical step following charge transfer.

It may be noted (cf. Fig. 2) that the anodic peak current for mesitylene is significantly higher and occurs at a less anodic potential than for the other three solvents. This shows that the chemical reaction following charge transfer is too slow to effect significantly the concentration of I_2 and regenerate a noticeable amount of I^- during the anodic sweep in all cases except when mesitylene is used as the solvent.

In conclusion it can be seen that the oxidation of iodide and subsequent bromination of the solvent in the present system is a complex process, and only qualitative conclusions can be drawn from cyclic voltammetry. It appears that: (*i*) the reactant (I^-) is adsorbed on the surface, (*ii*) the product (I_2) reacts further chemically, (*iii*) the reactant is regenerated in this chemical reaction, and (*iv*) the rate of the chemical reaction depends strongly on the solvent in the order: mesitylene $>>$ o-xylene $>$ ethyl benzene $>$ benzene.

Steady-state measurements.—Tafel plots obtained under steady-state conditions are shown in Fig. 6 and 7. The Tafel slopes and reaction orders (with respect to KI) are given in Table I. Several closely related mechanisms can give rise to the observed kinetic parameters and are also consistent with other experimental findings, namely the regeneration of I^- in the chemical reaction following charge transfer and the order of reactivity of the solvent molecules. One of these mechanisms will be treated in detail below.

The reaction pathway.—Consider the reaction sequence given in the following equations

$$M + I^- \overset{K_1}{\rightleftharpoons} MI^- \quad [12]$$

$$2MI^- \overset{K_2}{\rightleftharpoons} MI_2^- + M + e \quad [13]$$

$$MI_2^- + Br^- \overset{k_3}{\rightarrow} MI_2Br^- + e \quad [14]$$

$$MI_2Br^- + ArH \overset{k_4}{\rightarrow} M + 2I^- + H^+ + ArBr \quad [15]$$

where M represents a site of the surface, and from the condition of quasi-equilibrium in step [12] one has

$$\frac{\theta_{MI^-}}{1-\theta} = K_1 C_{I^-} \exp - g(\theta) \quad [16]$$

in which the function $g(\theta)$ is the rate of change of the apparent standard free energy of adsorption with coverage

$$g(\theta) \equiv \partial \Delta G^\circ_{ads}/\partial\theta \quad [17]$$

and θ without a subscript is the sum of the fractional coverage by all adsorbed species. At intermediate values of the coverage, where the Temkin isotherm applies, Eq. [16] can be written approximately (30, 31) as

$$\exp g(\theta) = K_1 C_{I^-} \quad [18]$$

[6] A scheme in which the irreversible chemical reaction following charge transfer does not regenerate the reactant would also lead to a similar dependence of the "current function" on sweep rate, but this is excluded on the basis of the other experimental evidence discussed above.

similarly for quasi-equilibrium in step [13] one has

$$\frac{\theta_{MI_2^-}}{\theta_{MI^-}{}^2} = K_2 \exp(\Delta\phi \mathbf{F}/RT) \exp g(\theta) \quad [19]$$

Note that the sign of the function $g(\theta)$ in the exponent is negative in Eq. [16] and positive in Eq. [19]. This arises because step [12] is an adsorption step, which is slowed down as the surface coverage increases while step [13] is a desorption step which is enhanced by increasing the coverage.

The mechanism in mesitylene.—Assume that step [14] in the above reaction sequence is the rate-determining step. The rate equation will be

$$v_3 = k_3 \theta_{MI_2^-} C_{Br^-} \exp(\beta\Delta\phi\mathbf{F}/RT) \quad [20]$$

If coverage is mainly by I^-, *i.e.*, $\theta_{MI^-} \sim \theta$ and $\theta_{MI_2^-} << \theta_{MI^-}$, we can rewrite the rate equation combining Eq. [18]-[20] as

$$v_3 = k'_3 C_{Br^-} C_{I^-} \exp[(1+\beta)\Delta\phi\mathbf{F}/RT] \quad [21]$$

where k'_3 is a combined constant and the change of the pre-exponential term in θ_{MI^-} has been neglected compared to the change in $\exp g(\theta)$ over the potential region where a linear Tafel plot is observed (30, 31). Equation [21] corresponds to a reaction order (ρ_{I^-}) of unity with respect to KI and a Tafel slope of

$$b = 2.3RT/(1+\beta)\mathbf{F} \sim 40 \text{ mV} \quad [22]$$

in excellent agreement with the observed values of $b = 40 \pm 1$ mV and $\rho_{I^-} = 1.1 \pm 0.1$ given in Table I. Bromination of mesitylene occurs very rapidly (21, 24) and thus step [15] could not be rate determining when this solvent is employed.

The mechanism in ethyl benzene.—The rate of bromination of ethyl benzene is much slower than that of mesitylene and this process (*i.e.*, step [15]) may reasonably be expected to become rate determining. The resulting rate equation will be

$$v_4 = k_4 \theta_{MI_2Br^-} C_{ArH} \exp[\alpha g(\theta)] \quad [23]$$

In this case step [14] can be regarded at quasi-equilibrium, yielding

$$\frac{\theta_{MI_2Br^-}}{\theta_{MI_2^-}} = K_3 C_{Br^-} \exp(\Delta\phi\mathbf{F}/RT) \quad [24]$$

substituting $\theta_{MI_2Br^-}$ in Eq. [23] from Eq. [24] and combining with Eq. [18] and [19]; assuming that I^- is still the main species on the surface and its adsorption follows the Temkin isotherm at intermediate values of coverage; lead to

$$v_4 = k'_4 C_{Br^-} C_{I^-}{}^{(1+\alpha)} \exp(2\Delta\phi\mathbf{F}/RT) \quad [25]$$

Equation [25] leads to a Tafel slope of 30 mV and a reaction order of 1.5 in good agreement with the values of $b = 34 \pm 1$ mV and $\rho_{I^-} = 1.4 \pm 0.1$ found experimentally (cf. Table I).

The mechanism in benzene.—In this solvent the rate of bromination is very slow and step [15] does not occur to a sufficient extent to effect the observed kinetic parameters. If the species I_2Br^- (which is stable in solution) is not removed from the surface by subsequent reaction with the solvent (as in the previous two cases) it may be expected to leave the surface in the oxidation step itself, leading to a slightly modified form of step [14],[7] namely

$$MI_2^- + Br^- \rightarrow M + I_2Br^- + e \quad [14a]$$

If this step is assumed to be rate determining, the rate equation will take the form

$$v'_3 = k_3 \theta_{MI_2^-} C_{Br^-} \exp(\beta\Delta\phi\mathbf{F}/RT) \exp[\alpha g(\theta)] \quad [26]$$

[7] This step may occur to some extent in the case of ethyl benzene leading to a slightly increased Tafel slope.

Combining Eq. [26] with Eq. [18] and [19] and making the same assumptions with respect to coverage by the different intermediates as in the above two cases we have

$$v'_3 = k'_3 C_{Br^-} C_{I^-}^{(1+\alpha)} \exp [(1+\beta)\Delta\phi \mathbf{F}/RT] \quad [27]$$

This leads to a Tafel slope of 2.3 $RT/(1+\beta)\mathbf{F} \sim 40$ mV and a reaction order of $(1+\alpha) \sim 1.5$ in excellent agreement with the experimentally observed values of $b = 39 \pm 3$ mV and $\rho_{I^-} = 1.6 \pm 0.1$ shown in Table I.

Alternative mechanisms.—Small variations in the above reaction sequence can lead to the same kinetic parameters and hence cannot be distinguished on the basis of the experimental results available. These include replacement of step [13] by

$$MI^- + I^- \rightleftharpoons MI_2^- + e \quad [13a]$$

all other steps being unchanged. Similarly, replacing step [13a] by

$$MI^- + Br^- \rightleftharpoons MIBr^- + e \quad [13b]$$

followed by

$$MIBr^- + I^- \rightarrow MI_2Br^- + e \quad [14b]$$

does not affect the kinetic parameters. These, however, are only minor variations of the basic reaction sequence which involves: (*i*) adsorption of I^-, (*ii*) oxidation to MI_2^- or $MIBr^-$, (*iii*) further oxidation to MI_2Br^-, and (*iv*) bromination of the hydrocarbon and regeneration of I^-. The first two steps are fast and the third or fourth steps are rate determining, depending on the ease of bromination of the aromatic solvent.

Conclusions

The oxidation of iodide in a solution of Al_2Br_6 and KBr in aromatic hydrocarbons proceeds with initial adsorption of I^- on the electrode surface. The iodine formed reacts partially with Br^- or other bromide-containing species such as $Al_2Br_7^-$ to form Br_2 or IBr which react with the aromatic solvent to brominate it. This unusual process of oxidation of Br^- by iodine is possible because of the small differences in the standard potentials of different redox couples in this solvent system, as discussed earlier (17, 18, 23). Iodide is regenerated in the chemical reaction following its electrochemical oxidation to iodine. Reduction of iodine and bromination of the solvent can occur also as a chemical bulk reaction, although it is probably catalyzed by the electrochemical pathway. The qualitative mechanistic information obtained from analysis of the cyclic voltammograms is confirmed by considering the Tafel slopes and reaction orders measured under steady-state conditions.

Galvanostatic Transients in Lutetium Diphthalocyanine Films

M. M. Nicholson* and F. A. Pizzarello

Rockwell International, Electronics Research Center, Anaheim, California 92803

ABSTRACT

The anodic oxidation of lutetium diphthalocyanine films on tin oxide in 1M KCl was investigated by a galvanostatic transient technique. The reaction was monitored by simultaneous measurement of the optical transmission. At current densities of 0.3-6 mA/cm^2, the kinetics was controlled by an ionic space charge in the red oxidation product. A dielectric constant of 10 was estimated for this material, using the solid-state mobility of the chloride ion determined in a previous moving-boundary study.

A rare earth diphthalocyanine film in contact with an aqueous electrolyte undergoes a series of faradaic reactions that cause pronounced color changes. The dependence of color on potential was first reported by Moskalev and Kirin, who examined a film of lutetium diphthalocyanine [$LuH(Pc)_2$] on a tin oxide electrode of unspecified resistance (1, 2). The electrolyte was 0.1M KCl. We subsequently investigated this system for electrochromic display applications (3, 4). It was found that the color changes could occur in milliseconds under potentiostatic pulses when the substrate resistivity was approximately 10 Ω/square. This is a fast response for an electrode process converting one insoluble organic material to another as a layer about 50 molecules thick.

A lutetium diphthalocyanine film is initially green. It can assume four or five discrete color forms, depending on the oxidation state of the complex. To account for the fast electrode kinetics, we proposed that all of these forms were electrically conductive in the solid state. $NdH(Pc)_2$ was already known to be an electronic conductor (5). In a recent study by a moving-boundary technique, we showed that the red oxidation product of $LuH(Pc)_2$ prepared with a potassium chloride or a sodium sulfate electrolyte was also conductive (6). Those experiments were performed with the dye film on an insulating alumina substrate instead of tin oxide. Only the end of the film was immersed in the electrolyte. Under constant applied current, a red/green boundary generated at the electrolyte contact travelled upward along the dry film a distance of several millimeters. The experiments took about two hours because the film resistance was high in the direction of current flow. The charges used in the coloring process corresponded approximately to a 2-electron oxidation of $LuH(Pc)_2$ in both electrolytes. Carrier concentrations and mobilities determined in the oxidation products suggested that the red materials were solid anion conductors. For a chloride solution contact, the proposed reaction was

$$LuH(Pc)_2 + 2Cl^- \rightarrow LuH(Pc)_2 \cdot 2Cl + 2e$$

The chloride ions which entered the solid to compensate the lost electrons then remained as charge carriers with a room temperature mobility of 4×10^{-6} $cm^2/Vsec$. A later investigation with radioactive chloride confirmed the presence of the anion in the red film at a ratio of approximately 1.5 anions to one molecule of dye (7). Thus the proposed oxidation mechanism was verified.

This paper reports a kinetic investigation of the same electrode process on tin oxide in 1M KCl by a galvanostatic pulse technique. The electrode potential and the optical transmittance of the film were monitored simultaneously during the pulse. Since the film was completely immersed in the electrolyte and the direction of current flow was perpendicular to the film surface, the color conversion was completed in times ranging from milliseconds to seconds. The transients are discussed in relation to several physical models for the rate-controlling process. It will be seen that the data for current densities up to 6 mA/cm^2 conform to equations based on control by an ionic space charge in the dye film.

Experimental

Working electrodes were prepared by vacuum sublimation of lutetium diphthalocyanine dye onto a Corning tin oxide-glass substrate (6). The tin oxide layer, which was produced chemically by a fog process, had a sheet resistivity of 10-15 Ω/square. The weight of dye per unit area and the approximate film thickness were determined from the optical density in the initial green state at the absorption maximum near 670 nm (3). The dye was deposited over the entire front surface of a 1.25 × 5 cm tin oxide plate. An active electrode area within this plate was defined and electrically contacted in two different ways. For initial experiments, a metal contact was made at the top of the plate, and most of the area below was insulated from the electrolyte by Apiezon W wax applied directly over the dye. A window of dye about 1.5 cm^2 in area remained exposed near the lower end. This electrode is designated as one with an upper SnO_2 contact. A lower resistance working electrode was needed for more detailed transient studies. Its structure is shown in Fig. 1(a). In this case, a gold film was sputtered over the dye surface, leaving only a window approximately 0.6 × 1.0 cm for the active area. Apiezon W was applied on top of the gold, except for a strip at the upper end of the plate, which served as the electrical contact. This electrode is identified as one with a peripheral Au contact. The estimated series resistance in the tin oxide was 3-6Ω with the peripheral contact and 25-35Ω with the upper SnO_2 contact.

The reference and counterelectrodes were both Ag/AgCl strips prepared by anodizing porous silver in 1M KCl. The porous silver was obtained by thermally decomposing a layer of Ag_2O that had been spread on a silver ribbon approximately 0.5 cm wide.

For the electro-optical measurements, the electrodes were assembled in a flat-sided glass Klett colorimeter cell containing air-saturated 1M KCl. The cell and instrumentation were arranged as shown in Fig. 2. The light source was a tungsten-filament microscope lamp operated with a regulated d-c power supply. Between the source and the cell was a Bausch and Lomb high-intensity monochrometer, Kaelite Corporation Model 7400PR, set at 670 nm. The transmitted light was monitored with an EG&G silicon photodetector having a rise and decay time of 100 nsec. To minimize extraneous electrode processes, the PAR 173 galvanostat was programmed to provide a single current pulse only slightly longer than the time required to complete the green-to-red transformation. The potential of the working electrode and the output of the photodetector

were recorded simultaneously during the pulse on a Tektronix 564B dual-trace storage oscilloscope equipped with a Polaroid camera. After each pulse, the working electrode was returned to the Ag/AgCl potential in 1M KCl by manually shorting it to the counterelectrode. The color thereupon returned to a green shade.

Results and Discussion

The data and results are summarized in Table I. Transients recorded for both types of electrode structures are shown in Fig. 3. At current densities up to 66 mA/cm^2, the voltage curve had a transition typical of a material depletion process. Since the optical transmission reached a maximum level at about the same time, it can be surmised that the transition marked the end of the dye reaction. Curves of the type shown in Fig. 3(a), for a peripheral-contact electrode at relatively low current density, were amenable to detailed interpretation. The electrical transition time τ_{elec} was measured from the beginning of the stored oscilloscope trace to the intersection point of tangents drawn to the sloping and final plateau portions of the curve. Under conditions of Fig. 3(b), the ohmic effect in the tin oxide was much larger and probably time-dependent due to nonuniformity of the current density

over the electrode surface (8). Although the transition time should have had its usual significance in such cases, the voltage curve was subject to distortion, and the optical curve may also have been influenced. In the following discussion, the optical response is first analyzed to determine the transition time, independent of that found electrically. The kinetics of the dye electrode process is then considered.

The optical transient.—The optical transient, represented by the lower curve in Fig. 3(a), was converted to linear form by application of Beer's law. Two models of the reacting film may be considered for this purpose.

In the first case, the reactant and product molecules are assumed to be uniformly mixed at the respective volume concentrations c_1 and c_2 in a film of constant thickness l. Then

$$c_1 + c_2 = c_0 \qquad [1]$$

where c_0 is the initial concentration of dye in the film. If the corresponding molar extinction coefficients at the selected wavelength are e_1 and e_2, the total optical density D of the film at a time t following application of the current is given by

$$D = (e_1c_1 + e_2c_2)l \qquad [2]$$

From Eq. [1] and [2]

$$dD/dt = (e_2 - e_1)l \cdot dc_2/dt \qquad [3]$$

Since dc_2/dt is constant at constant current density, dD/dt is also constant, and the optical density at time t may be expressed as the linear function

$$D = e_1c_0l + (dD/dt)t \qquad [4]$$

where e_1c_0l is the optical density of the film before the current is applied.

The second model is that of two optical filters in series. This corresponds to the case in which a sharp reaction boundary moves through the film in the direction of current flow, as depicted in Fig. 1(b). Then the optical density of the film is given by

$$D = e_2c_0x + e_1c_0(l - x) \qquad [5]$$

where x is the thickness of the converted layer. Hence

$$dD/dt = (e_2 - e_1)c_0\, dx/dt \qquad [6]$$

In the mixture model, the amount of dye converted in a time dt is expressed as $l\ dc_2$. In the moving-boundary model, the same quantity of material is converted, but it is given by c_0dx. Therefore, Eq. [3] and [6] can be reduced to the common form

$$dD/dt = 10^{-3}(e_2 - e_1)I/(n\mathbf{F}) \qquad [7]$$

where I is the magnitude of the current density in A/cm^2, n is the number of electrons transferred per molecule of dye, and $\mathbf{F}$ is the faraday. The uniform-mixture and moving-boundary cases therefore could not be distinguished on the basis of the optical data. The optical transient was used, however, to confirm the constancy of the color-conversion rate and to obtain an independent value of the transition time. The analysis is as follows.

It can be shown that the change in optical density of the cell at time t due to the dye reaction is given by

$$\log (T_\tau/T_t) = (t - \tau)dD/dt \qquad [8]$$

where T_τ is the measured limiting intensity of transmitted light following the color transition at time τ, and T_t is the intensity in the interval $0 \leq t \leq \tau$. A plot of $\log (T_\tau/T_t)$ *vs.* t should therefore be a straight line with a slope equal to dD/dt in Eq. [7] and an intercept on the t-axis equal to the transition time.

An experimental plot of this type is shown in Fig. 4. The optical transition time τ_{opt} of 1.2 sec found by extrapolation is comparable to the electrical transition time τ_{elec} of 1.5 sec for the same experiment.

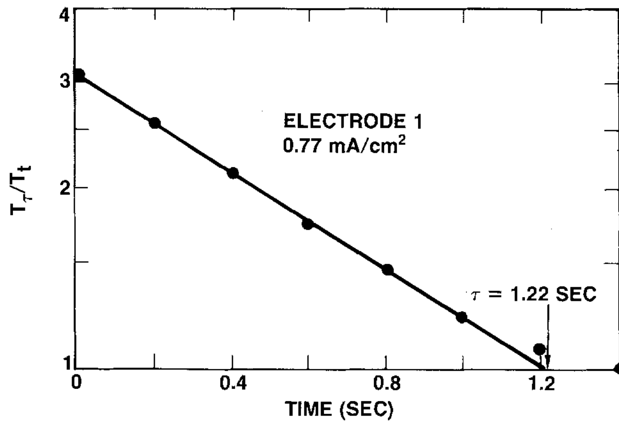

Fig. 4. Determination of optical transition time

The electrical transient.—Each potential-time curve began with a sharp rise that included terms due to the ohmic resistance of the electrode, any significant faradaic resistance, and any fast-charging capacitance in the electrode system. A thermodynamic potential arising from creation of a new red/green boundary within the organic solid would also be established at the outset of the conversion process. We shall not attempt to analyze the earliest part of the transient in this discussion. The primary objective is to account for the time dependence of potential as the reaction proceeds to completion. Five models are considered for the rate-controlling mechanism: concentration polarization in the liquid electrolyte, ionic charge transfer at the electrolyte/dye interface, a solid-solution film acting as a reversible couple, a two-layer film behaving as variable ohmic resistors in series, and a two-layer space-charge model.

Concentration change in electrolyte.—Since chloride ion is utilized in the faradaic reaction of the dye, the possibility of a significant voltage shift due to depletion of the anion in the liquid phase must be examined. This effect may be calculated from equations developed by Morris and Lingane for chronopotentiometry in the absence of a supporting electrolyte (9). In KCl, the concentration of chloride ion at an electrode surface where it is consumed is given by

$$C^{\circ}_{Cl^-}(0,t) = C^{\circ}_{KCl} - \frac{I}{FD_{Cl^-}}\left(\frac{D_{KCl}}{\pi}\right)^{1/2} \cdot t^{1/2} \quad [9]$$

in which C°_{KCl} is the bulk concentration of the salt and D_{Cl^-} and D_{KCl} are diffusion coefficients with the respective values of 2.03×10^{-5} and 2.00×10^{-5} cm^2/sec (at infinite dilution) (10).

At the highest current density used in the present work (265 mA/cm^2), the transition time for the dye reaction was 7 msec. For those conditions, Eq. [9] indicates that the ratio of surface to bulk concentration of chloride ion was 0.97. The corresponding shift in equilibrium potential at the interface between the red film and the electrolyte should have been only 0.86 mV. Since the observed change was $>$ 1V in most cases, it is evident that mass-transfer overvoltage at the liquid interface made no appreciable contribution to the potential-time curve.

Ionic charge transfer at the electrolyte interface.—If the transfer of chloride ion across a potential barrier at the dye/solution interface were controlling, the current density might be expressed, at moderate to large overvoltages, by the equation

$$I = FC_{Cl^-} \cdot k_f \quad [10]$$

in which k_f is a potential-dependent heterogeneous rate constant for the forward reaction, and C_{Cl^-} is the constant chloride ion concentration on the liquid side of the interface. For this case, the potential shift ΔE should be a linear function of log I, with a Tafel slope of the order of 50 mV. Moreover, the value of ΔE should remain fixed during a given pulse, once a steady-state condition is established at the electrolyte interface. The observed transients in the lower current series (Electrodes 1 and 2) had quite different characteristics. The potential was almost independent of current density near the beginning of the pulse, and it rose continuously during the color conversion.

Solid-solution film acting as reversible couple.—It was shown above that a two-layer dye film could not be distinguished from a solid-solution film by means of the optical transient. Such a distinction is feasible, however, with the electrical transient. For the solid-solution case, the red component may be defined as the organic cation plus a stoichiometric quantity of chloride ion. The chloride concentration in the liquid phase will again be denoted by C_{Cl^-}, while c_g and c_r will represent the concentrations of the green and red components in the solid film. Since C_{Cl^-} is almost constant during the current pulse, the time dependence of the electrode potential arises from the variations of c_g and c_r.

If the faradaic process is reversible, and activities are assumed equal to concentrations, the electrode potential $E_{g/r}$ should be given by the Nernst equation

$$E_{g/r} = E^{\circ}_{g/r} + (RT/nF)\ln[c_r/(c_g \cdot C_{Cl^-}{}^{n})] \quad [11]$$

in which $E^{\circ}_{g/r}$ is a standard potential of the green/red dye couple with respect to the Ag/AgCl electrode. Since

$$c_r = c_o(t/\tau) \text{ and } c_g = c_o[(1 - t/\tau)] \quad [12]$$

a potential-time curve may be calculated from Eq. [11], taking $n = 2$. The predicted potential change in the interval $0.1 \leq t/\tau \leq 0.9$ is 0.056V, regardless of the current density. From Fig. 3(a), it is obvious that this model does not fit the experimental data; the actual potential change was about 20 times larger.

Two variable ohmic resistors in series.—In the moving-boundary study of lutetium diphthalocyanine, the red and green films on alumina had lengths of the order of 1 cm. They were treated as two ohmic resistors in series (6). Approximate bulk resistivities of both phases and the carrier concentration in the red phase are known from that work. Since the current path in the present experiments was about five orders of magnitude shorter, a departure from ohmic behavior due to higher fields would not be surprising. However, it is essential to know the time-dependent voltage drop that would occur in such a thin film if it conformed to a two-layer ohmic model represented by Fig. 1(b). This drop, ΔE_{ohmic}, is given by

$$\Delta E_{ohmic} = Il\,[\rho_g + (\rho_r - \rho_g)(t/\tau)] \quad [13]$$

where ρ_r and ρ_g are bulk resistivities with the respective values of 1300 and 370 Ω-cm (6). A film with a thickness l of 1×10^{-5} cm and a current density of 6 mA/cm^2 may be taken as an example. Equation [13] predicts for this case an initial potential jump of 0.02 mV at $t = 0$, while the film is all green, and a final ohmic drop of 0.08 mV at $t = \tau$, when it is all red. The difference between these values is insignificant compared to the potential increase of $\sim$1V observed for Electrode 1 under such conditions.

Two-layer space-charge system.—Referring again to Fig. 1(b), we may envision two space-charge layers, rather than two ohmic resistors, in series. A related model was used by Faughnan, Crandall, and Lampert to describe the bleaching of a tungsten oxide electrochromic film (11). They developed equations for a single predominant space-charge layer with a thickness that increased continuously under constant applied voltage. Here, we consider two space-charge layers as a more general case and assume the condition of constant applied current density.

The time-dependent part ΔE_t of the total potential change is given by

$$\Delta E_t = \Delta E_1 + \Delta E_2 \quad [14]$$

where ΔE_1 is the potential drop across the reactant layer (green) and ΔE_2 is the drop across the product layer (red). As in the resistance model, the time dependence arises from variation of the layer thicknesses as the boundary propagation distance x increases.

At a constant current density I, the boundary velocity is given by

$$\frac{dx}{dt} = \frac{I}{z_i c_i F} \quad [15]$$

where c_i is the volume concentration of the ion incorporated in the solid reaction product and z_i is the magnitude of its valence.

It will be assumed, as an approximation, that each layer has a square-law current-voltage characteristic,

If the reactant layer is a one-carrier material conforming to Child's law

$$\Delta E_1^2 = \frac{I}{\kappa_1 \epsilon_0 \mu_1} \cdot (l - x)^3 \quad [16]$$

A similar equation for the product layer is

$$\Delta E_2^2 = \frac{I}{\kappa_2 \epsilon_0 \mu_2} \cdot x^3 \quad [17]$$

In Eq. [16] and [17], μ_1 and μ_2 are carrier mobilities; κ_1 and κ_2 represent dimensionless dielectric constants, and ϵ_0 is the permittivity of space (8.85×10^{-14} f/cm).

Equation [16] should apply to a simple one-carrier electronic conductor. The rationale for using Eq. [17] in this instance is more complex, since the red layer is a special type of double-injection system. Anions are injected at the solution interface, while positive charges are generated at the red/green reaction boundary. We may regard the latter process as injection of holes that are immediately trapped to form organic cations. The injected anions are mobile, however. A double-injection system in which one of the carriers is strongly trapped can behave in accordance with Child's law (12). For that model, Eq. [17] should be applicable to the red layer, and μ_2 should closely approximate the mobility of the chloride ion.

Noting from Eq. [15] that the propagation distance and the transition time are related by

$$x/l = t/\tau \quad [18]$$

we find from Eq. [14]-[17] that

$$\Delta E_t = \left(\frac{z_i c_i \mathbf{F}}{\kappa_2 \epsilon_0 \mu_2 \tau}\right)^{1/2} l^2 \left[(t/\tau)^{3/2} + (1 - t/\tau)^{3/2} \cdot \left(\frac{\kappa_2 \mu_2}{\kappa_1 \mu_1}\right)^{1/2} \right] \quad [19]$$

For convenience, a dimensionless potential Φ may be defined by

$$\Phi = \frac{\Delta E_t}{\Delta E_\tau} = \frac{\Delta E_t}{\left(\frac{z_i c_i \mathbf{F}}{\kappa_2 \epsilon_0 \mu_2 \tau}\right)^{1/2} \cdot l^2} \quad [20]$$

Then, with Eq. [19]

$$\Phi = (t/\tau)^{3/2} + (1 - t/\tau)^{3/2} \cdot \left(\frac{\kappa_2 \mu_2}{\kappa_1 \mu_1}\right)^{1/2} \quad [21]$$

Equation [21] predicts the shape of the galvanostatic transient for different values of the mobility parameter $(\kappa_2\mu_2)/(\kappa_1\mu_1)$. Figure 5 shows a family of these curves, which have several distinctive features. All are concave away from the time axis, and all converge, by definition, at $\Phi = 1$ when $t = \tau$. The function Φ reaches a minimum at a time t_{min} given by

$$\frac{t_{min}}{\tau} = \left(\frac{\kappa_2 \mu_2}{\kappa_1 \mu_1 + \kappa_2 \mu_2}\right) \quad [22]$$

or, if $\kappa_1 = \kappa_2$, by

$$\frac{t_{min}}{\tau} = \left(\frac{\mu_2}{\mu_1 + \mu_2}\right) \quad (\kappa_1 = \kappa_2) \quad [23]$$

Hence, when $(\kappa_2\mu_2)/(\kappa_1\mu_1)$ is zero, the voltage transient starts from the origin, with zero initial slope. If this ratio is larger than zero, the potential rises at $t = 0$ when the current is applied, then decreases and passes through a minimum. When $(\kappa_2\mu_2)/(\kappa_1\mu_1)$ is unity, the minimum potential occurs at $t/\tau = 0.5$.

The potential transient in Fig. 3(a) is typical of the low-current data for lutetium diphthalocyanine. Concavity away from the time axis is evident through most of the reaction period, and no decrease in potential occurs. This shape is characteristic of a space-charge system with a much higher $\kappa\mu$ in the reactant phase than in the product.

The data may be presented in other forms for quantitative comparisons with the space-charge model. It is known from previous work that the red product is an ionic conductor with a carrier mobility of 4×10^{-6} cm^2/Vsec, and the green reactant is an electronic conductor. To a good approximation, therefore

$$\frac{\mu_i}{\mu_e} = 0 = \frac{\kappa_2 \mu_2}{\kappa_1 \mu_1} \quad [24]$$

where μ_i and μ_e are the ionic and electronic mobilities. Equation [19] then reduces to Eq. [17], which is Child's law for the red layer. According to that relationship, a plot of log I *vs.* log ΔE_t at a given time should be a straight line with a slope of 2. Figure 6 shows this plot for Electrodes 1 and 2 in terms of the total current i and the potential change ΔE evaluated at the optical transition time. Although the data for both films lie on the same straight line, the experimental slope is 2.7 rather than 2.0. The higher slope is actually consistent with a double-injection system in which neither charged species is fully immobilized (12).

A more detailed test of the square-law model is based on the relationship

$$\frac{\Delta E_t}{I^2} = \left(\frac{1}{\kappa \epsilon_0 \mu_i}\right)^{1/2} \left(\frac{1}{z_i c_i \mathbf{F}}\right)^{3/2} \cdot t^{3/2} \quad [25]$$

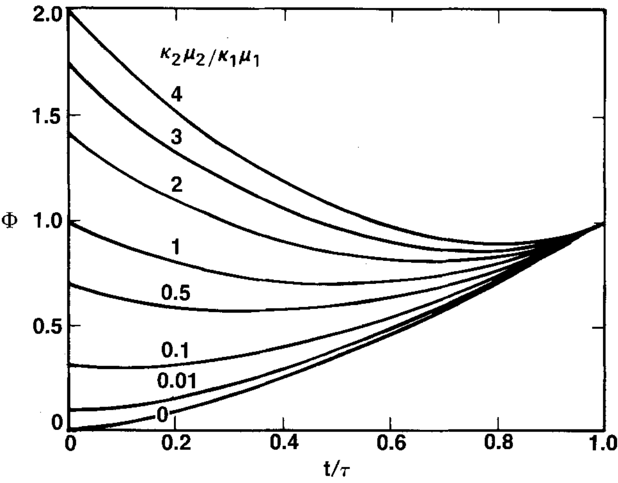

Fig. 5. Dimensionless potential function for different values of the mobility parameter.

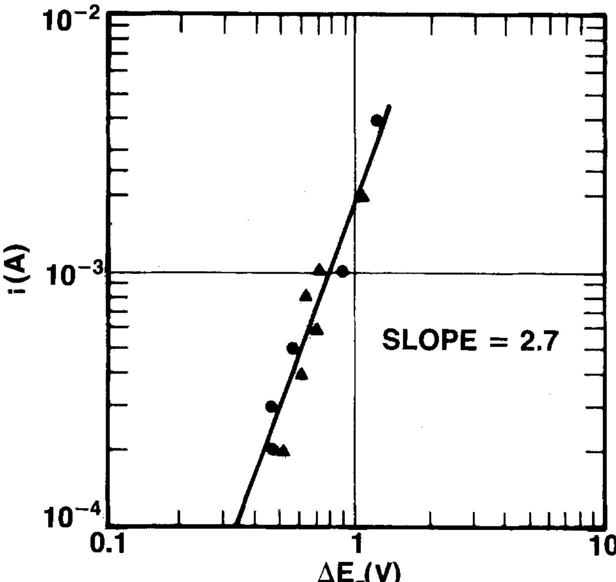

Fig. 6. Current-potential relationship at the optical transition time. Circles, Electrode 1; triangles, Electrode 2; ΔE_τ evaluated at τ_{opt} from type of plot shown in Fig. 7.

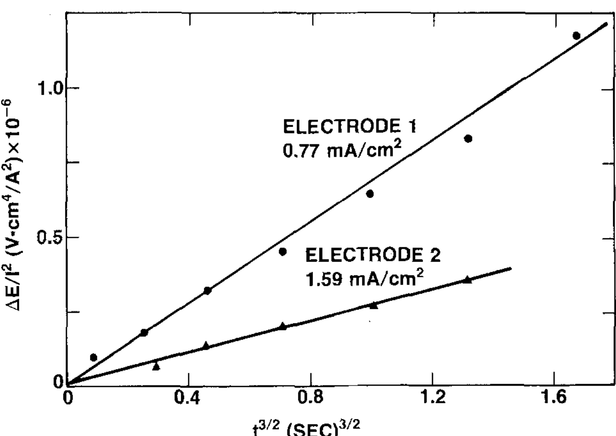

Fig. 7. Space-charge plots for determination of $\kappa\mu_i$ in the oxidation product.

or its equivalent

$$\frac{\Delta E_t}{I^2} = \left(\frac{1}{\kappa\epsilon_0\mu_i}\right)^{1/2}\left(\frac{l}{z_i I \tau_{opt}}\right)^{3/2} \cdot t^{3/2} \qquad [26]$$

A plot of $\Delta E_t/I^2$ *vs.* $t^{3/2}$ should be a straight line passing through the origin, with a slope from which the product $\kappa\mu_i$ for the red material may be evaluated. Figure 7 shows this plot for Electrodes 1 and 2. Potentials here and in Fig. 6 are referred to a zero level found by extrapolating the main transient[1] back to $t = 0$, thus neglecting the early part of the curve. The values of $\kappa\mu_i$ from the slopes at different current densities are 3.9×10^{-5} and 4.3×10^{-5} cm²/Vsec. A chloride ion mobility of 4×10^{-6} cm²/Vsec was found for the red oxidation product in the moving-boundary study on alumina (6). Hence, a dielectric constant of 10 is estimated for the red film. This value is quite acceptable in comparison with 4.85, which has been reported for copper phthalocyanine in pressed-powder form (13). The ionic character of the red material should impart additional polarizability, which would result in a higher dielectric constant.

A lower limit of the electron mobility in the green material can be estimated by means of Eq. [23]. Although no minimum was actually observed in the potential-time curves, a minimum would have been detectable, generally, if it had occurred after the first 5% of the reaction time. Then with $t_{min} < 0.05\tau$ and $\mu_i = 4 \times 10^{-6}$ cm²/Vsec, Eq. [23] indicates $\mu_e > 8 \times 10^{-5}$ cm²/Vsec.

Faradaic n values and transients at high current densities.—The number of electrons lost per molecule of dye, based on the optical transition time, is given as the effective n value n_{eff} in Table I. Average n's of 2.5 and 1.5 had been found in prior studies with 1M KCl (6, 7). While none of these n determinations was very precise, Electrode 1 in the present work yielded a significantly lower n_{eff} of 0.77. It was evident visually and from the optical transmission measurements that this film did not fully return to the normal green color when the cell was shorted. To minimize such an effect in the transient analysis, the ion concentration c_i for Eq. [15], [19], and [20] was based on the optical transition time, or the effective n, rather than the assumption that $n = 2$. The geometric film thickness l was calculated, however, from the optical density determined in the dry state before the film was used in the electrochemical cell.

The high current-density data for Electrode 3 led to several interesting observations. At 265 mA/cm², the green-to-red transformation occurred in only 7 msec, with no decrease in the current efficiency as indicated by n_{eff}. This conversion rate is faster than required for most electronic display applications. The high current efficiency suggested that the product layer, next to the electrolyte, had essentially no electronic conductivity. Anodic decomposition of the electrolyte simultaneously with the dye oxidation should be blocked in such a system, but consecutive oxidation of Cl^- after the red film reaches the tin oxide interface should be permitted, since the converted film acts as a solid chloride-ion conductor.

In the highest current-density range explored (132-265 mA/cm²), the electrical transition was no longer discernible, although the optical transition was still defined. This may signify a change from space-charge control to another control mechanism such as ionic charge transfer across the solution/red-film interface. This concept has a precedent in the tungsten oxide electrochromic system, for which proton transfer across the liquid/solid boundary is believed to govern the coloring kinetics (11).

[1] Concave downward in Fig. 3(a).

Conclusions

The anodic oxidation of a lutetium diphthalocyanine film on tin oxide in 1M KCl occurs by propagation of a reaction front from the electrolyte interface, through the film, to the tin oxide boundary. The results of this study confirm our previous observations that electrons lost by the dye are compensated by anions migrating into the organic material under an electric field.

In films approximately 10^{-5} cm thick, the electrode process is space-charge-limited at current densities from 0.3 to at least 6 mA/cm². On comparing the shape of the experimental voltage transient with those predicted for a two-layer space-charge model, it is concluded that a predominant space charge resides in the red oxidation product, which is an ionic conductor. No space charge is observed in the green reactant layer under these conditions, since it is an electronic conductor of higher carrier mobility.

The dielectric constant-mobility product $\kappa\mu_i$ in the red phase, evaluated by means of the space-charge theory, is 4×10^{-5} cm²/Vsec. The corresponding product estimated for the electronic carrier in the green phase is at least 8×10^{-4} cm²/Vsec. With the chloride ion mobility of 4×10^{-6} cm²/Vsec from previous work, a dielectric constant of 10 is found for the red material.

Details of the voltage transient at higher current densities can be obscured by ohmic drop in the tin oxide. However, the optical transient shows that the color transformation still proceeds with high current efficiency, even at 265 mA/cm². Ionic transfer at the electrolyte interface, rather than space-charge conduction, may then control the electrode kinetics.

The Electrocatalytic Oxidation of Ethylene on Platinized Platinum at Different Saturation Pressures

W. E. Triaca, A. M. Castro Luna, and A. J. Arvía*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, 1900 La Plata, Argentina

ABSTRACT

The influence of the hydrocarbon partial pressure (10^{-3} atm $\leq P_E \leq 1$ atm) in the electrooxidation of ethylene on platinized platinum in 1*N* H_2SO_4 was investigated from potentiodynamic and stationary state data. A positive effect of the ethylene saturation pressure on the electrochemical reaction rate has been observed over the whole pressure range. At $P_E > 5 \times 10^{-2}$ atm, the electrochemical reaction rate tends to become pressure independent. The characteristics of the electrochemical reaction can be explained through a reaction pathway involving the electrosorption of ethylene followed by an electron transfer step as rate determining. The present results confirm the recently proposed reaction mechanism for the ethylene potentiodynamic electrooxidation on platinum.

The electrooxidation of ethylene on platinized platinum in acid electrolytes in the 40°-80°C range yields CO_2 and hydrogen ions in solution with an efficiency close to 100%. The electrochemical reaction has been investigated by both stationary-state and relaxation techniques (1-22). The overall ethylene electrooxidation process was earlier interpreted through a reaction mechanism involving the adsorption of the hydrocarbon molecule on the electrode surface followed by the discharge of water on bare platinum sites, the latter stage being the rate-determining step (1). Then, the hydrocarbon oxidation is accomplished through fast reactions involving the adsorbed hydrocarbon and the

Key words: electrocatalysis, ethylene electrooxidation, platinized platinum, ethylene electrosorption.

adsorbed OH species. This reaction model, derived principally from quasistationary kinetic data, yields a negative ethylene pressure influence on the rate of the overall reaction, which apparently explained the trend of the experimental results in the $1\text{-}10^{-4}$ atm ethylene pressure range.

On the other hand, the results obtained under nonstationary conditions furnish a distinction of the various types of processes involved in the overall electrode reaction. Thus, the reaction implies a diffusion and an electroadsorption of the reacting species prior to actual electrochemical reaction. The latter involves the electrooxidation of the electrosorbed species through the participation of water and finally, at sufficiently high anodic potentials, the electrooxidation of the platinum surface. Recent potentiodynamic results obtained, avoiding any hydrocarbon readsorption, have shown that the earlier accepted mechanism for the ethylene electrooxidation is unsatisfactory (23). The new reaction mechanism was based on the initial deprotonation of the electrosorbed species on the electrocatalyst surface as the rate-determining step. Consequently, the influence of the ethylene partial pressure on the reaction should correspond to two limiting cases: (*i*) Under saturation coverage, a pressure independent reaction rate should be reached and (*ii*) when the degree of surface coverage depends on the equilibrium pressure according to the corresponding adsorption isotherm, a positive pressure influence should be observed.

The present paper deals with the influence of the ethylene partial pressure on the hydrocarbon electrooxidation rate both under potentiodynamic and under steady-state conditions. A positive influence of the ethylene saturation pressure on the potentiodynamic electrooxidation rate is clearly observed, particularly below 0.1 atm. The effect appreciably decreases as the ethylene saturation pressure increases and the reaction rate tends to become pressure independent.

Experimental

The experimental setup, materials, and techniques used, were the same as those described in a recent publication (23). Two procedures were used for the working electrode preparation, namely, using either a platinized plating bath without lead acetate addition (23) or a plating bath containing up to a maximum of 0.02% of lead acetate according to the procedure reported elsewhere (1, 2). The electrochemical response of the different electrodes was independent of the preparation procedure. The real area of the platinized-platinum surface was determined from the charge transferred during the adsorption of a monolayer of hydrogen adatoms. The potential of the working electrode was measured against a reversible hydrogen electrode in contact with the electrolyte ($1N$ H_2SO_4).

Saturation of the electrolyte with the hydrocarbon (10^{-3} atm $\leq P_E \leq 1$ atm) was achieved by bubbling ethylene (CP grade Matheson), either pure or diluted with purified nitrogen. A.R. H_2SO_4 (Merck) and triply distilled water, which satisfied the purity standards recently referred in the literature (24), were employed. Experiments were carried out at 60°C.

The following measurements were performed: (*i*) potentiodynamic E/I curves at 0.4 V/sec to avoid the hydrocarbon readsorption (23) and (*ii*) stationary current/potential curves.

Results

Potentiodynamic runs.—The potentiodynamic runs were made with triangular potential sweeps initiated from the potential range related to the maximum adsorption ($E_{ad} \approx 0.25\text{-}0.30$V) up to 1.5V, immediately after the electrode pretreatment indicated in Fig. 1. The rationale behind the various potential steps has been discussed in detail elsewhere (23). Experiments were performed either in the absence (blanks) or in the presence of ethylene under exactly the same per-

turbation conditions. In the $1\text{-}10^{-2}$ atm ethylene partial pressure range, the E/I profiles exhibit (Fig. 2), in principle, the same features previously described (23), namely, the initiation of the hydrocarbon electrooxidation at *ca.* 0.4V and its characteristic net anodic current peak at *ca.* 0.90V. The hydrocarbon electrooxidation is apparently completed at *ca.* 1.5V as deduced from the second positive-going potential scan (23). The total anodic charge includes that corresponding to the electrooxidation of the platinum surface. The negative-going potential scan exhibits the characteristic current peak corresponding to the electroreduction of the oxygen-containing layer formed on platinum.

The charge related to the electrooxidation of the electrosorbed ethylene species, Q_E, was evaluated by subtracting from the total anodic charge, previously corrected for the double layer effect, the cathodic charge pertaining to the electrodesorption of the oxygen-containing layer formed during the anodic scan. In this sense blank experiments served as reference (23).

At each ethylene partial pressure, the adsorption time (t_{ad}) at E_{ad} was chosen to reach the maximum stationary surface coverage by the electrosorbed species. The time required to attain it decreased as the ethylene saturation pressure increased (Table I). During the ethylene electrosorption process a net dehydrogenation charge, Q_H, was evaluated through the current transient recorded after applying to the interface a potentiostatic step at the maximum adsorption potential (23). This charge is related to the electrooxidation of hydrogen adatoms produced during the electrosorption process. The Q_E value is determined through a potentiodynamic scan immediately after the relaxing current reached the constant value of the blank ($I \approx 0$). The Q_H/Q_E charge ratio at 80°C and 1 atm hydrocarbon saturation pressure is in good correspondence with the formation of a C_2H_2 residual electrosorbed species (23).

In the 1-0.1 atm pressure range, the charge required to electrooxidize the electrosorbed ethylene species at 0.3V decreases slightly on decreasing the ethylene saturation pressure; but at pressures lower than 0.1 atm,

a faster decrease of that charge is observed (Table I). However, at the lowest ethylene saturation pressure the results are probably influenced by traces of impurities present in the system because large adsorption times are required to attain the corresponding stationary surface coverage at E_{ad}.

In the 1-0.1 atm ethylene saturation pressure range, the height of the current peak assigned to the hydrocarbon electrooxidation decreases slightly on decreasing the pressure, while at saturation pressures lower than 0.1 atm, the anodic current peak height approaches a linear dependence with the logarithm of the ethylene saturation pressure (Fig. 3). The same influence of the ethylene partial pressure is observed on the current read at a constant potential in the 0.55-0.75V range from the E/I profiles at 0.4 V/sec (Table II).

After equilibration at ethylene partial pressures larger than 10^{-2} atm the first positive-going potential scan shows that in the 0.25-0.40V range the hydrogen adatoms electrooxidation current is practically suppressed (Fig. 2). Contrarily, the hydrogen desorption

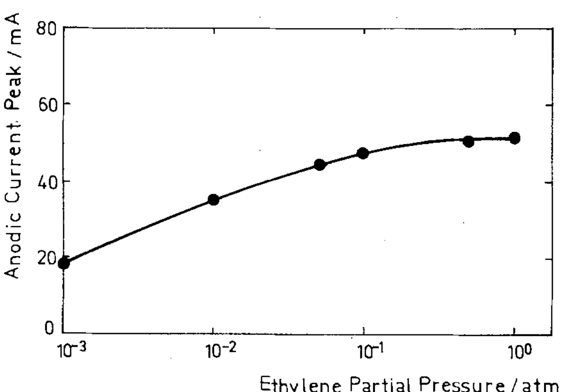

Fig. 3. Dependence of the anodic current peak height related to the electrooxidation of the adsorbed hydrocarbon species on the ethylene partial pressure. E_{ad} = 0.3V, t_{ad} at each P_E is indicated in Table I. Real electrode area = 78.3 cm^2.

current progressively contributes at ethylene saturation pressures lower than 10^{-2} atm. As a matter of fact, during the repetitive potential scans at potential sweep rates fast enough to avoid any appreciable ethylene readsorption, the electrooxidation current related to the hydrogen adatoms progressively increases during the successive potential scans. These results indicate that for values of the degree of ethylene surface coverage (θ_E) larger than *ca.* 0.5, the electrosorption of hydrogen adatoms on the electrocatalyst surface is appreciably hindered.

In the 1-10^{-2} atm ethylene partial pressure range, the anodic E/log I plots made with data taken from the initial portion of the E/I profiles recorded at 0.4 V/sec yield reasonably straight lines with slopes slightly larger than the 2.303($2RT/\mathbf{F}$) ratio. After the proper ethylene surface coverage correction described elsewhere (23), *e.g.*, when the currents are referred to the unit coverage of the ethylene surface species, Tafel lines with slopes equal to the 2.303 ($2RT/\mathbf{F}$) ratio are obtained (Fig. 4).

Steady-state E/I measurements.—The steady-state E/I measurements were made after perturbing the electrochemical interface with the E/time programs indicated in Fig. 5. The two perturbation programs involve initially the electrooxidation at 1.5V for a few seconds of any residual organic species existing on the electrocatalyst surface. Then, the potential is stepped down to 1.2V for 2 min to electroform an oxygen monolayer on platinum which prevents the electrosorption

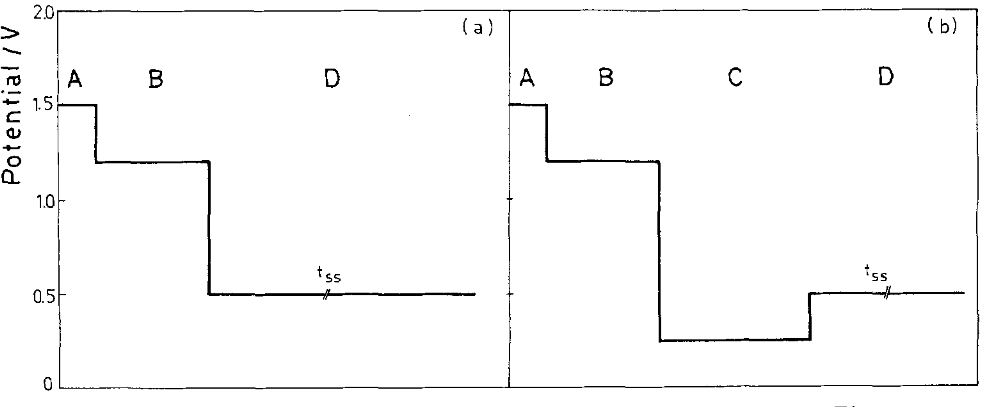
of ethylene from solution. Afterward, in the first case, the potential is stepped down from 1.2V to a preset potential in the 0.40-0.75V range where the oxygen-containing layer is electroreduced simultaneously with the initiation of the hydrocarbon electrosorption and its further electrooxidation. A steady current value at the preset potential is attained after a lapse comprised between 3 and 6 hr, depending on the preset potential value and the hydrocarbon saturation pressure.

In the second case, the potential is stepped down from 1.2 to 0.25V and the system is held at this potential value a time long enough to completely electroreduce the oxygen-containing surface species and to attain a maximum surface coverage by the ethylene electrosorbed species. The time required for the latter process depends on the ethylene saturation pressure. Then, the potential is brought to a preset value in the 0.40-0.80V range where the corresponding steady current is recorded. In this second case, a longer time is required to achieve the steady state current at constant potential and ethylene partial pressure than in the former case. However, the steady current at any preset potential and at a constant hydrocarbon saturation pressure is always independent of the potential program used.

From the steady-state measurements, reasonable linear Tafel regions are observed in the E/log I plots, which cover a smaller range as the ethylene partial pressure decreases (Fig. 6). Actually, the E/log I plots exhibit on the average a very slight curvature. This effect is due to the change of the ethylene surface coverage with the applied potential. Tafel lines with the slope equal to the 2.303($2RT/F$) ratio are obtained after the proper ethylene surface coverage correction described elsewhere (23) (Fig. 6). At potentials higher than *ca.* 0.6V the data deviate from the Tafel line due to mass transport contributions. From the E/log I plots, such as those depicted in Fig. 6, it is also concluded that at a constant potential in the 1-10^{-2} atm ethylene partial pressure range the rate of the electrooxidation process under stationary conditions is slightly lower as the ethylene saturation pressure decreases.

Tafel relationships can also be obtained with current values read by holding the system at a constant potential during a fixed time. In this case, however, the



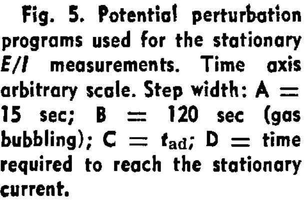


Fig. 5. Potential perturbation programs used for the stationary E/I measurements. Time axis arbitrary scale. Step width: A = 15 sec; B = 120 sec (gas bubbling); C = t_{ad}; D = time required to reach the stationary current.

Tafel slopes change appreciably with the lapse of time implied in the current reading (Fig. 7). The higher the slope the shorter the reading time. From the data of Fig. 7, it can be seen that Tafel slopes equal to the $2.303(2RT/F)$ ratio are approached after a 3 hr waiting time for the current reading at a constant potential. Therefore, any reaction order derived from experiments made either under slow potential sweeps or by reading the current at a fixed potential and at a constant preset time is unsatisfactory for mechanistic conclusions.

Discussion

The present results show that the electrooxidation of ethylene on platinized platinum under either stationary-state or potentiodynamic conditions involve a common Tafel slope when the data are referred to the unit coverage of the ethylene surface species. The coincidence of the Tafel slopes suggests that the electrooxidation process in both cases likely proceeds through the same basic reaction mechanism. Furthermore, both in the steady-state and in the potentiodynamic measurements and within the ethylene saturation pressure range investigated, a positive influence of the hydrocarbon pressure on the reaction rate is noticed. Under stationary conditions, at potentials more positive than the maximum adsorption potential where the hydrocarbon electrooxidation takes place and the Tafel line is approached, a decrease of θ_E with the increasing potential is observed in the $0.4 \leq \theta_E \leq 0.9$ range at 1 atm ethylene partial pressure (23). The stationary E/I plot at potentials exceeding the Tafel line range exhibits a limiting anodic current which corresponds to a mass transfer rate control of dissolved ethylene toward a partially electrochemically oxidized electrocatalyst surface. These contributions are more clearly seen at the lowest ethylene saturation pressures (Fig. 6).

The interpretation of the kinetic results over the whole pressure range investigated can be given by extending the reaction mechanism previously postulated for the potentiodynamic electrooxidation of ethylene on platinized platinum in the absence of hydrocarbon readsorption (23) to the reaction under stationary-state conditions.

As has been established earlier (23), the proper electrooxidation reaction implies the preceding electrosorption yielding protons and an adsorbed residual ethylene species. The electrosorption process is obviously preceded by the ethylene diffusion from the bulk of the electrolyte toward the reaction interface. The latter, in principle, exists as a surface which is covered either with H, OH, H_2O, or ions, depending on the electrode potential. Thus, the electrosorption of the hydrogen should imply a potential-dependent complex electrochemical reaction. Nevertheless, for the sake of simplicity any ionic adsorption is regarded as a constant contribution in the mechanistic interpretation of the reaction. It should be noted, however, that both sulfate and bisulfate ions particularly influence the reactions occurring at potentials which are more positive than the potential of zero charge of the electrochemical interface (25, 26). The latter is close to the potential where the maximum hydrocarbon adsorption takes place. Therefore, the simplest formalism to explain the electrooxidation of ethylene on platinum can be put forward in terms of the following sequence of partial stages

$$(C_2H_4)_b = (C_2H_4)_i \quad [1]$$

$$(C_2H_4)_i + (x+2)(H_2O)Pt = (C_2H_2)Pt_x + 2(H)Pt + (x+2)H_2O \quad [2]$$

$$2(H)Pt = 2H^+ + 2Pt + 2e \quad [3]$$

$$2[H_2O + Pt = (H_2O)Pt] \quad [4]$$

Step [1] corresponds to the diffusion of ethylene from the bulk of the solution to the electrochemical interface. Step [2] represents the dissociative electrosorption of ethylene on the platinum surface covered by water molecules in direct contact with the metal yielding the adsorbed residual ethylene species and hydrogen adatoms. The value of x, the average number of Pt sites occupied by the adsorbed radical, is *ca.* 2.3 (23). Step [3] is the electrooxidation of hydrogen adatoms. At potentials higher than 0.4V the rate of this reaction becomes so fast that steps [2] and [3] are then actually undistinguishable. Reaction [4] indicates that any available free platinum surface is immediately covered to a large extent by water molecules.

Steps [1] to [4] are followed by a deprotonation process. The latter may occur either through the following reaction

$$(C_2H_2)Pt_x = (R)PT_{(x-1)} + H^+ + Pt + e \quad [5a]$$

or through the solvent participation as follows

$$(C_2H_2)Pt_x + H_2O = (RHOH)Pt_{(x-1)} + H^+ + Pt + e \quad [5b]$$

R and RHOH denote intermediates produced in the course of the electrochemical reaction. At this stage, the average number of Pt sites related to these new intermediates is certainly unknown although it is likely that it decreases along the course of the reaction.

Another possible equivalent reaction which may contribute at ethylene surface coverages lower than the saturation coverage is

$$(C_2H_2)Pt_x + (H_2O)Pt = (RHOH)Pt_{(x-1)} + H^+ + 2Pt + e \quad [5c]$$

After either reaction [5a], [5b], or [5c] the water or the $(H_2O)Pt$ species react with the surface organic intermediates yielding finally CO_2 and H^+ through a sequence of undetermined fast reactions. These reactions can be expressed by the overall anodic process

$$\text{Surface organic intermediates} + H_2O \; [\text{or } (H_2O)Pt] \rightarrow CO_2 + H^+ + Pt + e \quad [6a]$$

The postulated reaction pathway involves the participation of water in the ethylene electrooxidation process at anodic potentials lower than those corresponding to the initiation of the oxygen monolayer formation.

Alternatively, the direct discharge of water

$$(H_2O)Pt = (OH)Pt + H^+ + e \quad [6b]$$

may contribute particularly at higher positive potentials. In the absence of organic adsorbates, there is evidence that step [6b] corresponds to a reversible fast electron transfer reaction over a relatively large potential range preceding the monolayer formation (27-

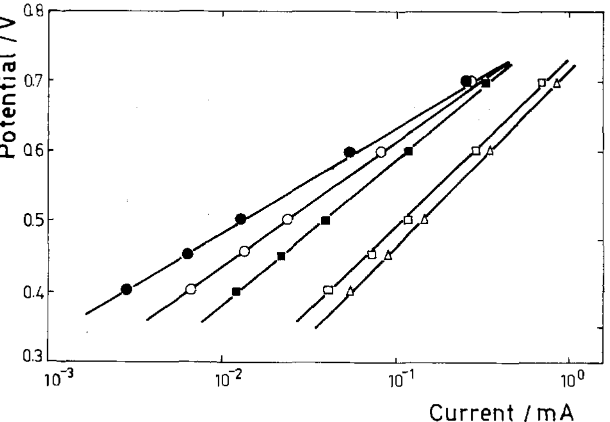

Fig. 7. Dependence of the Tafel plot at $P_E = 1$ atm on the waiting time for the current reading at constant potential. (△) 75 sec; (□) 120 sec; (■) 20 min; (○) 1 hr; (●) 6 hr. Real electrode area = 78.3 cm².

29). The (OH)Pt species reacts either with the surface organic intermediates yielding finally CO_2 and H^+ through a series of fast surface radical reactions or, as the surface organic intermediate concentration is depleted, it undergoes the oxygen monolayer formation according to a complex reaction pathway (29, 30), which can be formally put forward as follows

$$(OH)Pt = (O)Pt + H^+ + e \quad [7]$$

Under potentiodynamic conditions and in the absence of ethylene readsorption, either step [5a] or [5b] and the following ones describe the electrooxidation process occurring on platinum. As discussed earlier (23) the kinetic parameters sustain that the initial deprotonation of the adsorbed radical, either through reaction [5a] or [5b], is the likely rate-determining step. Similarly, for the stationary electrooxidation, both the Tafel slope and the pressure dependence of the reaction rate sustain, as in the potentiodynamic case, that any form of step [5] is the rate-determining step.

At intermediate electrode surface coverages by the adsorbed hydrocarbon species, the kinetics of the process is better represented by a Temkin-type isotherm. This conclusion is based on the approximate θ_E/log P_E linear relationship obtained at 0.3V, particularly at low ethylene saturation pressure (Table I and Fig. 8). The same relationship comes out from the linear dependence of the potentiodynamic anodic current peak with log P_E at ethylene saturation pressures lower than 0.1 atm. Then, the rate equation of the rds in terms of current density, i, is given by

$$i = k'\theta_E \exp(\alpha \mathbf{F}E/RT) \exp(f\theta_T) \quad [8]$$

where k' is the formal rate constant in electrical units, θ_E refers to the electrode surface coverage by C_2H_2 species, α is the transfer coefficient assisting the reaction in the anodic direction, f is a Temkin-type coefficient, and θ_T refers to the total surface coverage by the adsorbed radicals. When the effects of coverage by the adsorbed species on the activation energy of the reaction exactly compensate each other as one adsorbed species is progressively replaced by another one, the f value is zero. Taking into account the type of adsorbed species involved in reaction [5] it seems reasonable that the latter situation is actually approached. Then, Eq. [8] becomes

$$i = k'\theta_E \exp(\alpha \mathbf{F}E/RT) \quad [9]$$

so that an apparent Langmuir adsorption behavior of the intermediates results. Equation [9] involves a linear E *vs.* log (i/θ_E) relationship with the slope equal to the 2.303 $(RT/\alpha\mathbf{F})$ ratio. Therefore, the experimental Tafel slope obtained either from potentiodynamic or steady-state measurements agrees with the latter for $\alpha = 0.5$.

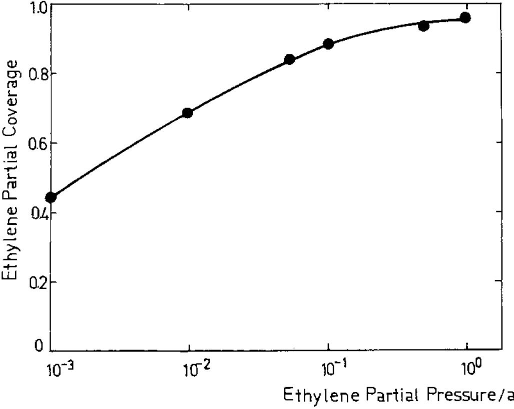

Fig. 8. Dependence of the degree of ethylene surface coverage at 0.3V on the ethylene partial pressure.

When step [5] is rate determining and the ethylene surface coverage degree is in the 0.2-0.8 range, the preceding steps can be regarded as in quasi equilibrium. The electrode surface is then significantly covered only by C_2H_2 species (and water) and therefore $\theta_T \approx \theta_E$. Hence, using an overall reaction for the preceding steps, under Temkin conditions, the rates in the forward (v_f) and in the backward (v_b) directions are given by

$$v_f = k'_f P_E (1 - \theta_E)^x \exp(2\alpha \mathbf{F}E/RT) \exp(-\gamma r_E \theta_E/RT) \quad [10]$$

$$v_b = k'_b C^2_{H^+} \theta_E \exp[-2(1-\alpha)\mathbf{F}E/RT] \exp[(1-\gamma) r_E \theta_E/RT] \quad [11]$$

where k'_f and k'_b are the corresponding formal rate constants; γ is a symmetry factor, and r_E is a coefficient which denotes the variation of the apparent standard free energy of adsorption with the coverage. Under quasi-equilibrium conditions ($v_f \approx v_b$) and for $\alpha = \gamma = 0.5$, it results

$$\theta_E = K + K' \log P_E + K''E\mathbf{F} \quad [12]$$

where the term K depends on the solution pH and temperature and K' and K'' are constants at constant temperature. This equation, under the present circumstances, is approached at the maximum adsorption potential where practically no steady-state ethylene electrooxidation occurs. Thus, at 0.3V, for $0.2 \leq \theta_E \leq 0.8$, the linear θ_E/log P_E relationship is justified. At potentials more positive than 0.35V the ethylene partial pressure at the interface decreases due to various contributions which are potential dependent such as the slow diffusion of ethylene from the bulk of the electrolyte toward the reaction interface and the duration of ethylene at the interface because of CO_2 generation. All these effects in addition to the electrosorption of oxygen which competes with the hydrocarbon for surface sites and to the oxidation of the adsorbed ethylene species reflect in the decreasing part of the already known θ_E *vs.* E plot at values of E more positive than 0.35V (23).

A further detail of the reaction concerning the activity of the electrocatalyst is given by the different times required to attain a stationary current when the potential is either stepped up from 0.25V to E or stepped down from 1.2V to E. This should be related to the reactivity enhancement of the surface produced in the second case during the electroreduction of the oxygen monolayer formed on Pt (30).

The explanation of the present results is given through the participation of (C_2H_2) as the main organic radical in the ethylene electrooxidation process. Other types of dehydrogenated chemisorbed particles (11-13, 21) which probably become important at higher temperatures are not discarded, but under the present circumstances they appear without appreciable kinetic relevance.

Finally, the present results indicate that the previously postulated mechanism (1), which was mainly based on the negative pressure influence on the reaction rate, is unsatisfactory. As a matter of fact, the negative ethylene pressure effect was reproduced in this laboratory when, for instance, the E/I records were obtained at a low potential sweep rate (*e.g.,* 0.01 mV/sec) and they were arbitrarily assigned to stationary E/I profiles. Under these circumstances, the fact that different times are required to attain steady currents at different potentials and hydrocarbon saturation pressures is overlooked.

Electrochemical Oxidation of H_2 and CO in Fused Alkali Metal Carbonates

W. M. Vogel,* L. J. Bregoli, and S. W. Smith*

United Technologies Corporation, Fuel Cell Operations, Power Systems Division, South Windsor, Connecticut 06074

ABSTRACT

By using meniscus electrodes and shift gases of relatively low CO content, it was possible to study the electrochemical oxidation of H_2 in molten carbonate with little interference by CO. Data are presented which indicate that the H_2 reaction proceeds with negligible activation polarization on Ni, Au, Pt, and Pt-Rh alloy. The observed overvoltages are explained as diffusion overvoltages for H_2, H_2O, and CO_2. Hydrogen diffusion through metal was appreciable for thin Ni membranes and very fast for Pd wires. The CO oxidation is far more complex and proceeds in stages. At low polarizations the rates are very small but increase greatly above approximately 200 mV. Applied to fuel cell anodes, the results suggest that, in order to utilize large CO content gases efficiently, internal shifting is required.

The H_2/H_2O and CO/CO_2 electrode reactions in molten carbonate can be written as

$$H_2 + CO_3^{=} = H_2O + CO_2 + 2e^- \quad [1]$$

$$CO + CO_3^{=} = 2CO_2 + 2e^- \quad [2]$$

The study of the hydrogen reaction is hampered by the fact that the four gas pressures are interrelated by the shift reaction which is the electrically neutral sum of reactions [1] and [2]. It is not possible, therefore, to vary the pressures of H_2, H_2O, and CO_2 independently of each other, nor can we investigate reaction [1] without any interference by reaction [2]. In order to obtain meaningful results it is necessary to control the gas composition rather closely, and some seemingly obvious experiments cannot be done at all. For instance, it is not possible to obtain useful voltammograms in the absence /presence of H_2, CO, H_2O, and CO_2. In the absence of CO_2 the melt turns solid (oxide formation). In the absence of CO the polarization curves reflect CO_2 reduction. Presence of H_2O automatically produces H_2, and vice versa. It is not neces-

* Electrochemical Society Active Member.

Key words: molten carbonate, fuel cell anode.

sary to start an experiment with a dry melt. The melt comes to equilibrium rather quickly with respect to H_2O (or OH^-). (Vacuum drying of the melt would in any event produce a solid mass of oxides rather than a dry carbonate melt.)

More complications arise from the methane and carbon reactions. We have, in addition to [1] and [2]

$$CH_4 + 4CO_3^= = 5CO_2 + 2H_2O + 8e^- \quad [3]$$

$$C + 2CO_3^= = 3CO_2 + 4e^- \quad [4]$$

In an electrochemical experiment, where an electrode is supplied with a nonequilibrated gas containing H, O, and C atoms, it is difficult to predict where the chemical reactions will take place. For instance, methane may be formed during preheating the gas, or electrochemically[1] at the electrode as product of a local cell with the partial reactions [1] and [3], *i.e.*

$$5CO_2 + 2H_2O + 8e^- \rightarrow CH_4 + 4CO_3^=$$

$$4H_2 + 4CO_3^= \rightarrow 4H_2O + 4CO_2 + 8e^-$$

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad [5]$$

Since the equilibrium constants of the chemical reactions vary with temperature, it is sometimes impossible to calculate the equilibrium potential from the composition of the initial feed gas. During preheating, carbon or methane may be formed even though neither reaction is possible at the operating temperature. Carbon formation would be irreversible under such conditions and methane reforming at the higher temperature may be too slow to reach equilibrium.

Many of these complexities can be avoided by using gas mixtures which cannot form carbon at any of the temperatures encountered, *i.e.*, usually between room temperature and operating temperature. In addition, it is prudent to preheat the gas in a manner which ensures equilibrium prior to entering the cell. When these precautions are taken, the open-circuit potential (ocp) agrees accurately with the (equal) equilibrium potentials of reactions [1]-[3] (1). Without these precautions, very large differences may be observed between ocp and the value calculated for the composition of the feed gas (1-3) even if the (cold) feed gas was mixed in the proportions corresponding to equilibrium at operating temperature. Recently, the present work and that of Ref. (1) were criticized (4) as erroneous. The basis for this criticism is a certain characteristic of molten carbonate systems.

Carbonate melts have very small buffer capacities. The acid is a gas (CO_2) of low solubility. It is not possible, therefore, to study the present reactions at constant melt acidity, the latter being expressed as $pCO_2 \equiv -\log P_{CO_2}$ (5), nor is it practical to use a reference electrode (RE) "in the same medium." The latter expression normally indicates that the RE and the working electrode (WE) are in the same ionic medium, including the same acidity. We do not mean that the media are truly identical, even with respect to small concentrations of , *e.g.*, dissolved gases. Identical media would, of course, result in a zero potential difference between the working and reference electrodes.

Different media imply liquid junction potentials and/or acidity differences with the effects of the two impossible to separate accurately in many cases. For example, we cannot change the *p*H of an acid very much and still measure it (against a constant reference electrode) because we simultaneously change the liquid junction between indicator and reference electrodes. However, we can vary the CO_2 pressure above a carbonate melt, and thereby the melt acidity, by many orders of magnitude without introducing or changing any liquid junction potentials. The same is true for changes in H_2O pressure. The concentrations of $O^=$ and OH^- ions in the melt are very small over a wide range of these pressures.

We can, therefore, separate the various electrodes from each other and supply each with a different gas without introducing junction potential errors. The only requirements are that each compartment be supplied with at least a few hundred parts per million of CO_2, and that the H_2O pressure not exceed a few atmospheres. Of course, rapid exchange of melt between compartments must be prevented.

It was the purpose of this study to obtain more information about the roles of reactions [1] and [2] in the overall process of oxidizing H_2-containing gases, to obtain information about the complex diffusion overvoltage, and to confirm previous findings (2, 6-8) that reaction [1] proceeds with negligible activation polarization at a variety of different metals.

[1] The possible electrochemical formation of CH_4 was not investigated. This would require use of gases which are (thermodynamically) capable of producing CH_4 at cell temperature. This falls outside the scope of the present studies for H_2 where the gases used were incapable of significant CH_4 formation at cell conditions.

Experiments

The cell is shown schematically in Fig. 1. The alumina parts consisted of COORS AD-998 grade alumina. The outer container was made from Incoloy 800.

The RE and WE (wires, tubes) were enclosed in alumina tubes. The lower ends of these tubes were closed except for 1 × 3 mm slits. To prevent convective melt exchange through these slits, inert powder ($LiAlO_2$) was pressed into the tube bottoms so that the powder/melt paste covered the slits. The gold wire of the RE was immersed a few millimeters into the melt within the alumina tube. The wire or metal tube WE was positioned in the alumina tube so that it barely touched the melt surface. In order to aid in centering the WE wires within the alumina tubes, and to prevent formation of erratic meniscuses between the wires and tube wall, these wires were sheathed in tightly fitting alumina tubes which extended to within 3 cm of the lower wire end. The melt compositions at the RE and this type of WE were governed by the respective feed gases supplied via tight fittings at the upper ends of the alumina tubes. The WE and RE assemblies were immersed in the bulk melt which also contained a gold counterelectrode.

In some experiments Ni membrane electrodes were used. These electrodes were constructed by welding circular Ni foils into gas housing. Gases were passed through the latter by means of two tubes welded onto the housing. The entire electrode assembly consisted of Ni. Two kinds of Ni foils were used: a nonporous foil and a foil containing regularly spaced tapered holes, perpendicular to the foil surface (supplied by Buckby-Mears, St. Paul, Minnesota). There were 2890 holes per 1 cm² of foil. The large hole diameter was approximately 5×10^{-3} cm. The tapered shape of the holes made it easy to maintain meniscuses in the holes without either flooding the pores or bubbling gas through

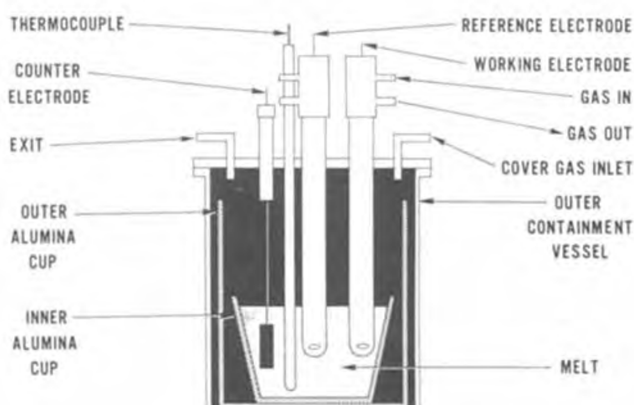

Fig. 1. Cell used with wire or tube electrodes

them. Both kinds of foils were 7.6×10^{-3} cm thick. These membrane electrodes, being rather bulky, were immersed directly into the bulk melt.

A blanket gas of 0.25 atm CO_2 and 0.75 atm N_2 was flowed slowly over the bulk melt. This gas, rather than the CO- or H_2-containing gas at the WE, was used for safety reasons and for convenience sake. It allowed the use of cells which were not completely gas tight between blanket gas and environment. The difference in gas composition above the bulk melt and at RE and WE was of no consequence for those experiments in which separated WE's were used (wires, tubes) as has been explained above. However, the Ni membrane electrodes were somewhat influenced by this difference. Thus, the ocp's of the two types of membranes were within 5 mV of each other but they were 10-20 mV higher than the equilibrium potential calculated for the feed gas to the WE. This difference presumably reflects formation of a mixed potential between the hydrogen reaction at the membrane and the CO/CO_2 reaction at the other more massive metal parts of these electrode assemblies. (If pure CO_2 rather than diluted CO_2 was used as blanket gas, all metal parts except the membrane surfaces evolved gas bubbles, presumably CO.) For the present purpose, the divergence of the ocp of the membrane electrodes was of minor importance since the primary interest was to determine the effect of pores on the polarization of an H_2(Ni) membrane electrode.

All gases were of CP grade. The dry gas mixture was analyzed in each case. The Au reference electrode was supplied with a mixture of 0.33 atm O_2 and 0.67 atm CO_2. The water pressures for the reactant gases were established by means of saturators and were verified by analysis. The gases were preheated prior to entering the cell.

The gases chosen for this study were such that carbon formation was impossible at all temperatures encountered, and such that the equilibrium methane pressure at operating temperature was negligible. The ocp of all but the membrane electrodes agreed within ± 2 mV with the thermodynamic potentials calculated with the gas compositions at equilibrium at 650°C. This close agreement indicated that methane formation at lower temperatures during preheating either did not occur or was reversed at the higher temperature.

The melt was prepared by fusing 62 mole percent (m/o) Li_2CO_3 and 38 m/o K_2CO_3, both of analytical grade.

The cell was heated in a Lindberg crucible furnace. All experiments were done at 650° ± 5°C, measured inside the WE and RE holders. Electrode potentials were controlled using either a PAR™ Potentiostat Model 173 or a solid-state programmable voltage generator designed and built in-house. Voltammograms were recorded with a Hewlett-Packard X-Y Recorder, Model 7044A.

The quoted potentials are referred to the O_2 (0.33 atm)/CO_2 (0.67 atm) reference electrode and are corrected for ohmic losses between WE and RE. Corrections were also applied for thermovoltages if dissimilar metals were at different temperatures. Since a gold wire was used as RE, this correction was necessary for all WE's other than gold. In some tests gold lead wires were welded to the WE, so that the drop from 650°C to the environmental temperature occurred on gold wires. In these experiments no correction for thermovoltage was applied. The thermovoltages were measured using the respective dissimilar metals under identical gases (usually shift gas). The measured values agreed well with those calculated from tabulated published data.

Results and Discussion

With the exception of the membrane electrodes, our electrodes were essentially meniscus electrodes. Such electrodes normally present very complex transport conditions associated with thin liquid films extending above the visible meniscus. We chose this configuration for the following reasons.

We were primarily interested in obtaining information about the H_2 and CO oxidation in the very complex porous gas diffusion electrodes used in fuel cells. To apply data obtained with simple immersed electrodes (wires, sheets, etc.) to such porous structures requires using models, the physical realism of which is difficult to prove. The uncertainties introduced by these models can easily lead to erroneous conclusions about the nature of the polarization. This is particularly true for molten carbonate electrodes. Thus, the observation of essentially linear polarization curves (i *vs.* E), or of long and linear Tafel lines ($\log i$ *vs.* E) might be interpreted as indications for ohmic or transfer polarizations even though these types of polarization curves can result from pure diffusion overvoltage under certain conditions.

To demonstrate the latter case of a long linear Tafel line assume identical and one-dimensional diffusion paths for H_2, H_2O, and CO_2. The diffusion overvoltage of reaction [1] is now[2]

$$\eta_d = \frac{RT}{2F} \ln \frac{(1 - i/i_{H_2O})(1 - i/i_{CO_2})}{1 - i/i_{H_2}} \qquad [6]$$

The limiting currents (i_j) for species (j) are negative (cathodic) for CO_2 and H_2O, and positive for H_2. The latter is equal to the experimental anodic limiting current. Assume now that $-i_{H_2O}$ and i_{H_2} are much larger than i_{CO_2}. Then

$$i = i_{CO_2} (\exp \eta/b' - 1), \qquad b' \equiv \frac{RT}{2F} \qquad [7]$$

The shape of a polarization curve following Eq. [7] is practically indistinguishable from that for pure one-electron transfer polarization which is given by

$$i = i_o [\exp \eta/b - \exp(-\eta/b)], \text{ b: Tafel slope} \qquad [8]$$

Curves of this general shape were observed with dipping Pd wires (Fig. 3). Without being able to change i_{CO_2} by changing the diffusion path length, it is very difficult to analytically distinguish between the two kinds of polarization. A distinction would be possible if a limiting current were observed. However, in Eq. [7] the limiting current would be seen only under cathodic polarization. In the case of porous gas diffusion electrodes, we have the additional problem that even limiting currents for the reactant rarely allow one to calculate the diffusion overvoltage at lower currents (9).

These difficulties in applying data obtained with immersed electrodes to porous electrodes are to a degree avoided by using meniscus electrode data which are more directly transferable, *i.e.*, without need for a model.

A second reason for using meniscus electrodes was the following. Accelerating the diffusional transport of the gases to and from the metal surface should diminish the effects of homogenous reactions such as the shift reaction which takes place between these gases in the liquid boundary adjacent to the metal surface, A meniscus is particularly effective in this respect. Most of the very large currents are generated in a narrow zone of the meniscus.

The third reason will become apparent from a study of Fig. 2 which reproduces the stationary polarization curve for a dipping Ni wire under a mixture of 0.512 H_2, 0.285 H_2O, 0.106 CO_2, and 0.097 CO (gas I, all in atm). The solid line was calculated from Eq. [6] with

[2] For this equation see, *e.g.*, K. Vetter, "Electrochemical Kinetics," eq. 2.93, p. 163, Academic Press, New York (1967). It would be incorrect only if the reaction product is H^+ (not OH^-), and if such H^+ could diffuse some distance into the surrounding melt. In such a case one could not use Fick's first law. This problem arises at the O_2 cathode. No problems arise from using Fick's law for the anode.

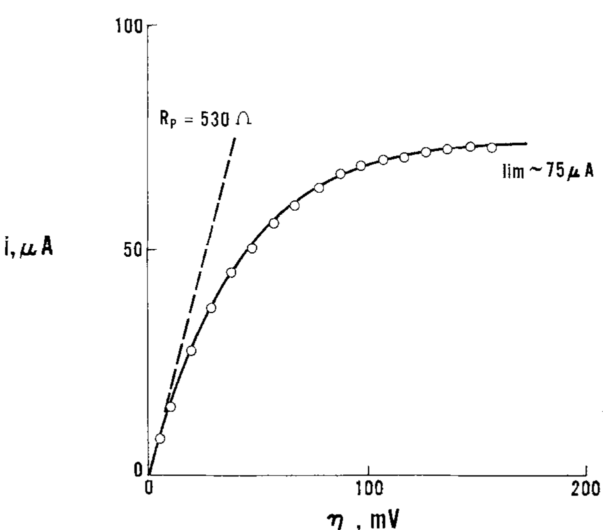

Fig. 2. Stationary polarization curve for dipping Ni wire on gas I $P_{H_2} = 0.512$, $P_{H_2O} = 0.285$, $P_{CO_2} = 0.106$, $P_{CO} = 0.097$ (all in atmospheres).

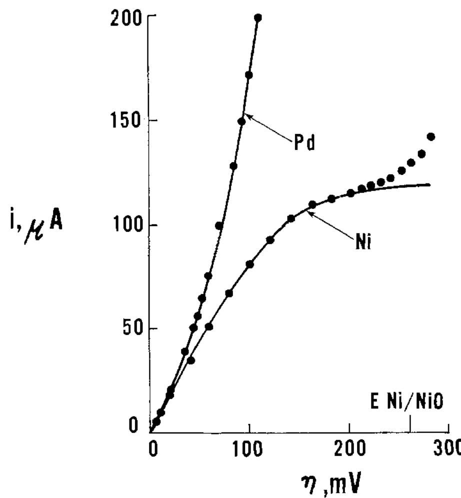

Fig. 3. Stationary polarization curves for dipping Ni and Pd wires on gas II $P_{H_2} = 0.799$, $P_{H_2O} = 0.140$, $P_{CO_2} = 0.014$, $P_{CO} = 0.047$ (all in atmospheres).

the fitting parameters $-i_{H_2O}$, $-i_{CO_2} >> i_{H_2} = 75$ μA.[3] The data fit this curve surprisingly well considering the fact that Eq. [6] applies to linear diffusion. The polarization resistance (R_p) in Fig. 2, calculated from the limiting current and Eq. [6], also agreed very well with the observed value.

The explanation of this agreement, we believe, is that the metal wires were poorly wetted by the melt, and that, therefore, liquid films above the visible meniscus should be of the nature of adsorption films. At extremely thin films no significant currents would be generated. Nearly all of the current would be produced in a narrow zone at the three-phase boundary where the diffusion path can be approximated by an average value. We assume that these conditions are somewhat analogous to a rotating wire which also can be frequently described with an average limiting current even though the exact transport conditions are very complex. Preliminary measurements yielded a value of 50° ± 10° for the contact angle with Ni at these potentials. We also noticed an abrupt change in appearance of the metal at the visible meniscus line. We assume that this change in appearance was caused by minute rearrangements in the metal surface in contact with melt which did not show up under the microscope but which were easily visible with the naked eye.

Data such as those in Fig. 2 were generally well reproducible in shape but not in i_{lim} which tended to vary within a range of ± 20%. This variation presumably reflected difficulties in reproducing the meniscus shape. The best reproducibility was achieved by lowering the electrode end into the melt surface. Lowering it and then retracting it to the just touching position gave generally erratic results.

Other metal wires (Au, Pt, Pt-Rh-alloy) yielded results nearly identical with Fig. 2. By repeatedly oxidizing and reducing the Ni wire surface, the metal roughness was varied by a factor of about 3 which had no effect on the results. The relative roughness was estimated from the area change under the NiO peaks in voltammograms.

Figure 3 presents the results for a dipping Ni wire under a different gas, *i.e.*, 0.799 H_2, 0.140 H_2O, 0.014 CO_2 and 0.047 CO (gas II, all in atmospheres). The solid line was calculated using Eq. [6] with $i_{H_2} = 120$ μA. The two cathodic limiting currents were −65 and −100 μA. (These cathodic limiting currents are curve fitting parameters. They were not actually observed. In fact, it is impossible to observe them in the present case because carbon formation begins at quite small cathodic overvoltages.) We see that, at low η, the currents on gas II were smaller than on gas I despite the higher H_2 pressure on gas II. The upturn in current at $\eta > 200$ mV in Fig. 3 was due to onset of NiO formation which in this case prevented the observation of a well-defined limiting current. (The Ni/NiO potential against our reference is $-758 + 91.6 \log P_{CO_2}$).[4]

We cannot tell which one of the two cathodic limiting currents, required to fit the data in Fig. 3, is to be assigned to H_2O and which to CO_2. They are of similar magnitude. Because of this, and because the H_2O pressure was ten times the CO_2 pressure, it appears that the product (solubility × diffusion coefficient) for CO_2 is much larger than that for H_2O. It should also be mentioned that the data in Fig. 3 could not be fitted with Eq. [6] and only one cathodic limiting current in addition to i_{H_2}.

The values for i_{H_2}, required to fit the data in Fig. 2 and 3, show the expected proportionality to P_{H_2}, *i.e.*, $i_{H_2}/P_{H_2} = 148 \pm 2$ μA/atm. For the cathodic currents we obtain, using the average of the two fitting parameters, $i_{H_2O}/P_{H_2O} \sim 600$ and $i_{CO_2}/P_{CO_2} \sim 6000$ μA/atm. Applying these values to gas I, we obtain for the data in Fig. 2 $i_{H_2O} \sim -170$ and $i_{CO_2} \sim -640$ μA. This agrees fairly well with the assumption made in fitting the data in Fig. 2, *i.e.*, that the H_2O and CO_2 limiting currents were large compared with that for H_2.

A more accurate determination of i_{H_2O}/P_{H_2O} and i_{CO_2}/P_{CO_2} was difficult and not attempted. In the case of H_2O, such a measurement would require large H_2 and CO_2 pressures, combined with a small H_2O pressure. Because of the shift reaction, such a gas would have a high CO pressure and interference by CO would be expected.

Included in Fig. 3 are the results for a dipping Pd wire under the same gas II. The solid line was calculated from Eq. [6] with $i_{H_2} \rightarrow \infty$ and the same values for i_{CO_2} and i_{H_2O} as were used to fit the Ni wire data. The anodic limiting current for the Pd electrode was very large. This is shown in Fig. 4 which extends the scale to higher overvoltages. The solid line in Fig. 4 is the calculated one.

Despite the very different shapes of the curves in Fig. 2, 3, and 4, they all follow Eq. [6] with approxi-

[3] The relative order of the three limiting currents follows from the curve shape. From the observation of a limiting current follows a predictable concentration overvoltage at lower currents. In the present case this overvoltage left no room for any other polarization form. (The fact that in this case P_{H_2O}, $P_{CO_2} < P_{H_2}$ does not contradict this assumption if it is understood that it is the concentrations of H_2, CO, CO_2 in the melt rather than the partial pressures which count. The Henry law constants can be very different for different gases.)

[4] The NiO formation has been carefully investigated (unpublished work). The results clearly demonstrate that in the present work the results relate to Ni electrodes, except in those cases mentioned elsewhere in this paper.

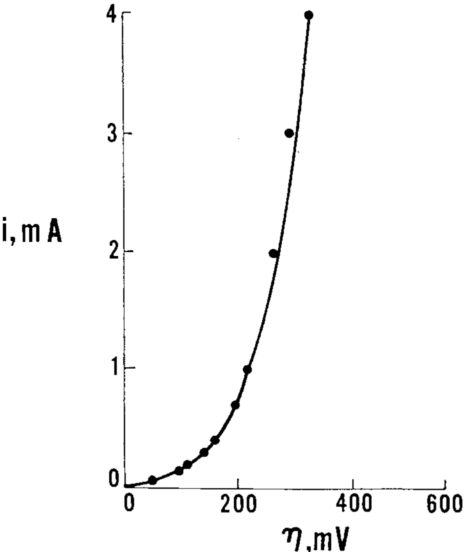

Fig. 4. Stationary polarization curve for dipping Pd wire. Extended range of polarization, same conditions as in Fig. 3.

mately the same values for the limiting currents for the gases, adjusting them for the particular gas pressures. The only exception is the H_2 limiting current on Pd which is hardly surprising.

The absence of an effect of metal nature (Au, Pt, Ni, Pt-Rh) on the results indicates that Pd is the exception and not Ni. The possibility that the low H_2 oxidation current on Ni, *vs.* that on Pd, is due to the influence of a NiO film is not supported. The similarity of the polarization curves for various metals (except Pd) also suggests that our data for Ni were not noticeably influenced by metallic H diffusion. This mode of hydrogen transport was of interest in applying wire data to porous Ni electrodes where the metallic diffusion may be much faster. For this reason, we studied this question in more detail.

Figure 5 shows results for a dipping Ni tube (0.225 cm ID, 0.318 cm OD). At this tube the inner meniscus was located above the outer one and significant hydrogen diffusion through the thin tube wall should have increased i_{H_2} relative to i_{H_2O} and i_{CO_2}. The data in Fig. 5 could be fitted reasonably well with Eq. [6] (solid line) and $i_{H_2} = 1550$, $i_{H_2O} = -840$, $i_{CO_2} = -1290$ μA. The ratio of these values is the same as that for the corresponding currents for the Ni wire under the same gas (Fig. 3, *i.e.*, $i_{H_2} : (-i_{H_2O}) : (-i_{CO_2}) = 1.85 : 1.54 : 1$). This result suggests that the Ni wire data in Fig. 2 and 3 were not significantly affected by metallic hydrogen diffusion.

Figure 6 reproduces results for a solid Ni membrane and for a perforated foil of the same thickness and size. The perforated foil can serve, as does the dipping wire, as a simple model for a porous fuel cell anode. The data for the nonporous membrane cannot be related directly to wire data because of the very different transport paths for H_2 and for H_2O, CO_2. The perforated foil should show the current generated at numerous meniscuses added to the current from the nonporous foil. Significant supply of hydrogen through the metal to the meniscuses in the pores should have been noticeable because this supply would be more pronounced than with a dipping wire.

We estimated the contribution of the holes to the current by adjusting the wire data for the difference in (total) length of the three-phase boundary. The length of this line for a single pore was determined from photomicrographs of frozen and cross-sectioned electrodes withdrawn from the melt under operating conditions. We assumed that the meniscus had the same shape when liquid. The total length of the three-phase boundary was obtained by multiplying that of a single pore by the total number of pores in the foil. The sum of this estimated meniscus current and that for the nonporous foil matched fairly well the actual data (see Fig. 6). (In passing, it may be remarked that a similar adjustment of the wire data for total length of the three-phase line in porous Ni fuel cell anodes, estimated from the mean pore size, also agreed well with actual data for the latter. In this comparison metallic hydrogen diffusion was neglected.) The efficiency of a meniscus as a gas electrode can be appreciated from the fact that the total cross section of holes was only $\sim$ 3% of the foil area.

One of the reasons why no interference by CO was noticed was that the CO pressures used were much smaller than the H_2 pressures. An equally important reason will become clear from the following.

At higher polarization (> 200 mV) the Ni oxidation obscured the anodic gas reaction on this metal. On more inert metals (Au, Pt, Pt-Rh), the current increased beyond the H_2 limiting current. These currents at > 200 mV were poorly reproducible. Closer investigation, using wires, suggested a strong dependency on time of exposure of the melt to gas, and some effect of H_2O pressure. We assumed that this reaction at larger η was due to the CO content of the gas and proceeded accordingly.

Figure 7 reproduces the data for the oxidation of dry CO/CO_2 mixtures at dipping wires of Ni, Au, and Pt. The data on Ni at > 200 mV were obscured by NiO formation. On Au and Pt, the current increased strongly above 200 mV, but was similarly unreproducible as that under H_2-containing gases in this potential region.

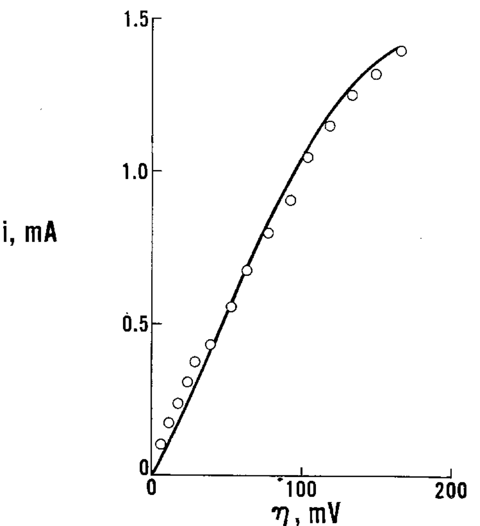

Fig. 5. Stationary polarization curve for dipping Ni tube. Same conditions as in Fig. 3.

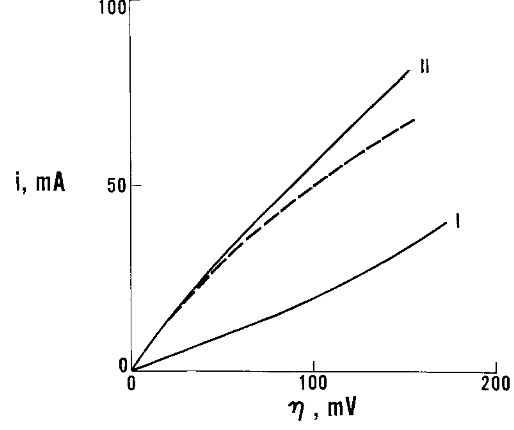

Fig. 6. Stationary polarization curves for a nonporous I and a perforated Ni foil II. Dashed curve: Sum of curve I and Ni-wire data, adjusted for meniscus length in pores of perforated membrane.

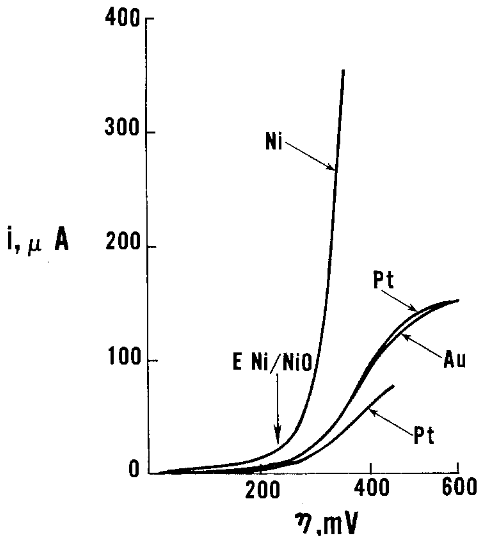

Fig. 7. Polarization curves for dipping wires of different metals on a mixture of 0.67 atm CO_2 and 0.33 atm CO.

Figures 8 and 9 show the changes in the voltammograms with elapsed time after replacing a CO/CO_2 mixture with an He/CO_2 mixture of the same CO_2 content (Fig. 8), and for the reverse process of reintroducing CO (Fig. 9). The slow changes evident in these figures could not be accelerated by agitating the melt. In contrast to the very slow changes in the main current wave at > 200 mV, the ocp responded very fast (seconds) to changes in CO pressure without, however, quite reaching for some time the equilibrium value on switching from He to CO. This behavior was in marked contrast to the H_2 reaction which responded very much faster to changes in the pressures of H_2, H_2O, and CO_2.

The results suggest that the oxidation of CO is a complex process. The first wave appears to be due to the direct oxidation of dissolved molecular CO. The much larger subsequent waves, of which there are at least two, apparently are not due to such dissolved CO molecules. It is difficult to reconcile the very slow increase of these waves with a simple dissolution process. The rapid response of the ocp to change in P_{CO} also contradicts such assumptions. Rather, these subsequent waves suggest oxidation of products formed by chemical reaction between CO and melt as has been suggested by Borucka and Appleby (10).

We analyzed a melt which had been exposed to CO for many hours. The frozen melt was dissolved in water. The solution was acidified and the remaining CO expelled by bubbling N_2. Titration with permanganate revealed substantial quantities of oxidizable substance which was not, however, identified qualitatively. (It seems likely that whatever had been present in the melt would have been altered by our analytical procedure.) A blank test with melt not subjected to CO did not show such oxidizable substance.

Borucka and Appleby, who made similar observations with submersed electrodes at 800°C in ternary Li, Na, K-carbonate melt, suggested formation of $CO_2^=$ ions

$$CO + CO_3^= = CO_2^= + CO_2 \qquad [9]$$

This substance, containing the highly reactive carbanion, would be expected to produce, *e.g.*, formate in the course of our chemical analysis. Our analysis, therefore, would not have distinguished between $CO_2^=$ and other possible compounds such as oxalate and/or formate in the melt. Borucka and Appleby based their conclusion of $CO_2^=$ formation on the proportionality of the second wave to $1/P_{CO_2}$ according to reaction [9]. These authors did not report any difficulties in achieving equilibrium between melt and gas such as are exemplified by the data in Fig. 8 and 9. Because of these difficulties we have been unable to determine the effect of CO_2 pressure on the second current wave. Borucka and Appleby also apparently did not observe the third wave in Fig. 8 and 9.

Generally, one should not expect $CO_2^=$ ions to be stable in the presence of CO_2 and/or H_2O. If this ion behaves similarly to other substances containing carbanion with a free electron pair at the carbon, we should expect formation of oxalate and/or formate (in the presence of H_2O). Formates decompose at high temperature to oxalate and H_2. Thus the following reactions, which are analogous to well-known industrial processes, cannot be excluded at present

$$CO + CO_3^= = (CO_2^= + CO_2) = C_2O_4^= \qquad [10]$$

$$CO + OH^- = HCOO^- \qquad [11]$$

$$2HCOO^- = H_2 + C_2O_4^= \qquad [12]$$

$$H_2O + CO_3^= = 2\,OH^- + CO_2 \qquad [13]$$

$$2CO + H_2O + CO_3^= = H_2 + C_2O_4^= + CO_2$$

$$[14] = [11] + [12] + [13]$$

These reactions can serve to explain several of our observations, some of which cannot be rationalized with the assumption of $CO_2^=$ ions. Intermediate formation of formate would explain the apparent accelerating effect of H_2O. Waves similar to those in Fig. 8 and 9 were also observed with shift gases but the waves at large η usually appeared much faster than with dry CO/CO_2.

In formate, as in $CO_2^=$, the formal oxidation state of carbon is the same as in CO. In fact, CO is the anhydride of formic acid not only formally but also exhibited in organic reactions. In oxalate, the oxidation state of carbon lies between those in CO and CO_2. The oxidation of CO to $C_2O_4^=$ can therefore also proceed electrochemically, and chemical formation of oxalate can occur by an electrochemical mechanism.

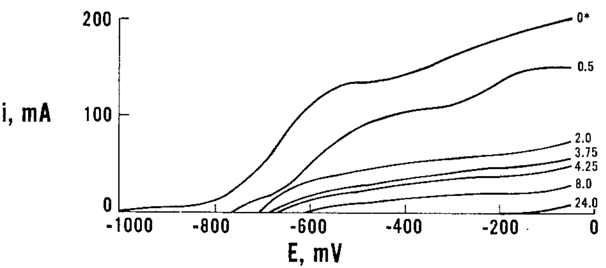

Fig. 8. Polarization curves for dipping Au wire. Parameters indicating time elapsed (hours) after replacing CO/CO_2 (1:2) mixture with an He/CO_2 (1:2) mixture.

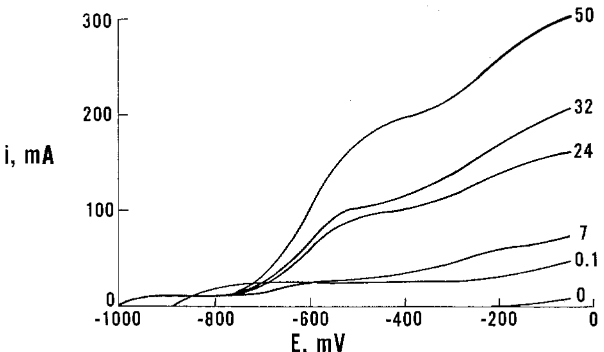

Fig. 9. Polarization curves for dipping Au wire. Parameters indicating time elapsed (hours) after replacing an He/CO_2 (1:2) mixture with a CO/CO_2 (1:2) mixture.

Instead of reaction [10] we then have

$$2CO + 2CO_3^= = C_2O_4^= + 2CO_2 + 2e^- \quad [15]$$

$$2CO_2 + 2e^- = C_2O_4^= \quad [16]$$

$$CO + CO_3^= = C_2O_4^= \quad [10] = [15] \text{ and } [16]$$

Reactions [15] and [16] represent the two-step oxidation of CO to CO_2 if both run anodically.

In order to explain our observations, we would assume that reaction [16] has a smaller rate constant than reaction [15]. Now, at a given overall anodic polarization, the polarization of [15] decreases because of accumulation of oxalate produced by the current. The steady-state current is small and not much larger than the equivalent rate of oxalate diffusion into the bulk melt. This may be the reason why the polarization resistance for the gold meniscus electrode in Fig. 7 is so much larger than those for immersed electrodes (10). A meniscus electrode may accumulate ionic intermediates more rapidly than an immersed one.

At higher polarization $C_2O_4^=$ would be oxidized and the current would increase accordingly. This current could be larger than the equivalent diffusion rate of CO because it would be the sum of the oxidation of CO and of accumulated oxalate. Removing or resupplying CO would have little effect on the large wave at $\eta > 200$ mV which would decay, or reappear slowly as oxalate is decomposed, or formed in the bulk melt (primarily by reaction [10]). However, the ocp would respond almost immediately to changes in P_{CO}. These intermediate ocp's although being mixed potentials, would be dictated by the $CO/C_2O_4^=$ electrode rather than by the CO/CO_2 reaction

$$\text{ocp} \sim E_o + \frac{RT}{2F} \ln (C_2O_4^=) P_{CO_2}{}^2/P_{CO}{}^2 \quad [17]$$

At very slowly changing oxalate activity, and P_{CO_2} = const., this potential would change rapidly with CO pressure.

Finally, the discussed reactions can also serve as rationalization for the fact that one frequently finds, with H_2-containing gases, ocp's which lie substantially (60-100 mV) below the equilibrium potential for gas (11). Initially, with very little oxalate present, the potential of reaction [15] would be strongly negative and the ocp can be explained as the mixed potential between the H_2/H_2O and $CO_2/C_2O_4^=$ reactions, both running cathodically, and the $CO/C_2O_4^=$ electrode running anodically. Formation of $CO_2^=$ could not be used as an explanation since any explanation requires an anodic partial reaction proceeding fast and at potentials below that of the H_2/H_2O electrode. $CO_2^=$ would be produced from CO without change in state of oxidation.

Conclusions

The data in Fig. 2-6 suggest that the polarization of the H_2/H_2O electrode is essentially diffusion overvoltage. This conclusion is supported by the absence of effects of metal roughness and the kind of metal, and it is in full agreement with previous findings (2, 6-8).

In the presence of very fast hydrogen transport, the diffusion overvoltage due to the products (H_2O, CO_2) bore a striking resemblance with activation polarization, particularly because no limiting current was observed. Under certain conditions, the polarization curve (I vs. E) can be approximately linear over a fairly wide range of currents. Small concentrations of CO had no noticeable effect on the H_2 reaction.

The electrochemical oxidation of CO is far more complex. For meniscus electrodes, and at polarizations smaller than 200 mV, this reaction is very slow. This reaction presumably is the oxidation of molecular CO (10). The nature of the reaction product(s) between CO and melt which gives rise to much larger current waves at $\eta > 200$ mV is not clear. It probably would require optical measurements in order to identify this product.

Applied to molten carbonate fuel cell anodes operating at around 650°C, the results suggest that H_2 is the fuel of choice. The utilization of CO as fuel is hindered by the very slow reaction rate at low overvoltages on meniscus electrodes which porous electrodes essentially are. The products of the direct reaction of CO with the melt are formed too slowly to sustain the cell current under steady operating conditions. Furthermore, the saturation concentration of molecular CO in the melt appears to be very small, much smaller than that of H_2. It seems questionable, therefore, that better catalysts would suffice to make efficient CO anodes.

As a consequence, we conclude that efficient CO utilization requires anode structures capable of functioning as internal shift reactors. Such a dual function implies long gas pores with walls which are catalytically active for the shift reaction. This shift reactor would be in series with the electrochemically active meniscus region at the end of the gas pore. Since long gas pores increase diffusional losses, it would appear necessary to use structures designed to optimize both functions. Such optimization, however, would become necessary only below a certain H_2/CO ratio for a given thickness.

ABSTRACT

During a photoelectrochemical reaction only a portion of the light energy absorbed by the semiconductor (CdS or TiO_2 single crystal) is utilized in the electrode reaction. The unused portion of energy is expended through various mechanisms as heat. Therefore by monitoring temperature changes within the photoanode as a function of electrode potential and light intensity, information concerning the efficiency of the process can be obtained. Experimental results are presented and interpreted using a model for the energy balance within the system. This permits the determination of the quantum and energy efficiencies simultaneously without the need to calibrate the light source.

A number of photoelectrochemical cells based on semiconductor electrodes for photoelectrosynthesis (*e.g.*, the photodecomposition of water) and the conversion of solar energy to electricity have been reported (1-15). The major factors determining the efficacy of these semiconductor electrode cells are the quantum efficiency for electron flow (*i.e.*, number of electrons flowing/number of photons absorbed), and the power conversion efficiency (*i.e.*, chemical or electrical power output/input radiant power). It is not uncommon to find near unity quantum yields for electron flow at a sufficiently high bias (positive for the case of n-type semiconductors) during irradiation with greater than bandgap energy light for many semiconductors. However, even when high quantum efficiencies have been obtained, the power efficiencies were much lower (10-15). For example, for photooxidation at a CdS single crystal anode, Wrighton *et al.* (15) reported that with an Se^{2-} solution the maximum monochromatic power efficiency obtained was 3.4% with a maximum quantum efficiency of 49%. Such findings demonstrate that the major part of the light energy absorbed by the semiconductor is not used for the photo-assisted oxidation but rather is converted to heat energy probably via radiationless transitions within the conduction band of the semiconductor (*i.e.*, when the photon energy is in excess of the bandgap energy) or electron-hole recombination processes. Consequently, thermal measurements of the semiconductor electrode during electrolysis can aid in the determination of the efficiencies and perhaps in the elucidation of the mechanism of the cell processes.

We recently described a new spectroscopic method called Photothermal Spectroscopy (PTS) (16). This technique involves placing a thermistor on or in close proximity to a sample and measuring temperature changes (*i.e.*, thermistor resistance changes) during sample irradiation with monochromatic light. This technique can be easily adapted to cases when the sample is a semiconductor electrode (17). Cahen (18) has also shown that similar measurements with photoacoustic spectroscopy can be used to determine the efficiency of solid-state photovoltaic devices. We report in this paper measurements of the conversion of light energy to chemical and/or electrical energy at CdS and TiO_2 photoanodes by direct determination of the temperature changes of semiconductor electrodes. The results were interpreted using a theoretical equation for the energy balance within the system. In this manner the quantum efficiency and power efficiency could be determined without calibration of the irradiation source.

Key words: photoelectrochemical, semiconductor electrode, quantum efficiency, energy efficiency, temperature changes.

Experimental

Procedure.—The basic photothermal experiment was essentially carried out as previously described with slight modifications (16, 17). In these experiments the photoanodes studied were CdS and TiO_2 single crystals. The results reported here are for monochromatic radiation at wavelengths corresponding to energies greater than the bandgap energy (for example, for CdS, 490 nm). The photothermal responses were obtained for the photoanodes during both anodic polarization and under open-circuit conditions in the electrolyte solutions. The corresponding current and temperature changes were then plotted as a function of potential. Experiments were carried out in two laboratories with two different experimental setups (referred to as A and B).

Instrumental.—Block diagrams of these are shown in Fig. 1 and 2. The apparatus (A) in Fig. 1 employed a 500W high pressure mercury lamp (Ushio Electric Company Limited) housed in an Ushio Model UI-501C housing. A lens was used to focus the light beam and interference filters (Koshin Kogaku Company Limited) were employed to select the wavelength of exciting light. A shutter with two timers, made by special order for this experiment (Ishikawa Seisakusho Company Limited) was used to fix precisely the irradiation period. System B is shown in Fig. 2. The light source was a 2500W short arc xenon lamp housed in an Oriel Model LH-152N housing. The output of the lamp was first chopped mechanically (on 20 sec; off 40 sec) and then focused using f/1 quartz optics on the entrance slit of a Jarrell-Ash Monochromator (Model 82-410). The resulting monochromatic light (10 nm bandpass) was then filtered of second order and finally focused on the photoanode within the electrochemical cell.

All cells were equipped with platinum counter-electrodes and saturated calomel reference electrodes (SCE). Irradiation was accomplished through optically flat windows both in the water baths and in the cells. The working electrodes were placed a sufficient distance from the cell window (~2 cm) to avoid any

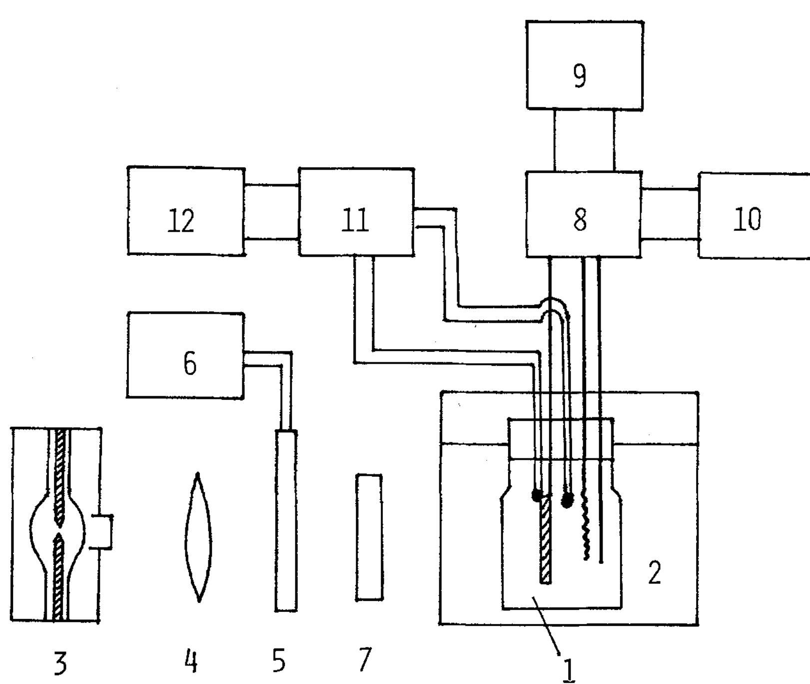

Fig. 1. Measurement assembly, A

heating effects due to window heating. A nitrogen bubbler was employed for deoxygenating the solutions. The cell temperature was maintained by a water bath which in System A was thermostatted.

The working electrodes were cadmium sulfide single crystals [(001) surface] (Teikoku Tsushin Company Limited) which had dimensions 10 × 10 × 1 mm and a carrier density of 4.8×10^{16} cm^{-3}, and titanium dioxide single crystals [(001) surface] (Nakazumi Crystal Company Limited) each having dimensions about 10 × 10 × 1.5 mm and treated by reduction to increase carrier density. The ohmic contacts were made by electroplating indium on one side of each crystal and then attaching a copper wire to the contact with conducting silver epoxy [Seisin Shoji Company Limited, No. 4992 (A), or Allied Products Corporation, New Haven, Connecticut (B)]. The back and sides of the crystal were insulated and mounted on a flat piece of glass attached to a glass rod with epoxy resin [Semedian Company Limited (A), or Devcon Incorporated, Danvers, Massachusetts (B)]. The semiconductor surfaces were polished with 0.3 μm polishing alumina prior to use. Then, in the case of CdS they were etched just before use in concentrated hydrochloric acid for 10 sec.

The structure of the semiconductor electrode (with a thermistor in place) is shown in Fig. 3. Matched pairs of thermistors were used: (A) Shibaura Electronics Model BSB4-41A; nominal resistance 4 kΩ sensitivity, 0.052°C/Ω or (B) Victory Engineering Incorporated, Model 32A223; nominal resistance, 2 kΩ, sensitivity, 0.013 °C/Ω. Both had time constants of 0.4 sec when immersed in unstirred water. The thermistors were used in a differential arrangement with one thermistor held against the front surface of the electrode and the other positioned behind the electrode while not touching it. The cell was carefully positioned so that the monochromatic light beam struck the whole exposed surface of the electrode but neither of the thermistors. Thus a change in temperature of the electrode caused a resistive change in the thermistor and produced a voltage imbalance in (A) the d-c or (B) the a-c bridges. This small voltage was amplified and then displayed on strip chart re-

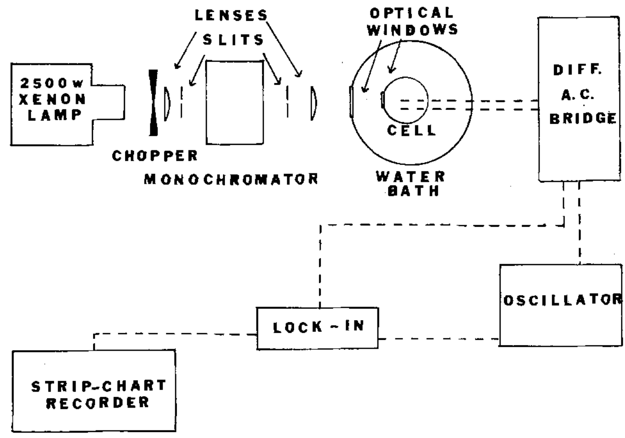

Fig. 2. Measurement assembly, B

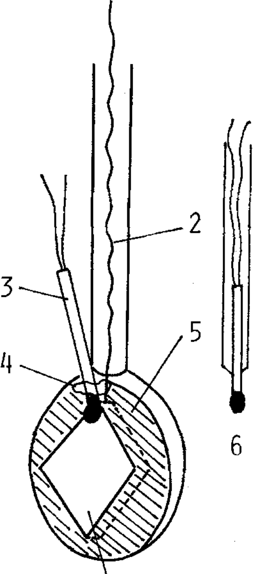

Fig. 3. Structure of semiconductor electrode. Light irradiates only the semiconductor surface and not the thermistors. The contact to the electrode and the thermistor is insulated from the solution by a thin layer of epoxy cement.

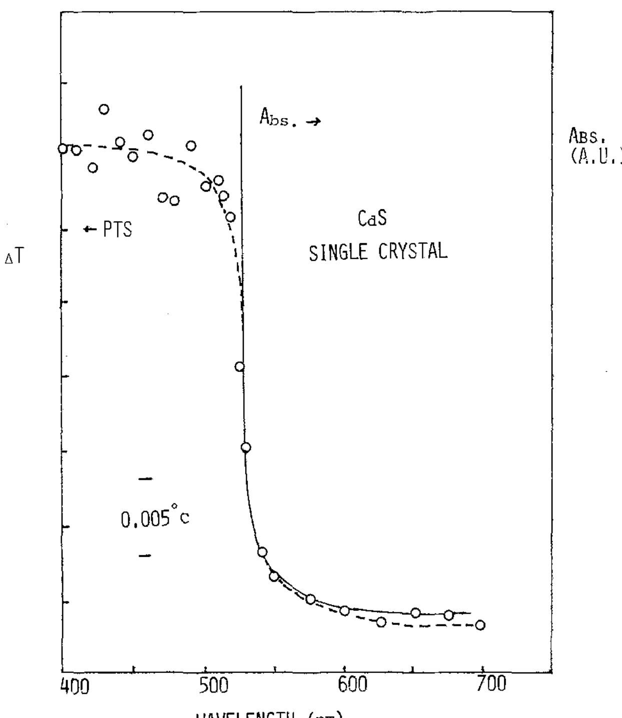

Fig. 4. Photothermal spectrum (PTS) of CdS single crystal. The solid line shows the absorption spectrum of the same crystal.

corders (A) Tao Electronics Model ERP-2T or (B) Tosely Model 7100B.

The current-potential and current-time curves were measured under potentiostatic conditions using potentiostats and potential programmers: (A) Nikko Keisoky Company Limited (Models NRGS-301 and NPS-2) and (B) Princeton Applied Research (Models 173 and 175). Cyclic voltammograms and current-time curves were displayed on an X-Y recorder [(A) Yokokawa Type 3078 or (B) Houston Instruments Model 2000].

The monochromatic lamp intensity was measured precisely using either (A) a chemical actinometric method (potassium ferrous oxalate) or (B) an EG&G radiometer/photometer Model 550-1. All chemicals were of reagent grade and were used without further purification.

Results

Previous studies with photothermal spectroscopy (PTS) have shown that the temperature changes which occur upon light absorption correlate well with the results of optical absorption spectroscopy. This is demonstrated in the PTS of single crystal CdS (Fig. 4) where irradiation with light of energy greater than the bandgap produces electron-hole pairs which, if the semiconductor is not a fluorescent, phosphorescent, or photochemically active material, recombine through radiationless transitions to produce heat. Although the spectrum shown in this figure was observed for the sample in air, similar PTS spectra of smaller magnitude were measured in water. The magnitude of the observed signal depends on the thermal conductivity and the heat capacity of the sample and its environment.

When an n-type semiconductor is used as a photoanode of a photoelectrochemical cell, that portion of the impinging radiant energy which is not converted to electrical energy or stored as chemical energy is dissipated as heat. One source of this heat is the difference between the photon energy, E $(=h\nu)$, and the bandgap energy, E_g; this represents radiationless processes within the conduction band after light absorption. Other factors leading to heat dissipation are the difference between the valence band energy level and the solution redox level, $|E_{VB} - E_{redox}|$ and the difference (usually small) between the Fermi level and conduction band level, $|E_{F,flatband} - E_{CB}|$. Note that even when the quantum efficiency is unity, dissipation caused by these factors will cause heating at the electrode surface.

$CdS/Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$ system.—The photothermal experiment was applied to the photo-oxidation of $K_4Fe(CN)_6$ at the CdS photoanode. The solution used was 0.1M $K_4Fe(CN)_6$, 0.001M $K_3Fe(CN)_6$, and 0.2M Na_2SO_4 as the electrolyte. Current-potential curves using the CdS electrode showed typical behavior of an n-type semiconductor electrode (V_{FB} = −1.0V *vs.* SCE). The quantum efficiency of the CdS crystal was calculated to be nearly 100%, when the crystal was irradiated with greater than bandgap light (490 nm) (which was not absorbed by the electrolyte solution) and the electrode maintained at 2.0V *vs.* SCE. When the crystal was used as a photoanode in the solution. there was no change in photocurrent with time and no sulfur was detected on the surface after prolonged use. Therefore, we conclude that the $K_4Fe(CN)_6$ was the species oxidized and that the photoanode was stable in this solution.

The changes in temperature *vs.* time were measured at each applied potential while the photocurrent was recorded simultaneously. In the dark, no change in temperature was observed either at open circuit or at potentials positive of V_{FB}, where the observed currents were less than 10^{-9} A/cm². Figure 5 illustrates typical changes in temperature with time upon irradiation with greater than bandgap light (490 nm) at open-circuit condition and with various applied potentials. The temperature increased almost linearly when the light pulse was initiated. When the light pulse was terminated (after 20 sec irradiation) the temperature decreased quickly. We have already dis-

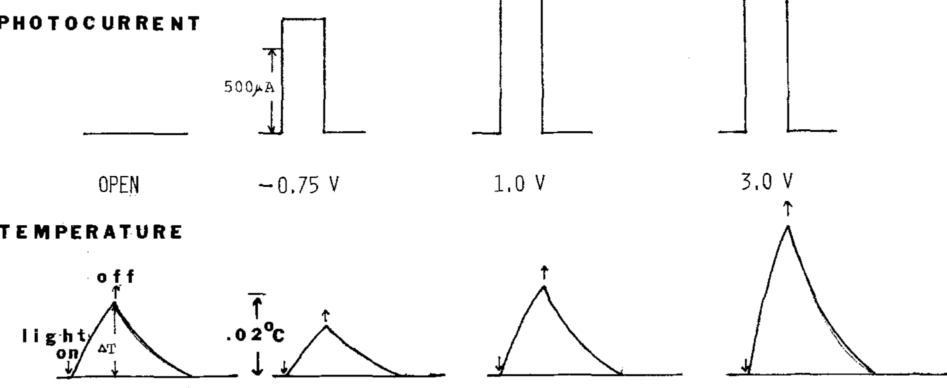

Fig. 5. The change in temperature vs. time for the CdS anode in 0.1M $K_4Fe(CN)_6$, 0.001M $K_3Fe(CN)_6$, and 0.2M Na_2SO_4. Upper curves show the anodic photocurrent vs. time.

cussed this behavior in the simplified theory of PTS (16).

In Fig. 6 the temperature change *vs.* potential and the corresponding photocurrent-potential curves are experimentally plotted. These results are representative of those obtained with both systems. Compared with the heating observed at open circuit, the temperature increase was smaller at −0.5V and larger at 2.0V and 4.0V, respectively.

TiO_2/H_2SO_4 system.—As the TiO_2 photoanode, three different TiO_2 single crystals were used. Each was reductively treated under vacuum at various temperatures and for different lengths of time: (*i*) 3 hr at 650°C; (*ii*) 3 hr at 550°C; (*iii*) 4 hr at 800°C. The experiments were conducted using each TiO_2 single crystal electrode in a 1M sulfuric acid solution. Since the bandgap of TiO_2 is 3.0 eV, the wavelength of the light chosen for irradiation was 370 nm. The irradiation period was fixed at 20 sec in each case. The results of a typical experiment using the first (and most efficient) TiO_2 electrode are shown in Fig. 7. The three different crystals showed quite different slopes for the temperature increase *vs.* potential curves. The semiconductor electrode which produced the largest photocurrent showed the steepest slope.

Theoretical Treatment

The experimental results can be interpreted by considering the energy balance within the photoelectrochemical cell. The first aspect of this formulation will be to examine a simple electrochemical reaction from a thermodynamic point of view to determine what information concerning the system can be obtained via thermal measurements. This model will then be modified to fit the constraints of the photoelectrochemical system which is slightly more complex yet very similar. The resulting thermal relationships will then be used to investigate the quantitative aspects of various photoelectrochemical devices.

Calorimetry has been used by previous investigators to measure the enthalpy change (ΔH_c) which occurs during an electrochemical reaction (19). Such a system can be described by the equation

$$\Delta H_c = Q - W_e \quad [1]$$

where W_e is the electrical work into (or out of) the system and Q is the heat evolved in the system from reversible and irreversible work. The electrical work can be expressed in terms of current, voltage, and

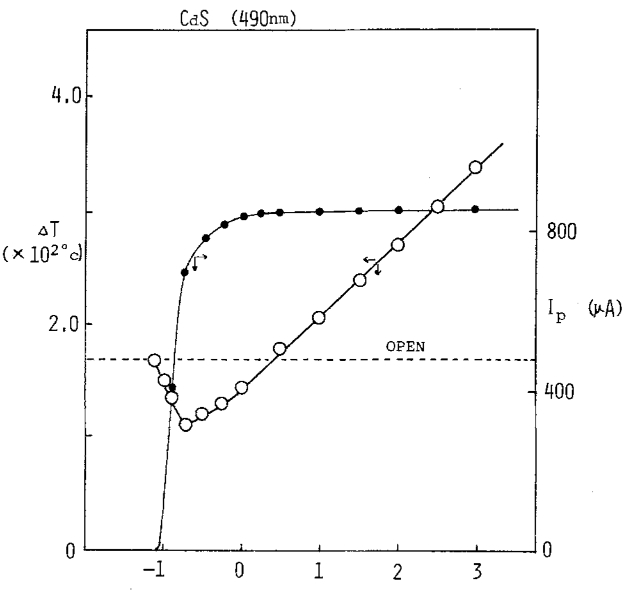

Fig. 6. Temperature change *vs.* potential (○) and photocurrent *vs.* potential (●) of the CdS single crystal electrode.

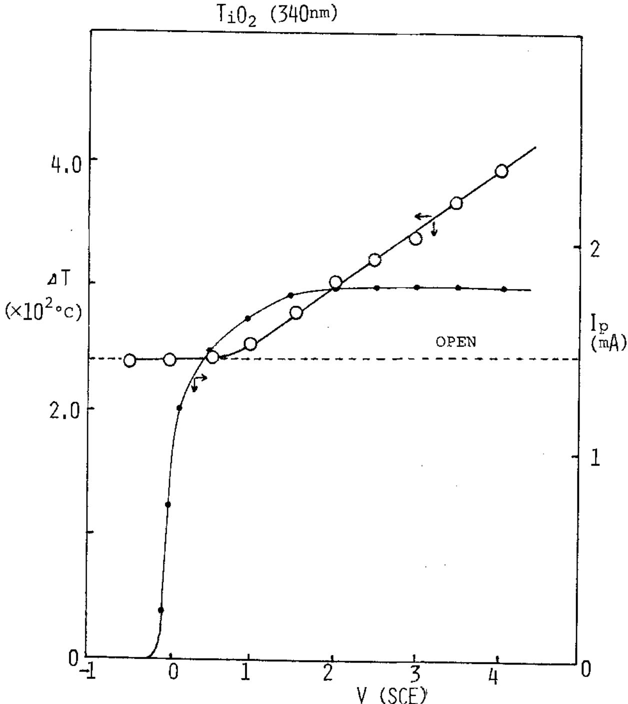

Fig 7. Temperature change *vs.* potential (○) and photocurrent *vs.* potential (●) of the TiO_2 single crystal electrode. TiO_2 single crystal was treated in the vacuum for 3 hr at 650°C.

time (Vit) and the heat evolved in terms of an entropy change for the whole cell reaction ($T\Delta S$), activation energy, in terms of overpotential, η, (ηit) and the contribution from electrode and solution resistance, R, (i^2Rt). The total expression for the enthalpy is thus

$$\Delta H_c = T\Delta S + \eta it + i^2Rt - Vit \quad [2]$$

This equation is directly applicable to the photoelectrochemical situation by considering two additional energy terms and by reevaluating the electrochemical cell in terms of energy in and out.

For the case of a photoelectrochemical device one must now consider that the electrode is illuminated with a monochromatic light pulse having an energy E (eV/photon), with an average absorbed intensity I (photon/sec) for a time t (sec). Therefore the total energy put into the system per light pulse is EIt (eV). This energy can then either be used by the semiconductor to promote the electrode reaction with production of electrical work (Vit) or evolved as heat in the semiconductor (Q_{sc}) via recombination and other radiationless processes. The resulting equation for the overall photoelectrochemical reaction is

$$\Delta H_c = Q_T - W_T \quad [3]$$

where

$$Q_T = T\Delta S + \eta it + i^2Rt + Q_{sc} \quad [4]$$

$$W_T = EIt + Vit \quad [5]$$

therefore

$$\Delta H_c = T\Delta S + \eta it + i^2RT + Q_{sc} - EIt - Vit \quad [6]$$

Upon rearrangement the relationship between the measured quantity, Q_T, and the rest of the variables we obtain

$$Q_T = Q_{sc} + T\Delta S + \eta it + i^2RT = EIt + Vit + \Delta H_c \quad [7]$$

This final equation can now be related to the actual photoelectrochemical experiment. Although determination of Q_T by calorimetric means is possible, in the photothermal experiments relative temperature changes are measured and these are used to extract the desired information. This is done by comparing Q_T

measured during current flow in the photoelectrochemical experiment to that measured when the cell is at open circuit. In the open circuit case no net electrochemical reaction occurs and all the absorbed light energy is converted to heat, Q^{o}_{T}, within the semiconductor, so that

$$Q^{o}_{T} = Q_{sc} = EIt \quad [8]$$

This condition shows that the heat absorbed by the system is directly proportional to the light energy put into this system. Therefore

$$\frac{Q_T}{Q^{o}_{T}} = \frac{Q_{sc} + T\Delta S + \eta it + i^2RT}{EIt} \quad [9]$$

The corresponding relative change in temperature at the semiconductor surface can be represented by

$$\frac{\Delta T}{\Delta T^{o}} = \Delta T_{rel} = \frac{Q_{sc} + T\Delta S + \eta it + i^2RT - k\Delta T}{EIt - k\Delta T^{o}} \quad [10]$$

where $k\Delta T$ is the heat lost by conduction from the electrode. Several assumptions must be made at this point concerning these temperature measurements. The first and most important is that temperature changes occurring on the electrode surface both in the semiconductor (Q_{sc}) and in solution ($T\Delta S + \eta it + i^2Rt$) are equally detectable. This is a good assumption because in general, the thermal conductivity of the electrode is at least an order of magnitude greater than that of the solvent. Other assumptions which must be made to simplify the treatment are that the terms $k\Delta T$ and i^2RT are very small and can therefore be neglected. This is acceptable because the temperature changes measured are typically on the order of millidegrees and the total resistance is usually very low. Note that if the $k\Delta T$ terms are not negligible, corrected values of ΔT can be obtained by extrapolation of the initial linear portion of the temperature rise with time to the value ΔT_{corr} at the time when the temperature begins to fall. In the activation term the overpotential, η, is actually $V - V_{FB}$ (where V_{FB} is the flatband potential of the semiconductor) so that Eq. [10] can be written as

$$\frac{\Delta T}{\Delta T^{o}} = \frac{Q_{sc} + T\Delta S}{EIt} + \frac{i(V - V_{FB})}{EI} \quad [11]$$

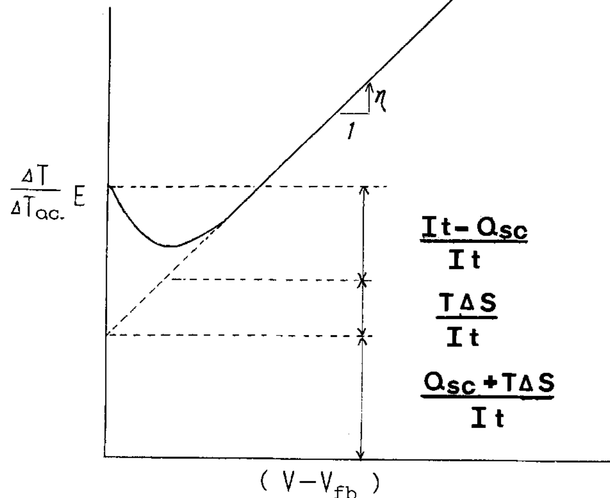
The left side of the equation can be given specific energy units to facilitate the mathematical treatment to finally yield

$$E\frac{\Delta T}{\Delta T^{o}} = \frac{Q_{sc} + T\Delta S}{It} + \eta_q(V - V_{FB}) \quad [12]$$

where $\eta_q = i/I$ = quantum efficiency of the photooxidation and $(Q_{sc} + T\Delta S)/It$ is the total heat change (usually evolved) in the system (at the photoanode). Therefore under constant illumination conditions (*i.e.*, EIt held constant) a plot of $E\frac{\Delta T}{\Delta T^{o}}$ against $(V - V_{FB})$ yields the quantum efficiency, η_q, from the slope of the straight line and the loss term, $(Q_{sc} + T\Delta S)/It$, is obtained from the intercept of the $E\frac{\Delta T}{\Delta T^{o}}$ axis at $V = V_{FB}$ as shown in Fig. 8. We define the single electrode, monochromatic energy efficiency of the system as

$$\eta_e = \frac{EIt - Q_{sc}}{EIt} \times 100 \quad [13]$$

The efficiency as defined above can then be obtained by making the appropriate correction for the entropy change associated with the electrode reaction. The details associated with this correction are described in the following discussion.



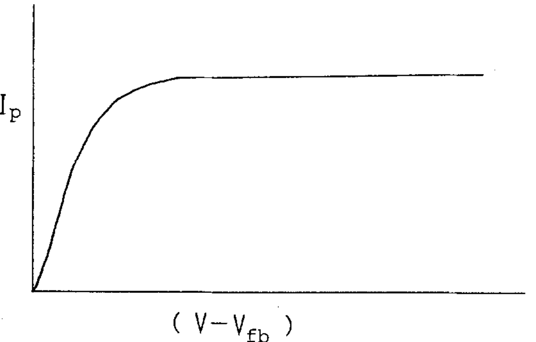


Fig. 8. (Top) Theoretical behavior of the photothermal signal *vs.* potential according to Eq. [12]. (Bottom) Photocurrent *vs.* potential.

Discussion

To illustrate the use of the Eq. [12] in obtaining the quantum and energy efficiencies, the results shown in Fig. 6 and 7 are replotted in Fig. 9 and 10, in which the ordinate is $E\frac{\Delta T}{\Delta T_{oc}}$ and the abscissa is $(V - V_{FB})$.

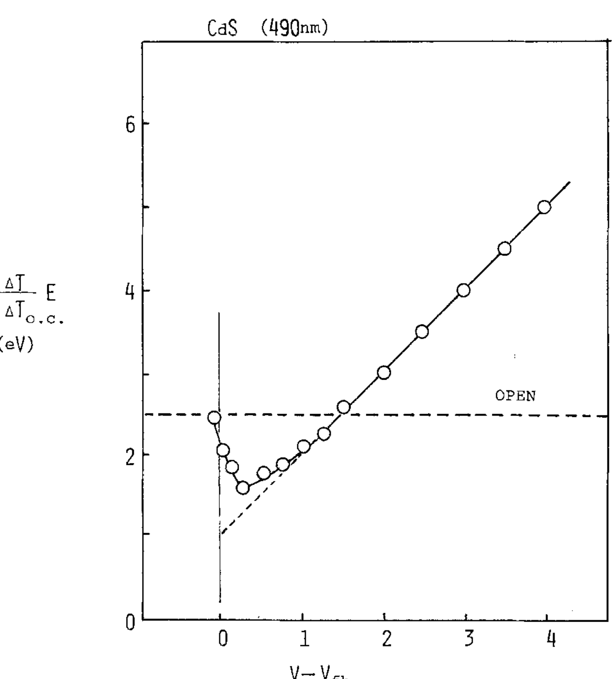

Fig. 9. Normalized photothermal signal *vs.* potential from the flatband potential of the CdS electrode.

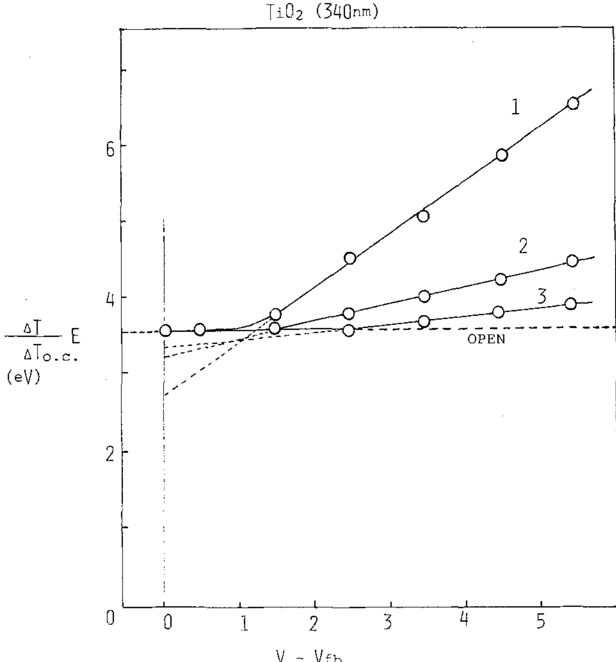

Fig. 10. Normalized photothermal signal vs. potential from the flatband potential of the TiO_2 electrodes. TiO_2 single crystals were treated in the vacuum atmosphere, No. 1: for 3 hr at 650°C; No. 2: for 3 hr at 550°C; No. 3: for 4 hr at 800°C.

For the $CdS/Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$ system the temperature increase of 1.7×10^{-2}°C which was measured at open circuit corresponds to $E = 2.5$ eV because 490 nm monochromatic light was used to excite the CdS electrode (Fig. 9). In the limiting photocurrent region, we find a straight line with a slope equal to 1.0. This means that the quantum efficiency of the photoreaction on the CdS electrode is unity, which is similar to the value found from the photocurrent and the calibrated light intensity (number of photons striking the electrode). From the intercept of the Y-axis obtained by extrapolating the linear portion of the curve to the flatband potential, we can calculate the energy efficiency of the photosemiconductor reaction, if entropic heat attributable to the electrode reaction ($T\Delta S$ or the Peltier heat) can be obtained. The behavior known as the electrochemical Peltier effect (*i.e.*, the entropy change at the electrode surface) has been investigated by Tamamushi (20). This effect can be attributed to three contributions: the entropy of the electrode reaction, the entropy attributed to the migration of ions and electrons, and the entropy caused by electrochemical polarization. Tamamushi investigated this effect during a study of the electrochemistry of the $K_4Fe(CN)_6/K_3Fe(CN)_6$ redox couple at a gold electrode. Cooling was observed during the oxidation step and heating occurred during reduction at potentials near the equilibrium potential; this can be attributed primarily to an entropy effect of the electrode reaction. This same effect must also be included in the photochemical reaction on the CdS surface.

To obtain the appropriate corrections in our thermal measurements, the electrochemistry of the $K_4Fe(CN)_6$/ $K_3Fe(CN)_6$ couple at a platinum electrode was studied. The entropy effect was similar to that found by Tamamushi in which cooling occurred under the anodic polarization and an equal amount of heating occurred under the cathodic polarization. It is only necessary to make this further correction for the electrochemical reaction entropy near the equilibrium potential, because the polarization effect was already included in the $\eta_q(V - V_{FB})$ term in Eq. [8] and the migration effect would be negligible (the solution and the CdS electrode, resistivity $= 1\text{-}2$ Ω/cm, were both highly conductive).

In this same solution, heating was also observed during the dark cathodic reaction on the CdS electrode under nitrogen bubbling. The amount of heating was 3.4×10^{-3}°C (which corresponds to 0.5 eV in this case), when a cathodic current of 850 μA (which was the same as the saturated photoanodic current) was passed for 20 sec. Therefore, assuming that the photoanodic reaction entropy is equal but opposite to this entropy (from the results on the platinum electrode), the endothermic entropy change on the CdS photoanode for a 20 sec light pulse was determined to be 0.5 eV.

The value of the intercept in Fig. 9, $(Q_{sc} + T\Delta S)/It$, was 1.0 eV. So, taking $T\Delta S/It = 0.5$ eV (endothermic), we find $Q_{sc}/It = 1.5$ eV. In this case (490 nm irradiation), the monochromatic energy conversion efficiency is $100 \times EIt - Q_{sc}/EIt = 100 \times 1.0/2.5 = 40\%$. This result is also consistent with the fact that only a fraction of the energy is being utilized for the oxidation of $Fe(CN)_6^{4-}$ to $Fe(CN)_6^{3-}$; *i.e.*, for the whole cell

$$CdS/0.1M\ K_4Fe(CN)_6;\ \ 0.001M\ K_3Fe(CN)_6/Pt$$

the maximum cell voltage obtainable is $|V_{FB} - V_{redox}| \simeq 1.0$V, while the energy of the incoming radiation is 2.5 eV (490 nm).

As shown in Fig. 10 for the TiO_2/H_2SO_4 system, three different lines were obtained, with slopes of 0.7, 0.3, and 0.1. These correspond to the quantum efficiencies of the different TiO_2 photoanodes. Again, as in the case of CdS, calculations using the intercepts of these lines can yield the various energy efficiencies. As is obvious from the results in Fig. 10, the photoanode which shows the smallest quantum efficiency (*i.e.*, smaller slope) has the largest intercept (*i.e.*, the lowest energy conversion efficiency). To get the actual energy conversion efficiency, we must again correct for the Peltier entropy effect, which is proportional to the magnitude of the photocurrent. The oxidation on the TiO_2 photoanode was oxygen evolution based on water decomposition. Contrary to the oxidation of $Fe(CN)_6^{4-}$ as mentioned above, oxygen evolution on the electrode showed exothermic heating behavior, mainly due to the entropy of the electrochemical reaction. To make the appropriate corrections for this entropy effect the reduction of $K_3Fe(CN)_6$ was examined at TiO_2 and platinum and the results compared to those observed during the oxidation of water at platinum. In this manner the magnitude of the entropy effect occurring during the photo-oxidation at TiO_2 could be estimated. When the anodic photocurrent was 1.8 mA (No. 1 in Fig. 10), it was found that the entropy effect corresponded to 0.5 eV. Therefore for electrode 1, since $E = 3.5$ eV (340 nm), $Q_{sc} + T\Delta S/It = 2.7$ eV (from the intercept), and $T\Delta S/It = -0.5$ eV (the entropy effect). Therefore, $Q_{sc}/It = 2.2$ eV. The energy conversion efficiency can be determined as

$$100 \times \frac{EIt - Q_{sc}}{EIt} = 100 \times 1.3/3.5 = 37\%$$

The fraction of the photon energy that is not used in the oxidation of the redox species is dissipated as heat via two possible mechanisms as shown in Fig. 11. The first mechanism, (a), represents the filling of a valence band hole by the reduced species in solution to produce a vibrationally excited species. This energy is quickly dissipated in the solution as heat. The second mechanism, (b), represents the isoenergetic electron transfer from the reduced species in solution to a surface state which then recombines with a hole in the valence band of the semiconductor, with the heat dissipated in the semiconductor itself. However, at this time we can not distinguish the difference between heat produced in solution or heat on the electrode itself. Therefore neither mechanism can be verified using only the temperature measurement.

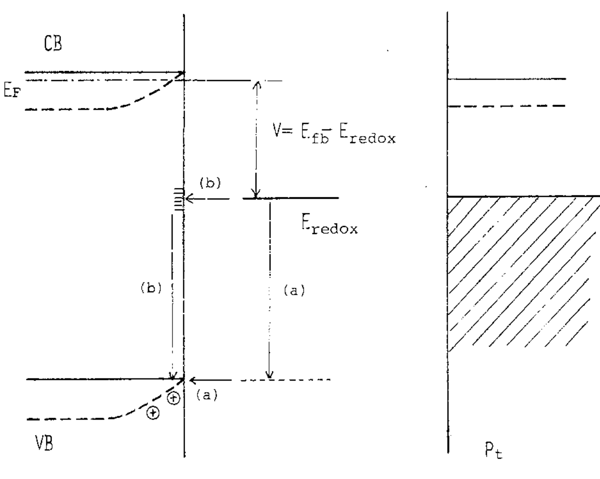

Fig. 11. Maximum open-circuit photopotential and heat dissipation mechanism.

Conclusion

By *in situ* temperature measurements of the semiconductor electrode, the quantum and energy efficiency of the electrode reaction could be obtained. The advantage of this type of measurement lies in the fact that it is a relative measurement and therefore does not depend upon knowing the light intensity. This eliminates the need for calibration of the excitation source and establishes a method by which results in different laboratories can be compared more easily. A disadvantage of the technique is that the precision of the measurements ($\sim \pm 1\%$) limits its use to the more efficient systems.

In considering the efficiencies obtained in this manner one should note that the results presented refer to the efficiency of the electrode reaction and not to the entire photoelectrochemical cell. In this work no attention was given to the reaction occurring at the counterelectrode or to whether the cell was photovoltaic or photosynthetic. In order to treat the entire system thermal measurements during the cell reaction would be necessary. Such measurements could be carried out in a manner similar to that described above or by placing the entire photoelectrochemical cell in a photocalorimeter and measuring the overall thermal change of the cell resulting from illumination. By using the former method both the electrode and cell efficiencies could be determined while calorimetric techniques would only yield the cell efficiency.

ABSTRACT

The electrochemical reactions of PbTe in acetate buffer of pH 4.9 were compared with those in strongly acidic and alkaline solutions. Rotating ring-disk studies provided information on the nature of soluble products, while the composition of the surface layers was analyzed by XPS. In the potential range of 0-0.4 V_H a Te-layer of only ~3Å thickness is formed and an equivalent amount of Pb^{2+} is dissolved, this Te-layer being too thin for coating or passivation purposes. At >0.4 V_H an oxide layer is formed which contains mostly TeO_2 (H_2TeO_3) and ~30% PbO on the surface. There is a competing process between oxide film growth and dissolution of approximately 50% of these oxides. The reduction of TeO_2 and PbO to elemental Te and PbTe occurs at <0 V_H and the reduction of Te to soluble tellurides at < −0.5 V_H. By appropriate cyclic oxidation and reduction the Pb concentration in the anodic oxide and the reduced layer can be further decreased to ~15%. The oxide layers are not good insulators (~1000Å film, anodic current ≧10 mA/cm^2 at 1.5 V_H). The use of electrochemical processes on PbTe for forming well passivating or insulating surface layers is limited.

The best qualities of infrared photovoltaic detectors on PbTe and $Pb_{0.8}Sn_{0.2}Te$ materials can only be obtained by a surface passivation which minimizes surface leakage with respect to bulk leakage. Investigations of PbTe-$Pb_{0.8}Sn_{0.2}Te$ heterodiodes have shown that the reverse currents of diodes with Te-coated surfaces are more than an order of magnitude lower than those with surfaces oxidized in air (1). The Te coating has been prepared by preferential etching of the PbTe and $Pb_{0.8}Sn_{0.2}Te$ surfaces. A previous paper (2) has demonstrated that PbTe surfaces etched with $HBr-Br_2$ or HNO_3 yield thin elemental Te layers (~600Å thick) which, however, may be quite porous. They only partially prevent oxidation at the underlying PbTe interface and are insufficiently passivating. Therefore, new processes producing thin protective Te layers on PbTe and $Pb_{0.8}Sn_{0.2}Te$ surfaces are still desirable.

Electrochemically controlled etching gives decisive advantages with respect to pure chemical processes. The surface reactions can be controlled using an electronic potentiostat. Formation, reduction, and thickness of surface layers are determined by the fixed electrode potential and are measured by the electrical charges related to the corresponding reactions. The semiconductor surface can be prepared with identical starting conditions and can be cleaned of any initial surface layers by dissolution processes at appropriate potentials. Even electronically insulating continuous and poreless surface layers may be formed because the redox process at the oxide/electrolyte interface is replaced by the potentiostatic circuit. One may envisage the direct anodic oxidation of PbTe to Te and dissolution of Pb^{2+} into the electrolyte similar to the preferential etching by oxidizing solutions. A different possibility for forming a Te layer exists in the anodic oxidation of the PbTe surface preferentially into a TeO_2 film and its subsequent reduction to elemental Te. The latter process would also yield information on oxide layers which may be useful for CCD device fabrication similar to the case of $Hg_{.07}Cd_{0.3}Te$ (3). In general MIS devices and CCD operation on PbTe are limited by the high dielectric constant of PbTe.

For the preparation of Te and TeO_2 layers on PbTe and $Pb_{0.8}Sn_{0.2}Te$ the conditions for the different oxidation and reduction processes must be known. The electrochemical reactions become more complex with an increasing number of elements in the semiconductor compound. Therefore, the electrochemical behavior of the simpler binary compound PbTe is presented in this paper and is compared with the properties of pure Pb and Te.

Like PbTe, Te is a semiconductor with a low bandgap of about 0.3 eV (4). The Fermi levels for n and p doping are close to each other and no rectification is observed in diode structures at 300°K. Therefore, the electrochemical behavior of these materials should be similar to those of metals and alloys. Usual potentiodynamic and potentiostatic experiments were performed and the soluble products were determined with a rotating ring-disk arrangement. The composition of the surface after the different electrochemical treatments was examined by XPS analysis. The value of XPS for the surface analysis of electrochemically treated semiconductors has been demonstrated by depth profiling of anodic oxide films (5).

Experimental

The samples were mostly PbTe films freshly prepared by evaporation with a modified hot wall technique (6) on cleaved <111> BaF_2 platelets. The epitaxially grown films were single crystalline, 5-10 μm thick with a surface of <111> orientation and 0.3 cm^2 area. The sample surface was covered by native oxide during air exposure before the electrochemical experiments (7). Depending on the partial pressure of Te p- and n-type films were grown with typical electrical properties of n, p = 10^{17}-10^{18} cm^{-3} and μ (300°K) = 1000-2000 cm^2V^{-1} sec^{-1}. However, the doping was irrelevant, because we did not observe differences in the electrochemical behavior between n and p samples, in agreement with the low bandgap. For test experiments and the ring-disk arrangement large sized poly and single crystalline bulk material was used. The disk front surface was oriented to <111> within 10 degrees and the doping was p ~ 10^{18} cm^{-3}.

The Te experiments were performed with large sized polycrystalline platelets and disks with front surface parallel to the $\{\bar{1}1.0\}$ cleavage planes (4). The electrical properties are p ~ 10^{16} cm^{-3} and μ (77°K) ~ 10^3 cm^2V^{-1} sec^{-1}.

The specimens were welded with indium to a copper wire for good ohmic contact. The contact area was covered with epoxy resin and fixed to a glass tube for good

Key words: rotating ring disk, film growth, passivation, XPS analysis.

mechanical stability of the electrodes. No resin was used for the XPS measurements so as to achieve a rapid sample transfer from the electrolyte into the UHV chamber. Electrochemical reactions at the unprotected contact area do not interfere with the processes at the clean parts of the samples and therefore no contamination is observed. A potentiostat. Tektronix pulse generators of Type 26 G3, and a function generator for linear potential variations were used for the electrochemical measurements. The pulse program was directly fed into the adder of the potentiostat.

The formation of soluble products during the electrochemical reactions was measured with a rotating Pt ring-PbTe(Te) disk electrode. A cylindrical PbTe specimen was drilled ultrasonically from a single crystal and covered with a 0.025 cm epoxy film. Two half Pt cylinders were fixed to the specimen and the whole assembly was inserted into a Plexiglas cylinder filled with epoxy resin. The front plane was mechanically polished with a final 1 μm graded diamond paste. The tellurium ring-disk electrode was prepared in the same way. A modified ASR 2 Pine disk rotator with rotating mercury contacts was used. Two coupled potentiostats built with differential amplifiers provided independent variation of the potential for the disk and the analytical Pt ring. The two potentiostatic circuits worked with a common grounded Pt counterelectrode and one reference electrode.

$Hg/Hg_2SO_4/1N\ H_2SO_4$ served as reference electrode. In this paper all potentials are given relative to the standard hydrogen electrode and are corrected for liquid junction potentials. Most experiments were performed in acetate buffer pH 4.9 with 0.073M Na acetate and 0.029M acetic acid providing good solubility for Pb^{2+} and low solubility for TeO_2, as desired. In Ref. (8) a similar slightly acidic electrolyte was used for anodic oxide film preparation on $Pb_{1-x}Sn_xTe$. Some experiments were performed in strongly acidic pH = 1.1 (0.1M $HClO_4$, HBr, and HNO_3) and alkaline solutions pH = 12.9 (0.1M KOH). All solutions were prepared with analytically pure substances and triply distilled water.

The surface composition was measured with x-ray photoelectron spectroscopy (XPS) in a Leybold-Heraeus system equipped with a sample interlock, a spherical sector analyzer, and a MgKα x-ray source (1253.6 eV). The resolution was ~1 eV and the detection depth ~20Å. Before introduction into the UHV chamber the electrochemically prepared samples were rinsed with triply distilled water.

Results and Discussion

Investigation of tellurium.—Electrochemical studies.—Potentiodynamic polarization curves of tellurium in acetate buffer pH 4.9 show a current increase at $\epsilon > 0.4\ V_H$, a peak of 1.3 mA/cm^2 at 0.65 V_H, and a current plateau of 0.8 mA/cm^2 up to several volts (Fig. 1). No oxygen evolution is observed despite the high electrode potentials. An electronically insulating tellurium oxide layer may explain the suppression of oxygen evolution. At $\leq 0\ V_H$ the reduction of the covering oxide to elemental tellurium is shown by a cathodic current peak with its maximum at -0.10 to $-0.20\ V_H$. A second cathodic peak appears at more negative potentials especially when the anodic oxide film is grown at high potentials. The onset of the anodic current density fits reasonably well to the thermodynamic value of the formation of TeO_2 or H_2TeO_3 from

$$Te + 2H_2O \rightarrow TeO_2 + 4H^+ + 4e^-$$

$$\epsilon^\circ = 0.528\ V_H \qquad \epsilon = 0.239\ V_H \qquad [1]$$

and

$$Te + 3H_2O \rightarrow H_2TeO_3 + 4H^+ + 4e^-$$

$$\epsilon^\circ = 0.589\ V_H \qquad \epsilon = 0.298\ V_H \qquad [2]$$

ϵ° is calculated with the values for the standard free enthalpy ΔG° of the compounds involved in the processes of Ref. (9). ϵ refers to pH 4.9. The cathodic reduction of the oxide occurs at more negative potentials as expected. Apparently this process is not reversible enough. The cathodic peak appears only if anodic polarization to $>0.40\ V_H$ is performed. The height and area of the cathodic peak increase with the maximum potential reached during the anodic scan (Fig. 1). This demonstrates qualitatively the formation and thickening of the oxide layer on Te with increasing electrode potential.

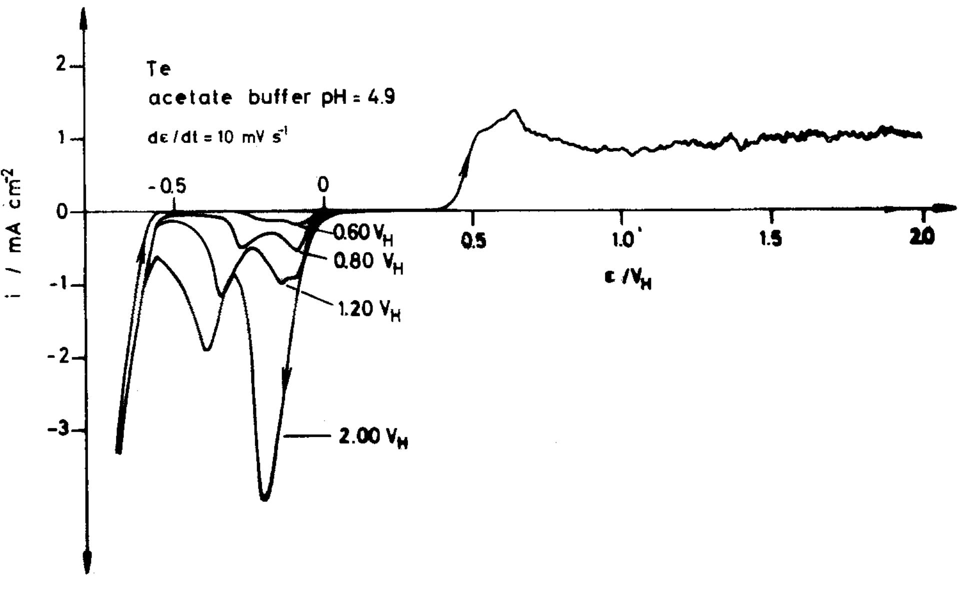
At $< -0.50\ V_H$ the reduction of Te to Te^{2-} or Te_2^{2-} leads to a strong increase of the cathodic current from

$$Te + 2e^- \rightarrow Te^{2-}$$

$$\epsilon^\circ = -0.92\ V_H \qquad \epsilon = -0.77\ V_H \qquad [3]$$

ϵ refers to a solution with 10^{-5}M of Te^{2-} to simulate a bulk electrolyte virtually free of soluble tellurium compounds.

Ring-disk voltammetry.—Examination with the rotating ring-disk electrode reveals that the oxidation product at the disk is quite soluble (Fig. 2). At a ring potential of $\epsilon_R = -0.25\ V_H$ a cathodic ring current I_R is observed, corresponding to the anodic disk current I_D at $\epsilon_D > 0.4\ V_H$. With potentiodynamically decreasing disk potential (10 mV/sec) the value of the cathodic ring current is unchanged even for $\epsilon_D < 0.40\ V_H$ when no corresponding anodic oxidation at the disk takes place, indicating that the oxide layer is still dissolving



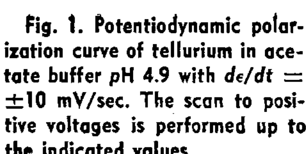


Fig. 1. Potentiodynamic polarization curve of tellurium in acetate buffer pH 4.9 with $d\epsilon/dt$ = ±10 mV/sec. The scan to positive voltages is performed up to the indicated values.

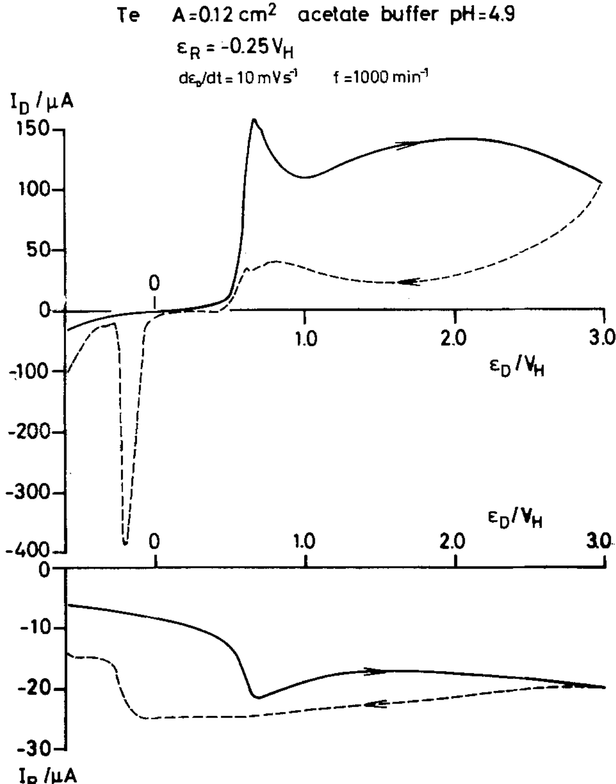

Fig. 2. Potentiodynamic polarization curve with a rotating Pt ring-Te disk electrode in acetate buffer pH 4.9 with variable disk potential $d\epsilon_D/dt = 10$ mV/sec, fixed ring potential $\epsilon_R = -0.25$ V_H, disk current I_D, ring current I_R, $f = 1000$ min^{-1}, disk area $A = 0.12$ cm^2.

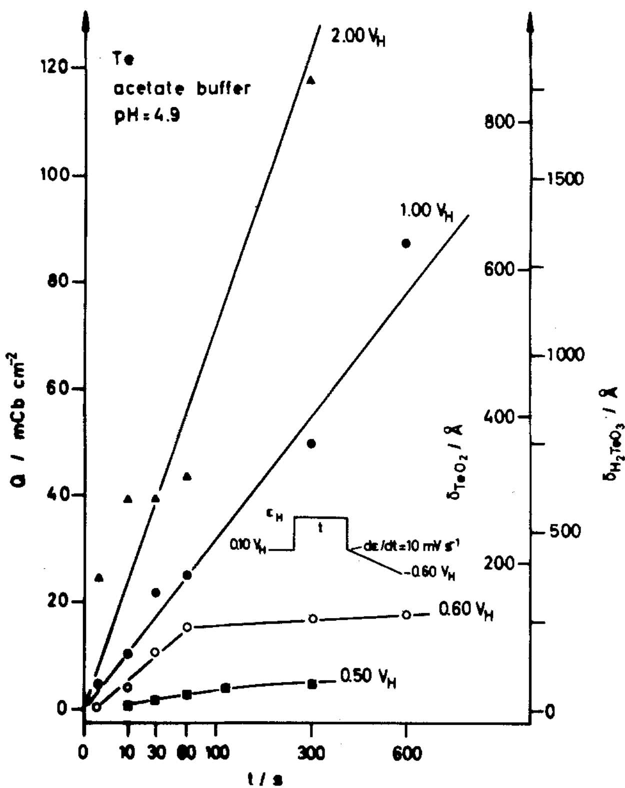

Fig. 3. Increase of the cathodic charge Q and the related oxide thicknesses δTeO_2 and δH_2TeO_3 with oxidation time of tellurium in acetate buffer pH 4.9 for four fixed potentials. Charge Q is determined by the indicated potentiodynamic reduction with $d\epsilon/dt = -10$ mV/sec.

until it is reduced at $\epsilon_D = -0.1$ V_H. Consequently, the cathodic ring current becomes less negative for $\epsilon_D < -0.1$ V_H. For quasistationary current conditions, 2 min after a potential in the current plateau is established, the collection efficiency for the ring is 17%. This is ~66% of the value expected theoretically for the geometry of the ring-disk electrode used if all anodic products at the disk would be soluble. Therefore only ~34% of the disk current has to be attributed to the formation of a stable $TeO_2(H_2TeO_3)$ layer on the Te surface.

In the plateau region the quasistationary current densities I_D and I_R increase with the square root of the rotation frequency. The anodic current is therefore determined by a diffusion-controlled process as given by the Levich equation. The TeO_2 layer is continuously dissolved as tellurite and its transport into the bulk solution by diffusion is the rate-determining step.

Thickness of the tellurium oxide layer.—The partial consumption of the anodic current density for the oxide film growth is seen more directly by the determination of the film thickness. The oxide was formed at sufficiently positive potentials ($\geqq 0.50$ V_H) for a definite period of time and reduced potentiodynamically (10 mV/sec) in the potential range of 0.10 to -0.60 V_H. The charge of the integrated cathodic current peaks Q is used to obtain a value of the layer thickness of TeO_2 or H_2TeO_3 applying Faraday's law to reactions [1] and [2] for oxide reduction.

Molar volumes of 27.5 and 58.23 cm^3/mole are used for TeO_2 and H_2TeO_3, respectively.

The increasing layer thickness with the time of oxidation for four different electrode potentials is given in Fig. 3. A constant layer thickness of ~100Å TeO_2 is obtained within about 1 min for 0.5-0.6 V_H while a linear increase of the oxide thickness with the square root of time up to several hundred angstroms is obtained for higher potentials. No growth saturation is observed. The increase of oxide thickness with the electrode potential for a fixed time of anodic oxidation is nearly linear (300Å at 4.0 V_H after 10 sec). These values, however, cannot be related to a constant layer thickness because it is still increasing with time.

It seems reasonable to assume a double structure of the covering oxide. A dense inner layer prevents the direct contact of the tellurium surface to the electrolyte. Therefore, no oxygen evolution takes place. An outer part is presumably porous or has a good ionic conductivity. The oxide thickness obtained is relatively high for the small electrode potentials. The layer does not effectively block the further anodic oxidation. The double structure of the cathodic current peak for high oxidation potentials (Fig. 1) might be an indication for a double structure of the anodic oxide. The oxide thickness decreases by dissolution in the electrolyte for open-circuit conditions or at 0.10 V_H when neither oxide formation nor reduction occurs. Approximately 60% of the oxide is dissolved during the first 50 sec whereas the rest is not removed within 200 sec, another hint for a double structure of the oxide.

Investigation of lead telluride.—Electrochemical studies.—The potentiodynamic polarization curve of PbTe-films at pH 4.9 has two distinct anodic peaks AI and AII (Fig. 4). At potentials more positive than peak AII the current density shows a weak plateau and then increases again at >0.9 V_H. The scan in negative direction reveals two cathodic peaks CI and CII (Fig. 4), the latter being observed only if the potential has been more positive than peak AII, while peak CI is closely related to peak AI. AI is only observed if the potential has crossed the CI position and vice versa. The close relation between the anodic and cathodic peaks demonstrates, therefore, that stable anodic oxidation products on the surface are reduced during the cathodic scan.

The potentiodynamic curve of PbTe can be compared directly to that of elemental Te. The increase of the anodic current at 0.40 V_H and the AII peak occur at the

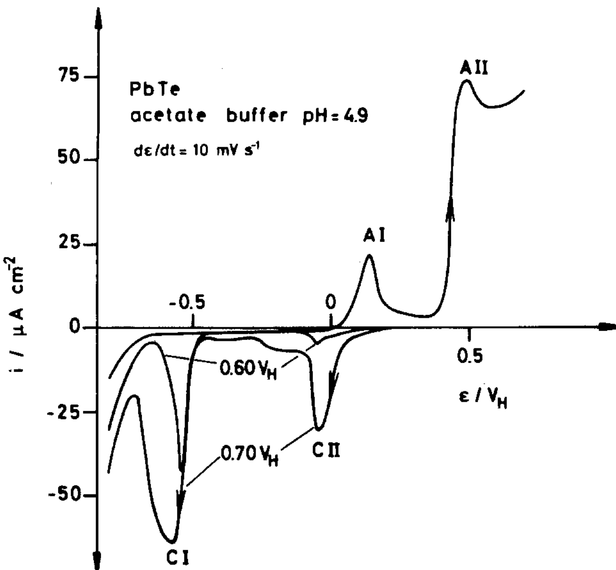

Fig. 4. Potentiodynamic polarization curves of PbTe in acetate buffer pH 4.9 with $d\epsilon/dt = \pm 10$ mV/sec and scans up to 0.6 and 0.7 V_H.

same potential as the anodic structure for the pure Te specimen. Peak CI is in the position of the increasing cathodic current for Te at -0.55 V_H and CII for the PbTe film is observed at about the same position as the cathodic peak of Te. Its position shifts in negative direction with increasing scan rate of the potential. A shoulder at negative potentials is obtained similar to Te. Only the AI peak is a new feature of PbTe.

For freshly deposited PbTe films, the current plateau at potentials more positive than 0.5 V_H (peak AII) reaches values in the range of 60 $\mu A/cm^2$. Higher current densities of some 100 $\mu A/cm^2$ are observed in subsequent experiments which is a consequence of surface roughening during anodic oxidation. This current plateau ends at 0.9 V_H where a further steep current increase is obtained. In contrast to the behavior of pure tellurium no limiting current is achieved, with the current density rising to more than 10 mA/cm^2 at potentials of ≥ 1.5 V_H.

The relevant electrochemical reactions occurring at the PbTe surface in the potential range of interest (-0.8 to 1.3 V_H) are given below with the standard potentials $\epsilon°$, which are calculated from the standard free enthalpy of formation of the compounds involved in the processes (9). The $\Delta G°$ value for PbTe is obtained from the standard enthalpy of formation and the standard entropy of Ref. (10). The electrode potentials ϵ refer to a solution of pH 4.9 and to a concentration of 10^{-5}M for all soluble substances which are not part of the composition of the bulk electrolyte

$$PbTe \rightarrow Pb^{2+} \cdot aq + Te + 2e^-$$
$$\epsilon° = 0.247\ V_H \qquad \epsilon = 0.100\ V_H \qquad [4]$$

$$PbTe + 2H_2O \rightarrow Pb^{2+} \cdot aq + TeO_2 + 4H^+ + 6e^-$$
$$\epsilon° = 0.435\ V_H \qquad \epsilon = 0.193\ V_H \qquad [5]$$

$$PbTe + 3H_2O \rightarrow Pb^{2+} \cdot aq + H_2TeO_3 + 4H^+ + 6e^-$$
$$\epsilon° = 0.475\ V_H \qquad \epsilon = 0.261\ V_H \qquad [6]$$

$$PbTe + 4H_2O \rightarrow PbO + H_2TeO_3 + 6H^+ + 6e^-$$
$$\epsilon° = 0.601\ V_H \qquad \epsilon = 0.354\ V_H \qquad [7]$$

$$PbTe + 2e^- \rightarrow Pb + Te^{2-} \cdot aq$$
$$\epsilon° = -1.286\ V_H \qquad \epsilon = -1.134\ V_H \qquad [8]$$

The anodic oxidation in the potential range of 0-0.4 V_H and the current peak AI at 0.140 V_H correspond to reaction [4], this being in agreement with the calculated potential value of $\epsilon = 0.10$ V_H. Te remains at the surface and blocks a further oxidation leading to small stationary current densities of ~ 0.5 $\mu A/cm^2$ (Fig. 4 and 8). The reduction of the Te layer to soluble Te^{2-} according to reaction [3] $\epsilon = -0.77$ V_H starts at -0.5 V_H with the CI minimum at -0.55 V_H (Fig. 4), analogous to the reduction of elemental Te in the same electrolyte (Fig. 1). The reduction of PbTe to Pb and soluble Te^{2-} at ≤ -0.5 V_H according to reaction [8] can be excluded because of the very negative value $\epsilon = -1.13$ V_H.

The anodic oxidation of Te and PbTe according to the reactions [1], [2], and [5] to [7] is expected in the potential range of 0.20-0.35 V_H after the thermodynamical values. These values are in fair agreement with ~ 0.40 V_H and the AII peak found experimentally for both materials. In the range of peak CII from -0.10 to -0.40 V_H the oxide layer is reduced to elemental Te and PbTe which is supported by the XPS measurements described later.

Some characteristic differences are observed for the polarization curves in strongly acidic solutions like 0.1M $HClO_4$, HNO_3, and HBr (pH = 1.1) (Fig. 5). Peak AI remains unchanged at 0.2 V_H. The independence of pH is expected because no H^+ ions are involved in reaction [4] occurring in this potential range. In the range of the AII peak, at >0.5 V_H, a pronounced current increase is obtained. No second plateau is reached as in acetate buffer pH = 4.9. Soluble oxidation products are apparently forming and no stable surface films. Consequently, no pronounced cathodic current peaks are obtained with potentiodynamic investigations for negative potential scans. These results agree with those of tellurium in the same strongly acidic solutions (not shown in this work). An oxide layer is detected by a small cathodic peak only when its reduction is performed immediately after its formation by a rapid cathodic potential scan. TeO_2 (H_2TeO_3) dissolves too fast and no protective layer remains on the semiconductor surface for a longer period of time. The shift of the current increase at 0.40 V_H for pH 4.9 to 0.60 V_H at pH 1.1 can be explained by the usual change of the potential of oxide formation with the pH value (40 mV/pH, Eq. [5] and [6]). At -0.3 V_H a small anodic peak is superimposed for positive scans. The peak is related to the oxidation of Pb to soluble Pb^{2+}, the Pb having been deposited by reduction of Pb^{2+} in solution, dissolved during a previous experiment.

Results in strongly alkaline solution of 0.1M KOH (pH 12.9) are similar to those in acidic solutions. The steep anodic current increase (AII range) is shifted to -0.2 V_H (Fig. 5), this change corresponding to a pH shift of 8 and 12 units compared to the acidic solutions pH 4.9 and pH 1.1, respectively. The anodic peak at -0.5 V_H is due to oxidation of Pb to PbO deposited cathodically during a previous run. However no anodic peak related to AI is observed because the potential shift of the AII reaction conceals it. No pronounced cathodic peaks are detected, this indicating unstable anodic surface film formation.

Etching solutions like HBr/Br_2 or HNO_3 were used successfully to obtain Te surface layers of some 100Å thickness. The electrode potential depends on the kinetics of the partial reactions of PbTe, the oxidant, and the thermodynamic conditions. In the case of the chemical etchants above this has not been measured, however, it should be in the range of 0.1-0.6 V_H when Te is formed at the surface but no TeO_2. The polarization curve of PbTe in 0.1M HNO_3 (Fig. 5) shows a pronounced current plateau of ~ 20 $\mu A/cm^2$ in this potential range. The relatively thick Te layers have to be porous to enable the Pb^{2+} transport into the solution. This apparently results in the poor coating properties of the films against oxidation in air for longer exposure (2). Similar results were obtained for Te-rich films produced by cyclic electrochemical oxidation and reduction (see section on XPS investigation).

Fig. 5. Potentiodynamic polarization curves of PbTe in 0.1M solutions of $HClO_4$, HNO_3, HBr (*p*H 1.1), and KOH (*p*H 12.9)

During the electrochemical examination of PbTe films in acetate buffer *p*H 4.9 in the potential range −0.80 to 0.80 V_H, no change of the surface smoothness is observed. If, however, the potential is increased above 0.9 V_H the steep current increase is accompanied by a local attack of the surface and the formation of black deposits (Fig. 6), which grow and finally coalesce into a continuous surface film. The presence of some irregular pits again demonstrates the local attack of the semiconductor surface.

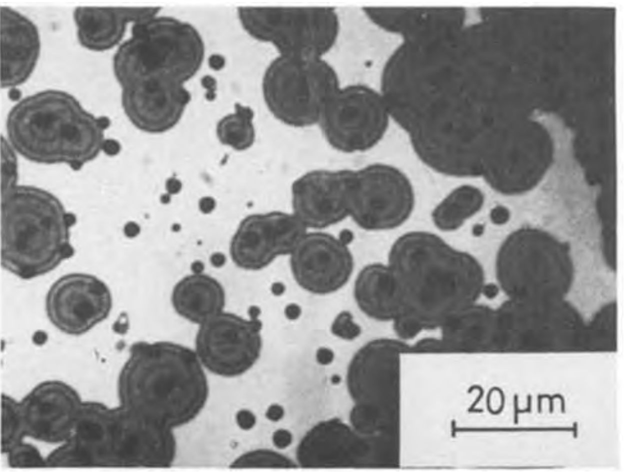

Fig 6. Photomicrograph of local attack and formation of deposits on a PbTe film after electrochemical treatment at 1.00 V_H for 5 min in acetate buffer *p*H 4.9.

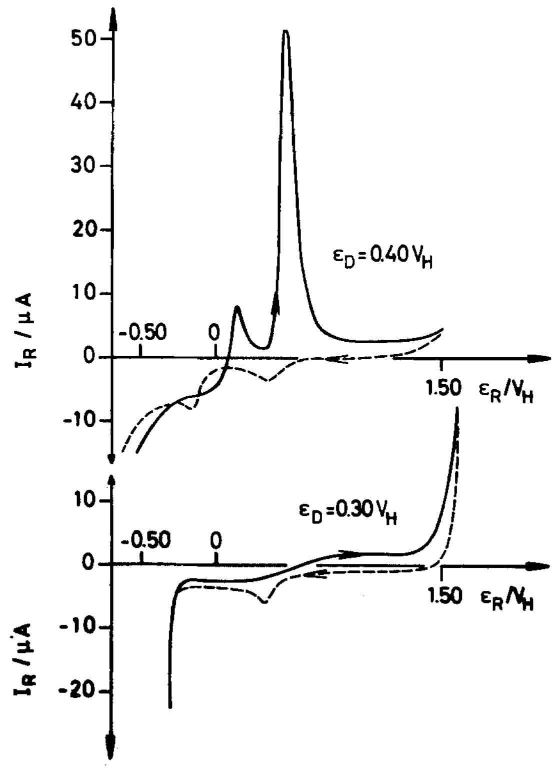
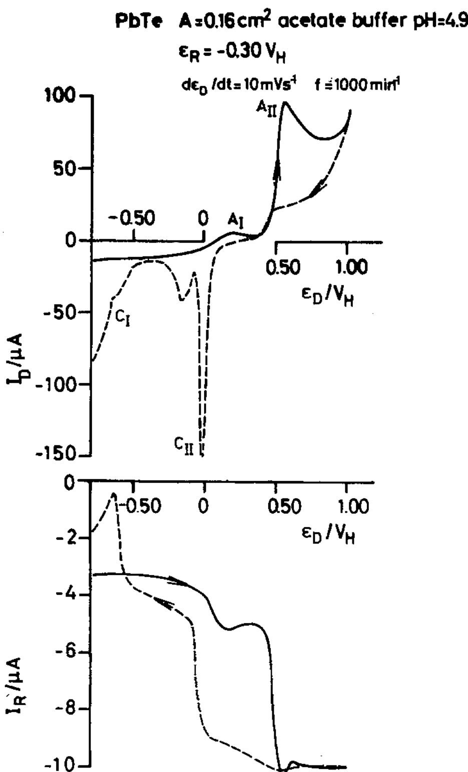
Ring-disk voltammetry.—To examine whether the rotating ring-disk arrangement is suitable for the determination of the soluble oxidation products of PbTe in acetate buffer *p*H 4.9 the potentiodynamic polarization curve of the Pt ring was examined (Fig. 7a). For disk potentials $\epsilon_D \geqq 0.40$ V_H the dissolution of tellurite is indicated by a cathodic step of I_R at $\epsilon_R = -0.1$ V_H (reaction [1] and [2]) for negative potential scans. At $\epsilon_R \leqq -0.30$ V_H the reduction of Pb^{2+} is superimposed. For disk potentials $\epsilon_D \leqq 0.30$ V_H this step is not observed because no oxidation products are formed. The steeper current increase at $\epsilon_D < -0.3$ V_H and $\epsilon_R > 1.40$



(a) Ring current I_R vs. ring potential ϵ_R with $d\epsilon_R/dt = \pm 10$ mV/sec and two fixed disk potentials $\epsilon_D = 0.30$ V_H ($i_D = 0$) and $\epsilon_D = 0.40$ V_H ($i_D = 0.22$ mA/cm^2).



(b) Ring I_R and disk I_D current vs. disk potential ϵ_D with $d\epsilon_D/dt = \pm 10$ mV/sec and fixed ring potential $\epsilon_R = -0.30$ V_H.

Fig. 7. Potentiodynamic polarization curve of a rotating Pt ring-PbTe disk electrode in acetate buffer pH 4.9 with $f = 1000$ min^{-1}, disk area $A = 0.16$ cm^2.

V_H is caused by an enhanced hydrogen or oxygen evolution on the clean platinum ring not covered by any oxidation or reduction products of PbTe. The cathodic peak at 0.40 V_H for both disk potentials is correlated to the reduction of platinum oxide formed at potentials $\epsilon_R > 0.7$ V_H. The products deposited by cathodic reduction on the ring cause anodic peaks at $\epsilon_R = 0.10$ and 0.50 V_H for positive scans. Apparently similar reactions are occurring as on PbTe suggesting the formation of PbTe and Te during cathodic reduction of the dissolution products of the disk.

Analogous to Fig. 2 for Te, Fig. 7b shows the close correlation of the ring and disk current for a potentiodynamic variation of the disk potential. The anodic disk current I_D of 6 μA around peak AI gives rise to a cathodic ring current I_R of $\Delta I_R = 1.5$ μA, the current values agreeing with the theoretical collection efficiency of $\sim$20%. These observations may be explained by reaction [4]. A Te film is produced on the disk, while Pb^{2+} is completely dissolved in the electrolyte and is reduced to Pb at the ring with the same number of electrons.

The current increase at $\epsilon_D > 0.4$ V_H is accompanied by a higher cathodic ring current, and the collection efficiency of about 10% indicates better oxide formation and less dissolution than for the case of elemental Te (theoretical efficiency 20%). Again I_R becomes less negative when the surface oxide is reduced in the range of 0 to -0.10 V_H, and presumably some PbO in the oxide layer is reduced between -0.10 and -0.50 V_H (see XPS results in later section). At $\epsilon_D < -0.50$ V_H and $\epsilon_R = -0.30$ V_H a superimposed anodic current peak at the ring results from the oxidation of Te^{2-} which is produced and dissolved at the disk. The cathodic disk current at $\epsilon_D < -0.50$ V_H corresponds to peak CI when the tellurium at the surface is reduced to soluble telluride.

Thickness of the surface layers on PbTe.—The close relation between the peaks AI and CI has been pointed out already. If a PbTe film is anodically oxidized for a sufficiently long time at 0.20 V_H (>AI = 0.15 V_H) the anodic current density almost vanishes (< 1 μA/cm^2) (Fig. 8). However, after the cathodic reduction at peak CI < -0.50 V_H, AI regains its original height, indicating that the anodic reaction AI leads to a reproducible passivation film on the semiconductor surface. The reduction of the anodic product at peak CI reestablishes the original surface, peak CI being observed only after an anodic oxidation in the range of AI. The cathodic charge increases with the anodic potential and with the time of AI oxidation for a constant potential (Fig. 9). The structure and area of CI does not change with the scan rate, only the peak position is slightly shifted to more positive values with decreasing scan rates. At potentials between the CI and AI peak and at open-circuit conditions the area of CI is maintained for at least 2 min, thus demonstrating no dissolution of the anodic film. Its position, however, is slightly shifted to more negative values. The cathodic charge Q_{CI} amounts to 0.33 mC/cm^2 for 10^3 sec oxidation at 0.2 V_H, approximately the same charge obtained for peak AI. With a surface roughness factor of one for a freshly deposited PbTe film and with the interpretation of peak AI by reaction [4] (see sections on Electrochemical studies, Ring-disk voltammetry, and Fig. 7b) a maximum Te layer of 3.4Å is obtained ($V_{M,Te} = 20.4$ cm^3).

The one to two monolayer thick Te layer, produced by direct oxidation, is too thin to provide a sufficient surface coating or passivation for devices. Thicker layers ($\sim$100Å) would require transport of Pb^{2+} ions through a continuous poreless Te film into the electrolyte. Normally such processes involve migration in high electric fields, however the appropriate field strength cannot be built up because of the anodic oxidation of Te and PbTe which occurs at $\geqq 0.4$ V_H.

The thickness of the oxide layer, formed at the AII peak > 0.4 V_H, is estimated assuming a complete TeO_2

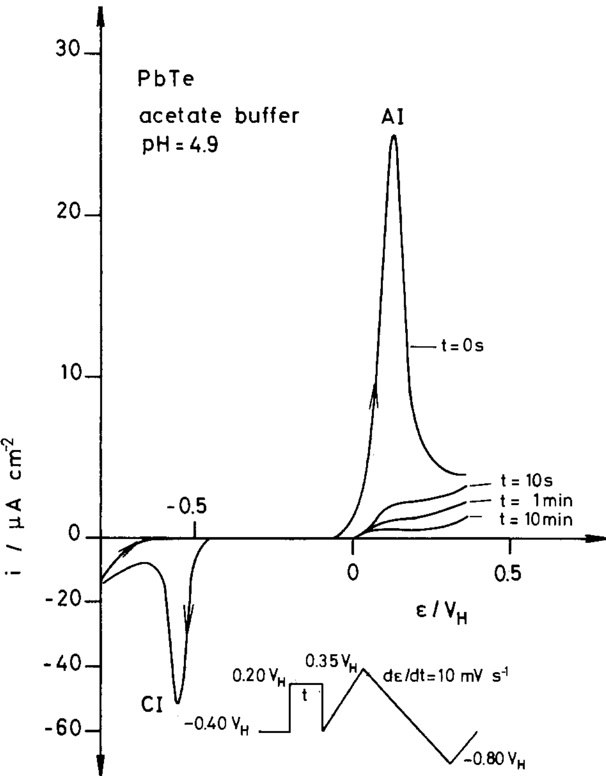


Fig. 8. Decrease of the potentiodynamic anodic current peak AI by prepassivation at 0.20 V_H for different times and the related cathodic reduction peak CI in acetate buffer pH 4.9.

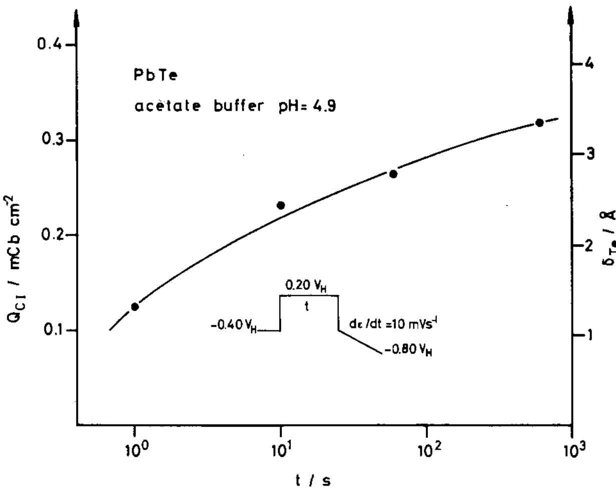

Fig. 9. Cathodic charge Q_{CI} and thickness of Te layer formed by anodic oxidation at 0.20 V_H for different times t.

or H_2TeO_3 composition. XPS measurements discussed later however will show that this assumption is not quite correct. The thickness is determined by the charge corresponding to the cathodic peak CII which is essentially the reduction of the AII oxide film to the element. The interpretation and calculation is the same as for the pure Te sample discussed in an earlier section. In the plateau range from 0.5 to 0.9 V_H the oxide film thickness increases linearly with the logarithm of the oxidation time so that after 100 sec at 0.8 V_H 8 mC/cm^2 are transferred, corresponding to ~60Å TeO_2 or ~120Å H_2TeO_3. No growth saturation within this time and voltage range is observed.

XPS investigation.—After the different oxidation and reduction processes, the specimens were analyzed by XPS. The relative transition intensities provide information about the composition of the surface within the detection depth of ~20Å, while the different chemical bonds give rise to chemical shifts. Figure 10 shows the expanded spectra of the core level transitions Pb $4f^7$ and Te $3d^5$ from samples which have undergone the indicated electrochemical treatments. The positions of the peaks for the elements and the compounds of interest are in agreement with other authors (11-14): Te^{4+} in TeO_2 −576.3 eV, Te° in elemental Te −573.0 eV, Te^{2-} in PbTe −572.3 eV, PbO final oxidation stage −138.8 eV, Pb^{2+} in PbTe −137.8 eV, Pb° in metallic Pb −136.9 eV. The difference in chemical shift between Te° and Te^{2-} is at our resolution (~1 eV) too small for a clear separation. We would like to note that no sputter profiling of the surface layers was attempted, therefore, the XPS results only represent the actual surface in contact with the electrolyte.

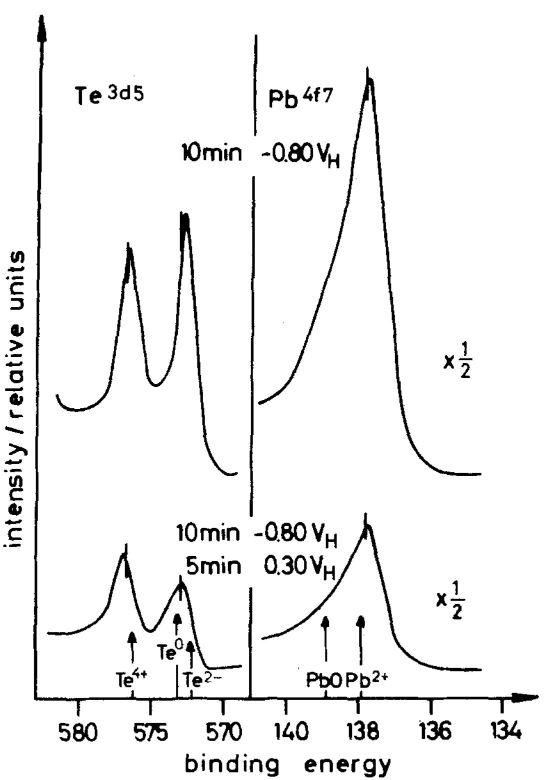
After reduction of PbTe for 10 min at −0.80 eV (< CI peak, Fig. 10a) the first Te-peak has a binding energy of 572.6 eV as expected for Te^{2-}. Oxidation at 0.30 V_H (> AI peak) for 5 min shifts this peak to 573.1 eV. This slight shift might be attributed to contributions from elemental Te which supports the interpretation of the electrochemical results. In both cases a second peak at 576.9 eV shows TeO_2 on the surface. The wet PbTe surface oxidizes in air during sample transfer from the electrolyte to the UHV chamber and therefore complicates the interpretation. The Pb $4f^7$ transition remains the same after each treatment with the prominent peak at the position of Pb^{2+} of PbTe and a PbO shoulder at higher binding energies resulting from oxidation during sample transfer.

The anodic AII oxidation starts at 0.45 V_H and leads gradually to an oxidation of the surface to TeO_2 and PbO within the detection depth (Fig. 10b), an appreciable PbO concentration being incorporated into the TeO_2 layer. The peaks of Pb^{2+} and Te^{2-} are still observed after 5 min indicating that the oxide formation does not exceed ~20Å.

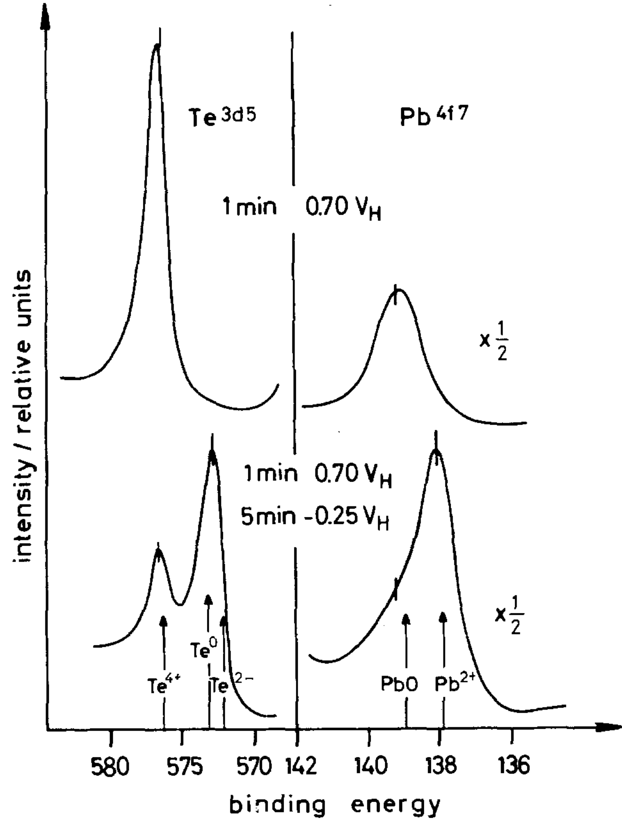
Anodic oxidation within the current plateau at potentials >0.5 V_H leads to a rapid and complete coverage of the surface by TeO_2 and PbO (Fig. 10c). The intensity ratio of Pb $4f^7$/Te $3d^5$ is smaller by a factor of ~1/3 compared to peaks on a clean PbTe surface (7) and this change is used for an estimate of the Pb concentration within the oxide surface at 30%. At −0.25 V_H (< CII peak) the oxides are reduced to elemental Te (Te°) and PbTe (Pb^{2+} and Te^{2-}), the oxide peaks (TeO_2 and PbO) resulting from oxidation during sample transfer. A shorter reduction period of 1 min increases the PbO shoulder and the TeO_2 peak demonstrating that the reduction of such a ~70Å thick oxide layer takes more than 1 min. After the CII reduction no change of the Pb/Te ratio is observed with no preferential dissolution of one of the elements. Oxide layers grown > 0.9 V_H show a similar Pb/Te ratio in the film as described above.

In order to reduce the Pb concentration in the oxide layer, a cyclic oxidation and reduction was carried out the oxidation being performed at 0.70 V_H and the reduction at −0.25 or −0.40 V_H. After two or four cycles no appreciable decrease of the Pb concentration is observed for equal oxidation periods. If, however, the second oxidation is only half as long as the first one the Pb/Te ratio decreases by another factor ~0.5. In the second oxidation less TeO_2 should be formed than in the first one to prevent the oxidation of the bulk PbTe which produces new PbO and compensates, therefore, the Pb losses of the surface film during oxidation.

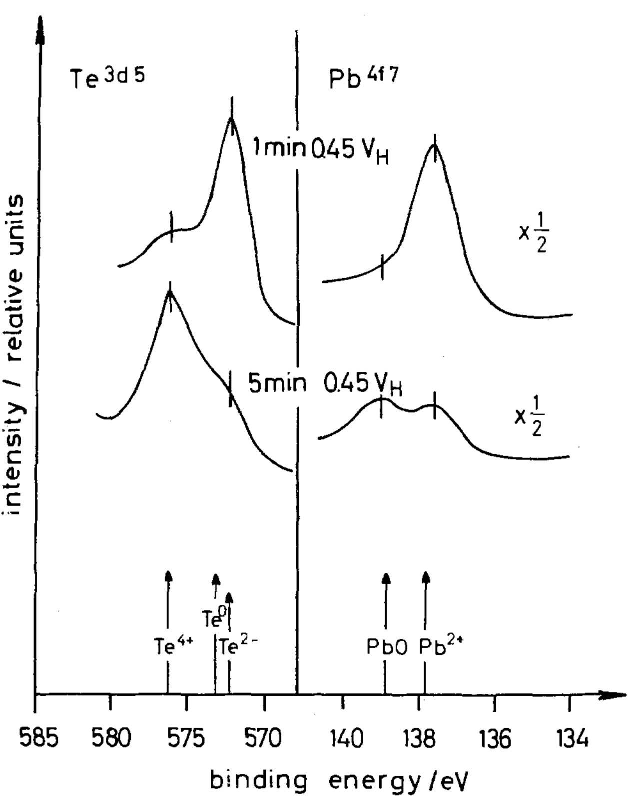
The formation of a continuous, poreless, Pb-free layer of TeO_2 or Te° by AII oxidation or CII reduction cannot be expected in principle. In any case the Pb^{2+} ions have to pass through a dense oxide film which automatically leads to its Pb content. A 50% Pb-bulk material does not allow an appreciable accumulation at its interface to the oxide layer. The preferential dissolution of Pb^{2+} requires the presence of a porous layer as mentioned above.



(a) Reduction 10 min at —0.80 V_H (CI peak) and additional oxidation 5 min at 0.3 V_H (AI peak).



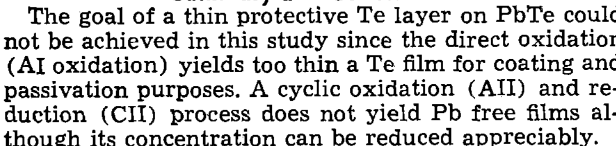
(c) Complete anodic oxidation 1 min at 0.70 V_H (AII peak) and reduction 5 min at —0.25 V_H (CII peak).



(b) Beginning of anodic oxide growth at 0.45 V_H (AII peak)

Fig 10. Expanded Te $3d^5$ and Pb $4f^7$ XPS spectra measured on PbTe films after the indicated electrochemical treatments in acetate buffer pH 4.9.

Summary and Conclusions



The goal of a thin protective Te layer on PbTe could not be achieved in this study since the direct oxidation (AI oxidation) yields too thin a Te film for coating and passivation purposes. A cyclic oxidation (AII) and reduction (CII) process does not yield Pb free films although its concentration can be reduced appreciably.

The AII oxidation shows that in a competing growth and dissolution process TeO_2 (H_2TeO_3) rich surface layers can be produced. After a cyclic process they contain at least ~15% PbO on the surface which is in contact with the electrolyte. This value is, therefore, a lower limit of the Pb concentration within the whole oxide film. Thus claims of anodic oxide films on PbTe, $Pb_{1-x}Sn_xTe$ consisting mostly of TeO_2 (8), must be checked by a critical evaluation of the preparation process. If the sample is chemically etched, in HBr-Br_2 for instance, before anodic oxidation the surface is al-

ready covered by a Te layer (1, 2). Therefore, the Te enrichment may be not only due to the anodic oxidation but essentially due to the previous chemical etching. The oxide films are quite conductive and porous because of the high current densities at high anodic potentials.

Similar results to those reported in this paper are expected for $Pb_{0.8}Sn_{0.2}Te$. Although Sn and especially SnO_2 behave differently than Pb, Te, and their oxides in chemical solutions, the Sn concentration is still low. Preferential oxidation, reduction, and dissolution processes and growth of thick surface layers have to deal, therefore, with similar diffusion and migration problems of one of the elements in the surface layer as was encountered in PbTe.

Acknowledgment

We are indebted to H. Maier of AEG-Telefunken, Heilbronn (FRG), for supplying single crystalline PbTe bulk material and T. Jakobus for the epitaxial PbTe films. The critical reading of the manuscript by K. Eisele is appreciated. We acknowledge the technical assistance of B. Titze.

Mechanism of the Electrochemical Oxidation of Lead to Lead Dioxide Electrode in H_2SO_4 Solution

D. Pavlov* and Z. Dinev

Central Laboratory of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia 1040, Bulgaria

ABSTRACT

The electrode system Pb/PbO layer/$PbSO_4$ membrane/H_2SO_4 solution forms when a lead electrode immersed in an H_2SO_4 solution is in the potential range between −400 and +960 mV (*vs.* the $Hg/HgSO_4$ electrode). When the electrode potential is raised above +960 mV the PbO and $PbSO_4$ layers are oxidized to PbO_2. The mechanism of this oxidation is determined by the electric properties and the crystal structure of PbO and $PbSO_4$. The paper deals with the electrochemical behavior of the electrode during potential sweeps from the PbO into the PbO_2 potential ranges. It was found that first PbO is oxidized via solid-phase reactions to nonstoichiometric PbO_n without a change of its crystal structure. This takes place via the electrochemical reaction

$$k\text{PbO} + \frac{m}{2}\text{H}_2\text{O} = k\text{PbO}_n + m\text{H}^+ + me^-$$

which proceeds at the PbO/solution interface. Since PbO_n is a semiconductor, the oxidation of the Pb^{2+} ions in its crystal lattice probably takes place through a mechanism in which surface states and mobile acceptors take part. Such are O^- and O, evolved during the reaction of oxygen evolution. When n reaches a critical value $n = d$, α-PbO_2 nucleation commences in the pores of the $PbSO_4$ membrane. When this phase reaches the H_2SO_4 solution the oxidation of $PbSO_4$ crystals to β-PbO_2 begins. This takes place according to the mechanism

dissolution of $PbSO_4$ → diffusion of Pb^{2+} ions → oxidation of Pb^{2+} at the PbO_2 surface → precipitation of β-PbO_2

The dissolution of $PbSO_4$ crystals begins at the apexes of the crystals and continues at their edges and faces.

The processes occurring during electrochemical oxidation of the Pb electrode to PbO_2 in H_2SO_4 solution depend on the structure and composition of the anodic layer (1-4). They all are determined by the electrode potential (3, 4). There are three potential regions, according to the anodic layer phase composition (3, 4). Upon oxidation of Pb from −970 to −400 mV (*vs.*

* Electrochemical Society Active Member.

Key words: LSV (linear sweep voltammetry), lead dioxide electrode, oxidation of PbO, oxidation of $PbSO_4$, solid-state reactions, electrochemical reactions in anodic multilayer deposit.

Hg/Hg_2SO_4 electrode), the anodic layer consists of $PbSO_4$ crystals, so this is the lead sulfate region. From −400 to +960 mV (lead oxide region), the anodic layer acquires the following structure

Pb/tet-PbO layer/$PbSO_4$ membrane/H_2SO_4 solution

Above +960 mV (lead dioxide region) the anodic layer contains α- and β-PbO_2 and tet-PbO. The method of oxidation (potentiostatic or galvanostatic) affects only the ratio of the phases, but not their presence in the anodic layer.

During the last decade linear sweep voltammetry was used to study the anodic layer oxidation to PbO_2 layer (5-11). These papers contain considerable information concerning the behavior of the lead electrode both on anodic polarization and cathodic reduction of the PbO_2 layer. Valeriote and Gallop (12) recently carried out a potentiostatic study of the anodic layer oxidation, taking into account the existence of PbO and $PbSO_4$ phases. They treat the aspects of ion diffusion in the anodic layer solution and of PbO_2 nucleation.

The present paper aims to determine the mechanism of electrochemical oxidation of the Pb/PbO/$PbSO_4$ electrode system to the Pb/PbO_2 electrode.

Experimental Methods

The electrode was a 99.999% Pb cylinder, pressed into a Teflon holder, so that only its base with an area of 0.5 cm^2 is oxidized. Before every series of experiments a thin layer was cut off from the electrode so that a fresh surface was formed. Then the electrode was rinsed in triply distilled water and inserted into the cell. A 5 min reduction at −1200 mV followed and then the potential was set to the desired value.

A one-compartment glass cell was used. The window wall facing the electrode was optically flat. The counterelectrode was of platinum. An electrolyte of 1*N* H_2SO_4 was used for both the cell and the reference Hg/Hg_2SO_4 electrode. All potentials in this paper are presented against the Hg/Hg_2SO_4 electrode. The temperature of the cell and the reference electrode was maintained at 25°C by means of a thermostat. The potentiostat was Radelkis, Type OH-405.

To obtain a Pb/PbO/$PbSO_4$/H_2SO_4 electrode system the electrode was oxidized initially for 4 hr at +600 mV in the dark.

The Pb/PbO_n/$PbSO_4$/H_2SO_4 system was formed by means of photoactivation. During the oxidation at +600 mV the electrode was recurrently illuminated with white light. Experimental details concerning photoactivation are given in Ref. (13).

Both systems were oxidized by potentiodynamic polarization from +700 mV to a potential of the PbO_2 region in the dark. A cathodic potential sweep followed to indicate the formation of PbO_2. Various scanning rates and upper potential limits were tried in order to separate the different chemical and electrochemical reactions.

Experiments and Discussion

Nature of the overvoltage at the oxidation of Pb/PbO/$PbSO_4$/H_2SO_4 to Pb/PbO_n/$PbSO_4$/H_2SO_4 system in the dark.—The structure of the anodic layer (Fig. 1), formed in the PbO region, was determined by x-ray diffraction analysis and electron microscope observations (4).

The $PbSO_4$ crystals form a membrane. The processes in the solution during its formation were elucidated in Ref. (14) Pavlov and Popova (15) established and determined the electrochemical properties of the membrane. Later Ruetschi (16) has confirmed these properties on chemically precipitated $BaSO_4$ and $PbSO_4$ membranes. The dense layer of tet-PbO is obviously situated between the $PbSO_4$ sublayer and the metal.

Sometimes during anodic polarization small quantities of basic lead sulfates are formed. However, these compounds are not of a primary importance and are omitted here.

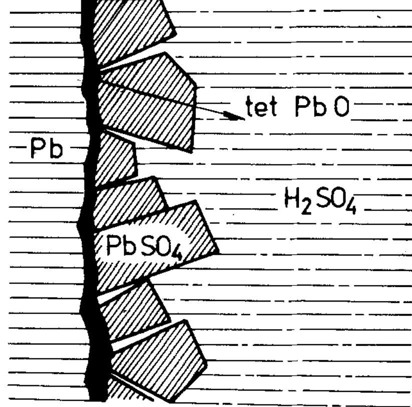

Fig. 1. Structure of the anodic layer formed in the PbO potential region.

In two previous studies (13, 17) we have shown that when the electrode is not illuminated, the rate of Pb oxidation is limited by the tet-PbO layer ionic conductivity. It was suggested that the conductivity is realized by migration of oxygen vacancies from the metal/oxide interface to the oxide/solution one. A possible model of this process was given in Ref. (17) and is presented in Fig. 2. Let us assume for simplicity that the PbO crystal lattice is built up of PbO molecules. At the Pb/PbO interface Pb is oxidized to PbO by the reaction

$$Pb \rightarrow PbO\square^{2+} + 2e^- \quad [1]$$

$PbO\square^{2+}$ marks a PbO molecule containing an oxygen vacancy ($O\square^{2+}$). Under the action of the electric field the $O\square^{2+}$ vacancies migrate into the oxide layer and reach the oxide/solution interface. Here they react with water, whereby PbO and H^+ ions are formed

$$PbO\square^{2+} + H_2O \rightarrow PbO + 2H^+ \quad [2]$$

The H^+ ions migrate through the $PbSO_4$ membrane into the bulk of the solution.

Such a system was subjected to potentiodynamic polarization at a scanning rate of 10 mV/sec. Figure 3

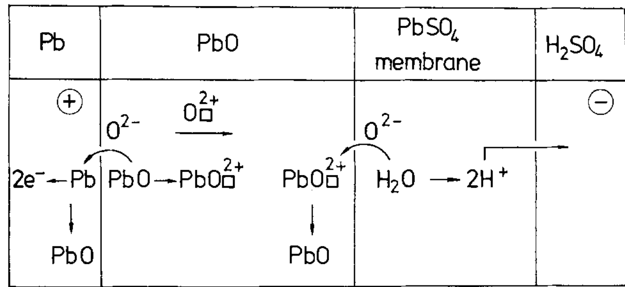

Fig. 2. Scheme of the elementary reactions at current flow through the anodic layer during oxidation of Pb in the PbO potential region.

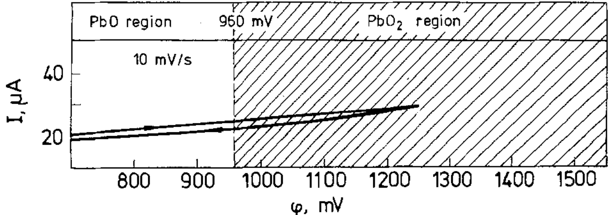

Fig. 3. Voltammogram of a sweep to 1250 mV

present the voltammogram of a potential sweep to 1260 mV. Except oxidation of Pb to PbO, no new electrochemical reaction takes place, although the potential reaches 300 mV deep into the PbO_2 region. The positive-going sweep follows Ohm's law.

Figure 4 presents the voltammograms of five successive potential sweeps to 1450 mV. When 1325 mV is reached, a new electrochemical reaction occurs, causing a rise of the anodic current (first sweep). At the first three sweeps no minimum is observed during the negative-going sweep. This means that the product of the new reaction is not reduced and remains in the anodic layer. Thus the nature of the electrode is changed and the electrochemical reaction begins at more negative potentials at the post-coming sweeps.

A minimum only appears at the fifth sweep. It may be related to PbO_2 reduction. Some changes occur, therefore, in the anodic layer before PbO_2 formation.

We may assume that it is only the stoichiometric composition of the oxide that is changed. The over-all reaction of nonstoichiometric oxide PbO_n formation may be presented by the equation

$$k\text{PbO} + m/2\,\text{H}_2\text{O} = k\text{PbO}_n + m\text{H}^+ + me^- \quad [3]$$

where

$$n = \frac{k + m/2}{k}$$

PbO_n can be formed in the tet-PbO lattice by solid-state reactions without the formation of a new phase (17).

The comparison of Fig. 3 and 4 suggests that initially there is a potential barrier in the PbO layer, hindering reaction [3]. When PbO is oxidized to PbO_n, this barrier decreases and reaction [3] begins at more negative potentials.

The nature of this barrier may be understood by comparing the electric conductivity of PbO and PbO_n. Lappe (18) has studied the dependence of PbO_n conductivity on its stoichiometric coefficient. Figure 5 presents this relationship, based on Lappe's experimental data. Tet-PbO has very low conductivity. It is

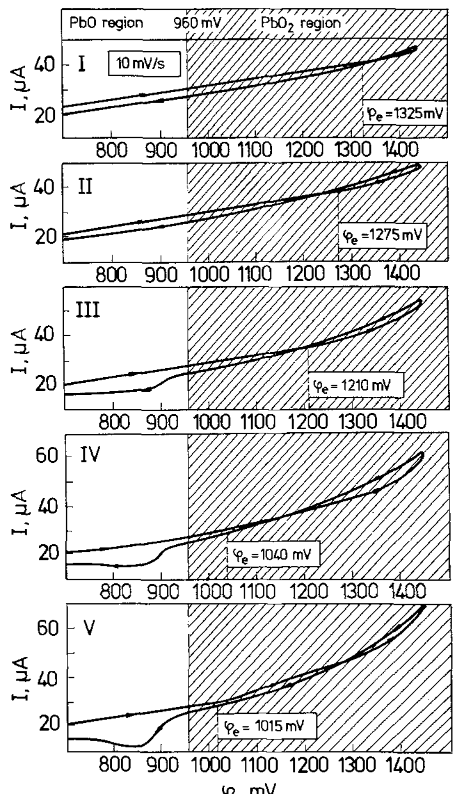

Fig. 4. Voltammograms of a series of successive sweeps to 1450 mV at 10 mV/sec.

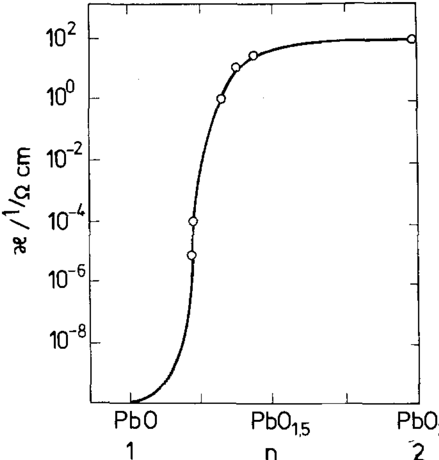

Fig. 5. Dependence of PbO_n specific electric conductivity on its stoichiometric coefficient *n*.

an ionic conductor (19). Such an oxide is formed during potentiostatic oxidation at +600 mV in the dark. With the increase of n, electric conductivity rises too. PbO_n is a semiconductor (20). When n becomes equal to about 1.4 the oxide acquires electronic conductivity.

Reaction [3] proceeds at the PbO/solution interface. Its rate depends on the interface potential, which in its turn depends for a given electrode potential on the oxide layer thickness and specific conductivity. Let us for simplicity assume that the potential drops linearly across the PbO layer and is marked by ϕ_0, the potential at which reaction [3] commences.

On the basis of the experimental data, presented in Fig. 4, we suggest that the following changes take place on the electrode as a reslt of the sweeps (Fig. 6):

The oxide has the initial composition of PbO. Let us mark the oxide/solution interface potential prior to the first sweep by ϕ_1. Its value is unknown, but it is obviously negative of ϕ_0, since no electrochemical reaction except oxidation of Pb to PbO takes place. When at the first sweep the oxide/solution potential reaches ϕ_0, reaction [3] begins. This corresponds to 1325 mV. PbO_n piles up. Before the second sweep the potential at the oxide/solution interface ϕ_2 is more positive than ϕ_1 because the PbO_n layer has higher conductivity than the PbO layer. Hence reaction [3] at the second sweep begins earlier (at 1275 mV). Thus the transformation of PbO into PbO_n results in in-

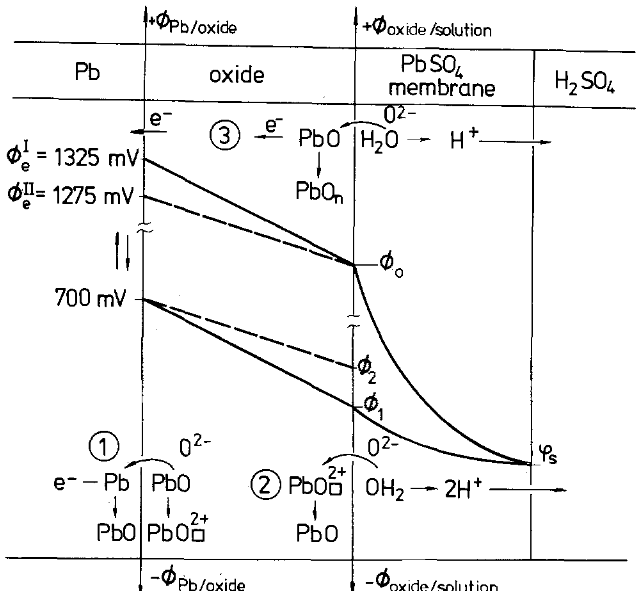

Fig. 6. Scheme of potential distribution across the anodic layer and the reactions at the PbO interfaces.

creasing the oxide layer conductivity and lowering the barrier to reaction [3].

The value of n is potential dependent. Reactions [1] and [2] tend to decrease it and reaction [3] to increase it.

Elementary reactions during oxidation of the PbO_n layer.—Electrochemical behavior of the electrode at the increase of n in PbO_n.—To study these reactions it is necessary to keep the $PbSO_4$ membrane structure unchanged. So the potential was swept to values just entering the PbO_2 region.

Some information about the elementary reactions may be obtained from the voltammogram shape. The reactions can be separated by varying the sweep rate and the upper potential of the sweep.

To obtain reproducible voltammograms we should eliminate the initial influence of the potential barrier, discussed previously. To this aim the oxidation of PbO to PbO_n was effected by means of photoelectrochemical reactions. The processes during photoactivation were discussed in Ref. (13). The electrode was oxidized at +600 mV for 4 hr, being illuminated every 30 min with white light for 3 min. Then three sweeps were carried out from +700 to +1100 mV and backward at a rate of 1 mV/sec in the dark. This electrode was subjected to oxidation by sweeps at three rates (10, 5, and 1 mV/sec) from +700 mV to various upper potentials. After each sweep the electrode was polarized at +600 mV for 10 min.

Figure 7 presents voltammograms to +960 mV. Three interesting features can be observed on them. First, the reaction begins at more positive potentials when the sweep rate increases. Second, at the negative-going sweep the current rises for some time, passes through a maximum and only then decreases. Third, the current due to reaction [3] is higher when the sweep rate is lower.

We believe that this behavior is due to the electrode system structure. The potential sweep produced by the potentiostat is applied to the Pb/PbO_n interface. Then begins a rearrangement of the ionic charges in the PbO_n layer. As this process is slow, the sweep arrives with a delay at the PbO_n/solution interface where reaction [3] takes place. For this reason electrochemical reaction [3] begins at more positive potentials when the sweep rate is high (first feature). When the sweep rate is low, the potential at the PbO_n/solution interface follows more closely the potential at the Pb/PbO_n interface. For this reason the rate of reaction [3] increases when the sweep rate is low (third feature).

When at +960 mV the potential sweep is switched over to negative direction, because of the delay of the sweep through the PbO layer, the potential at the PbO_n/solution interface continues to rise. From Fig. 7 it follows that the sweep of the potentiostat arrives at the PbO_n/solution interface for a period of 5-20 sec. During this period the rate of reaction [3] increases although that of the potential at the Pb/PbO_n interface decreases. The current maximum, corresponding to the highest positive potential which is reached at the PbO_n/solution interface, appears at a more negative potential than the upper potential limit of the sweep (second feature).

Figure 8 presents voltammograms of sweeps to 990 mV. The anodic maximum on Fig. 8c is due to the formation of PbO_2. At the negative-going sweep a minimum appears at 935 mV due to the reduction of PbO_2.

Figure 9 shows sweeps to 1020 mV and Fig. 10 to 1080 mV. At 10 mV/sec (Fig. 10) the electrode is still not passivated although the anodic current reaches 1.5 mA. The current in the negative-going sweep becomes negative and almost constant. No minimum is observed to +700 mV.

Figure 10b shows that the anodic current passes through a maximum in the sweep to 1080 mV at a rate of 5 mV/sec. The value of the maximum is 750 μA. A PbO_2 reduction minimum appears at 910 mV in the negative-going sweep.

Figure 11 presents sweeps at a rate of 10 and 5 mV/sec to 1140 mV and at a rate of 10 mV/sec to 1200 mV. At the sweep rate of 10 mV/sec a maximum is seen at about 1075 mV.

Figures 8 to 11 show that PbO_2 formation, expressed through an anodic maximum, depends on the sweep rate. Table I shows the potentials and currents, corresponding to the anodic maximum. It is seen from

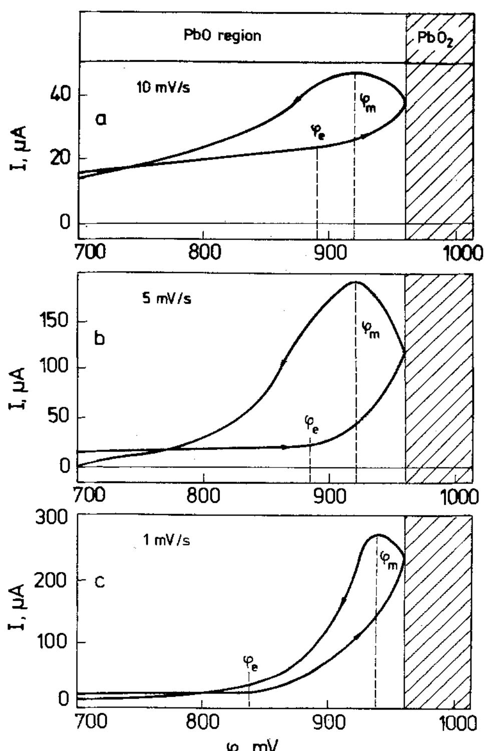

Fig. 7. Sweeps to 960 mV

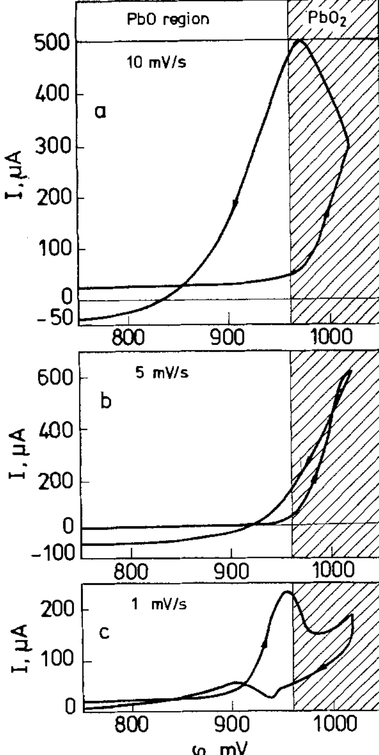

Fig. 9. Sweeps to 1020 mV

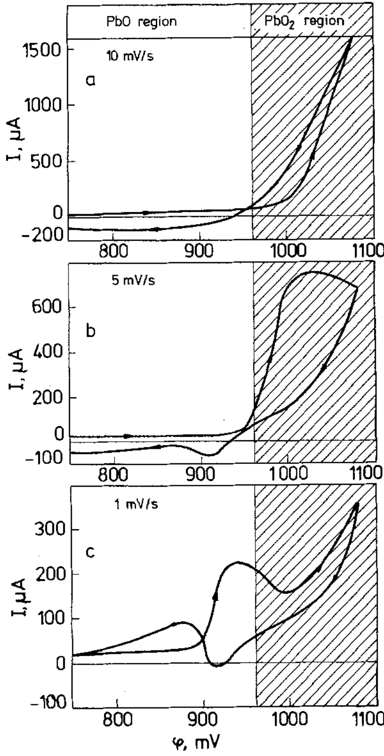

Fig. 10. Sweeps to 1080 mV

the table that when the sweep rate increases 10 times, i_{max} also increases about 10 times.

Table II shows the quantity of electricity flown until the maximum at each sweep. The values of Q vary between $1.02 \cdot 10^{-2}$ and $1.44 \cdot 10^{-2}$C. We assume that this is one single value with its errors. Obviously PbO_2 formation begins after a certain quantity of electricity (Q_d) has flown through the electrode, regardless of the sweep rate in the PbO_2 potential region.

We can generalize our interpretation of the experimental data as follows. Reaction [3] causes an increase of the value of n in the PbO_n layer. When a certain quantity of electricity Q_d has flown, n reaches a critical value. A crystal lattice of the new phase, PbO_2, begins to be formed.

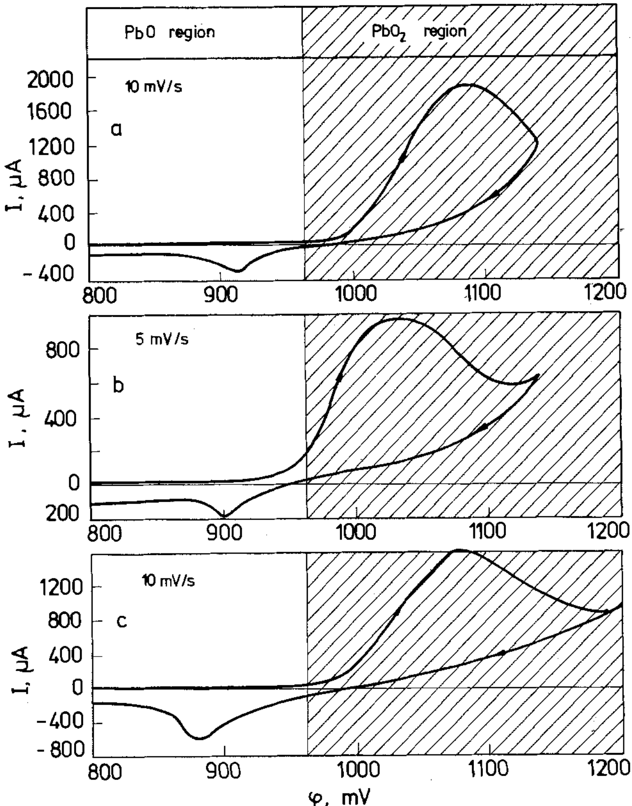

Fig. 11. Sweeps to 1140 and 1200 mV

Model of the elementary reactions at the anodic oxidation of PbO_n.—As PbO_n is a semiconductor, the mechanism of the elementary processes of PbO_n oxidation should be based on the energy band scheme (17). Two electrons have to jump over the bandgap (1.9 eV) for the oxidation of each Pb^{2+} ion of the crystal lattice to a Pb^{4+} ion. In the dark a possible way to overcome the bandgap is through surface states. This is a process of electron exchange between species, chemisorbed on the PbO_n/solution interface and the PbO_n conduction and valence bands. A possible model of this process was given in (17). We shall use this model to explain the experiments of this study. A simplified scheme of the processes is presented in Fig. 12.

The chemisorbed OH^- ions, OH and O^- radicals, and O atoms may serve as surface states. Let us simplify the model by eliminating the voltage drop across the PbO layer, though it influences the starting potential of electrochemical reaction [3].

OH^- ions are adsorbed on the PbO_n/solution interface. They have an electron energy level, which at

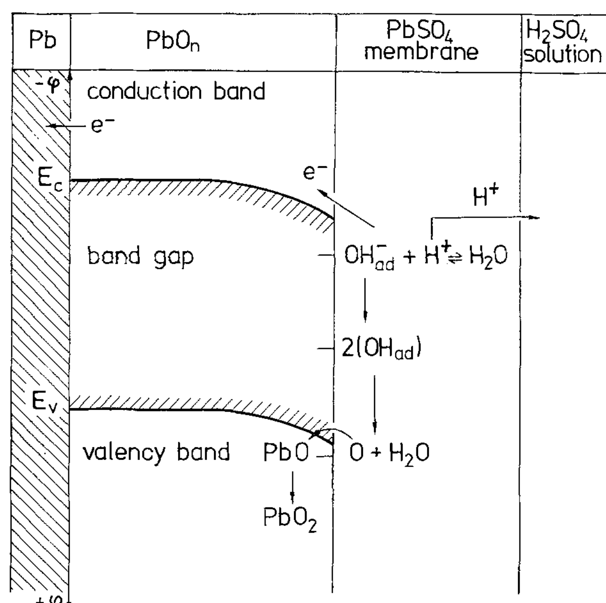

Fig. 12. Energy band scheme of PbO_n

+700 mV is at the PbO_n bandgap. When the potential is increased, the conduction band gets closer to this level. Electrons are injected from the OH^- ions into the conduction band and the following reaction takes place

$$PbO + OH^- \rightarrow PbO/OH_{ad} + e^- \quad [4]$$

The chemisorbed OH_{ad} radicals are unstable and they recombined

$$PbO/2\,OH_{ad} \rightarrow PbO/O_{ad} + H_2O \quad [5]$$

The oxygen atom is a strong acceptor. Its electron energy level lies in the valency band or near it in the bandgap. The O atom may attract electrons from the Pb^{2+} ions whereby a PbO_2 molecule is formed

$$PbO/O_{ad} \rightarrow PbO_2 \quad [6]$$

The tet-PbO unit cell is built up of 4 molecules (21). As they are not oxidized simultaneously, nonstoichiometric PbO_n is formed within the tet-PbO crystal lattice

$$pPbO + qPbO_2 \rightarrow PbO_n$$

The chemisorbed OH_{ad} radicals may recombine with OH^- ions too, giving O^- radicals. They are electron acceptors too, capable of partially oxidizing PbO molecules.

Tet-PbO has a layer structure (21, 22). Its crystal structure is given in Fig. 13. The O^{2-} ions are arranged in one layer and there is an empty layer between 2 layers of Pb^{2+} ions. The OH^- ions have a radius of 1.52Å, the O^{2-} ion 1.32Å, and the O atom 0.66Å. The O^- radical has a radius intermediate between that of the O atom and the O^{2-} ion. Obviously the O atom and the O^- radical have a smaller diameter than the width of the tet-PbO lattice free layer (Fig. 13). So they may penetrate into it and oxidize PbO molecules within the PbO_n layer. They behave thus as mobile acceptor levels. As a result of these processes the value of n is highest at the PbO_n/solution interface, decreases in the layer, and is lowest at the Pb/PbO_n interface.

Formation of α-PbO_2 phase during PbO_n oxidation.— The formation of PbO_2 crystal lattice may take place either through rearrangement of the tet-PbO lattice or by destruction of the tet-PbO crystal structure and building up of a new one. To determine the mechanism of PbO_2 crystal lattice formation electron microscope observation of the anodic layer was made after a potential sweep to 1050 mV at a rate of 1 mV/sec.

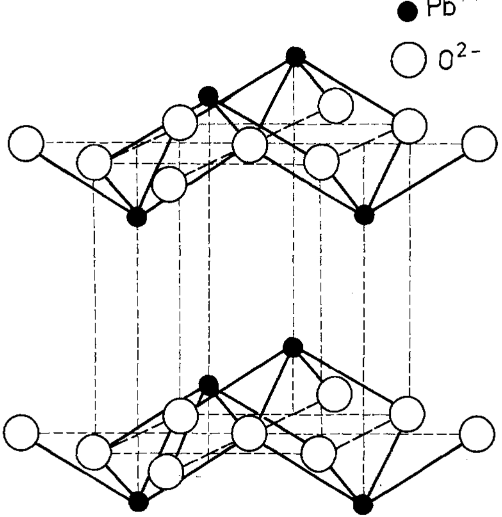

Fig. 13. Crystal structure of tet-PbO

Figure 14 presents three electron micrographs. A carbon-platinum replica was made. It was separated from the electrode in NH_4CH_3COO solution, which dissolves PbO and $PbSO_4$. PbO_2 remains on the replica and can be observed.

The $PbSO_4$ membrane is built up by well-shaped crystals. The PbO_2 phase (black spots) is a shapeless mass, streaming out of some of the pores (Fig. 14c). We can assume on this basis that PbO_2 is formed as a new phase on the PbO_n/solution interface. The PbO_2 phase nucleates in the pores. The newly formed nuclei of PbO_2 push out of the pores the nuclei formed before.

The following elementary reactions may occur along this model of the mechanism: The OH_{ad} radical concentration at the PbO_n/solution interface becomes so high that the bond between the surface PbO molecules, at which 2 OH radicals are chemisorbed, and the PbO_n lattice is weakened and broken. Some of the molecules undergo oxidation

$$Pb^{2+}O/2(OH)_{ad} \rightarrow Pb^{4+}O(OH)_2 \quad [7]$$

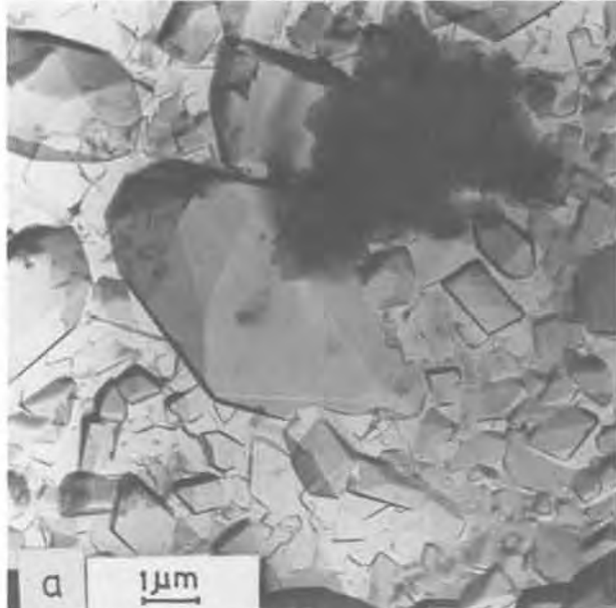
Nucleation takes place after dehydration

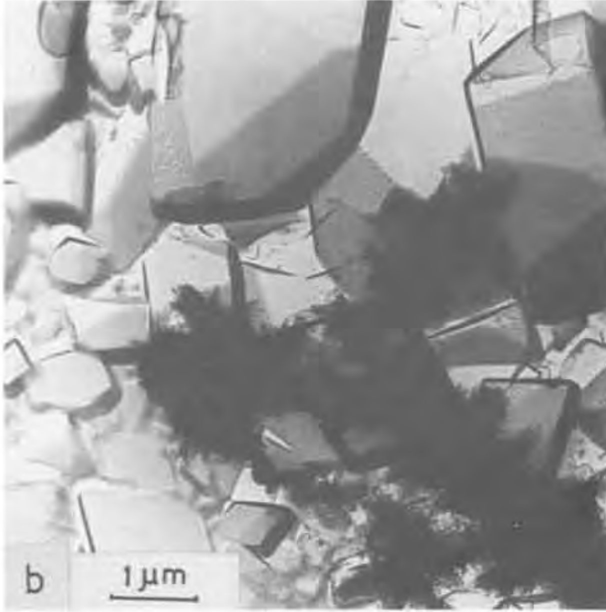
$$P[PbO(OH)_2] \rightarrow (PbO_2)_p + pH_2O \quad [8]$$

One PbO_2 nucleus is formed by $pPbO_2$ molecules. The concentration of $PbO(OH)_2$ is highest on the PbO_n/solution interface so nucleation probably begins here. The solution in the pores is alkaline, so α-PbO_2 is formed. The new phase fills partially or entirely the $PbSO_4$ membrane pores. The access of water to the PbO_n surface is hindered and the rate of electrochemical reaction [4] decreases. The current passes through a maximum and begins to decrease (Fig. 8-11). The water, which is evolved in reaction [8], supplies for some time reaction [4] with OH^- ions. The H^+ ions migrate into the H_2SO_4 solution. The PbO_2 nuclei, formed at this stage, ensure electron contact between PbO_n and PbO_2.

As a result of reactions [7] and [8], the PbO_n layer becomes thinner. The PbO_n/solution interface turns into a PbO_n/PbO_2 interface. The pores are relatively short and the PbO_2 phase goes out of them, coming into contact with the H_2SO_4 solution.

According to Lappe (18) (Fig. 5), the conductivity increases until n reaches 1.4. On the other hand, Ljamina, Korolkova, and Gorbunova (23) established that on reduction of α-PbO_2 in solid state, the stoichiometric coefficient decreases from 1.9 to 1.4 and lattice defects increase, but the α-PbO_2 crystal lattice remains unchanged. Aguf (24) studied the change of the PbO_2 electrode thermodynamic performance when the oxygen content in it decreases. We can assume, therefore, that the critical value of $n = d$ is about 1.4.





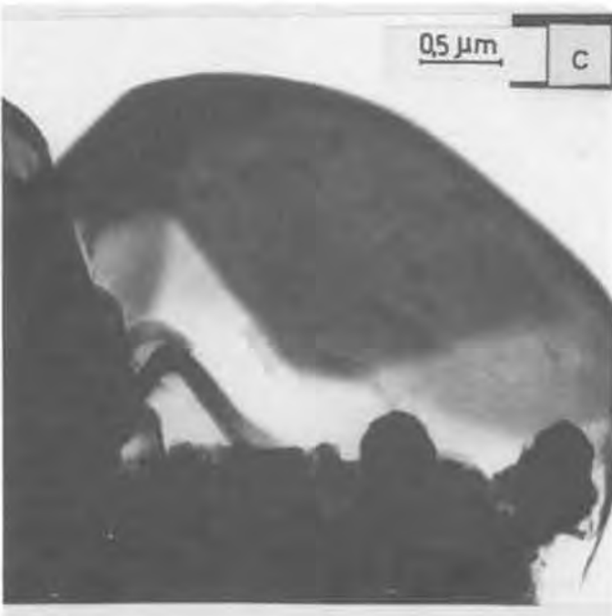


Fig. 14. Electron micrographs of the initial stage of PbO_2 formation.

It is seen from the micrographs (Fig. 14) that PbO_2 phase is formed only in some of the $PbSO_4$ membrane pores. They are probably the largest ones, where there is easy ion exchange between the PbO_n surface and the bulk of the solution. The ion exchange is hindered in the narrower pores and impossible in the third kind of pores, which are entirely blocked.

We can generalize the tet-PbO layer oxidation to α-PbO_2 as follows. Tet-PbO is first oxidized to PbO_n through solid-state reactions. During the oxidation tet-PbO crystal lattice remains unchanged, because the Pb^{2+} ion sublattice is stable and does not change significantly at low values of n. This is why no new phase

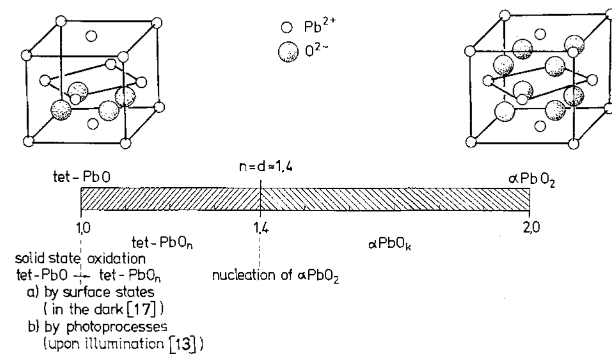

Fig. 15. Model of tet-PbO oxidation to α-PbO_2

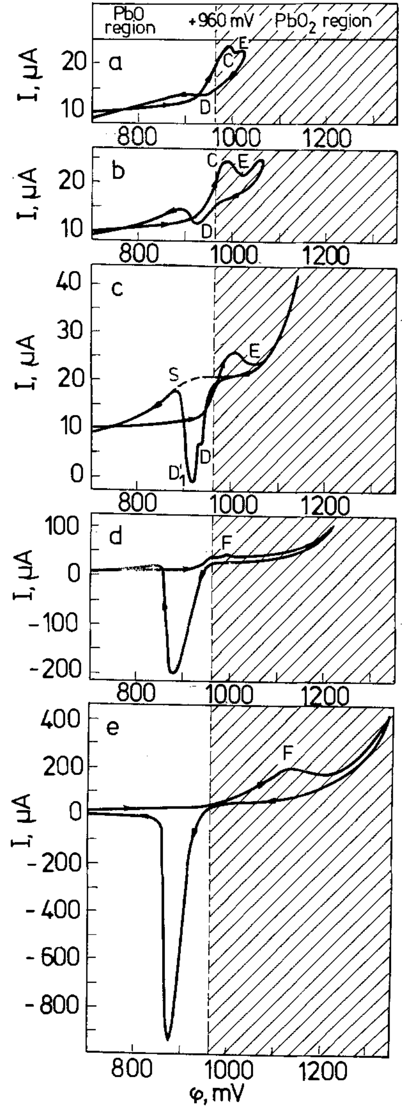

Fig. 16. Sweeps to potentials of $PbSO_4$ membrane destruction

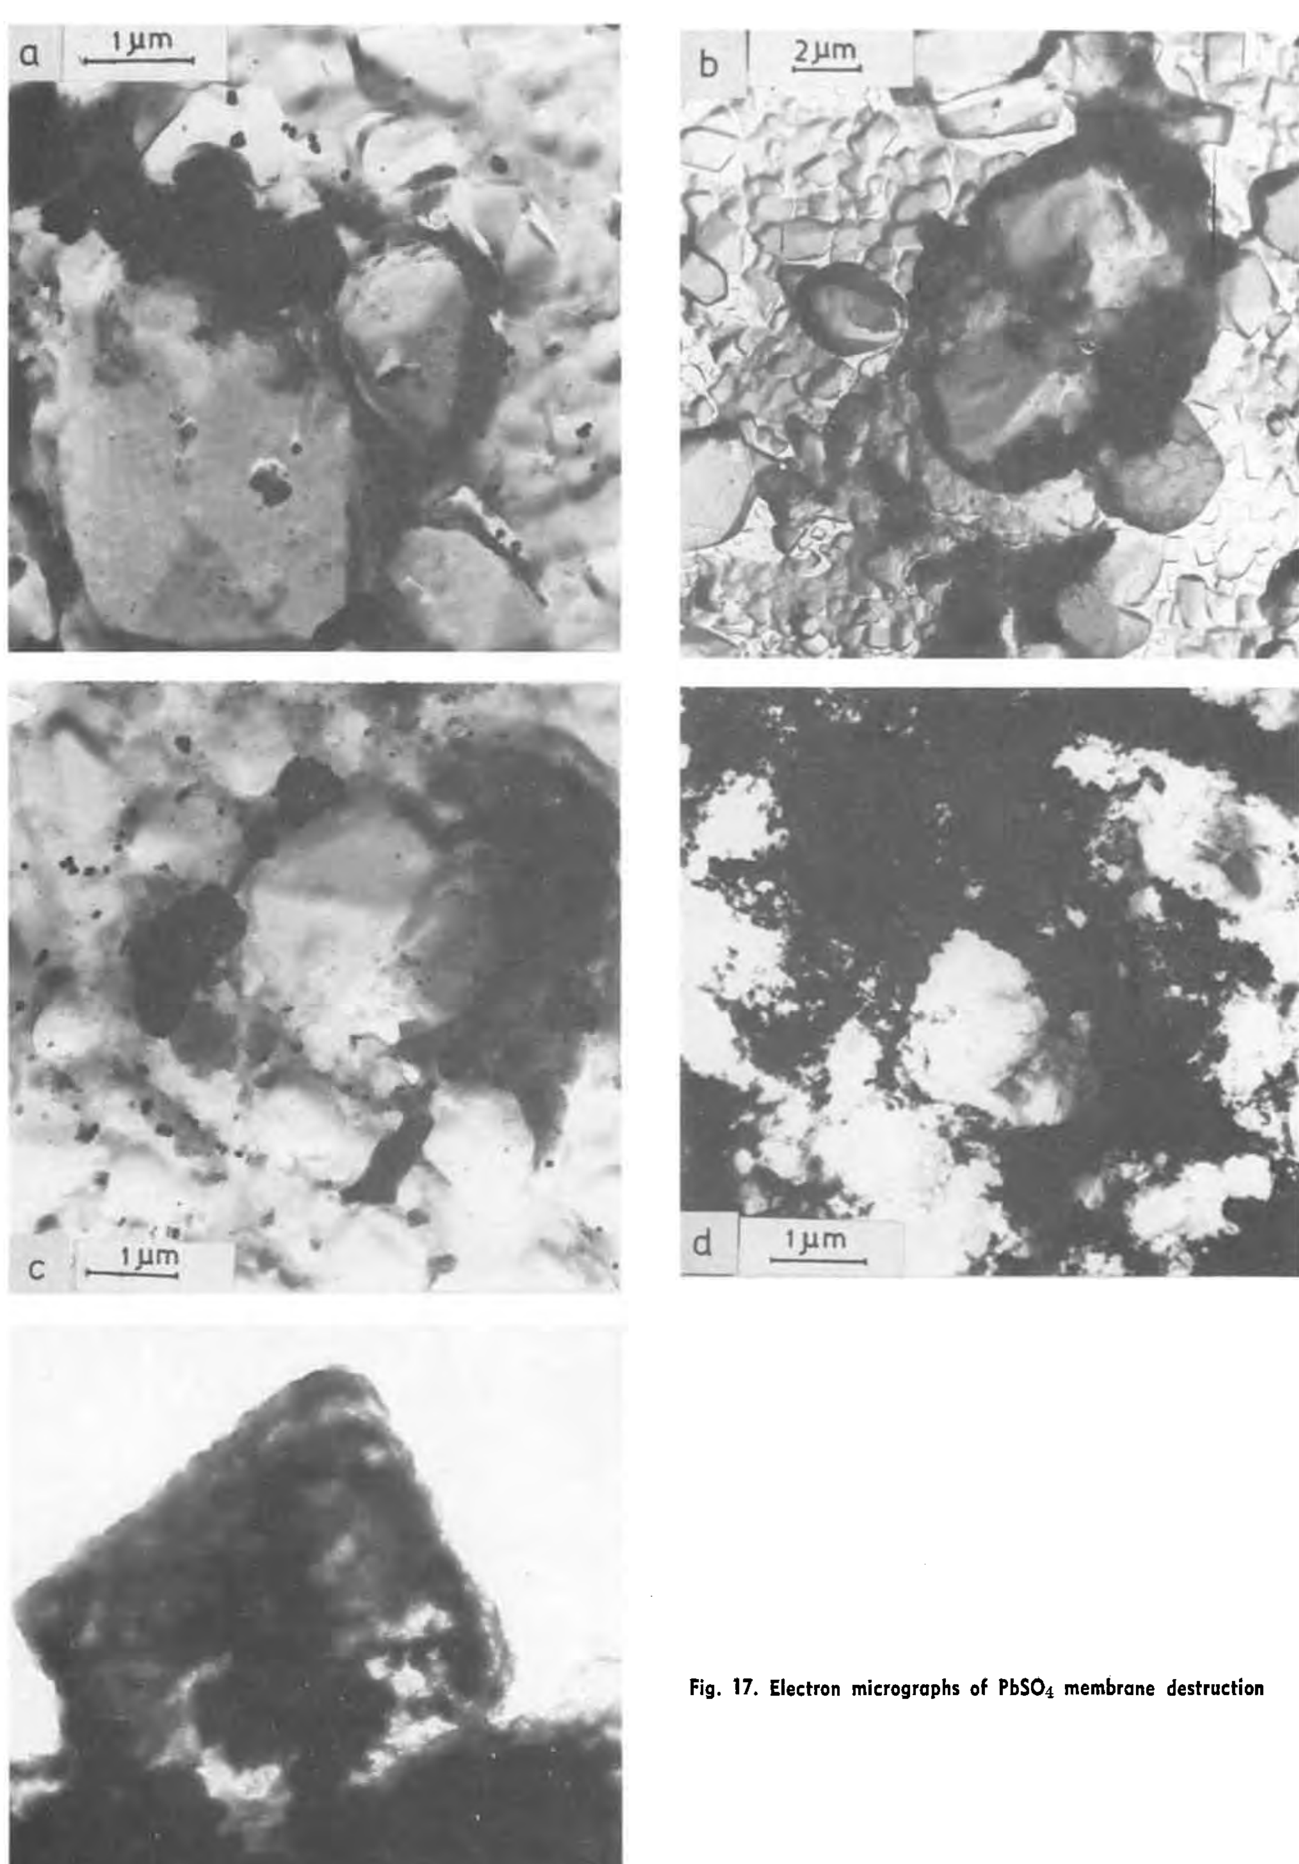

Fig. 17. Electron micrographs of $PbSO_4$ membrane destruction

nucleation occurs during the oxidation of tet-PbO to PbO_n. The O^{2-} ion sublattice is rather mobile due to the presence of empty layers and oxygen vacancies in it. The O^{2-} ion sublattice determines the solid electrolyte properties of PbO_n.

The Pb^{2+} ion sublattice determines the semiconductor properties of PbO_n. As the width of the bandgap is 1.9 eV, the oxidation of Pb^{2+} to Pb^{4+} is possible if the valency electrons receive energy higher than 1.9 eV. The oxidation of Pb^{2+} ions may take place through the mechanism of surface states. Such surface states are O atoms and O^- radicals, evolved during the reaction of oxygen evolution (Fig. 15).

When n rises to a critical value of $n = d \approx 1.4$, the defect concentration in the PbO_n crystal lattice becomes so high that rearrangement of the lattice begins through α-PbO_2 nucleation. This process is facilitated by the similarity of tet-PbO and α-PbO_2 crystal lattice (21). The newly formed α-PbO_2 phase is probably also nonstoichiometric, with values of the oxygen coefficient k from 1.4 to 2.0 (Fig. 15).

Oxidation of the $PbSO_4$ layer to PbO_2.—These processes were studied on an electrode, prepared as in the case of PbO_n oxidation. The potential was, however, swept to more positive potentials at which the $PbSO_4$ membrane is destroyed. Figure 16 shows voltammograms of this series.

At the first sweep a maximum C appears, which we attribute to α-PbO_2 formation in the $PbSO_4$ membrane pores. When the α-PbO_2 phase comes into contact with the H_2SO_4 solution, a new electrochemical process begins on its surface. The Pb^{2+} ions of the solution (obtained as a result of the dissolution of $PbSO_4$) are oxidized

$$Pb^{2+} + 2H_2O \rightarrow PbO_2 + 4H^+ + 2e^- \quad [9]$$

Due to this process, the current rises after the minimum E (Fig. 16a, b, c). β-PbO_2 is formed, because the process takes place in the H_2SO_4 solution.

During the negative-going sweep a second minimum appears at a more negative potential than the first one. It is probably due to β-PbO_2 reduction (Fig. 16c) Further on the shape of the voltammogram may depend on the processes of the membrane destruction. One or more maxima F appear at the anodic sweep. As the destruction of the membrane progresses, the two cathodic minima D and D′ merge into one and the latter shifts to more negative potentials (Fig. 16d, e).

A maximum S is observed after the minima D and D_1 (Fig. 15c). Sharpe (8) relates it to the increased rate of Pb oxidation. The PbO_n layer becomes thinner as PbO_2 is formed. When PbO_2 is reduced at the cathodic sweep, the PbO_n surface comes into contact with the solution and the rate of Pb oxidation (reactions [1] and [2]) increases. The dotted line presents the rate of oxidation as given by Sharpe (8).

After the $PbSO_4$ membrane destruction the current passes through a minimum and increases again. This increase is related to the reaction of oxygen evolution on the PbO_2 surface. The slowest stage of this process, according to Kabanov (25), is recombination of O atoms into a molecule. This stage sustains a certain concentration of O atoms at the PbO_2 surface.

Figure 17 shows electron micrographs of the $PbSO_4$ layer destruction. PbO_2 is seen predominantly among the biggest $PbSO_4$ crystals (Fig. 17a). During the oxidation of $PbSO_4$ to PbO_2 the pores widen and the access of H_2SO_4 into them becomes possible.

It is seen from Fig. 17a, b, c that the $PbSO_4$ crystals dissolve initially at the apexes and the edges and only later at the faces. The crystals become round and the membrane turns into a shapeless layer (Fig. 17c), partially covered with a PbO_2 layer (Fig. 17d). A possible interpretation of these observations is that $PbSO_4$ is oxidized along the following mechanism: dissolution of Pb^{2+} ions → diffusion of Pb^{2+} ions → oxidation of Pb^{2+} ions on the PbO_2 surface → precipitation of PbO_2.

The growth of PbO_2 is determined by the flow of Pb^{2+} ions. Figure 17e shows the profile of a $PbSO_4$ crystal surface. The Pb^{2+} ions move by surface diffusion along the $PbSO_4$ crystal surface toward the PbO_2 phase, where they are oxidized.

The PbO_2 phase looks like an amorphous deposit (Fig. 17). Fine crystals of one or both PbO_2 modifications are detected by x-ray analysis (3-4). There is probably an amorphous mass too (26). The fine structure of PbO_2 indicates that the rate of nucleation exceeds many times the rate of PbO_2 crystal growth.

Effect of the Distribution of Current Within a Pit on the Variation in Potential in the Vicinity of the Pit

P. H. Melville

Central Electricity Research Laboratories, Materials Division, Leatherhead, Surrey, England

ABSTRACT

A technique using integrals of Bessel functions has been used to calculate the effect of an anodic current distribution of the form $j_a = j_m(\beta_o + \beta_1 r^2/a^2 + \beta_2 r^4/a^4)$ within the pit on the potential distribution in the plane of the electrode surface, and analytic solutions have been obtained for situations where linear polarization kinetics may be assumed. If the radius of the pit is small compared to the Wagner polarization parameter L_c for the unpitted electrode, the potential distribution is independent of the polarization parameter, and thus insensitive to the assumption of linear kinetics. The potential within the pit depends mainly on the value of the total current flowing from the pit, and is less sensitive to the form of the current distribution. The potential outside the pit on the surface of the electrode depends on the mean current density and is virtually unaffected by the form of the current distribution.

In a recent paper (1) a Fourier integral technique has been used to calculate the distribution of potential around a scratch in a passive film. This has been extended (2) to cylindrical coordinates to calculate the variation in potential around a pit, assuming that the current density flowing from the pit is uniform across the pit. Here this method of solution is extended to allow for a variation in the current density across the pit. As in Ref. (2) it is assumed that the pit (the anode) is very small compared with the rest of the electrode, which may be treated as infinite, so that integration may be used as in Ref. (2-4) instead of summation, which is necessary for finite systems with this geometry (5-7).

Mathematical Model

As in Ref. (2) the problem considered is that of an infinite plate perpendicular to the z-axis at $z = 0$ with a small pit of radius a at the origin $r = 0$. The general solution for the distribution of the electrostatic potential P is given from the Laplace equation with the boundary conditions that P is a constant at $z = \infty$, and that the solutions are symmetric about $r = 0$. This requires that $P(r, z)$ is of the form

$$P(r,z) = B_o + \int_0^\infty B(t) J_o(rt) e^{-zt} dt \qquad [1]$$

where $J_o(\ )$ is a Bessel function of the first kind of order zero, and where the constant B_o and the function $B(t)$ have to be determined from the boundary conditions at the electrode surface. If the change in potential is small, linear polarization kinetics may be assumed as in Ref. (1) and (2) and as in the solutions of Waber and his associates (8-13) for strip geometry and by Gal-Or *et al.* (5) and McCafferty (6, 7) for circular geometry. The current density at the electrode surface is given by

$$j(r) = -\sigma \frac{\partial P}{\partial z}\bigg|_{z=0} \qquad [2]$$

where σ is the conductivity of the electrolyte.

This has to satisfy the electrochemical relations for the electrode, which if linear polarization kinetics are assumed is of the form

$$j^* = \frac{\sigma}{L_c}(E^* - E_c) \qquad [3]$$

where E_c is the free corrosion potential and L_c the Wagner polarization parameter (14) for the unpitted area (the cathode), and E^*, the electrode potential, is related to the electrostatic potential by

$$E^*(r) = V - P(r, 0) \qquad [4]$$

where V is some constant. At $z = 0$ this then gives

$$j(r) = \frac{\sigma}{L_c}[P + (E_c - V)][1 - \phi(r/a)] + j_a(r) \qquad [5]$$

where $\phi\ (r/a)$ is the step function

$$\phi(r/a) = 0, \quad r < a$$
$$= 1, \quad r > a \qquad [6]$$

The terms in $j_a(r)$ describe the current density flowing from the pit, so that $j_a(r) = 0$ for $r > a$. Within the pit ($r < a$), $j_a(r)$ is equal to the current density flowing from the pit, provided that this current density is much larger than that flowing in the unpitted region. If, as in Ref. (1) and (2), it may be assumed that the current density over the anode is very much greater than the current density elsewhere, Eq. [5] reduces to

$$\sigma \frac{\partial P}{\partial z} = \frac{\sigma}{L_c}[P + (E_c - V)] - j_a(r) \qquad [7]$$

This equation is most readily solved, if $j_a(r)$, like $P(r, z)$ (see Eq. [1]) may be expressed as an integral of Bessel functions. This may be achieved by using the relation

$$\int_0^\infty J_{2n+1}(at) J_o(rt)\, dt = \frac{1}{a} P_n\left(1 - 2\frac{r^2}{a^2}\right) \quad r < a$$
$$= 0 \qquad r > a \qquad [8]$$

which is a special result of an integral given by Erdélyi *et al.* (15) [see also (16)]. Here $J_{2n+1}(\ )$ is a Bessel function of the first kind of order $2n + 1$ where $n = 0, 1, 2, \ldots$ and where $P_n(\ )$ is a Legendre polynomial of order n, where

$$P_o(x) = 1 \qquad [9]$$

Key words: anodic current distribution, pitting, integral of Bessel functions.

$$P_1(x) = x \quad [10]$$

$$P_2(x) = \tfrac{1}{2}(3x^2 - 1) \quad [11]$$

In the analysis presented here only terms as far as $n = 2$ will be considered, but further terms may be included, if necessary. The current density $j_a(r)$ may thus be expressed as

$$j_a(r) = aj_m \int_0^\infty [J_1(at) + \alpha_1 J_3(at) + \alpha_2 J_5(at)] J_o(rt)dt \quad [12]$$

which gives

$$j_a(r) = j_m \left[(1 + \alpha_1 + \alpha_2) - (2\alpha_1 + 6\alpha_2)\frac{r^2}{a^2} + 6\alpha_2 \frac{r^4}{a^4} \right], \quad r < a$$

$$= 0, \qquad r > a \quad [13]$$

where j_m, α_1, and α_2 are constants, and where integra- of Eq. [13] over the area of the pit gives

$$I = \int_0^a j_a(r)\, 2\pi r dr = \pi a^2 j_m \quad [14]$$

so that j_m may be identified as the mean value of $j_a(r)$. Substitution for the integral representations for $P(r, 0)$, dP/dz, and $j_a(r)$ into Eq. [7] then gives

$$\sigma \int_0^\infty tB(t) J_o(rt)dt = -\frac{\sigma}{L_c}[B_o + (E_c - V)] - \frac{\sigma}{L_c}\int_0^\infty B(t)J_o(rt)dt + j_m a \int_0^\infty [J_1(at) + \alpha_1 J_3(at) + \alpha_2 J_5(at)]\, J_o(rt)dt = 0 \quad [15]$$

from which the constant B_o and the function $B(t)$ are given by

$$B_o = -(E_c - V) \quad [16]$$

$$B(t) = \frac{j_m a}{\sigma}\left[\frac{J_1(at) + \alpha_1 J_3(at) + \alpha_2 J_5(at)}{t + 1/L_c}\right] \quad [17]$$

The potential distribution may then be found by substitution for B_o and $B(t)$ in Eq. [1] and integration.

Potential at Center of Pit

At the center of the pit ($r = 0$, $z = 0$) $J_o(rt) = e^{-zt} = 1$, so that from Eq. [1], [16], and [17] the potential may be expressed as

$$P(0,0) = -(E_c - V) + \frac{j_m a}{\sigma}\int_0^\infty \frac{J_1(x) + \sigma_1 J_3(x) + \alpha_2 J_5(x)dx}{x + \delta} \quad [18]$$

where at has been replaced by x and where $\delta = a/L_c$. The third and fifth order Bessel functions may be expressed in terms of Bessel functions of order zero and one by use of the identities

$$J_3(x) = \left(\frac{8}{x^2} - 1\right) J_1(x) - \frac{4}{x} J_o(x) \quad [19]$$

$$J_5(x) = \frac{12}{x}\left(1 - \frac{16}{x^2}\right) J_o(x) + \left(\frac{384}{x^4} - \frac{72}{x^2} + 1\right) J_1(x) \quad [20]$$

Repeated application of the identity

$$\frac{1}{x^n(x + \delta)} = \frac{1}{x^{n-1}\delta}\left[\frac{1}{x} - \frac{1}{x + \delta}\right] \quad [21]$$

may then be used to reduce Eq. [18] to the known integrals

$$\int_0^\infty \frac{xJ_o(x)}{x + \delta}dx = \frac{\pi}{2}[\underset{\sim}{H}_o(\delta) - N_o(\delta)] = f_o(\delta) \quad [22]$$

$$\int_0^\infty \frac{xJ_1(x)}{x + \delta}dx = \delta\left\{\frac{\pi}{2}[\underset{\sim}{H}_1(\delta) - N_1(\delta)] - 1\right\} = \delta f_1(\delta) \quad [23]$$

(16, 17) [see also (2)] and integrals in terms of $x^{-n}J_o(x)$ and $x^{-n}J_1(x)$, where $n = 0, 1, 2, 3, \ldots$, $\underset{\sim}{H}_o(\ )$ and $\underset{\sim}{H}_1(\ )$ are Struve functions of order zero and one, respectively, and $N_o(\ )$ and $N_1(\ )$ are Bessel functions of the second kind of order zero and one. The functions $f_o(\delta)$ and $f_1(\delta)$ are defined by these equations. The terms in $x^{-n}J_o(x)$ and $x^{-n}J_1(x)$ may be grouped together and identified with the standard relations

$$\frac{d}{dx}J_1(x) = J_o(x) - \frac{J_1(x)}{x} \quad [24]$$

$$\frac{d}{dx}J_2(x) = \frac{2J_o(x)}{x} + \left(1 - \frac{4}{x^2}\right)J_1(x) \quad [25]$$

$$\frac{d}{dx}J_3(x) = \left(\frac{12}{x^2} - 1\right)J_o(x) + \left(5 - \frac{24}{x^2}\right)\frac{J_1(x)}{x} \quad [26]$$

$$\frac{d}{dx}J_4(x) = \frac{8}{x}\left(\frac{12}{x^2} - 1\right)J_o(x) - \left(\frac{192}{x^4} - \frac{40}{x^2} + 1\right)J_1(x) \quad [27]$$

$$\frac{d}{dx}J_5(x) = \left(\frac{960}{x^4} - \frac{84}{x^2} + 1\right)J_o(x) - \left(\frac{1920}{x^4} - \frac{408}{x^2} + 13\right)\frac{J_1(x)}{x} \quad [28]$$

where since $J_m(0) = J_m(\infty) = 0$ where $m = 1, 2, 3 \ldots$ integrals of these groups of terms are zero. Integrals of the remaining terms in $J_o(x)$ and $J_1(x)$ are obtained from

$$\int_0^\infty J_o(x)dx = \int_0^\infty J_1(x)dx = 1 \quad [29]$$

The integral of Eq. [18] is then given by

$$P(0,0) = -(E_c - V) + \frac{j_m a}{\sigma}[g_o(\delta) + 1/3\,\alpha_1 g_1(\delta) + 1/5\,\alpha_2 g_2(\delta)] \quad [30]$$

where

$$g_o(\delta) = 1/\delta - f_1(\delta) \quad [31]$$

$$\frac{1}{3}g_1(\delta) = \left(\frac{8}{\delta^3} - \frac{8}{\delta^2} + \frac{1}{\delta}\right) + \frac{4}{\delta}f_o(\delta) - \left(\frac{8}{\delta^2} - 1\right)f_1(\delta) \quad [32]$$

$$\frac{1}{5}g_2(\delta) = \left(\frac{384}{\delta^5} - \frac{384}{\delta^4} + \frac{24}{\delta^3} + \frac{8}{\delta^2} + \frac{1}{\delta}\right) + \frac{12}{\delta}\left(\frac{16}{\delta^2} - 1\right)f_o(\delta) - \left(\frac{384}{\delta^4} - \frac{72}{\delta^2} + 1\right)f_1(\delta) \quad [33]$$

where the functions $f_o(\delta)$ and $f_1(\delta)$ are defined in Eq. [22] and [23]. The functions $g_o(\delta)$, $g_1(\delta)$, and $g_2(\delta)$ are shown in Fig. 1. In the limit of small δ (*i.e.*, $a << L_c$) $g_o = g_1 = g_2 = 1$. As shown in Fig. 1, the error made, if δ is set equal to zero is small ($\lesssim 10\%$), provided $\delta \lesssim 0.05$, *i.e.*, if the pit radius $a \lesssim L_c/20$.

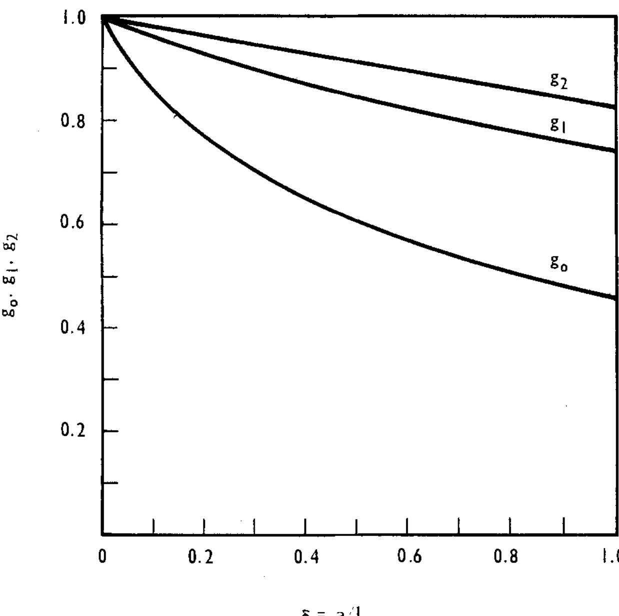

Fig. 1. $g_0(\delta)$, $g_1(\delta)$, and $g_2(\delta)$ (see Eq. [31]-[33]), giving the effect of the relative magnitudes of the size of the pit a and the Wagner polarization parameter L_c.

Distribution of Potential on the Electrode Surface

If the pit is much smaller than the Wagner polarization parameter, so that $\delta = a/L_c$ may be set equal to zero, the potential along the surface of the electrode is given by

$$P(r,0) = -(E_c - V) + \frac{j_m a}{\sigma} \int_0^\infty \frac{[J_1(at) + \alpha_1 J_3(at) + \alpha_2 J_5(at)]}{t} J_o(rt)dt \quad [34]$$

This is the zeroth order term in an expansion in δ, and is valid provided both a and r are small compared with L_c, *i.e.*, it is restricted to positions close to the pit. Expansion of the integral in terms of δ is discussed in Ref. (2). The first term in the integral [see (2, 4)] is given by Erdélyi *et al.* (15) as

$$\int_0^\infty \frac{J_1(at)J_o(rt)dt}{t} dt = \frac{2}{\pi} E\left(\frac{r}{a}\right), \quad r < a$$

$$= \frac{2}{\pi}\frac{r}{a}\left[E\left(\frac{a}{r}\right) - \left(1 - \frac{a^2}{r^2}\right)K\left(\frac{a}{r}\right)\right], \quad r > a \quad [35]$$

where $K(\ )$ and $E(\ )$ are complete elliptic integrals of the first and second kinds, respectively. The other terms are obtained as a special result of an integral by Watson (17) and Magnus and Oberhettinger (18) [see also (14)] which in this case gives

$$\int_0^\infty \frac{J_{2n+1}(at)J_o(rt)}{t} dt = \frac{1}{(2n+1)} F\left(n + \tfrac{1}{2}, -(n + \tfrac{1}{2}); 1; \frac{r^2}{a^2}\right), \quad r < a$$

$$= \frac{(-2)^n}{\pi n(2n+1)^2} F\left(n + \tfrac{1}{2}, n + \tfrac{1}{2}; 2n + 2; \frac{a^2}{r^2}\right), \quad r > a \quad [36]$$

for $n = 1, 2, 3, \ldots$, where $F(, ; ;)$ are hypergeometric functions. In this case for integer n these hypergeometric functions are related to complete elliptic integrals of the first and second kinds, which may be expressed in terms of hypergeometric functions as

$$K(k) = \frac{\pi}{2} F(\tfrac{1}{2}, \tfrac{1}{2}; 1; k^2) \quad [37]$$

$$E(k) = \frac{\pi}{2} F(-\tfrac{1}{2}, \tfrac{1}{2}; 1; k^2) \quad [38]$$

respectively. The hypergeometric functions of Eq. [36] may thus be reduced to complete elliptic integrals by repeated use of the Gauss recursion relations. After some algebra this eventually gives

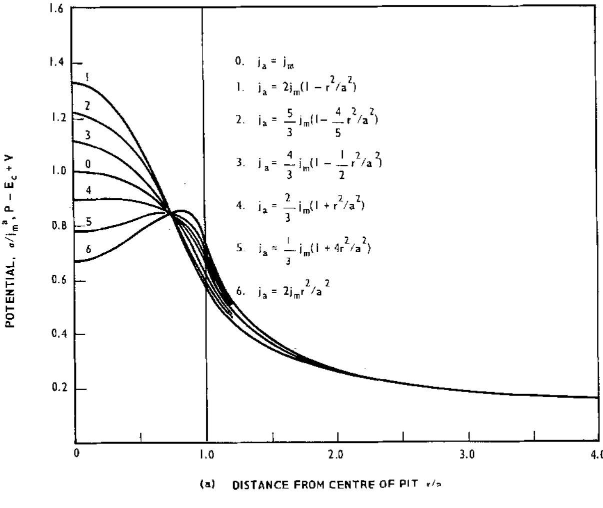
$$\int_0^\infty \frac{J_3(at)J_o(rt)}{t} dt = \frac{2}{9\pi}\left[\left(7 - 8\frac{r^2}{a^2}\right)E\left(\frac{r}{a}\right) - 4\left(1 - \frac{r^2}{a^2}\right)K\left(\frac{r}{a}\right)\right], \quad r < a$$

$$= \frac{2}{9\pi}\frac{r^3}{a^3}\left[-\left(8 - 7\frac{a^2}{r^2}\right)E\left(\frac{a}{r}\right) + \left(8 - 3\frac{a^2}{r^2}\right)\left(1 - \frac{a^2}{r^2}\right)K\left(\frac{a}{r}\right)\right], \quad r > a \quad [39]$$

$$\int_0^\infty \frac{J_5(at)J_o(rt)}{t} dt = \frac{2}{75\pi}\left[\left(43 - 168\frac{r^2}{a^2} + 128\frac{r^4}{a^4}\right)E\left(\frac{r}{a}\right) - 4\left(7 - 16\frac{r^2}{a^2}\right)\left(1 - \frac{r^2}{a^2}\right)K\left(\frac{r}{a}\right)\right], \quad r < a$$

$$= \frac{2}{75\pi}\frac{r^5}{a^5}\left[\left(128 - 168\frac{a^2}{r^2} + 43\frac{r^4}{a^4}\right)E\left(\frac{a}{r}\right) - \left(128 - 104\frac{a^2}{r^2} + 15\frac{a^4}{r^4}\right)\left(1 - \frac{a^2}{r^2}\right)K\left(\frac{a}{r}\right)\right], \quad r > a \quad [40]$$

The potential distributions are thus found by substituting for these integrals (Eq. [35], [39], and [40]) into Eq. [34]. The solutions obtained in this way for the variation of potential along the electrode surface are valid for zero order in r/L_c, and the current density flowing from the electrode outside the pit is effectively ignored (since L_c is large). The situation is thus similar to that for a disk electrode embedded in an insulating layer, and the solution obtained for constant current density from the pit, *i.e.*, $\alpha_1 = \alpha_2 = 0$ gives a potential distribution identical to that obtained by Nannis and Kesselman (4) for the disk electrode problem. Potential distributions predicted by these equations are shown in Fig. 2 for a number of different values of α_1 and α_2 but for the same value of the mean current density j_m. The corresponding current density distributions are shown in Fig. 3. Current density distributions of the form $j_a = j_m(\beta_o + \beta_1 r^2/a^2)$ are considered in Fig. 2a and 3a, $j_a = j_m(\beta_o + \beta_2 r^4/a^4)$ in Fig. 2b and 3b, and $j_a = j_m(\beta_o + \beta_1 r^2/a^2 + \beta_2 r^4/a^4)$ in Fig 2c and 3c. The potentials shown here are in the plane of the electrode surface. Despite the wide variation in the form of the current density distributions, the curves for the potential distribtion are not as dissimilar in the region of the pit and are virtually identical outside the pit. The potential generally has a single maximum at the center of the pit, but there is a dip in the potential at the center, if the current density



POTENTIAL. σ/j_m a, P − E_c + V

0. $j_a = j_m$
1. $j_a = \frac{3}{2} j_m(1 - r^4/a^4)$
2. $j_a = \frac{4}{3} j_m(1 - \frac{3}{4} r^4/a^4)$
3. $j_a = \frac{6}{5} j_m(1 - \frac{1}{2} r^4/a^4)$
4. $j_a = \frac{3}{4} j_m(1 + r^4/a^4)$
5. $j_a = \frac{1}{2} j_m(1 + 3r^4/a^4)$
6. $j_a = 3j_m r^4/a^4$

(b) DISTANCE FROM CENTRE OF PIT r/a

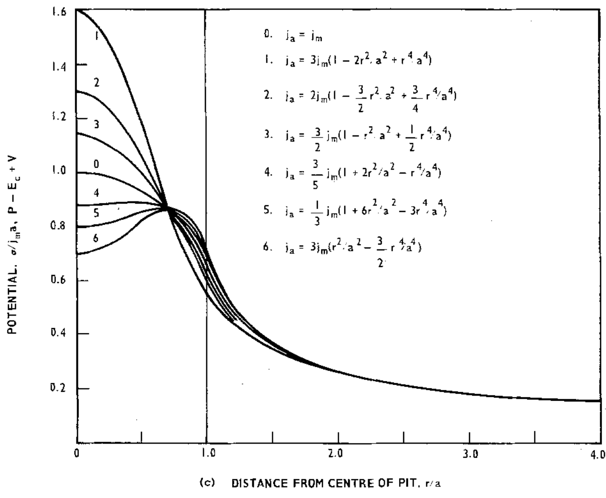


Fig. 2. Variation in potential for different current distributions

here is less than about half the mean value. Values of the potential that are of particular interest are the potential at the center of the pit

$$P(0,0) = -(E_c - V) + \frac{j_m a}{\sigma}\left[1 + \frac{1}{3}\alpha_1 + \frac{1}{3}\alpha_2\right] \quad [41]$$

(see also Eq. [30]) and the potential at the edge of the pit given by

$$P(a, 0) = -(E_c - V) + \frac{j_m a}{\sigma}\left(\frac{2}{\pi}\right)\left[1 - \frac{1}{9}\alpha_1 + \frac{1}{25}\alpha_2\right] \quad [42]$$

When compared with the expressions for the current density at the center and edge of the pit

$$j_a(0) = j_m[1 + \alpha_1 + \alpha_2] \quad [43]$$

$$j_a(a) = j_m[1 - \alpha_1 + \alpha_2] \quad [44]$$

it may be seen that the potential at the center of the pit is less sensitive to the values of α_1 and α_2 than is the current density ($1/3\alpha_1$ and $1/5\alpha_2$ instead of α_1 and α_2) and that the potential at the edge of the pit is still less sensitive ($1/9\alpha_1$ and $1/25\alpha_2$), in agreement with the observations made above.

Conclusions

1. A technique using integral of Bessel functions has been used to calculate the effect of an anodic current distribution of the form $j_a = j_m(\beta_o + \beta_1 r^2/a^2 + \beta_2 r^4/a^4)$ within the pit on the potential distribution in the plane of the electrode surface.

2. Analytic solutions have been obtained for situations where linear polarization kinetics may be assumed, *e.g.*, where the pit is small so that the change in potential $\sim j_m a/\sigma$ is small.

3. If the radius of the pit a is small compared to the Wagner polarization parameter L_c for the unpitted electrode, *i.e.*, $a \lesssim L_c/20$, the potential distribution is independent of the polarization parameter, and thus insensitive to the assumption of linear kinetics.

4. The potential depends mainly on the mean value of the current density flowing from the pit, and is less sensitive to the form of the current distribution.

5. Quite large changes in the form of the current distribution are required to produce changes in the potential at the center of the pit for the same mean current density, and the potential at the edge of the pit is still less sensitive to the form of the current distribution.

6. The potential outside the pit on the surface of the electrode depends on the mean current density and is virtually unaffected by the form of the current distribution.

Studies in Selenious Acid Reduction and CdSe Film Deposition

M. Skyllas Kazacos* and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The reaction sequence for the reduction of H_2SeO_3 in 1M H_2SO_4 at various surfaces and the formation of selenide films in this medium with and without metal ions present have been investigated by rotating disk and ring-disk electrode techniques. The system is complicated by competitive paths leading to selenium formation from Se(−2)-Se(+4) chemical reactions and the result is sensitive both to the nature of the substrate with the possibility of metal selenide formation and to the concentration of solution species. The implications for cathodic deposition of semiconductors like CdSe, from voltammetric and photospectral data, are discussed.

n-CdSe single crystals have been used as photoanodes in semiconductor liquid junction solar cells to give overall power conversion efficiencies of 7.5% (1). Pressure sintered CdSe polycrystalline electrodes have shown 70% of the single crystal efficiency (2). Films anodically generated from cadmium metal in selenide solution exhibit the spectral properties of the single crystal form, but much lower power conversion efficiencies (3). A number of problems are recognized with the anodic films grown for photovoltaic purposes, including limited thickness, uncertain composition, defects, unknown doping, and small crystallite size (3, 4).

Deposition of CdSe by cathodization in a selenious acid-cadmium ion solution has been accomplished by the Weizmann Institute group (5), and layers up to several microns have been achieved on a Ti substrate. Although the problem of limited thickness can be overcome by this technique, codeposition of excess selenium is difficult to control, and poor crystallinity gives rise to reduced photoresponse in the as-deposited material. These can be offset to some extent by a subsequent annealing process which increases the crystallinity and stoichiometry of the films. A mechanistic understanding of the deposition process is presently lacking and is an object of this study. Insights into the reaction sequence may lead to improving the quality of the films.

Considerable work has already been done on the kinetics of Se(IV) reduction and a number of mechanisms have been proposed. From a detailed study of the polarographic behavior of tetravalent selenium, Lingane and Niedrach (6) suggested the following overall equation to describe the initial main wave

$$H_2SeO_3 + 4e + 4H^+ + Hg \rightleftarrows HgSe + 3H_2O \quad [1]$$

This actually results from the superimposed partial processes of

$$H_2SeO_3 + 6e + 6H^+ \rightleftarrows H_2Se + 3H_2O \quad [2]$$

and the anodic dissolution of mercury by

$$Hg + H_2Se \rightarrow HgSe + 2H^+ + 2e \quad [3]$$

In acidic and alkaline solutions, a second cathodic wave is observed and corresponds to the six-electron reduction of Se(+4) species to Se(−2). In the intermediate *p*H range, however, a net four-electron process is observed because H_2Se reacts sufficiently rapidly with Se(+4) by

$$H_2SeO_3 + 2H_2Se \rightleftarrows 3Se + 3H_2O \quad [4]$$

Jónás (7) investigated the polarographic behavior of Se(+4) in a large number of buffer and nonbuffer solutions and observed up to four different cathodic waves depending on the *p*H value. She concluded, however, that reaction [4] does not take place during the reduction of Se(+4), attributing the presence of the first wave to reaction [1], and the second wave to reaction [2]. The further waves were ascribed to $HSeO_3^-$ and SeO_3^{2-} reduction, depending on *p*H.

A number of workers (8-10) have asserted that the second wave of Se(+4) in acidic solutions might represent catalytic hydrogen evolution in addition to reaction [2]. Thus, the reduction in acidic solutions could end with elemental selenium via reaction [4].

Several other polarographic studies (11-14) show a similar disagreement concerning the mechanism of Se(IV) reduction, in particular, with regard to the nature of the final product. This is especially of importance in the cathodic CdSe deposition since the concurrent formation of elemental selenium at the electrode surface is one of the major problems associated with this technique.

Rotating disk (RDE) and ring-disk electrode (RRDE) studies were initiated to investigate selenious acid reduction in 1M H_2SO_4 at various metal surfaces and the mechanism of the CdSe film deposition in solutions also containing Cd(II) ions. In addition, sinusoidal hydrodynamic modulation (SHM) of rotation speed, which is useful in discriminating between surface and mass transfer controlled reactions, was also applied where appropriate. The results are examined with respect to electrochemical preparation of photoactive II-VI semiconductor substrates.

Experimental

The construction and electronics of the RRDE have previously been described (15), as has the apparatus for the sinusoidal speed modulation (16). The RRDE's used were either gold disk-gold ring, or silver disk-carbon ring electrodes. RDE studies were also carried out on platinum, copper, amalgamated gold, and wax impregnated carbon surfaces.

The electrodes were rotated in a three compartment cell equipped with a bottom optical flat window to enable illumination of the disk surface. Solutions were prepared with triply distilled water and reagent grades of Na_2SeO_3, $CdSO_4$, and 95% H_2SO_4. A saturated calomel electrode served as reference and unless otherwise specified, a rotation speed of 1600 rpm was used in all experiments.

Results and Discussion

Reduction of Se(IV) in 1M H_2SO_4.—The cathodic behavior of H_2SeO_3 in sulfuric acid was found to be strongly influenced by the nature of the disk electrode used. In general, however, these could be grouped into two different categories depending on how "noble"

* Electrochemical Society Active Member
Key words: electrodeposition, voltammetry, semiconductor.

these electrodes behaved with respect to the electroactive reactants or intermediates.

Rotating disk voltammograms in 5 mM H_2SeO_3 for Group I electrodes (gold, platinum, and carbon) in the potential range 0 to $-1.2V$ *vs.* SCE, are shown in Fig. 1-3 as curve 1, for scans first positive to negative, then reverse. In each case, a single reduction wave can be observed before the current increases rapidly with H_2 evolution. The reduction wave is decidedly better defined on the reverse, although there is some limiting current loss on the step. With each successive full cycle of the potential (not shown) the limiting current decreases due to the formation of a passivating red selenium film on the electrode surface. The carbon electrode is seen to passivate more rapidly than the others so that already on the reverse (positive-going) scan of the first cycle no reduction wave can be observed.

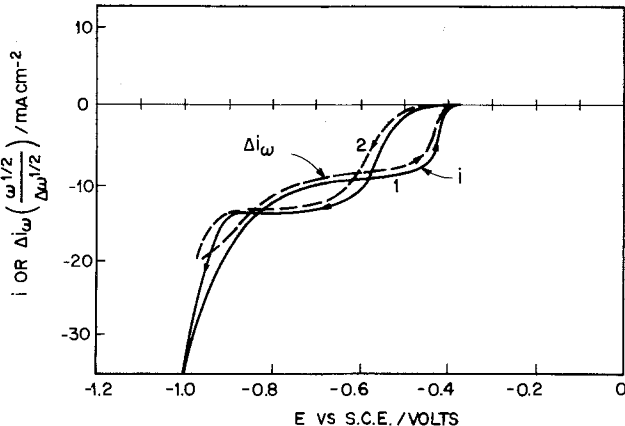

Fig. 1. Curve 1, Controlled potential sweep cycle of 0.175 cm² gold disk in 5 mM H_2SeO_3-1M H_2SO_4 at 10 mV sec^{-1} scan rate. Curve 2, Modulated component of disk current for potential scan of curve 1. Central rotation speed, ω = 1600 rpm; modulation amplitude, $\Delta\omega^{1/2}$ = 2 rpm$^{1/2}$; modulation frequency, f = 1 Hz.

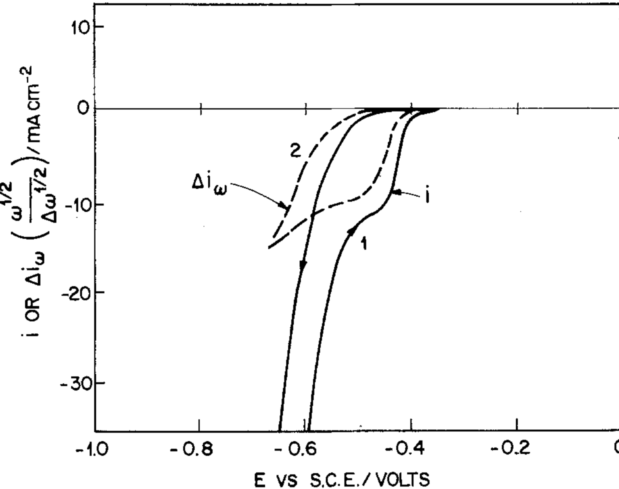

Fig. 2. Curves 1 and 2 as Fig. 1 but with platinum disk

If the potential is scanned and held at a value corresponding to copious hydrogen evolution, the red film gradually disappears. This can be accounted for by either a further reduction of Se to H_2Se or to a mechanical removal of the Se by the action of the hydrogen bubbles.

The $i/\omega^{1/2}$ values at the first step, curve 1, for the limiting currents (or the maximum current for carbon which passivates more rapidly) are equal for all three electrodes. In order to confirm a mass transfer limited process for the cathodic step and to see whether a second reduction wave is present and hidden by H_2 evolution, sinusoidal hydrodynamic modulation experiments were performed and shown as curve 2 in Fig. 1-3. (Curves 1 and 2 of these figures were actually obtained in the same experiment where i is the average total current. The results for curve 1 are independent of the superimposed SHM). The corresponding Δi_ω values are in accord with Levich equation expectation, as shown by the near superposition of the $\Delta i_\omega \times \omega^{1/2}/\Delta\omega^{1/2}$ and i curves in these regions.

Using this technique, it should be possible to differentiate between a convective diffusion controlled process such as H_2SeO_3 reduction, for which SHM response is expected, and a process which is not kinetically reversible and not limited by the rate of diffusion of an electroactive species to the electrode surface (*i.e.*, H_2 evolution at gold in 1M H_2SO_4 at these currents). The latter is thus insensitive to ω variation. The curves for gold show the best evidence for the presence of a second wave for a further reduction of Se to H_2Se beyond the hydrogen potential. However, because of the interference both of the sharply rising hydrogen current and bubble evolution, a quantitative ratio of limiting currents for the two processes cannot be established.

The reduction of H_2SeO_3 on Au-Hg and Ag (Group II) disk electrodes is shown in Fig. 4 and 5, respectively. Both electrodes exhibit a different behavior from the Group I electrodes with the most significant common feature being a more positive first wave potential suggestive of some interaction between the electrode surface and the solution species. The appearance of a black film, if the potential is held at a value more positive than $-0.4V$, implies HgSe and Ag_2Se formation in the respective cases. At more negative potentials, the red selenium deposit appears. In the case of Au-Hg, the presence of several small peaks during the initial scan from $-0.2V$ is probably the result of HgSe formation [initiating at $-0.35V$, in agreement with other work (6, 7)]. The inhibition of

current by this film is followed by a subsequent reduction of the HgSe to Hg and H_2Se, not separated from hydrogen evolution. Reversal of the scan gives rise to a single smooth wave corresponding to Se deposition on Hg, then on HgSe. The initial HgSe peak is absent since the Hg electrode is now isolated from the solution by the Se-HgSe film.

On the silver electrode Ag_2Se is deposited until the rate of diffusion of Ag to the electrode surface is limited by the thickness of the film. Then, through electronic conduction in the film, Se deposition takes place. Since four electrons are involved in each reaction, *i.e.*

$$H_2SeO_3 + 2Ag + 4H^+ + 4e \rightarrow Ag_2Se + 3H_2O \quad [5]$$

and

$$H_2SeO_3 + 4H^+ + 4e \rightarrow Se + 3H_2O \quad [6]$$

only one reduction wave is observed for the two reactions. At potentials more negative than −0.6V, a large cathodic peak can be seen, together with the appearance of a black deposit of Ag. Thus, at these potentials, Ag_2Se is reduced to Ag with the release of H_2Se. It should therefore be possible to detect at a ring electrode, any H_2Se released into solution. Using a silver disk-carbon ring electrode and potentiostatting the ring at 0.2V, the disk potential was scanned negative from 0.2V. Curve 3 of Fig. 5 shows the anodic ring peak which appears as the Ag_2Se is reduced at the disk. Thus, as Ag_2Se is reduced, Ag deposits on the disk electrode, and as the H_2Se that is not reacted by H_2SeO_3 in transit is swept across the ring electrode, it is oxidized to Se.

From the above, although it is apparent from the visual evidence that elemental selenium is the product of the reduction of selenious acid, it remains necessary to distinguish between two different mechanisms; either a four electron reduction as given by Eq. [6], or a six electron reduction to H_2Se followed by a fast chemical reaction as given by Eq. [2] and [4]. If the latter is true and the rate of the subsequent chemical reaction is dependent on the rate of diffusion of the species H_2SeO_3 to the electrode surface, the rate of reaction [4] should be influenced by the concentration of H_2SeO_3 in solution.

Using a 0.5 mM solution of H_2SeO_3 in 1M H_2SO_4, the voltammograms shown in Fig. 6-8 were obtained for Au, Ag, and Cu (Cu is a Group II type) electrodes, respectively. The most significant feature here is the presence of two reduction waves on silver and copper. Figure 9 shows Levich plots for both waves in each of the limiting current regions (*i.e.*, at −0.3 and −0.6V). The results for both metals essentially superimpose, yielding two straight lines with a slope ratio of approximately 2:3 for each system. Thus, if four electrons

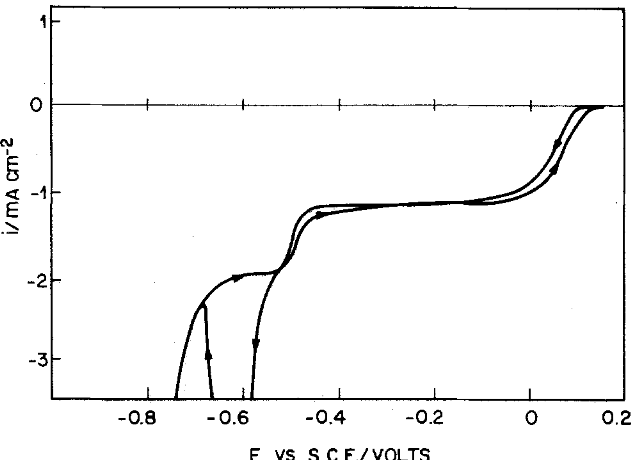

Fig. 7. Conditions of Fig. 5 at silver disk, without modulation, except solution is 0.5 mM H_2SeO_3-1M H_2SO_4.

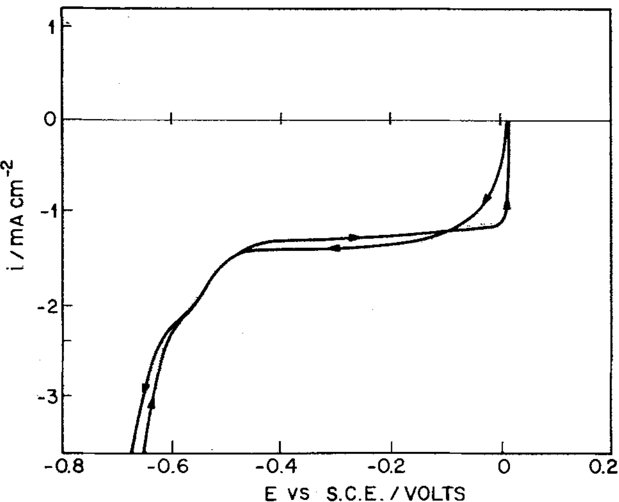

Fig. 8. Conditions of Fig. 7 at copper disk.

are involved in the first reduction step, with the formation of Ag_2Se and Cu_2Se, respectively, the second cathodic wave corresponds to the six electron reduction of H_2SeO_3 to H_2Se.

The Levich plots of wave height/concentration *vs.* $\omega^{1/2}$ for 0.5 mM H_2SeO_3 solutions (Fig. 10) at a gold disk also give a slope 50% higher for the more dilute solution, consistent with an apparent change from 4 to 6 in electrons transferred. Furthermore, holding the potential of the disk electrodes in the region of H_2Se

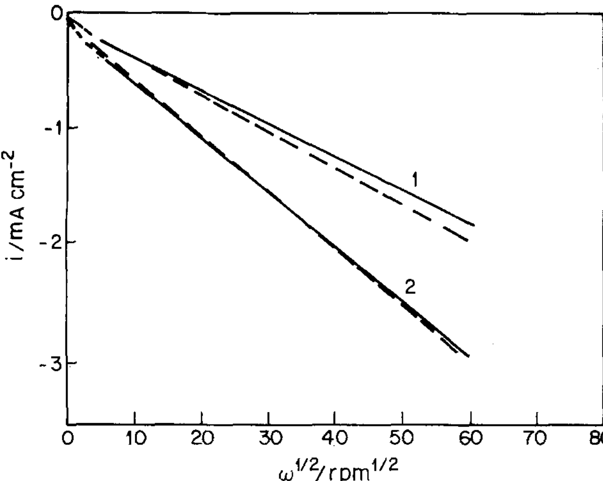

Fig. 9. Levich plots for silver and copper rotating disks in 0.5 mM H_2SeO_3-1M H_2SO_4. Curve 1, currents at $E = -0.2V$ vs. SCE; Curve 2, currents at $E = -0.6V$ vs. SCE. ——— Ag; - - - Cu.

formation for several minutes in the 0.5 mM H_2SeO_3 solution does not lead to the deposition of any observable amount of red selenium at the disk. A red film is, however, formed outward from the periphery of the electrode, again showing that Se formation does result from a chemical interaction between H_2Se and H_2SeO_3. Thus, the following sequence is proposed for the reduction of H_2SeO_3 in 1M H_2SO_4 at a "noble" electrode

$$H_2SeO_3 + 6H^+ + 6e \rightarrow H_2Se + 3H_2O \quad [7]$$

followed by the chemical reaction

$$2H_2Se + H_2SeO_3 \rightarrow 3Se + 3H_2O \quad [8]$$

The rate of the chemical reaction is dependent on the concentration of H_2SeO_3, so that at high H_2SeO_3 concentrations, reaction [8] is fast and the overall process taking place at the electrode surface appears to be

$$H_2SeO_3 + 4H^+ + 4e \rightarrow Se + 3H_2O \quad [9]$$

For the Group II electrodes however, an interaction takes place between the metal surface and the electroactive species. The following reaction occurs at these electrodes

$$nM + H_2SeO_3 + 4H^+ + 4e \rightarrow M_nSe + 3H_2O \quad [10]$$

where M stands for Hg, Ag, or Cu, respectively, with $n = 1$ for Hg, 2 for Ag and Cu. These reactions take place more readily, *i.e.*, at more positive potentials, because of the additional driving force of the insoluble metal-selenide formation, than does H_2Se formation by reaction [2]. However, as the flux of the species M by diffusion through the also electronically conducting selenide film decreases, reaction [7] or [9] takes over.

A further feature of the selenious acid reduction is the irreversibility of the reaction, with no reoxidation wave appearing after selenium deposition. It is also to be noted that Se(IV) cannot be oxidized to Se(VI) in this system and such a ring reaction is not available to determine the number of electrons transferred in disk reaction consuming Se(IV).

Deposition of CdSe.—The technique developed by the Weizmann Institute group (5) for the cathodic deposition of CdSe, involves the use of millimolar SeO_2 solutions in 1M H_2SO_4 in the presence of relatively high concentrations of $CdSO_4$. Using a Cd stick as anode and a Ti plate as substrate, no external voltage is required when the two electrodes are shorted together. Solution stirring and concentration of SeO_2 are adjusted so as to maintain a current of 5-10 mA cm^{-2} of Ti. Higher SeO_2 concentrations result in the formation of a red insulating layer of Se which prevents further deposition.

From the results presented in the section "Reduction of Se(IV) in 1M H_2SO_4," the reduction of selenite in 1M H_2SO_4 gives rise to H_2Se which undergoes a rapid chemical reaction with the solution to yield elemental selenium at the electrode surface. In solutions of high H_2SeO_3 concentrations, *i.e.*, $\gtrsim$ 5 mM H_2SeO_3, the post chemical reaction is so fast that the overall process appears as a four electron reduction to Se. Under such conditions, the precipitation of Cd^{2+} at the surface of the electrode would not be able to compete favorably, even at high Cd^{2+} concentrations with Se deposition. Decreasing the concentration of H_2SeO_3 however, slows down the subsequent chemical reaction of H_2Se so that a six electron reduction results at the surface of the electrode. Under such circumstances, it should be possible to deposit CdSe more efficiently, although excess Se could still be expected if the chemical reaction [8] is fast enough.

Figure 11 shows a voltammogram obtained for a gold electrode in a 1M H_2SO_4 solution containing 0.5 mM Na_2SeO_3 and 0.1M $CdSO_4$. A reduction wave, corresponding to the six electron reduction of H_2SeO_3, appears at approximately $-0.5V$ *vs.* SCE. At potentials more negative than $-0.7V$, the current increases rapidly due to the reduction of Cd^{2+}. Reversal of the scan from that point gives rise to an anodic peak cor-

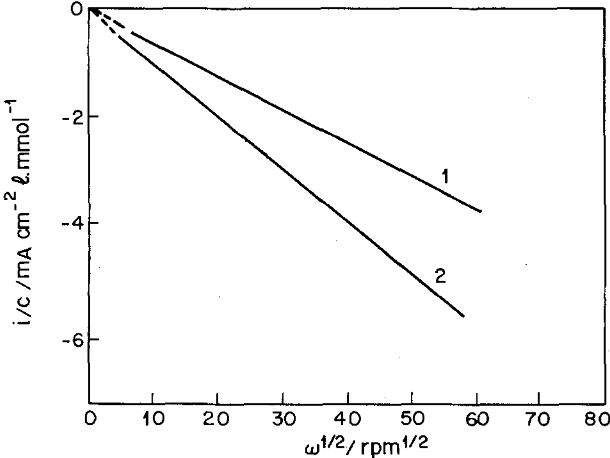

Fig. 10. Levich plots for gold rotating disk on limiting current steps of H_2SeO_3 reduction wave in 1M H_2SO_4. Curve 1, 4 mM H_2SeO_3, $E = -0.65V$ vs. SCE; Curve 2, 0.5 mM H_2SeO_3, $E = -0.5V$ vs. SCE; (see curves of Fig. 1 and 6).

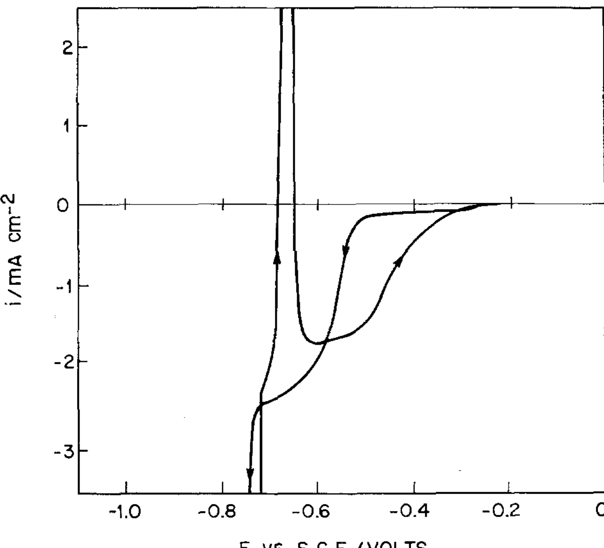

Fig. 11. Controlled potential sweep cycle at Au disk in 0.5 mM H_2SeO_3 + 0.1M $CdSO_4$ in 1M H_2SO_4. Conditions as for Fig. 1.

responding to the reoxidation of Cd, superimposed on the H_2SeO_3 reduction wave. The hysteresis observed in the region of −0.4V indicates that once sufficient CdSe has been deposited, the reduction of H_2SeO_3 can occur at less negative potentials.

These results thus illustrate the relatively high nucleation overpotential associated with the deposition of CdSe on a gold surface. A similar effect was also observed on a carbon electrode. Ti surfaces (5) have not been investigated here.

Using 0.1M $CdSO_4$ solutions in 1M H_2SO_4, containing H_2SeO_3 in concentrations ranging from 1 to 3 mM, CdSe films were deposited on both carbon and gold surfaces. This was accomplished by stepping the potential to −0.6V *vs.* SCE and plating for 1/2 hr or until the electrode passivated. Electrode passivation was quite rapid in solutions containing 2 mmoles per liter or higher H_2SeO_3, showing that selenium deposition is still relatively fast under these conditions. On illuminating the electrodes with white light, p-type behavior was observed, this also being indicative of excess Se present in the CdSe films.

Figure 12 shows a typical open-circuit photovoltage spectral response curve which was obtained for a CdSe electrode prepared by the above method. For this spectrum, "d-c" monochromatic incident radiation from a 100W quartz halogen (filament) lamp was used. The electrode was immersed in 1M H_2SO_4 and the open-circuit potential was measured *vs.* SCE. The main feature of such spectra is wavelength regions with net p- or n-type behavior. The photoresponse extends to about 720 nm, equivalent to the known approximately 1.7 eV bandgaps of either CdSe or Se. Presumably since the higher wavelength region is dominated by the direct gap, n-type CdSe, it represents the CdSe bandedge. We ascribe no further significance to the compensation point at 550 nm or to the shapes of these spectra other than the particular composition produced by a given electrodeposition run.

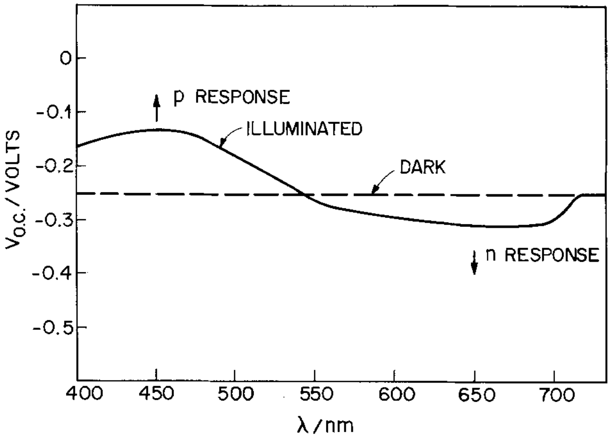

Fig. 12. Photovoltage spectral response curve for CdSe film electrode prepared by cathodic deposition. Open-circuit potential of CdSe measured *vs.* SCE in 1M H_2SO_4.

In solutions containing less than 2 mM H_2SeO_3, or for current densities below 5 mA cm^{-2}, electrode passivation was much slower by the above technique, and in some cases slight n-type behavior could be observed when illuminating the films with white light. The very low photovoltages with monochromatic light, however, were inadequate to obtain reliable photovoltage spectra.

A lower plating rate in dilute H_2SeO_3 solutions thus appears to minimize the level of excess selenium incorporated in the CdSe films prepared cathodically. However, the low photoresponse of these films, probably due to poor crystallinity, means that a final annealing process is still unavoidable if these electrodes are to be used as photoanodes in liquid junction solar cells. Finally, we note that a slower plating rate also resulted in improved adherence of the deposited films on the substrate. This is a major problem with the films prepared from more concentrated solutions.

Temperature Study of Oxide Film Growth at Platinum Anodes in H_2SO_4 Solutions

A. Damjanovic,* L.-S. R. Yeh,* and J. F. Wolf

Allied Chemical Corporation, Corporate Research Center, Morristown, New Jersey 07960

ABSTRACT

The growth of anodic oxide films at platinum in sulfuric acid solution was studied at different temperatures using galvanostatic transients. The activation energy and preexponential factor for the rate of growth were evaluated. In the plane in which the rate-determining step occurs the surface density of ions, or ion pairs participating in the growth process, is about 10^{15} cm^{-2}. This is close to the density of atoms in the surface of the metal. The analysis appears to support the process at the metal/oxide interface being the rate-determining step. However, the same value for N is compatible with the field-assisted place exchange process as the rate-determining step at the metal/oxide interface or within the oxide phase. Because the growth follows the same rate equation from the very early stages of oxide formation, the process at the metal/oxide interface seems to be the rate-determining step.

It has recently been reported that the kinetics of oxide growth at platinum anodes in acid solutions from about 1.0V *vs.* RHE to the potential at which O_2 evolution becomes the predominant reaction is represented by the equation (1, 2)

$$i_{og} = i_{og,o} \exp \frac{\alpha(V - V_o)}{d} \quad [1]$$

Apparently, the growth process follows (1-4) the well-known formalism of the Cabrera-Mott model (5) for the high field-assisted formation of "very-thin" oxide films. If the growth indeed proceeds according to this model, then the rate of growth given as the change of the average thickness of the oxide film, d, with time satisfies the equation [cf. Ref. (5, 6)]

$$\frac{d(d)}{dt} = ri_{og} = 2N\nu\lambda\omega \exp\left[\frac{-W}{kT}\right] \exp\left[\frac{ze\lambda\Delta V_{of}}{kTd}\right] \quad [2]$$

In this equation ze is the charge and λ is the half-jump length of the migrating ions, ν is their mean vibration frequency, W is the activation energy, and ω is the area of the oxide layer per single metal ion in the oxide phase. Factor r ($= 9 \times 10^3$ Åcm^2/C) converts experimentally determined charge density q (in C cm^{-2}) into thickness in angstroms (1), *i.e.*, $d = rq$. ΔV_{of} ($= V - V_o$) is the potential difference across the oxide film. N is the surface density of the ions participating in the growth process for the plane in which the rate-determining step occurs (5, 6).

In the original Cabrera-Mott theory, it was assumed that only cations migrate in the process of growth. Further, it was assumed that a process at the metal/solution interface in the very early stage of growth, or a process at the metal/oxide film interface in subsequent stages of growth, is the rate-determining step. With this assumption, N should closely be equal to the surface density of atoms in the metal itself, *i.e.*, about 1.5×10^{15} cm^{-2}. This may be contrasted with the migration of interstitial cations within the oxide phase being the rate-determining step [the Verwey model (7)]. In this case N should be equal to the surface density of interstitial cations in the reaction plane, *i.e.*, should be much less than 1.5×10^{15} cm^{-2}.

Parameter α was found to be 160 ÅV^{-1}. This value checks favorably with the theoretically predicted value for $\alpha = ze\lambda/kT$ when $z\lambda = 4$Å (1). It implies that $z = 2$ and $\lambda = 2$Å and that Pt^{++} ions are the migrating species in the oxide phase. The phase itself was identified by ellipsometry as $Pt(OH)_2$ (8, 9). The agreement evidently provided support, if not confirmation, for the proposed model of growth. It was further suggested (1) that the process at the metal/oxide film interface was the rate-determining step. This is because the rate equation describes the growth from the very early stages when the film is perhaps only one atomic layer thick [cf. Ref. (10)]. The exchange current density, $i_{og,o}$ ($= 1.8 \times 10^{-10}$ Acm^{-2}), was found (11) to be independent of pH, as expected for the model (cf. Eq. [1] and [2]).

Though much has been learned in recent years about oxide growth at Pt anodes [cf. Ref. (1-4, 8-15)], the question concerning the over-all path and rate-determining step remains open. For instance, is the process at the metal/oxide film interface or the process within the oxide phase the rate-determining step? Could the process at the oxide/solution be the rate-determining step? The latter process has not been considered to be rate determining. An analysis of the exchange current density

$$i_{og,o} = 2N\nu\lambda\omega r^{-1} \exp\left[\frac{-W}{kT}\right] = i_o \exp\left[\frac{-W}{kT}\right] \quad [3]$$

can provide information concerning the rate-determining step if i_o is known so that the product $N\nu$, and hence N, can be evaluated. For, if the process of ion migration in interstitial positions within the oxide phase is the rate-determining step, N is expected to be a few orders of magnitude less than N for the process of ion formation at the metal/oxide film interface. Here, we report kinetic data on anodic oxide growth at Pt anodes in 2N H_2SO_4 solution at different temperatures and correlate the factor N to the rate-determining step.

Experimental

An all-glass cell was used in this work. The working and reference electrode compartments of the cell were jacketed so that the solutions in both compartments could be maintained at a given temperature by circulating a thermostated liquid through the jackets around both compartments. The working platinum wire electrode was "sealed" in a soft glass tube. The stated purity of platinum was better than 99.99%. The roughness factor ($R = 1.7$) was determined from capacitance measurements in the polarizable region and used to correct all data reported here. To ensure uniform field distribution at the working electrode, three Pt gauze counterelectrodes were symmetrically placed around the working electrode at a distance of about 1

* Electrochemical Society Active Member.

Key words: metals, electrode, kinetics.

cm. The solution in the working electrode compartment was saturated with high purity grade O_2. A hydrogen electrode in the same solution and temperature was used as the reference electrode.

The constant current charging technique was used in this study. Details of the experimental procedures and instrumentation were the same as previously described (1, 2, 11).

Results and Discussion

When a constant current is applied to a prereduced electrode initially at the rest potential, the potential after an initial sharp and nonlinear rise increases linearly with time, or charge density q, until a point is reached when O_2 starts evolving (1, 11). As previously shown, in the linear region the charge is used almost entirely for oxide film formation (1, 11). From the experiments at room temperature, these linear V-q traces at different constant current densities are shown to follow Eq. [1].

In Fig. 1, V-q traces are shown for 1.5×10^{-5}, 1.5×10^{-4}, 1.5×10^{-3}, and 1.5×10^{-2} Acm^{-2} in $2N$ H_2SO_4 solution at 50°C. As expected, the general forms of these traces are similar to the charging curves at room temperature [cf. Fig. 1 and 2 in Ref. (11)]. However, for the same current density, dV/dq slopes of the V-q traces at 50°C are significantly lower than the slopes at room temperature. In Fig. 2, the dV/dq slopes are plotted against the logarithm of the applied current density at 0°, 23°, 50°, 65°, and 75°C. Slopes of these dV/dq *vs.* $\log i$ traces increase as temperature increases. This is shown in Fig. 3. Before proceeding with the

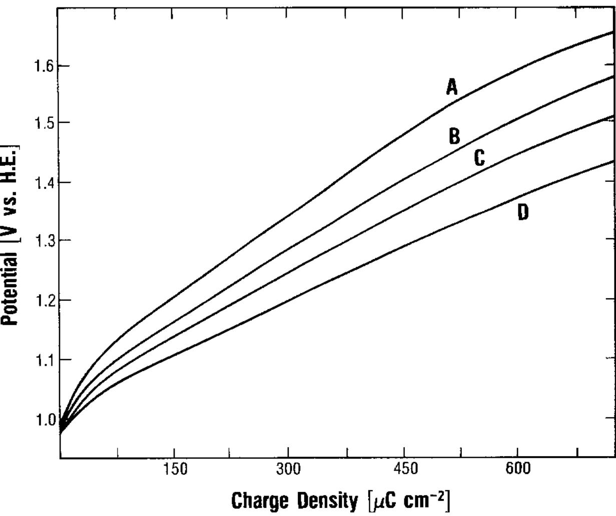

Fig. 1. V-q transients at: A, 1.5×10^{-2}; B, 1.5×10^{-3}; C, 1.5×10^{-4}; and D, 1.5×10^{-5} Acm^{-2} at 50°C.

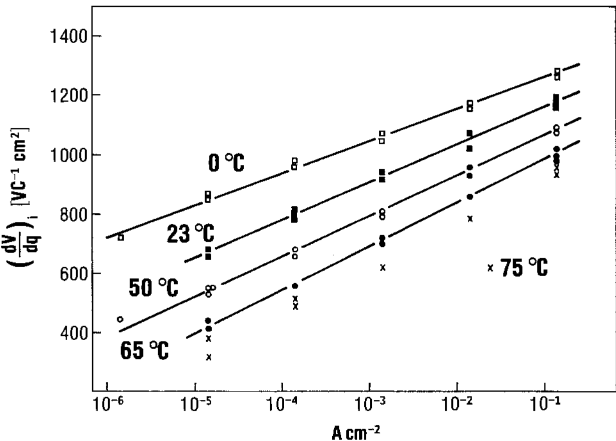

Fig. 2. dV/dq dependence on log i for 0°, 23°, 50°, 65°, and 75°C.

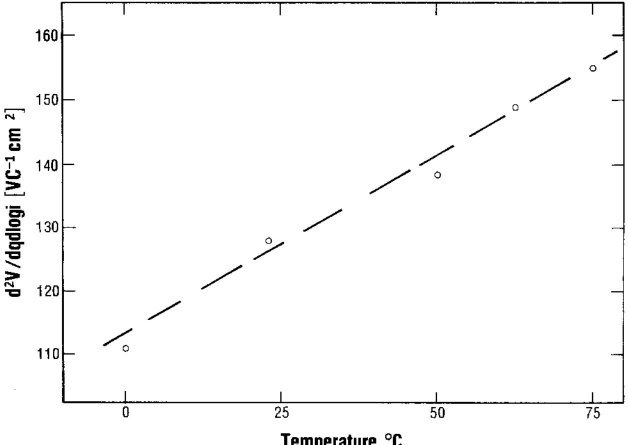

Fig. 3. Slopes of the dV/dq vs. log i traces as function of temperature.

analysis of data in Fig. 2 and 3, it is helpful to examine Eq. [2]. From this equation by differentiation one obtains

$$\left[\frac{dV}{d(d)}\right]_{i,T} = \frac{kT}{ze\lambda}\ln\frac{i_{og}}{i_o} + \frac{W}{ze\lambda} + \frac{d}{ze\lambda}\frac{dW}{d(d)} \quad [4]$$

As previously shown (1, 15) and confirmed in this work, for a constant temperature and a given i_{og}, $dV/d(d)$ is constant and independent of d. It follows that $W \neq f(d)$ and the last term in Eq. [4] can be dropped. Other parameters in the equation do not depend on d either. Since $d = rq$, the observed linear dependence of dV/dq on $\log i_{og}$ for over five decades of current densities (cf. Fig. 2) is accounted for by the model of "thin oxide film growth." The linear increase of the slopes of dV/dq *vs.* $\log i_{og}$, *i.e.*, of $d^2V/dqd \ln i_{og}$, with temperature is also in accordance with the model (cf. Eq. [4]). From such a slope at room temperature, the $z\lambda$ product was previously calculated and z $(= 2)$ and λ $(= 2Å)$ analyzed (1, 11). It follows from Fig. 2 and 3 that z and λ are independent of temperature as expected for the model. (In this narrow temperature range the change in the unit cell dimensions, and hence in λ, is insignificant.)

Parameter i_o, and hence N, can readily be obtained from Eq. [4] using the relationship

$$\left(\frac{\Delta \frac{dV}{dq}}{\Delta T}\right)_i = \frac{kr}{ze\lambda}\ln\frac{i}{i_o} \quad [5]$$

For $i = 1$ Acm^{-2}, this relationship simplifies to

$$\left(\frac{\Delta \frac{dV}{dq}}{\Delta T}\right)_{1\ Acm^{-2}} = \frac{-kr}{ze\lambda}\ln i_o \quad [6]$$

with i_o given in Acm^{-2}.

In these equations it is taken that $W \neq f(T)$. This is certainly true for a narrow range of temperature as in the present experiments.

Now, returning to the experimental data of Fig. 2, the separation of the dV/dq *vs.* $\log i$ lines at 1 Acm^{-2} for the temperature difference of 75°C is -280 VC^{-1} cm^2. This is shown in Fig. 4 in which dV/dq extrapolated to 1 Acm^{-2} are plotted *vs.* temperature. If follows from Eq. [6] that i_o is 6×10^8 Acm^{-2}. It should be noted that i_o is not the exchange current density but the preexponential term in the exchange current density $i_{og,o}$ (cf. Eq. [3]). In this calculation, the factor r $(= 9 \times 10^3$ $Åcm^2/C^{-1})$ is used to convert coulombs/square centimeter into thickness in angstroms. An error in r, however, does not affect this numerical evaluation of i_o since the product $z\lambda$, used for this evaluation, was determined using the same factor and any error that

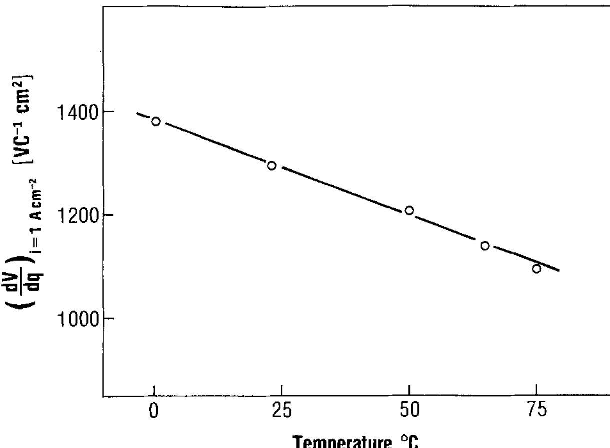

Fig. 4. The values of dV/dq extrapolated to $i = 1$ Acm^{-2} at different temperatures.

might be introduced with r cancels out. With $i_o = 6 \times 10^8$ Acm^{-2}, the $N\nu$ product can be calculated from

$$N = \frac{i_o r}{2\nu\lambda\omega} \qquad [7]$$

if ω is known. From the definitions of various parameters it follows that $2\lambda\omega$ is the volume of the oxide film per single migrating cation (of charge z). Consequently, the product $2\lambda\omega r^{-1}$ is the number of coulombs per single cation. This, however, is nothing else but ze, so that N in Eq. [7] is given by

$$N = \frac{i_o}{ze\nu} = \frac{6 \times 10^{23} i_o}{zF\nu} \qquad [8]$$

With $z = 2$, $N\nu = 1.9 \times 10^{27} \sim 2 \times 10^{27}$ cm^{-2} sec^{-1}. Now, with $\nu = 3k\Theta/(4h)$, where Θ, k, and h are Debye temperature [$= 225$°K for Pt (16)], Boltzmann's constant, and Planck's constant, respectively, the mean vibrational frequency is calculated as $\nu = 3.5 \times 10^{12}$ sec^{-1}. With $\nu = 10^{12}$ sec^{-1}, as usually taken, the surface density of sites, N, that are active in the rate-determining reaction plane is 2×10^{15} cm^{-2}. Even if $\nu = 3.5 \times 10^{12}$ sec^{-1}, N is surprisingly close to the density of atom sites in the surface of the metal ($\sim 1.5 \times 10^{15}$ cm^{-2}). This close agreement appears to provide strong evidence for the ion formation at the metal/oxide interface as the rate-determining step in the over-all reaction path.

Finally, the activation energy can be determined from i_o and the exchange current density, $i_{og,o}$, according to Eq. [3]. An easy way to obtain $i_{og,o}$ is to read from Fig. 2 the value of dV/dq as $i = 1$ Acm^{-2} and a given temperature and apply this value to

$$\left(\frac{dV}{dq}\right)_{T,i=1\ \text{Acm}^{-2}} = \frac{-rkT}{ze\lambda} \ln i_{og,o} \qquad [9]$$

This relationship follows directly from Eq. [4]. Again, $i_{og,o}$ is not affected by the conversion factor r. The exchange current density at 23°C is 2×10^{-10} Acm^{-2}. This value compares well with that previously reported (1) for room temperature (1.8×10^{-10} Acm^{-2}). The exchange current density increases with temperature as expected from Eq. [3]. With $i_{og,o}$ for a given temperature and with i_o as determined above, the activation energy is 1.08 eV or close to 25 kcal-mole. This value, though on a high side, compares well with the activation energies reported for growths of oxide films at valve metals and Al.

The present study, therefore, confirms the view that the oxide films at platinum anodes grow according to the simple model of high field-assisted formation of metal ions at the metal/oxide interface and their migration in the field from one presumable interstitial position to another. Further, it appears that the rate-determining step is the process at the metal/oxide film interface.

A conclusion regarding the rate-determining step that is based on the numerical value of N may, however, be subject to an uncertainty due to a possible amorphous character of the oxide film. In an amorphous oxide all sites could be regarded as "interstitial" and active in the process of growth. In this case N cannot differentiate between the two rate-determining steps. Electron diffraction indicates (17), however, that, even in these very thin oxide films, there is a degree of ordering and perhaps the uncertainty is limited.

The process of growth may, however, be more complex than it is pictured by the simple model discussed above. First of all, anions too may participate in the growth process as in the case of Ta (18). There is no way to distinguish with the present experimental data between the anionic and cationic transport in the platinum oxide films. With OH^- as the charge transporting anions, and with $z\lambda = 4$Å, the half-jump distance would become too large, *i.e.*, 4Å. This calculation, however, only indicates, but it does not prove, that OH^- is not the charge-carrying species. It is in general possible that both anions and cations participate in the charge transport. However, if these two processes are independent of each other, it is unlikely that their rates will be comparable. This is because the activation energies for these two so widely different ions are expected to be different. If indeed both anions and cations independently participate in the charge transport with comparable rates, it is unlikely that a linear dV/dq *vs.* log i dependence would be observed for five decades of current density, as in the present study. This is because the slope of this dependence would in this case vary with the field and hence with applied current density.

The place-exchange mechanism is another process for oxide growth that is, however, usually reserved for the direct logarithmic growth. This process too may be field assisted and, if it is nonsimultaneous [cf. Ref. (19)], it could easily account for the observed kinetics. In this mechanism, both anions and cations participate with equal or comparable rates in the charge transport. In Fig. 5, simultaneous rotation of one Pt^{++} and two OH^- ions illustrates in a simple way such a place-exchange process. For the place-exchange mechanism, N will be the same both for the process at the interface(s) and for the process within the oxide phase as rate-determining steps. Therefore, if one accepts the place-exchange mechanism as a possible process, the value of

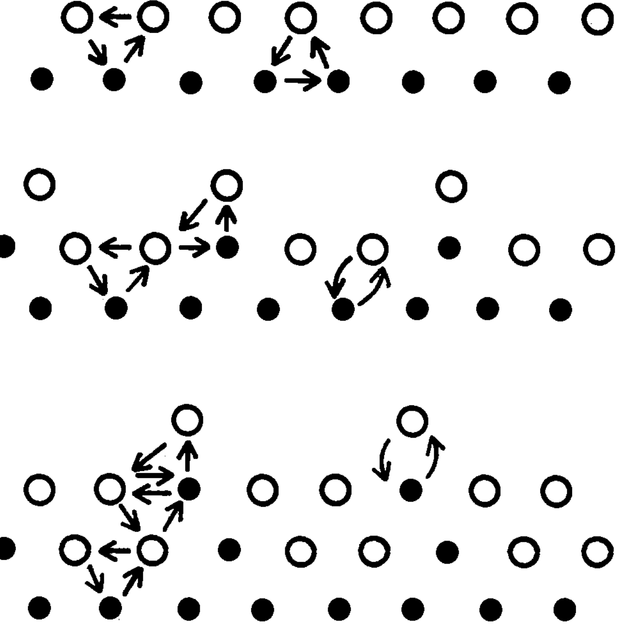

Fig. 5. Representations of the field assisted place-exchange process. Open circles, OH^-; full circles, M^{++}.

N alone cannot serve as a criterion for the choice of the rate-determining step. Then, only the fact that the observed kinetics is described by Eq. [2] from the earliest stages of growth supports the process at the metal/oxide interface as the rate-determining step. Further studies, not necessarily electrochemical ones, are still needed to elucidate the over-all mechanism and rate-determining step. It should be noted that the initial growth is followed by an extended growth which is known (14) to proceed according to the direct logarithmic growth law (*i.e.*, $i = i_0 \exp(\alpha V - \delta d)$. The transition from the initial stages of growth, which proceeds according to Eq. [1], to the extended growth is not clear, and an analysis of the transition itself may help in elucidating the growth processes in both regions of growth. We shall discuss these problems in subsequent papers.

Technical Notes

Mixed Electrolyte Solutions of Propylene Carbonate and Dimethoxyethane for High Energy Density Batteries

Y. Matsuda* and H. Satake

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube, Yamaguchi, Japan

Interest in high energy batteries has increased in recent years and some kinds of Li batteries with organic electrolytes have been developed (1-10). During the course of the investigations in this field, some workers reported on the mixing effect of the organic electrolytes (11-14). One of the authors (15) has reported on the improvement of anodic performance of Mg in mixed PC and 1,2-dimethoxyethane (DME) system, and in formamide and tetrahydrofuran (THF) system, and the mixing effect of solvents on cathodic performance of some metal sulfides (16). Recently, Koch and co-workers (17) have reported on THF-based electrolytes for secondary Li electrodes, and Ikeda and co-workers (4) have adopted PC-DME electrolytes in the Li/MnO_2 batteries. However, the reason for the synergistic effect of mixed organic electrolytes has not been clarified in these investigations. In this study, the effects of mixing the organic solvents, PC-DME, containing some perchlorates were investigated in connection with the electric conductance, dielectric constant, and viscosity.

* Electrochemical Society Active Member.

Key words: mixed organic electrolyte solution, propylene carbonate—1,2-dimethoxyethane system, electric conductance of organic electrolyte solution.

Experimental

PC and DME were purified by the methods described in previous papers (15, 18). The water content was measured, using Karl Fisher reagent, and it was below 80 ppm in PC and 50 ppm in DME. Lithium perchlorate was an extra pure reagent by Kanto Kagaku Company Limited, and the other perchlorates were the same grade reagents by Wako Pure Chemical Industries, Limited. They were used after drying under reduced pressure at 160°-170°C for 24 hr. The dielectric constant of solvents was measured with a bridge method using 1 kHz a.c., and viscosity was measured with a modified Ostwald viscometer. The electric conductance of the electrolytes was measured with an impedance bridge using 1 kHz a.c.

Results and Discussion

The viscosities of PC-DME with and without 1M $NaClO_4$ as a function of the composition of the solvents are shown in Fig. 1. The viscosity of the mixed solvent increased with addition of PC into DME and the experimental value was lower than that expected according to the assumption that the theory of the ideal solution would be applied on the viscosities of the mixed solvents.

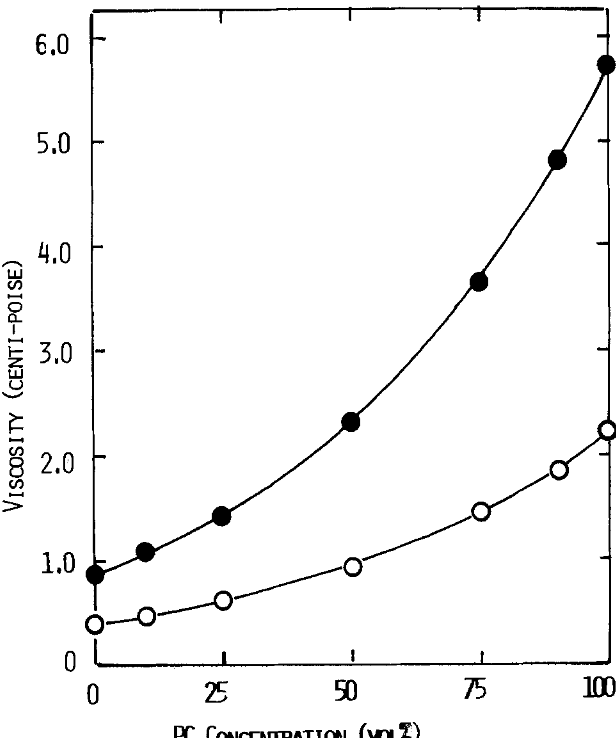

Fig. 1. Correlations between the composition of PC-DME system and the viscosity. ○: solvent only, ●: the solution containing 1M $NaClO_4$ 30°C.

The dielectric constants of the mixed solvents were then measured, and the results are shown in Fig. 2. The values increased by adding PC into DME. The measured values were almost linear, but a small deviation was observed between the experimental values and those expected from the additive properties of each component. Also, the densities of PC-DME system were measured, and these increased linearly with addition of PC into DME though the increase was small.

In Fig. 3, the equivalent conductance of PC-DME containing 1M $NaClO_4$ is shown as a function of the mixed ratio. The conductance of the mixed electrolytes was higher than that of each single solvent with $NaClO_4$ and the maximum value of the equivalent conductance was obtained at the mixing ratio of about one to one. The very significant factors affecting the conductance of ionic solutions would be the dielectric constant and the viscosity in connection with the solvation of the ions and the solvent-solvent interaction. The increase of equivalent conductance of the solution due to addition of DME into PC in Fig. 3 is probably caused by low viscosities of DME. However, the conductance decreased again in DME-rich solutions. This phenomenon might be caused by some variation of solvation of the cation and the anion, and the Stokes' radii, and these would be concerned with the specific solvation (19-21) and the low ionization of the solute due to the decrease of the dielectric constants of the solvents (22-24).

The equivalent conductances (Λ) of $NaClO_4$ in PC, DME, and these 1:1 mixture are shown in Fig. 4 as a function of the solute concentration. In the case of the PC and PC-DME (1:1), the relation between Λ and concentration of $NaClO_4$ was found to be almost linear in the region of diluted concentration though the mechanism of the conductance has not been clarified. The equivalent conductance of the mixed organic electrolyte (PC-DME, 1:1) was higher than that of each single system (PC or DME). Among those, the behavior of the DME system was entirely different from that of the others. But a similar phenomenon has been observed in THF containing $NaClO_4$ (25).

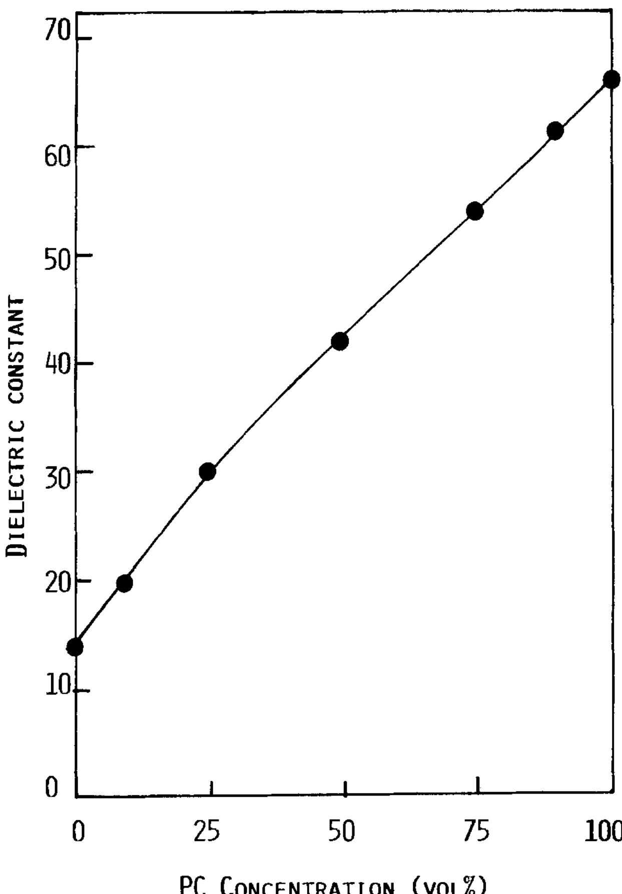

Fig. 2. Correlation between the composition of PC-DME and the dielectric constant, 20°C.

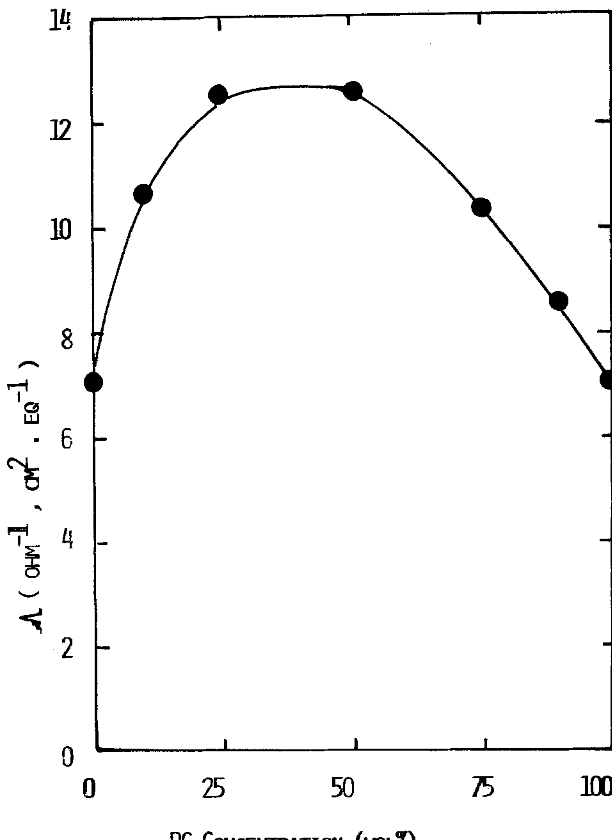

Fig. 3. Correlation between the composition of PC-DME containing 1M $NaClO_4$ and the equivalent conductance of $NaClO_4$, 30°C.

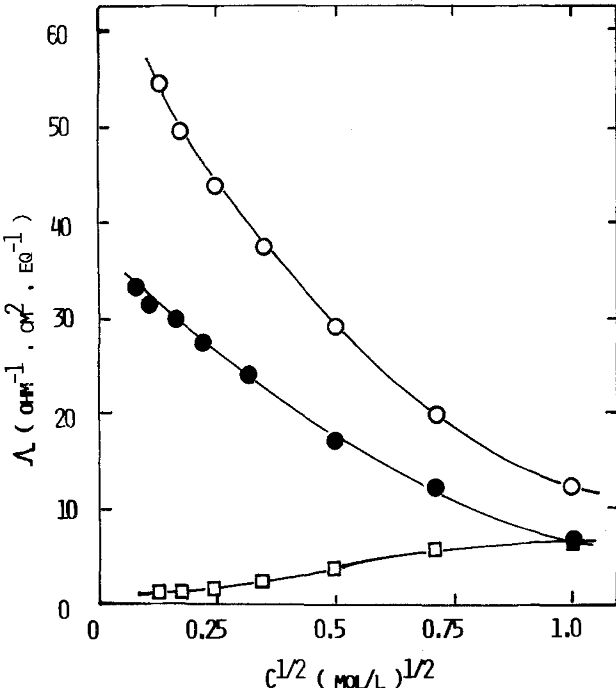

Fig. 4. Correlations between concentration of $NaClO_4$ and the equivalent conductances of $NaClO_4$ in PC, DME, and PC-DME (1:1). ●: in PC, ○: in PC-DME (1:1), □: in DME, 30°C.

Cathodic Deposition of a Trivalent Chromium Film as a Bonding Interface Between Copper and Polyethylene

F. Simchock, K. Ramachandran, R. Haynes,* and F. J. Jannett

Western Electric Company, The Engineering Research Center, Princeton, New Jersey 08540

Many studies are available concerning the use of various surface treatments of copper for bonding to various dielectrics (1). Most of these studies are performed on simple geometries and may not be comparable directly to the present system. Few studies (2) have been done on the specific application to millimeter waveguide systems such as that recently investigated for the Bell System's (3) WT4.

The purpose of this study was to test the durability of copper oxide and chromate as bonding interface between copper and polyethylene in copper plated steel tubes, 51 and 60 mm ID, to be used for dielectric lined millimeter waveguides.

* Electrochemical Society Active Member.

Key words: films, interfaces, bonding.

Experimental Procedure

Steel tubes, 51 and 60 mm ID, were copper plated from a copper cyanide solution at 20 A/ft^2 to a thickness of 12 μm. Copper was either oxidized or chromated depending on the bonding interface to be bonded. Copper was oxidized electrochemically from a 2N NaOH solution saturated with copper oxides at 160°F at 3.5, 7.1, and 13.6 mA/cm^2 to obtain oxide thicknesses of 4000, 10,000, and 14,000Å. Ratios of cuprous to cupric oxides were determined by chronopotentiometric technique from 0.2N NH_4Cl at 1 mA/cm^2. Cuprous oxide was maintained in the range of 20 to 40% of the total oxide thickness. Chromate was deposited on copper by cathodic polarization at 25°C from 3% aqueous solution of sodium citrate, chromate, and carbonate. The thick-

ness of the chromium-containing film is approximately 1.0 μg/cm². ESCA studies (4) indicate the film is not a simple uniform monolayer structure. Low density polyethylene was hot melt bonded to either the oxidized or chromated copper interface. A tubular film of electrical grade low density polyethylene (such as Union Carbide—DFDA 0166), 150 μm thick was sealed at one end. A pressurizing cap was applied at the other end and the liner inflated with nitrogen. The exterior surface (bonding surface) of such an inflated liner was cleaned by wiping with Freon TF solvent and dried. The liner was then inserted into the pipe and end caps applied at both ends. Interior of the liner and the interface was next evacuated. The liner was then inflated with oxygen-free nitrogen at a pressure of 1200 mm Hg to press against the treated copper surface. Such an assembly was next heated to bonding temperatures by passing through an induction coil. The pipe was allowed to cool down slowly. A typical heating cycle is shown in Fig. 1. It is to be noted here that temperatures referred to in the following sections are the peak temperatures attained at copper surface in such a heating cycle. When the pipe has cooled down to room perature, sections were cut off for testing. To prepare samples for 180° peel tests, a second layer of polyethylene (150 μm thick) was bonded at a temperature of 135°C with induction heating and allowed to cool under ambient conditions.

Peel lips for fitting into the Instron jaws were obtained by two techniques: (*i*) Dipping one end of a section in HCl, a small length (approximately 2.5 cm) was delaminated; or (*ii*) A ring was cut from the pipe. The interior of the ring was machined off of all polyethylene to expose steel to a length of about 2.5 cm from one end. 180° peel tests were done at room temperature on an Instron machine with a jaw separation rate of 50.8 mm/min.

Results

The results of this study are shown in Table I and Fig. 1-3. Table I shows results after sections were left in a humid environment of 35°C and 90% RH. As seen, thinner oxides show a decrease of about 40% in peel strengths while thicker oxides show no appreciable change.

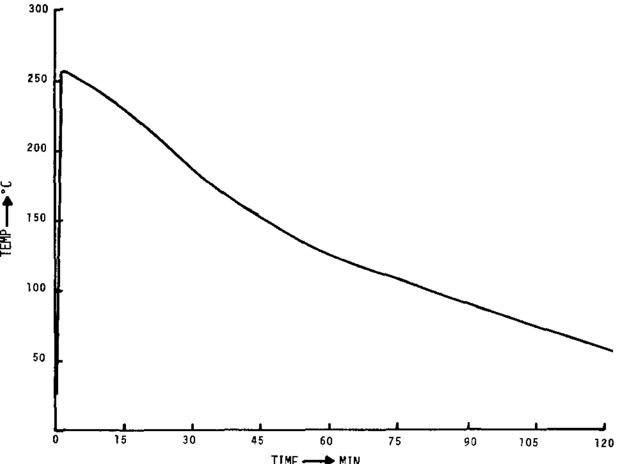

Fig. 1. Temperature rise and cool down of test sections

With cathodic chromate as an interface, a sharp rise in bond strength was observed when inductively heated to temperatures above 265°C. As seen from Fig. 3, at a temperature of about 300°C, a 150 μm thick polyethylene can be bonded to the surface such that failures occur through the thickness of polyethylene when peeled.

Section of chromated samples were tested for 180° peel-creep under humid conditions of 35°C and 90% RH by applying a constant load of 400 g/cm for 24 hr. When bonded at 300°C, no peeling was observed.

Scanning electron micrographs of oxidized and monolayer surfaces of copper show chromated copper yields a smooth interface.

Conclusion

It has been shown that cathodic chromate can be used as a bonding interface between polyethylene and copper. Such an interface is smooth and yields bonds of

Table I. Effect of humidity on oxidized samples

THICKNESS		OXIDE COMPOSITION		PRESSURE	PEAK TEMP.	180° PEEL STRENGTH	
LINER	OXIDE	CUPROUS	CUPRIC			INITIAL	AFTER 24hrs @35°C&90%RH

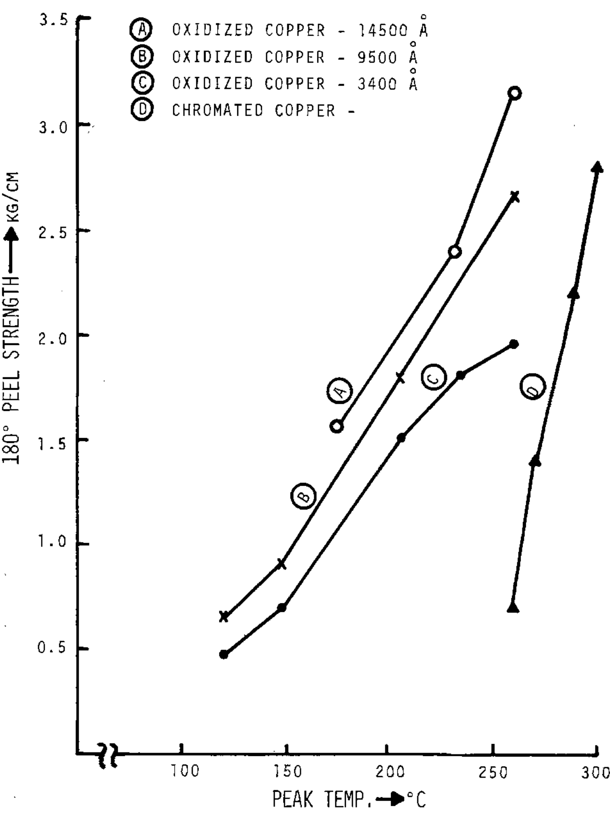

Fig. 3. 180°C peel strengths of polyethylene oxidized copper vs. chromated copper: a comparison of bonding temperatures.

quality comparable to those obtained with thicker oxides in the range 10,000-14,000Å. Hence, when smoothness and electrical characteristics of interface are considered crucial, cathodic chromate may be investigated as an alternate. Both these interfacial processes were scaled up to pilet plant capability. High frequency loss measurements were made (in the millimeter waveguide range) on both systems. The chromate interface was chosen because of less electrical loss and approximately 13 miles of waveguide tubes were processed (3).

Manuscript submitted June 8, 1979; revised manuscript received Oct. 11, 1979. This was Paper 367 presented at the Atlanta, Georgia, Meeting of the Society, Oct. 9-14, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Electrochemistry in Hexamethylphosphorotriamide (HMPA)

I. The H_2(g,Pt)|HCl(HMPA)|TlCl(s)|Tl(Hg) Cell

Carlos H. Contreras-Ortega[1] and Peter A. Rock*

Department of Chemistry, University of California, Davis, California 95616

We have investigated the cell

$$H_2(g,Pt)|HCl(HMPA)|TlCl(s)|Tl(Hg) \quad [1]$$

where HMPA is the solvent hexamethylphosphorotriamide $[(CH_3)_2N]_3PO$, as part of an electrochemical study of the thermodynamics of hydrogen-isotope-exchange reactions (1). At the outset of this work HMPA looked promising as an aprotic solvent for use in electrochemical cells. HMPA has a wide liquid range (7° to 235°C at 1 atm), the vapor pressure at 25°C is less than 0.1 Torr, and the dielectric constant of 30 is high enough to permit the dissolution of electrolytes. However, HMPA is difficult to prepare in a high purity anhydrous state, and as was found in this study, HMPA slowly decomposes in the presence of HCl. However we were able to obtain an estimate of the standard potential for cell [1] by extrapolating the measured cell voltage to zero time. The value of $\mathcal{E}^o$ obtained is compared with $\mathcal{E}^o$ values for cells of the type [1] involving other solvents.

Because of the need to exclude oxygen and water from the cell, the entire cell was set up and studied as an automatically controlled closed system on the vac-

Key words: hexamethylphosphorotriamide, HMPA, hydrogen electrode, thallium electrode.

uum line. The details of the cell construction, hydrogen and Tl(Hg)|TlCl(s) electrode preparations, HCl(g) and HCl (solution) preparation, and the measurement system have already been described (2, 3). The HMPA (Dow Chemical Company, Dorcol, Practical Grade) used was purified by the method of Gal and Yvernault (4) which involves three successive vacuum distillations; the first over a Na mirror, the second over $CaH_2(s)$, followed by storage for 48 hr over molecular sieves in a helium atmosphere, and the third vacuum distillation utilizes a 50 cm adiabatic column with a larger inner surface (head temperature 60°-80°C, pressures less than 1 Torr). The final collected middle fraction (about one third of the initial volume) was stored under vacuum in a black container. Tests for primary and secondary amines were negative.

The molalities of the HCl(HMPA) cell solutions were determined by potentiometric titration of weighted samples obtained from the solution preparation flask on the vacuum line. The analyses were carried out on the solutions immediately after preparation. The HCl(HMPA) sample was added to 10 ml of 0.1M $NaClO_4$(aq) diluted to 50 ml and then titrated with carbonate-free NaOH(aq) (Beckman E-2 glass electrode *vs.* a saturated calomel). The end point was not affected by addition of pure HMPA to the solution.

The results of our measurements on cells of the type [1] are given in Table I. The emf, pressure, and temperature readings were taken at 1 hr intervals over approximately an 80 hr period for each cell. The observed emf values increased in an approximately linear manner over the life of the cell at a rate of less than 0.3 mV/hr. The rate of increase was roughly proportional to the concentration of HCl in the cell solution. The concentration of HCl in the cell solution as determined potentiometrically also decreased linearly with time. After about 80 hr the cell solutions were noticeably brownish yellow. The emf values reported in Table I were obtained from least squares zero-time intercept of an emf *vs.* time plot, where time zero was defined as the time that the cell solutions were prepared.

Other electrochemical studies (conductivity and potentiometry) involving HCl(HMPA) solutions (4, 6, 7) had not reported the decomposition of HCl(HMPA) solutions with time possibly because the time required for the experiments was much less than in the present study. The decomposition of the HCl(HMPA) solutions with time is also evidenced in the potentiometric titration curves. Fresh HCl(HMPA) + H_2O solutions yield [on titration with NaOH(aq)] a titration curve with a single inflection point, whereas older solutions yield titration curves with two inflection points. The appearance of a second inflection point occurs more rapidly if the HCl(HMPA) solution is heated. The second inflection point is presumably due to the production of $(CH_3)_2NP(O)(OH)_2$ (6).

Table I. Results of measurements on the cell $H_2(g,Pt)|HCl(m,HMPA)|TlCl(s)|Tl(Hg,X_{Tl} = 0.0376)$ ($T = 297° \pm 1°K$)

M_{HCl} (mole · kg^{-1})	P_{H_2} (Torr)	$\mathcal{E}$ (expt)* (mV)	$\mathcal{E}°$ (calc) (mV)
0.0276	736	−383	−546
0.00828	731	−369	−563
0.00610	724	−360	−561
0.00111	727	−305	−549
0.0320	723	−396	−554
0.0131	725	−363	−544
0.00659	724	−353	−552
0.00546	732	−337	−542

* The last four cells in this table were run with 99.5% D_2, 99.9% DCl(HMPA) rather than with H_2 and HCl(HMPA). The reported emf values for the deuterium cells were converted to hydrogen cells by subtracting 8 mV from the measured emf values (5). Because of the instability of the HCl(HMPA) solution the values of $\mathcal{E}$ (expt) are uncertain by about ±5 mV (see text).

The postulated cell reaction for [1] is

$$H_2(g) + 2TlCl(s) = 2Tl(Hg) + 2HCl(HMPA) \quad [2]$$

Application of the Nernst equation to this reaction yields ($\omega = RT/\mathbf{F}$)

$$\mathcal{E} = \mathcal{E}° - \frac{\omega}{2} \ln \left\{ \frac{a^2_{Tl(Hg)} a^2_{HCl(HMPA)}}{a_{H_2(g)} a^2_{TlCl(s)}} \right\} \quad [3]$$

If we take $a_{H_2(g)} = (P_{H_2}/760,)$ $a_{Tl(Hg)} = X_{Tl}\gamma_{Tl}$, $a_{TlCl(s)} = 1$, and $a_{HCl} \approx m_{HCl}$ [HCl in HMPA has been shown by conductance measurements (6) to be a weak electrolyte], then

$$\mathcal{E}° = \mathcal{E} + \omega \ln X_{Tl}\gamma_{Tl} + \omega \ln m_{HCl} - (\omega/2) \ln (P_{H_2}/760) \quad [4]$$

The thallium amalgam used had $X_{Tl} = 0.0376$ for which $\ln \gamma_{Tl} = 0.456$ (8, 3). Application of Eq. [4] to the data in the first three columns in Table I ($\omega = 25.56$) yields the values of $\mathcal{E}°$(calc) given in the last column of Table I. The average of these values is $\mathcal{E}°_m = -551 \pm 6$ mV which is standard potential (on the molality scale) at 297°K for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2HCl(HMPA) \quad [5]$$

The value of the standard potential on the mole fraction scale [$\mathcal{E}°_x = \mathcal{E}°_m - \omega \ln (1000/179.2)$] is $\mathcal{E}°_x = -594 \pm 6$ mV. Based on our previously reported cell data (2, 3) the value of $\mathcal{E}°_x$ at 297°K for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2HCl(DMF) \quad [6]$$

(where DMF represents N,N-dimethylformamide) is -744 ± 3 mV (undissociated HCl, mole fraction composition scale), whereas for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2HCl(\text{n-hexanol}) \quad [7]$$

$\mathcal{E}°_x = -809 \pm 2$ mV (undissociated HCl, mole fraction composition scale).

The data for the three solvents DMF, HMPA, and n-hexanol can be combined to calculate the Gibbs energy of transfer of HCl (undissociated, mole fraction scale)

HCl(DMF) = HCl(HMPA) $\Delta G° = -14.4$ kJ

HCl(n-hexanol) = HCl(HMPA) $\Delta G° = -20.7$ kJ

The dipole moments for the three solvents are HMPA (5.37), DMF (3.82), and n-hexanol (1.60), whereas the dipole moment of HCl is 1.03. The negative $\Delta G°$ values for the solute transfer reactions reflect the stronger dipole-dipole interaction between HCl and the HMPA solvent dipoles than that between HCl and the DMF or n-hexanol solvent dipoles. In the mean-spherical model of solutions for which dipolar interactions are dominant (9), the Gibbs energy of transfer is approximately equal to $-k(\hat{\mu}_2^2 - \hat{\mu}_1^2)$ where $2\,\hat{\mu}_i^2 = \mu^2_{\text{solvent}_i} + \mu^2_{\text{solute}}$ (10) and k is a constant characteristic of the solute. The above data yield a value of k for HCl of 1.7 ± 0.1 kJ/Debye^2.

Errata

In the paper "Atmospheric Corrosion of Cobalt" by D. W. Rice, P. B. P. Phipps, and R. Tremoureux that appeared on pp. 1459-1466 in the September 1979 JOURNAL, Vol. 126, No. 9, the concentration legend in the upper middle of Figure 9 on page 1463 should read:

× 1415 $\mu g/m^3$
● 810 $\mu g/m^3$
▲ 136 $\mu g/m^3$
■ 0 $\mu g/m^3$

Also, the first row of data, fourth column of Table IV should read 0.32 not 0.82.

Editor's Note: It is of interest to note that this was called to our attention by Ulick R. Evans who is well known to all who have worked in the field of Corrosion.

In the paper "A Finite Difference Numerical Analysis of Galvanic Corrosion for Semi-Infinite Linear Coplanar Electrodes" by P. Doig and P. E. J. Flewitt which appeared on pp. 2057-2063 in the December 1979 JOURNAL, Vol. 126, No. 12, in the Discussion Section on page 2063, the last sentence of the first paragraph should read: "Clearly, for fixed values of i_o and C, the earlier approximation of unidirectional current flow becomes more accurate as the value of this parameter increases."

The Stability of Tellurium Films in Moist Air; A Model for Atmospheric Corrosion

Alfred Milch and Pedro Tasaico[1]

Philips Laboratories, Briarcliff Manor, New York 10510

ABSTRACT

The effect of extended shelf life on the information storage capability of tellurium films on polymethylmethacrylate (PMMA) was investigated. Aging tests were performed for as long as fourteen months under various temperature and humidity conditions. The rate of change of sensitivity to the writing of information (hole formation by laser machining) was chosen as the basis on which to estimate stability quantitatively. It is suggested that aging is caused by oxidation, and a theoretical model for film oxidation as a function of temperature and relative humidity is proposed. Preliminary experimental support for the model is presented, based on the comparison of predicted and observed accelerated decay.

The primary objective of this work was to assess the suitability of tellurium films on polymethylmethacrylate (PMMA) as an information storage medium after extended periods of shelf life. Information is impressed in the Te films as a series of micron-sized holes which are formed by the absorption of energy from a properly modulated and focused laser beam (1, 2). If the films are stored in air, the efficiency of the hole forming process decreases. It is also observed that the films oxidize in air. When the air is sufficiently moist, it is possible to convert the tellurium film entirely to the white TeO_2 in a short time. The oxide is almost completely transparent to the employed laser radiation. Since the incident radiation is only partially absorbed in the Te, with a portion being transmitted, less energy is absorbed in a thinner film. Hence the decay of hole forming efficiency, which is the criterion by which film stability was judged, is ascribed to a thinning of the metallic portion of the film via atmospheric corrosion.

A widely used method of studying corrosion is by accelerated aging. The processes that are operative in normal decay are artificially intensified so as to accelerate the aging process and hence make available quickly results that would develop more slowly under normal conditions. An important assumption here is that the acceleration does not significantly distort natural aging. This assumption is frequently not entirely justified, and it is therefore very important to validate, independently if possible, the results of aging experiments. In the present work, the atmospheric corrosion of tellurium films vacuum-deposited on PMMA substrates was studied as a function of temperature and relative humidity (T/H) within the range 2-70% relative humidity and 25°-90°C. If the oxidation is of the simple Arrhenius type, a straight line relationship between the logarithm of the rate and reciprocal temperature should be observed. In this case, however, highly nonlinear Arrhenius plots were obtained when the absolute ambient humidity was left constant while the temperature was varied.

A model was constructed which reproduces the distorted Arrhenius plots. Theoretical parametric curves are displayed which predict rates of accelerated corrosion over the entire T/H field. Isolated experimental points are in reasonable agreement with these predictions. The well-known phenomenon of critical humidity appears as part of the model.

Experiment

Sample substrates were made from PMMA slips 1 mm thick by 18 mm square which were cleaned with ultrasonic agitation in hot aqueous detergent followed by hot running tap water and running deionized water. Immediately thereafter, substrates were placed eight at a time in a conventional vacuum coater where they received a tellurium deposit 300Å thick by 16 mm diam. Substrates were held at ambient temperature during deposition. It is assumed that the films were microcrystalline and nonoriented. After deposition, sets of samples identified by evaporation number and mask position symbol were stored vertically in slotted polypropylene carriers (Fluoroware Type PA-45) designed for maximum circulation of ambient around each sample. The carriers themselves were tested for exposure to the most severe conditions anticipated. They proved quite satisfactory during testing and later in service. During T/H aging, the loaded carriers were stored unenclosed in their respective environmental chambers. Upon periodic removal for testing, they were held in clean plastic boxes to protect them against accidental damage.

Initially, aging experiments were carried out at 25°, 55°, 75°, and 90°C, all at ambient humidity. Normal lab ambient humidity was approximately 50%. The laboratory environment is air conditioned and relatively constant and uncontaminated. Hence the presence of pollutants was assumed to produce negligible bias. The humidities experienced at the other test temperatures are displayed in Table I. Subsequent higher humidity experiments were performed in a Blue-M Model AC temperature/humidity cabinet.

25 (ambient)	0.50 (ambient; P_{H_2O} = 12 mm)
55	0.10
75	0.041
90	0.023

The apparatus for producing holes is sketched in Fig. 1. It consists of three major parts: a Lexel Model 85 argon ion laser emitting at 4881Å, a Coherent Radiation Model 3025 electrooptic modulator, and a focusing arrangement containing a 0.85 N.A. Olympus objective lens. Desirable operating conditions are constant power density at focus, high extinction ratio in the modulator, a square pulse, and a focused spot that is circular, has a Gaussian energy distribution, and is about one micron in diameter. The hole diameter of interest is one micron. The system was operated in the out-of-focus, static model (1), which allowed large numbers of observations to be made in a relatively short time. The beam was incident on the film side of the sample. For testing, a sample was caused to pass through the pulsed laser beam several times at different beam power levels producing tracks of holes in the metal film. For each track, the largest hole corresponds to optimum matching between beam power level, out-of-focus spot size, pulse duration, and the thermal properties of the metal film substrate. The samples were then photographed at 400× and 2000× magnification in order to record and measure the resulting tracks. Typical examples are shown in Fig. 2. A disadvantage of this method is that the holes are formed by laser beams whose degree of focus and hence energy distributions change from moment to moment as the sample traverses the beam. Thus, while the total power which forms the hole is known, the energy distribution is not. In particular, that portion of the out-of-focus beam which is effective in hole formation is unknown, hence the measured power constitutes an upper limit on that required to form a hole.

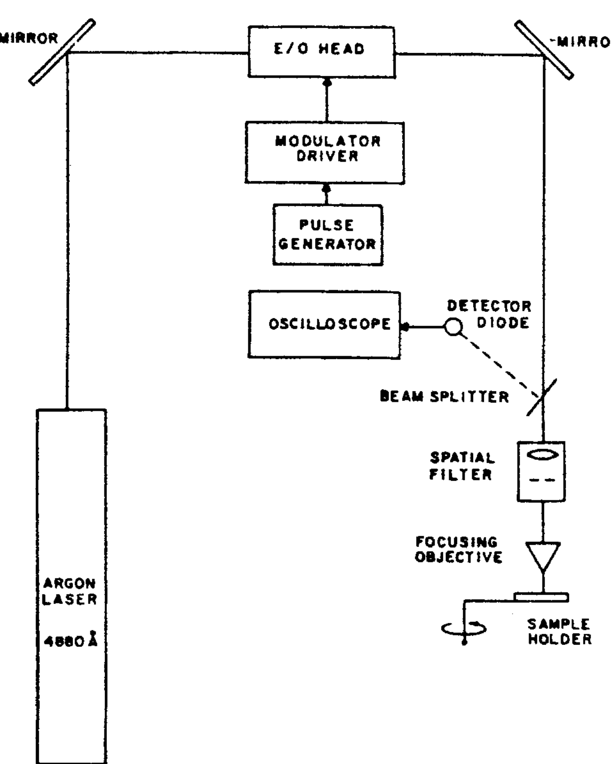

Fig. 1. Hole forming apparatus

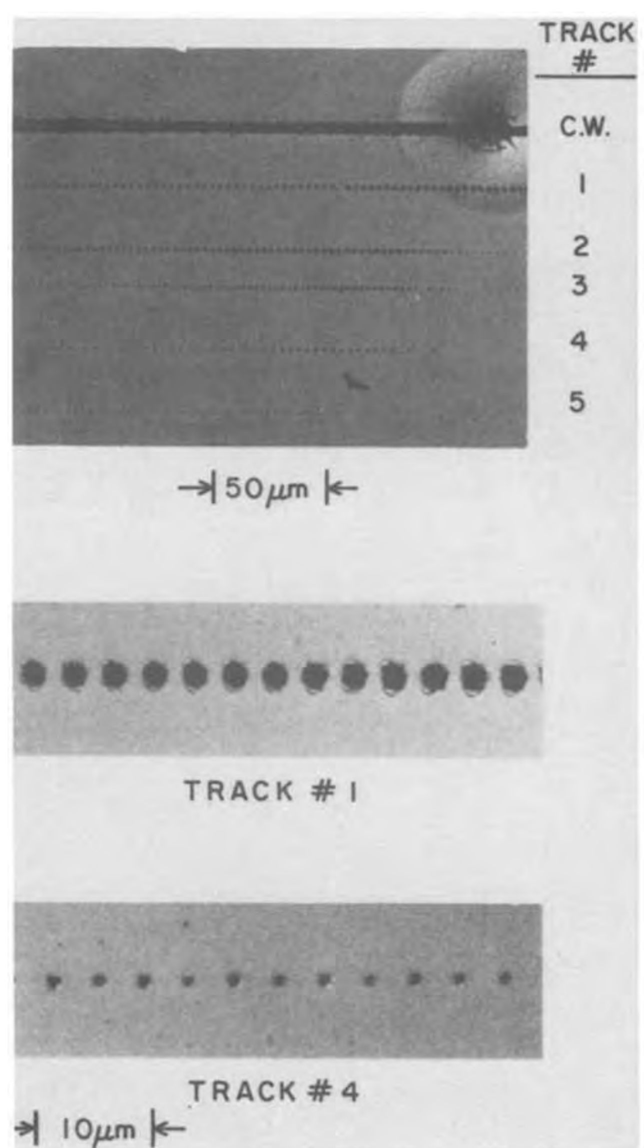

Fig. 2. Typical static hole burning in Te on PMMA. λ = 4881Å (Ar ion laser); pulse width = 750 nsec; pulse separation = 100μsec.

Track No.	Power mW	Hole diam μm	S mJ/cm²
C.W.	—	—	—
1	12.5	2.6	177
2	6.7	1.3	351
3	5.0	1.1	361
4	4.0	1.0	382
5	3.1	0.6	701

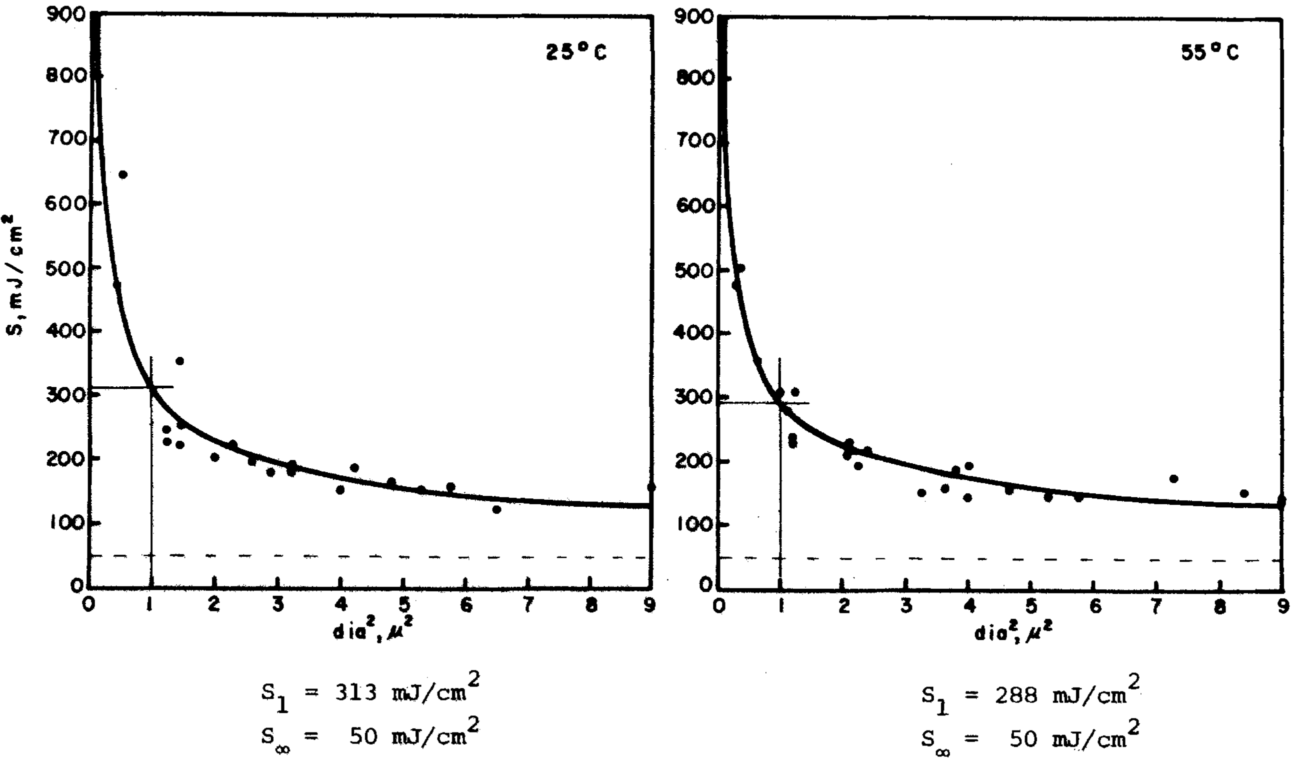
From a 2000× photograph of each track, a measurement was made of the hole diameter, d(cm), of the largest hole produced by a laser burst of known power, P (mW), and duration τ (sec). Sensitivity in mJ/cm² is defined as the energy per unit hole area required to form a hole of diameter d(cm)

$$S_d = 4P\tau/\pi d^2 \quad [1]$$

Pulse durations of 750 nsec were employed. The very high magnification and high speed, grainy film employed led to relatively large errors in measuring hole diameters. Consequently, errors of about 50% were encountered in estimating the areas of one micron holes (2 mm image). The importance of statistically averaging large amounts of data is obvious.

Analysis of Results

In order to reveal certain important properties of the hole forming process, results are plotted in terms



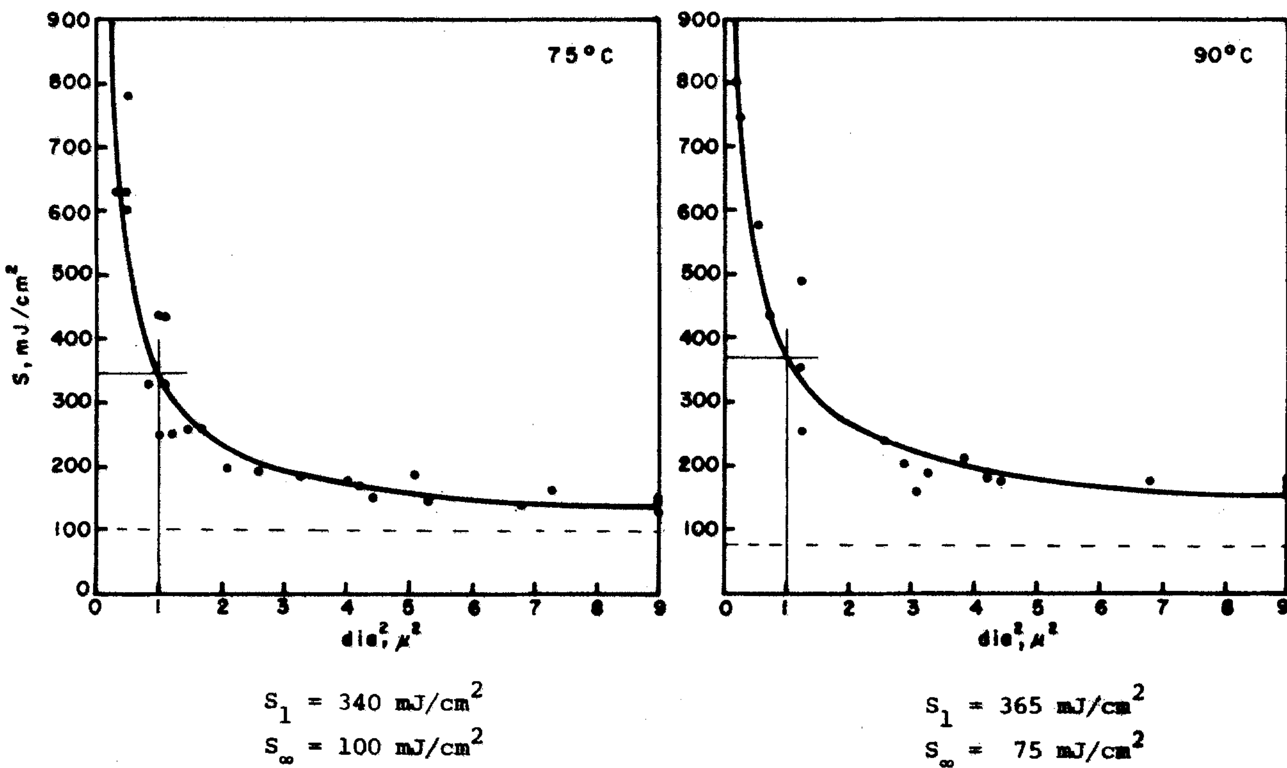


Fig. 3. Typical result of hole forming experiment (aged 4728 hr)

of sensitivity *vs.* relative hole area. A typical plot is displayed in Fig. 3. Vertical and horizontal asymptotes appear. We have found empirically that the hyperbolic dependence of S_d on d^2 required by Eq. [1] takes the functional form

$$\frac{\pi d^{2m}}{4} \cdot (S_d - S_\infty) = E_c \qquad [2a]$$

where m is close to unity but is included for generality. The $\pi/4$ term maintains consistency with Eq. [1]. The constant, S_∞, is the value of the horizontal asymptote, *i.e.*, it is the sensitivity for the formation of very large holes. Comparison with Eq. [1] (assuming $m = 1$) in the form $(P\tau)_\infty = S_\infty \cdot \pi d_\infty^2/4$ shows that the energy required to form large holes is directly proportional to the area of the holes for a given film thickness; that is,

to the amount of material removed. Hence, S_∞ may be viewed as the sensitivity for moving material from within the hole area.

The constant, E_c, is an energy term. If the indicated multiplication in Eq. [2a] is performed, one may write

$$E_d - E_{d,\infty} = E_c \quad [2b]$$

where $E_d = \pi d^2 S_d/4$ (see Eq. [1]) is the total energy required to form a hole. $E_{d,\infty} = \pi d^2 S_\infty/4$ is, according to Eq. [1] and the above interpretation of S_∞, the energy required to move material from the hole area. It follows, then, that E_c is that portion of the energy in the hole forming process that initiates the hole and enlarges the perimeter. Since it is a constant, the energy required to enlarge the perimeter must essentially be zero. As hole size decreases, E_d approaches E_c, and the vertical asymptote follows from the nearly constant E_d for any hole, no matter how small.

A statistical estimate for one micron holes may be arrived at by putting Eq. [2a] into linear form

$$\ln (S_d - S_\infty) = m \ln d^2 + \ln C \quad [3]$$

where

$$C = 4E_c/\pi$$

Equation [3] was treated by a least squares analysis for the case in which errors were expected in both S_d and d^2. This yielded values for m, C, and the correlation coefficient, r. The method was applied repeatedly to a given set of data, varying the value of S_∞ as an adjustable parameter, until r^2 was maximized. The lines drawn in Fig. 3 are a result of this type of analysis. Thirty-eight samples were followed for over 10,000 hr, during which time over 1000 pairs of S *vs.* d measurements were made. The results are gathered in Table II.

To a first approximation, the rate of decay in sensitivity, R, given in terms of sensitivity units per 1000 hr (s.u./1000 hr) should be initially linear with time

$$S = S_o + Rt \quad [4]$$

where the unsubscripted "S" henceforth refers to sensitivity for one micron holes. A linear least squares analysis was applied to the data in Table II assuming no errors in the measurement of time. The method yielded the rate, R, the zero-time sensitivity, S_o, the one standard deviation errors on the rate, ϵ_r, on S_o, ϵ_b, and the standard deviation of fit, σ. The results are shown in Table III. Also shown are shelf lives based upon an initial sensitivity of 340 sensitivity units/1000 hr and a criterion of 20% maximum allowable decay during use. It is clear that tellurium has only a limited useful shelf life at ordinary lab ambient and that the combined effects of temperature and humidity on this important property are not straightforward.

Equation [4] is plotted in Fig. 4 for a typical case. Also plotted is the one standard deviation error envelope for predicting the location of the line within a confidence interval of 50%

$$\epsilon_{line} = \pm\sqrt{\epsilon_b^2 + \epsilon_r^2 t^2} \quad [5]$$

An Arrhenius plot of the information contained in Table III is shown in Fig .5.

Discussion

Interpretation of data.—By the law of mass action, the oxidation rate of tellurium in the chemical change: $Te + O_2 \rightarrow TeO_2$, at a fixed temperature is given by

$$r = K \cdot C_{Te} \cdot C_{O_2} \quad [6]$$

where K is the reaction rate constant and C's are concentrations. In its initial stages, the oxidation rate in air is constant at constant temperature since the con-

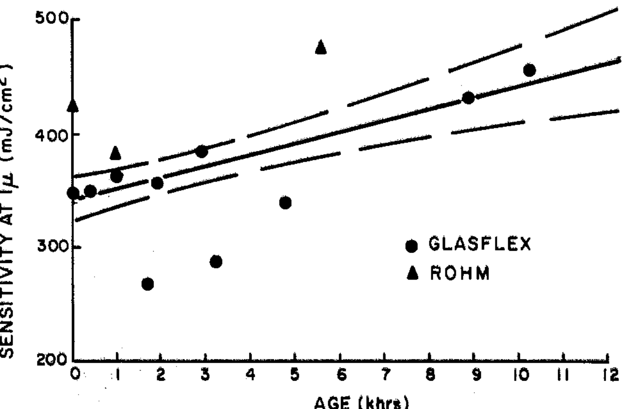

Fig. 4. Typical aging characteristic (storage temperature: 75°C)

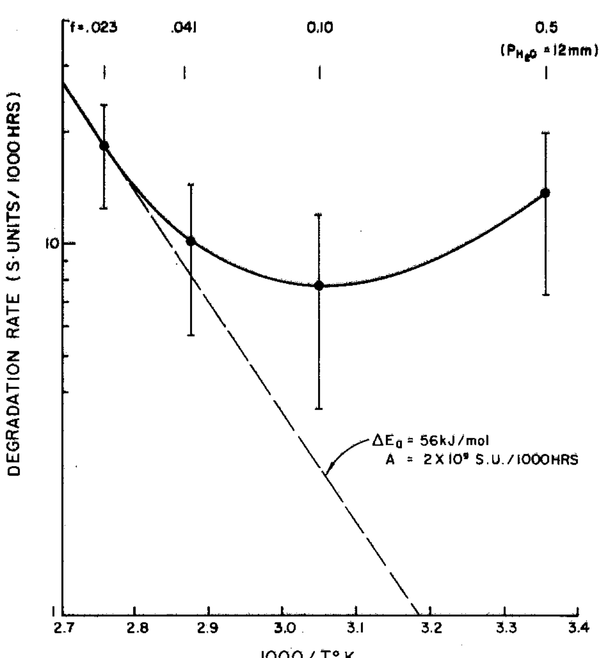

Fig. 5. Experimental Arrhenius plot

centration terms are effectively constant. Hence, we may equate the rate constant to the observed rate, R, as

$$K = r/C_{Te} \cdot C_{O_2} = \propto R \quad [7]$$

where $\propto$ is the constant of proportionality.

As transparent TeO_2 forms and metallic Te disappears, the hole forming efficiency diminishes. Hence, the oxidation rate is identified with the sensitivity decay rate, R, appearing in Table III. Because of the restriction embodied in Eq. [7], the Arrhenius equation expressing the temperature dependence of the rate constant may thus be stated in terms of the observed rate

$$R = A \exp(-\Delta E_a/kT) \quad [8]$$

where A is the Arrhenius constant, ΔE_a is the activation energy, k is Boltzmann's constant, and T is the absolute temperature.

Very often in aging experiments, the accelerated rate at an elevated temperature is compared to the normal rate at ambient temperatures via Eq. [8] as follows

$$\frac{\text{time at ambient}}{\text{time under acceleration}} = \frac{R_{accel}}{R_{amb}} = \exp\left[\frac{\Delta E_a}{k}(T_{amb}^{-1} - T_{accel}^{-1})\right] \quad [9]$$

where the first equality implies equal chemical action at the two conditions. This ratio, the acceleration factor, F, specifies the time at normal temperature required to produce the same oxidation observed at the aging temperature. This factor may be plotted against activation energy for a given $T_{ambient}$ such as 25°C. Predicted oxidation aging time at 25°C may be obtained from this figure by multiplying the time under acceleration by the factor, F, corresponding to the appropriate activation energy and aging temperature. Such a plot is valid as far as it goes; that is, in a dry environment. But it fails in conditions of significant air humidity owing to the unavailability of a unique value of the activation energy as is demonstrated in Fig. 5.

According to Eq. [8], the experimental data should yield a straight line with a negative slope, $-\Delta E_a/k$. The very strong "U"-shaped curvature in Fig. 5 is attributed to the effect of relative humidity based on the following qualitative argument.

All aging was performed in ordinary air ovens at ambient humidity (average 50% at 25°C); that is, the partial pressure of water vapor at all temperatures was 12 mm Hg, approximately. Hence the (fractional) relative humidity, f, varied strongly with temperature as shown across the top of Fig. 5. At high humidity, moisture tends to condense on sample surfaces. Hence the normal effect of decreasing temperature on corrosion rate is overcome by the increasing chemical reactivity in the adsorbed water layer. In principle, at still lower temperatures, the slope must again go negative with an activation energy characteristic of a corrosion mechanism in a liquid water medium.

At low humidity, the reverse is true and dry environmental conditions are approached. The straight line extrapolation in Fig. 5 of the high temperature tangent portion of the "U" curve is an expression of this conclusion. It is employed to yield limiting "dry" values of the Arrhenius parameters.

A model for atmospheric corrosion.—There exists a vast literature on corrosion (3), both in book and periodical form. In the older literature, atmospheric corrosion received relatively little attention, and most of that was devoted to empirical descriptions of the effects of chemically active contaminants, such as sulfur oxides and nitrogen oxides. One significant concept, that of critical humidity in the onset of enhanced, or "accelerated" atmospheric corrosion (4, 5), has been described. This important principle states that atmospheric corrosion is significantly accelerated only when the relative humidity exceeds a certain value. Only recently, in connection with microelectronic circuits, has detailed work begun to appear on the effect of relative humidity alone on atmospheric corrosion (6-14).

A model is here proposed in which the Arrhenius equation is modified so as to yield the quantitative functional dependency of atmospheric corrosion rate on temperature and relative humidity. An essential feature of this model is the well-known concept that the initial water adsorbed from the atmosphere on a clean metal surface is chemically bound to form a "hydroxylated" surface (8); *i.e.*, an oxidized monolayer of more or less unspecified stoichiometry. Since this first monolayer is strongly bound (13, 14) to the underlying metal it provides for little or no ionic motion and therefore does not contribute to electrolyte activity. Subsequent adsorption of atmospheric water forms the adphase in which ion motion and consequently accelerated corrosion takes place. It is assumed that the ionic population of the adlayer is drawn from the ionization of the water itself, from dissolved air, and from mobile species of tellurium formed by detachment of ions which have diffused through the immobile oxidized layer (12). We suggest that the formation of the first, immobile, hydroxylated monolayer may be associated with the critical humidity, below which accelerated corrosion does not occur. Hence, the value of critical humidity should be very much a function of the reactivity of the metal under consideration.

A knowledge of how the adlayer thickness varies with humidity and temperature is crucial to an understanding of the corrosion process. This dependence is described adequately by the Frenkel-Halsey-Hill (FHH) adsorption isotherm (15), which is valid in the relative humidity range 10-90%

$$\theta = \left(\frac{-q}{kT \ln f}\right)^{1/s} \quad [10]$$

where θ is the adlayer thickness in monolayers, q is the heat of adsorption of the mobile admolecules, f is the (fractional) relative humidity, and s is a measure of the rate of decay of the adsorption potential on moving far from the surface.

In the present state of knowledge, the value of q, and possibly of s, are little more than parameters to be adjusted in order to obtain a reasonable fit to a particular set of data. Thus if estimates of material constants are taken from Ref. (8) (q = 5.5 kJ/mole, s = 2.33), then Eq. [10] calls for $\theta < 1$ over most of the range of interest, while the experimental Arrhenius plot (Fig. 5) indicates significant corrosion acceleration ($\theta > 1$) in most of the same range. This contradiction implies that Cerofolini's value for q is not appropriate for the system being studied here. That is, the heat of adsorption of the mobile portion of the adphase on tellurium may be significantly different from that given for the hypothetical metal described in Ref. (8).

At a sufficiently low relative humidity, linear Arrhenius behavior is expected. The deviation from linear Arrhenius behavior with decreasing temperature in Fig. 5 appears to occur at about 90°C/2.3% RH. This signals the critical humidity condition below which corrosion acceleration does not occur, and according to our model, coincides with the (hydroxylated) monolayer state: $\theta = 1$. We therefore insert the above values of T, f, and θ into Eq. [10] to determine that the heat of adsorption of the mobile water adphase on tellurium is q = 11 kJ/mole. The rate of atmospheric corrosion in the absence of water vapor is determined solely by the Arrhenius equation as described above. When water vapor is introduced and after an aqueous adlayer forms, the rate is accelerated

by a factor which depends on the number of dissolved ions in the vicinity of the surface and on their thermal diffusivity. For very thin adlayers and dilute solutions, the number of ions is proportional to the thickness of the adlayer. Hence the accelerated rate may be represented by a modified Arrhenius equation as follows

$$R(\text{acc}) = \text{const} \cdot \theta D \cdot A \exp(-\Delta E_a/kT) \quad [11]$$

D is the ionic diffusivity according to Einstein's equation

$$D = kT\mu/e \quad [12]$$

where μ is the ionic mobility and e is the electronic charge.

We adopt now a simplified version of the scheme presented in Ref. (8). Ionic mobility in the adphase is assumed to be a thermally activated process with an activation energy that is linearly dependent on the thickness of the layer

$$E(\theta) = E_o \left(\frac{\theta_c - \theta}{\theta_c} \right) \quad [13]$$

where E_o = activation energy for mobility for zero coverage and θ_c = critical coverage in monolayers at which bulk water properties appear.

This expression has the properties that $E(\theta)$ is at a maximum for very small coverages, decrease linearly with increasing θ, and vanishes in liquid water where $\theta = \theta_c$. If an activation energy for mobility persists in liquid water, it is assumed to be small compared to E_o. Ionic mobility in the adphase then becomes

$$\mu = \mu_o \exp\left[-E_o \left(\frac{\theta_c - \theta}{\theta_c} \right) \Big/ kT \right] \quad [14]$$

where μ_o is the temperature independent part of ionic mobility. Defining the term θD in Eq. [11] as the "sheet diffusivity" $D_{\square}$, we arrive at

$$D_{\square} = \frac{kT\mu_o\theta}{e} \exp\left[-E_o \left(\frac{\theta_c - \theta}{\theta_c} \right) \Big/ kT \right] \quad [15]$$

Equations [10] and [15], taken together, give the explicit dependence of the adlayer sheet diffusivity on the environmental factors temperature and relative humidity. Since failure is a result of accelerated corrosion via ionic diffusion in the presence of the adlayer electrolyte, $D_{\square}$ may be taken as a measure of risk of failure. Recalling that at the critical coverage, $\theta = 1$, little, if any, corrosion acceleration is to be expected

$$D_{\square, \theta=1} = \frac{kT\mu_o}{e} \exp\left[-E_o \left(\frac{\theta_c - 1}{\theta_c} \right) \Big/ kT \right] \quad [16]$$

This expression defines the critical sheet diffusivity below which no corrosion acceleration is to be expected. We normalize Eq. [15] to this limiting condition to yield

$$\frac{D_{\square, \theta}}{D_{\square, \theta=1}} = \theta \exp\left[E_o \left(\frac{\theta - 1}{\theta_c} \right) \Big/ kT \right] \quad [17]$$

in order to obtain the factor by which corrosion is enhanced at any temperature and humidity above critical humidity.

Equation [17], then, complements Eq. [9] as the acceleration factor by which a corrosion rate is enhanced. But while Eq. [9] is merely the Arrhenius equation rewritten, Eq. [17] is the factor which modifies the Arrhenius equation so as to take both temperature and relative humidity explicitly into account

$$\text{Rate}(T, f) = A\theta \exp\left[\left(E_o \left(\frac{\theta - 1}{\theta_c} \right) - \Delta E_a \right) \Big/ kT \right] \quad [18]$$

In other words, the constant of proportionality for Eq. [11] is $1/D_{\square, \theta=1}$. Somewhat similar equations have appeared elsewhere (6, 7), but they are empirical modifications of the Arrhenius equation, they do not show the important phenomenon of critical humidity, and they do not revert to the Arrhenius equation at low humidity. Perhaps their chief drawback is that they tacitly assume that corrosion acceleration is absent in the absence of metallic electrodes and applied electric fields.

It is now possible to construct an Arrhenius plot for the experimental data in Table III with the help of Eq. [18]. Material constants employed are: $\Delta E_a = 56$ kJ/mole (from Fig. 5, extrapolated "dry" value); $A = 2 \times 10^9$ (from Fig. 5, extrapolated "dry" value); $E_o = 43$ kJ/mole [Ref. (8)]; and $\theta_c = 7$ (a curve fitting parameter).

Equation [18] and the experimental rate data are plotted in Fig. 6. During the plotting, a point is reached at which $\theta = 1$ and Eq. [18] reverts to the normal Arrhenius relation (Eq. [8]). For the small segment where $\theta < 1$ ($T > 90°C$), Eq. [8] was employed. This may be justified if we assume that for $\theta < 1$ the adphase exists as a patchwork of $\theta = 0$ and $\theta = 1$ areas. For $\theta = 0$, Eq. [8] is valid by construct, and for $\theta = 1$, Eq. [18] is valid as a limiting case and reduces to Eq. [8]. Hence the model includes the concept of critical humidity described above. The cutoff at low relative humidity is in recognition of the fact that for $\theta \leq 1$ the admolecules are immobile and the electrolyte-diffusivity approach is invalid.

Equation [18] is mapped onto a temperature/humidity field as lines of constant accelerated Arrhenius rates in Fig. 7. Rates are normalized to unity at a laboratory ambient of 25°C and 50% relative humidity. Predicted aging at lab ambient is obtainable by multiplying time under test by the acceleration factor (relative rate) corresponding to the appropriate test temperature and relative humidity. For example, suppose samples exposed to 40°C and 80% relative humidity degraded to failure in four weeks. According to Fig. 7, these conditions would produce an accelerated rate of 100 relative to lab ambient. Therefore the model predicts a life to failure of 400 weeks at 25°C and 50% relative humidity.

A more precise validation of the model is highly desirable. An experiment was designed to meet this

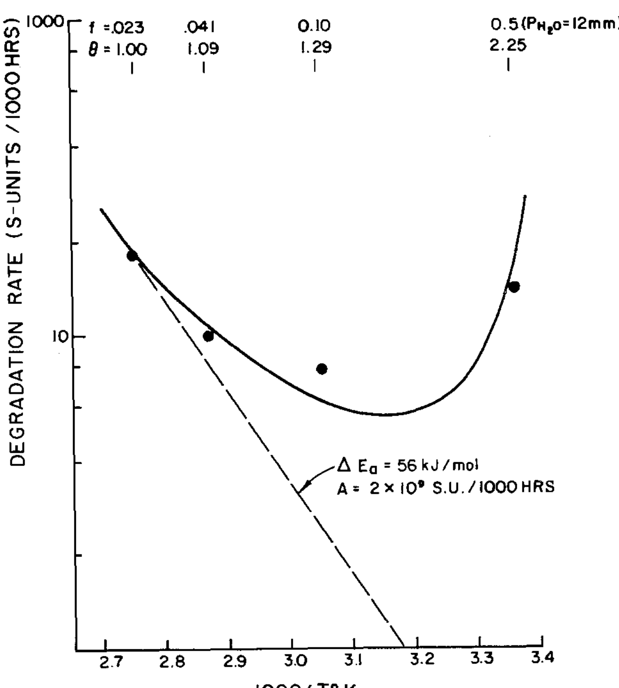

Fig. 6. Arrhenius plot, theoretical curve

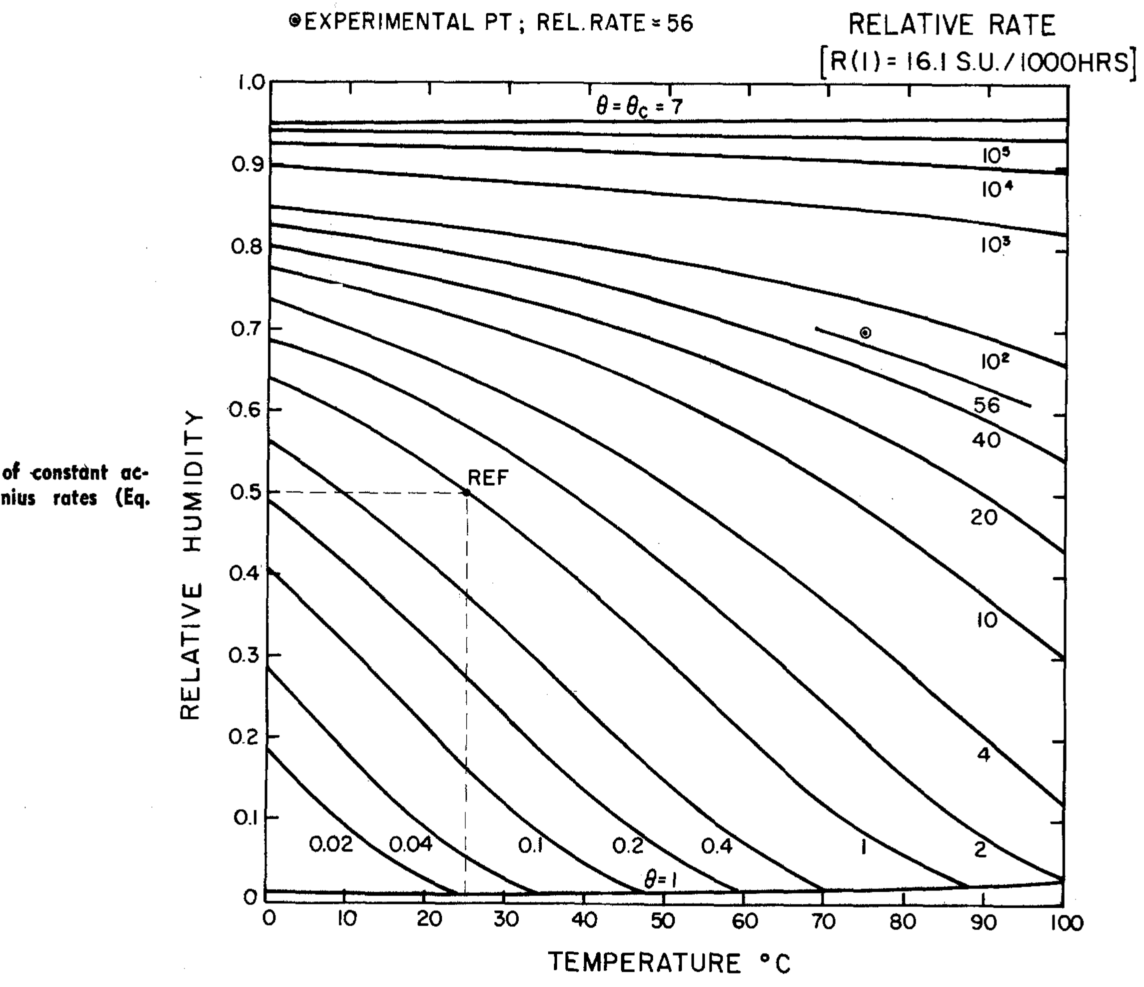

Fig. 7. Lines of constant accelerated Arrhenius rates (Eq. [18]).

requirement. A set of isobarically accelerated Arrhenius curves are plotted in Fig. 8 from which the 75°C/70% relative humidity point (P_{H_2O} = 203 mm) was chosen. One set of eight samples of tellurium on PMMA was aged for about 300 hr at 75°C and 70% relative humidity. The results are plotted in Fig. 9. By best estimate, the initial degradation rate was approximately 900 sensitivity units per one thousand hours. This single experimental point is plotted onto Fig. 7 and 8.

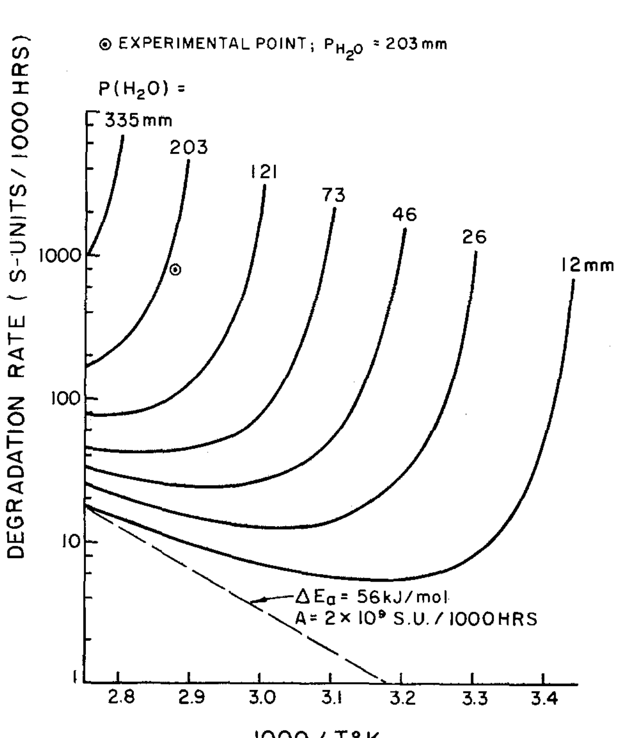

Fig. 8. Isobarically accelerated Arrhenius rates (Eq. [18])

An additional interesting example of the usefulness of the Arrhenius rate mapping in Fig. 7 is presented in Table IV. In it, the data from Table III are converted to conditions of 25°C ambient for each of the relative humidity conditions encountered. The results demonstrate the overriding importance of relative humidity in determining the useful shelf life of tellurium films on PMMA when used as an optical disk storage medium.

Conclusions

Tellurium, as a medium for information storage via laser machining, suffers from a drawback of signifi-

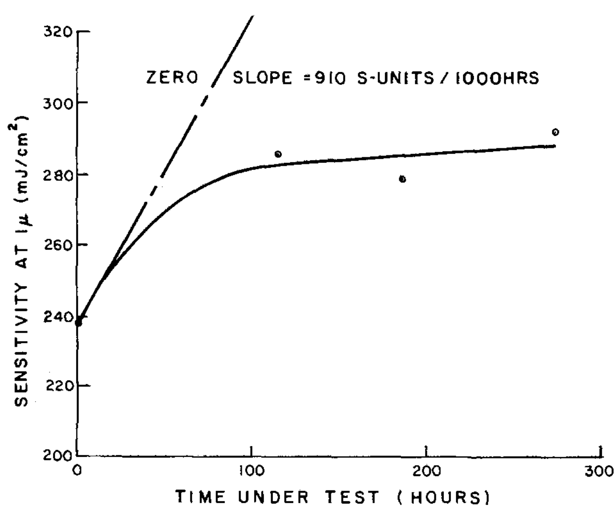

Fig. 9. Aging characteristics at 75°C and 70% relative humidity

Table IV. Decay rates for Table III data assuming 25°C throughout

Relative humidity (%)	Relative rate from Fig. 9	Useful life
50	1	6 months (observed)
10	0.06	8 years
4	0.03	17 years
3	0.02	25 years

cant atmospheric corrosion within a period of one or two years. Rates of decay are somewhat reduced by storing the films at a slightly elevated temperature (approximately 55°C) when the normal laboratory ambient is 25°C and 50% relative humidity. Significant improvement could be obtained by reducing the ambient humidity to 10% or lower.

A model for atmospheric corrosion is presented. It is based on a version of the Arrhenius equation modified to express the effects of both temperature and relative humidity explicitly via an adsorbed layer of water which accelerates corrosion. The concept of critical humidity appears in terms of monolayer coverage below which corrosion acceleration does not occur. Under this condition, the rate equation reduces to the normal Arrhenius relationship. Limits of validity are from monolayer coverage ($\theta = 1$) to the appearance of bulk water behavior ($\theta = \theta_c$). Experimental evidence in support of the model is presented.

Acknowledgments

The authors extend their appreciation to George Kenney for his enthusiastic encouragement and support in all phases of this work. We are grateful to Gertrude Neumark for her very generous theoretical assistance. David Lou provided helpful discussions and assistance in the experimental design, and Gertrude Neumark and Gerard Blom assisted in critically reading the manuscript.

Manuscript submitted Aug. 3, 1979; revised manuscript received Nov. 13, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Philips Laboratories.

Indoor Corrosion of Metals

D. W. Rice,* R. J. Cappell, W. Kinsolving, and J. J. Laskowski

IBM Corporation, General Products Division, San Jose, California 95193

ABSTRACT

The indoor corrosion rates of copper, silver, nickel, cobalt, and iron were measured at eight locations in the United States. Concurrent pollutant and relative humidity measurements were also made at six sites. The rates are shown to be lognormally distributed over the sample population. A statistical comparison of outdoor and indoor rates shows that Ag corrodes approximately the same both indoors and outdoors. Cu and Ni corrode 100 times faster outdoors, and Fe corrodes 2000 times faster outdoors. The corrosion rate sensitivity to relative humidity is speculated to explain these differences. Pollutant concentrations are shown to be generally attenuated indoors except for NH_3 and reduced forms of sulfur. The indoor corrosion rates of copper and silver are reasonably well correlated to the measured reduced sulfur concentrations. Nickel rates correlate best to the acid chlorine containing gases.

The atmospheric stability of copper, silver, nickel, cobalt, and iron is determined to a large extent by the chemistry and integrity of surface reaction products. These metals and the alloys prepared from them are thermodynamically unstable with respect to most practical operating environments. Faraday recognized this over a century ago (1). A significant effort has been expended to understand the factors that influence outdoor marine and urban atmospheric corrosion (2-4). Relative humidity, temperature, pollutant concentration, particle concentration, and sample orientation are among the more important ones. Only limited success has been achieved in relating outdoor corrosion rates to these atmospheric parameters (5, 6).

It is well recognized that outdoor atmospheric parameters may be significantly changed inside structures (7-10). Pollutant adsorption and particle deposition on internal surfaces, humidification and dehumidification, temperature control, filtration, air flow design, and internal pollutant sources all modify the internal environment with respect to outdoor conditions. The purpose of this paper is to discuss the indoor corrosion of copper, silver, nickel, cobalt, and iron at a limited num-

ber of test sites in the United States. Particular emphasis is given to the magnitude of indoor corrosion, indoor corrosion products, statistical aspects of indoor corrosion, indoor atmospheric parameters, and indoor-outdoor comparisons of rates and pollutant levels. This is the first published indoor study that measures both rates and atmospheric parameters concurrently. Insight is gained on the important pollutants for certain metals as well as the buffering capability of buildings.

Experiment

Metallic foils, 2.54 cm squared, were sent to eight indoor locations in the United States. The suppliers specified purities of the five metals tested are given in Table I. The geographical location, local outdoor environment, and the nature of the internal air conditioning for the eight sites is given in Table II. The metal foils were cleaned by a sequence of hot xylene, ethanol, and D.I. water immersions and weighed to the nearest one microgram. The samples were then clamped along two opposite edges in a flow control tunnel that pulled air from the indoor environment over them at 2.5 M/sec. Samples were retrieved from the sites at 6 (4380 hr), 12 (8760 hr), and 18 (13,140 hr) month intervals.

The test began in December, 1973 and ended in May, 1975. The returned samples were rinsed in benzene to remove organic deposits, then reweighed. The change in wt/cm^2 of metal divided by the test time interval is the reported rate of weight gain.

High resolution x-ray photoelectron spectroscopy (XPS) was used in the majority of cases to analyze the corrosion products (11). Auger electron spectroscopy was used for nickel (12). Corrosion product analysis was made only on the 18 month samples. Both AES and XPS spectroscopy sample the uppermost 1.0 nm (10Å)-5.0 nm (50Å). XPS yields some limited bonding information about the elements, while Auger yields only atomic composition. Neither method is particularly quantitative for a complex problem like atmospheric corrosion product identification. The hydrocarbon contribution to the XPS C(1s) spectra was not used in the surface composition calculation. XPS sensitivity factors, published by C. D. Wagner (13), were used to convert the integrated peak intensities to the percentage atomic compositions given in the tables. Auger sensitivity factors, published by Palmberg *et al.* (14), were used to convert the peak-to-peak intensities of the surface products on nickel to the atomic compositions.

The pollutant concentrations were measured at six of the eight sites. Sulfur dioxide (SO_2), nitrogen dioxide (NO_2), ammonia (NH_3), reduced sulfur gases (H_2S, S_8, CH_3SH), inorganic (or acidic) chlorine gases (Cl_2, HCl), and airborne dust were monitored by pulling a known volume of site air through a series of filters designed to trap specific pollutants. The procedure required a month of sampling because of the low concentration of most pollutants indoors. The reported data are, therefore, approximately one-month integrated averages. The reported standard deviations would be significantly greater for shorter sampling intervals. The filters were returned to the laboratory after each sampling period and analyzed by specially developed wet chemical procedures. Relative humidity was measured using calibrated human hair bundles as the sensing element (15). Calibration at 6 month intervals was necessary to assure an accuracy of ±5% RH.

Results

Table III summarizes the corrosion rates at the eight sites for the three test exposure intervals. All the rates were used to fit to a lognormal distribution. Table IV summarizes these fits with the 10-99% cumulative percentage of measurement data points, the standard deviation of the logs, and the correlation coefficient that relates the fit to the data. Lognormal statistics are obeyed by many naturally occurring processes (16). It is not surprising that the corrosion rates should obey this distribution. Table IV also summarizes the composite indoor distribution function, which includes the data in this study plus other reported literature for indoor corrosion, and an estimate of the outdoor lognormal distribution function. The data are also given on lognormal probability coordinates in Fig. 1, 3, 4, 6, and 7.

Table V is a statistical summary of the pollutant data at each site. The arithmetic mean values, M_a, are the most reliable because they are determined directly from the pollutant data and are weighted to account for the length of each sampling period. The lognormal functions which include the geometric mean, M_g, and the standard geometric deviation, S_g, were calculated from the equations shown and are based on the assumption that the data are lognormal distributed. Table VI is a summary of the relative humidity distribution and mean relative humidity for each site, as well as a composite humidity distribution using all humidity data obtained in this study.

Specific monthly pollutant concentration variability will be presented in the body of the discussion sections as will the corrosion product summary. The measured

concentration is shown numerically either within or above the vertical bars. Note that when a vertical bar in Fig. 9-14 does not exist no data (ND) were obtained.

Discussion

Metallic corrosion.—The indoor environment can significantly influence the level of each atmospheric parameter as well as its distribution. Pollutant concentrations are generally reduced indoors except when internal sources are present (9). Shair *et al.* have developed a theoretical mass balance model that relates indoor pollutant levels to outdoor levels for the case without internal sources (7). The corrosion rates inside buildings would be expected to be less than outside, but the magnitude of reduction is not clear because of the complexity of the rate expression. We will focus our attention on each metal followed by a discussion of the indoor atmospheric parameters.

Copper.—The corrosion rate of copper at the eight indoor sites shows a general decrease with time particularly for the less corrosive sites. This is characteristic of parabolic or higher order kinetics. The corrosion products inhibit further copper oxidation by limiting cation and/or anion flux. Campbell and Thomas (10) observed a similar behavior for copper in telephone switching rooms in the U.S.

The corrosion products on the 18 month exposure samples, as measured by high resolution XPS, are complex combinations of copper hydroxide, chloride, sulfate (sulfite), carbonate, and nitrate. Table VII

Table VII. Surface corrosion products on 18 month exposed copper samples measured by XPS

Site	Atomic percentage					
	Cu ($2p_{3/2}$) (934.4 eV)	O (1s) (531.4 eV)	C (1s) (288 eV)	Cl (2p) (197.8 eV)	S (2p) (167.6 eV)	N (1s) (399.5 eV)
Los Angeles	25	50	17	5.9	0.0	2.5
Chicago	25	47	14	7.5	1.8	4.3
New York City	—	—	—	—	—	—
Texas	52	31	7.6	3.0	1.4	5.1
Indiana	10	53	13	6.2	1.9	11
S. Carolina	25	50	13	4.4	0.0	8.2

summarizes the atomic percentage (a/o) of each element at each site as well as the associated binding energy (BE) of the photoelectrons. The dominant copper binding energy at 934.3 eV is characteristic of oxidized copper $2p_{3/2}$ photoelectrons. The oxygen 1s BE is 531.6 eV and typical of oxygen in OH^-, $SO_4^=$, $CO_3^=$, and NO_3^-, but not in oxide $O^=$. Carbonate, adsorbed CO_2, and adsorbed CO could account for the observed carbon 1s spectra at 288 eV. The chlorine 2p doublet at 198.1 and 199.5 eV, respectively, is characteristic of chlorides. The sulfur 2p BE was 168 eV and characteristic of sulfate or sulfite, not sulfide. The sulfide 2p BE would occur at 162 eV. Finally, the nitrogen 1s BE at 399.4 eV is typical of nitrite or nitrate.

The indoor copper corrosion rate distribution for the 23 measurements in this study was a lognormal function with an excellent correlation coefficient, 0.97. Furthermore, the indoor work of Campbell and Thomas (10), and Sharma (17) was combined with this study to produce a composite indoor distribution function. A lognormal approximation was again an appropriate fit. Figure 1 compares the data of this study with the composite data. Table IV summarizes the geometric means

$$r_{50\%} = e^{\Sigma \ln r/n}$$

the standard deviation

$$\sigma = \frac{\ln r_{84.1} - \ln r_{15.9}}{2}$$

and the correlation coefficients. The fact that the indoor corrosion rate of copper over a range of times and sites is lognormally distributed can help assess failure rates of copper materials, the cost associated with field repairs, and field maintenance plans.

The outdoor corrosion rate distribution function for copper corrosion was generated from data reported by others (18-23). The lognormal distribution is an excellent approximation. Figure 1 and Table IV summarize the fitting parameters. Indoor corrosion is two orders of magnitude less than outdoor corrosion. For example, comparison of the geometric means, $r_{50\%}$, shows outdoor corrosion to be 119 times greater than indoor corrosion. Corrosion products on outdoor exposed samples have been reported to be complex copper hydroxides, sulfates, carbonates, and chlorides (24). These are similar to our indoor results.

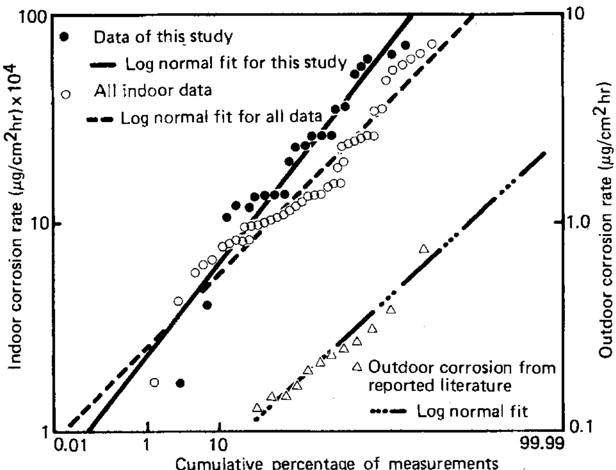

Fig 1. Copper corrosion rate distribution

The fact that the indoor corrosion of copper is orders of magnitude less than outdoors is not surprising. The indoor environment is less severe from an atmospheric parameter point of view. Copper has been reported to be sensitive to relative humidity, sulfur dioxide, sulfur gases, and chloride contaminants since the pioneering work of Vernon (25, 26). Rice *et al.* have shown that the functional dependence of corrosion rate, r, on relative humidity, RH, is of the form $r = ae^{4.6RH}$ with little evidence for a critical humidity in a complex environment. Sulfur dioxide, H_2S, and O_3 were also shown to have a significant influence while NO_2, Cl_2, and NH_3 have little influence (27). Leidheiser (24) has reviewed much of the current understanding of copper corrosion.

Examination of pollutant data, Table V, measured at the sites in this study during the same interval as the copper exposure indicates the reduced sulfur content, S_x, of the indoor environment is the best pollutant indicator of copper corrosion. Figure 2 is a presentation of the fit and actual rate *vs.* reduced sulfur concentration data. The form of the numerical fit is $r = 30 \times 10^{-4} (S_x)^{0.76}$ with a correlation coefficient equal to 0.8. It would be naive to presume that reduced sulfur is the only operative in the polluted environment; however, it may be an effective guide to indoor environmental severity with respect to copper.

Silver.—The corrosion rate of silver, like copper, decreased with time for most of the sites. Silver has been used as a classic example of a material that corrodes parabolically; in particular, the kinetics of iodization (28) and sulfidation (29) are parabolic. The corrosion products were silver sulfide, chloride, hydroxide, and nitrate (nitrite). The binding energies of electrons as-

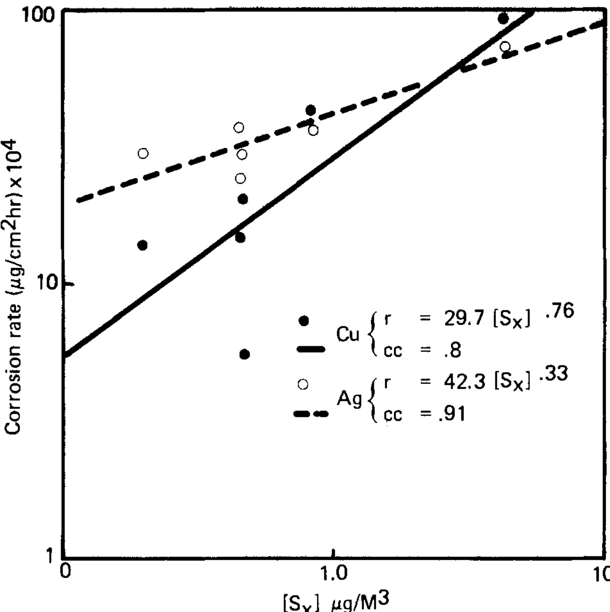

Fig. 2. Field corrosion rate of copper and silver vs. mean reduced sulfur concentration at each site.

Table VIII. Surface corrosion products on 18 month exposed silver samples measured by XPS

Site	Atomic percentage				
	Ag ($3d_{5/2}$) (368.4 eV)	O (1s) (531.8 eV)	Cl (2p) (198.3 eV)	S (2p) (161.6 eV)	N (1s) (399.5 eV)
Los Angeles	49	29	5.8	9.3	6.6
Chicago	52	24	6.2	11	7.1

Indiana	66	23	1.3	2.3	7.9
S. Carolina	61	15	3.9	16.4	3.6

sociated with all anions, except sulfur, were similar to those observed on copper. The sulfur was present as a sulfide not sulfate on these returned samples. This is in general agreement with the work of others (30). However, the presence of significant chlorides, hydroxides, and nitrates/nitrites complicates the picture somewhat. Table VIII summarizes the corrosion product results.

The indoor corrosion rate distribution for this study and for the composite of reported indoor data (10) both fit lognormal statistics with a correlation coefficient equal to or greater than 0.97. Figure 3 compares the results. The standard deviation for silver is significantly less than copper, while the mean corrosion rate is greater.

The outdoor corrosion of silver, a recognized problem, is not well documented. The limited data that the authors could find (31) fit a lognormal distribution well, as shown in Fig. 3. Unlike copper and the other metals in this study, silver corrodes indoors at approximately equivalent rates to outdoors. In fact, the geometric mean of the outdoor data is only 43% of the indoor geometric mean. The reason for this similarity between outdoor and indoor rates is speculated to be the independence of silver corrosion rate on relative humidity (27). Extremes in outdoor humidity will not accelerate silver corrosion, while the corrosion rate of the other metals in this study will be markedly accelerated. Subtle influences such as flow velocity and reduced sulfur gas concentrations will then account for the comparative differences between indoor and outdoor rates. Silver corrosion rate is dependent on the reduced sulfur pollutant concentration which can often be greater indoors than outdoors.

As with copper, the total reduced sulfur in the indoor atmosphere correlates better than the other measured pollutants with the observed indoor corrosion of silver. Figure 2 plots the observed rate *vs.* the reduced sulfur content of the environment. The equation is $r = 42.3 \times 10^{-4} (S_x)^{0.33}$ where r is the mean site corrosion rate and S_x is the reduced sulfur arithmetic mean over the test interval. This is even more

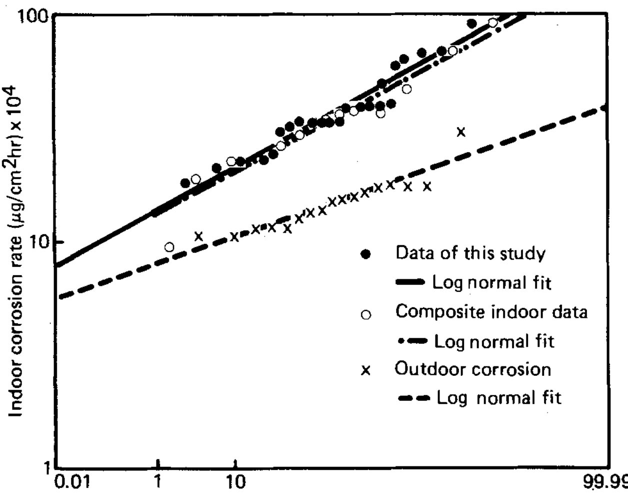

Fig. 3. Silver corrosion rate distribution. x — 9 × 15 = cumulative percentage of measurements.

plausible for silver because it is less sensitive to SO_2 and RH than copper (27).

Nickel.—The corrosion rate of nickel showed linear kinetics for most of the indoor locations, unlike copper and silver. Campbell and Thomas (10) showed a marked seasonal dependence for nickel indoor corrosion in switching rooms. Winter corrosion was often only 10-20% of the summer value. The fact that we observed linear kinetics over the 1.5 year interval may indicate that the air conditioned facilities buffer the humidity extremes and average the corrosiveness of the environment.

The corrosion products on nickel were only measured by AES, Table IX summarizes the results. Suffice it to say that in addition to nickel, sulfur, chlorine, oxygen, carbon, and nitrogen were present in the corrosion product. The corrosion product on nickel exposed to outdoor environments is a complex combination of basic nickel hydroxy chloro sulfate as summarized by Aziz and Goddard (32).

The indoor and outdoor corrosion rates were fit to the lognormal distributions summarized in Table IV and shown in Fig. 4. The lognormal fit was good. The composite indoor distribution agreed with this study. The geometric mean of the outdoor rates (33) is 100 times that of the indoor rates. This again demonstrates the significant positive influence buildings have on reducing materials corrosion.

The corrosion rate of nickel has been shown in laboratory studies to be strongly influenced by relative humidity, SO_2, NO_2, Cl_2, and hygroscopic salts (34-37). The field mean site indoor corrosion rates correlated best with the chloride content, Cl_x, of the environment yielding an equation of the form $r = 0.0448 (Cl_x)^{2.24}$

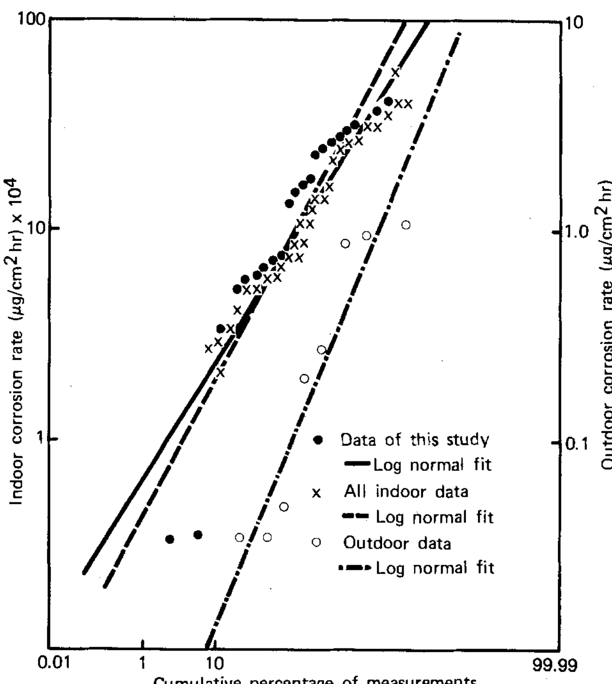

Fig. 4. Nickel corrosion rate distribution

with a correlation coefficient equal to 0.93. Unlike copper and silver, nickel shows little correlation with the reduced sulfur levels in the environment. Figure 5 shows the data and fit comparison.

Cobalt.—Cobalt's chemistry is very similar to nickel and we would expect its atmospheric corrosion to be similar. Very litle has been published on the atmospheric corrosion of cobalt, although it is a significant alloying additive in many corrosion resistant materials (38). Cobalt's indoor corrosion rate was very similar to nickel in this study. The kinetics were closer to linear except for the very clean Texas site. The mean indoor corrosion rate was less than both copper and silver.

The corrosion product summary is given in Table X. The cobalt was present in an oxidized bonding state at concentrations ranging from 6.8 to 13 a/o. A large quantity of oxygen was present ranging from 57 to 72 a/o. Chlorides were present between 2.1-8.6 a/o. Sulfur was in the form of sulfate or sulfite, not sulfide.

Figure 6 summarizes the lognormal fit of the cobalt indoor corrosion rates. There has been neither indoor nor outdoor data published on cobalt for comparison to this study.

Like nickel, cobalt corrosion is significantly influenced by relative humidity, sulfur dioxide, and chlorine (38). The correlations of any one pollutant to the observed field corrosion rate were not good for cobalt.

Iron.—The indoor corrosion of iron showed a range of kinetics from parabolic at the less corrosive sites to linear at the more corrosive sites. The nonair-conditioned sites exhibited the highest rates. The indoor data were fit to a lognormal distribution with a correlation coefficient equal to 0.98. The iron indoor corrosion rates showed the largest standard deviation of the metals tested. A comparison of the indoor data to an outdoor distribution created from some of the published data (39-41), Fig. 7, shows that the indoor environment reduces iron corrosion by a factor of 1/2000, significantly more than for the other metals tested. The corrosion products (Table XI) show the presence of oxidized iron, sulfate, nitrite, hydroxide, oxide, and carbonate. Only one site showed chlorides. There is no simple correlation of pollutant concentration with the observed iron corrosion rates.

Metallic corrosion summary.—A summary of the metallic corrosion results is given in Table XII. The

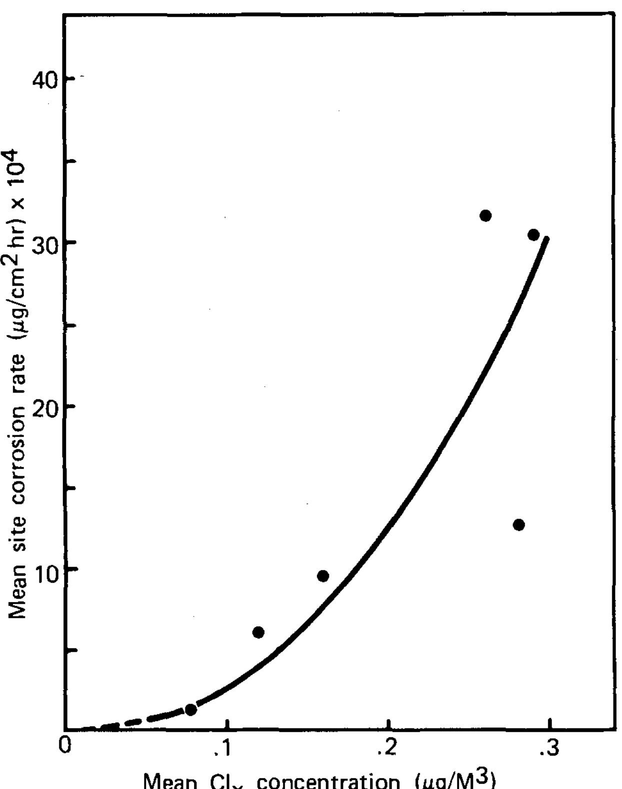

Fig. 5. Nickel corrosion rate vs. chlorine gas concentration

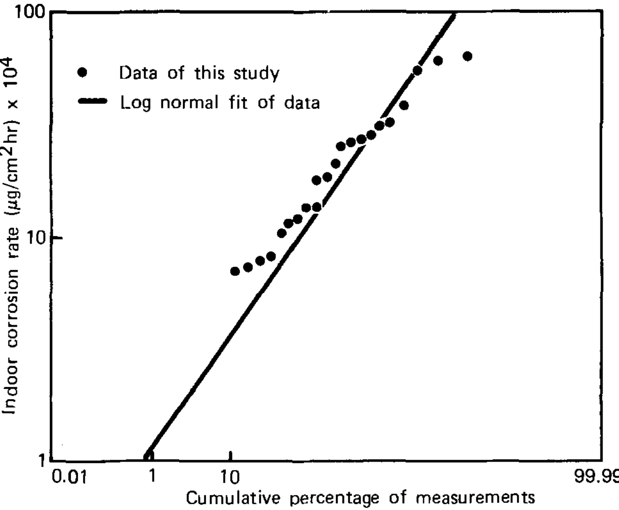

Fig 6. Cobalt corrosion rate distribution

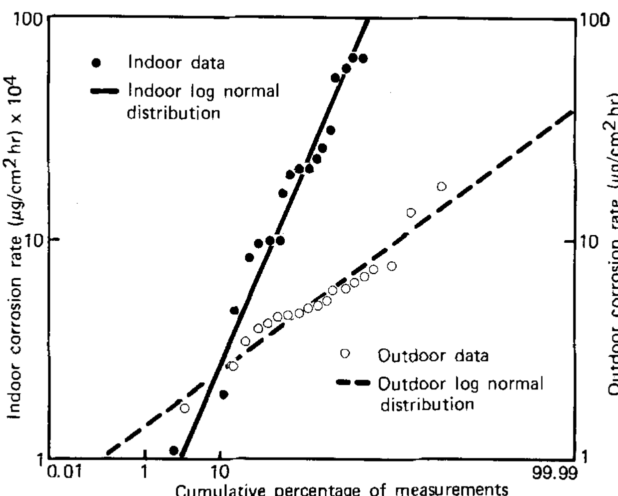

Fig. 7. Iron corrosion rate distribution

corrosion kinetics range from linear to parabolic. Corrosion products are complex consisting of sulfates (sulfites), chlorides, carbonates, nitrates (nitrites), and hydroxides. Silver showed the presence of sulfide instead of sulfate.

The indoor corrosion rate geometric means, obtained from the lognormal distributions for each metal, differed by only a factor of 3, with silver being the most corrosive and nickel the least. Lognormal statistics were obeyed by all corrosion rates both indoors and outdoors over the site populations studied. A comparison of outdoor to indoor rates shows silver to corrode similarly indoors and outdoors, copper and nickel to corrode 100 times greater outdoors, and iron 2000 times greater. We propose that the reason for this marked difference in the indoor/outdoor ratio for these metals is in their corrosion rate sensitivity to relative humidity. Iron is markedly accelerated by outdoor high humidity excursions, while silver is not at all. The corrosion rate, r, dependence on relative humidity, RH, for each metal can be expressed by an equation of the form $r = ae^{bRH}$ where b is the measure of the corrosion rate sensitivity to RH. Table XII summarizes the constant b for each metal and shows iron to be comparatively sensitive, silver insensitive, and Cu, Ni, Co to be sensitive and about the same. In outdoor environments where higher humidities are more probable, iron will be most affected and silver least. Iron had the largest sigma, while silver had the lowest sigma for indoor corrosion. This may result from the same sensitivity to RH as shown above.

Atmospheric Parameters

Pollutants.—The environmental factors that influence metallic corrosion are as varied as the types of metals. Some of those factors that are clearly established include water vapor, sulfur dioxide, sulfur gases, chlorides, and salt particles (2-6). These factors may be significantly influenced inside buildings by loss mechanisms on internal surfaces (42), air filters, and air conditioning systems (7, 8). Models that relate outdoor to indoor pollutant levels have been proposed with some demonstrated success for ozone (7).

Relative humidity.—The relative humidity mean for the air-conditioned sites ranged from a low of 44% at New York to a high of 59% at the Texas site. While a normal distribution, Fig. 8, was found to fit the composite data, it did not at all represent each of the individual sites. Multimodal distributions were observed at some of the sites. These could be related to seasonal variations. Generally, the summer months were the biggest contributor to the high humidity peaks and the winter months to the low humidity peaks. One clearly cannot account for the relative severity of sites on the basis of RH alone. The Texas site was generally the least corrosive but exhibited the highest mean RH. Furthermore, the site severity did not correlate very well with high humidity excursions alone.

Sulfur dioxide.—Sulfur dioxide is the most studied pollutant with respect to atmospheric corrosion. It is highly soluble in aqueous phases, can profoundly influence metallic corrosion, and is present at comparatively high concentrations in urban environments. Burning of fossil fuels is the predominant anthropogenic source. The indoor SO_2 measurements made in this study are shown in Fig. 9. Significant seasonal trends were observed for the eastern U.S. sites. This is typical of the trends of outdoor levels in the high fossil fuel use regions of the U.S. In New York, the indoor concentrations range from 106 in the winter to less than 2 $\mu g/m^3$ in the summer. Indiana and Chicago sites exhibited similar seasonal fluctuations. The mean indoor SO_2 concentration in the New York City site, 39.6 $\mu g/m^3$, was approximately 50% of the outdoor level reported at stations in Manhattan in 1974 (43). Furthermore, the mean indoor site SO_2 average concentration from this study, 12.2 $\mu g/m^3$, is 69% of the mean outdoor site average, 17.6 $\mu g/m^3$, for 840 monitoring stations reported by the U.S. Environmental Protection Agency in 1975 (44).

Nitrogen dioxide.—Nitrogen dioxide's influence on metallic corrosion has not been studied extensively. It is a precursor to nitrous and nitric acid. Its urban concentrations are comparatively high. Urban anthropogenic NO_2 is a secondary pollutant resulting from the oxidation of NO. It shows regional highs in the western U.S. Figure 10 shows the indoor results for the six sites monitored in this study. Los Angeles has the highest NO_2 level and the seasonal fluctuations are typical of outdoor Los Angeles. The indoor Los Angeles NO_2 concentration, 55.8, is approximately 80% of the outdoor levels of 69 $\mu g/m^3$ in major California urban areas (45). The mean NO_2 indoor site average is 26 $\mu g/m^3$. This indoor mean is 60% of the outdoor average of 43.5 $\mu g/m^3$ for 701 U.S. monitoring stations for 1975 (46).

Reduced sulfur.—The reduced sulfur gases, which include H_2S, sulfur vapor, and mercaptans, significantly influence copper and silver corrosion (27), as well as accelerate stress corrosion cracking of steel (47). The source is predominantly organic decay processes, fossil fuel combustion, and refining. There is a paucity of published data for H_2S or reduced sulfur gas levels. This is due to the extremely low levels normally encountered in the atmosphere and the lack of sensitive, reliable measurement methods. The best reported estimates of the H_2S background levels in unpolluted air are from 0.2 to 0.5 $\mu g/cm^3$ (48). Urban levels around 34 $\mu g/m^3$ have been reported, but these were probably near localized sources of H_2S (49, 50). Our limited measurements in four cities (Chicago, Los Angeles, New York, and San Jose) indicate that the average outdoor total reduced sulfur levels are below 1 $\mu g/m^3$.

The monthly average measurements for each of the indoor sites are summarized in Fig. 11. A slight seasonal dependence is seen for all sites. The winter levels are higher, probably resulting from enhanced fossil fuel use. The indoor levels, except for South Carolina, are only slightly higher than reported background levels; however, they are quite near the expected outdoor levels as indicated above. In an independent

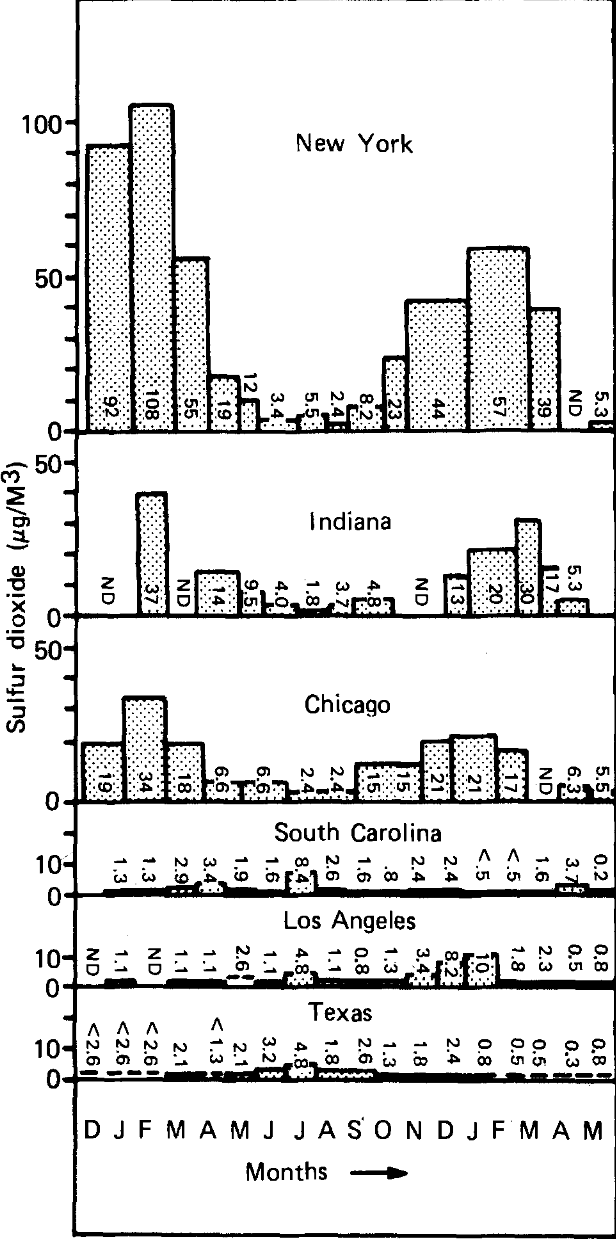

Fig. 9. Indoor concentration of sulfur dioxide at 6 sites for 18 months.

study, using the measurement techniques outlined here, indoor and outdoor reduced sulfur levels were monitored continuously for one to two years at sites in Los Angeles and San Jose, California. In both cases the indoor measurements were made in modern, air-conditioned office buildings. The results for San Jose showed an average outdoor level of 0.25 and an indoor level of 0.19 $\mu g/m^3$. For Los Angeles the average outdoor level was 0.32 and the indoor level was 0.35 $\mu g/m^3$. There was obviously little attenuation of reduced sulfur gas levels from outdoor to indoor environments. In fact, the higher indoor level in Los Angeles indicates some internal source of this gas. The silver corrosion data tend to confirm the similar indoor and outdoor levels, in that the corrosion rates are also similar, and the reduced sulfur gases are known to be primarily responsible for silver corrosion.

Ammonia.—Ammonia accelerates the corrosion of cobalt and silver, but not nickel and copper, degrades organics, dissolves readily in water, and originates from many anthropogenic and natural sources (50).

The ammonia in the indoor environments showed the monthly average concentrations shown in Fig. 12. Five of the sites had geometric means between 10-22

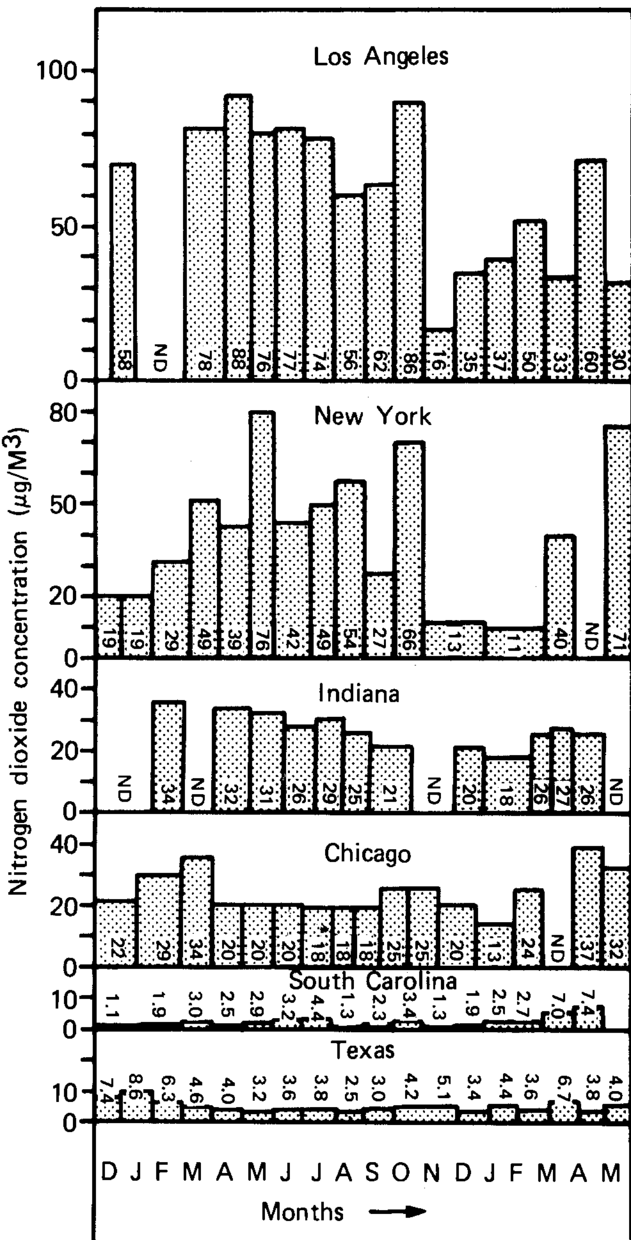

Fig. 10. Indoor concentration of nitrogen dioxide at 6 sites for 18 months.

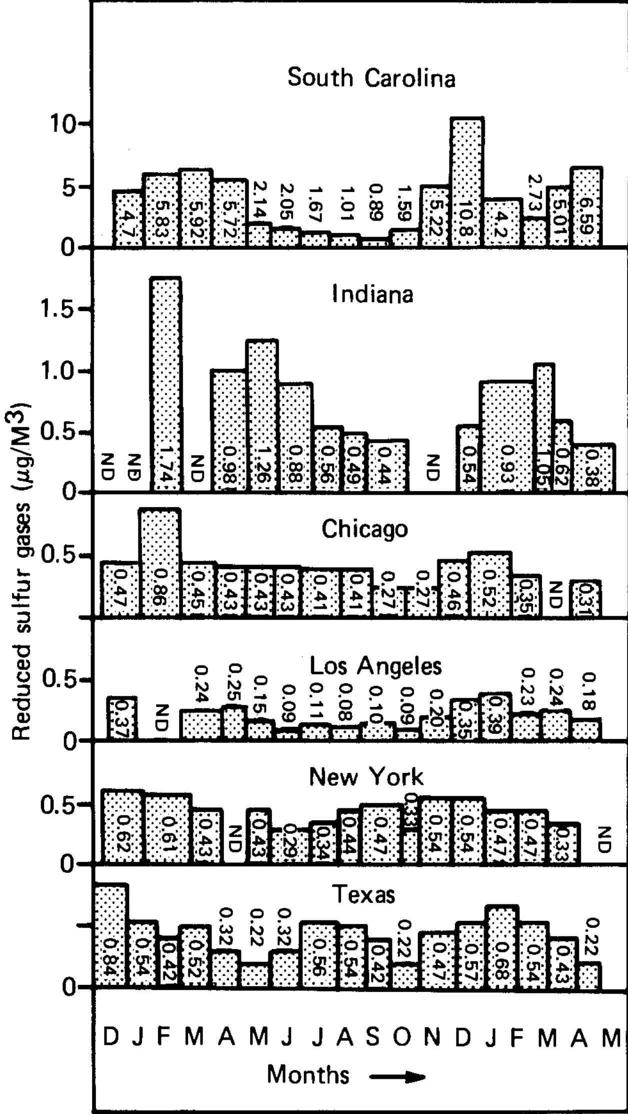

Fig. 11. Indoor concentration of reduced sulfur gases at 6 sites for 18 months.

μg/m³. These values are equal to or slightly greater than reported outdoor urban concentrations of 10 μg/m³ (51). Furthermore, no seasonal variations are apparent in the indoor data. Internal generation of ammonia is expected to be a significant source unlike most of the other pollutants. The air-conditioned industrial Texas site showed NH_3 concentrations at least an order of magnitude greater than the others, which is suspected to result from a reproduction system using anhydrous ammonia in an adjacent room.

Chlorine gases.—Chlorine gases, which include Cl_2 and HCl, accelerate the corrosion of nickel, cobalt, and silver, enhance pinhole corrosion of many materials, and degrade insulator surfaces. The critical role of chlorides in aqueous electrochemical decay of metals is well recognized. The anthropogenic nonindustrial sources of the chlorine gases are incineration of synthetics, burning of fossil fuels, water treatment, and insecticides. Interaction of NO_2 with chloride containing salts from ocean spray is thought to be an important natural source of HCl (52).

The indoor measurements are shown in Fig. 13. The geometric mean ranged from 0.08 to 0.29 μg/m³. No significant seasonal variation was observed. These indoor values are 20% or less of the values estimated for outdoor urban areas, 1.52 μg/m³ (53, 54). Indoor chlorine gas concentration correlated reasonably well with nickel corrosion.

Airborne dust.—Airborne dust can settle on materials which may increase the amount of local water as well as result in mechanical failures. Particles come from industrial sources, fuel combustion, fires, and natural processes. The median outdoor level is 61 μg/m³ from 3760 sites (55). The dust levels in our study show a site mean between 3-33 μg/m³, Fig. 14. The mean site average is 16 μg/m³ which is 26% of the outdoor mean. No significant seasonal variation was observed for the indoor data. It seems obvious that the indoor dust level is greatly influenced by the quality of the air conditioning and air handling systems.

Pollutant summary.—The measured indoor pollutant mean site concentrations are generally less than mean outdoor values in the United States except for NH_3 and reduced sulfur. Table XIII summarizes the mean indoor and outdoor levels as well as the ratio of indoor to outdoor concentrations.

Conclusions

The indoor corrosion rates of Cu, Ag, Ni, Co, and Fe are lognormally distributed with respect to the sam-

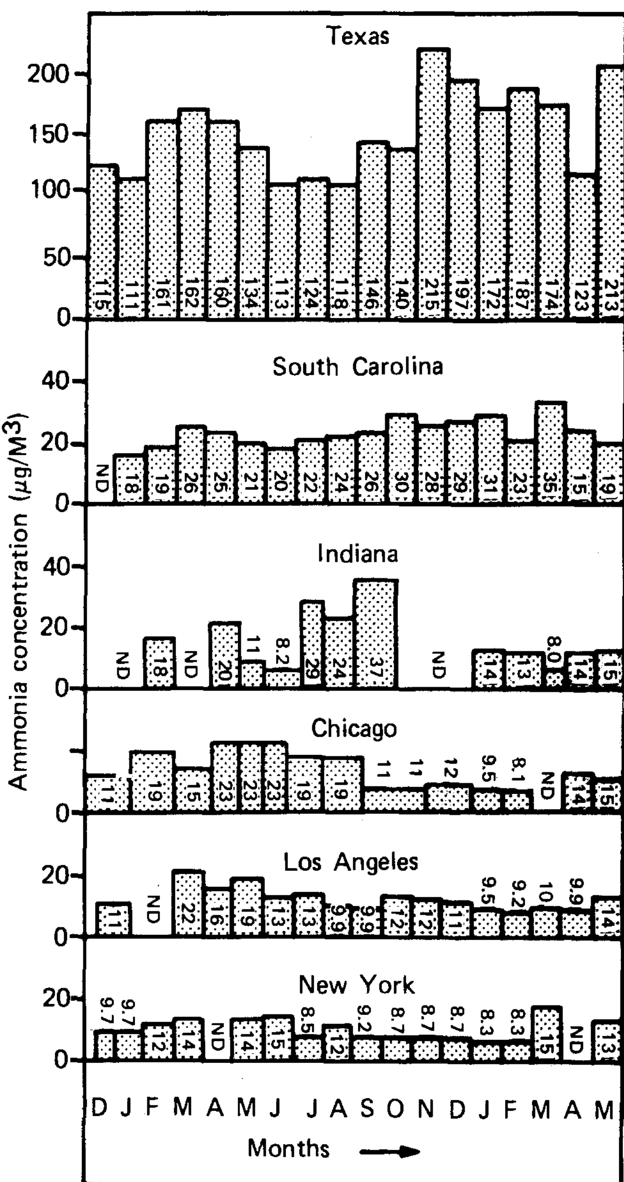

Fig. 12. Indoor concentration of ammonia at 6 sites for 18 months

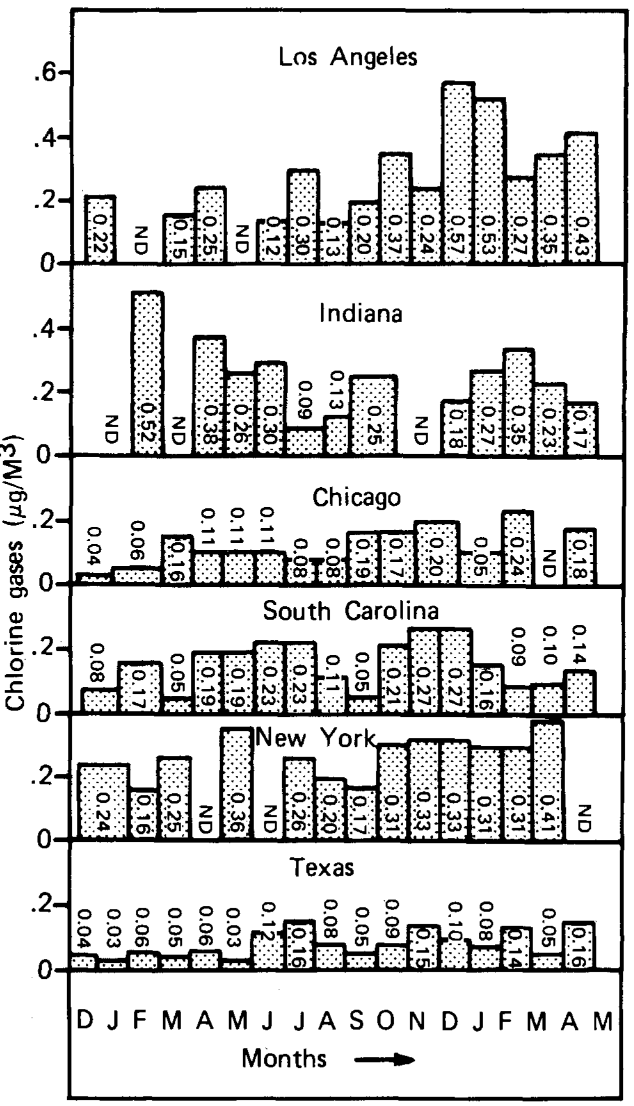

Fig. 13. Indoor concentration of chlorine gases at 6 sites for 18 months.

ple population in this study. The rates are significantly less than outdoor values except for silver. The corrosion products on all of these metals are complex hydroxides, carbonates, sulfates or sulfides, nitrates, and chlorides. Indoor pollutant concentrations of reduced sulfur and chlorine gases are reasonable indicators of the atmospheric corrosive severity toward Cu/Ag and Ni, respectively. The indoor pollutant levels, except for NH_3, and possibly reduced sulfur gases, are less than mean outdoor levels. The marked reduction in indoor metallic corrosion must be accounted for by both a reduction in high humidity occurrences and a reduction in pollutant level. The fact that silver corrosion is about the same indoors and outdoors is accounted for by the similarity of reduced sulfur gas levels and the lack of a corrosion rate dependence on relative humidity.

Table XIII. Comparison of indoor and outdoor pollutant concentrations (μg/m³)

Pollutant	Indoor* (C_I)	Outdoor** (C_O)	$\frac{C_I}{C_O} \times 100$ (%)
SO_2	12.2	17.6	69
NO_2	26.0	43.5	60
NH_3	14.9	10.0	149
Reduced sulfur	0.48	0.48***	100
Chlorine gases	0.2	1.5	13
Airborne dust	16.0	61.0	26

* Average of site means.
** See text for references and discussion.
*** This number is based upon two California sites where indoor and outdoor levels are approximately equivalent.

Steam Oxidation of Fe-32% Ni-23% Cr Alloys with Manganese and Carbon

H. F. Bittner,*[,1] J. T. Bell, and J. F. Land

Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

Effects of manganese and carbon on oxidation properties of simulated Incoloy 800 were determined. Iron-base alloys containing 32% nickel and 23% chromium were prepared with 0, 1, or 2% manganese and residual (0.002%) or 0.1% carbon. Samples were exposed at 660°C to 0.94 atm steam for 2, 48, 528 hr, and resulting oxides were examined by optical microscopy and analyzed using Secondary Ion Mass Spectrometry (SIMS) as well as x-ray diffraction techniques. Carbon additions in all cases led to thicker oxides with higher αFe_2O_3 to Cr_2O_3 ratios. Manganese was incorporated into the spinel phase, forming $Mn(Fe_{1-x}Cr_x)_2O_4$. Manganese additions to alloys containing carbon tended to mitigate the effects of carbon additions, leading to thinner oxides with lower αFe_2O_3 to Cr_2O_3 ratios.

This work is part of an effort to characterize high temperature oxidation properties of structural materials important to energy systems. Within this study, *in situ* formed oxide coatings on steam generator materials have been proposed as tritium permeation barriers, and tritium permeation through oxide coatings on Incoloy 800 has been measured (1). These *in situ* formed oxides have been chemically analyzed (2), and it was found that manganese, which comprised less than 1% of the bulk Incoloy 800, became greatly enriched in the oxide, to more than 80% in one case. It also became apparent that carbon played an important role in determining the nature of the oxidation products. In order to understand the effects of these two constituents on the oxidation properties of Incoloy 800, iron-chromium-nickel alloys with various amounts of manganese and carbon were prepared with concentrations approximating those of Incoloy 800 (commercial Incoloy 800 contains, in weight percent, 30.0-35.0 Ni, 19.0-23.0 Cr, 37.0-47.0 Fe, 1.5 max Mn, 0.1 max C, 1.0 max Si, 0.15-0.60 Al, 0.15-0.60 Ti). Tab samples of these alloys were oxidized under the same conditions employed in the earlier studies involving Incoloy 800 (1, 2), and resulting oxides were analyzed using SIMS, x-ray diffraction, and optical microscopy.

Effects of manganese on the oxidation properties of several different alloys have been investigated by other researchers. Caplan *et al.* (3) studied the effect of 1% manganese addition to Fe-26Cr, exposing the alloys to 1 atm pure oxygen at 870°C for 98 hr or 1090°C for 20 hr. Analysis of resulting oxides showed that manganese addition promoted formation of a spinel structure, probably $MnCr_2O_4$. Under the experimental conditions of that study, the alloy containing manganese showed a greater weight gain. Francis (4) studied 20Cr-25Ni-Nb stabilized steels with and without 0.7% manganese. Oxidation was performed in carbon dioxide at 750° or 850°C for 100 hr. At the higher temperature, manganese promoted formation of the spinel $Mn_xFe_{3-x}O_4$. At both temperatures, manganese led to a greater weight gain, and decreased the amount of Fe_2O_3 in the surface film. Douglas and Armijo (5) studied the effect of manganese addition to Ni-20 Cr alloys. Oxidation conditions were 0.21 atm oxygen at 600°, 1100°, and 1200°C for times up to 3 weeks. Three percent addition of manganese promoted formation of an inner layer of $MnCr_2O_4$, whereas 1% manganese addition did not. It was concluded that 3% manganese resulted in a reduced oxidation rate; however, as these authors point out, if spalling occurred at short oxidation times, this conclusion based on weight gain measurements might not be valid.

The effect of carbon on oxidation properties of stainless steels has been recognized for some time; Bain *et al.* (6) stated that austenitic stainless steels, after exposure to moderately elevated temperatures, became susceptible to intergranular corrosion. These authors developed a phenomenological model which attributed this sensitization to formation of chromium carbides at grain boundaries with concomitant depletion of chromium in adjacent regions. A detailed review of research performed concerning the role of carbon in sensitization of stainless steels has appeared (7). In that review, the chromium depletion theory is supported as the most widely accepted model to account for intergranular corrosion as a result of sensitization. Factors promoting sensitization are increased carbon content, decreased chromium content, and heat-treatments high enough to promote carbide precipitation at grain boundaries, but sufficiently low so as not to allow chromium diffusion into the chromium depleted regions. Carbon-gettering materials are added to some steels to preferentially tie up the carbon, such as titanium in the case of Incoloy 800, and thereby minimize sensitization. The temperature range for sensitization of Incoloy 800 is 540°-760°C (8). Generally, sensitization studies have been associated with passivation *vs.* nonpassivation; to our knowledge no studies have been carried out associated with effects of carbon on the chemical species of oxide produced.

Comparison of oxidation studies must be done carefully because the number of variable parameters is large, and includes oxidizing atmosphere, pressure, temperature, time, alloy composition, and sample pretreatment. Our previous work (2) has shown that sample pretreatment can be especially important to oxidation characteristics. For this reason, fabrication of the alloys was carried out under strictly prescribed conditions, based on findings of our earlier studies. Other parameters involved in the oxidation process were comparable to those in our previous work (1, 2).

Experimental

Samples were prepared from high purity materials using induction melting techniques. Ingots were subsequently hot-rolled at 1100°C to 0.403 cm, then cold-rolled to 0.315 ± 0.008 cm. The materials were then stress relieved at 900°C for 30 min. Coupons approximately 1.5 × 0.5 cm were cut from the sheets, degreased, and then electropolished. Samples were tested for susceptibility to intergranular corrosion using the

Table I. Compositions of alloys

Sample number	Metal composition (weight percent) Fe	Cr	Ni	Mn	Carbon content (weight ppm)
1	45.2	22.6	31.9	—	986
2	45.1	22.6	32.2	—	17
3	45.9	22.6	31.4	1.04	916
4	44.8	22.4	31.0	1.05	17
5	46.1	21.3	31.4	2.17	948
6	44.8	21.4	30.8	2.15	16

acid ferric sulfate test (ASTM Designation G28-71). Samples which contained added carbon sustained a significant weight loss, indicating sensitization, while those samples which contained only residual carbon showed virtually no weight loss. Therefore, without consideration for the effects of manganese, it was expected that samples containing added carbon would undergo a greater degree of oxidation due to intergranular corrosion.

Coupons were oxidized for 2, 48, and 528 hr at 660°C in 0.94 atm steam carried by an argon-hydrogen mixture yielding a hydrogen to water ratio of 2.2×10^{-5}, simulating the environment of previous tritium permeation experiments (1). Intact oxide coatings on samples exposed 528 hr were analyzed by x-ray diffraction techniques. Cross sections of all samples were mounted in epoxy, polished, and then analyzed by secondary ion mass spectrometry (SIMS) and optical microscopy. Relative amounts of phases identified by x-ray diffraction were calculated by integrating the area under the most intense reflection for each phase. Lattice parameters were obtained by standard techniques.

Results and Discussion

Samples oxidized for 528 hr were characterized in some detail, using SIMS, x-ray diffraction, and optical microscopy. The bulk of this section will be devoted to a discussion of these results. Samples oxidized for 2 and 48 hr were analyzed in a more cursory fashion with SIMS and optical microscopy, and will be briefly discussed towards the end of this section; results from these samples help elucidate the mechanism for formation of the oxides.

Compositions of alloys based on chemical analyses are given in Table I. X-ray diffraction results are presented in Table II for the oxides on samples oxidized 528 hr, along with oxide thicknesses measured by optical microscopy. In general, oxides formed after 528 hr exposure were relatively uniform in thickness and adherent to the base metal, with the exception of sample 1. This sample, which contained 0.1% carbon and no manganese, had a thick oxide which showed evidence of spalling and was less uniform than oxides on other samples; the micrograph for the cross section of this sample is presented in Fig. 1(a). Micrographs for cross sections of sample 2, which contained no manganese and residual carbon, and sample 3, which contained 1% manganese and 0.1% carbon, are presented in Fig. 1(b) and (c), respectively.

The effect of carbon with no manganese was best seen by comparison of ion microprobe profiles for samples 1 and 2, exposed for 528 hr, containing 0.1% and residual carbon, respectively (see Fig. 2 and 3). The oxide on the sample with added carbon was considerably thicker (see Table II), and enriched in iron at the surface with an enrichment of chromium beneath the iron. SIMS results, Fig. 2, indicated a greater total amount of chromium than iron in the oxide, but x-ray diffraction results indicated a ratio of αFe_2O_3 to Cr_2O_3 of 1.3; therefore, the bulk of the chromium must have been incorporated in the spinel phase. The lattice parameter measured for the spinel phase, $a_o = 8.35Å$, is in agreement with a stoichiometry $(Ni_{1-x}Fe_x)Cr_2O_4$, according to Yearian *et al.* (9). The nickel enrichment towards the surface of the oxide, Fig. 2, likely was in the form $(Ni_{1-x}Fe_x)Fe_2O_4$, which has a lattice parameter very similar to that of the $(Ni_{1-x}Fe_x)Cr_2O_4$ system (9), and could therefore not be distinguished by x-ray diffraction. The specimen with no added carbon, sample 2 shown in Fig. 3, had a much thinner oxide; the ratio of spinel phase to hexagonal phases (αFe_2O_3 and Cr_2O_3) was about the same; however, the ratio of αFe_2O_3 to Cr_2O_3 was about 0.5, much lower than the sample with 0.1% carbon. The lattice parameter for the spinel phase on the sample with residual carbon was only slightly smaller than the one for that phase on the sample with added carbon; therefore, the composition of this spinel phase also was expected to be $(Ni_{1-x}Fe_x)Cr_2O_4$. The major difference in these two samples, then, is that the sample with no added carbon had a much thinner oxide with a smaller αFe_2O_3 to Cr_2O_3 ratio.

The effect of manganese in the absence of added carbon was apparent from comparison of samples 2 and 4 oxidized for 528 hr containing 0 and 1% manganese, respectively. SIMS results for sample 2 are shown in Fig. 3, and indicate that the oxide is rich in chromium. SIMS results for sample 4, containing 1% manganese, showed that the oxide was rich in chromium and manganese. The oxide on this sample was approximately half as thick as that observed on sample 2 which contained no manganese; however, relative amounts of αFe_2O_3, Cr_2O_3, and spinel phase were similar for each sample. Lattice parameters for the spinel phases were different; the larger lattice parameter for sample 4, $a_o = 8.41Å$, is consistent with a spinel containing manganese (10), and similar to that for $MnCr_2O_4$, $a_o = 8.426Å$ (11). (Diffraction peaks for the spinel phase on samples which contained manganese were broader relative to reflections for spinels on samples without manganese. This indicated a strained structure or the presence of several spinel phases of similar lattice parameter.)

Effects of manganese were most apparent in comparison of samples 1 and 3, exposed for 528 hr, the former containing no manganese and the latter 1%, and both containing 0.1% added carbon; SIMS results are shown in Fig. 2 and 4, respectively. The oxide on the sample containing manganese was almost a factor of ten thinner, and was rich in chromium and manganese, whereas the oxide in the sample with no manganese

was rich in iron at the surface. X-ray diffraction results, Table II, show that the sample containing manganese had a lower αFe_2O_3 to Cr_2O_3 ratio, and that the spinel phase comprised a greater percentage of the total oxide. The spinel lattice parameter for the sample containing manganese, a_o = 8.46Å, probably corresponded to $Mn(Fe_{1-x}Cr_x)_2O_4$ (11), while the primary spinel phase on the sample with no manganese was $(Ni_{1-x}Fe_x)Cr_2O_4$, as discussed previously.

Results for the specimens containing 2% manganese, with 0.1 and 0.0% carbon (samples 5 and 6, respectively) oxidized for 528 hr, are not greatly different

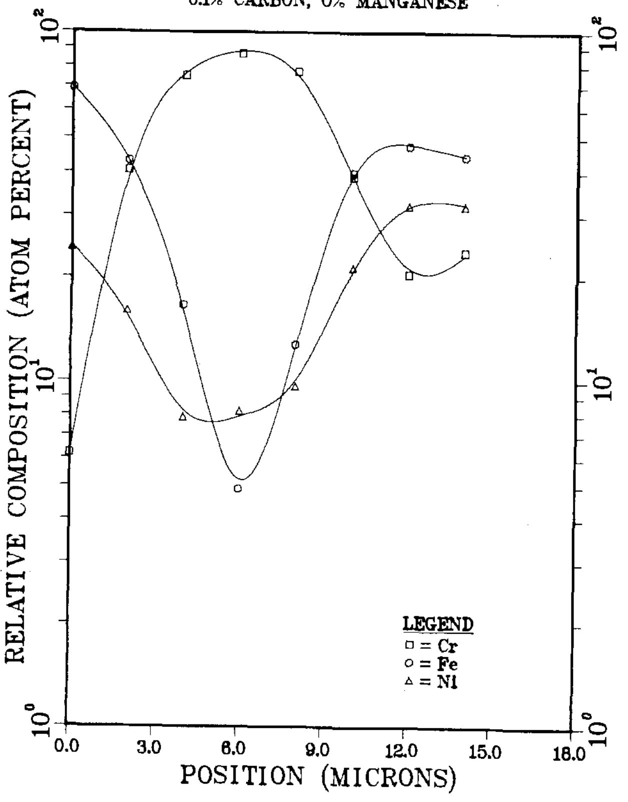

Fig. 2. Ion microprobe profile for sample 1, oxidized for 528 hr. Steam-oxide interface is at zero microns.

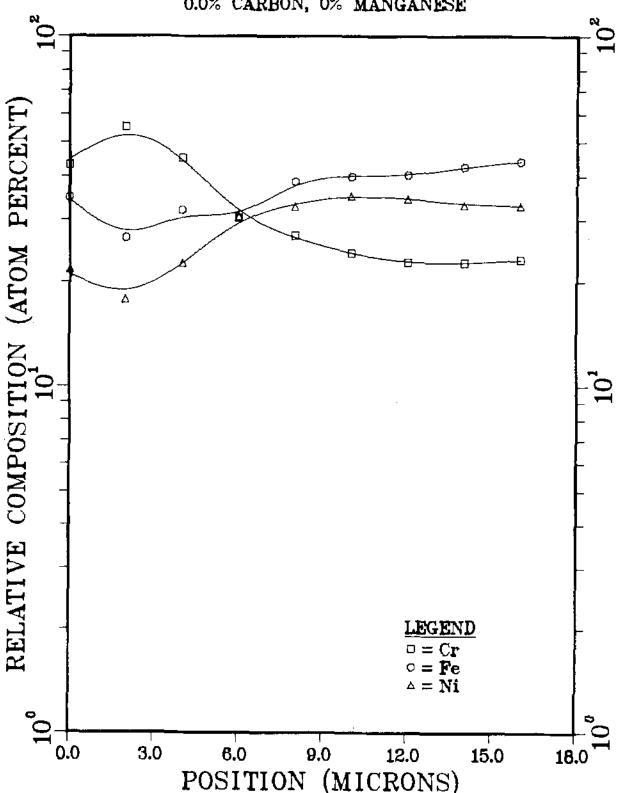

Fig. 3. Ion microprobe profile for sample 2, oxidized for 528 hr. Steam-oxide interface is at zero microns.

than those for specimens containing 1% manganese, samples 3 and 4. The higher manganese content led to a somewhat larger percentage of spinel phase in the oxide and to a slightly larger αFe_2O_3 to Cr_2O_3 ratio. The oxide thickness was virtually identical for specimens containing 1 and 2% manganese and no added carbon, samples 4 and 6. However, in the presence of added carbon, 2% manganese led to a somewhat thicker and less uniform oxide than the sample containing 1% manganese. The difference in thickness was not large, 2.1 *vs.* 1.4 microns, particularly in comparison with the 11 microns thick oxide on the sample containing added carbon and no manganese. It may be that approximately 1% manganese substitution is the optimum content for producing a thin protective oxide coating. It is noted here that Caplan *et al.* (3) and Francis (4) found greater weight gains after 100 hr oxidation for samples containing manganese. However, spalling might have occurred with longer oxidation times, as was observed in the present work, discussed below.

Ion microprobe analyses were performed for samples exposed 2 and 48 hr; results are summarized here, and give an indication of the mechanism for formation of the oxides after 528 hr exposure. Sample 1, containing 0.1% carbon and no manganese, formed a very thick, scaly iron oxide at the surface for all exposure times studied. Regions of chromium-rich oxide, which formed beneath the iron oxide layer, grew with longer exposure times; chromium was not observed at the surface of the oxide. Sample 2, which contained no added carbon or manganese, showed regions of chromium oxide at the surface interspersed with regions of iron oxide after 2 hr oxidation; further exposure resulted in a more uniform oxide comprised primarily of chromium. Apparently the iron oxide, which formed initially, spalled with further oxidation; this characteristic was found for other samples. The general trend was that those samples which contained carbon required a longer exposure time to effect formation of a uniform chromium oxide layer, with concomitant spalling of the outer iron oxide; manganese showed the opposite effect, tending to promote formation of the uniform chromium oxide layer at the surface. The two extremes are sample 1, containing no manganese and 0.1% carbon, which never formed a chromium oxide layer at the surface, and sample 6, containing 2% manganese and only residual carbon, which formed a nearly complete chromium oxide layer after 48 hr. This mechanism for formation of a chromium oxide layer, via initial iron oxide formation which subsequently spalls, was also found for commercial Incoloy 800 in our earlier work (2).

These results clearly indicate that carbon stimulates a greater degree of oxidation after 528 hr steam exposure, with the oxide containing a large amount of iron. This may be due to formation of chromium carbide precipitates along grain boundaries, which could deplete chromium in these regions and inhibit formation of a protective Cr_2O_3 layer (7). The greater iron content of the oxides on samples containing added carbon would be consistent with chromium depletion at the grain boundaries. Manganese substitution, however, seemingly reversed the effects of added carbon. The reasons for this are not clear; however, Glen (12) reported that manganese reduced the diffusion of carbon in carbon steel, and Austin (13) found that manganese in carbon steel caused a re-solution of iron carbide and subsequent precipitation of manganese carbide. It is unlikely, though, that manganese would cause a re-solution of chromium carbide, since the latter is more stable (14). From the present study it is apparent that manganese subsequently led to formation of a manganese-containing spinel, in agreement with the findings of Caplan *et al.* (6); the formation of this phase may account for the different oxidation characteristics of carbon-containing samples with and without manganese substitution.

Summary

The following observations have been made regarding the 660°C steam oxidation for 528 hr of Fe-32 Ni-23 Cr alloys with manganese substitutions and carbon additions:

1. In the absence of manganese, addition of 0.1% carbon led to a much thicker oxide with a higher αFe_2O_3 to Cr_2O_3 ratio.
2. In the absence of added carbon, substitution of 1% manganese led to a somewhat thinner oxide, but did not greatly change the αFe_2O_3 to Cr_2O_3 ratio.
3. For samples containing 0.1% carbon, substitution of 1% manganese led to an oxide one-tenth the thickness with a lower αFe_2O_3 to Cr_2O_3 ratio.
4. Higher manganese substitutions led to a greater percentage of spinel phase in the oxides.
5. In the absence of manganese, the predominant spinel phase was probably $(Ni_{1-x}Fe_x)Cr_2O_4$, whereas for samples containing manganese, the spinel lattice parameters were in close agreement with $Mn(Fe_{1-x}Cr_x)_2O_4$.

A Microstructure Study of Corrosion in Ag-Cu Flex Leads

K. Kumar

The Charles Stark Draper Laboratory, Incorporated, Cambridge, Massachusetts 02139

ABSTRACT

85 Ag-15 Cu flex leads, used as current-carrying conductors in inertial instruments, corrode in a BTFE (bromotrifluoroethylene) fluid environment. The corrosion scale has a nodular appearance similar to that of the Ag-rich particles which are present in the flex lead matrix. The Ag-rich phase is the predominant phase in the material and exists as discrete particles surrounded by the Cu-rich phase located at what appears as a quasi-continuous network of grain boundaries. Corrosion proceeds along the Cu-rich phase resulting in separation of the Ag-rich metallic particles from the matrix and incorporation into the corrosion debris. After buildup of a certain thickness, the corrosion layer detaches from the flex lead (contaminating the fluid) and exposes fresh metal surface for more attack. When the chemical etching behavior of a good lead (one that showed negligible corrosion) was compared to that of a poor lead (where substantial corrosion effects were observed), the good lead was found to etch more slowly, by at least a factor of six. The differences in etching behavior have been attributed mainly to differences in prior thermal history, and partly to possible local variations in overall composition. The observed corrosion has been explained by mechanisms involving chemical reaction between the metallic phases and the fluid, and those involving the formation of an electrochemical corrosion cell.

Current-carrying conductors (flex leads) are used in inertial instruments for transferring power from externally located sources to electromechanical assemblies contained in sealed metal containers which are floated in a fluid medium. Bromotrifluoroethylene (BTFE) fluid is commonly used for suspending the float in a bouyant state. The material selected for flex lead fabrication needs to be solderable (for easy installation and disassembly), have high resistance to deformation from cyclic mechanical loading (to retain its properties with small movements of the float), and have a high electrical conductivity (to reduce energy losses in the form of heat). All of these constraints severely limit the number of materials that can be considered for application.

85 Ag-15 Cu ribbons produced by alternating drawing and annealing processes[1] have been used as flex leads in a BTFE environment. Many of these flex leads have corroded with extended use. The extent of damage introduced has varied from negligible to severe, in some instances even resulting in failure in the current-carrying capability of the flex lead through fracture occurring in the corrosion environment. In addition to the observed deterioration of the flex lead, degradation of fluid properties has also occurred from the chemical reactions that accompany the corrosion processes and from the contamination that is introduced when the corrosion scale separates from the flex lead. Since all of this affects instrument life and reliability, this study was initiated to develop a correspondence between the observed corrosion and the microstructure of the samples. It was hoped that such an approach would aid in the understanding of the causes of the observed failures. This paper reports on the results of these investigations.

Experimental

About 0.5 cm long, 0.0009 cm thick, and 0.025 cm wide 85 Ag-15 Cu ribbons (at different stages of corrosion) were mounted in a resin-containing cast and polished for metallographic examination using standard techniques. The samples were mounted such that the viewing direction was perpendicular to the direction of drawing. The lateral (thin) side of the sample was examined after appropriate chemical etching of the exposed polished surface. The etching solution consisted of 50 ml H_2O, 42 ml HCl, and 8 ml HNO_3. Etching was accomplished by immersing the samples into the

Key words: etch behavior, heat-treatment, phase separation.

[1] Manufactured by Sigmund Cohn Corporation, Mount Vernon, New York.

etching solution at room temperature. The bath was manually agitated during the entire etching procedure. The etched surfaces were photographed using optical and scanning electron microscopy. Chemical analysis was performed using the EDAX (energy dispersive analysis of x-rays) technique.

Results and Discussion

Figure 1 represents an as-polished view of a poor flex lead (one that showed substantial corrosion). The corrosion scale consisted of several submicron size, equidimensional, shiny, metallic-looking particles individually surrounded by a dull-gray exterior. The corrosion scale was about 2 μm thick and appeared to extend fairly uniformly (over its surface) into the ribbon interior. When this sample was etched for 1 min to determine its bulk microstructure, small, submicron size, equidimensional, grain-like features (similar in appearance to the particles found in the corrosion scale) were observed. (See Fig. 2a). The contrast developed upon etching this sample was considered an indication of a two-phase microstructure which was expected for this composition from the binary Ag-Cu phase diagram (1).

The etching response of this poor lead was quite different from that observed for a good lead (one that had shown negligible corrosion). Figure 2b was obtained on the good lead after etching for 1 min. In contrast to the quick response to etching of the poor lead, the good lead showed a fairly featureless interior. Upon increasing the time of etching, however, the contrast was observed to improve and after 6 min of etching, the good lead appeared to assume a level of contrast similar to that observed in Fig. 2a for the poor lead (see Fig. 2c). This slow response to etching of the good lead was interpreted as resulting mainly from differences in second phase composition and distribution (because of differences in prior thermal history,) and from possible slight differences in overall chemical composition (which could give rise to a somewhat lesser amount of the second phase, resulting in an apparently lower level of observed contrast). In any event, it was considered significant that the lead that etched more rapidly was also the one that corroded more severely than the lead that showed a slow response to the etching treatment.

The effects of thermal treatment on etching behavior were investigated by subjecting as-received samples, for different time, to temperatures of 590° and 950°K in hydrogen. Exposure at temperature was followed by rapid removal of the muffle from the furnace resulting in quick cooling of the samples. Subsequent studies were then directly related to the time and temperature of exposure without regard for effects resulting from slow cooling of the material. The heat-treated samples were mounted and polished, and examined for etching response. It was found that increased thermal exposure resulted in a decreased resistance to development of contrast. The micrographs in Fig. 3 show that even a 48-hr exposure to a reasonably low, 590°K, temperature resulted in an enhanced contrast (compared to the as-received material). This thermally activated, enhanced-contrast behavior must have resulted from separation and agglomeration of the second (Cu-rich) phase. The phase agglomeration process is more dramatically illustrated in Fig. 4 which was obtained on a sample that was exposed to 950°K for 24 hr. The Cu-rich phase, in this sample, appears as discrete second phase particles of about 2 μm size, possibly representing a close-to-equilibrium microstructure. 950° and 590°K were selected for sample exposure mainly because the ribbons are subjected to these temperatures during manufacturing and subsequent processing stages. 950°K is used by the manufacturer for annealing (in between drawing operations) and 590°K is used for forming the ribbon into flex lead geometry by conforming the shape of the flex lead ribbon to the curved surface of a preselected metal mandrel. The lack of a

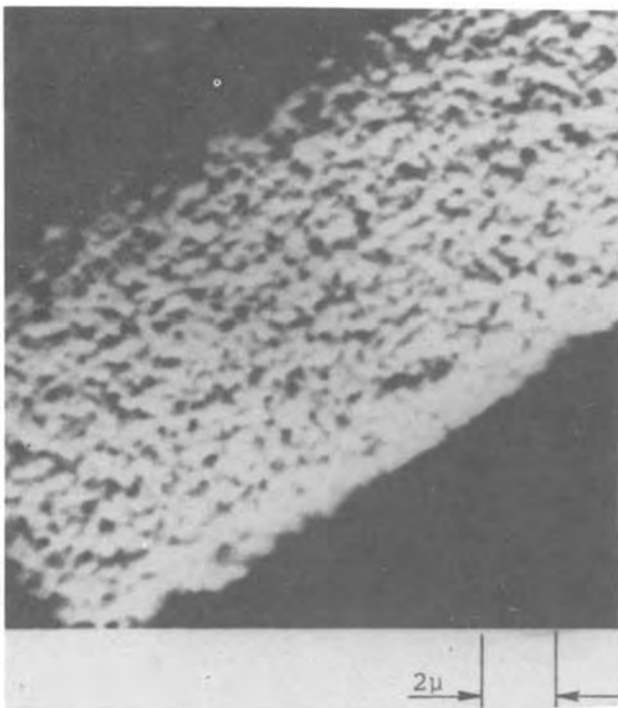

Fig. 5. SEM photograph of 1 min etch poor lead surface showing nodular features.

fibrous texture in the microstructure of these ribbons is attributed to the annealing treatment used by the manufacturer. It is evident that the length of exposure to 950°K during the annealing treatment used by the manufacturer must be considerably shorter than the 24 hr used in this study. This is consistent with the very fine segregation of the Cu-rich phase (at what appears as grain boundaries) present in the as-received material, as opposed to the large discrete Cu-rich particles observed in this study after a 24-hr exposure at 950°K.

The etched sample surfaces were examined in the scanning electron microscope. Nodular-shaped features shown in Fig. 5 were observed in both (the good and poor) flex lead samples. An EDAX analysis of the etched surface showed a deficiency of copper compared to the amount of copper observed for the bulk on the as-polished surface. The copper deficiency was more pronounced in the 1 min etch poor lead sample than in the 6 min etch good lead sample. This is consistent with the slower etching behavior of the good lead sample, and may well indicate that the Ag-rich phase in this sample contains more copper (and, therefore, the Cu-rich phase contains more silver) than in the poor lead sample. The difference in the response of these two samples, as indicated earlier, could then have resulted from the heat-treatment that these leads were subjected to before use in the BTFE fluid. Alternatively, as stated earlier, it could also be argued that the differences in the etching behavior of these samples may have resulted from differences in the relative amounts of the second (Cu-rich phase) present in the samples. But this fails to explain the higher amount of copper measured in the Ag-rich phase of the 6 min etched good lead sample compared to the 1 min etched poor lead sample. In a two-phase alloy, such as this, the composition of the individual phases is determined solely by the heat-treatment that is employed. Changes in overall alloy composition will only affect the relative amounts of the two phases and not their individual compositions. It is, however, clearly possible that both the above mechanisms might have contributed, to some degree, to the differences in the etching behavior of these samples.

The EDAX scans obtained on these samples are shown in Fig. 6. Figure 6 also contains an EDAX scan obtained on the surface of an unattacked region of a flex lead and is, therefore, an indication of the overall composition of this material. These EDAX analyses clearly demonstrate that the chemical etching treatment resulted in preferential dissolution of the Cu-rich phase leaving the Ag-rich nodular phase exposed at the surface. The SEM micrograph of Fig. 5 also suggests that the dissolved (Cu-rich) phase must have been located all around the nodular Ag-rich particles at what appears as a quasi-continuous network of grain boundaries. The as-received microstructure of the ribbons, therefore, essentially consisted of the major, nodular Ag-rich phase dispersed in the minor, quasi-continuous Cu-rich matrix.

The nodular morphology of the Ag-rich particles is quite similar to that found for the corrosion scale. Figure 7 shows SEM photographs obtained on corroded flex lead samples where in one instance part of the scale had separated from the underlying alloy ribbon exposing fresh surface for more attack. This sample, shown in Fig. 7a, had also failed in its current-carrying ability through fracture occurring in the corrosion environment. The exact mode of fracture in these materials is not clear. However, since the flex leads are subjected to very low levels of stress at relatively low frequencies (with small movements of the float), it is possible that fracture resulted from corrosion fatigue of the material. The presence of corrosion products over the entire area of the fracture surface and the absence of the appearance of a region indicative of a shiny brittle-type fracture is attributed to the subsequent corrosion of the freshly formed surface in the fluid environment. Corrosion was found to have occurred at the tip of the flex lead, where fracture had probably taken place, as also on the newly exposed surface, which resulted from separation of the corrosion scale. Even more interesting, however, was the close similarity in appearance of the etched alloy surface (Fig. 5) and the corrosion scale surface (Fig. 7b), thereby clearly indicating a close correspondence between the observed corrosion and the microstructure of the sample.

Corrosion is mostly observed to take place along the Cu-rich phase. This contention is supported by the micrograph of Fig. 1 which shows that the corrosion scale consists of shiny, metallic-looking equidimensional particles surrounded by a dull-gray exterior. These particles exist through the entire thickness of the corrosion scale. Since the thickness of the corrosion layer is considerably more than the size of these particles, it is clear that the corrosion reaction proceeds

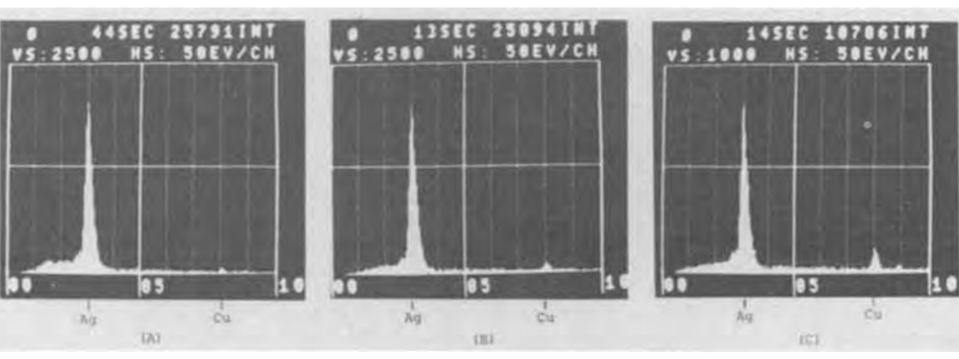

Fig. 6. EDAX scans on (a) poor lead, 1 min etch, (b) good lead, 6 min etch, and (c) unattacked flex lead samples.

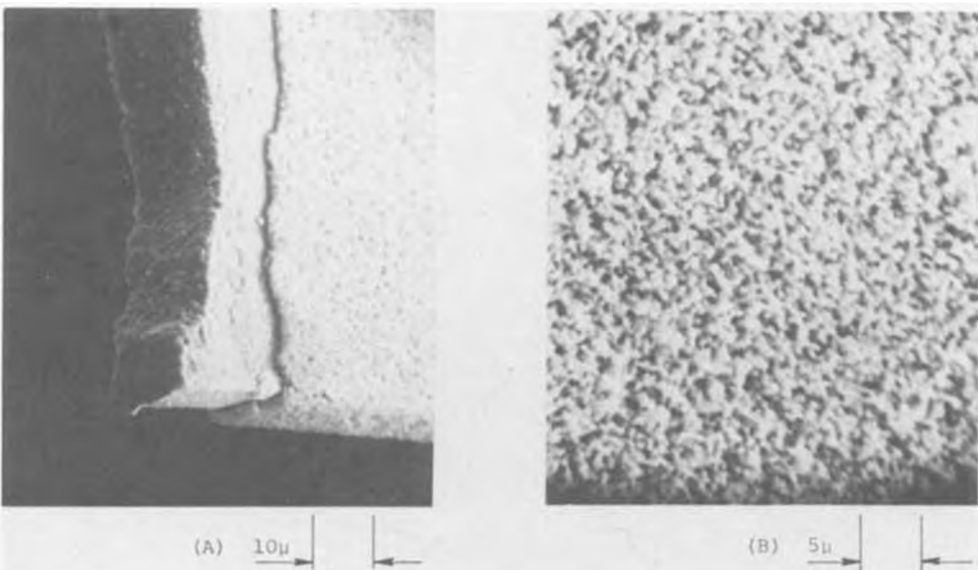

Fig. 7. SEM photographs of (a) corroded flex lead showing area where scale had separated and tip where fracture occurred, and (b) the corrosion scale.

much more rapidly through the (Cu-rich) layer that surrounds the particles than it does into any given (Ag-rich) particle. This results in separation of the Ag-rich particles from the alloy matrix and incorporation into the corrosion debris. The Ag-rich particles in the debris are separated from each other and from the alloy matrix by the dull-gray phase which is believed to be the product of the corrosion reaction. The corrosion scale, therefore, consists of small Ag-rich, single-phase, nodular particles surrounded by a corrosion product which contains bromine (as verified by an EDAX scan) in addition to Cu and Ag. The corrosion layer increases in thickness with continued exposure to the fluid. Detachment of the corrosion scale from the surface, as is found in some instances, is believed to result from an increased interfacial stress buildup with increasing corrosion layer thickness. The presence of bromine in the corrosion scale is a firm indication of fluid degradation. This degradation, in addition to fluid contamination resulting from detachment of the corrosion layer from the ribbon surface, leads to a gradual deterioration in fluid properties, and all of this severely affects satisfactory performance of the inertial instruments.

Chemical reactions between the alloy phases and the fluid, and galvanic-type corrosion of the less-noble, Cu-rich phase (accelerated in instances where air and moisture were trapped during handling) are believed to be the dominant mechanisms in the observed corrosion (2). Both these mechanisms are consistent with past experiences which show that flex lead corrosion effects vary from negligible, to moderate, to severe from one inertial instrument to another. All leads, in any given instrument, usually show a similar level of corrosion. Since all of the leads that are mounted in any one instrument are subjected to the same heat-treatment (for forming purposes), and since all of them are in contact with the same fluid (during instrument operation), the sources of corrosion must originate either from microstructure changes induced in the flex lead, as a result of heat-treatment, or from environmental (air and moisture) contamination of the fluid. The presence of bromine in the corrosion product can be explained by the formation of bromides as a consequence of these two corrosion processes. The metal ions formed from galvanically promoted dissolution of the less-noble, Cu-rich phase are free to combine with bromine ions, which are also believed to be present in the fluid through chemical interaction between the BTFE fluid and the epoxy materials that are used for instrument fabrication. Alternatively, direct chemical reaction between the metals and the fluid can also account for the formation of metal bromides. Either way, it is interesting to note that the Cu-rich phase that contains a higher amount of Ag (as was indicated for the good lead sample) will be less reactive chemically (because Ag-bromides possess higher free energy of formation values than do Cu-bromides) and will also be less susceptible to galvanic-type corrosion (because of a reduced potential difference between the two phases resulting from a higher Ag-content in the Cu-rich phase and a higher Cu-content in the Ag-rich phase). Differences in the relative amounts of the two phases, as mentioned earlier, will also play a role in determining the extent of the corrosion in the material.

The foregoing suggests that it is important to exercise good control over the 590°K heat-treatment that the flex leads are subjected to during the shape-forming stages, and over the avoidance of environment-related contaminants in the BTFE fluid during instrument filling and handling operations. While it is recognized that some diffusion-related phenomenon must occur for the flex leads to assume the shape of the metal mandrel, it is important to note that this treatment should be confined to the minimum that is required. Excessive thermal activation leads to excessive second-phase separation and agglomeration, and this has an adverse effect on the corrosion-resisting properties of the 85 Ag-15 Cu flex lead material.

Summary and Conclusions

1. The as-received microstructure of the 85 Ag-15 Cu flex lead ribbons consisted of the major, nodular submicron size Ag-rich phase dispersed in the minor, quasi-continuous Cu-rich matrix. The Cu-rich phase was located at what appeared as grain boundaries.

2. A close correspondence was found between the etching characteristics of the samples (which are an indication of the microstructure) and the observed corrosion. It is suggested that differences in etching behavior resulted from differences in prior thermal treatment and overall composition. The sample that etched slowly was also the one that showed very few signs of corrosion.

3. Corrosion is found to proceed along the Cu-rich phase resulting in separation of the Ag-rich particles from the metal matrix and incorporation into the corrosion layer. After build-up of a certain thickness, the corrosion layer detaches from the surface (possibly because of an increased interfacial stress), and exposes fresh metal surface for more attack.

4. The morphology found for the Ag-rich particles (which were exposed at the surface by a chemical etching treatment) was quite similar to that observed for the corrosion scale. The processes believed to be responsible for giving rise to the observed corrosion are those resulting from chemical interaction of the metallic phases with the fluid and those related to an existing electrochemical corrosion cell.

TEM Observations of Pyramidal Hillocks Formed on (001) Silicon Wafers during Chemical Etching

Fumio Shimura

NEC-TOSHIBA Information Systems Incorporated, Research Laboratories, Miyazaki, Takatsu-ku, Kawasaki, 213 Japan

ABSTRACT

The pyramidal hillocks bounded by four convergent {111} planes have appeared on annealed (001) silicon wafers. Observations by TEM (transmission electron microscope) of an annealed (001) wafer with oxidation-induced stacking faults show that the pyramidal hillock is not an extraneous substance such as SiO_2 precipitate but an intrinsic part of the substrate silicon crystal. A possible mechanism of hillock formation discussed in detail verifies the formation of pyramidal hillocks on annealed (001) silicon wafers. By using the ultrasonic agitating etching technique, a flat (001) surface without pyramidal hillocks can be obtained.

It is well known that various types of microdefects are generated when bulk dislocation-free silicon crystals containing oxygen are annealed at high temperature (1, 2). Recently, surface- and inner-microdefects in annealed (111) silicon wafers examined after a two-step annealing process have been compared and related to the intrinsic gettering phenomenon (3). The result showed that all such microdefects resulted from "precipitates" generated in an annealed wafer. The type of Si-O complex precipitate generated strongly depended on annealing temperatures. The Si-O complex precipitate generation is also strongly dependent on the oxygen concentration in as-grown silicon crystals. In the case that the oxygen concentration of silicon crystal is low, Si-O complex precipitates are difficult to generate even after high temperature annealing (4).

Pyramidal hillocks, which seem to be Si-O complex "precipitates," with a micro substance at their apexes were easily observed by TEM in (001) wafers. However, this phenomenon was quite different from that in the annealed (111) wafers mentioned above.

This study takes a detailed look at these pyramidal hillocks in annealed (001) silicon wafers by means of TEM. The essence of pyramidal hillock is revealed from TEM observation results and a possible mechanism of hillock formation is discussed in detail.

Experimental

The wafers used in this study were grown by Czochralski technique and (001) oriented with the backs chemically etched and the fronts mirror polished. The n-type (P-doped) wafers, 75 mm in diameter and 400 μm in thickness, had a resistivity of 4-7 $\Omega\cdot$cm. The oxygen content of as-grown wafers measured by the infrared absorption (at 1106 cm^{-1}) method was 11×10^{17} cm^{-3} using the calibration given by ASTM F-121 (5). According to our sorting, this oxygen concentration is included in "low concentration" mentioned above. The wafers were annealed at temperatures from 900° to 1200°C for 16 hr in a dry O_2 atmosphere.

Key words: chemical etching, oxidation-induced stacking fault, ultrasonic agitation, extraneous substance.

Surface- and inner-parts (about 30 μm chemically etched off from the front surface of a wafer) were examined using TEM. For the preparation of TEM samples, 3 mm diam disks were cut with an ultrasonic cutter. These disks were mechanically polished to a thickness of about 60 μm, then chemically thinned to electron transparency ($\lesssim 2$ μm) with an etchant of 3 parts concentrated HNO_3 and 1 part 49% HF. The TEM observations were carried out at an accelerating voltage of 200 kV and goniometer stage was used.

All the electron micrographs presented are bright-field images printed emulsion up and indexed assuming a (001) crystal normal. Moreover, the image plane normal (z), diffraction vector (g), and crystal tilt sense were defined in the usual way from the Kikuchi pattern.

Results and Discussion

As shown in Fig. 1, various sizes of pyramidal hillocks were observed in both surface and inner parts of (001) wafers annealed at all temperatures from 900° to 1200°C. Using stereo TEM techniques, it was found that the pyramidal hillock is bounded by four convergent {111} planes or their approximation. The shape seems to be exactly the same form as the half of a regular octahedral precipitate generated in (111) silicon wafers annealed at temperatures above 1100°C (3). This octahedral precipitate was identified as silicon oxide directly by the analysis of electron energy loss spectra (6). Furthermore, an octahedral precipitate is most likely amorphous SiO_2 from the infrared absorption data (7).

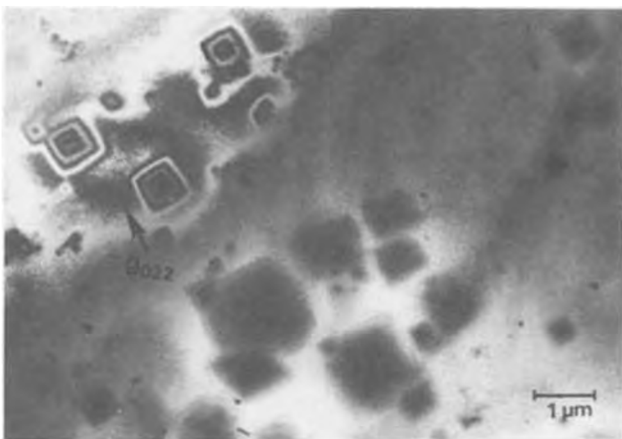

Fig. 1. TEM image of pyramidal hillocks in (001) wafer annealed at 1100°C. $g = [0\bar{2}2]$, $z = [001]$, $s \sim 0$.

However, if these pyramidal hillocks are SiO_2 precipitates, certain discrepancies would have to be resolved:

1. The total volume of pyramidal "SiO_2 precipitates" observed here seems to be in excess of the amount of the oxygen concentration of wafers ($\sim 10^{18}$ cm^{-3}).
2. In the annealing experiments of (111) silicon wafers, octahedral precipitates were generated only at temperatures higher than 1100°C (3). On the contrary, the pyramidal hillocks were observed in (001) wafers annealed at all temperatures from 900° to 1200°C.
3. The size of octahedral precipitates generated in annealed (111) wafers were around 0.3 μm in diameter (3), however, the size of pyramidal hillocks generated in (001) wafers ranged from 0.1 μm to a few microns.
4. In spite of such large "precipitates," no prismatic punched-out dislocations were observed around the "precipitates."

Such discrepancies would seem to preclude the idea that the pyramidal hillocks shown in Fig. 1 are Si-O complex precipitates. Instead, they support the conception that the hillocks are part of the silicon substrate crystal itself.

To verify this, TEM observations were carried out on an annealed (001) wafer with oxidation-induced stacking faults (OSF). The OSF shown in Fig. 2 intersects a pyramidal hillock in a (001) wafer annealed at 1100°C for 16 hr in a dry O_2 atmosphere. In this case, dynamical theory of image contrast proves that the breadth of the stacking fault TEM image is proportional to the thickness of the TEM sample. That is, the variation in the breadth of OSF fringes represents the shape of the sample where OSF is intersecting as schematically

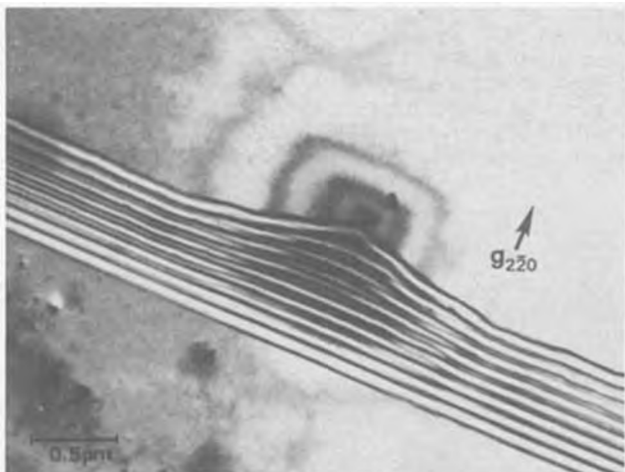

Fig. 2. TEM image of stacking fault intersecting pyramidal hillock in (001) wafer annealed at 1100°C. $g = [2\bar{2}0]$, $z = [001]$, $s = 0$.

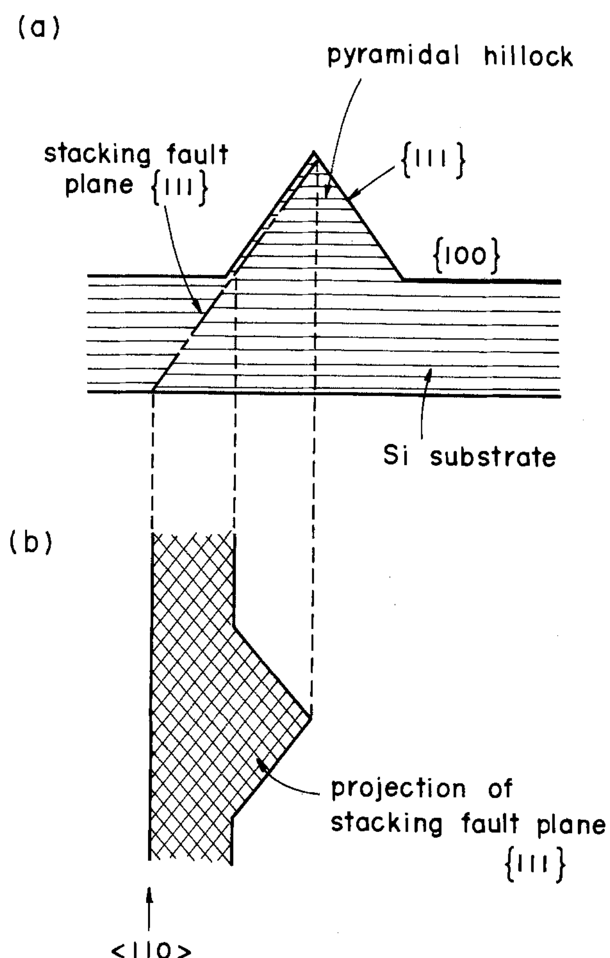

Fig. 3. Schematic illustration of stacking fault intersecting pyramidal hillock; (a) cross section of stacking fault plane and pyramidal hillock viewed from <110> direction, (b) projection of stacking fault plane.

shown in Fig. 3. It must be emphasized that continuous stacking fault fringes at the part of the pyramidal hillock shown in Fig. 2 can only verify that the pyramidal hillock is not an extraneous substance such as SiO_2 but an intrinsic part of the substrate, namely the silicon crystal itself. Moreover, the thickness of the TEM sample and the height of the pyramidal hillock shown in Fig. 2 were estimated at 0.85 and 1.17 μm, respectively. The triangular projections of the stacking fault plane shown in Fig. 2 and 3 are somewhat different from each other. That is, the convergent planes of the pyramidal hillock which are observable in Fig. 2 are $\sim${113} deviating slightly from {111} planes shown in Fig. 3.

In addition, the TEM image of a stacking fault intersecting an octahedral precipitate generated in a (111) wafer annealed at 1100°C for 16 hr in a dry O_2 atmosphere (see Fig. 4) is completely different from the previous TEM image as is the correlation between a precipitate and stacking fault projection (Fig. 5). Stacking fault fringes as definitely shown in Fig. 4 and 5 cannot be produced with a precipitate.

Consequently, pyramidal hillocks shown in Fig. 1 and 2 are not an extraneous substance such as amorphous SiO_2 but hillocks of an intrinsic part of the silicon substrate crystal itself. The pyramidal hillocks seem to be formed by chemical thinning when a thin foil for TEM observation was prepared.

Using stereo TEM techniques, a micro substance, a few nm in size, was observed at the apex of some pyramidal hillocks as shown in Fig. 6. This micro substance must have participated when the pyramidal hillock was formed by chemical thinning. A model for the formation of pyramidal hillocks by chemical thinning is presented schematically in Fig. 7. When the polished sample is chemically thinned to electron transparency,

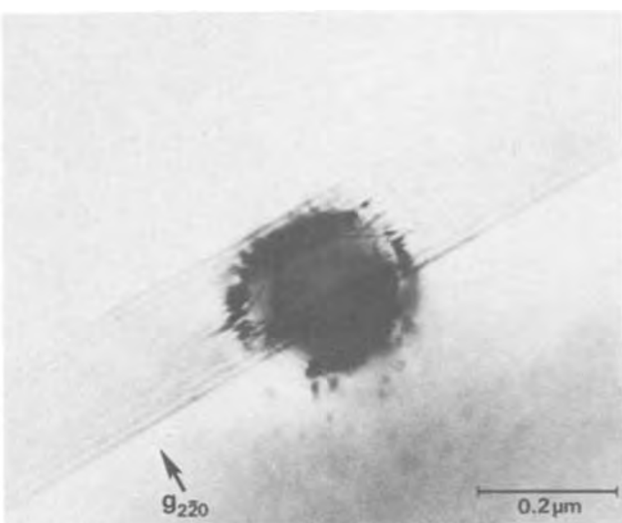

Fig. 4. TEM image of stacking fault intersecting octahedral precipitate generated in (111) silicon wafer annealed at 1100°C. $g = [2\bar{2}0]$, $z = [111]$, $s = 0$.

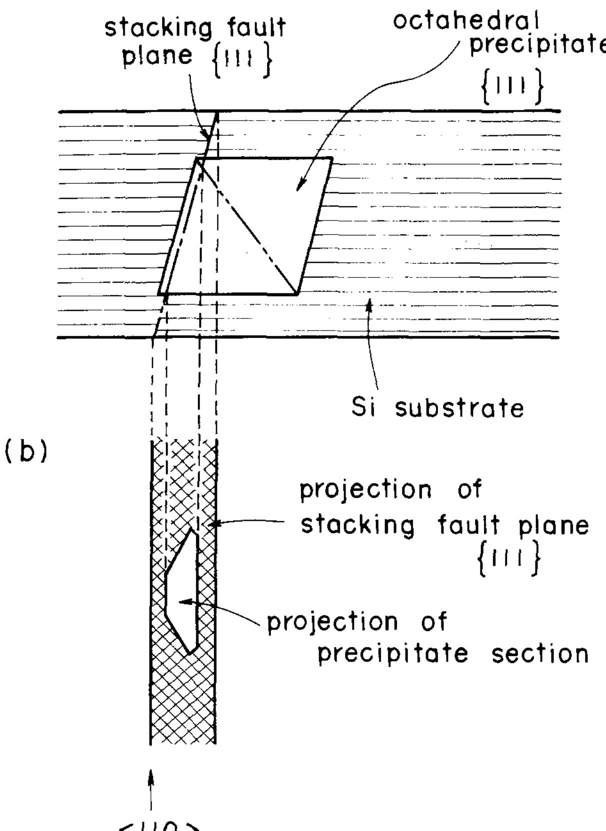

Fig. 5. Schematic illustration of stacking fault intersecting octahedral precipitate; (a) cross section of stacking fault plane and octahedral precipitate viewed from <110> direction, (b) projection of octahedral precipitate and stacking fault plane.

the etching rate depresses where the extraneous substance exists. No anisotropic etching occurs on a (111) silicon surface on which the etching rate is the minimum, however, in the case of a (001) surface, pyramidal hillocks bounded by four convergent {111} planes or their approximation are formed as a consequence as the chemical etching proceeds leaving {111} planes. Bassous *et al.* (8) reported square pyramidal cavities bounded by convergent {111} planes that were formed by chemical jet etching with an orifice. Both

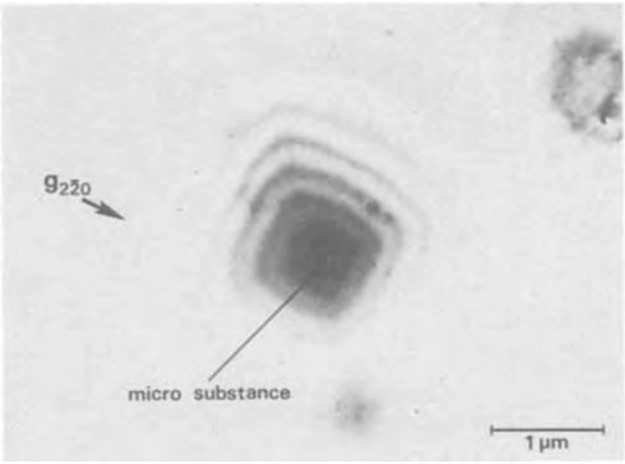

Fig. 6. TEM image of micro substance located at pyramidal hillock apex. $g = [\bar{2}20]$, $z = [001]$, $s = 0$.

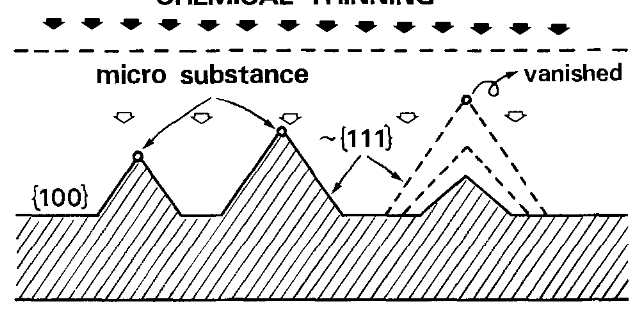

Fig. 7. Schematic illustration of pyramidal hillock formation model by chemical etching with micro substance.

the pyramidal cavity and hillock bounded by convergent {111} planes are caused from the anisotropy of the etching rate among crystal planes. As shown in Fig. 7, some micro substances vanish in the middle of the chemical thinning and some remain at the apex of pyramidal hillocks. Pyramidal hillock size depends on the position of the micro substance in a wafer and/or the substance disappearance time.

The micro substance mentioned above seems to be a micro precipitate and/or adsorbed impurities. The exact identification of the micro substance located at the apex of a pyramidal hillock has not yet been accomplished at present. However, it is very important in the silicon industry to identify the substance that results in pyramidal hillocks.

Annealed (001) wafers were chemically etched by various techniques to obtain a flat etched surface without such hillocks and to verify the pyramidal hillock formation model presented here. Optical microscope images of surfaces chemically etched by both a usual manner and an ultrasonic agitating technique using a $1HF:3HNO_3$ mixture as an etchant mentioned before are shown in Fig. 8. With ultrasonic agitation, far fewer

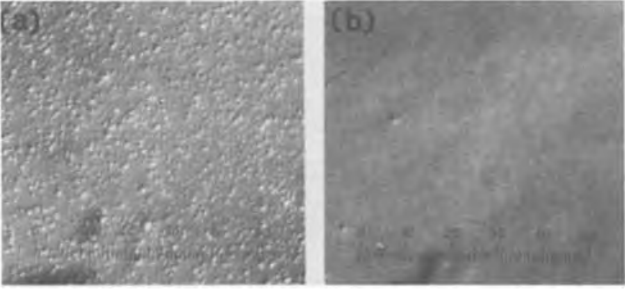

Fig. 8. Etched surfaces of annealed (001) silicon wafer with 1 HF: 3 HNO_3 mixture; (a) usual manner, (b) with ultrasonic agitation.

pyramidal hillocks were formed on the surface than the usual manner. The difference between the surface shapes etched in different manners verifies the model mentioned above, that is, these pyramidal hillocks are formed as a result of chemical etching and a micro substance at the apex of pyramidal hillock. Ultrasonic agitation should sweep away micro substances which affect the formation of pyramidal hillocks. Furthermore, ultrasonic agitation is also required to minimize etching artifacts due to gas bubble formation during etching (9), and to minimize the etching time necessary to achieve the required thickness of electron transparency.

Summary

Pyramidal hillocks bounded by four convergent {111} planes or their approximation on the (001) silicon surface are not extraneous substances such as octahedral amorphous SiO_2 precipitates but an intrinsic part of the silicon substrate crystal. They are formed by chemical etching. By using ultrasonic agitation, the formation of these pyramidal hillocks can be avoided.

Analysis of the Main Factors Influencing the Thickness Uniformity of VPE GaAs Thin Layers

Jean-Paul Chané

Laboratoires d'Electronique et de Physique Appliquée, 94450 Limeil-Brévannes, France

ABSTRACT

It is shown that the homogeneity in thickness of a large area GaAs thin layer obtained by VPE is a function of the composition of the gaseous phase, its homogeneity, and the hydrodynamics of its flow in the vicinity of the substrate. The influence of each of these factors has been investigated. Modifications have consequently been introduced into the low temperature growth technique using $AsCl_3/H_2/GaAs$ which lead to very uniform layers with a pinch-off voltage variation of $\pm 5\%$ for FET.

State of the art GaAs microwave devices use widely epitaxial material. A great deal of attention is devoted to the field effect transistor and GaAs IC's which are currently entering into industrial development. In order to assure high production efficiency the material should not only be of high quality but should also be homogeneous, particularly in its essential parameters of thickness and doping.

In the field of GaAs integrated circuits, it would even seem, at the present time, that an increase of area with uniform thickness is an essential condition for the use of epitaxial layers. Usually, the observed dispersions were attributed to the hydrodynamics of the gas flow for which it was possible to have only an intuitive idea. Although certain publications (1-4) have detailed the CVD growth of Si in a cold wall reactor, little has been published concerning hydrodynamics in hot wall reactors using the $AsCl_3$ method. Fairman and Solomon (5) found a variation of the epitaxial layer thickness along the flow axis; this variation depends on the thermal gradient in the deposition zone. Komeno *et al.* (6) derived a growth rate equation on the basis of a model (7) which assumes a laminar boundary layer. The use of this equation permits the description of the growth rate variation along the substrate with different conditions of flow and temperature. However the authors used a few microns thick epitaxial layers and a growth method with inert gas.

In this work, the problem was investigated by systematic measurements of velocity by mean of an anemometric probe. For low temperature growth, using the $AsCl_3/H_2/GaAs$ method (8), it appears that the phenomena responsible for the inhomogeneities in a thin layer are located at three different positions: (*i*) at the sample, where the flow of gas is concerned; (*ii*) at the entrance to the deposition zone, where the chemical homogeneity of the gas phase is involved; and (*iii*) finally at the GaAs source, where the pseudo-equilibrium of the gas is concerned.

Experimental Technique

The influence of the composition of the gas phase at the source on the homogeneity of the growth has been studied in a conventional epitaxial reactor (Fig. 1). The source consists of GaAs polycrystals inside a quartz tube T ($\phi = 28$ mm) with a 10 mm exit aperture. A small tube feeds the source with hydrogen saturated with $AsCl_3$. Downstream from the source is a baffle C. The substrate is placed on a rectangular sample holder

Key words: gas, epitaxy, circuits.

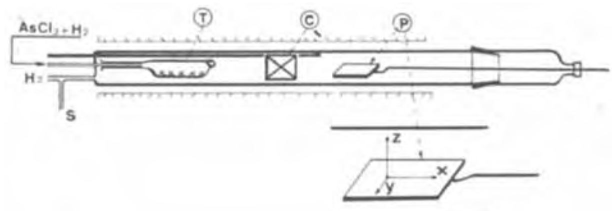

Fig. 1. Schema of the epitaxial reactor

P which can be inclined with respect to the axis of the reactor.

The temperature of the source is 660°C and that of the substrate 630°C. Flow rates are, respectively, 200 and 650 cm^3/min for source and carrier gases. $AsCl_3$ mole fraction after dilution is $3 \cdot 10^{-3}$. The doping is obtained by a sulfur circuit which is connected to the hydrogen carrier gas.

Epitaxial growths on Cr-doped substrates were performed in these conditions. The thickness of the layers are evaluated using *C-V* measurements with the double mercury Schottky probe described earlier (9).

The homogeneity of the gas phase at the entrance to the growth zone has been studied by simulating the flow with TiO_2 fumes. The reactor used is of identical geometry to that described above (Fig. 2). A flow of hydrogen saturated with $TiCl_4$ is introduced into the source; at its exit it meets a flow of humid hydrogen coming from upstream of the reactor. The mixture of the two gases then passes into a homogenization chamber. The degree of homogenization is easily controlled by observing the white TiO_2 fumes at the exit of the chamber. Experiments have been performed at room temperature, however the conclusions can also be applied to the effective operating conditions as it corresponds to a constant temperature region of the reactor.

The gas flow in the region of the sample holder has been experimentally determined by measuring the velocity throughout the stream of gas. In order to effect these measurements the preceding reactor was equipped with a sliding trolley which supported an anemometric probe that had been specially adapted for small velocities (0-30 cm/sec) (Fig. 3 and 4) The probe consists of a hot oscillating wire (250 Hz) whose output voltage is a linear function of the gas velocity. Its sensitivity is 0.1 cm/sec. The fine construction of the probe causes no detectable perturbation in the measurements.

Measurements were performed at room temperature using nitrogen carrier gas in order to keep the Reynold number close to the practical values in the epitaxy reactor ($2 < Re < 10$).

Results and Discussion

Influence of the source geometry.—Some short growths (a few minutes, leading to around 0.3 μm of deposit) have been carried out in the reactor described above. It has been found for consecutive growths that the growth rate, determined on the thin layer, and the dispersion in thickness were very sensitive to: (*i*) the granulation of the polycrystalline GaAs introduced in the tube T: an increase of the granulation increases the growth rate while the dispersion in thickness tends to decrease; and (*ii*) the filling of tube T. By filling only the bottom of the tube, the average thickness increases progressively, from one run to the next one.

The experimental conditions used were such that the control of the gas flow (10, 11), could not be held responsible for these fluctuations. Possible explanations are related to the residence time of the gas, the total surface available for reaction and the surface faceting (12). All these effects induce variations of the supersaturation in the gas phase and the effect of this on the growth rate is even more serious for submicronic layers as steady-state conditions may not be reached. Optimum source loading has been empirically determined in order to obtain reproducible growth rate over several dozen successive growths.

Homogeneity of the gases after dilution.—The source gases meet the hydrogen stream at the exit of the tube T (Fig. 1), and the problem is to get a homogeneous gas phase before its arrival at the growth zone.

The TiO_2 visualization technique reveals the difference of velocity between the gas at the source exit (V_s) and the hydrogen carrier gas V_H. It also shows that a period of several minutes is necessary to reach a fully developed phase when the flow corresponding to V_s is established in the already existing carrier flow (for $V_S/V_H \sim 10$, a typical time is about 10 min). The practical consequence of this is that the solid/gas interface at the sample surface is not under uniform partial pressure conditions, which is particularly detrimental for short growth times.

In fact, the gases must be well mixed together before reaching the neighborhood of the sample. One way of ensuring this is to interpose a baffle between the source exit and the growth zone (11).

Hydrodynamics of the flow in the growth zone.—Anemometric measurements, carried out in the vertical plane above the sample holder every cm, along 0x, and every mm, along 0z (Fig. 1) have confirmed the existence of a boundary layer at the surface of the sample.

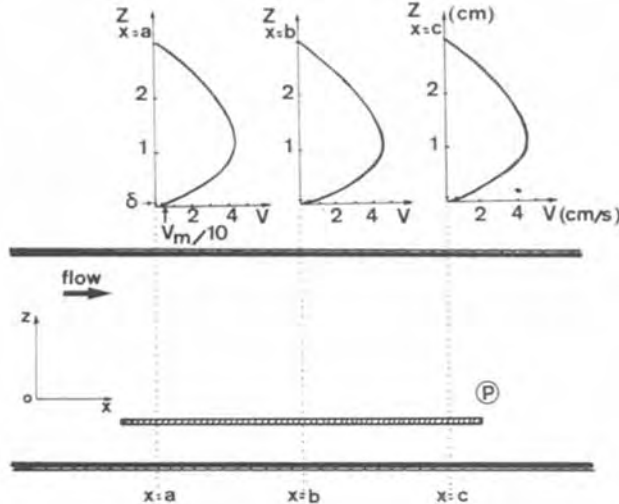

Fig. 5. Velocity profile along 0z above the sample holder and parallel to the flow axis.

The boundary layer is defined as being the height of the fluid below which the velocity is 10% of the input velocity. Its thickness (δ) is directly measurable using the anemometer. However, it appears that it is very small. So, in order to increase the accuracy of the measurements, attention was in fact focused on the gas layer where $V = V_m/2$ whose behavior above the substrate is similar to that of the boundary layer since the velocity profile in this region is linear.

In the case of a horizontal reactor, the velocity profile above the sample holder does not have the same form along the flow axis 0x, and the perpendicular axis 0y.

Along the flow axis.—If the sample holder is parallel to 0x, the vertical velocity profile is of a parabolic nature and remains the same across the holder. It depends only on the input velocity of the gases (Fig. 5). Slight deviation from the parabolic shape is due to the misalignment of the input pipe.

This situation is changed should the sample holder be inclined with respect to 0x. The velocity profile becomes deformed across the holder and the flattening effect of the parabola becomes more accentuated with increasing tilt angle (Fig. 6a, 6b). Under these circumstances, the boundary layer is no longer of uniform thickness. $\delta(x)$ becomes a decreasing function of x and its derivative $d\delta(x)/dx$ is a function of: (*i*) the input velocity of the gas. $\delta(x)$ decreases less quickly when the velocity increases; (*ii*) the tilt angle of the sample holder. A total variation of δ of 100%, for $V_m = 8$ cm/sec and a holder length of 7 cm (along 0x) was measured for a tilt of 8°, and 250% for an angle of 16° (Fig. 7).

These results are similar to those obtained by Eversteyn (2) with the exception that our hydrodynamic approach is essentially experimental and does not necessitate the knowledge of the growth rate for the determination of δ.

Along the direction perpendicular to the flow.—The anemometric measurements have shown that the velocity profile depends on the ratio R of the width of the sample holder to the diameter of the reactor. Figure 8 shows the forms of three profiles for a width practically equal to the diameter, $R = 100\%$; R equal to 75% (which is usually the case in our reactors). The presence of a very mobile stream of gas either side of the sample holder is observed; finally R equal to 90%. This is an optimum value, empirically determined.

It may be deduced that the thickness, $\delta(y)$, of the boundary layer also depends on R. $\delta(y)$ is constant for $R = 90\%$ but in the case where $R = 75\%$ it decreases in value at the edges of the sample holder.

Influence of the thickness of the boundary layer on the homogeneity of the epitaxial growth.—In this section, it is supposed that the problems associated with the source have been solved and that the composition of the gas arriving in the growth zone is constant. Growths have been carried out under these conditions on samples of the same area and the velocity of the gas flow was identical throughout. The experiment revealed two factors: the supersaturation γ and the growth rate τ, influence the homogeneity of the growth thickness. Figure 9 summarizes the following observations: (*I*) the supersaturation γ is low: the thickness of the epitaxial layer decreases regularly along the flow direction; and (*II*) the supersaturation is high: two possibilities exist: (*i*) the growth rate is small and the thickness of the epitaxial layer is practically constant along 0x. (*ii*) τ is large in which case a gradient in thickness reappears along 0x. In both cases, the presence of such a gradient signifies a decrease in the supersaturation ($\Delta\gamma$), along the substrate which produces a corresponding reduction in growth rate ($\Delta\tau$).

These results (I and II) agree with those of Hollan *et al.* (13), concerning the influence of the supersaturation on the growth rate even though their results in-

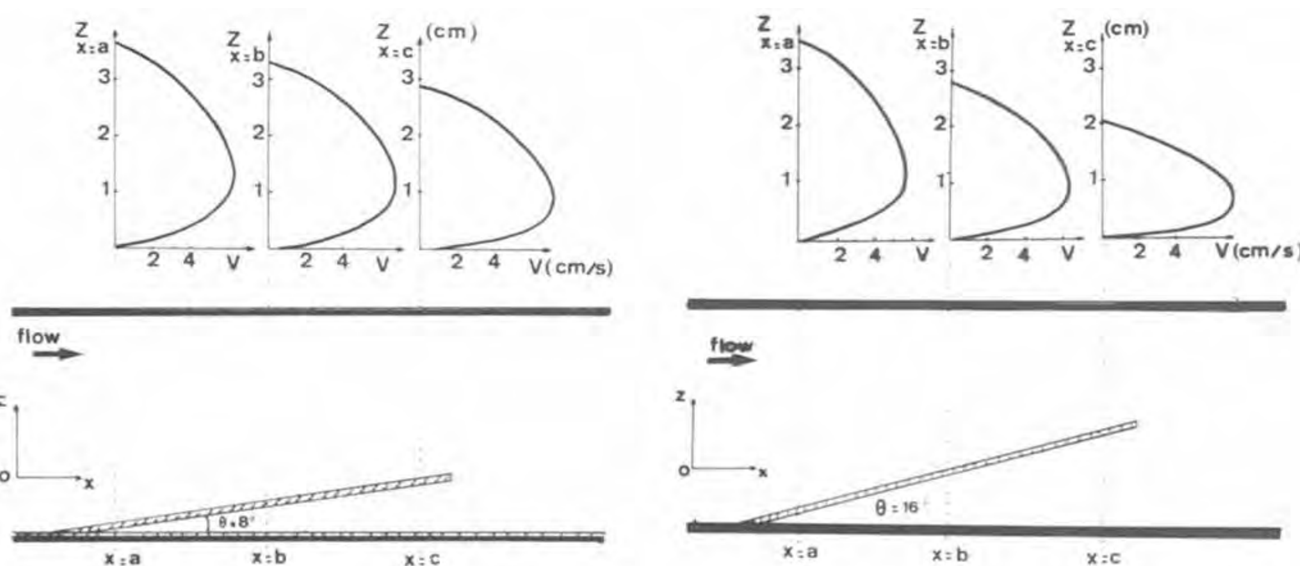

Fig. 6. (a, left) Velocity profile along 0z above the sample holder tilted at $\theta = 8°$ with respect to the flow axis 0x. (b, right) Same profile with $\theta = 16°$.

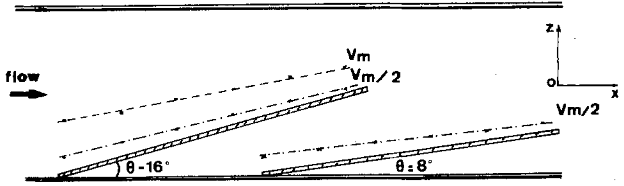

Fig. 7. Thickness profile of the gas layer corresponding to $V_m/2$ measured above the sample holder which is tilted at 8° and 16°.

$$R = \frac{\text{width of the sample holder}}{\text{diameter of the reactor}}$$

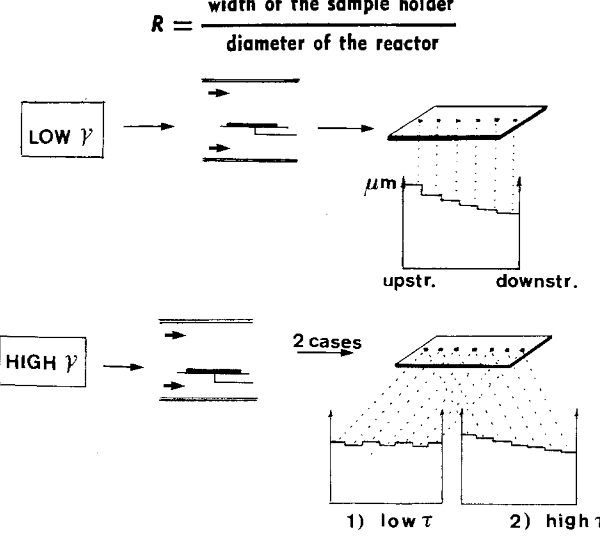

Fig. 9. Table showing the respective influences of the thermodynamics, the surface kinetics, and the hydrodynamics on the homogeneity of the growth.

volved average growth rates calculated from growths of several microns.

Figure 10, which summarizes their results, shows: (*i*) that at low γ the curves always present a steep slope irrespective of the growth temperature. This slope $\Delta\tau/\Delta\gamma$ explains the gradient of the thickness which is always observed on thin layers at low γ (Fig. 9, low γ). (*ii*) it also shows that, at high $\gamma (\gamma \geqq 3)$, the slope of the curves varies as a function of T_D. At $T_D \leqq 680°C$ $\Delta\tau/\Delta\gamma \sim 0$ which corresponds to case 1, high γ in Fig. 9; the thickness of the epitaxial layer is uniform. Above 700°C $\Delta\tau/\Delta\gamma$ is no longer zero, this corresponds to case 2, high γ in Fig. 9 where a gradient in the epitaxial layer thickness reappears.

The dispersion can be explained by the mass transfer limitation of the growth: the boundary layer plays the role of a screen through which the gas molecules must diffuse in order to reach the crystal (2, 6). This is a mass transfer by diffusion; the substrate is under isothermal conditions and consequently the flux of matter, J (expressed in mole · cm^{-2} · sec^{-1}) which reaches the crystal is given by

$$J = D\frac{C_G - C_i}{\delta} \quad \text{for each element}$$

where δ = thickness of the boundary layer in x, D = diffusion coefficient, C_G = concentration of the element in the gas, and C_i = concentration of the element at the solid/gas interface.

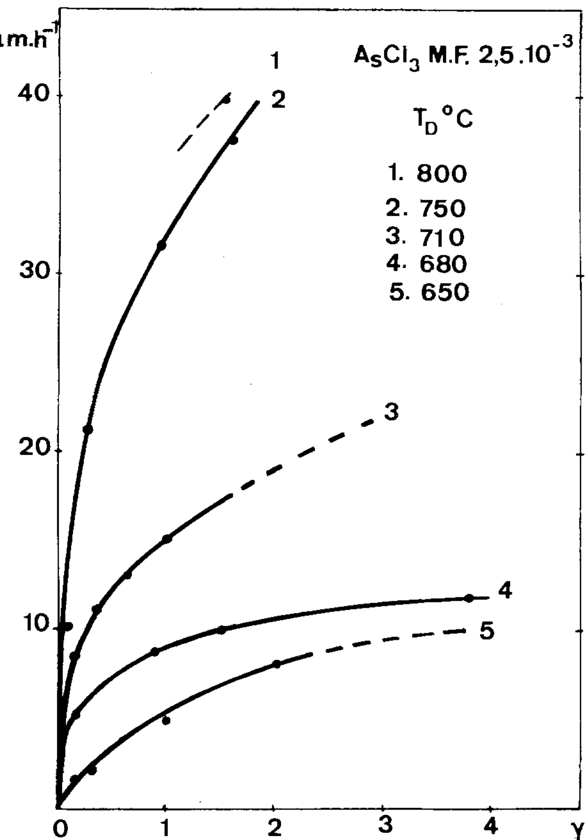

Fig. 10. GaAs deposition rates τ as a function of the supersaturation γ [after (13)].

At the limit

$$C_i = 0 \quad \text{then} \quad J = D\frac{C_G}{\delta}$$

The growth thickness would be homogeneous if substrate were exposed to the same flux at its extremities x_1 and x_2. Then

$$\frac{DC_G(x_1)}{\delta(x_1)} = \frac{DC_G(x_2)}{\delta(x_2)}$$

and hence

$$\frac{\delta(x_1)}{\delta(x_2)} = \frac{C_G(x_1)}{C_G(x_2)}$$

In other words, the homogeneity of the growth requires that the boundary layer should decrease in thickness across the layer in the same proportions as the concentration in the gas stream.

It would be possible to calculate the tilt angle of the sample holder which would satisfy the above condition. But the calculation is not straightforward because it would be necessary to consider each individual gaseous component and take them into account. Furthermore, all concentrations are not known. Thus, the tilt angle was obtained experimentally. Another method to obtain a thickness uniformity consists in establishing a thermal gradient along the substrate (5). But this is more difficult to control.

Application.—In the following, the tilt angle of the substrate holder with respect to 0x is 15°.

Epitaxial layers of 0.25 μm in thickness, with a doping level of about $1 \cdot 10^{17}$ cm^{-3} in order to give a pinch-off voltage $V_p \sim 4.5$V are grown. Figure 11 shows the dispersion in thickness, and Fig. 12 displays the V_p variation along 0x and 0y.

The variation in V_p is less than 25% along the largest dimension of the sample (oriented parallel to the axis of the gas flow). This variation decreases to as little as 10% if the first and last two millimeters of the samples are neglected (edge effects).

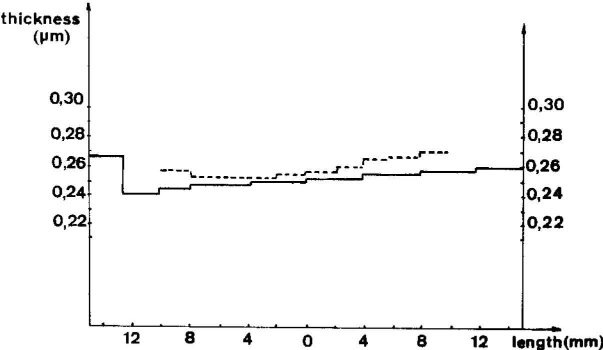

Fig. 11. Dispersion of the layer thickness along the flow axis (full line) and the perpendicular axis (dashed line) (accuracy ±50Å).

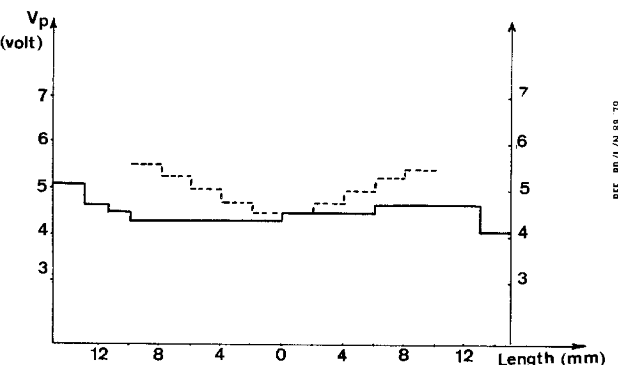

Fig. 12. Dispersion in the pinch-off voltage, V_p, of a FET epitaxial layer along the flow axis (full line) and the perpendicular axis (dashed line) accuracy = ±0.05V.

The dispersion is bigger along the perpendicular axis. This is explained by the width of the sample holder which only represents 75% for the reactor diameter.

Conclusion

The uniformity in thickness of a thin layer of GaAs grown by vapor phase epitaxy (trichloride method) is essentially determined by three factors: (*i*) the composition of the gas phase at the exit of the source; (*ii*) the homogeneity after dilution; and (*iii*) the hydrodynamics of the flow.

The second factor may be considered separately. A solution has been proposed which has given satisfactory results (interposition of a baffle between the source exit and the growth zone).

The other two factors, however, cannot be considered separately.

It is necessary that the progressive exhaustion of the gas phase resulting from the growth along the axis of the gas flow, be compensated by a continuous reduction thickness of the boundary layer which screens the crystal.

The determination of the best compromise resulted from experimental measurements of the thickness of the boundary layer using an anemometric probe in relation with the supersaturation of the vapor phase.

This work has been applied to the growth of thin epitaxial layers for FET's. Considerable improvement in their uniformity of pinch-off voltage has been observed, particularly in the direction of the gas flow, where it has been reduced to ± 5%.

However, the dispersion along the perpendicular axis is slightly larger. The optimization of the ratio:

$$\frac{\text{width of the holder}}{\text{diameter of the reactor}} \text{ should reduce it.}$$

Acknowledgments

The author would like to express his gratitude to Mme J. Baelde for her technical assistance, to Mr. Lyot for his help with the anometric measurements, and finally to Dr. Hallais for many helpful discussions.

Transparent Conducting Cadmium-Tin Oxide Films Deposited by RF Sputtering from a $CdO-SnO_2$ Target

N. Miyata, K. Miyake, K. Koga, and T. Fukushima

Faculty of Engineering, Yamaguchi University, Ube, Japan

ABSTRACT

Transparent conducting films of cadmium-tin oxide (CTO) were prepared by rf sputtering from a sintered $CdO-SnO_2$ target in an Ar or an $Ar-O_2$ atmosphere. The electrical and optical properties of the films were found to depend upon the oxygen concentration in the gas mixture. The films with the lowest resistivity of 4.82×10^{-4} Ω-cm and high optical transmission of 85% over the visible region were obtained without post-heat-treatment.

The films of cadmium-tin oxide (CTO) are attractive materials as transparent electrodes on optoelectronics devices. Nozik (1) and Haacke (2, 3) have reported the physical properties of CTO films deposited by rf sputtering from a hot-pressed polycrystalline Cd_2SnO_4 target. The films were annealed in an H_2 or an Ar-CdS atmosphere after the deposition in order to obtain high transparency and high conductivity, respectively. We have reported that CTO films were deposited by d-c reactive sputtering from a Cd-Sn alloy target (4-6), and that films with high transparency and high conductivity were obtained without post-heat-treatment; the properties of as-sputtered films were almost equivalent to those of post-annealed films in an H_2 or an Ar-CdS atmosphere. We suggested that it is possible to adjust the electrical and optical properties of films by varying the oxygen concentration in an $Ar-O_2$ atmosphere (4).

This paper describes a method to prepare transparent, conducting CTO films by rf sputtering from a sintered $CdO-SnO_2$ target without post-heat-treatment.

Experimental

Films of cadmium-tin oxide (CTO) were deposited by rf sputtering from a $CdO-SnO_2$ target. The experimental apparatus is an rf sputtering system which is capable of achieving an ultimate pressure of 1×10^{-6} Torr. Sintered $CdO-SnO_2$ targets (CdO/SnO_2 mole ratio of 2/1, 58 mm in diam) were utilized. The rf power was in the range of 100-360W. The sputtering atmosphere used was an Ar or $Ar-O_2$ mixture. The pressure of pure Ar or $Ar-O_2$ mixtures was in the range of 2.0×10^{-2}-8.0×10^{-2} Torr. The water-cooled target to substrate spacing was kept at 66 mm in all experiments. The sputtering chamber was equipped with a stainless shutter that was placed between the target and substrate during evacuation and predeposition.

The chamber was initially evacuated to 1×10^{-6} Torr and then Ar gas or $Ar-O_2$ mixtures were introduced through a variable leak valve, by which the total pressure was controlled to maintain at a given constant value. The time of presputtering was 15 min. The deposition rate was in the range of 5-30 Å/min. Borosilicate glass plates ($26 \times 12 \times 1.0$ mm) used as substrates to measure the optical transmission and electrical resistance were cleaned chemically prior to mounting on the substrate holder. The thickness of deposited films was in the range of 0.1-1.5 μm. The substrate temperature was measured with a Chromel-Alumel thermocouple attached to the substrate.

Resistivity measurements were made using the four-point probe method or the Van der Pauw technique which is also used for Hall coefficient measurements. The spectral transmission was measured over the visible and near infrared regions (from 0.34 to 2.6 μm) with a Hitachi 323-type double beam spectrophotometer. A 9 kG electromagnet was used in the Hall coefficient measurements. The sign of the charge carriers was determined from the Hall effect measurement and the thermoelectric hot probe technique. The structure of the deposited films was examined by x-ray diffraction.

Results

The deposition rate of the films depends upon the rf power in a pure Ar or an $Ar-8\%O_2$ atmosphere, and the rate increases linearly with increasing rf power. At 300W rf power, the deposition rate of films in a pure Ar atmosphere was about 30 Å/min and that of films in an $Ar-8\%O_2$ atmosphere was about 20 Å/min.

Figure 1 shows the relations between sheet resistance and thickness of CTO films deposited in a pure Ar gas, $Ar-2\%O_2$, and $Ar-13\%O_2$ mixture, respectively.

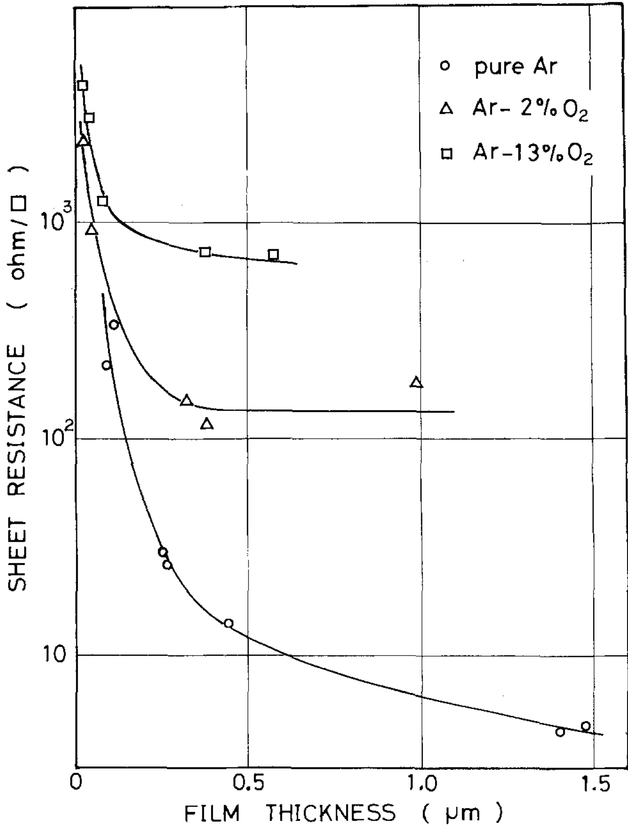

Fig. 1. The relations between sheet resistance and thickness of CTO films deposited in an Ar or $Ar-O_2$ mixtures.

Key words: transparent electrodes, cadmium-tin oxide films, electrical sheet resistance, optical transmission.

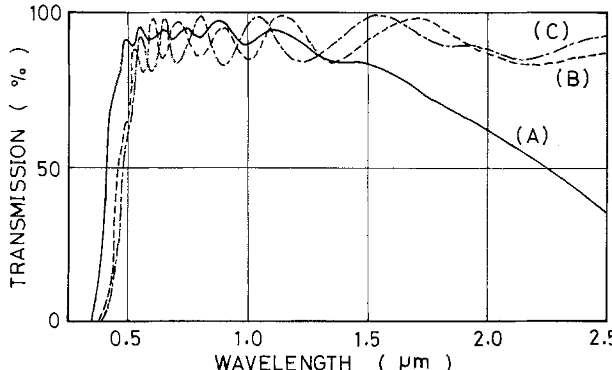

Fig. 2. The visible and near-infrared transmission of CTO films formed in Ar or Ar-O_2 mixtures (blank substrate in the reference beam).

The sheet resistance of thick films (more than 0.6 μm) deposited in a pure Ar atmosphere was below 10 Ω/square, and the lowest resistivity achieved was 4.82 × 10^{-4} Ω-cm, the visible transmission being approximately 85%. The sheet resistance of films deposited in an Ar-O_2 atmosphere increases with increasing oxygen concentration in gas mixtures.

Figure 2 shows spectral transmission of three CTO films (approximately 0.4 μm thick) in the visible and infrared region. Curve (A) is for the film formed in a pure Ar with resistivity 6.2 × 10^{-4} Ω-cm, sheet resistance 14 Ω/square, curve (B) for the film formed in an Ar-2%O_2 with resistivity 4.4 × 10^{-3} Ω-cm, sheet resistance 120 Ω/square, and curve (C) for the film formed in an Ar-13%O_2 with resistivity 1.8 × 10^{-2} Ω-cm, sheet resistance 460 Ω/square. The average optical transmission of these films was more than 85% in the wavelength range of 0.5-0.7 μm. As shown in the figure, the transmission of the films deposited in a pure Ar atmosphere drops rapidly in the near infrared region (36% transmission at 2.5 μm wavelength).

Figure 3 shows that the optical bandgap of CTO films derived from a plot of $(\alpha h\nu)^{1/2}$ *vs.* $h\nu$ varies with the oxygen concentration in the sputtering atmosphere, where α is the absorption coefficient. The absorption edge shifts toward shorter wavelength with decreasing oxygen concentration. From the figure, the bandgap of the film formed in a pure Ar was determined to be 2.71 eV and that of the film formed in an Ar-2%O_2 and Ar-13%O_2 determined to be 2.45 eV and 2.39 eV, respectively.

Thus, the electrical and optical properties of CTO films depend upon the sputtering conditions, especially oxygen concentration in the Ar-O_2 atmosphere. Physical properties of typical samples are summarized in Table I. It is apparent that oxygen concentration is an important factor in determining the electrical and optical properties of films.

Furthermore, from conductivity measurement as a function of temperature in the range of 110°-295°K, it was found that the films with carrier concentration more than 4 × 10^{19} cm^{-3} were n-type degenerate semiconductors. For the CTO films deposited in a pure Ar or an Ar-O_2 atmosphere, x-ray diffraction patterns exhibit a broad Cd_2SnO_4(130) peak (7).

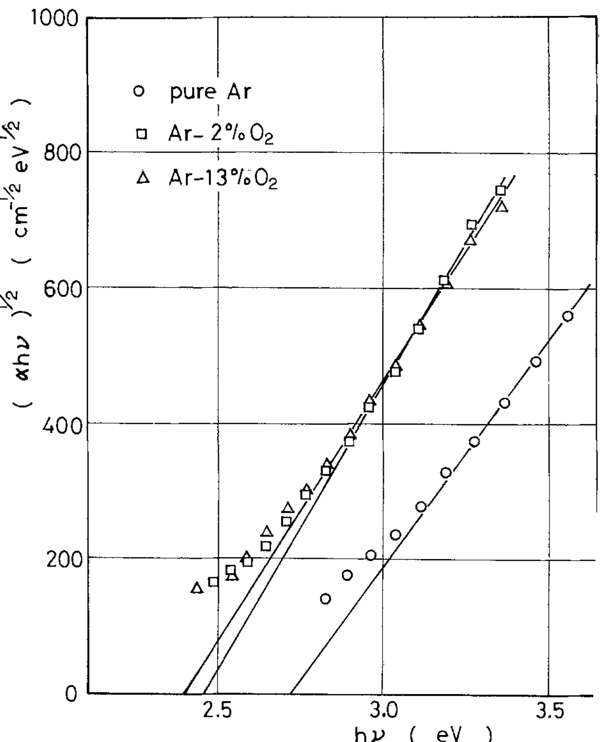

Fig. 3. $(\alpha h\nu)^{1/2}$ *vs.* $h\nu$ for CTO films

Conclusions

Transparent, conducting CTO films were prepared by rf sputtering from a sintered CdO-SnO_2 target in an Ar or Ar-O_2 atmosphere. For the sputtered films in a pure Ar atmosphere, the lowest sheet resistance achieved was 4 Ω/square (1.5 μm thick), the lowest resistivity obtained was 4.8 × 10^{-4} Ω-cm and the 80% average optical transmission of the films was obtained in the visible region.

For the sputtered films in an Ar-O_2 atmosphere, it is apparent that the resistivity increases with increasing oxygen concentration in a gas mixture and the absorption edge shifts toward longer wavelength. The resistivity of the films deposited in an Ar-2%O_2, and in an Ar-13%O_2 was 4.4 × 10^{-3} Ω-cm (0.37 μm thick), and 1.8 × 10^{-2} Ω-cm (0.4 μm thick), respectively. The absorption edge energy of these films was 2.45 and 2.39 eV, respectively. The carrier concentration (8.2 × 10^{17}-5.0 × 10^{20} cm^{-3}), Hall mobility (8-73 cm^2/Vsec), and optical bandgap of the films have almost the same values as those of films prepared by Nozik and Haacke.

Acknowledgment

The authors wish to thank the Narumi China Corporation for their preparing CdO-SnO_2 targets. They want to thank Mr. M. Nakao for his technical assistance in this study.

Thermally Stimulated Discharge Current Studies in Photoresist KTFR

V. K. Jain, C. L. Gupta, R. K. Jain, and Prem Swarup

Solidstate Physics Laboratory, Delhi-110007, India

ABSTRACT

Efforts have been made to study the electret and photoelectret effects in pure and doped negative photoresist KTFR. In KTFR, dipoles are available to form electret and photoelectret effect due to the photopolymerization. This term can be applied to cross-linking of polymers. Details are not available regarding the initial steps of the photoreaction but it is clear that N_2 is split off and nitrene is formed as a highly reactive intermediate, which can subsequently add to double bonds or insert into labile-CH or -NH groups in polymeric materials. Doping of impurities created certain new energy levels or molecular states. More investigations are required for the optimization to change the sensitivity of this material on other wavelengths without changing its basic properties.

The experimental investigations of electrets (1-4) have so far mainly been confined to the nature of the charge developed in different types of dielectric materials. But very little work has been done in complex dielectric systems. Here, the efforts have been made to study the electret and photoelectret (5, 6) effects in photoresist (7) material. These are the organic compounds whose structure and solubility change on exposure to ultraviolet light. The use of photoresist materials in semiconductor technology (8) is well known. Photoresists, in liquid state, are less sensitive to light, but sensitivity increases rapidly as they become dry, as the solvent retention interferes with cross-linking by exposure. During the exposure of these materials to light, photocrosslinking takes place. The cross-linking (9) process involves a chain reaction in which a considerable number of molecules interact to form a high molecular weight material.

A negative photoresist, KTFR (10) made by Kodak Company, has been selected for study. It contains a photocrosslinking agent along with a synthetic polymer in a solvent-based solution. The polymer has been established as a partially cyclized cispolyisoprene with a double bond content of the polymer of 17% which corresponds to one double bond per ten carbon atoms. A proposed structure for this polymer is (10)

CH_3 CH_3 CH_2—
C C
—CH C—CH_3
CH_2 CH_2

A diazide is used as the photoinitiator to promote photocrosslinking in this solution. This material has an advantage that it can be used to make electrets as well as photoelectrets. The photoelectret behavior is different in this material from that in regular photoelectrets. Once a photoelectret of this material is made, the material cannot be used again and depolarization current cannot be observed with the help of exposure to light.

This paper presents the thermally stimulated discharge current studies of KTFR material and calculations for trap depth, relaxation time, and charge, etc. These parameters are very helpful in understanding the nature of the material. Efforts are also made to dope this material with impurities like iodine and rhodamine to study their effect in changing the basic properties of the material.

Key words: discharge, current, electret.

Experimental

Thin films of KTFR were made on glass slides (8). To achieve coatings of controlled and uniform thickness, xylene was used to lower the viscosity of the resist solution. For making the thin films, glass substrates were kept on a motor driven rotary vacuum chuck mounted in a bowl. The surface is then flooded with the liquid resist through a syringe with a filter membrane and the motor is turned on. The centrifugal forces distribute the viscous liquid evenly before much solvent evaporation takes place, and the excess material thrown off at the substrate edges. The platform was rotated with a speed of 1000 rpm. The film thickness of these deposited films varied from 5 to 8 μm. Doped films of this resist were also made by mixing the known quantity of I_2 and rhodamine in benzene and alcohol with resist solution (11). These films were then baked in a thermostat at 80°C for half an hour to remove the solvent from the films.

Aluminum electrodes were vacuum-evaporated onto these films leaving a parallel gap of 1 mm between the electrodes for the TSC measurements. The films were subjected to a high d-c field for polarization, at temperature T_p for a fixed period of time, and then cooled to room temperature under the same electric stress.

Ten minutes after the removal of the electrical field the films were placed in a shielded chamber to measure TSC in which the temperature increased at a constant rate, *i.e.*, 5°C min^{-1} from room temperature to 200°C. The temperature of the sample was measured with a copper-constantan thermocouple. An X-Y (Varian F-80) recorder and a Keithley 610C electrometer were used for the measurements (11).

Theory (12, 13)

The discharge current associated with the change of polarization due to heating is given by

$$i = \frac{p_o}{\tau} \exp\left(-\int_o^t \frac{dt}{\tau}\right) \quad [1]$$

where p_o is the initial polarization of the sample and τ is the relaxation time. The total charge thermally released is given by

$$Q = \int_o^\infty i\, dt \quad [2]$$

The temperature dependence of the relaxation time can be written as

$$\tau = \tau_o \exp\left(\frac{u}{kT}\right) \quad [3]$$

where τ_o is a constant, u is the activation energy, k is the Boltzmann constant, and T is the temperature. Equation [1] can be written as

$$i(T) = \frac{p_o}{\tau_o} \exp\left[-\frac{u}{kT} - \frac{1}{\beta\tau_o}\int_{T_o}^{T} \exp\left(-\frac{u}{kT}\right) dT\right] \quad [4]$$

where β is the heating rate.

The temperature T_m for the maximum current is now given by

$$\tau_o = \frac{kT_m^2}{\beta u \exp\left(\frac{u}{kT_m}\right)} \quad [5]$$

while the low temperature distribution in Eq. [4] can be written as

$$\ln i(T) = \text{const.} - \frac{u}{kT} \quad [6]$$

The activation energy u can now be determined from a semilog plot of the temperature dependence of the current. τ_o can be calculated from Eq. [5]. The TSC peaks have been analyzed by other workers in the case of semiconductors and dielectrics. Grossweiner (14) has extended the TSC technique to find the capture cross section and also the detrapping frequency. The expressions used are

$$\sigma_n = \frac{\nu}{2.9 \times 10^{24} T_m^2} \quad (m^2)$$

$$\nu = \frac{3T'\beta}{2T_m(T_m - T')} \exp\left(\frac{u}{kT_m}\right) \quad [5']$$

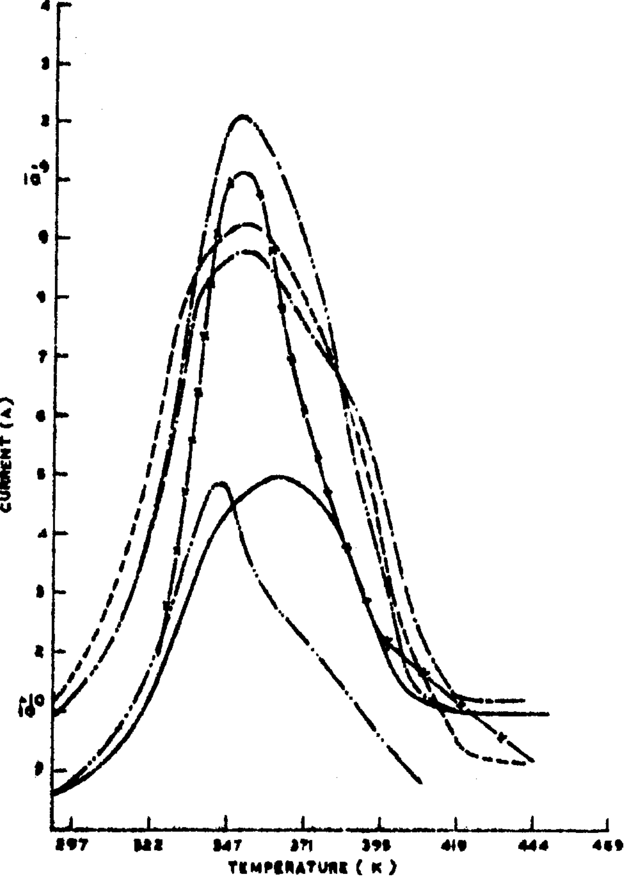

Fig. 1. TSC spectra of pure KTFR films polarized at various temperatures (E_p = 1.5 kV/cm; t_p = 45 min). ——— 333°K, - - - 353°K, -x-x- 373°K, -·-·- 396°K, -··-··-·· 423°K, -···-···- u.v. light.

where σ_n is the capture cross section, ν is the attempt to escape frequency, β the heating rate, and T' the temperature at half maximum intensity on the low temperature side.

Results

The TSC spectra of pure and doped KTFR is shown in Fig. 1-4. Figure 1 shows the spectra of pure KTFR films polarized at different temperatures under the electric field of 1.5 kV/cm. These curves show that the charge retaining capacity increases with the increase of the polarizing temperature. The various parameters were calculated from these curves and are shown in Table I. Relaxation time (τ_o) decreases with the increase of polarizing temperature. As the material is sensitive to u.v. light, the samples having a polarizing field of 1.5 kV/cm were exposed to it at room temperature and for the same polarizing time. It was found that the energy of u.v. light is sufficient in KTFR sample to polarize it and give the photoelectret effect. The results can be seen in Fig. 1. The sample was exposed for 30 min by a 100W mercury lamp, for u.v. irradia-

tion, kept at a distance of 8 cm. The sample was maintained at room temperature in the presence of air. This exposure produces charge in the sample at room temperature comparable to the result obtained with the thermo-electrets prepared at 60°C with the same polarizing field.

Figure 2 shows the results obtained with the samples of KTFR polarized at different polarizing fields and at 431°K for 40 min. The samples attained more charge with the increase of polarizing field. The calculated parameters are shown in Table II. It is observed that the relaxation time increases with the increase of polarizing field. Figure 3 shows the TSC spectra of 5% rhodamine-doped KTFR films polarized with 1.5 kV/cm for 40 min at different polarizing temperatures. The first intense peak occurs around 350°K, while the second peak was observed with the samples polarized at higher temperatures and disappeared at lower temperatures. Figure 4 shows the TSC spectra of 5% iodine-doped KTFR films polarized at various polarizing temperatures. The current increases with the increasing polarizing temperature in a similar way to that observed in the case of KTFR films. Two peaks were observed in this case. Calculated parameters are shown in Tables III and IV.

KTFR films doped with rhodamine were polarized under u.v. radiation at different polarizing voltages, and at room temperature. The results are shown in Fig. 5. One sample was polarized at zero field which did not show any significant polarization effect. Other samples polarized with polarizing fields show the presence of two TSC peaks. It clearly shows that during the polymerization, if there is a d-c field applied, exposure

can produce electrets at room temperature. Figure 6 shows the variation of peak currents of TSC spectra with their respective temperatures.

Discussion

The decay of an electret proceeds slowly at room temperature, therefore, it is advisable to stimulate the discharge by heating. Bucci and Fieshi (12) have put forward a theory of ITC. This theory has been generalized by Gross (15), Perlman (16), and Thurnbout (17) for electret effect (18). The permanent polarization in electrets has been attributed mainly to the orientation of dipoles, but no observation in this respect has been recorded so far. The electric polarization of these dielectrics can be produced by dipole alignment, migration of ions within the material, or charge injection from the electrodes. The trapping center originates in the transition of the crystalline state into amorphous regions, in the rearrangement of molecules in the polymer chain, and from the presence of impurities and defects in the material. The various defects, in addition to giving rise to their own characteristic trapping levels, can also combine with other trapping centers present around them, and thus they can modify qualitatively as well as quantitatively the TSC spectra observed under different conditions. It is, therefore, difficult to correlate a peak with a particular configuration of defects in the material. Since this material has a special property of its sensitivity to ultraviolet radiation, it can be used to give a photoelectret also (5).

Photopolymerization of monomers involves a chain reaction in which a considerable number of molecules interact to form a high molecular weight material. When insolubility is required a poly-functional monomer is added to the monomer mixture in order to promote cross-linking. Photoinitiated polymerization requires the generation of an initiating species under the influence of light. Therefore, the photopolymerization process is restricted to monomers subject to free radical initiation and propagation. The generation of free radicals at room temperature occurs when this material is exposed to light. Photocrosslinking of a polymer may be achieved by several different methods. However, in all cases preformed polymers are converted into higher molecular weight. Cross-linking may result when polymers containing functional groups subject to photosensitized dimerization are exposed to

light or upon photolysis of polymers containing groups which are photolabile.

The negative photoresist (KTFR) was made by dissolving bis(4-azidobenzal)-cyclohexanone

and cyclized polyisoprene in Kodak KTFR thinner (19, 20), cyclized polyisoprene was prepared by refluxing a solution of toluene, cis-1,4-polyisoprene, and p-toluenesulfonic acid. Cyclized rubber was dissolved in KTFR thinner and bisazide was added based on polymer. The available information is ambiguous regarding the initial step in the photoreaction of a variety of bisazides. But it is clear that N_2 is split off and nitrene formed as a highly reactive intermediate which can subsequently add to double bonds or insert labile —CH or —NH groups in polymeric materials. Bisazide derivatives can be used as cross-linking additives to polymers containing residual unsaturation, *e.g.*, cis-I, 4-polyisoprene, cyclized rubber, or cyclized polyisoprene and chlorinated rubber. When the azide groups are attached to a polymer, backbone photocrosslinking occurs.

The first photoelectret was formed with u.v. irradiation of ordinary KTFR and then with rhodamine-doped KTFR. In this case, unlike an ordinary photoelectret, a discharge current is not possible by reilluminating the sample with the u.v. light since the u.v. absorbing bisazide is photodecomposed and hence TSC measurements have been made by increasing the temperature at a linear rate. These results are not sufficient to give a conclusion about the effect of the rhodamine dopings on the basic properties of the material. Efforts are in progress to see whether the photosensitivity of this material can be changed to some other wavelength without changing the basic photocrosslinking property of the material.

Similar type of behavior, *i.e.*, of thermoelectret phenomenon was observed with ordinary and I_2-doped KTFR. It cannot be confirmed until the material doped with I_2 is studied with conductivity, EPR, infrared spectroscopy, etc. measurements, that I_2 will be able to link the polymer molecules by forming donor-acceptor complexes at appropriate sites on the chain. Electron transfer from a polymer chain to iodine then allows easy movement of charge along with the molecule.

Conclusion

It is possible to form thermoelectrets and photoelectrets using KTFR. Doping of impurities created certain new molecular states. Further detailed measurements are required to optimize the sensitivity of this material to other wavelengths without changing its basic properties. With this change, utility of this material in semiconductor technology will increase.

Capless Annealing of Ion-Implanted Gallium Arsenide by a Melt-Controlled Ambient Technique

C. Lawrence Anderson,* K. V. Vaidyanathan,* H. L. Dunlap, and G. S. Kamath

Hughes Research Laboratories, Malibu, California 90265

ABSTRACT

A novel capless technique for the annealing of ion-implanted GaAs is described. The apparatus employed consists of a large solution of GaAs in Ga, into which is immersed a suitable sample holder containing the wafer to be annealed. Se-implanted layers annealed using this technique behave electrically in the manner expected for well-annealed group VI dopant implants into GaAs. The electrical activity of implanted Si, however, decreases with increasing anneal temperature in the range from 800° to 900°C. Possible explanations for the behavior of the implanted Si are discussed.

Dielectric encapsulants such as SiO_2 (1), Si_3N_4 (2, 3, 4), and AlN (5) are commonly used to prevent dissociation of GaAs during the annealing cycles required to electrically activate ion-implanted impurities. In such "capped" annealing cycles, the dielectric encapsulant must perform a number of partially contradictory functions if the implanted layer is to exhibit good electrical properties. The encapsulant must possess sufficient mechanical integrity and adherence to GaAs to remain intact during the annealing cycle, yet it must be sufficiently plastic that it will not stress the GaAs severely as a result of thermal expansion mismatch. It must be chemically stable and inert to prevent it from reacting with and/or doping the GaAs, yet it must be readily removable by chemical means. To maintain surface stoichiometry, it must also be impermeable to the outdiffusion of Ga and As.

Considering the diverse demands on the dielectric encapsulants during "capped" annealing, it is not surprising that there has been considerable interest recently in encapsulant-free or "capless" annealing techniques. Previously reported successful techniques include performing the anneals in flowing ambients with controlled arsenic vapor pressure (6), embedding the sample in powdered graphite previously saturated with Ga and As (7), and placing the implanted sample in close proximity to an unimplanted GaAs sample (8). In this paper we discuss a novel approach to capless annealing of GaAs (9). In this technique, a highly stable controlled ambient is provided by a solution of Ga saturated with GaAs. The sample, contained in a specially designed sample holder, never comes into physical contact with the solution, but vapor phase contact is maintained between the solution and the sample. Thus, the solution acts as a large thermodynamic reservoir which provides a highly reproducible arsenic vapor pressure in the vicinity of the sample. For this reason, we have termed this annealing concept the melt-controlled ambient technique, or MCAT.

Description of Apparatus and Experimental Procedure

The apparatus used in MCAT annealing was originally developed for liquid phase epitaxial growth of III-V compound semiconductors employing a large solution (10-12). This system, illustrated schematically in Fig. 1, consists of a crucible which contains the required solution, which typically has a mass of a few kilograms. This crucible is contained in an all-quartz annealing chamber which is connected to a stainless steel entry chamber through a high vacuum valve. The interior annealing chamber is continuously maintained in an ambient of palladium-diffused hydrogen. If desired, it could be maintained easily with other ambients. The entry chamber can be independently evacuated and purged. By use of a linear motion feedthrough mounted in the top cap of the entry chamber and by employing adequate purging procedures, it is possible to introduce samples into the annealing chamber without introducing significant amounts of gaseous contaminants into the system.

Samples to be annealed are held in a specially designed graphite sample holder. The chamber which contains the sample is enclosed by a sliding cover. This design does not allow the melt to come into contact with the samples being annealed. The sample holder, while liquid tight, is not vapor tight. Annealing is performed by immersing the samples in the melt maintained at the required temperature. Using this technique, samples of ion-implanted GaAs have been annealed at temperature up to 900°C. The surface morphology of MCAT annealed samples is generally indis-

tinguishable from that of unannealed samples under electron microscopic examination.

Experimental Results

Samples from (100) Cr-doped semi-insulating ingots obtained from Crystal Specialties, Incorporated were implanted with either 260 keV Se or 100 keV Si. The Si implants were performed at room temperature. Se implants were performed at either 250°C or at room temperature. The samples were tilted at ~ 7° relative to the incident ion beam to avoid channeling effects. The samples were then MCAT annealed at the required temperature. Square (~ 4 × 4 mm) Hall specimens cleaved from the implanted wafers were prepared by making ohmic contacts at the corners using an In:Ag:Ge alloy.

Results from Hall effect measurements performed on room temperature Se-implanted samples are presented in Table I. A range of doses from 1×10^{13} cm^{-2} to 1×10^{14} cm^{-2} was covered and the samples were MCAT annealed at the temperatures shown. The electrical activation in all cases studied is rather poor. This result is consistent with previous studies which show that high activation from the moderate fluence Se implants is generally obtained only from samples implanted at elevated temperatures (> 150°C) (13-15). Since considerable surface dissociation can take place at implant temperatures in excess of 400°C (16-17), elevated temperature Se implants were performed at 250°C. These samples were MCAT annealed at temperatures between 800° and 900°C for 30 min. The electrical properties of these layers are presented in Fig. 2. This figure shows the variation of sheet electron concentration (cm^{-2}) and sheet electron mobility (cm^2 V^{-1} s^{-1}) as a function of anneal temperature for samples implanted to fluences ranging from 1×10^{13} cm^{-2} to 1×10^{14} cm^{-2}. The electrical activation at all doses increases with anneal temperature. In the case of low fluence implants (1×10^{13} cm^{-2} and less), over 90% of the implanted ions become electrically active when annealed at 900°C for 30 min. The mobilities in these layers were > 3200 cm^2 V^{-1} s^{-1}. In the case of high fluence implants (1×10^{14} cm^{-2}), sheet carrier concentrations of 6×10^{13} cm^{-2} with mobilities of ~ 1800 cm^2 V^{-1} s^{-1} were measured following an anneal at 900°C. These results are in excellent agreement with the highest activation reported for Se-implanted GaAs annealed with an encapsulant.

Figure 3 shows the measured sheet carrier concentration for samples annealed at 900°C as a function of the implant dose. The dashed line represents the case of 100% apparent electrical activation. At low fluences (< 10^{13} cm^{-2}), almost all the implanted ions are electrically active. Approximately 80% apparent electrical activation is obtained at a fluence of 5×10^{13} cm^{-2}. At high doses, the measured carrier concentration saturates at ~ 7×10^{13} cm^{-2}. These results are in excellent agreement with the earlier results of Donnelly *et al.* (15).

Figure 4 illustrates the variation of sheet electron concentration and electron mobility as functions of an-

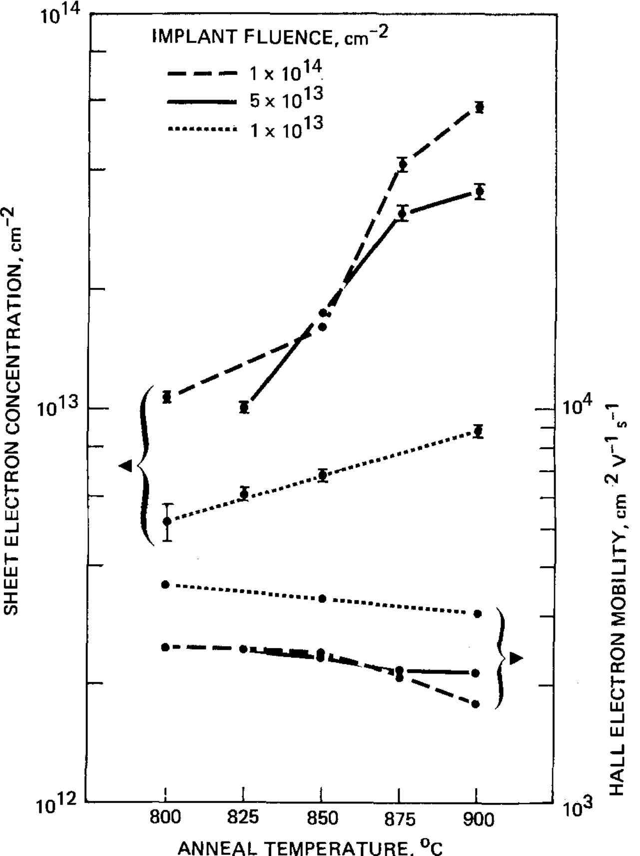

Fig. 2. Variation of sheet carrier concentration and mobility of 260 keV Se-implanted samples as a function of anneal temperature. The samples were implanted at 250°C to fluences indicated.

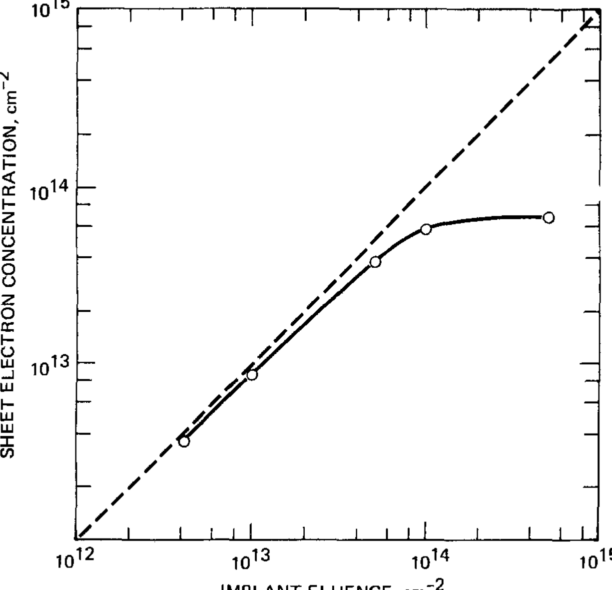

Fig. 3. Sheet carrier concentration *vs.* dose for 260 keV Se-implanted GaAs. The implants were performed at 250°C and post-annealed using MCAT at 900°C for 30 min.

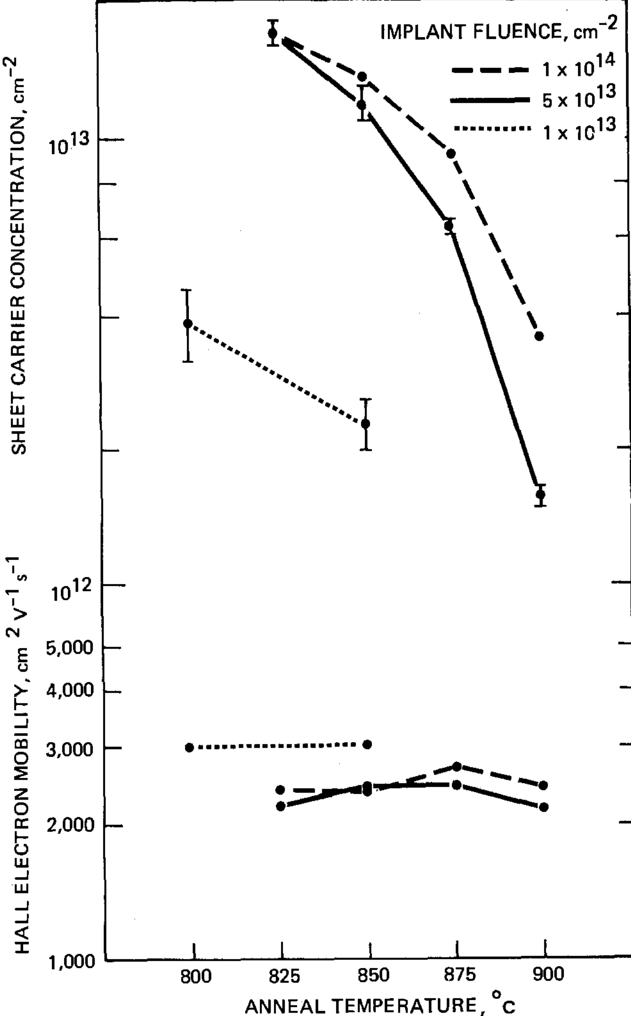

Fig. 4. Sheet carrier concentration and mobility as a function of anneal temperature for 100 keV Si-implanted GaAs.

neal temperature for samples implanted at room temperature to different fluences with 100 keV Si^+. In contrast to the behavior of the Se-implanted samples, the measured sheet carrier concentration in the Si-implanted samples decreases as the anneal temperature is increased in all cases studied. The mobility stays essentially constant. These results are contrary to the normal encapsulated annealing behavior of Si-implanted GaAs.

Two possible explanations for the anomalous annealing behavior of silicon-implanted MCAT annealed GaAs are as follows: first, drastic redistribution of implanted silicon during annealing with concurrent loss of silicon due to outdiffusion would explain the observed results. Preliminary secondary ion mass spectrometry (SIMS) studies of the annealed sample indicate that the silicon distribution remains roughly gaussian following MCAT annealing. Second, the implanted silicon may be exhibiting amphoteric doping behavior. If the solution is not completely saturated at the anneal temperature, or if the vapor exchange between the sample and the solution is insufficient, As vacancies may be generated in the sample. In the presence of these vacancies, the implanted silicon will tend to occupy As sites and thus act as an acceptor. Recently, Walukiewicz *et al.* (18) have studied the effect of compensation on electron mobility in GaAs. Using their data in conjunction with the measured mobility, we estimate the compensation ratio in these samples to be greater than 0.5. We believe that the poor activation observed in Si-implanted MCAT annealed samples can be explained at least in part on the basis of the amphoteric doping behavior of silicon in GaAs. Techniques to alter the vapor pressure of As within the sample holder, and the effect of these techniques on the electrical behavior of implanted Si, are presently under investigation and should help clarify the situation. In addition, extension of this technique to other semiconductors (*e.g.*, InP) and to other dopants in GaAs is in progress.

Conclusions

The melt-controlled ambient technique (MCAT), which employs the vapors of a solution of GaAs in Ga as a source of As overpressure for capless annealing, has been used to anneal Si- and Se-implanted GaAs. Excellent electrical activation and high electron mobilities have been achieved in Se-implanted samples. In the case of Si-implanted samples, however, low electrical activation and mobilities consistent with moderately high compensation have been observed. This behavior has been attributed to amphoteric behavior of Si under As-deficient conditions.

Aluminum Etching in Carbon Tetrachloride Plasmas

K. Tokunaga* and D. W. Hess**

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Etch rates of aluminum and native aluminum oxide films in carbon tetrachloride plasmas were investigated as functions of substrate temperature and electrode material in a parallel plate plasma etching system. Use of stainless steel electrodes resulted in the formation of a carbon-chlorine polymer which precluded aluminum etching. Anodized aluminum electrodes minimized polymer formation and etching was achieved. Several inherent differences in the electrode materials were considered to account for this effect. Analysis of the effluent from the reactor suggested possible chemical reactions occurring in the carbon tetrachloride plasma, as well as a precursor to polymer formation.

Although liquid etching techniques abound in current integrated circuit fabrication processes, the intense interest in micron and submicron geometries has recently kindled extensive efforts in plasma-assisted etching (1). Much of this effort has centered around plasma (or reactive ion) etching of silicon-based materials, *e.g.*, polysilicon, silicon nitride, and silicon dioxide. Somewhat less information is available on plasma etching of aluminum or aluminum alloys, which are the most common metallization layers in silicon IC's.

Several investigators have reported the successful etching of aluminum films in a parallel plate plasma etcher using chlorine- or bromine-containing gases (2-7). In particular, aluminum and aluminum alloys have been plasma-etched in boron trichloride (3, 4) and in carbon tetrachloride vapor containing argon (3, 6) or helium (5, 6). Less success has been achieved using hydrogen chloride or chlorine plasmas, presumably due to the inability of these gases to etch through the native aluminum oxide layer on the aluminum surface (3). Reactive ion etching (RIE), however, has demonstrated the ability to etch aluminum and its silicon- and copper-containing alloys in gas mixtures of argon with either chlorine, bromine, hydrogen chloride, or hydrogen bromide, although these processes were not always reproducible (7). Excellent results were obtained with RIE (7) using carbon tetrachloride/argon mixtures.

Information concerning the plasma etching of aluminum films in pure carbon tetrachloride vapor is absent in most studies. Mention has been made of the fact that etching in carbon tetrachloride is possible, at least in RIE (7) or under conditions of very high power densities (6). In this paper. we describe the results of plasma etching aluminum films in carbon tetrachloride vapor using a parallel plate plasma etcher. Successful etching of these films is shown to be dependent upon minimization of a carbon-based polymer resulting from the decomposition of carbon tetrachloride.

Experimental Procedure

The parallel plate plasma etcher used in this investigation is shown in Fig. 1. The substrates were laid on a 20.4 cm diam lower electrode, which was resistance-heated by a coil of stainless steel encased Nichrome wire, and was cooled by circulation of a cooled fluid through 1/8 in. stainless steel tubing, also coiled beneath the electrode. Power from a 13.56 MHz rf generator was supplied to the top electrode, which was separated from the grounded lower electrode by a distance of 2.5 cm. The temperature was monitored by an iron-constantan thermocouple attached to the bottom electrode.

Etch gases were metered through needle valves and rotameters, and entered the plasma region through holes in the hollow upper electrode. The ideal gas flow rate at standard conditions was determined for the CCl_4 rotameter by measuring the rate of weight loss of the CCl_4 container at 20°C. The pressure was monitored by a capacitance manometer, and could be changed by varying the setting of a throttle valve on the pump and/or by changing the etch gas flow rate. A liquid nitrogen cold trap between the pump and the vacuum system prevented oil back-diffusion and protected the pump from corrosive gases.

Etch samples were prepared by evaporating aluminum from a tungsten filament on to 2.2 cm diam Pyrex cover slips or onto oxidized silicon wafers. The film thicknesses studied ranged from 30 to 1000 nm, but were usually 400 nm.

A test run was generally performed to establish the etch gas flow rate and the rf power and impedance matching. Etch runs were typically carried out at

100W rf power (0.3 W/cm²), and 67 Pa (0.5 Torr) pressure, which corresponds to ~30 sccm CCl_4 for the above system. Since etching commenced on the edge of the samples and proceeded toward the center of the substrates, the etch time was taken as the time necessary to completely clear the aluminum film.

Results and Discussion

It is well known that aluminum films have on their surface a native oxide film, that presents a low etch rate barrier to chlorinated etch gases (3-7). In an attempt to determine both the aluminum and the native oxide etch rates, data were taken simultaneously on both thin (30-40 nm) and thick (>300 nm) aluminum films. The total etch time for these two films can then be expressed by

$$t_1 = \frac{(T_{ox})_1}{r_{ox}} + \frac{(T_{Al})_1}{r_{Al}} \quad [1]$$

$$t_2 = \frac{(T_{ox})_2}{r_{ox}} + \frac{(T_{Al})_2}{r_{Al}} \quad [2]$$

where t_1, t_2 = etch times for samples 1 and 2, T_{ox} = the thickness of the native aluminum oxide film, T_{Al} = the thickness of aluminum film, r_{ox} = the etch rate of native aluminum oxide film, and r_{Al} = the etch rate of aluminum film. However, since $(T_{ox})_1 = (T_{ox})_2 \cong 3$ nm (11), etch time measurements allow the calculation of etch rates for both aluminum and the native aluminum oxide films. It should be mentioned that the etch rates determined for the native oxide films by this method assume that the inhibition of aluminum etching by chlorinated gases is due solely to the slow etching aluminum oxide coating. Since water oxidation of several aluminum samples (8) has shown large increases in oxide etch time, this is in part a reasonable assumption. However, another factor which contributes to the etching inhibition is the presence of moisture adsorbed on the system walls, possibly resulting from hygroscopic aluminum chloride (9). In our experiments, effects of aluminum chloride are minimized, because our chamber and electrodes are cleaned between etch runs. Despite such drawbacks for the exact determination of native aluminum oxide etch rates, these considerations have little effect on the aluminum etch rate.

Stainless steel electrodes.—Initial experiments utilizing stainless steel electrodes, pressures up to 100 Pa CCl_4, substrate temperatures up to 150°C, and rf power levels to 120W, resulted in no aluminum etching for plasma exposure times in excess of 40 min. Subsequent experiments demonstrated that argon addition did not significantly improve the etching ability of CCl_4 under the above conditions. Further, in all cases, a brown deposit (Fig. 2) was observed on the electrodes and substrates. Since etching was easily accomplished under identical conditions using a BCl_3 plasma, and this procedure yielded no deposit, a carbonaceous residue was suspected. Indeed, an Auger spectrum (Fig. 3) indicated that a carbon-chlorine compound was present on the surface of the aluminum samples. In addition, Fig. 3 shows that little aluminum oxide could be detected, suggesting that the polymer-type deposit was thicker than 2 nm. Subsequent Auger analyses using a Physical Electronics Model 590 Scanning Auger Electron Microprobe demonstrated that the micron-sized particles shown in Fig. 2 had the same composition as the regions adjacent to them. Thus it would appear that either these particles formed as a result of polymer nucleation or contamination present on the sample surface, or that the particles arose directly from the polymer coating, perhaps by sputtering. Presently, it is not clear whether the polymer immediately coats the aluminum surface, or whether the polymerization rate is simply greater than the native oxide etch rate in CCl_4. Nevertheless, the final result

Fig. 2. Deposit observed on almuinum film exposed to a CCl_4 plasma using stainless steel electrodes. Plasma conditions were 67 Pa CCl_4, 100W, 100°C, and 2.5 cm electrode spacing.

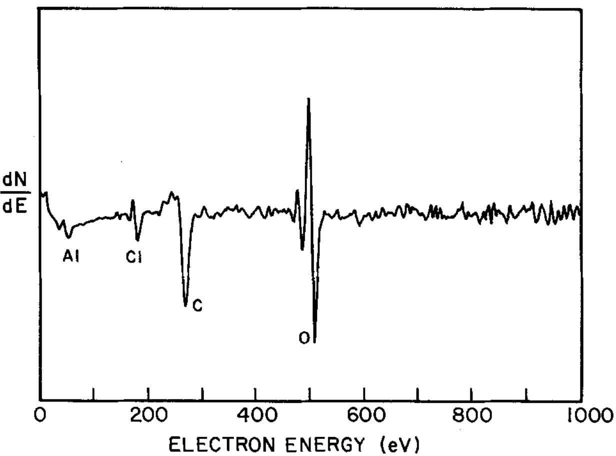

Fig. 3. Scanning Auger spectrum of aluminum film exposed to a CCl_4 plasma using stainless steel electrodes. Electron beam energy was 5 keV. Plasma parameters are the same as noted for Fig. 2.

is the same—inhibition of aluminum etching due to a carbon-chlorine film.

Anodized aluminum electrodes.—Preliminary results indicated that aluminum films could be plasma-etched in CCl_4 using aluminum electrodes without significant polymer formation, although the reproducibility of this procedure is questionable. In order to minimize attack of the electrode material, aluminum electrodes were oxidized in hot (60°-80°C) DI water (8) to increase the surface oxide thickness. Since this process greatly improved the reproducibility of the etch rate data, and little or no polymer was observed on the electrode surfaces, aluminum electrodes were anodized in an aqueous sulfuric acid solution (15% by volume) under constant current conditions to a thickness of ~10 μm.

The results of etching aluminum films at 100W rf power and 67 Pa CCl_4 pressure using anodized aluminum electrodes are given in Fig. 4. The change in etch rate due to a change in electrode material is dramatic —from an etch rate of zero to ~130 nm/min at an electrode temperature of 100°C.

The Arrhenius plot shown in Fig. 4 yields an activation energy for the etching of aluminum and native aluminum oxide films in pure CCl_4 plasmas of 0.3 eV/mole, which is similar to activation energies for the plasma etching of other thin film materials (10). It is curious that the activation energies for the etching of native aluminum oxide and aluminum films are essentially the same, since the primary etchant species for these two materials are probably different (3).

Preliminary results obtained with BCl_3 plasmas have shown that the etch rates of aluminum films are more reproducible with anodized aluminum electrodes than with stainless steel electrodes (11). Since Auger spectroscopy did not detect iron contamination on samples etched in CCl_4 on stainless steel electrodes, it is unlikely that the difference in etch reproducibility cited above is a result of iron chlorides in the case of stainless steel electrodes and BCl_3. Also, aluminum etch rates using BCl_3 displayed no temperature dependence on anodized electrodes (11), which is consistent with previous BCl_3 studies on stainless steel electrodes (3). These data suggest that under the above plasma conditions, the rate-limiting step in BCl_3 etching is the gas-phase generation of "active" chlorine species.

Comparison between stainless steel and anodized aluminum electrodes.—It is interesting to speculate about the reasons for the gross inconsistencies in aluminum etching results observed with CCl_4 on stainless steel *vs.* anodized aluminum electrodes. Oxygen has been shown to play an important role in the etching of silicon in fluorinated hydrocarbon gases (12-15). In particular, surface studies (13) have demonstrated the participation of lattice oxygen in removing carbon films deposited by CF_3^+ bombardment of a silicon surface.

Figure 5 shows the effect of oxygen addition to a CCl_4 plasma on the etch time of a 540 nm aluminum film. Additional data with oxygen additions up to 14% (by volume) indicated that the etch rate decreased up to 12% oxygen, after which no etching was observed, even on anodized aluminum electrodes. Further, an etch run utilizing 50 ppm oxygen (by dilution in argon) in CCl_4 also diminished the etch rate on anodized aluminum electrodes, and failed to produce etching on stainless steel electrodes. Such results suggest that the etchant species responsible for aluminum oxide (and possibly aluminum) etching is consumed by oxygen, thereby slowing or ultimately precluding etching. Since carbon compounds should react readily with oxygen, these data lend support to the proposal that CCl_3 or CCl_2 groups are responsible for aluminum oxide etching (3).

An additional concern with oxygen inclusion during plasma etching of aluminum is that aluminum oxidation could occur, thus increasing further the etch time for the aluminum film. Plasma oxidation of metals is well known (16), but under the present plasma and substrate bias conditions, it is unlikely that significant aluminum oxide growth will take place, although the differences in etch rate between aluminum oxide and aluminum suggest that a small amount of oxide would increase the overall etch time considerably.

A second consideration with regard to the observed differences between anodized aluminum and stainless steel electrodes relates to the differences in secondary electron emission from the electrode material. It has been demonstrated that insulators display greater secondary electron emission than do metals (17). In fact, this observation has been invoked to explain the increase in etch rate of silicon in CF_4 when silicon dioxide, rather than aluminum, serves as a cathode material (18). For the present investigation, however, it is felt that the changes in etch rates on the two electrode

Fig. 4. Arrhenius plot of the etch rates of aluminum and native aluminum oxide films in CCl_4 plasmas. Plasma conditions were 67 Pa CCl_4, 100W, and 2.5 cm electrode spacing.

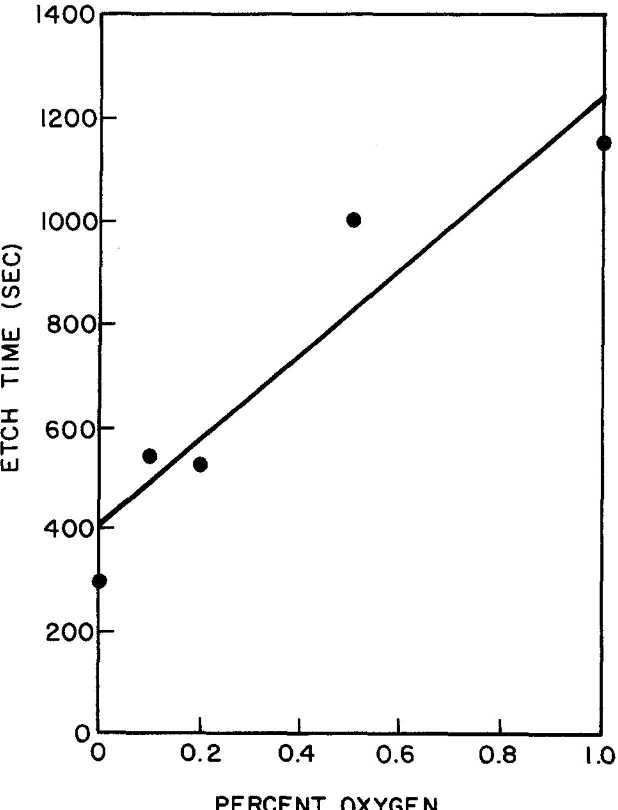

Fig. 5. Effect of oxygen addition (volume percent) to a CCl_4 plasma on the total etch time of a 540 nm aluminum film. Plasma parameters were 67 Pa CCl_4, 100W, 100°C, and 2.5 cm electrode spacing.

materials are too large to be accounted for by an increase of a factor of 2-5 in secondary electron emission.

A third difference between anodized aluminum and stainless steel electrodes involves the fact that alumina is an insulator, and stainless steel is a metal. It is well known that surfaces exposed to a plasma and not externally grounded or biased assume a floating potential which is negative with respect to the plasma potential (19). Since anodized aluminum is an insulator, the high negative potential generated on this surface can cause an increase in positive ion bombardment relative to that experienced by the stainless steel (metal) electrode, thereby enhancing the etch rate under similar plasma conditions (20). This possibility was investigated by placing a sheet of Teflon between the stainless steel lower electrode and the heating and cooling assembly (which was grounded) to electrically isolate the electrode. However, aluminum etching was still not successful using CCl_4, indicating that the insulating character of the electrode is not the controlling factor in aluminum etching on these two electrode materials.

A final consideration in the use of stainless steel *vs.* anodized aluminum electrodes involves the surface chemistry of chlorocarbons on these two materials. Although stainless steel was found to be a good recombination surface for fluorine atoms (15), extension of this model to chlorine is not obvious, since BCl_3 showed significant etch rates of aluminum oxide and aluminum using stainless steel electrodes. Recombination of carbon-containing species is a possibility, however, since polymer deposits were always found with CCl_4 plasmas using stainless steel electrodes. Indeed, iron and nickel are both Fischer-Tropsch catalysts (21), and are thus used to generate long chain hydrocarbons (C_5-C_{30}) from carbon monoxide and hydrogen. Such a mechanism could be operative on stainless steel electrodes when chlorocarbon fragments are present, thereby generating polymer-type films.

Further indication of a surface controlled reaction on stainless steel electrodes using CCl_4 arises from two additional sets of experiments. First, in at least one experiment it was observed that if the carbon-chlorine coating is not removed after an initial CCl_4 plasma, and virgin aluminum samples are subsequently exposed to a CCl_4 plasma, etching can be achieved. Second, aluminum etching has been attempted with an upper stainless steel and a lower anodized aluminum electrode, with the result that etching proceeded at approximately the same rate as it would have if both electrodes were anodized aluminum. However, the reverse electrode configuration (SS bottom, anodized aluminum top) again precluded etching.

Plasma chemistry of CCl_4.—In an attempt to elucidate the chemistry occurring in CCl_4 plasmas, the effluent from the reactor shown in Fig. 1 was collected by means of a series of cold traps between the system and the vacuum pump. Combustion analysis of a white powder which was routinely observed whether stainless steel or anodized aluminum electrodes were used, proved the compound to be hexachloroethane (C_2Cl_6). Chlorine gas was also found in the effluent, and was quantitatively analyzed by titration techniques (22). Gas chromatographic studies (Hewlett Packard Model No. 5840A) of the liquid portion of the effluent identified tetrachloroethylene (C_2Cl_4) and CCl_4 as reaction products.

The above data suggest possible mechanisms for the breakdown of CCl_4 in a plasma environment. First, the CCl_4 undergoes decomposition upon electron bombardment

$$e + CCl_4 \rightarrow CCl_3 + Cl + e \qquad [3]$$

although ionization to CCl_3^+ and Cl^- probably occurs to some extent. Further breakdown of the CCl_3 can also take place

$$e + CCl_3 \rightarrow CCl_2 + Cl + e \qquad [4]$$

Indeed, these species have been observed by other investigators (3, 24) and in addition, CCl has been reported from optical emission (23) and mass spectroscopic studies of CCl_4 plasmas and vapors (24). Finally, one can envision other more complicated reactions occurring, stemming from the breakdown of C_2Cl_6, as has been shown for the case of C_2F_6 (14).

Recombination on the wall or in the gas phase of the various fragments indicated in Eq. [3] and [4] then generate the observed products in the cold traps (along with unreacted CCl_4)

$$CCl_3 + CCl_3 \rightarrow C_2Cl_6 \qquad [5]$$

$$Cl + Cl \rightarrow Cl_2 \qquad [6]$$

$$CCl_3 + Cl_2 \rightarrow CCl_4 + Cl \qquad [7]$$

$$CCl_2 + CCl_2 \rightarrow C_2Cl_4 \qquad [8]$$

The chlorine radical, as generated by Eq. [3], [4], and [7], is probably responsible for aluminum etching, as proposed previously (3, 6, 7). Finally, aluminum reacts with Cl to form AlCl, $AlCl_2$, or $AlCl_3$ (ultimately) as noted by other investigators (3, 23). By way of comparison, species such as CCl_3, CCl_2, CCl_3^+ and CCl_2^+ are most likely the etchants for Al_2O_3 (3, 7). It should be mentioned that the proposed chemical reaction mechanisms for aluminum etching in CCl_4 plasmas reported in this paper are consistent with results reported for the gas phase photolysis of CCl_4 (25), as well as with Si and SiO_2 etch studies using CF_4 (15).

Still another indication of the importance of surface effects in the plasma environment arises from comparison of the yield of reaction products on stainless steel *vs.* anodized aluminum electrodes. Table I gives the weight percent of the observed products (relative to the weight of CCl_4 input) from a CCl_4 plasma created using the two electrode materials. The factor of 10 increase in C_2Cl_4 yield with stainless steel electrodes suggests that this compound is in part responsible for polymer formation (note that the material balance is incomplete for the stainless steel electrodes, due in large part to polymer formation within the reactor). To be sure, a C_2Cl_4 plasma resulted in polymer formation under the above plasma conditions, even on anodized aluminum electrodes.

Table I. Effluent composition from CCl_4 plasma at 100W, 67 Pa, 100°C substrate temperature, and 2.5 cm electrode spacing using anodized aluminum and stainless steel electrodes

	Weight percent			
	CCl_4	C_2Cl_6	Cl_2	C_2Cl_4
Anodized Al	73.8	14.3	8.6	0.8
Stainless steel	57.1	13.9	6.8	8.3

The chemical mechanism responsible for the increase in C_2Cl_4 content for stainless steel electrodes is not clear at the present time. As discussed earlier, a surface effect involving either the stainless steel surface or the resulting carbon-chlorine polymer surface is probably operative, but other possibilities exist. For instance, if stainless steel does not permit the generation of large amounts of free chlorine radicals, due to recombination, then a mechanism similar to that described by Flamm for the observation of C_2F_4 from C_2F_6 discharges might occur (15).

Summary

The etch rates of aluminum and native aluminum oxide films in CCl_4 plasmas were studied as functions of substrate temperature and electrode material in a parallel plate plasma etcher. Formation of a carbon-chlorine polymer precluded aluminum and aluminum oxide etching when stainless steel electrodes were used. Anodized aluminum electrodes permitted aluminum and aluminum oxide etching with an activation energy of 0.3 eV/mole. The etch rate of aluminum was found to be 100 times greater than that of aluminum oxide. Several possible differences between the two electrode

materials were considered including oxygen effects, electric potential, and secondary electron emission. However, the most probable cause of the electrode effects involves the surface chemistry of chlorocarbon fragments.

Analysis of the effluent vapors from the parallel plate reactor demonstrated the presence of CCl_4, C_2Cl_6, Cl_2, and C_2Cl_4. These constituents suggest possible chemical reactions taking place in the CCl_4 plasma. Little difference between stainless steel and anodized aluminum electrodes was observed in the quantities of CCl_4, C_2Cl_6, and Cl_2 obtained from the CCl_4 plasma. However, a factor of ten increase in C_2Cl_4 was noted for stainless steel relative to anodized aluminum electrodes, indicating that dimers and possibly higher homologues of CCl_2 are formed when stainless steel electrodes are used. Aluminum etching is thus inhibited by C_2Cl_4 polymerization along with the formation of higher molecular weight polymers via surface recombination of many chlorocarbon fragments.

Time Dependent MOS Gate Oxide Defects Using Liquid Crystals

A. K. M. Zakzouk*

Electrical Engineering Department, Riyadh University, Riyadh, Saudi Arabia

ABSTRACT

Localized conducting regions of silicon dioxide are a major source of failure of integrated circuits. By using nematic liquid crystals in contact with the oxide, and simultaneously applying an electric field across such a sandwich structure, defective regions can be nondestructively identified. By examining the number of defects as a function of the magnitude and polarity of the applied voltage, time, and oxide thickness, it is possible to obtain information on the cause and nature of these localized regions of high conduction. Measurements have been performed on oxide conduction in thin layers (1000-2000Å) of silicon dioxide, similar to those commonly employed as gate dielectrics in MOS devices, grown in dry oxygen. The liquid crystal technique has been shown to be a valuable nondestructive technique for studying the behavior of oxide defects as a function of the magnitude and polarity of the applied voltage, time, and oxide thickness.

A major source of loss of yield and/or reliability of integrated circuits is caused by the presence, or formation during life, of defects in the silicon dioxide layer on the surface of the silicon. These defects have been the subject of studies by a number of investigators (1-3). For this reason also, fundamental studies of oxide conduction (4, 5) and breakdown (6) have been under-

* Electrochemical Society Active Member.
Key words: integrated circuit testing, dielectric, liquid crystals, oxide defects, field, time dependence.

taken. The study of defective oxide was, until recently, hampered by the lack of a reproducible nondestructive technique for locating the defects. A review of the available techniques has been presented by Kern (7).

Di Stefano (8) has used photoemission measurements to show that a highly localized reduction of the silicon dioxide barrier can occur, particularly after contamination of the oxide by impurity ions such as sodium. The barrier is lower after applying an electric field across the oxide which drives the impurity ions to the silicon surface. Williams *et al.* (9) have suggested that the cause of the localized barrier lowering is a condensation of sodium ions at particular points on the silicon surface. The potential energy of a particular ion is shown to be lower when it is situated near to a metallic-like surface. An accumulated silicon surface approximates such a surface and the positive sodium ions will induce such a surface condition. The effect promotes the condensation and would be expected to produce the highly localized barrier lowering described by Di Stefano (8).

Raider (10) has demonstrated that sodium drift can be responsible for time-dependent breakdowns, presumably due to electron injection into the film at localized regions where the barrier is lowered. Fritzsche (11) found that the primary mode of breakdown in silicon dioxide was electronic in nature, thus exhibiting no dependence on the duration of the applied field. In contrast, Worthing (12) found that when a constant, positive voltage was applied to the metal for the time required to cause breakdown, the breakdown field of silicon dioxide films on n-type, degenerate silicon was proportional to $(\text{time})^{-1/4}$. This particular time dependence has been frequently observed for bulk insulators where it is known as Peek's law (13). This has the effect of lowering the dielectric strength of the silicon dioxide film from 6.7 MV/cm for fast stressing rates to approximately 3 MV/cm for a testing voltage applied at an infinitely slow rate. However, no time dependence was observed by Worthing when the silicon was positively biased.

Inconsistent with Fritzsche's breakdown model (11), which implies that processing steps promoting local crystallization of the oxide will result in an increase in defect-related breakdown, Chou and Eldridge (2) have demonstrated that: (*i*) while a lowering of the concentration of mobile impurities reduces the occurrence of defect-related breakdown, it does not change the magnitude of the primary (intrinsic) breakdown strength (7-9 MV/cm) of silicon dioxide; (*ii*) under identical silicon dioxide growth conditions, reduction of film thickness is accompanied by an increase in the density of oxide faults. Excessively high defect density in the oxide gives rise to a time dependence of the breakdown characteristics and can therefore lower the magnitude of the primary breakdown strength under certain testing conditions; and (*iii*) sodium contamination can result in severe oxide deterioration, especially during film growth at temperatures in the 1000°-1200°C range. This has been followed by a large amount of work on the effect of sodium on conduction and breakdown (14, 15), all of which must ultimately be fitted into any general theory of oxide conduction and breakdown.

Conduction has been studied in oxides with, presumably, minimal amounts of barrier lowering by Lenzlinger and Snow (4). Their results, obtained on MOS capacitor structures, indicate that conduction is primarily limited by Fowler-Nordheim tunneling either from the metal or silicon into the oxide. Osburn and Weitzman (5) have arrived at similar conclusions, but also indicate the importance of mobile ions and trapping phenomena in the conduction process. The tunneling distance and barrier height can be reduced by the presence of positive charge, a short distance from the interface (8), within the oxide, or by a large applied electric field. The effect of the electric field may be enhanced by the presence of physical irregularities (16-18) at the silicon surface causing field intensification. Only when one of these effects is present will the conduction process be limited by the silicon dioxide bulk properties. When this is the case, we have a defective region and relatively high currents will flow, a premature breakdown is then possible. This is particularly important in integrated circuits containing thin oxides (*e.g.*, MOS and CCD devices). Breakdown may occur by a self-healing (19) process whereby the metal is blown clear of the hole after melting. Frequently, however, device failure will result when the oxide becomes short-circuited. This process is not well understood, but statistical evidence would suggest that it becomes increasingly probable with thicker metal layers (>1 μm), or with passivated structures, and is presumably associated with the inability of the metal to evaporate.

The Liquid Crystal Technique

In order to study oxide defects it is desirable to have a nondestructive technique for locating them. On the basis of the evidence currently available, the liquid crystal technique (1) (LCT) is such a method. The negative nematic liquid crystal used in the present work was contained between the plane parallel electrodes (16), the lower of which is the oxidized silicon slice, the upper a glass plate coated on its underside with a conducting, but transparent, layer (*e.g.*, tin oxide).

With a voltage difference between this conducting layer and the silicon slice, defects can be seen through the glass plate, with an optical microscope, as areas of turbulence. The thickness of the liquid crystal layer, under the weight of the glass slice was in the 10-25 μm range. When the required test voltage is applied between the tin oxide layer and the silicon slice, turbulence is seen in the liquid crystal, wherever there is a current leakage path to the substrate and a field greater than the threshold of approximately 5 kV/cm across the liquid crystal. Typically, 7 or 8V were required for a display on uninsulated parts of the substrate, but higher voltages were required before there was sufficient leakage current to give a display on other parts of the substrate. The current density required to produce a display is extremely small, approximately 30 mA/m^2. The highly resistive liquid crystal is in series with the sample under test, therefore, even if the breakdown voltage of the dielectric is exceeded, the current is limited and no permanent damage occurs, although there is sufficient current to produce a display. Breakdown of the defective region of the film is prevented by an increasing fraction of the applied voltage being taken up by the liquid crystal, as the current increased. Displays can be reproduced many times. The turbulence at the location of a defect is caused by molecules in the liquid crystal absorbing electrons from the oxide. The passage of these charged molecules causes a hydrodynamic torque on the rod-like molecules of the liquid crystal.

Preparation of Samples

All the results described here, unless otherwise stated were obtained on (111) orientation 5 Ω-cm n-type polished silicon substrates. The silicon was initially degreased and was then boiled in nitric acid, followed by treatment in hydrofluoric acid, before washing in deionized water. The oxidation was carried out in dry oxygen at 1000°C for sufficient lengths of time to produce 1000-2000Å thick films. The furnace was resistance heated and the silicon slices were contained on a quartz boat in a single wall quartz tube. All the oxidations were carried out with the slices horizontal, fully supported by the quartz boat. This minimizes the stress on the silicon during oxidation and cooling. In many cases this procedure was preceded by steam oxidation of the silicon. Using conventional photolithography small windows were etched in the steam oxide ($\gtrsim 1$ μm) and the thin dry oxide was

grown in the windows. This procedure was carried out to facilitate precise location of a particular region of oxide during the experiments and to simulate typical processing steps of MOS and charge coupled device (CCD) oxides. The oxide was removed from the back of the slice and this was placed in contact with an aluminum plate. A small amount of the nematic liquid crystal (MBBA) was then placed on the top of the oxidized surface of the slice, and the apparatus was set up as shown in Fig. 1.

Experimental Results and Discussion

Measurements on (111) orientation, n-type silicon, with the liquid crystal technique (LCT) and the arithmetic mean of the numbers of defects in a large number of small areas, were used.

Using LCT a range of phenomena becomes apparent (16, 18, 20-23):

1. The density of turbulent areas is considerably greater with the silicon negative rather than positive. Those defects occurring only when the silicon negative are termed type II. Type I occurs under both polarities.
2. Type II defects grow in number with time, reaching apparent saturation densities in approximately 15 min for effective applied oxide field $\simeq$ 1 MV/cm.
3. By photoengraving windows in thick oxide followed by the production of thin oxide in these windows, it is found that type II defects cluster around the edge of the windows at the ledge of the silicon.

These phenomena, together with work (8) on the study of impurity ion migration and clustering, lead to a relatively simple model (16) for a defect. Impurity ions, such as sodium, migrate through the film and form clusters at the interface. The resulting enhanced Fowler-Nordheim, or Schottky emission, gives rise to increased electron currents in the oxide, from the silicon when the latter is negative. Physical irregularities at the silicon surface cause field intensification and enhance electron currents both directly and by promoting the ion clusters as shown in Fig. 2. The model developed depends on the cooperative effects of impurity ions and slow trapping. The purpose of this publication is to present experimental results of time-dependent thin (1000-2000Å) oxide defects.

Voltages of both polarity were applied to the silicon and the samples were observed for long periods of time. With positive bias on the silicon, very few turbulent regions were seen. The oxide itself showed faults in these regions when viewed without liquid crystal, and it is believed that these regions are pinholes presumably caused by contamination during the oxidation process. We shall, henceforth, refer to these as type I defects. Figure 3a shows a type I defect.

With negative bias applied to the silicon, many more defects were seen, although type I defects are still present. We shall refer to those defects occurring under negative bias only as type II defects. Figure 3b shows the appearance of a sample after applying negative bias to the silicon. Figure 3c shows the same region of oxide sometime later. Both Fig. 3b and 3c show the type I defect present in Fig. 3a. There is also, clearly, an increase in the number of type II defects with time.

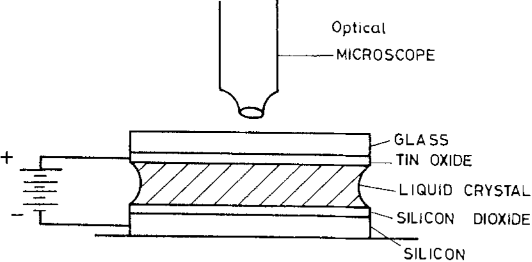

Fig. 1. The apparatus used for the study of oxide defects using liquid crystal. No spacers are necessary since the tin oxide coated glass plate is supported by the liquid crystal film.

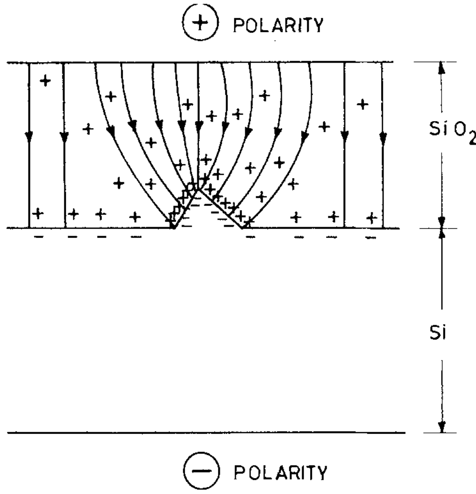

Fig. 2. Shows a point of field intensification and positive impurity ions in the silicon dioxide film condensed at that point.

Figure 4 shows the way in which the log of the defect density increases with the fourth root of time for two films of thickness 0.10 μm (curves A and B) and 0.2 μm (curves C and D) at different conditions. For both films the defect density (D), with negative bias on the silicon substrate, was found to increase exponentially with the fourth root of time as follows

$$D = D_0 \exp\left(\frac{t}{\tau}\right)^{1/4}$$

in the time range of $0 \leq t \leq T_s$. Where D_0 and τ are constants dependent on the applied field, oxide thickness, and the history of the oxide. T_s is the saturation time dependent on the oxide thickness, the history of the oxide, and the applied field. The wafer-to-wafer variability is within $\pm 10\%$ for similar oxides. The defect density saturates with time after approximately 5 min for 0.1 μm thick film (curve A) and approximately 15 min for 0.2 μm thick film (curve C). If positive bias is applied to the silicon substrate for certain time, only type I defects are visible, but on subsequent negative biasing the density of type II defects is initially reduced (curve B). However, after a further time has elapsed the defect density rises above its earlier value and ultimately saturates after longer saturation time.

The tendency for type II defects to be distributed along ledges in the silicon (Fig. 5) indicates the importance of silicon imperfections in these phenomena. During the application of the negative voltage to the silicon substrate as shown in Fig. 2 any scratches or similar discontinuities act as points of field intensification and positive impurity ions in the film condense at these points. This, together with the field intensification due to the geometry of irregularities (18), causes barrier lowering. Since the height of the barrier primarily controls the current, the current increases. Because of the relatively high mobility of electrons in the silicon dioxide, the barrier can be reduced by a large amount before the conduction becomes bulk limited. Presumably, the current ultimately becomes limited by some form of Poole-Frenkel conduction. As positive charge enters the region of field intensification by diffusion from other parts of the film, one would expect the current and, hence, size of the turbulence to increase. Ultimately the total number of defects seen will saturate, either due to the number of available im-

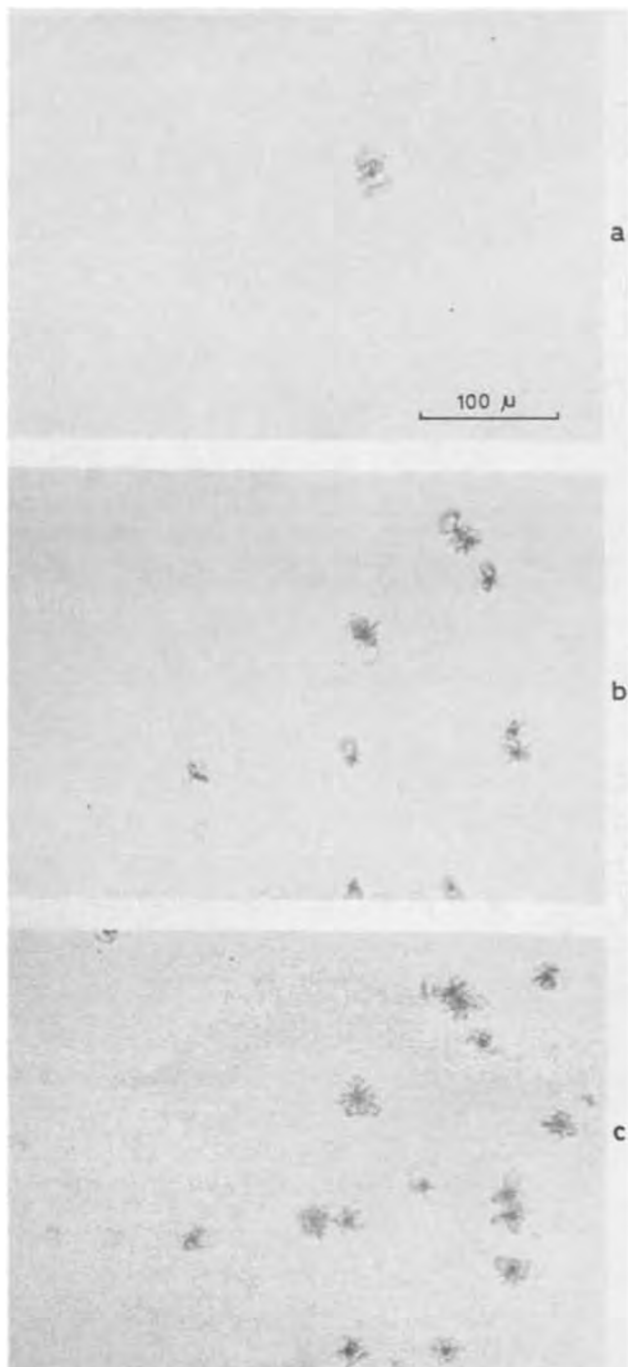

Fig. 3. The appearance of a region of 0.1 μm thick oxide using liquid crystal technique. (a) With a positive voltage applied to the silicon substrate. A type I defect is present (applied voltage = 40V). (b) After reversal of the applied voltage polarity, more defects are seen (type II defects), but type I defect still present (applied voltage = −40V). (c) After 10 min the density of type II defects has increased considerably.

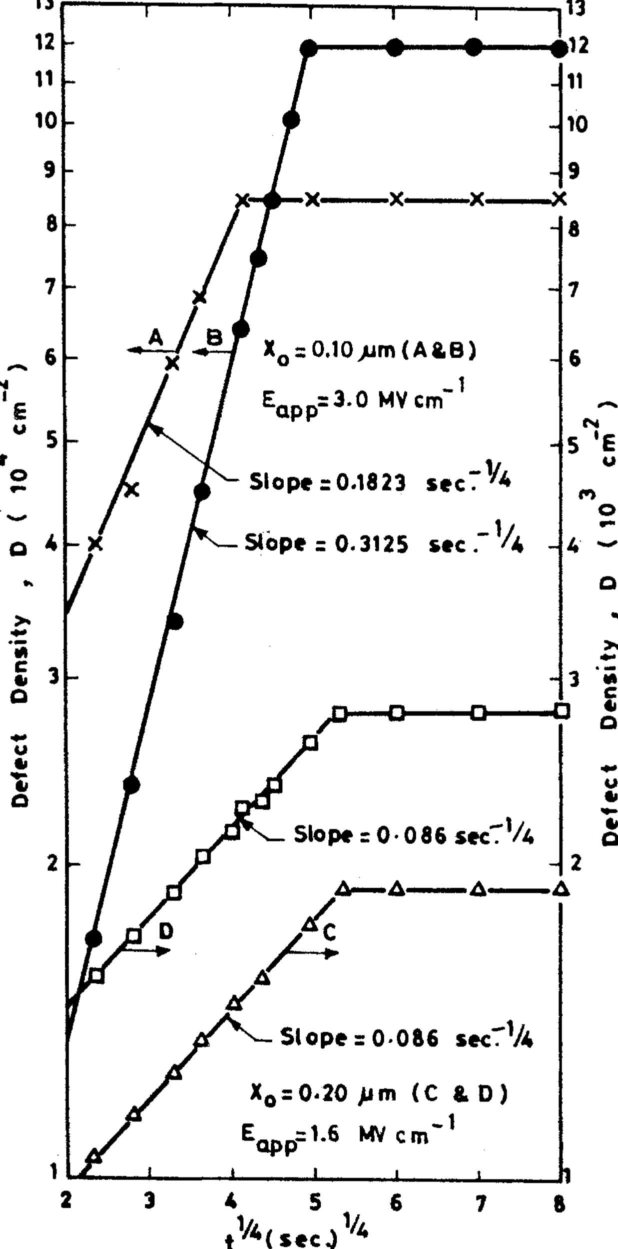

Fig. 4. Time dependent silicon dioxide defect density, with the silicon substrate is negatively biased. Curves A and B for a 0.1 μm thick film and an applied field of 3.0 MV cm^{-1}, but curve B was obtained after biasing the silicon substrate positively for 35 min with a field of 3.0 MV cm^{-1}. Curves C and D for a 0.2 μm thick film and an applied field of 1.6 MV cm^{-1}, but curve D was obtained after biasing the substrate positively for 35 min with a field of 5.3 MV cm^{-1}.

purity ions becoming exhausted, or when all the available silicon sites are producing turbulence.

On applying positive voltage to the silicon substrate, the positive ions are removed from the region of the silicon surface and geometrical effects cause the positive ions to spread out into the oxide. No turbulence is now present in the liquid crystal indicating that all the voltage is now falling across the oxide. It is well documented that such a high field causes the release, by tunneling, of electrons from traps in the oxide. The tunneling process involves no change of electron energy and the traps must therefore have energies coincident with the conduction band in the presence of the applied field for charge to transfer to the conduction

Fig. 5. After opening windows in the thick (steam) oxide, the thin (dry oxygen) oxide was grown. This thin oxide is contained within the circular area. It can be clearly seen that type II defects occur preferentially at the intersection of thin and thick oxides where a ledge in the silicon is situated (circle diameter = 168 μm).

band. Positive charge is created in the oxide. On returning to negative voltage on the silicon substrate, the number of turbulences would be expected to be initially small. Impurity ions condense with the lapse of time and gradually the number of defects increases. The total positive charge is now due to not only impurity but also the ionized traps obtained through the previous application of positive bias to the silicon substrate. It is not surprising that curves B and D of Fig. 4 show an increased number of turbulences since some smaller defects may now have sufficient positive charge surrounding them to produce large enough electron currents for them to become visible.

Since curves A and C of Fig. 4 show quite definite saturation, we are forced to deduce that we are primarily limited by the concentration of impurity ions in the oxide. Curves B and D of Fig. 4 indicate that more silicon imperfections are present in the sample than are shown in A and C.

In view of the comparatively large amount of liquid crystals in contact with the oxide, it was decided to check the effect of liquid crystals on the oxide films. The capacitance-voltage technique was used to show that the liquid crystal is not a source of contamination. The oxidized silicon wafer was divided into two pieces. The first one was examined by the liquid crystal technique for long time (about 1 hr) under negative bias on the silicon substrate condition. After washing the liquid crystal, the two pieces were cleaned and metallized at the same time with the same pattern of aluminum dots. The C_g-V_g curves were plotted for the similar MOS diodes of both pieces. The results are shown in Fig. 6 where curve a for the second piece (which was not examined by liquid crystals) and curve b for the first piece (which was examined by liquid crystals). The small reduction in the magnitude of the flatband voltage, after applying the liquid crystals to the oxide film, is due to the expected variation in the flatband voltage throughout the film surface and the measurement errors. Over several measurements for several oxide films the change in flatband voltage after applying the liquid crystals was within the limits of -0.5 to $+0.5$V due to the mentioned reasons. This very small change in flatband voltage corresponds to $\Delta Na = \pm 5.4 \times 10^{10}$ ions cm^{-2} which represent a variation in the mobile ions density of $\pm 2.25\%$ for these oxides.

Conclusions

Measurements have been performed on oxide conduction in thin (1000-2000Å) layers of silicon dioxide grown in dry oxygen. The liquid crystal technique has been shown to be a valuable nondestructive technique for studying the behavior of oxide defects as a function of both magnitude and polarity of applied voltage, time, and oxide thickness. The liquid crystal is not a source of contamination to the oxide. Two types of defect have been found. Type I defects are probably pinholes and have a very low density. Type II defects occur only under negative bias (on the silicon substrate) and show a strong dependence of density on time.

The defect density (D), with negative bias on the silicon substrate, was found to exponentially increase with the fourth root of time, in the time range $0 \leq t \leq T_s$, where T_s is the saturation time dependent on the applied field, the oxide thickness, and the history of the oxide. The defect density saturates with time after approximately 5 and 15 min for 0.1 and 0.2 μm thick films, respectively. By cycling the voltage between positive and negative, it has been possible to suggest a simple qualitative model for the behavior of defects which would seem to be associated with physical irregularities in the silicon. The model developed depends on the cooperative effects of impurity ions and slow trapping. It suggests that devices will be subject to failure from oxide defects for either type of polarity. Further experimental and theoretical studies for the time dependence on SiO_2 defects are in progress and will be published later.

Molecular Beam Epitaxial Growth of ZnTe and ZnSe

Fumitaka Kitagawa, Tomoyoshi Mishima, and Kiyoshi Takahashi

Department of Physical Electronics, Tokyo Institute of Technology, Meguro-ku, Tokyo, Japan 152

ABSTRACT

The electrical and optical properties of ZnTe and ZnSe prepared by molecular beam epitaxy have been studied. Epitaxial growth was found to take place at $\gtrsim$ 250°C for ZnTe on GaAs and ZnTe and at $\gtrsim$ 300°C for ZnSe on GaAs; the epitaxial growth ceased at 430° $\sim$ 470°C for ZnTe and at 450° $\sim$ 500°C for ZnSe because of the reevaporation of compound and/or impinging molecules. The observed growth rate dependence on substrate temperature and on impinging rate ratio has been explained on the basis of a model in which the number of incorporated and reevaporated molecules are strongly coverage dependent. ZnSe on GaAs, and ZnTe on GaAs and ZnTe had good mirror smooth surfaces. ZnTe on InAs and ZnS, however, had a rather rough surface. Ga was found to diffuse, due to a large number of misfit defects at GaAs-ZnTe interface, from the GaAs substrate into ZnTe influencing the electrical and optical properties of grown layers considerably. The resistivities of undoped layers were $\sim$5 Ω-cm for ZnTe on ZnTe and $\sim 10^4$ Ω-cm for ZnSe on GaAs. Sb was used to increase the hole concentration of ZnTe on ZnTe up to $\sim 10^{18}$ cm^{-3}. The resistivities of ZnSe on GaAs were found to decrease to $\sim$0.07 Ω-cm by Ga doping. The results of photoluminescence measurement suggest that the higher substrate temperature makes the better quality layers.

Zn- and Cd-chalcogenides have the wide and direct forbidden bandgaps and high electro-optic coefficients which are attractive for opto-electronic devices and acousto-optic waveguide modulators etc. Furthermore, ZnTe and CdTe have large effective atomic numbers making them promising materials for γ-ray detectors. However, II-VI compound solid-state devices with good device performance have not been fabricated yet. This is partly due to the lack of crystal growth techniques to obtain epitaxial layers and bulk crystals with good optical and electrical properties, and partly due to the difficulty of carrier concentration control because of self-compensation effects.

Most of II-VI compound materials for electronic devices, *e.g.*, EL displays, CRT, etc., are at present used in powder or polycrystalline forms. High quality epitaxial layers, however, are desirable for aforementioned solid-state devices and heterojunction devices in particular. In the present work, epitaxial growth of ZnTe and ZnSe was tried by molecular beam epitaxy (MBE) (1) due to lower growth temperature as compared to other growth methods (this permits low growth rates for achieving good thickness control and reduces the interdiffusion in multilayer structures). MBE method also allows the easy choice of growth environment for the better control of stoichiometry. Although many epitaxial II-VI compound layers grown by MBE (2-5) and vacuum evaporation (6) have been reported, very little of the electrical and optical properties has been mentioned. The present paper discusses the molecular beam epitaxial growth of ZnTe and ZnSe, and their electrical and optical properties.

Experimental

Crystal growth.—The high vacuum growth chamber is pumped by a 110 liter/sec noble-ionpump and by titanium sublimation pumps which are backed with two sorption pumps. A four-positioned substrate holder in growth chamber allows four samples to be prepared in one growth run. The high purity carbon effusion cells are surrounded with a liquid-nitrogen-cooled shroud. Source materials are evaporated from these effusion cells heated by tungsten wire wound around them. The temperatures were held within ±2°C at set temperature. One of the effusion cells, *i.e.*, the Zn effusion cell, has an ionizer to ionize part of Zn atoms evaporated from the effusion cell. The details of this ionizing system have been previously reported (7) and the results will be reported elsewhere. The base pressure of growth chamber was $\sim 10^{-7}$ Pa before growth and $\lesssim 10^{-6}$ Pa during growth (the increase in pressure occurs mainly because of evaporant vapors). All of the source materials used, *i.e.*, Zn, Se, Te, Ga, As, Sb (the latter three materials were used as dopants) have 6-nines purity.

The substrates used were {100}, $(\overline{111})$ GaAs for ZnSe, $(\overline{111})$ InAs, {100} GaAs, $(\overline{111})$ ZnS, {100}, {110}, {111} ZnTe for ZnTe. However {100} GaAs for ZnSe and {100} GaAs, {111} ZnTe for ZnTe were most frequently used. GaAs substrates were etched in H_2SO_4:H_2O_2:H_2O (3:1:1 by volume) for 1 min at 80°C. ZnTe substrates, which were cut from ingots grown by Bridgman method (8) in our laboratory, were oriented to {100}, {110}, or {111} plane within ±5°, and were etched in $K_2Cr_2O_7$ (1g) + H_2O (40 ml) + H_2SO_4 (5 ml) for 30 sec at 80°C and/or in Br-methanol for a few minutes at room temperature. Deteriorative Cr compounds, probably Cr oxide, were sometimes found to be deposited on the substrate surface when the former etchant was used. Therefore, subsequent etching by the other etchant such as Br-methanol was necessary. Both etchants were found to be excellent for obtaining a mirror smooth surface. As-grown undoped ZnTe substrates were p-type with hole concentration $p \sim 10^{14}$ cm^{-3} and hole mobility $\mu_h = 70 \sim 100$ cm^2 V^{-1} sec^{-1} at room temperature. After chemical etching, these were thermally etched in the ultrahigh vacuum growth chamber for 20 $\sim$ 30 min at 450° $\sim$ 500°C for ZnTe substrates and at 600°C for GaAs substrates just before growth.

Films were deposited at substrate temperature T_{sub} = 200° $\sim$ 450°C with various group-II/VI impingement rate ratio F_1/F_2, where F_1 and F_2 are impingement rates of group II and VI molecules, respectively. The values of F [cm^{-2} sec^{-1}] were estimated using Eq. [1]

$$F = K\sqrt{P/MT}/r^2 \quad [1]$$

where K is the form factor determined by the shape of effusion cell etc., P (Pa) vapor pressure (9), T (°K) the cell temperature, M the molecular weight and r [cm] is the distance between the effusion cell and the substrate. The discrepancy between the values calculated from Eq. [1] and the actual values are estimated to be within ±20% in consideration of the shape of effusion cell, which was not Knudsen-type, and the

Key words: semiconductor, resistivity, photoluminescence, epitaxy.

strong dependence of source material vapor pressure on the material surface temperature which did not always coincide with the measured effusion cell temperature. The thickness of the epitaxial films was about 10 μm for resistivity measurements and 2 ~ 3 μm for other purposes. The typical deposition rate was ~1 μm/hr.

Characterization.—The resistivities of grown layers were measured using In-doped ZnTe and Cr-doped GaAs substrates with resistivities ~10^8 Ω-cm or more. The influence of substrate resistivity on the layer resistivity measurement (due to shunt effects) can be ignored for low resistivity layers ($\lesssim 10^3$ Ω-cm), however, cannot be ignored for high resistivity layers ($\gtrsim 10^5$ Ω-cm) because these sheet resistances are comparable to or more than those of substrates. Therefore, the following method was used for calculation of resistivity of high resistivity layers. The apparent conductivity σ_{ex} obtained from measured resistance $R_{ex} = L/\sigma_{ex}t_fW$ of a composite layer (as shown in Fig. 1a) can be represented by

$$\sigma_{ex} = \sigma_f + (\sigma_s t_s/t_f) \quad [2]$$

where σ_f and σ_s are conductivities, t_f and t_s are thicknesses of the layer and of the substrate, respectively. σ_{ex} was extrapolated to $t_s/t_f = 0$ by etching step by step as shown in Fig. 1b and assuming a uniform layer with no lattice defects and no influence of the interface

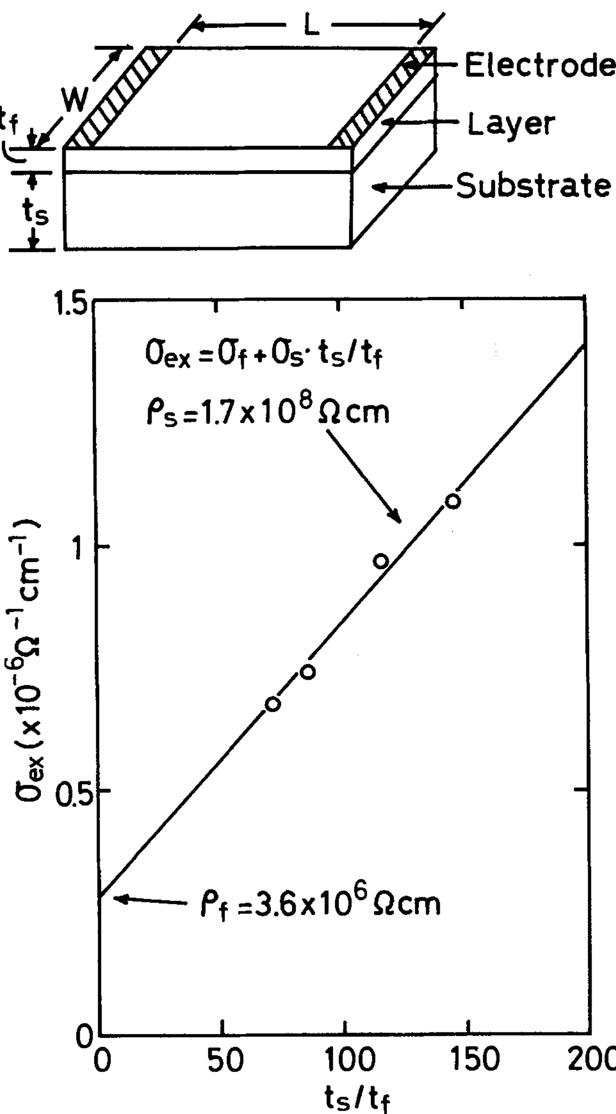

Fig. 1. Resistivity measurement method for high resistive layers: (a, top) shape of samples, (b, bottom) σ_{ex} vs. t_s/t_f used for extrapolation to calculate resistivities.

between the layer and the substrate. Hall measurements were made by the van der Pauw method. Contacts were made with electroless plated Ag for ZnTe and by evaporated In-Ga (2:1 by weight) with subsequent heating in N_2 for 3 min at 300°C for ZnSe.

ZnS and GaAs substrates were used for optical transmittance measurements of grown layers. ZnS substrates are nearly transparent in the measured wavelength region of 450 ~ 800 nm for ZnTe and of 400 ~ 800 nm for ZnSe, the influence of the substrate on the measured transmittance was, however, subtracted with the aid of refractive index of ZnS substrate $n = 2.37$, and product of the absorption coefficient α and substrate thickness d, *i.e.*, $\alpha d = 0.1$ (these values were confirmed by transmittance measurement of the substrate before growth). GaAs substrates were etched off in H_2O_2:NH_4OH (20:1 by volume) at room temperature to obtain very thin layers (1 ~ 3 μm) for transmittance measurements. Etching rate of ZnTe was negligibly small and very small for ZnSe in the aforementioned etchant.

Photoluminescence was measured for estimation of crystallographic quality using Ar laser (488 nm, 100 mW) for ZnTe and Hg lamp for ZnSe as excitation source.

Results and Discussion

Crystal growth.—The growth rate was found to depend on F_1 and F_2 for lower value of impingement rate as shown in Fig. 2 for ZnTe and the substrate temperature as shown in Fig. 3. This is consistent with the results reported by Smith and Pickhardt (2) and can be explained as follows.

Since the vapor pressure of AB (10) is much lower than that of A and B, it seems reasonable to assume that the lifetime τ_{11} of an impinging A atom adsorbed into A atom on AB surface is much smaller than the lifetime τ_{12} of an impinging A atom adsorbed into B atom on AB surface, *i.e.*, $\tau_{11} << \tau_{12}$, at the growth temperature. The vaporization kinetics of element A and compound AB have been considered similar, where A and B are the group II- and VI-atom and subscripts 1 and 2 pertain to A and B, respectively. A similar assumption holds for the case of impinging B molecules, *i.e.*, $\tau_{22} << \tau_{21}$. Dissociation reaction of B molecules is also assumed. Based on these assumptions, the following reaction sequences can be considered

$$A(gas) + V_A \rightleftarrows A(surf.) \rightleftarrows A(bulk) \quad [3]$$

$$B_n(gas) + mV_B \rightarrow B_{n-m}(surf.) + mB(surf.) \quad [4]$$

$$lB(surf.) \rightarrow B_l(gas) + lV_B \quad [5]$$

$$B_{n-m}(surf.) \rightarrow B_{n-m}(gas) \quad [6]$$

$$B(surf.) \rightleftarrows B(bulk) \quad [7]$$

where subscripts (gas), (surf.), and (bulk) denote an impinging molecule, a surface species, and an atom incorporated into bulk crystal, and V_A and V_B mean adsorbed sites for A and B atom, respectively. Since S and Se generate a series of polyatomic molecule, several dissociation reactions as shown in Eq. [4] occur simultaneously. For simplicity, however, only one reaction will be taken into consideration. Assuming $n = m = l$, the above reaction sequence leads to following steady-state equations

$$R \propto \frac{dn_1}{dt} = \frac{dn_2}{dt} \quad [8]$$

$$\frac{dn_1}{dt} = [k_1F_1\theta_2 - (\theta_1/\tau_{12})]N_s \quad [9]$$

$$\frac{dn_2}{dt} = [k_2F_2^{1/n}\theta_1 - (\theta_2/\tau_{21})]N_s \quad [10]$$

where R is the growth rate, n_1 and n_2 the number of A and B atom per unit area in the grown layer, N_s the total number of adsorbed sites, F_1 and F_2 the imping-

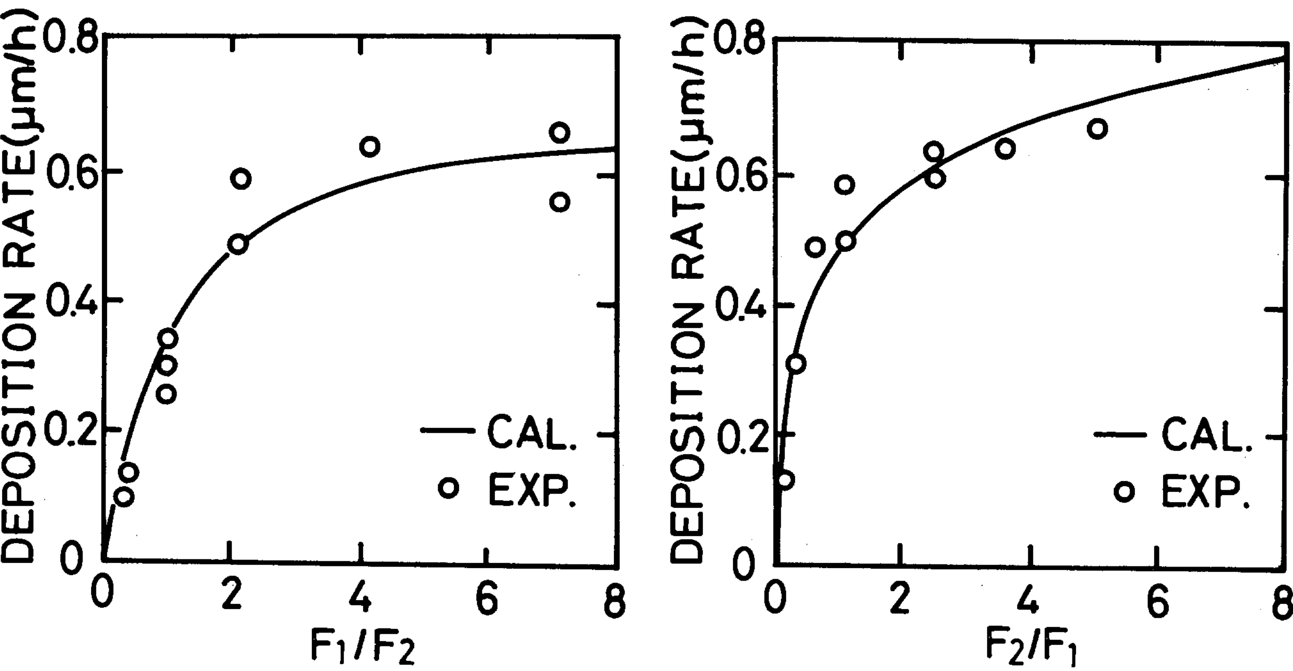

Fig. 2. Dependence of ZnTe growth rate on impingement rate ratio (a, left) for constant Te cell temperature (T_{Te} = 285°C, $F_2 = 1.75 \times 10^{14}$ cm^{-2} sec^{-1}, $k_1/k_2 = 2.13\ F_2^{-1/2}$) and (b, right) for constant Zn cell temperature (T_{Zn} = 240°C, $F_1 = 5.86 \times 10^{14}$ cm^{-2} sec^{-1}, $k_1/k_2 = 1.51\ F_1^{-1/2}$).

ing molecule fluxes of A and B, and θ_1 and θ_2 the fraction of N_s adsorbed by A and B (then $\theta_1 + \theta_2 = 1$). From Eq. [8] ~ [10]

$$R \propto \frac{k_1F_1k_2F_2^{1/n} - (1/\tau_{12}\tau_{21})}{k_1F_1 + k_2F_2^{1/n} + (1/\tau_{12}) + (1/\tau_{21})} \quad [11]$$

Equation [11] is a very simplified form derived from the above assumptions. It, however, expresses well the actual growth kinetics of II-VI compounds and suggests that the growth of II-VI compounds should cease at high substrate temperatures due to increasing value of $1/\tau_{12}\tau_{21}$ in numerator and/or decreasing k_1 and k_2. The growth rate depends on k_1F_1 and/or $k_2F_2^{1/n}$ in the optimum substrate temperature region for epitaxial growth. The increase of $1/\tau_{12}\tau_{21}$ means the reevaporation of constituent elements. The decrease of k_1 and k_2 means the reevaporation of impinging molecules before compound formation. The substrate temperatures for which growth of ZnSe and ZnTe were found to cease under the typical growth condition (the growth rate $R \sim 1$ μm/hr) were 450° ~ 500°C and 430° ~ 470°C, respectively, and it slightly depended on impinging molecular fluxes. The evaporation rates of ZnSe and ZnTe reached 1 μm/hr at 560° and 470°C, respectively, as calculated from the equilibrium vapor pressure of compounds (14, 15). These results suggest that the upper limit of the epitaxial growth temperature depends on reevaporation of compound for ZnTe and of impinging molecules for ZnSe. Solid lines in Fig. 2 show the calculated values of deposition rates as functions of F_1/F_2 from Eq. [11]; sticking coefficients of Zn and Te for $F_1/2F_2$ = 1/10 and 10, respectively, are $S_{Zn} = 0.8 \pm 0.2$, $S_{Te} = 0.6 \pm 0.2$. Experimental results are in good agreement with calculated values within experimental fluctuation. At lower substrate temperatures, Eq. [11] is invalid because the assumptions of $\tau_{11} << \tau_{12}$ and $\tau_{22} << \tau_{21}$ no longer hold true, *i.e.*, unreacted impinging molecules are incompletely reevaporated and remain on the substrate surface. Therefore, the precipitation of constituent elements is expected to occur. However, no precipitation was observed above 250°C for growth rate 1 μm/hr with various molecular flux ratios for ZnTe and ZnSe. On the analogy of the Ueda's results for CdTe (19), this expectation will be realized at <200°C. Sticking coefficient and consequently growth rate also depended on substrate orientation, and increased in the following order: {100} $\lesssim$ {110} < {111} for ZnTe on ZnTe substrate and {100} < $(\bar{1}\bar{1}\bar{1})$ for ZnSe on GaAs. The ratio of growth rate on {111} and {100} $R_{\{111\}}/R_{\{100\}}$ is about 1.6 for both of ZnTe and ZnSe.

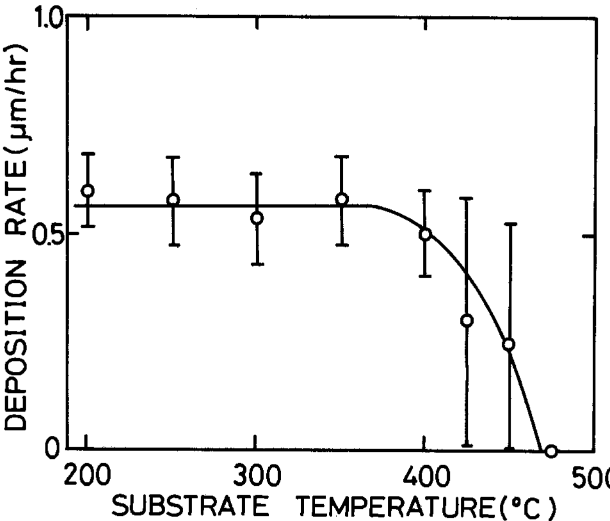

Fig. 3. Dependence of growth rate on substrate temperature

Epitaxial growth temperature is $\gtrsim$ 250°C for ZnTe and $\gtrsim$ 300°C for ZnSe. Figure 4 shows the RHEED pattern of ZnTe film grown at 250°C with $F_1/2F_2 = 1/2$. The lower limit of the epitaxial growth temperature strongly depends on the ratio of impingement rate F_1/F_2. In the case of ZnTe, epitxial growth occurred only around $F_1/2F_2 = 1/2$ at 250°C. In addition, the results of x-ray analysis suggest that films deposited under excess Te condition have better crystallographic quality than those under excess Zn condition, even if these are polycrystalline in structure.

ZnSe and ZnTe on GaAs substrates had good mirror-smooth surfaces independent of substrate orientation. However, rough surfaces were obtained for most of ZnTe films on InAs and ZnS, and for a few of ZnTe on

Fig. 4. RHEED pattern of ZnTe on GaAs grown at 250°C, $F_1/2F_2 = 1/2$.

ZnTe. In former case, RHEED patterns showed that rough surface samples always had a twin structure and smooth surface samples did not. In addition, results of RHEED analysis suggest that these twin structures are derived from the defect structures of substrates. It is, therefore, necessary that good quality substrates without twins should be used to obtain the films with good mirror-smooth surfaces. In the latter case, SEM photographs of rough surface showed pyramid-like structures as shown in Fig. 5. The shape of these pyramids was very sensitive to substrate orientation. It is found that the occurrence of grown layers with rough surfaces increased in the following order: $\{111\} < \{110\} < \{100\}$. The origin of this tendency is not yet well understood. It is, however, expected that the substrate orientation dependence of growth rate and the occurrence of rough surface layer are due to the reactivity of substrate surface.

No impurity other than surface contaminants was detected in undoped layers by ion microprobe analysis (IMA) except for ZnTe layers on GaAs. IMA results of ZnTe layers on GaAs suggest that a large amount of Ga ($10^{18} \sim 10^{19}$ cm^{-3} at the surface of grown layers) diffuses from the GaAs substrate. This large Ga diffusion is supposed to be attributed to lattice defects, *e.g.*, misfit dislocations, caused by a large lattice misfit (7.6%), *i.e.*, defect-induced diffusion. Another evidence of misfit defects in ZnTe on GaAs is the poor cleavage faces of grown layers compared with mirror cleavage faces of substrates and grown layers on ZnTe and InAs.

Electrical properties.—Electrical resistivity of undoped ZnTe layers on GaAs was $\gtrsim 10^4$ Ω-cm and a little sensitive to impingement rate ratio F_1/F_2; the resistivity of the ZnTe layer grown under Te excess was a little lower than that of layer grown under Zn excess. On the other hand, the resistivities of undoped ZnTe layers on ZnTe were about 5 Ω-cm with no dependence of impingement rate ratio. High resistivity of the former is attributed to a large amount of lattice defects and Ga diffusion from the GaAs substrate. The dependence on impingement rate ratio is probably due to the variation of native defect concentration. No observation of such dependence for ZnTe on ZnTe is supposed by small variation of native defect concentration compared with a large amount of unintentionally doped acceptor. The hole mobility of undoped ZnTe on ZnTe was $47 \sim 70$ cm^2 V^{-1} sec^{-1}. This is lower than that of bulk ZnTe [120 cm^2 V^{-1} sec^{1-} (11)] and implies the existence of scattering centers which result in reduced mobility.

Arsenic and antimony were used as dopants for ZnTe. Arsenic was not effective in increasing the hole concentration even if the As impinging rate was more than ten times that of Zn or Te. The sticking coefficient of As was estimated to be $\sim$0 on the assumption that the whole of incorporated As atoms were ionized and contributed to hole concentration without any other effects on electrical properties. In contrast, the increase of hole concentration up to 10^{18} cm^{-3} was achieved with Sb doping as shown in Fig. 6. Though the hole mobility decreased significantly with increasing hole concentration (Fig. 6), the resistivity decreased only by two orders of magnitude; the minimum value was 0.3 Ω-cm. On the basis of the same assumptions as for the As case, the sticking coefficients of Sb was estimated to be $10^{-2} \sim 10^{-3}$ from measured hole concentration and Sb impinging rate. It is expected that for this case the significant decrease of mobility with the increase of hole concentration occurs partly due to the disturbance of epitaxial growth by a large amount of impinging Sb molecules. The impinging Sb flux was more than those of Zn and Te during growth to obtain a hole concentration of $\sim 10^{18}$ cm^{-3}.

Undoped ZnSe layers on GaAs had the resistivity of $\sim 10^4$ Ω-cm. Simultaneous Ga doping in the ZnSe layer was attempted during the growth to reduce the resistivity. The resistivity of ZnSe layers decreased to 0.07 Ω-cm with increasing temperature of Ga effusion cell up to $\sim$380°C above which it increased as shown in Fig. 7. The increase of the resistivity at higher temperatures is attributed to the reduction of crystallographic quality judging from the fact that $K\alpha_1$ x-ray diffraction intensity of ZnSe decreased with increasing

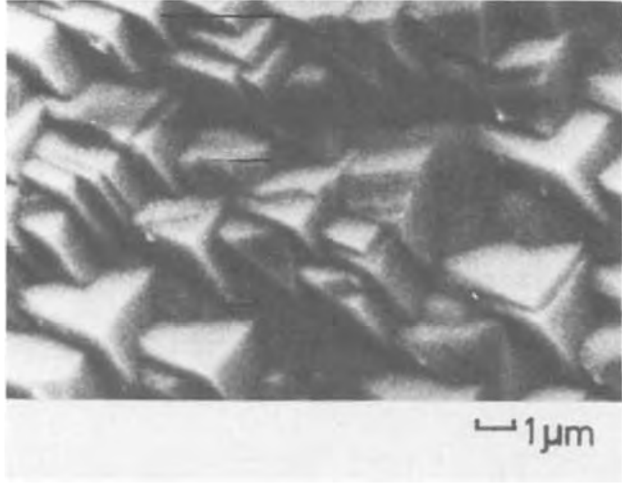

Fig. 5. SEM photographs of pyramid-like surface of ZnTe on {110} ZnTe.

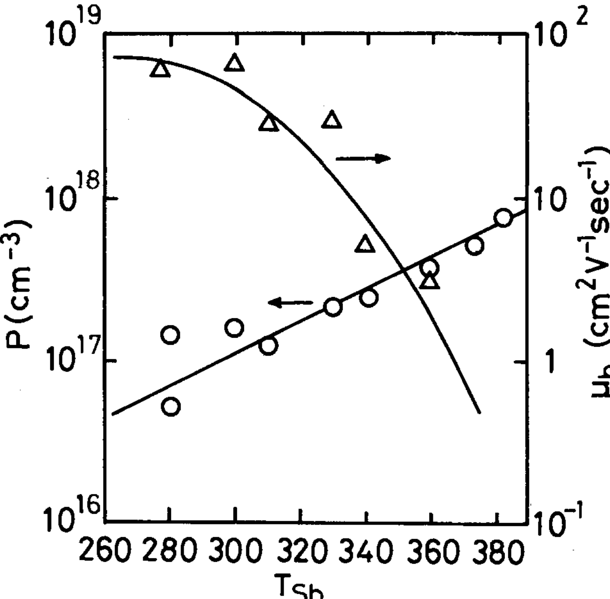

Fig. 6. Dependence of hole concentration and hole mobility of ZnTe on ZnTe on Sb cell temperature.

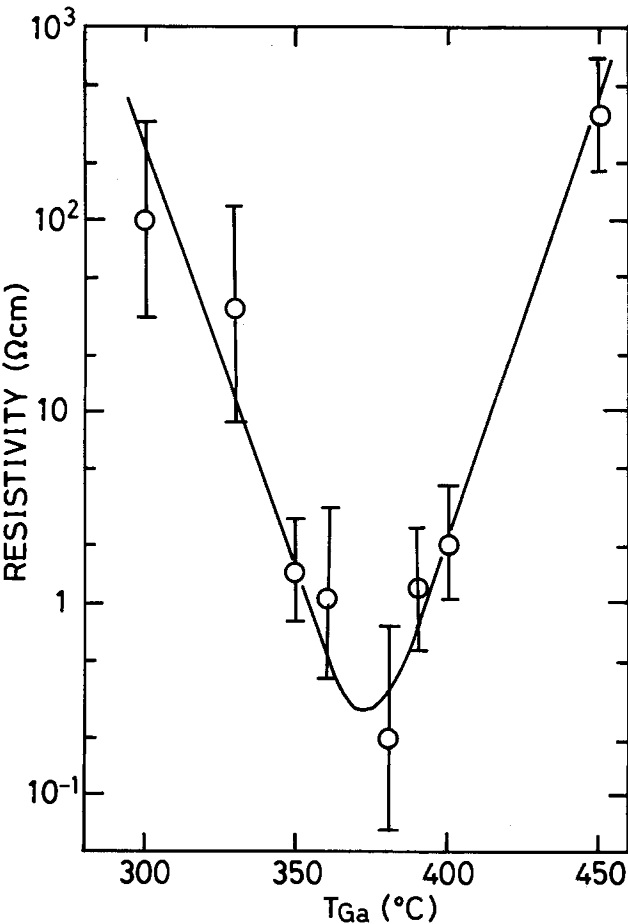

Fig. 7. Dependence of resistivity of ZnSe on Ga cell temperature

Ga effusion cell temperature, while that of GaAs substrate remained nearly unchanged as shown in Fig. 8. Electron mobility in low resistive ZnSe layers was 200 ~ 250 $cm^2 V^{-1} sec^{-1}$ with no temperature dependence.

Optical properties.—Transmittance of ZnSe and ZnTe and their temperature dependence were measured in the wavelength range of 400 ~ 800 nm and 450 ~ 800 nm, respectively. Figure 9 shows transmittance spectra of ZnSe and ZnTe layers at room temperature. Relatively low values in the transparent region for ZnSe and ZnTe on GaAs substrate are due to a surface roughening caused during the selective etching of the substrate. More desirable results in the transparent region were obtained from ZnTe layers on ZnS as shown in Fig. 9. The fringes of the spectra are due to interference effects. No temperature dependence of transmittance spectra was observed except for the absorption edge shift as shown in Fig. 10, and no absorption band due to lattice defects was observed.

Figure 11 shows photoluminescence spectra of undoped ZnTe on ZnTe and GaAs at 4.2°K (listed in Table I). All emission lines and bands from ZnTe on ZnTe were stronger and sharper than those from ZnTe on GaAs, which implies that the former layer had better quality than the latter. Two broad emission bands observed in the spectra of ZnTe on GaAs (centered at 578 and 765 nm) were absent in the spectra of ZnTe on ZnTe. These two emission bands are reported to be absent in the spectra of ZnTe on Ge (5). These, therefore, cannot be attributed to misfit defects, but arise due to Ga diffusion from GaAs substrate into ZnTe layer. The diffused Ga is expected to form Ga center and the complex centers with misfit or native defects giving rise to emission bands centered at 578 and 765 nm. Photon energies of these two emission bands were 2.15 and 1.62 eV. Reported values of the

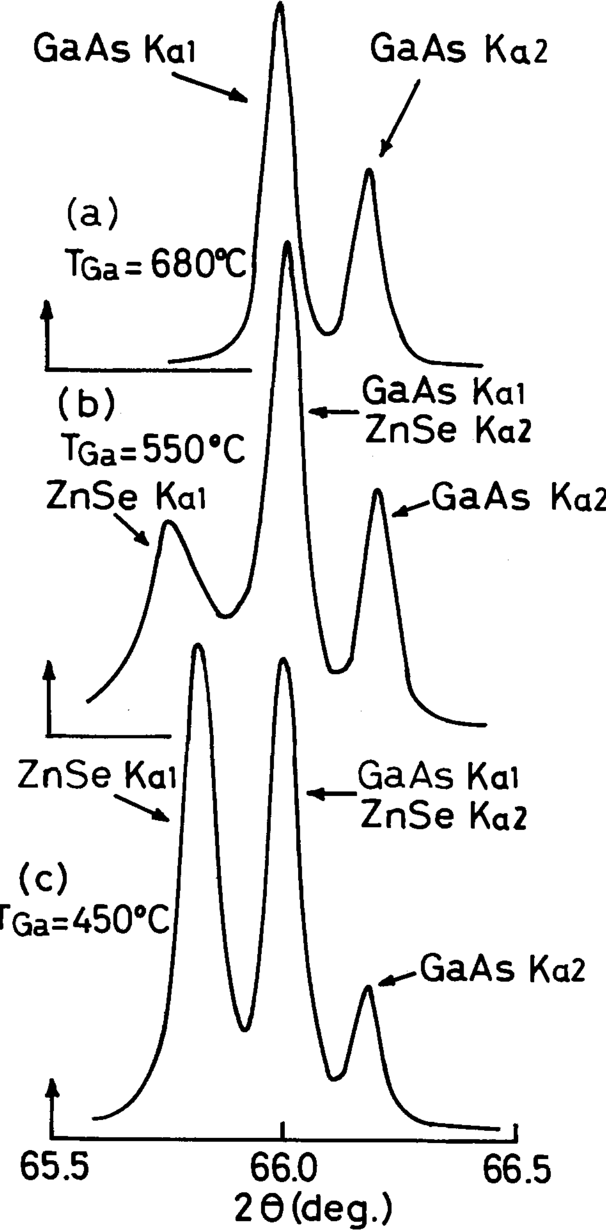

Fig. 8. X-ray patterns of ZnSe on GaAs {100}: (a) Ga cell temperature T_{Ga} = 680°C, (b) T_{Ga} = 550°C, (c) T_{Ga} = 450°C.

second level of Zn vacancy, Ga donor level, and Ga complex level are 0.14, 0.24, and 0.6 eV, respectively (12). Therefore, the observed bands are expected to be due to the radiative transitions between valence band and Ga donor level (0.24 eV) and between Ga complex level (0.62 eV) and the second level of Zn vacancy (0.14 eV). Haynes rule (13) has suggested that I_A (5218.5Å) and I_B (5220.7Å) lines in the spectra of ZnTe on ZnTe are due to excitons bound to shallow acceptor corresponding to A (5303Å) and B (5322Å) lines, respectively. I_1 line in the spectra of ZnTe on GaAs are probably due to the similar excitons. A series of emission lines between 625 and 700 nm are attributed to be due to oxygen isoelectronic traps (16). The intensity of all emission lines increased with increasing substrate temperature suggesting that the higher substrate temperature makes the better quality layer.

Figure 12 shows the photoluminescence spectrum of Ga-doped ZnSe on GaAs at 77°K. These emission lines and bands remained even at room temperature though with reduced intensity. Since the intensity of broad emission bands increased with increasing Ga effusion cell temperature, these bands are, therefore, attributed to Ga doping and/or its associated mechanism.

Conclusion

The epitaxial growth by molecular beam epitaxy of ZnTe and ZnSe was found to occur at $\gtrsim$ 250° and at $\gtrsim$ 300°C, respectively, and to cease at 450° ~ 500°C for ZnSe and at 430° ~ 470°C for ZnTe with small impinging rate dependence. It was possible to explain the observed dependence of growth rate on substrate temperature and impinging rate ratio on the basis of a model in which the number of incorporated and re-

Table I. Emission lines and bands in photoluminescence spectra of ZnTe layers at 4.2°K

	Wavelength	Photon energy (eV)	Half-width (A)	Origin	Remarks
ZnTe on ZnTe	5218.5A	2.3758	~1	Bound exciton	With phonon replica
	5220.7A	2.3748	~1		
	5303A	2.338	~20	Shallow acceptor	
	5322A	2.330	~20		
	625			Oxygen isoelectronic traps	
	~700 nm				
ZnTe on GaAs	5245A	2.364	~20	Bound exciton	
	~578 nm	2.15		Ga donor?	
	625			Oxygen isoelectronic traps	
	~700 nm				
	~765 nm	1.62		Ga complex to 2nd Zn vacancy level?	

evaporated molecules, and consequently the sticking coefficients of group II- and VI-molecules, are strongly coverage dependent: *e.g.*, the sticking coefficient of group II-molecules depends on group VI atom coverage and vice versa. ZnSe and ZnTe on GaAs and ZnTe on ZnTe had good enough mirror-smooth surfaces for the preparation of solid-state devices. Most of ZnTe layers on InAs and ZnS, however, had rather rough surfaces. The rough surface is probably due to a poor substrate surface preparation as judged from the results of RHEED analysis. The growth rate of ZnSe on GaAs and ZnTe on ZnTe depended on the substrate orientation, *e.g.*, the {111} face had faster growth rate than the {100} face.

The resistivity of undoped ZnTe on GaAs and on ZnTe was $\gtrsim 10^4$ and ~ 5 Ω-cm, respectively. The high resistivity for the former case is attributed to a large amount of lattice defects and the outdiffusion of Ga from the GaAs substrate into the ZnTe layer. The hole mobility of undoped ZnTe on ZnTe was $47 \sim 70$ cm^2 V^{-1} sec^{-1}. It was found that As is not effective for simultaneous doping of a ZnTe layer, *i.e.*, the sticking coefficient of As is ~ 0. Antimony is, however, used to increase the hole concentration up to $\sim 10^{18}$ cm^{-3} and to decrease the resistivity to ~ 0.3 Ω-cm. The sticking coefficient of Sb is estimated to be $10^{-2} \sim 10^{-3}$.

The resistivity of undoped ZnSe on GaAs was $\sim 10^4$ Ω-cm and could be decreased to ~ 0.07 Ω-cm by simultaneous doping of Ga. The electron mobility of Ga-doped ZnSe was typically $200 \sim 250$ cm^2 V^{-1} sec^{-1}. Their temperature independence implies the existence of such a scattering center as neutral impurities.

In the photoluminescence spectra of ZnTe on ZnTe at 4.2°K, two emission lines due to shallow acceptors and two exciton lines bound to them with their phonon replicas and a broad emission band due to oxygen isoelectronic traps were observed. In addition to these lines and band, two additional broad bands were observed in ZnTe on GaAs. These bands are attributed to the diffused Ga and their complex center with lattice defects. The results of photoluminescence measurement suggest that the higher substrate temperature makes the better quality layer. However, the ceasing of the epitaxial growth over a certain substrate temperature requires a suitable compromise between its single crystalline nature and overall quality.

In the photoluminescence spectrum of Ga-doped ZnSe on GaAs, an emission line and two broad emission bands were observed. These broad bands are attributed to Ga doping.

Growth Kinetics and Polymorphism of Chemically Deposited CdS Films

Inderjeet Kaur, D. K. Pandya, and K. L. Chopra

Department of Physics, Indian Institute of Technology, Delhi, New Delhi 110029, India

ABSTRACT

The kinetics of growth for chemical deposition of CdS films from alkaline solutions of cadmium salts has been studied with respect to temperature of deposition and the relative concentrations of the various reactants in the solution. It has been established that the growth of the film takes place either by ion-by-ion condensation of Cd^{+2} and S^{-2} ions or by adsorption of colloidal particles of CdS formed in the solution, depending on the various deposition parameters and the method of preparation. The former process of growth results in thin, hard, adherent and specularly reflecting films, whereas the latter results in thick, powdery and diffusely reflecting films. Occurrence of different polymorphic phases of CdS (hexagonal and cubic) has been observed under different growth conditions. A model for growth mechanism has also been proposed.

Multicomponent materials like compound semiconductors and their alloys are of considerable technical interest in the field of electronic and electrooptical devices. In general, it is difficult to prepare these materials in bulk form over a wide range of compositions because of limited solubility of materials in each other.

Key words: CdS, chemical deposition, growth kinetics, thin films.

However, synthesis can be readily achieved in case of thin films, where the solubility conditions are known (1) to relax. The commonly used methods of preparation of thin films of these materials are vacuum evaporation, sputtering, and spray pyrolysis.

A relatively less common but inexpensive and convenient method for large area preparation of thin films at low temperatures is a chemical solution growth technique, which has been known (2-6) for some time for thin film deposition of such compound semiconductors as CdS, PbS, PbSe, CdSe, and ZnSe. In this method, thin films of sulfide can be prepared by decomposition of thiourea (or thioacetamide) in alkaline solutions of the salts of the corresponding cation. In general, the process involves the application of a controllable chemical reaction which proceeds at a low rate in an aqueous solution containing the various reactants. The substrates are immersed in this solution. The reaction rate can be controlled by adjustment of *p*H, temperature, and the relative concentrations of the various reactants in the solution. Since the solution growth technique is a low temperature (less than 90°C) deposition method, it does not limit the choice of the substrate material. By contrast, in spray pyrolysis only a limited number of substrate materials which can withstand high temperature and chemical corrosion during pyrolysis can be used. Further, in a solution growth technique, since the deposition is from ions in aqueous solution, which are slowly being generated, the solubility product helps to maintain the stoichiometry constant for any ratio of cations and anions. As a result of these processes homogeneous phases of compounds are obtained. It must be emphasized that formation of homogeneous and stoichiometric compound films by vacuum evaporation requires a critical adjustment of the substrate and various source temperatures, as well as the adjustment of the concentrations of the various components. Note that homogeneous precipitation by *in situ* generation of the precipitating anion is well known in chemistry for improving the stoichiometry of the precipitates.

In spite of considerable interest, the solution growth technique (2-13) has remained recipe-oriented and little is known about the kinetics of the process. It is essential to understand the kinetics and mechanism of the growth of films formed by this technique so that it may be extended to other semiconducting materials. CdS is an important material for application in large area solar cells. Therefore, we have undertaken a study of the process of deposition of CdS films by the solution growth technique. This paper reports on the kinetics of growth of CdS films and the occurrence of different conditions in the solution. A model for the growth mechanism has been proposed.

Experimental

Thin films of sulfides of Cd/Zn/Pb can be prepared by decomposition of thiourea in an alkaline solution containing a salt of Cd/Zn/Pb. The chemical reaction involved for a typical case of formation of CdS films from $Cd(CH_3COO)_2$ is as follows

$$Cd(CH_3COO)_2(aq) + (NH_2)_2CS(aq) + 2\,OH^- \rightarrow CdS + H_2CN_2 + 2H_2O + 2CH_3COO^-$$

$CdSO_4$, $Cd(NO_3)_2$, $CdCl_2$, etc. can also be used in a similar way. Reaction mixtures can be prepared in two ways. Different types of films are obtained from solution depending on whether the solution is being stirred or not during the deposition of the films.

(*i*) Appropriate volumes of 1M $Cd(CH_3COO)_2$, 14M NH_3 solution and distilled water are mixed slowly at room temperature with continuous stirring. Substrates are then immersed in the beaker containing the reaction mixture. The beaker is placed in a water bath having automatic temperature control. The solution is stirred with the help of a magnetic stirrer, as shown in Fig. 1. The solution is heated with continuous stirring to the required temperature of deposition, and the temperature is controlled to within ±1°C. An appropriate amount of 1M thiourea solution is then added with continuous stirring. Thereafter, the stirring is stopped in one case and continued in the other. Substrates are then taken out after a suitable time, washed with distilled water, and dried.

(*ii*) A reaction mixture of composition: 0.1M $Cd(CH_3COO)_2$, 6M NH_3, and 0.2M thiourea is prepared at room temperature. Substrates are then immersed in the solution and the solution is slowly heated to about 75°C, with continuous vigorous stirring. After about half an hour, substrates are taken out, washed with distilled water, and dried.

The substrates used in our study are ultrasonically cleaned glass slides, freshly etched single crystal silicon slices, and Sb-doped SnO_2-coated conducting glass slides. These were chosen with a view to studying the kinetics on different types of substrate materials, *viz.*, insulating, semiconducting, and conducting; the last one being used for making solar cells.

The film thickness was measured by a mechanical stylus arrangement (Talystep). Electron diffraction studies were done using an AEI-EM 802 electron microscope. The lattice constants were calculated by routine methods.

Results

The qualitative nature of the growth kinetics is the same on all the three substrate materials. Detailed studies were carried out on glass substrates. The quantitative differences arise due to differences in the nature of the substrate surface. Figures 2-5 show the growth kinetics on glass substrates.

We have found that different qualities of films can be obtained under different conditions in the working solution. Previous results of Kitaev *et al.* (2, 11-13) on kinetics show that film formation is possible only in the presence of $Cd(OH)_2$ in the working solution, but we have found that this is not always true. NH_3 plays a major role in determining the quality of the films. For convenience we have divided the whole NH_3 concentration range covered in the present study into three regions:

(*i*) The region in which (*a*) the amount of NH_3 is not sufficient (less than 1.8M) to redissolve completely the white precipitate of $Cd(OH)_2$ formed by the addition of NH_3 solution to the salt solution. (*b*) Although the amount of NH_3 is sufficient to completely

(*ii*) The region in which the amount of NH_3 is just sufficient to completely redissolve the white precipitate of $Cd(OH)_2$.

(*iii*) The region in which the amount of NH_3 is in much excess, 3-4 times as much as in region *ii*. The solutions in regions *ii* and *iii* are clear before the addition of thiourea.

Turbid solutions containing a thin suspension of $Cd(OH)_2$ give rise to thin (thickness ~600Å), adherent, physically coherent, and specularly reflecting films. These we refer to as A-quality films. The kinetics of growth for such films is shown in Fig. 2a. The dotted curve corresponds to films formed in region *i*(*b*) and the continuous curves in region *i*(*a*). These have wurtzite (hexagonal) structure when the solutions are vigorously stirred during the deposition. The films prepared under the same conditions but without stirring have wurtzite (hexagonal) structure with a large fraction of sphalerite (cubic) phase also, as shown in Table I, showing the d values of the various phases. Also, these films are less reflecting than the ones obtained by stirring.

Table I.

Unstirred clear solutions in region *ii* give rise to thick (thickness ~1-3 μm depending on the various deposition parameters), less adherent and powdery films having sphalerite (cubic) structure (Table I). These we refer to as B-quality films. Films obtained by stirring the solutions in this region are not very different from those obtained without stirring. Curve 3 in Fig. 2b shows the kinetics of growth for one of such films.

Unstirred solutions in region *iii* give rise to thick (thickness ~5 μm) adherent B-quality films having cubic structure. Curves 1 and 2 in Fig. 2b show the kinetics of growth for films prepared from unstirred solutions with different ammonia concentrations in this region. When the solutions are vigorously stirred during deposition, thin (thickness ~500Å) A-quality films (curve 5 in Fig. 2b) are obtained, with a structure corresponding to mixed hexagonal and cubic phases.

In procedure (*b*) the solution is slowly heated to about 75°C with continuous stirring, in the presence of thiourea [in contrast to method (*a*) where thiourea is added to the reaction mixture only after bringing it to the required temperature of deposition and maintaining it]. Films prepared by this procedure were ~6000Å thick, of A-quality with a structure corresponding to mixed hexagonal and cubic phases (curve 4 in Fig. 2b).

The lattice constants of the hexagonal and cubic phases, as calculated are: hexagonal, a = 4.16Å and c = 6.67Å; cubic, a = 5.82Å. These values are very close to the known values of the bulk material as given in ASTM cards. Standard values: hexagonal, a = 4.138Å and c = 6.713Å; cubic, a = 5.818Å.

Discussion

The main results of our study are: (*i*) the films prepared in presence of $Cd(OH)_2$ in the solution are very adherent, physically coherent, and specularly reflecting; (*ii*) vigorous stirring of the solution decreases the powdery nature and increases adhesion, physical coherence, and specular reflectance of the films; (*iii*) in general, the higher the deposition rate, the lower is the saturation thickness; and (*iv*) A-quality films are formed more readily on smooth surfaces while B-quality films are formed more readily on rough surfaces.

Based on the experimentally observed facts, we have proposed a model for the mechanism of growth of these films, which explains all the above features of growth. Similar to formation of precipitate in the solution, formation of film on the substrate takes place by nucleation and growth processes. It is well known that nucleation of a precipitate in the solution starts at some local inhomogeneities present in the solution (*e.g.*, due to some solid impurities), where the ionic product exceeds the solubility product. Growth of these nuclei by addition of more ions from the solution results in formation of stable nuclei of size greater than the critical size. Further growth, up to a particle size of 10 μm, results in formation of a colloidal dispersion. Nucleation on the substrate, according to Kitaev *et al.* (2) takes place by adsorption of these primary colloids. Growth takes place as a result of surface coagulation of these particles, resulting in thin, adherent, and specularly reflecting A-quality films. An important result of our previous studies, which completely rules out the possibility of nucleation of A-quality films by adsorption of colloidal particles and cluster-by-cluster growth model, is the possibility of occurrence of epitaxial growth in some of the cases (14) on suitably chosen single crystal substrates. This strongly suggests the atomistic (that is, ion-by-ion) nature of nucleation and growth. Other evidence in favor of the ion-by-ion growth model (and against the cluster-by-cluster growth model) is the strong adhesion and specular reflectance of A-quality films. Note that electrophoretic deposits, which grow cluster-by-cluster from a colloidal dispersion, are known (15) to be loose and powdery. The fact that the structure of A-quality films is either pure hexagonal or a mixture of hexagonal and cubic phases, whereas the precipitate is always cubic, again suggests ion-by-ion growth of A-quality films. Cluster-by-cluster growth of B-quality films is supported by the fact that they have a structure similar to that of the precipitate (cubic). Cluster-by-cluster growth of B-quality films explains the experimentally observed fact that they are more readily formed on rough surfaces.

Formation of CdS nuclei by the combination of ions on the substrate surface requires preferential adsorption of at least one type of the reacting ions on the substrate. Preferential adsorption of either Cd^{+2} or S^{-2} on glass surfaces from aqueous solutions is not known; so that formation of CdS nuclei on the substrate requires some catalytic solid phase on the substrate which can preferentially adsorb Cd^{+2} or S^{-2} ions. We have seen that a glass slide dipped in a suspension of $Cd(OH)_2$ has a layer of $Cd(OH)_2$ on it, which is known (13) to stimulate the decomposition of thiourea. This suggests that in solutions containing a suspension of $Cd(OH)_2$, this layer is converted to CdS by adsorption of S^{-2} ions formed by decomposition of thiourea on the catalytic surface of $Cd(OH)_2$. Further growth takes place on CdS by addition of more Cd^{+2} and S^{-2} ions. Vigorous stirring of the solution increases the rate of arrival of Cd^{+2} and S^{-2} ions on the substrate and also the rate of coagulation of colloidal CdS particles in the solution. This results in precipitation of the colloidal CdS particles which now cannot be adsorbed on the substrate leaving the films to grow by only ion-by-ion growth. This also explains, why, if solutions are not stirred, films contain a large fraction of cubic CdS also. The colloidal CdS particles which are adsorbed if solution is not stirred give rise to scattering in the films, thus decreasing their specular reflectance.

In case of clear solutions containing no $Cd(OH)_2$ in the bulk of the solution, accumulation of CdS in the solution takes place homogeneously by slow hydrolysis of thiourea and decomposition of the complex $Cd(NH_3)_4{}^{+2}$. The colloidal CdS solution is stable in this case for a long time when the solution is not being stirred, so that nucleation and growth of film take place by colloidal particles resulting in B-quality films. But when the clear solution is vigorously stirred, the colloid becomes unstable due to enhanced coagulation,

forming larger particles of CdS which cannot be adsorbed to start nucleation. In unstirred solutions very few Cd^{+2} and S^{-2} ions reach the substrate, since most of them condense on colloidal CdS formed in the solution. But during stirring the substrate surface is bombarded with a large number of Cd^{+2} and S^{-2} ions. This, coupled with the fact that a hydrophilic surface preferentially adsorbs OH^- ions from aqueous alkaline solutions, results in formation of $Cd(OH)_2$ nuclei on the substrate, although there is no $Cd(OH)_2$ in the solution due to high NH_3 concentration. (We have seen that on hydrophobic surfaces like Teflon, greasy glass slides, A-quality films are not formed. B-quality powdery films can be obtained on any surface, including hydrophobic, if the surface is not smooth). These $Cd(OH)_2$ nuclei act as nucleation centers for CdS. These nuclei grow ion-by-ion and coalesce to form a continuous CdS film. This ion-by-ion growth of film proceeds until some large precipitate particles of CdS collect on the substrate surface.

The various other features of growth kinetics (Fig. 2-5) can be explained on the basis of a diagram (Fig. 6) which represents a graphical solution of equations representing the equilibria

$$Cd^{+2} + 2\,OH^- \rightleftharpoons Cd(OH)_2$$

$$Cd^{+2} + 4NH_3 \rightleftharpoons Cd(NH_3)_4{}^{+2}$$

This diagram has been drawn on a basis similar to that of Kitaev *et al.* (13). The analysis is as follows.

From standard tables, the solubility product constant of $Cd(OH)_2$ and the instability constant of $Cd(NH_3)_4{}^{+2}$ are given, respectively, by

$$SP = 2.2 \times 10^{-14} \quad (pSP = 13.66)$$

$$K = 7.56 \times 10^{-8} \quad (pSP = 7.12)$$

That is

$$[Cd^{+2}][OH^-]^2 = 2.2 \times 10^{-14}$$

$$\frac{[Cd^{+2}][NH_3]^4}{[Cd(NH_3)_4{}^{+2}]} = 7.56 \times 10^{-8}$$

Converting to logarithmic concentrations

$$pH = 0.5p[Cd^{+2}] + 7.17 \qquad [1]$$

$$p[Cd^{+2}] + 4p[NH_3] - p[Cd(NH_3)_4{}^{+2}] = 7.12 \qquad [2]$$

Using base hydrolysis of NH_3

$$NH_3 + H_2O \rightleftharpoons NH_4{}^+ + OH^-,$$

$$K_b = 1.8 \times 10^{-5} \quad (pK_b = 4.76)$$

$$2p[OH] = 4.76 + p[NH_3]$$

$$p[NH_3] = 23.24 - 2pH \qquad [3]$$

Substituting $p[NH_3]$ from [3] into [2] and assuming that NH_3 is present in excess so that $[Cd(NH_3)_4{}^{+2}] \simeq$ [salt], we obtain for 0.1M $Cd(CH_3COO)_2$

$$pH = \frac{1}{8}p[Cd^{+2}] + 10.6 \qquad [4]$$

This is true only for $[NH_3] >> 4$ [salt], so that the approximation $[Cd(NH_3)_4{}^{+2}] >> [Cd^{+2}]$ is valid. Equations [1] and [4] when plotted as pH *vs.* $p[Cd^{+2}]$ are called hydroxide line and complex line, respectively. $Cd(OH)_2$ is formed in the solution only for pH values above the hydroxide line, and the complex $Cd(NH_3)_4{}^{+2}$ is stable only for pH values below the complex line. For pH values above complex line, the complex is hydrolyzed to $Cd(OH)_2$. The $p[Cd^{+2}]$ scale has been converted to $p[NH_3]$ scale using Eq. [2] (with $[Cd(NH_3)_4{}^{+2}] \simeq [salt] = 0.1$). The pH value of the solution for a given $[NH_3]$ can be calculated from the solution of Eq. [1] and [2]. From [1] and [2], eliminating $p[Cd^{+2}]$, we obtain

$$pH = 11.23 - 2p[NH_3] \text{ for } 0.1M\ Cd(CH_3COO)_2$$

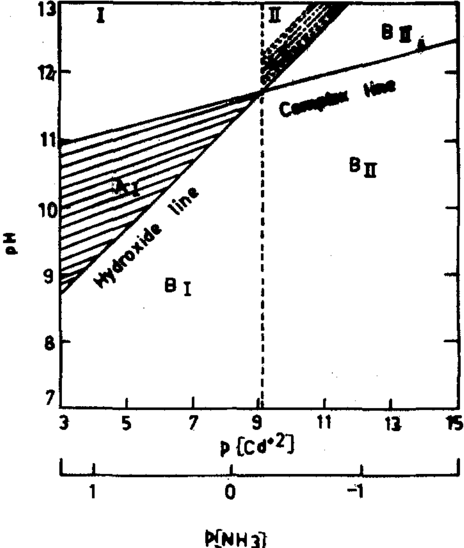

Fig. 6. A plot of Eq. [1] and [4]

pH values of different solutions as calculated by this equation are in close agreement with the experimentally measured values, shown in Fig. 2b.

The whole diagram can be divided by a vertical line, into two regions I and II. In region I, the complex line lies above the hydroxide line, implying that $Cd(OH)_2$ and $Cd(NH_3)_4{}^{+2}$ inevitably exist in the solution in the region between the hydroxide and the complex line. The true equilibrium of the system $Cd(CH_3COO)_2$-NH_3 in water is represented by some curve lying in A_I in region I and by the complex line in region II. Working at other points in the diagram requires additional introduction of an acid or alkali. Region A_I is, thus, the theoretically predicted region for coexistence of $Cd(OH)_2$ and $Cd(NH_3)_4{}^{+2}$. For very small amounts of $Cd(OH)_2$ in the solution, A-quality films are formed in this region. Larger amounts of $Cd(OH)_2$ lead to precipitation only and no film formation. Kinetics of growth for these films is shown by solid curves in Fig. 2a. Since below the hydroxide line, there is no $Cd(OH)_2$ present in the solution, A-quality films are not expected in the region B_I. Experimentally this has also been found to be true.

In region II, the hydroxide line lies above the complex line. The solutions are clear in the region below the hydroxide line, and to form $Cd(OH)_2$ in the working solution, an alkali must be introduced into the solution. Thus, A-quality films are expected in the region A_{II}. The film thickness decreases rapidly as higher pH values are approached where, due to rapid reaction, only precipitation will occur. The dotted portion shows the experimental values for obtaining A-quality films of measurable thickness, thus verifying the theoretically predicted results. The kinetics of film growth in this region is shown in Fig. 2a, dotted curve. Thus, A_I and A_{II} correspond to region *i* mentioned earlier in the text under Results. In region B_{II} below the hydroxide line, no $Cd(OH)_2$ can exist in the solution and B-quality films are expected with no stirring (solid curves 1, 2, and 3 in Fig. 2b) and A-quality with vigorous stirring (dashed curve 5 in Fig. 2b). In this region, most of the Cd^{+2} ions are bound in the complex form and only a very small fraction ($\sim 10^{-13}$) is present as free Cd^{+2}. Moreover, there is no solid phase of $Cd(OH)_2$ present to enhance the decomposition of thiourea. It is, therefore, expected that film formation will take place only above a certain temperature for each concentration of NH_3. This arises from the fact that below this temperature, the product $[Cd^{+2}][S^{-2}]$ is less than the solubility product of CdS. Heating of the solution helps the decomposition of thiourea and also provides kinetic energy to the ions, resulting in increased number of collisions and hence their combination to form

CdS. This is in conformity with the experimental observations. For example, solutions containing 5.6M NH_3 must be heated to temperatures greater than 45°C to obtain films.

The saturation behavior of the film thickness in kinetics curves (Fig. 2a, 2b, 3, and 4) is because of eventual reduction of the ionic product of CdS in the solution to values below the solubility product and coagulation of colloidal particles of CdS to form larger particles which cannot be adsorbed.

Figure 6 shows that as the NH_3 concentration increases, the Cd^{+2} concentration decreases, resulting in slow rates of deposition at high NH_3 concentrations. Also since Cd^{+2} ions are being generated very slowly, the rate of precipitation is very much reduced, giving more time for film formation, thus accounting for the general observed feature that the lower the deposition rate, the higher the ultimate film thickness obtained (Fig. 5).

As mentioned earlier, the increase of deposition rate with increase of temperature is because of the increased number of collisions between Cd^{+2} and S^{-2} ions and thermal decomposition of thiourea to give more S^{-2} ions. The increase of deposition rate with increasing thiourea is very obvious, as the rate of any chemical reaction is proportional to the concentration of the reacting species. The saturation thickness *vs.* $[(NH_2)_2CS]$ shows a maximum because at lower concentrations of thiourea, the number of S^{-2} ions is insufficient to combine with all the available Cd^{+2} ions. At high concentrations of thiourea, the rate of reaction becomes very high, resulting in lower film thicknesses.

Conclusions

1. According to our growth model, the growth of the chemically deposited CdS films takes place either by ion-by-ion condensation of Cd^{+2} and S^{-2} ions or by adsorption of colloidal CdS particles formed in the solution.

2. The former process of growth results in thin, adherent, and physically coherent films whereas the latter results in thick and powdery films. The growth in the first case being ion-by-ion suggests the possibility of mixing various materials in the film, revealing a novel technique for making multicomponent materials, such as semiconductor alloys, in thin film form.

3. The thickness, adhesion, and physical coherence of films are determined by the temperature of deposition, relative concentration of the various reactants in the solution, and method of preparation.

4. Different polymorphic phases (cubic and hexagonal) of CdS and their mixtures can be stabilized in films under different growth conditions.

Reduction of the Dislocation Density in $GaAs_{1-x}Sb_x$ Layer on GaAs Grown by an Improved LPE Method

Yorimitsu Nishitani, Kenzo Akita, Akio Yamaguchi, and Tsuyoshi Kotani

Fujitsu Laboratories, Limited, Nakahara-ku, Kawasaki, Japan

ABSTRACT

An improved LPE method in which the solid surface is always covered by a solution during step-graded growth of $GaAs_{1-x}Sb_x$ on GaAs substrates produces etch pit densities of 3-6 $\times$ 10^5 cm^{-2}. In contrast, layers grown by conventional step or continuously graded LPE have EPD of 6 $\times$ 10^6-2 $\times$ 10^7 cm^{-2}. The composition of the top layer is approximately $GaAs_{0.9}Sb_{0.1}$ in all cases. The reduction of EPD by the improved LPE method is attributed to limiting the nucleation of small islands to the first buffer layer, under the conditions that the grown surface is always covered by the solution subsequent to the growth of the first buffer layer.

$GaAs_{1-x}Sb_x$ is a useful material for the optoelectronic devices (1-4). However, it is difficult to directly grow device quality $GaAs_{1-x}Sb_x$ crystals with $x > 0.05$ on the GaAs substrates by liquid phase epitaxy (LPE) because of the large mismatch in lattice constants between the epitaxial layer and the substrate. Usually, the buffer layers are inserted between the layer and the substrate to reduce the lattice mismatch.

Two types of the buffer layers, stepwise and continuous graded buffer layers, have been reported (5-8). Nagai and Noguchi (6), reported that the dislocation density of $GaAs_{0.86}Sb_{0.14}$ on GaAs decreased from 1 $\times$ 10^7 to 2 $\times$ 10^6 cm^{-2} by changing the buffer layer from stepwise to continuous grading. This continuously graded buffer layer of about 30 μm thick was realized by utilizing the high distribution coefficient of phosphorus in the Ga-rich solution. Nahory *et al.* (4) reported that the GaAsSb crystalline quality of stepwise graded buffer layer was better than the continuously graded buffer layer, but they did not report the dislocation density.

In this paper, we report the reduction of the dislocation density in the GaAsSb layer grown by an improved LPE method in which the substrate is always covered with the solution during the growth of multilayers (9, 10). We also discussed the comparison of the dislocation density among the three kinds of buffer layers.

Experimental

A horizontal LPE growth system was used for the growth of $GaAs_{1-x}Sb_x$ layers. Two types of boats were employed. One type is a conventional sliding boat and another type is an improved sliding boat in which the partition between the compartments for the solution lifts by 500 μm when the container is moved and the piston on the solution is pushed mechanically by the piston-pusher to eliminate the melt mixing. Figure 1 shows a cross section of this new boat. A (100) oriented GaAs crystal was used for the substrate. The thickness was 300 μm and etch pit density (EPD) was less than 5000 cm^{-2}. The substrate was etched in $5H_2SO_4$-$1H_2O_2$-$1H_2O$ solution before the growth. The starting growth temperature and the cooling rate were 850° and 0.4°C/min, respectively.

Three kinds of buffer layers were grown. (*i*) A stepwise graded buffer layer consisting of 3-5 layers of $GaAs_{1-x}Sb_x$ using the conventional sliding boat; the x value of each layer was increased ~0.03.

(*ii*) A continuously graded $GaAs_{1-x}Sb_x$ buffer layer grown using the conventional sliding boat. Phosphorus was added to the solution as GaP for lattice matching at the interface between the epitaxial layer and the substrate. The lattice constant of $GaAs_{1-x-y}Sb_xP_y$ increases along the growth direction because of depletion of phosphorus in the solution. The optimum GaP content was determined by x-ray diffraction measurement on about 1 μm thick layers. Various amounts of GaP were added to the solution for the growth of a final layer with a composition of $x = 0.1$. The lattice constant of initial growth matched that of the GaAs substrate when the GaP content in the solution was 0.36 weight percent (w/o), as shown in Fig. 2. Using this solution containing 0.36 w/o GaP, when the interface layer thickness reaches about 35 μm, the GaP mole fraction in the solid was almost zero.

(*iii*) A stepwise graded buffer layer grown by using the improved boat. The layer structure was the same as (*i*).

The GaSb mole fraction was determined by the band-edge peak of photoluminescence and electron probe microanalyzer (EPMA) measurement. Etch pits were revealed by immersing the sample in the molten KOH

contained in a SiC crucible for 5 min at 340°C. All the $GaAs_{1-x}Sb_x$ layers were 10-20 μm thick. To reveal etch pits 3-5 μm were removed by the KOH. The etch pit density was calculated from the number of etch pits in a 200 × 200 μm area of the photograph.

Results and Discussion

Shapes of the etch pits.—Figure 3 shows a typical shape of the etch pits revealed on the $GaAs_{1-x}Sb_x$ layers after etching with molten KOH. They were hexagonal, independent of the GaSb mole fraction (x), and always contained centers. It is impossible to associate these pits with dislocations by x-ray topography because of high density (more than 10^4 cm^{-3}). However, these pits have certain shapes and centers. They are thought to show dislocations (11). In the case of the stepwise graded buffer layer, these etch pits were observed, independent of the growth method. In the case of the continuous graded buffer layer, small etch pits of a different shape, as shown in Fig. 4, were observed.

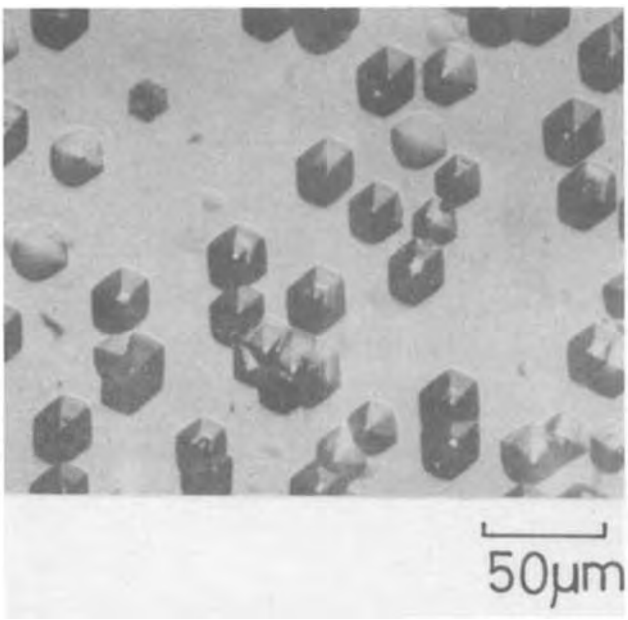

Fig. 3. Typical etch pits of $GaAs_{1-x}Sb_x$ layer revealed by molten KOH for 5 min at 340°C.

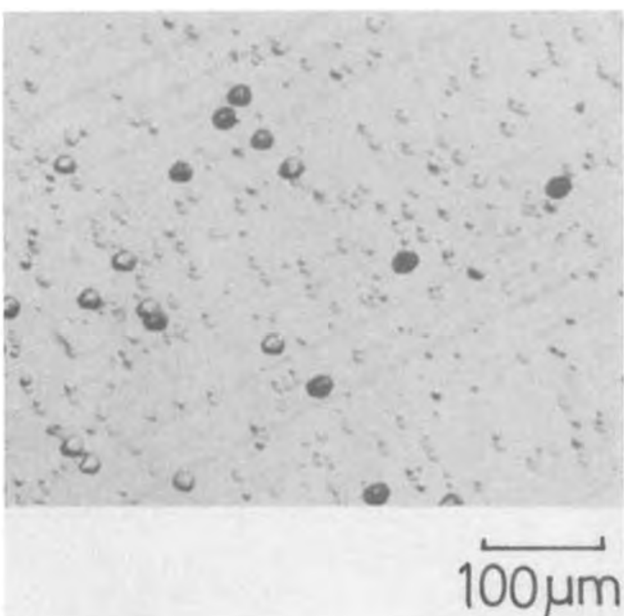

Fig. 4. Another shape of etch pits revealed on the surface of 10 μm thick $GaAs_{1-x}Sb_x$ layer with phosphorus added for the lattice matching.

These small etch pits were thought to show dislocations also, because they have centers. These etch pits were revealed on the surfaces of layers more than 5 μm in thickness and were not observed on the stepwise graded buffer layers. These extra pits are like "pair pits," but each pair pit has a center. Only the center was counted as an etch pit. This type of etch pit is thought to be produced on the $GaAs_{1-x-y}Sb_xP_y$ layer.

Etch pit distribution.—Figure 5a shows the etch pit distribution on the surface of the stepwise graded $GaAs_{1-x}Sb_x$ buffer layer grown by the conventional growth method. The clusters of the etch pits lie along the $<110>$ and $<1\bar{1}0>$ directions. Most of the pits indicate misfit dislocations due to the lattice mismatch. Figure 5b shows an enlarged photograph of the pattern shown in Fig. 5a. The etch pit densities were as high as 10^7-10^9 cm^{-2} in the areas of the clusters. These clusters may generate at the early stage of the growth. Figure 6 shows the etch pit distribution on the surface of the stepwise graded $GaAs_{0.9}Sb_{0.1}$ buffer layer grown by the improved method. These rectangularly shaped pits were produced by etching at a temperature of more

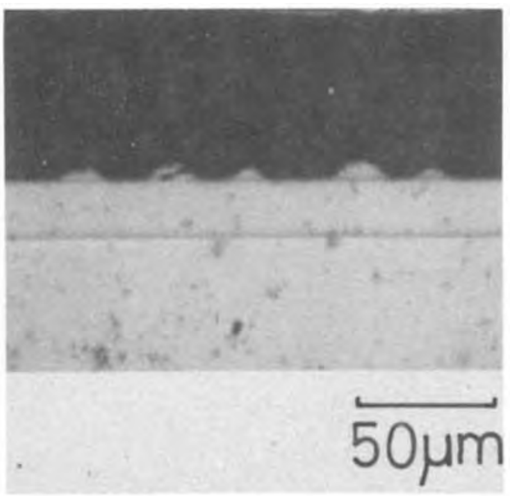

Fig. 7b. Cross section of the initial stage of the second layer growth.

Table I. Etch pit density under various growth conditions

Growth method	Layer structure	Layer thickness (μm)	Dislocation density (cm^{-2})
Improved	Stepwise	15	$3\text{-}6 \times 10^5$
Conventional	Stepwise	15	$3 \times 10^6\text{-}5 \times 10^7$
Conventional	Continuously	38	$2\text{-}6 \times 10^6$

than 340°C. The highest etch pit density observed on layers grown by the improved method was 5×10^5 cm^{-2}. The centers of the etch pits are separated so clearly that it is possible to count the number of pits easily in the photographic enlargements for densities less than 10^6 cm^{-2}. The etch pits shown in Fig. 6 are observed at random in comparison with the layer grown by the conventional method. Figure 7a shows the initial stage surface of the second layer grown by the conventional growth method, in which x is 0.06, and Fig. 7b shows the cross section of the same sample. Small nucleation sites lie in the <110> and <1$\bar{1}$0> directions with the separation distance of 10 μm or less. On the next stage of the coalescence, the misfit dislocations are introduced. On the other hand, such nucleation did not occur for the layer grown by the new method because the solution always covered the substrate.

Etch pit density.—Figure 8 shows the dependence of the etch pit density introduced in the continuously graded buffer layer on the layer thickness. It increases with increasing the layer thickness. The density was $2\text{-}7 \times 10^6$ cm^{-2} on the sample of 38 μm thick. Figure 9 shows the etch pit density on the stepwise graded buffer layer for various GaSb mole fractions (x) using two types of the growth boats. The etch pit density increased with increasing x in both cases. However, when the x was more than 0.03, the etch pit density in the case of the conventional boat increased more rapidly than in the case of the improved boat. This fact indicates that the improved growth method is not different from the conventional one in the first layer, but it is effective in reducing the introduction of dislocations in subsequent layers. The etch pits densities seem to be saturated at $3\text{-}6 \times 10^5$ cm^{-2} in the case of using this type of boat. These values are the lowest reported for $GaAs_{0.9}Sb_{0.1}$ layers grown on GaAs.

For the growth of $In_xGa_{1-x}As$ on GaAs substrates, the tetragonal distortions were usually observed. For example, 0.3% distortion has been observed in vapor phase epitaxial (VPE) $In_{0.1}Ga_{0.9}As$ on GaAs (12).

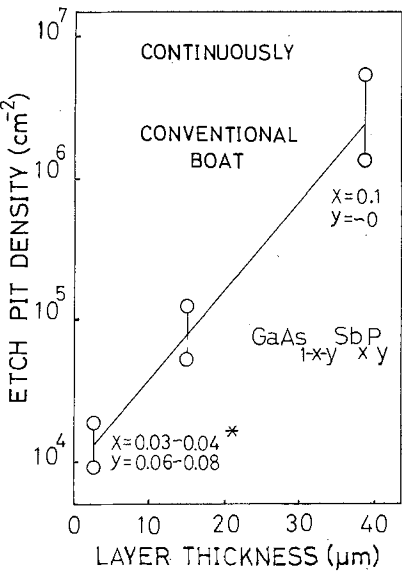

Fig. 8. Etch pit density of a continuously graded buffer layer as a function of the layer thickness [* values estimated from Ref. (6-7)].

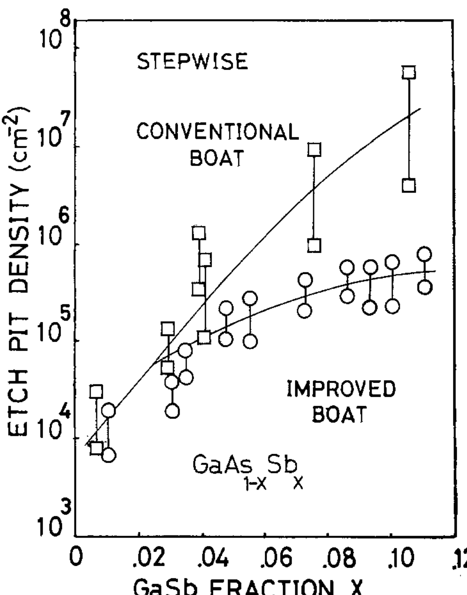

Fig. 9. Etch pit density of stepwise graded buffer layer for GaSb mole fraction, x.

Moreover, concave bending is usually observed in LPE $In_{1-x}Ga_xAs$ on GaAs (13). These facts indicate that $In_{1-x}Ga_xAs$ crystals tend to be deformed from cubic to tetragonal. On the other hand, $GaAs_{1-x}Sb_x$ crystals do not indicate large bending and suggest the release of the lattice stress by introduction of the misfit dislocations rather than by tetragonal distortions.

In the stepwise graded $GaAs_{1-x}Sb_x$ buffer layer grown by the conventional growth method, many etch pits were generated from a large number of the dislocation clusters lying along to the <110> and <1$\bar{1}$0> directions in the early stage of the growth.

In the case of a continuously graded buffer layer, the dislocations are introduced when the layer thickness exceeds the critical thickness. The largest dislocation density is estimated to be

$$\left[\frac{10^8}{a \times \frac{1}{\Delta a/a}}\right]^2$$

cm^{-2}, where a and Δa are the lattice constant of the substrate and the difference of the lattice constant (in angstroms) between the epitaxial layer and the substrate, respectively. For $GaAs_{0.9}Sb_{0.1}$ on GaAs (a = 5.653Å, $\Delta a/a = 0.008$), the dislocation density is estimated to be 10^{10} cm^{-2}. In the actual crystals, the dislocation density of 10^6 cm^{-2} was observed. This indicates the existence of much interaction between dislocations in the continuously graded buffer layer as reported by Olsen (12).

In the case of stepwise graded buffer layer grown by the improved method, the etch pits were distributed at random on the surface, in contrast with usual stepwise graded buffer layers. It is considered that the nucleation of small islands is suppressed at the intefaces, with the exception of the interface between the first layer and the substrate, and the islands may not be produced in the growth of successive buffer layers because the grown surface is always wetted with the solution. This suggests that the crystal bonds are continuous in contrast to the usual buffer layer in which the crystal bonds are closed by exposure to the H_2 atmosphere. The suppression of the island nucleation provides the possibility of a large amount of interaction between dislocations at the interfaces. The abrupt change of lattice constant introduces many dislocations with different direction of Burgers vector in the limited thickness of the epitaxial layer.

Conclusion

The etch pit density of $GaAs_{0.9}Sb_{0.1}$ was reduced from 5×10^6 cm^{-2} to 3-6 $\times 10^5$ cm^{-2} by using an improved growth method in which stepwise buffer layers were grown consecutively without exposure of the grown surface, except for the final layer, to the ambient gas. The reduction of the etch pit density is attributed to limiting the nucleation of small islands to the first buffer layer, because the grown surface is always covered with solution.

Optical Constants of Silicon by Unpolarized Incident Radiation

O. L. Russo

Department of Physics, New Jersey Institute of Technology, Newark, New Jersey 07102

ABSTRACT

It is shown that the reflectance of modulated unpolarized incident radiation at the pseudo-polarizing angle can be used to accurately determine the optical constants of absorbing media in the visible region. The approximation that the principal angle of incidence occurs at the pseudo-polarizing angle is assumed to contribute negligible error. Expressions for the refractive index, n, and the extinction coefficient, K, are given in terms of the pseudo-polarizing angle and the reflectance ratio of the parallel (to the plane of incidence) reflected wave vector intensity to the normal reflected wave vector intensity. The experimental values for n and K are determined at wavelengths in the visible spectrum between 4250 and 5750Å, for boron-doped p-type highly polished silicon of 0.01 and 95 Ω-cm resistivity. These values correspond to impurity concentrations of about 10^{-3}-10^{-6}%, respectively. The 0.01 Ω-cm K curve indicates the possibility that direct optical transitions between acceptor levels and the conduction band can be resolved and that this occurs at about 5250Å ($\simeq$2.4 eV).

Various methods of transmission or reflection of electromagnetic waves have been used by numerous investigators to determine the optical constants of solids. Transmission of a beam of radiation through a very thin layer (1) or by various modified reflectance methods (2-8) have been used to obtain the optical constants for semiconductors in the infrared and visible region of the spectrum. The transmission method although valuable because it permits the absorption centers to be easily identified has several disadvantages. There are difficulties in the measurement of the thickness and uniformity of the thin layer which causes errors in the determined optical constant values, and there are further inaccuracies caused by improper correction due to the reflection of the incident radiation from the two surfaces. The reflectance method has been by far the most successful and more commonly employed of the two methods, perhaps because of its versatility. There are numerous reflectance methods and most are variations of using normal reflectance, oblique reflectance, or reflectance at the polarizing angle. The reflectance method at normal incidence while being easy to implement, consequently extensively employed, can result in considerable inaccuracy for the refractive index, n, and the extinction coefficient, K, in the range of values for which n and K both vary between 1.0 and 4.0 (9).

The method in which the reflectance is measured for oblique incident radiation requires that, in general, the measurements be made at two or more incident angles. The data, notably the angles and reflectances are then used to determine the optical constants by graphical methods. The method has been applied to absorbing isotropic media using unpolarized (10) and polarized (11) incident light.

A graphical analysis in which the ratio of reflectances is measured at two or more incident angles has been shown to have the advantages of increased accuracy and independence of the sample surface size (12). Other methods using the reflectance ratio have been used to obtain the optical constants by geometric means (13, 14). It has been shown that the minimum in the ratio of the reflectance at its corresponding incident angle can be used to yield the optical constants (15).

The reflectance method in which the data is obtained at the polarizing angle is simpler and as accurate as the oblique method and certainly more accurate than the normal method. Determination of the optical constants n and K by this method requires that the ratio, ρ, of the reflected wave vector, R_p (parallel to the plane of incidence), to the reflected wave vector, R_s (perpendicular to the plane of incidence), be measured at the polarizing angle. The pseudo-Brewster or pseudo-polarizing angle, θ_p, however, for absorbing materials occurs when the value of R_p is a minimum, but not zero as is true in nonabsorbing media. The incident radiation is polarized and the azimuth of restored polarization which determines ρ must then be measured along with the pseudo-polarizing angle. The method although straightforward requires that the angle of restored polarization be measured with sufficient accuracy in order that errors in the optical constants be minimized. This measurement is critical especially if small values of the extinction coefficient K are to be accurately determined.

When the polarizer is positioned between the specimen and the detector, as in this study, the quantity ρ is determined simply by the ratio of two reflectances. Provided the incident radiation is unpolarized, one reflectance is always in the vertical plane and the other in the horizontal plane. There is the disadvantage, that in positioning the polarizer between the unpolarized source and specimen (incident light polarized), that either ρ be determined by measurement of the: (i) angle of restored polarization or (ii) reflectances, but, in which the plane of polarization is now rotated because of reflection. As a consequence, some systematic experimental error is introduced because the reflectances are no longer in their respective vertical and horizontal planes. The values thus are obtained by a search for a minimum and maximum value.

In this paper, measurement of the reflectance ratio at the polarizing angle is made using unpolarized incident modulated radiation. This facilitates the experimental procedure and eliminates the need for the measurement of the angle of restored polarization, which results in improved accuracy. Measurements made on highly polished doped silicon surfaces show that it is possible to resolve samples of differing conductivities. Expressions for the refractive index, n, and the extinction coefficient, K are given in terms of the pseudo-polarizing angle, θ_p, and the reflectance, ρ_p, measured at the angle, θ_p. The expressions are

Key words: reflectance, visible, doping, refractive index, extinction coefficient.

based on the assumption that θ_p occurs at the principal angle of incidence.

Experimental Arrangement

The diagram in Fig. 1 shows a positionally fixed monochromatic light source which consists of a tungsten bulb and a grating monochromator capable of wavelengths from 4000 to 7000Å with monochromaticity to within ±1Å at the 50% intensity points. The experimental values, however, were measured with the 50% bandwidth fixed at 50Å in order to keep the light intensity at reasonable levels in comparison to the system noise. A mechanical chopper wheel is used to modulate the light beam at a frequency of 2010 Hz while supplying a reference signal to the lock-in amplifier. After the modulated light beam is collimated, it reflects from the highly polished silicon wafer supported by a holder mounted on a turntable. The light beam then passes through an analyzer which has a permissible total integrated transmission to two crossed polarizers of 0.0005% over the wavelength region of the measurements. A photomultiplier used to measure the light intensity is equipped with a slotted mask (to reduce spurious light) over the face of the tube (RCA 6342A) which has a peak response in the visible range. When the photomultiplier and analyzer assembly is rotated, it is arranged to rotate through twice the angle of rotation of the turntable, consequently requiring that it always be at the angle of reflection.

The lock-in amplifier synchronized by the reference signal so as to have a peak response at the modulating frequency is then used to measure the intensities of the normal, R_s, and parallel, R_p, wave vectors of the reflected wave. These intensity measurements are made with the transmission axes of the analyzer parallel (for R_p) and then normal (for R_s) to the plane of incidence. The value of the normal reflected intensity is measured at the pseudo-polarizing angle which is determined as the angle where the measured parallel reflected intensity is a minimum.

Care was taken to minimize errors by insuring adequate linearity of the system over the range of intensities required for the measurements. Accuracy in the measurement of the modulated reflected intensity was achieved because of the relative independence of the a-c photomultiplier on small power supply fluctuations. The small amount of polarization in the incident beam was measured by directing the beam so as to be incident directly on the slot of the masked photomultiplier tube. Corrections for the amount of incident polarization were accounted for in the calculation of ρ.

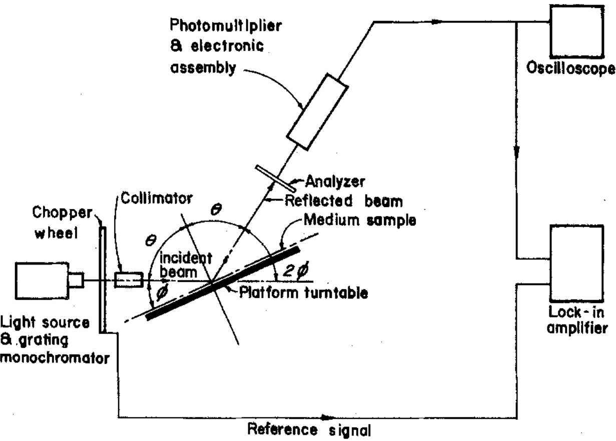

Fig. 1. Schematic diagram of the apparatus described in the text used for the measurement of the pseudo-polarizing angle and the reflectance ratio.

Theory

The Fresnel reflection equations as determined using the boundary conditions demand that the tangential components of the electric field vector, E, and the magnetic vector, H (no surface current density) be continuous and also that the normal components of the magnetic induction, B, and the displacement, D (no surface charge density), be continuous at an interface. These equations which are given in terms of the incident and refracted angles can be expressed in complex form as

$$\hat{R}_p = A_p \frac{\tan(\theta - \beta)}{\tan(\theta + \beta)} \quad [1]$$

and

$$\hat{R}_s = -A_s \frac{\sin(\theta - \beta)}{\sin(\theta + \beta)} \quad [2]$$

The complex quantities $\hat{R}_p$ and $\hat{R}_s$ are complex reflected wave vectors, respectively parallel and normal to the plane of incidence and the real quantities A_p and A_s, respectively incident wave vectors parallel and normal to the plane of incidence. The quantity θ is the angle of incidence in air and β is the complex refracted quantity which for a medium which is absorbing, is given by

$$\sin\beta = \frac{\sin\theta}{\hat{n}} \quad [3]$$

where $\hat{n}$, the complex refractive index of the medium

$$\hat{n} = n(1 - iq) \quad [4]$$

is given in terms of the real refractive index, n, and an attenuation constant, q.

The electric wave vectors, A, of unpolarized light, occupying planes intersecting concurrently with but randomly oriented in the plane of incidence, can be resolved into parallel, A_p, and normal, A_s, components. Each of these components undergoes upon reflection a phase shift between it and its associated reflected component. Then the complex reflected vectors which are given by

$$\hat{R}_p = R_p\epsilon^{i\delta_p} \quad \text{and} \quad \hat{R}_s = R_s\epsilon^{i\delta_s}$$

can be used with [1] and [2] to yield

$$\rho\epsilon^{i\delta} = -\frac{\cos(\theta + \beta)}{\cos(\theta - \beta)} \quad [5]$$

where $\rho = (R_p/R_s)/(A_s/A_p)$ and the relative difference of phase $\delta = \delta_p - \delta_s$. From [3] and [5], it can be shown that

$$\frac{1 + \rho\epsilon^{i\delta}}{1 - \rho\epsilon^{i\delta}} = \frac{\sin\theta\tan\theta}{(\hat{n}^2 - \sin^2\theta)^{1/2}} \quad [6]$$

As the angle of incidence θ changes from grazing incidence to normal incidence ($\pi/2$ to zero), the angle δ changes from zero to π. For some angle θ in this range, the angle $\delta = \pi/2$ which occurs at the angle θ which is the principal angle of incidence θ_i. It can be seen that when $\delta = \pi/2$ and using [4] in [6], then the expressions for n and q are given by

$$\frac{1 - q^2}{q} = \frac{1 - (4\rho_i\cos^2\theta_i(\tan\theta_i^2 - 1)}{2\rho_i\sin^2\theta_i} \quad [7]$$

and

$$n^2q = \frac{2z\sin^2\theta_i\tan^2\theta_i}{1 + 4z^2} \quad [8]$$

where

$$z = \frac{\rho_i}{1 - \rho_i^2}$$

and ρ_i is the value of ρ measured at θ_i.

The assumption is usually made that the pseudo-Brewster angle, θ_p, for visible light nearly occurs at the principal angle of incidence for metals whenever $n^2 + K^2 >> 1$ (16). The fact that the minimum in the ratio of R_p/R_s does not occur exactly at the principal angle of incidence, θ_i, has been examined carefully for opaque materials (17). Here it is shown that the error which may be important in the infrared is small for the visible region.

It is therefore assumed for silicon, in the visible region, where the refractive index is between 3 and 5 and K greater than zero, that, $\theta = \theta_i = \theta_p$ and $\rho_i = \rho_p$ where ρ_p is the minimum value of ρ (which occurs at θ_p). Then, for these conditions, Eq. [7] and [8] become

$$\frac{1 - q^2}{q} = \frac{1 - 4\rho_p \cos^2 \theta_p (\tan^2 \theta_p - 1)}{2\rho_p \sin^2 \theta_p} \quad [9]$$

and

$$n^2 q = \frac{2z_p \sin^2 \theta_p \tan^2 \theta_p}{1 + 4{z_p}^2} \quad [10]$$

where

$$z_p = \frac{\rho_p}{1 - {\rho_p}^2}$$

The value of the extinction coefficient is known from the relationship

$$K = nq \quad [11]$$

The value of ρ as given by Eq. [5] can be measured as a ratio of intensities or voltages. This is evident when it is considered that for a plane electromagnetic wave propagating in an absorbing medium, given by

$$E(x, t) = E_0 e^{i(\omega t - \hat{k} x)} \quad [12]$$

that the intensity of the electromagnetic field, I, which can be expressed as the product of the velocity of the wave and the time averaged electric energy density, is given by

$$I \propto E_0^2(x) \quad [13]$$

for observation times which are large compared to a period of oscillation of the wave.

Then, it follows that

$$\rho = \left[\frac{I_{R_p} I_{A_s}}{I_{R_s} I_{A_p}} \right]^{1/2} \quad [14]$$

where I_{R_p}, I_{R_s}, I_{A_p}, and I_{A_s} are the intensities corresponding to the reflected parallel, reflected normal, incident parallel, and incident normal waves, respectively.

Results and Discussion

The experimental values of the refractive index, n, and the extinction coefficient, K, for the semiconductor silicon were determined at room temperature by the reflectance of modulated unpolarized incident light at the pseudo-polarizing angle. The resistivity values for the silicon samples used in this study were 95 and 0.01 Ω-cm. These boron-doped p-type (111) orientation wafers correspond to impurity concentrations of from about 10^{-3} to 10^{-6}% of the host. A comparison of the refractive indexes for the two resistivity samples is given by Fig. 2 and of the extinction coefficients by Fig. 3. The results for the refractive index of 95 Ω-cm silicon is in agreement with those reported elsewhere for single crystal silicon (4, 18).

Inspection of Fig. 3 indicates that there is some peaking in the K curve for the 0.01 Ω-cm material which occurs near 5250Å (≃2.4 eV). This pronounced hump does not appear to be caused by any obvious anomaly in either the experimental arrangement or the procedure. The condition may be the result of direct transitions between the acceptor levels in the p-doped silicon to the conduction band. It is reasonable to expect that this will occur at energies just below

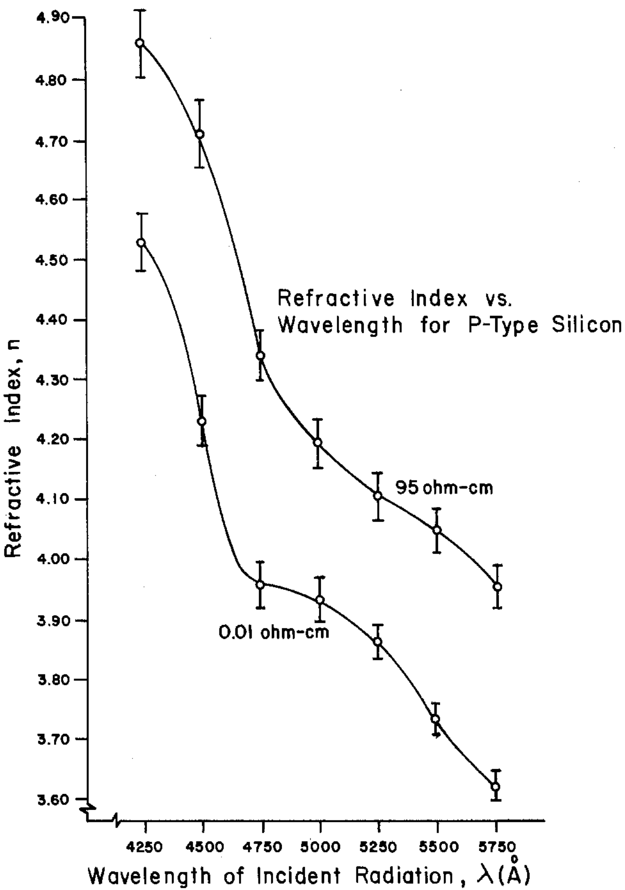

Fig. 2. Experimental curves for the refractive index as a function of wavelength at room temperature for polished p-type silicon of 0.01 and 95 Ω-cm resistivity.

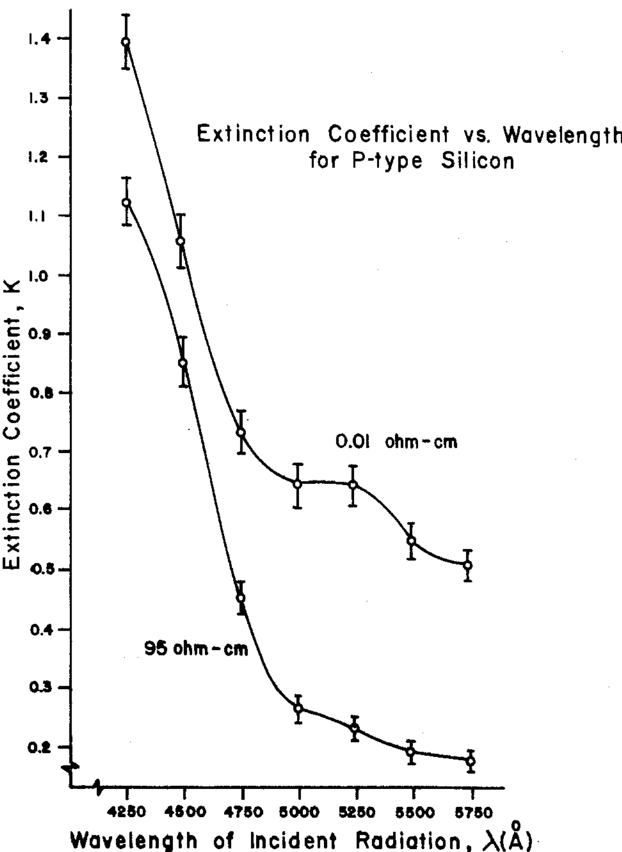

Fig. 3. Experimental curves for the extinction coefficient as a function of wavelength at room temperature for polished p-type silicon of 0.01 and 95 Ω-cm resistivity.

Table I. Optical constants of p-type silicon (boron doped) as a function of wavelength

	Resistivity			
	0.01 Ω-cm		95 Ω-cm	
Wave-length, λ (Å)	Refractive index, n	Extinction coefficient, K	Refractive index, n	Extinction coefficient, K
4250	4.52	1.39	4.86	1.12
4500	4.22	1.05	4.71	0.851
4750	3.95	0.730	4.34	0.463
5000	3.93	0.644	4.19	0.274
5250	3.87	0.639	4.11	0.240
5500	3.74	0.567	4.06	0.202
5750	3.61	0.520	3.95	0.191

the optical (valence-conduction) gap. The valence-conduction direct transitions can be seen from the curve to occur in the vicinity of 5000Å ($\simeq$2.5 eV). This hump is not manifest in the 95 Ω-cm curve, probably because of the relatively low impurity density.

Care was taken to prevent the formation of an oxide layer on the highly specular silicon surface. The surface preparation process consisted of cleansing the wafers in an alconox detergent solution, and after rinsing, etching in a 15 to 1 water to hydrofluoric acid bath for 10 min. Reflectance measurements were then made immediately after the samples were rinsed and dried. This procedure insures that an oxide formation while not completely eliminated will be minimized.

The accuracies of the measured parameters which consisted of the pseudo-polarizing angle (measured to ± one minute of arc) and the reflectance (to about 0.1%) were well within the range of the experimental error as shown in Fig. 2 and 3. The average for five independent trials is plotted and the error bars represent the statistical variations over the five trials taken within a time duration of 3 hr after etching. There was no conclusive evidence that an oxide layer was formed (increasing K with time) during the time interval of the experiment. It is reasonable to assume that some oxide layer (probably between 5-10Å) exists immediately after etching, however, it appears that the thickness of one layer may not be very different from the other.

Signal to noise considerations and the photomultiplier gain limitations demanded that a minimum bandwidth of 50Å be used for the incident radiation. This lack of monochromaticity, by itself, introduces some systematic error, because the intensity of the parallel, R_p, vector at the pseudo-polarizing angle is larger than that obtained by more monochromatic incident radiation of the same intensity.

The values of the attenuation constant, q, and the refractive index, n, requires that the pseudo-polarizing angle θ_p, and the ratio of the modulated reflected parallel to normal intensities, ρ_p, be measured. The ratio, ρ_p, is independent of the photomultiplier frequency response and to variations in the intensity of the incident beam. Also, the modulated beam when used with the lock-in amplifier results in a significant enhancement of the signal to noise ratio and a consequent improvement in accuracy and resolution over that which can be obtained by an unmodulated signal. This results in the apparent advantages of increased accuracy and repeatability when compared to measurements made as a reflectance ratio when the incident beam is not modulated, and also when compared to measurements of the azimuth of restored polarization (to determine q when the incident radiation is polarized). It is unlikely that measurements in which the azimuth of polarization as determined by the method of Drude (19) and subsequently by numerous authors can be resolved with the same precision.

The limiting factor in determining the value of the intensity I_{R_p} is the noise in the system, which can be minimized by lowering the temperature of the photomultiplier tube if necessary. It is essential that this be done when the medium under investigation has low values of q such as materials which can be classified as nonabsorbing (*e.g.,* glass). For the materials studied and reported here, the noise level was considerably less than the lowest I_{R_p} values so that the errors introduced were negligible.

Conclusion

It has been shown that the refractive indexes and extinction coefficients can be obtained for polished materials by measuring the reflectances at the pseudo-polarizing angle for incident unpolarized radiation. The ratio of the reflectances determines n and K more accurately than can be obtained by measurement of the azimuth of restored polarization (incident radiation polarized) especially when the media is such that the attenuation constant, q, is small. It is also significant that it is feasible to resolve the optical constants for host materials in which the impurity concentrations are different, and, further to discern variations caused by changing the impurity concentration. Although the boron-doped p-silicon material used had impurity concentrations which differ by about three orders of magnitude, the accuracy and resolution could be improved by careful attention to the signal to noise ratio and the monochromaticity of the radiation.

Optimization of the Deposition Conditions for Epitaxial Silicon Films on Czochralski Sapphire in the Silane-Hydrogen System

M. Druminski

Siemens AG, Research Laboratories, D-8000 München, Otto-Hahn-Ring 6, Germany

ABSTRACT

The deposition of epitaxial silicon films on $(\bar{1}012)$ Czochralski sapphire from the silane/hydrogen system was investigated for growth temperatures from 880° to 980°C and for growth rates from 0.2 to 6.0 μm/min. The film quality was evaluated by optical absorption measurements. The temperature range, in which epitaxial film quality was obtained, shifts with increasing growth rates to higher deposition temperatures. This epitaxial temperature range is rather broad, *e.g.*, 915°-965°C for 0.2-0.5 μm/min and 935°-985°C for 5.3-6.0 μm/min. A region for the optimum epitaxial deposition conditions, very suitable for MOS applications, is defined by the minimum values obtained from the optical absorption measurements. At temperatures below 915°C, decreasing crystalline quality was observed due to an increasing fraction of polycrystalline silicon. In addition the influence of the H_2O content on the crystalline quality of the silicon films was investigated; for the production of a good epitaxial silicon film the H_2O impurity fraction must be smaller than 1 ppm, especially in the low temperature region.

Thin epitaxial silicon films on insulators (ESFI), especially silicon on sapphire (SOS), have reached increasing importance in recent years (1, 2). Up to now distinct ways were chosen for the deposition of silicon on insulators with the goal of the production of good epitaxial film quality. First experiments by Manasevit and Simpson (3) and by Seiter and Zaminer (4) with $SiCl_4$ as silicon source showed that this system has the disadvantage of unwanted reaction products, especially due to the hydrogen chloride, which is evolved at higher temperatures. The use of silane, which decomposes irreversibly, became, therefore, the common way for the deposition of epitaxial silicon films on insulators. The advantages of this silicon source are: first; no unwanted reaction products such as chlorides are evolved and, second; a lower deposition temperature can be chosen than in the case of silicon tetrachloride.

Nevertheless the quality of such epitaxial silicon films is mainly limited by Eq. [1] (5) and [2] (6)

$$Al_2O_3 + 2H_2 \rightleftharpoons Al_2O + 2H_2O \qquad [1]$$

$$2Si + Al_2O_3 \rightleftharpoons 2SiO + Al_2O \qquad [2]$$

The influence of these reactions rises with increasing temperature, resulting in partial etching and autodoping effects:

Partial etching can more or less deteriorate the single crystal surface and may result in either polycrystalline growth or in the production of a layer with a high density of crystal imperfections. This can be prevented by lowering the deposition temperature which is possible according to Richman and Arlett (7) with silane in the SiH_4/He system for homoepitaxial silicon. Studies for heteroepitaxial silicon on sapphire and spinel from this system were published by several authors (8-10) and modified to the SiH_4/He/H_2 system by Manasevit for silicon on spinel (11).

Autodoping effects can occur due to reverse reactions which cause aluminum to be incorporated in the silicon film to be deposited. They can be reduced by using a low deposition temperature and a high growth rate simultaneously, in order to completely cover the surface of the substrate with a closed silicon film as quickly as possible. Once the surface and the sides of the wafers are completely covered no more reactions such as [1] and [2] can occur because there is no further formation or transport of volatile suboxides. Different two-step growth techniques with a first high growth rate (for quickly covering the substrate) followed by a lower growth rate were established by several authors (12-15).

All these methods are of interest for growing epitaxial films of good quality, but it seems rather difficult to control two different growth rates especially for thin ($< 1\ \mu$m) films.

Therefore, we endeavored to optimize the growing conditions by a more "conventional" method in order to have a deposition process that should be as simple as possible. After having studied the influence of the substrate preparation in an earlier work (16), we tried to establish optimum temperatures and corresponding growth rates for silicon films grown on $(\bar{1}012)$ sapphire.

Experimental

Substrate preparation.—Since the (100) orientation is preferred for MOS applications, sapphire slices with the $(\bar{1}012)$ orientation were used.[1] The slices were chemically-mechanically polished by the supplier or in our laboratories using colloidal silica;[2] they must be free of direct surface damage and of subsurface damage (16). This was confirmed before use by a preinspection of a representative number of slices from one polishing lot. These slices were etched at 275°C in KOH for 5 min. In Fig. 1 a comparison is made between two different surfaces: (a) with and (b) without subsurface damage. Only surfaces free of subsurface damage can be expected to provide good films. The small etch figures are due to dislocations, present in this case in Czochralski material (dislocation density of 2×10^5 cm^{-2}). The slices were first scrubbed to remove mechanical polishing compound residues; then a cleaning procedure similar to that described by Union Carbide (17) was followed. After the last rinsing step in water up to 18M Ωcm at 25°C, the slices were spin dried under hot filtered nitrogen of high purity (H_2O, $O_2 < 1$ ppm). This was always done immediately before deposition; because storage produced statically held particles on the substrate sur-

face, and this resulted in a deterioration of the film quality.

Reactor system and deposition.—The deposition was performed in a water-cooled reaction cell with rectangular cross section (80 × 35 mm) as previously described (15). The rf heated graphite susceptor[3] was coated with silicon (thickness about 20 μm) prior to film deposition on sapphire. The susceptor was tilted about 1.7° in the direction of the gas inlet and could be loaded with four 2 in. diam substrates. A timer was used to switch the required electromagnetic valves on and off thus enabling reproducible runs and results.

[3] Schunk and Ebe Company, Giessen, Germany (quality term FP 499).

The gas velocity in the reactor was about 100 cm/sec. The temperatures were measured by means of an optical pyrometer operating in the wavelength range around 0.65 μm. All temperatures given in this paper are uncorrected pyrometric temperatures. The lowest investigated temperature (880°C) corresponds to an actual temperature of 914°C, the highest investigated temperature (980°C) corresponds to a true temperature of 1020°C. The emissivity correction was taken from Allen's work (18).

Electronic grade silane (3% in hydrogen)[4] was used for the experiments. Hydrogen from the main gas line was purified by a hydrogen purifier.[5] The oxygen and water content in all gases, including hydrogen and nitrogen (for purging), were less than 1 ppm, controlled by a Shaw hygrometer[6] and an oxygen monitor.[7]

Substrate heating in hydrogen at 980°C for 10 min was followed by the film growth in the region from 880° to 980°C at a growth rate of 0.2-6.0 μm/min. The final thickness of the films was in all cases 0.8 μm.

Quality evaluation.—The quality of the silicon films was investigated by visual inspection, light microscopy, and optical absorption measurements.

For visual inspection a focused grazing light beam in an otherwise dark area was used. By this method major imperfections could easily be observed.

The investigation using the light microscope was made in the Nomarski interference contrast mode. In this way smaller particles (*e.g.*, polycrystalline crystals) could be detected.

The optical absorption measurements, described elsewhere in the literature (19), result in the absorption factor F_A describing the spectral dependence of the absorption constant α. F_A is defined as a product of the slope of the absorption edge and the absorption constant at a definite wave number: $F_A = (\alpha_{22} - \alpha_{16}) \cdot \alpha_{17} \cdot 10^6$ cm^{-2} (the subscripts denote the wave number in 10^6 cm^{-2}).

The absorption factor F_A agrees well with other methods, *e.g.*, electron diffraction and ion backscattering measurements. In addition, F_A is in good correlation with transistor parameters, as for example the channel mobility (20, 21). Therefore, F_A was used in this present work as a tool to define the epitaxial film quality. The closer the value for F_A approaches the value for single crystal silicon ($F_A = 90 \cdot 10^6$ cm^{-2}) the better the quality of the film. According to earlier investigation, F_A values of $140 \cdot 10^6$ cm^{-2} or less are acceptable for silicon on $(\bar{1}012)$ sapphire (16).

Results and Discussion

If the F_A values for the different growth rates r_g are plotted against the growth temperature T_g, curves as shown in Fig. 2 are obtained, their curvatures being rather similar. (The different signs in Fig. 2 are the average values of all F_A measurements made for a distinct growth rate or growth temperature, respectively. The vertical bars indicate the range in which all corresponding values were obtained. In the following considerations concerning the F_A curves these bars are included.) The curve for the lowest growth rate region (0.2-0.5 μm/min), investigated in this series, will be taken as an example: between 920° and 940°C a rather flat minimum of the curve with $F_A = 125\text{-}130 \times 10^6$ cm^{-2} exists. The F_A values increase both with decreasing and with increasing growth temperatures but remain smaller than $140 \cdot 10^6$ cm^{-2} between about 915° and 965°C, indicating an epitaxial film quality. The very obvious rise at the lower temperature region ($T_g <$ 900°C) indicates poor film quality due to an increasing fraction of polycrystalline silicon. According to Fig. 2, at growth temperatures above 950°C the rise of

the F_A values is only small. At higher growth temperatures than 980°C, which were not investigated in this present series, the rise of F_A is much more obvious. This is demonstrated by Fig. 3 which is taken from an earlier investigation series for a growth rate of 2.5 μm/min (16). The F_A value rises remarkably with higher temperatures, indicating the increasing influence of the above-mentioned etching reactions (1, 2). The curves represent the epitaxial quality of silicon films on chemically-mechanically polished sapphire: *a* is for results up to 1974, *b* shows the results in 1976. The better results in 1976 are due to the improved quality of the gases and an improvement in the polishing art. (The polishing of the slices from Fig. 3 was done exclusively in our laboratories, using colloidal silica.[8]

In addition to the growth rate range 0.2-0.5 μm/min as discussed above, in Fig. 2 further growth rate ranges are shown, *e.g.*, 1.25-1.5 μm/min, 2.25-3.25 μm/min, and 5.3-6.0 μm/min. As already mentioned, the F_A curves for these different growth rate ranges are similar. It can be seen, especially in the very low temperature range (880°-920°C): the higher the growth rate, the more the corresponding curve for the F_A values is shifted to a higher growth temperature range. With the exception of the lowest rate, this applies also to the flat minima of the F_A curves. These minima lie between 920° and 940°C for 1.25-1.5 μm/min, between 930° and 955°C for 2.25-3.25 μm/min, and between 950° and 970°C for 5.3-6.0 μm/min. It is obvious that the higher the deposition rate, the higher the deposition temperature must be for the production of a good epitaxial film and vice versa. It further can be seen that for the 0.2-0.5 μm/min range the slope of the curve is not as steep as for the other growth rate ranges, indicating that in this growth rate range the deposition conditions of epitaxial silicon are not so critical as for higher growth rates. On the other hand, the F_A minimum values for the lowest growth rate range are at a slightly higher level ($F_A = 125\text{-}130 \cdot 10^6$ cm^{-2}) than for all other investigated rates ($F_A = 115\text{-}120 \cdot 10^6$ cm^{-2}). This may be due to the slower coverage of the sapphire surface with silicon at the lower growth rates, thus allowing slightly increased etching reactions ([1] and [2]) and therefore a slight deterioration of the film. Nevertheless even with the lowest growth rates epitaxial films with $F_A < 140 \cdot 10^6$ cm^{-2} can be obtained.

If the curves of Fig. 2 are considered in direction to higher growth temperatures, a slight increase for all curves can be seen. The curves for the growth rate ranges 0.2-0.5 μm/min and 1.25-1.5 μm/min exceed the F_A value of $140 \cdot 10^6$ cm^{-2} at approximately 965°-970°C. The curve for the highest investigated growth rate range 5.3-6.0 μm/min exceeds this F_A value at about 985°C. Only the curve for the growth rate range 2.25-3.25 μm/min reaches the F_A value of $140 \cdot 10^6$ cm^{-2} at a higher temperature (approximately at 995°C), this being the most independent growth rate range concerning the choice of the deposition parameters. Growth rates smaller than 2.25-3.25 μm/min may be slightly too low so that the above-mentioned etching reactions ([1] and [2]) play an increasing role with rising temperature. The marked increase of the curve for the high growth rate range 5.3-6.0 μm/min could be attributed to the fact that nucleation in the gas phase with SiH_4 may occur resulting in the deterioration of the films, too.

As mentioned above, for every investigated growth rate range a certain corresponding growth temperature range exists, in which the F_A values are smaller than $140 \cdot 10^6$ cm^{-2}. If these "epitaxial temperature ranges" and the corresponding growth rate ranges are plotted against each other, an epitaxial deposition region is obtained concerning T_g and r_g, respectively. This epitaxial region is shown in Fig. 4 as the hatched area. Here again it can be seen, that for the growth rate range 2.25-3.25 μm/min a very large deposition temperature range can be chosen (930°-995°C) without deteriorating the film quality remarkably. Within the hatched area of Fig. 4 a crosshatched additional region is shown. The horizontal bars in this region represent the deposition temperature ranges, in which the flat minima of the F_A curves for the different growth rate ranges were obtained (see Fig. 2). From the crosshatched region in Fig. 4 the optimum deposition parameters for different growth temperatures and different growth rates can be determined. The "optimum epitaxial region" can be extended to even higher growth rates. This was verified experimentally by growing films at the very high growth rate of 7.5 μm/min. A growth temperature of 975°C was chosen simply by extrapolation from the optimum deposition conditions for the lower growth rate ranges (*i.e.*, 2.25-3.25 μm/min and 5.3-6.0 μm/min). The corresponding F_A values were found to be about $120 \cdot 10^6$ cm^{-2}, which

[8] Besides the above-mentioned Syton of Monsanto Chemical Corporation, Spectrolite and Mirrolux of Materials Development Corporation, Santa Monica, California were used in these earlier experiments.

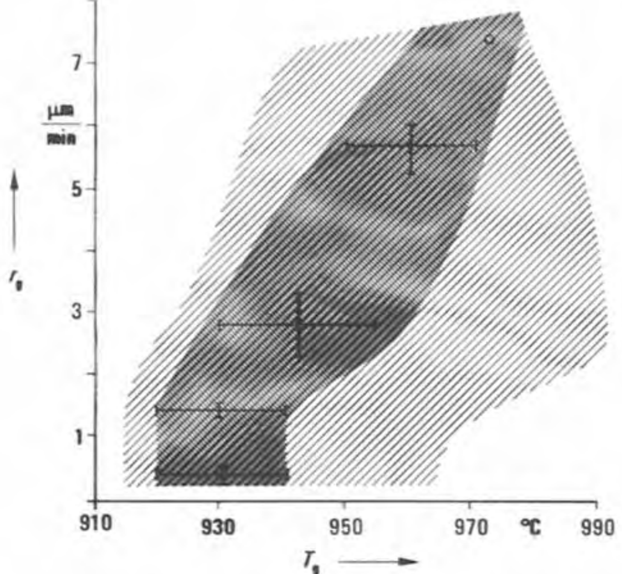

Fig. 4. Growth rate r_g as function of the growth temperature T_g for epitaxial silicon films on ($\bar{1}$012) sapphire with $F_A \leq 140 \cdot 10^6$ cm^{-2} (hatched area). The crosshatched region indicates the optimum deposition conditions ($F_A = 125$-$130 \cdot 10^6$ cm^{-2} for the 0.2-0.5 μm/min growth rate range and $F_A = 115$-$120 \cdot 10^6$ cm^{-2} for all other investigated growth rate ranges). The circle is from an additional experiment with $r_g = 7.5$ μm/min and $T_g = 975$°C (resulting in an F_A value of about $120 \cdot 10^6$ cm^{-2}; see text).

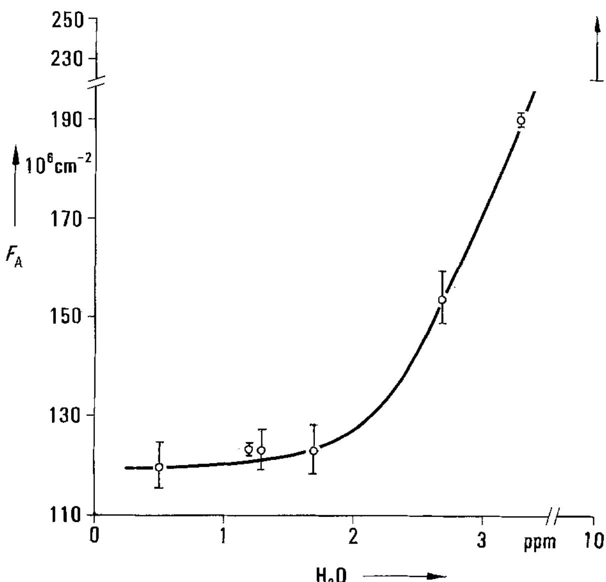

Fig. 5. Absorption factor F_A as a function of H_2O content added to the hydrogen. Deposition temperature 980°C, growth rate 2.5 μm/min.

is in the lower part of the above-mentioned F_A value region (this is not represented in Fig. 2, because only one growth temperature was verified experimentally; in Fig. 4 this additional experiment is included as a circle).

For the growth rate regions 0.2-0.5 μm/min and 1.25-1.5 μm/min the optimum epitaxial deposition range is nearly the same (920°-940°C). This indicates that below this temperature range further optimization was not possible. Growth temperatures of 900°C or less resulted in polycrystalline silicon in our case, indicating that these deposition temperatures are too low for a good arrangement of the silicon atoms in the silicon lattice and, therefore, for growth of an epitaxial film. From the viewpoint of autodoping due to the above-mentioned etching reactions [1] and [2], the growth temperature range $T_g = 920°$-$940°$C is most favorable in our system.

The lowest optimum growth temperature is not a constant based on physical or chemical principles, but depends very substantially on the surface quality of the substrate and consequently on the existing state of the polishing art. It can be assumed today that the art of polishing is rather advanced, because damage-free (including subsurface damage free) substrate surfaces can be produced (16).

The optimum deposition temperature depends additionally on the purity of the gases used, *e.g.*, H_2O or O_2 impurities, the geometry of the reactor cell, and the flow conditions. In Fig. 5 the influence of H_2O impurities on the epitaxial quality of the silicon films (growth temperature 980°C, growth rate 2.5 μm/min), represented again by the absorption factor F_A, is shown. These experiments were done with hydrogen with a known H_2O impurity fraction. (This hydrogen was taken from different cylinders without use of the gas purifier; the H_2O impurity fractions were measured before deposition with the Shaw hygrometer.) It can be seen that as the H_2O impurity level increases the quality of the films drops drastically. The rise in F_A at higher impurity concentrations may be attributed to the increasing fraction of silicon oxides, which are incorporated into the film. For the production of a good epitaxial film on sapphire the H_2O impurity fraction must be below 2 ppm for a growth temperature of 980°C. Further experiments showed that the H_2O impurity fraction at lower growth temperatures (*e.g.*, 930°C) must be even less (*e.g.*, < 1 ppm). Similar curves are expected, if traces of oxygen are introduced into the gas system.

Conclusion

For an optimization of the deposition conditions for epitaxial silicon on sapphire in the SiH_4/H_2 system, the following requisites must be supplied.

In addition to a suitable substrate material, *i.e.*, free of crystal imperfections due to the crystal growth: (*i*) the polishing of the substrate must be excellent (free of damage and subsurface damage) and the cleaning process (for the removal of polishing impurities) must be excellent; (*ii*) the purity of the gases is very important (*e.g.*, H_2O impurity fraction <1 ppm required for low growth temperatures); and (*iii*) during the growth, etching reactions between the sapphire surface and the deposited silicon can deteriorate the crystal film quality. This can be reduced to a minimum if the growth temperature is as low as possible, and if the growth rate is as high as possible, thus decreasing both the amount of and the time for the etching reactions. The growth temperature and the growth rate cannot be chosen independently but must be fitted, because for each growth rate range there exists an optimum deposition temperature range which can be determined with the data presented in this paper. By this method high quality epitaxial films were produced, *e.g.*, with 5.3-6.0 μm/min at 950°-970°C, with 2.25-3.25 μm/min at 930°-955°C, and with 1.25-1.5 μm/min at 920°-940°C.

Warpage of Silicon Wafers

B. Leroy* and C. Plougonven

Compagnie IBM France, 91102 Corbeil-Essonnes, France

ABSTRACT

High temperature processing of Czochralski grown silicon wafers can create temperature gradients high enough to generate slip. The generation of slip and the slip patterns have been found to depend on three factors: the temperature and the temperature gradient, the amount and form of the precipitated oxygen, and the direction of the initial bow and the wafer diameter over thickness ratio. A model is presented to fit experimental data of critical stress in silicon, temperature gradients, and wafer curvature to predict the critical temperature above which warpage will occur. An important result is that increased wafer diameter over thickness ratio makes the wafers more sensitive to warpage. When this is the case the difference in stresses on both sides of the wafer, because of the bending, makes the area affected by slip on the concave side much larger than on the convex side.

High temperature processing of silicon wafers often produces sufficient thermal stresses to generate slip and dislocations (1-3). The stresses arise during temperature transient because in order to enhance productivity the wafers are stacked vertically in diffusion or oxidation boats. When such a boat is inserted or pulled out of a high temperature furnace a temperature gradient arises between the center and edges of the wafers and the resulting stresses can be sufficient to generate dislocations which propagate in (111) type planes and form slip bands (4). The dislocations are generated where the resolved shear stress in a (111) slip plane along a (110) direction exceeds the critical shear stress. Patterns of slip lines can be different depending on temperature, wafer dimensions (thickness and diameter), and amount and form of oxygen precipitation inside the wafer. Generally the slip damage occurs at the periphery for small wafers and temperatures in the 1000°C range whereas larger wafers and lower temperatures (900°C range) result in slip in the center.

The experiments described here relate the critical stress dependence on oxygen precipitation, wafer dimension and shape, and temperature to the resulting slip patterns.

* Electrochemical Society Active Member.

Key words: critical shear stress, oxygen precipitation, plastic deformation, thermal gradient, warpage.

Experimental Procedure and Results

Experimental procedure.—<001> wafers sliced from Czochralski grown crystals have been used throughout the experiments. The wafers were chemically polished on both sides, 400 μm thick, and the diameter was 82.5 mm in most cases, with a few experiments on 57 mm wafers to evaluate the impact of the thickness over diameter ratio on the wafer deformation ability.

The first series of experiments were aimed at determining the pattern of slips observed when varying (*i*) the amount of precipitated oxygen, (*ii*) the cooling environment: open tube or capsule, (*iii*) the temperature of the furnace, and (*iv*) the diameter over thickness ratio.

For these experiments the wafers received an oxygen precipitation heat-treatment at temperatures between 900° and 1100°C for various durations. They were stacked in the vertical position in a boat with 2.5 mm distance between wafers and at least seven dummy wafers at the end to insure the same cooling kinetics of all the test wafers. At the end of the thermal treatment, the boat was quickly hand-pulled (about 1 sec), and as a result of the temperature difference between the edges and the center of the wafers, slips lines could be generated (1, 4). Typical slip distribution around the wafer has been described by Longo (5) and Hu *et al.* (6).

Slip pattern.—The wafers were then observed by x-ray topography using the (220) reflection in most cases. Figure 1 shows the slip pattern thus obtained on 82.5 mm wafers in the case of an open-tube processing, at two different temperatures 970° and 1050°C, and for high oxygen precipitation and no oxygen precipitation. For Czochralski grown crystals the oxygen precipitates along rings which correspond to the frozen-in microdefects formed during the crystal pulling operation. On x-ray topographs, two types of features can be observed: (*i*) dark rings concentric to the wafers which correspond to areas with a high density of oxide precipitates, and (*ii*) sharp lines in the <110> type direction, at the center or at the edge of the wafer which correspond to slip bands.

From the patterns of dislocations observed on Fig. 1 it can be stated that in the case of cooling from 1050°C slip occurs at the edge only when there is little oxide precipitation and slip occurs at the edge and in the center when the precipitation of oxygen is high, and in the case of cooling from 970°C slip has occurred only in the center of the wafers with a high oxygen precipitation.

Figure 2 shows the results of a similar experiment carried out with 57 mm wafers. The top row of topographs corresponds to wafers in a capsule quickly pulled out of a furnace at 1100°C. It shows that slip occurs only at the edge of the wafers even in the case of high oxygen precipitation. The bottom row shows topographs of wafers quickly pulled out of a furnace at 1050°C in an open tube. Here slip has occurred both at the edge and in the center, for the case of high oxygen precipitation as well as low oxygen precipitation. The same pattern was found on 82.5 mm wafers pulled out of the furnace at 1050°C in an open tube.

However, x-ray topographs show a picture of slip through the wafer. To look at the slip pattern emerging at the surface, wafers were Jenkins-Wright etched for 20 mn. Figure 3 shows a typical result on a 82.5 mm wafer: the center slip portion is much more extended on the concave side than on the convex side. To understand this interesting observation, high resolution x-ray topographs were performed on a wafer with little slip in the center. Figure 4 shows prismatic loops of dislocations generated around a center defect, which is assumed to be an oxide precipitate as such loops exist only in the dark rings corresponding to oxygen precipitation. This is similar to Matsui's observations (7). The wafer was then etched from the concave side and the same x-ray topograph was taken again (Fig. 4b). The size of the loops has decreased indicating that the loops extended toward the concave side, in (111) family planes. The emergence of such loops on the concave side forms the slip pattern visible after the Jenkins-Wright etch. The loops generated in the bulk extend to the concave side because it is the most compressed region, and it is where stresses have to be relieved first. This will be demonstrated later following the model of Dyer *et al.* (8). From contrast extinction analysis of x-ray topographs of such loops using (220), ($\bar{2}$20), (111), (1$\bar{1}$1), (11$\bar{1}$), ($\bar{1}$11), (400), and (040) reflections the Burgers vector associated with the dislocation loops is always <101> or <011> type and never <110> type. Slip associated with these loops in the center of the wafer will therefore be accompanied by a movement perpendicular to the surface, and the bow of the wafer is increased. This is generally called warpage (9, 10).

To summarize these observations, slip patterns are at the wafer edge only for capsule cooling and in case of little oxygen precipitation, and at the center of the wafer only for larger diameter wafers and with some oxygen precipitation. When plastic deformation occurs in the center of the wafer, the initial bow is increased. As the result of this plastic bending, slip lines will concentrate on the concave side, as is fully developed in the Discussion section.

Experimental determination of a critical temperature.—We define a critical temperature as the temperature above which the quick withdrawal of a boat of wafers will result in formation of slip. This critical temperature T_c is a function of: (*i*) the wafer loading geometry which imposes the temperature gradient and therefore the stress distribution on a wafer, (*ii*) the critical stress of silicon which is a function of oxygen precipitation, and (*iii*) the shape of the wafer at the furnace temperature, *i.e.*, the initial bow (9).

The experiments aimed at the determination of T_c were carried out on 82.5 mm diam wafers in the temperature range 800°-1000°C such as to be in the case of center slip, *i.e.*, where the presence or absence of

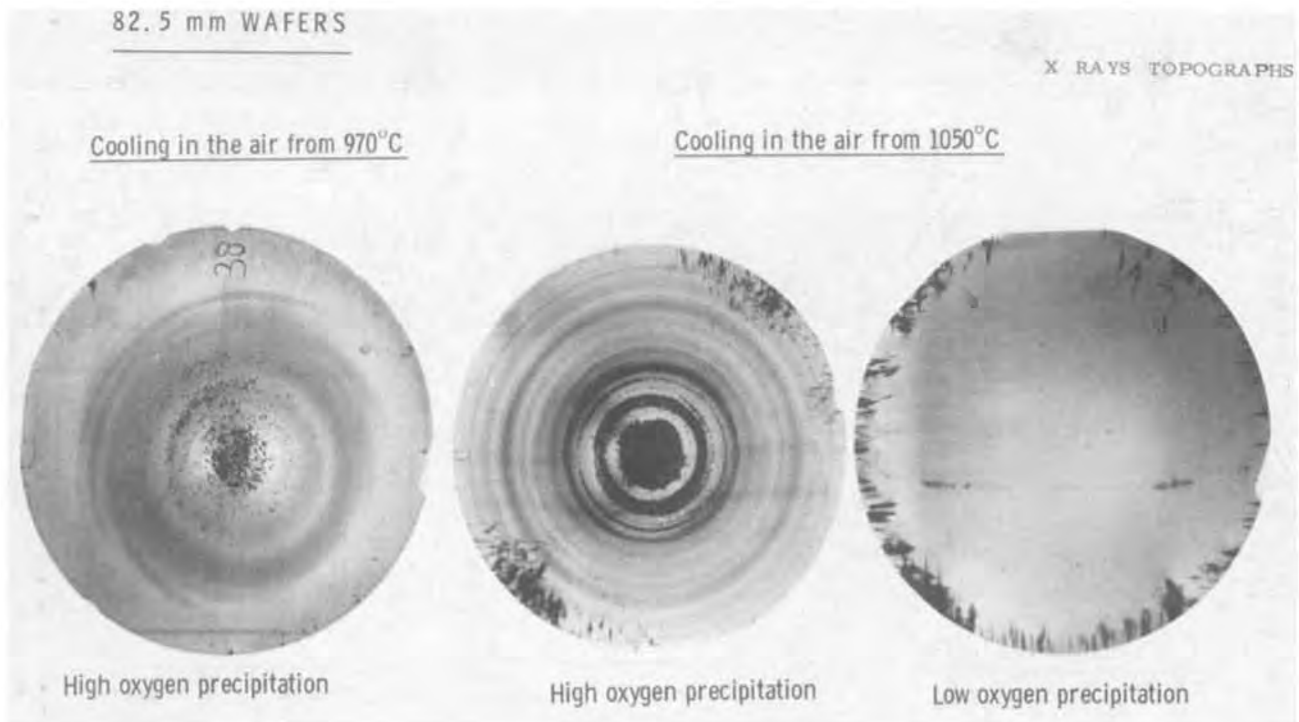

Fig. 1. X-ray topographs of 82.5 mm diam wafers after a thermal treatment which induced an oxygen precipitation

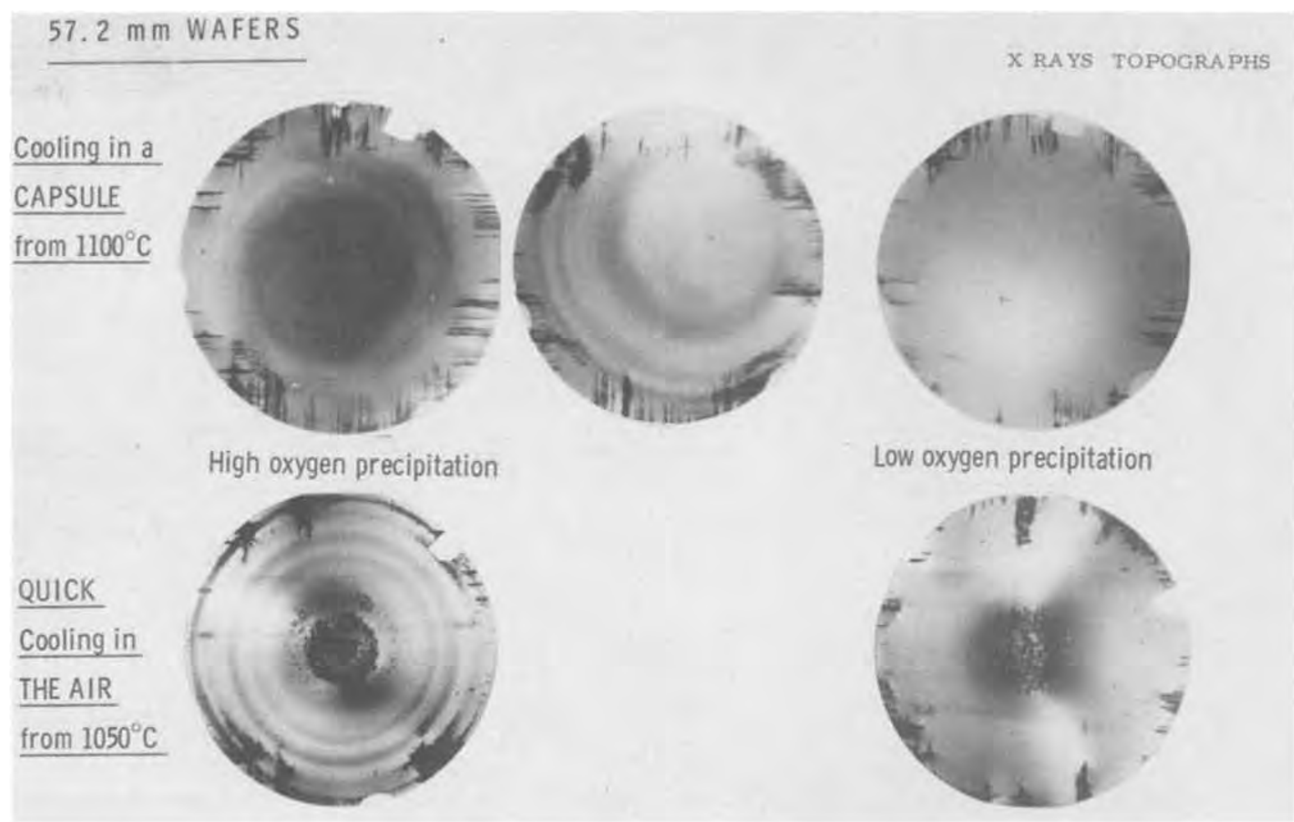

Fig. 2. X-ray topographs of 57 mm diam wafers after a thermal treatment which induced an oxygen precipitation

slip can simply be determined by a measurement of the bow increase before and after each heat-treatment. The wafer loading geometry was kept constant throughout the experiment with the following loading scheme: 2.5 mm spacing between wafers and at least seven dummy wafers on each end of the batch of experimental wafers.

The design of the boat was such that its heat mass was very small, which insures a nearly concentric temperature distribution during cooling.

The amount of precipitated oxygen was determined as the difference between the concentration of interstitial oxygen before and after a precipitation heat-treatment. This amount of precipitated oxygen was varied by choosing wafers with different initial oxygen content and by varying the precipitation heat-treatment or sequence of heat-treatment. The interstitial oxygen content was measured from infrared absorption peak at 9 μm using Patrick's (11) relationship $[O] = 2.8 \cdot 10^{17} x$, where x is the absorption coefficient in centimeters. The range of oxygen concentration was found to be $5 \cdot 10^{17} < [O] < 13 \cdot 10^{17}$ at./cm^3. Th actual wafer measurements were corrected using a calibration curve to account for the thin slice instead of the thick slugs measurements.

Finally in order to vary the initial bow of the wafers a layer of 1000 or 1600Å of silicon nitride was deposited on one side of some wafers. The nitride layer induces a tensile stress which bends the substrate (12). The bow of the wafers was measured by a standard Solex pressure gauge instrument. The extra deformation induced by the 1000 and 1600Å thick nitride film is, respectively, 16 and 25 μm at room temperature and is expected to be 30 and 50 μm, respectively, at 1000°C (12).

Table I summarizes the precipitation heat-treatments and the nitride deposition treatments.

The warpage experiments were carried out by quickly withdrawing the boat of wafers from an idling temperature T. In the case of wafers from groups A and B (Fig. 5) the furnace temperature was slowly lowered from the precipitation temperature (1000°C) to 900° or 950°C or it was left at 1000°C, and the boat was quickly hand-pulled out of the furnace (in about 2 sec). In the case of groups C or D wafers (Fig. 6) the wafers were reinserted in a furnace at a temperature $T_0 = 780°C$ after the precipitation heat-treatments and, after about 30 min to allow for temperature equilibrium, the wafers were quickly hand-pulled. The bow of every wafer was then remeasured and the

Table I. Summary of heat-treatments for each group of wafers

Wafer group	First-heat-treatment	Nitride film	Second heat-treatment	Warpage experiment
A	None	None	1000°C 3 hr Dry oxygen	Withdrawal at 900°, 950°, and 1000°C
B	None	None	1000°C 18 hr Dry oxygen	Withdrawal at 900°, 950°, and 1000°C
C	1000°C 20 hr Dry oxygen	Group C1: None Group C2: 1000A	None	Started at 780°C and incremented by 20°C at each experiment
D	925°C 100 mn Dry oxygen	Group D1: None Group D2: 1000A Group D3: 1600A	1050°C 20 hr Argon atmosphere	Started at 780°C and incremented by 20°C at each experiment

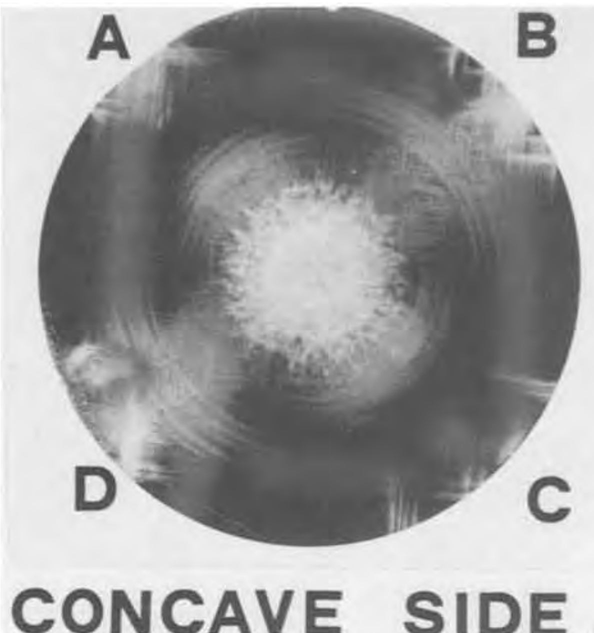

Fig. 3. Slip patterns on both sides of a plasticly warped wafer delineated by Jenkins-Wright etch.

plasticly deformed wafers were sorted out. The same experiment was then rerun at a temperature T_o + 20°C and subsequently by 20°C increments each time until all wafers were plasticly warped (Fig. 6). Therefore for groups A and B wafers, for a given furnace temperature, a critical amount of precipitated oxygen was determined as the boundary above which plastic deformation occurs. The role of different initial oxygen content was only to vary the amount of precipitated oxygen for a given heat-treatment. In the case of groups C and D wafers, a critical temperature was determined for each wafer. In this set of experiments no difference could be found between the groups of wafers with different initial bow and the first-order parameter on which T depends seems to be the oxygen precipitation.

To summarize the results from both groups of experiments a temperature *vs.* amount of oxygen precipitation diagram has been drawn (Fig. 7) showing the domain free of plastic deformation.

Theory

The main factors determining the dislocation pattern are: (*i*) the critical shear stress of the silicon which is a function of the oxygen precipitation, (*ii*) the wafer loading geometry which imposes the temperature gradient and therefore the stress distribution on a wafer, and (*iii*) the shape of the wafer at the furnace temperature, *i.e.*, the initial bow (9).

We will now determine the role of each factor and show how the experimental data illustrate this behavior.

Critical shear stress.—When a boat of closely spaced wafers is pulled out of a furnace, stresses build up across a wafer as a result of the temperature gradient. The stresses are compressive in the center and tensile at the edges. When the temperature gradient is large enough, dislocations are generated in the areas where the shear stresses exceed the critical shear stress τ_c in the (111) family plane in a [101] direction. Then the dislocations can glide from their source under the thermal stresses.

Experimental values of the yield point of silicon, *i.e.*, the critical stress σ_c, has been reported by Patel *et al.* (13, 14) as a function of oxygen precipitation, dislocation density, temperature, and strain rate. Figure 8 shows his data converted into resolved shear stress in a (111) glide plane by the relationship $\tau_c = \frac{1}{2} \sigma_c$ taking into account his crystal orientation. From Patel's tensile experiments it was established that a maximum applied stress τ_m had to be reached before plastic deformation could occur. Once τ_m has been reached, plastic deformation will continue under a smaller applied stress τ_f. τ_m decreases with increasing temperature, dislocation densities, precipitated oxygen, and with slower strain rates.

In order to take his critical stress measurements as the basis for our quantitative model to understand and predict occurrence of slip on silicon wafers, it must be verified that the conditions are the same. Patel's measurements were carried out at 800°C for the oxygen dependence and between 700° and 1000°C for the temperature dependence, compared with 800°-1000°C furnace temperatures in our warpage experiments. The oxygen precipitation heat-treatments were conducted at 1000°C both in Patel's experiments and for most of our wafers. The last parameter to be compared is the strain rate.

Patel's measurements of τ_m as a function of the strain rate were made with high strain rates ($\gamma \geqq 2 \cdot 10^{-3}$ mn^{-1}) and for the case of no precipitated oxygen. The strain rates in the case of cooling of a wafer are lower. Therefore, his results must be interpolated somewhere between the τ_m plot corresponding to $\gamma = 2 \cdot 10^{-3}$ mn^{-1} ($5 \cdot 10^{-3}$ cm/mn) and the τ_f plot. This is done on Fig. 8, which shows τ_m as a function of temperature for different strain rates. It will be verified by superimposing this plot on the wafer applied stress during cooling that these values are consistent.

The influence of a $7 \cdot 10^{17}$ at./cm^3 oxygen precipitation is shown by Patel to reduce the critical shear stress by a factor of 5 at 800°C. We suppose that this factor is independent of the temperature and the strain rate. This reduction of the critical resolved shear stress is due to the compressive stress fields around the precipitates (15). As the thermal stresses are compressive in the center of the wafer and tensile at the edge, the critical resolved shear stress may not be reduced by the same amount in these two cases, depending on the precipitate shape (globuli, platelet, etc.) and on the temperature.

As a result high oxygen precipitation favors defects in the center of the wafer because of the effect of the oxygen precipitates and the stress field surrounding them, and the low oxygen precipitation, favors defects at the edge because there is no lowering of τ_c in the center of the wafer due to the lack of oxygen precipitates (Fig. 1 and 2). Based on these remarks we take

Fig. 4. Magnification of x-ray topographs of dislocation loops generated in a region in the center of the wafer where oxygen is precipitated (a) before etching, (b) after etching 80 μm on the concave side. The right-hand side drawing shows a perspective of the loops in their (111) type glide plane.

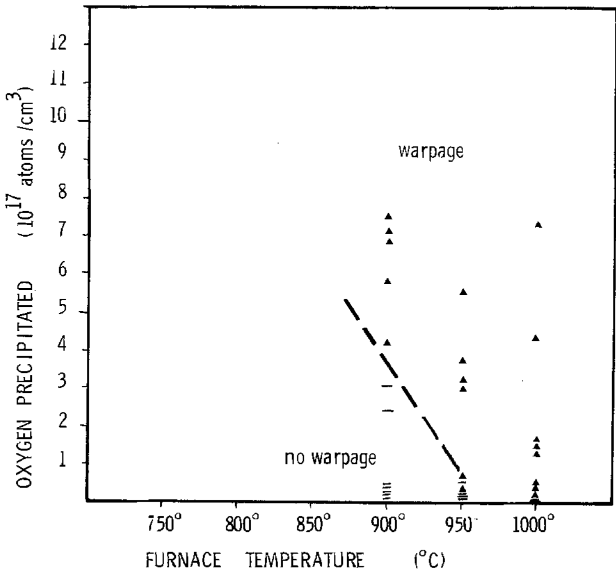

Fig. 5. Warpage of wafers from groups A and B: ▲ warped wafers; —— not warped wafers.

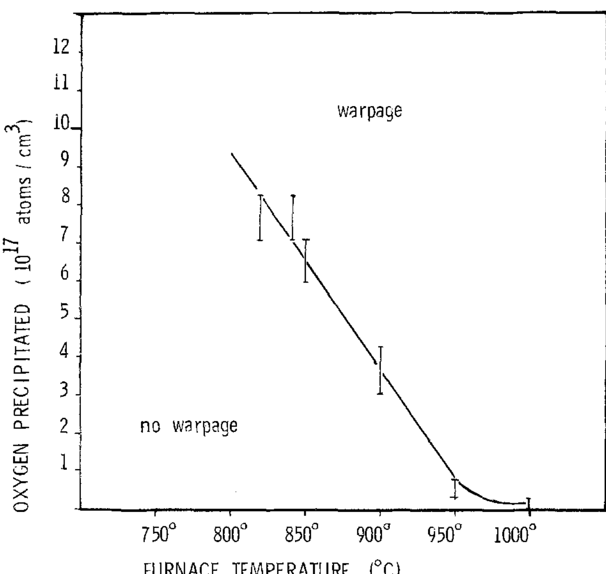

Fig. 7. Critical furnace temperature as a function of oxygen precipitation for generation of warpage. Solid line: curve calculated in text, section on Complete calculation.

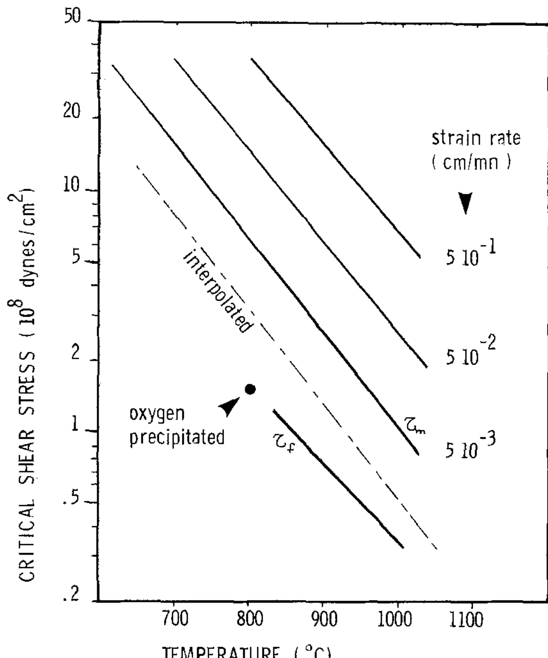

Fig. 8. Critical shear stress from Patel's data (13, 14) and interpolated values.

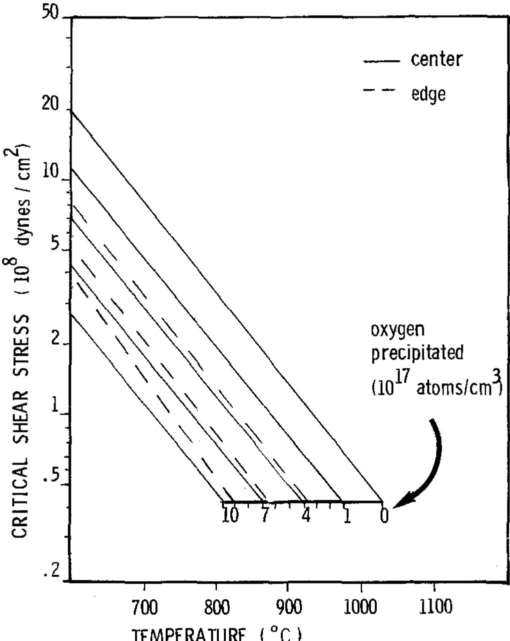

Fig. 9. Critical shear stress at the center (———) and at the edge (— —) of the wafer as a function of the temperature and the oxygen precipitated.

Patel's measurements as corresponding to τ_{ce}, *i.e.*, τ_c at the edge of the wafer, and so we have from Patel τ_{ce} for the case of no oxygen precipitation and for $7 \cdot 10^{17}$ at./cm^3 of oxygen precipitated.

In the center τ_{cc} is the same as τ_{ce} when there is no oxygen precipitation and a little smaller for high oxygen precipitation. To be consistent with the experimental data of Fig. 7, we suppose that the τ_{cc} varies linearly with the amount of oxygen precipitated when it is larger than 10^{17} at./cm^3. The resulting network of τ_{cc} *vs.* T is shown in Fig. 9. Now, to explain the results in capsule, *i.e.*, lower temperature gradient, higher temperature, and no center slip, we must suppose that the difference $\tau_{ce} - \tau_{cc}$ decreases when the temperature increases. Such values of τ_{ce} are illustrated in Fig. 9.

Temperature distribution during nonuniform cooling.—Morizane and Gleim (1) reported temperature gradients between the center and edge of a row of seven wafers, when inserted in or pulled out of a furnace, but their measurement was influenced by the large heat mass of the boat, which was not the case in our experiments. More recent measurements by Hearn *et al.* (16) on 57 mm diam wafers reported a ΔT of 170° during cooling from 1000°C and of 120° during cooling from 800°C. During heating to 1000°C ΔT was only 120°C. We will assume ΔT values close to Hearn's measurements. Other measurements by Kasper and Clauss (17) in the case of a 1200°C furnace show a ΔT of 150°C for heating and 300°C for cooling. The main difference between heating and cooling comes from the temperature at which the gradient is maximum: in the case of heating the larger ΔT occurs at a lower temperature than for cooling. As the critical stress increases rapidly with decreasing temperatures, only large ΔT at high temperatures will cause slip. Therefore, the model developed here will be for the case of cooling wafers rather than heating.

Calculations of the temperature distribution across wafers for ideal cooling conditions of a row of closely spaced wafers have been carried out by Hu (4) taking into account the heat losses by radiation and conduction.

Note that in this case, Hu (4) found a temperature distribution nearly independent of the wafer diameter, so we can extend his values as well as Hearn's actual measurements from 57 to 82 mm diam wafers.

Table II shows the maximum temperature gradient across the wafer for several starting temperatures as calculated from Hu's model and as measured in Hearn's experiments. There is good agreement for high temperature (1000°C and higher) but for lower temperatures the calculated ΔT becomes significantly higher than the measured one. The reason for this discrepancy is thought to be that the cooling by radiative process is overestimated at lower temperatures, *i.e.*, below 900°C. In this case heat losses by conduction become predominant and the temperature distribution is parabolic resulting in lower maximum ΔT. In real experimental conditions, two variations from this ideal cooling case exist.

First, open-tube processes are where the boat is withdrawn in a quartz tube outside of the furnace. In this case the proximity of the cooler quartz walls leads to slightly greater heat losses at the wafer edges by convection. Hearn's measurements were carried out in

Table II. Maximum temperature gradient across wafer

T (°C)	T (°K)	ΔT (max) [Hu (4)]	T (max) [Hearn (16)]	τ_{max} [Hu (4)] (10^8 dynes/cm²) Center	Edge	Parabolic app. [Hearn (16)] (10^8 dynes/cm²) Center	Edge
1100	1373	192	195	1.55	5.6		
1000	1273	178	170	1.43	5.2		
900	1173	164	145	1.31	4.8		
800	1073	150	120	1.2	4.4	1.6	3.9
700	973	136	95	1.1	4.0	1.26	3.0

these conditions and therefore his results reflect this effect which is probably negligible at high temperatures ($T > 900°C$) but not at lower temperatures.

Second is the case of a capsule process. When the boat inside the capsule is withdrawn from the furnace, the hot capsule quartz walls irradiate back at the wafers edge and hence reduce the cooling rate of the edges. These conditions are similar to the closed boat approach of Hearn where he measured a temperature difference of 65°C between the center and the edge of a wafer cooled from 900°C. It is, however, likely that the maximum ΔT is reached quickly in the case of the open tube and later when there is a compensation between the radiation of the quartz walls and the wafers.

Figure 10 shows the temperature drop calculated from Hu's model and for our experimental conditions. The capsule cooling temperature plot is adjusted to fit Hearn's measured ΔT.

Stresses distribution.—Timoshenko *et al.* (18) calculated the radial distribution of stresses induced by the thermal gradient, when the bending moment of the wafer can be neglected (flat wafer).

The ratio of the thermal stresses to the maximum of shear stress was taken from Hu (4) to be 2 at the edge and $\sqrt{6}$ in the center.

So by assuming the temperature distribution across the wafer discussed previously, the maximum shear stress can be calculated in the center of the wafer and at the edge as a function of the center and the edge temperature, respectively. Figure 11 shows such plots for different starting temperatures: 800°, 900°, 1000°, and 1100°C. τ_m has been plotted as a function of the temperature T instead of time in order to later compare τ_m with τ_c which also varies with temperature but not with time.

In order to determine when plastic deformation will start τ_m must be compared to τ_c at any given time. τ_m and τ_c vary with temperature and therefore it is convenient to represent on the same figure the plots of τ_m *vs.* T and τ_c *vs.* T. Plastic deformation will occur when the two plots intersect and for a given wafer, *i.e.*, where τ_c is determined, the critical ΔT admissible is determined by making τ_m *vs.* T become tangent to τ_c *vs.* T.

Figures 12 and 13 show, respectively, for air cooling and capsule cooling two cases of τ_m *vs.* T compared to τ_c *vs.* T for different starting temperatures. The stress curves in the open-tube case (Fig. 12) are taken from Fig. 11 and in the capsule case they are derived from the cooling curves of Fig. 10.

Note that the center stress curve has to be compared to τ_{cc}, *i.e.*, τ_c corresponding to the center whereas the edge stress curve must be compared to τ_{ce}, *i.e.*, τ_c corresponding to the edge. Let us consider each case separately.

Open-tube case.—Cooling from high temperature ($T > 1000°C$), the critical shear stress is reached first at the edge. Three types of slip time patterns can therefore result: (a) little oxygen precipitation, *i.e.*, high τ_c; no slip lines will form; (b) moderate oxygen precipitation; slip lines are generated first at the edges of the wafer thereby relieving the thermal stresses and preventing slip in the center, and (c) high oxygen precipitation; slip occurs both at the center (lower τ_c) and at the edge of the wafers. Such patterns are shown on Fig. 1 and 2. Note that the reduction of the cooling rate has the same effect as a reduction of precipitated oxygen. Cooling from lower temperatures: cases (*a*) and (*c*) described above remain the same but case (*b*) leads to slip in the center only due to

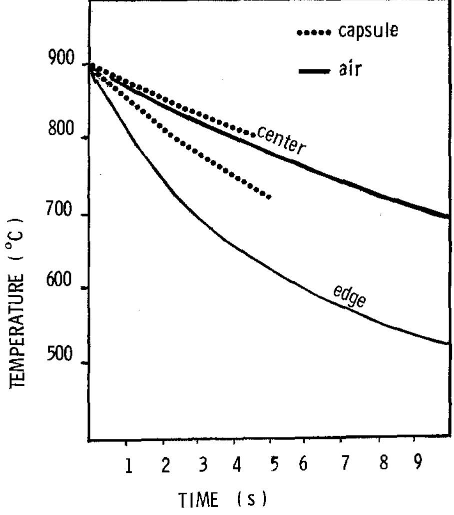

Fig. 10. Cooling kinetics at the center and at the edge of the wafers during cooling in the air (——) and cooling in a capsule (. . . .).

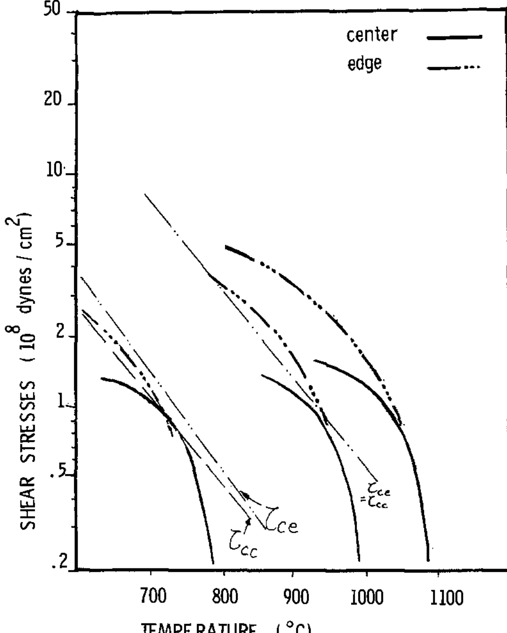

Fig. 12. Plot of the calculated maximum shear stress and the critical shear stress at the center and at the edge of the wafers during cooling in the air from 800°, 1000°, and 1100°C.

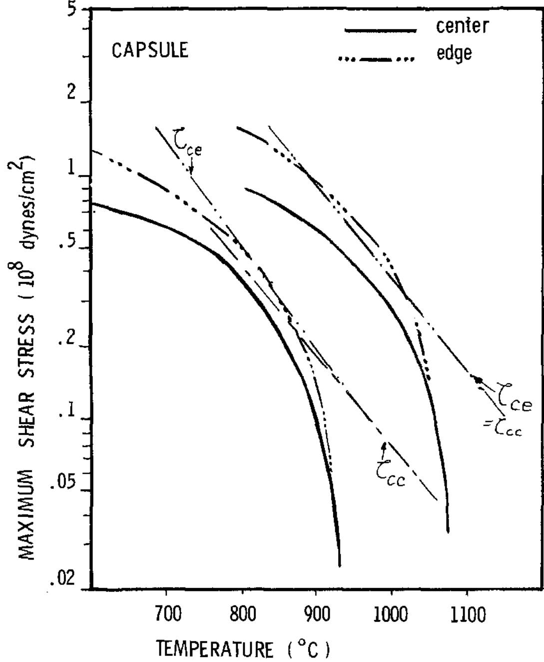

Fig. 13. Plot of the calculated maximum shear stress and the critical shear stress at the center and at the edge of the wafers during cooling in a capsule from 950° and 1100°C.

the smaller critical stress of the edges as discussed previously. When slip occurs in the center the wafers warpage increases.

Cooling in a capsule.—Due to the reduced radial temperature differential in a capsule compared to an open tube, the generation of dislocations in a capsule requires a starting temperature of the order of 100°C greater than the tube case. At this temperature, the critical shear stress is nearly the same at the center and at the edge and is always reached first at the edges (Fig. 13). This is consistent with the slip pattern shown in Fig. 2.

Bending.—The radial temperature distributions, therefore, can be such that peripheral and/or center slip can take place. However, the thin membrane flat disk approach is a good approximation only for flat wafers with a not too large diameter over thickness ratio. For larger wafers two variations from the membrane case must be taken into account: (*a*) the wafer can no longer be accurately approximated as a flat disk. Its equilibrium shape can be described as a circular disk with a finite initial curvature, and (*b*) when the ratio of diameter over thickness increases, as a result the resistance to bending decreases. When such a wafer is submitted to a radial temperature differential ΔT during cooling a hot central portion is trapped within a cold annular zone. The compressive stresses in the center will tend to increase the curvature of the wafer.

The complete stress analysis taking into account the effects of this increased elastic curvature of the wafer has been carried out by Dyer *et al.* (8). The total radial and tangential stresses are composed of membrane stresses plus bending stresses. The effect of the elastic bending due to the compressive stresses in the center of the wafer is to increase the stresses on the concave side and to reduce them on the convex side (8) compared to the membrane case.

Using Dyer's (8) solutions the deflection w and the tangential ($\sigma_{\phi\phi}$) and radial (σ_{rr}) stresses have been calculated as a function of the initial deflection w_o for small ΔT, with the geometrical parameters of the wafers used in our experiment, *i.e.*, a radius $R = 4.12$ cm and a thickness $h = 385$ μm. Figure 14 shows the radial distribution of $\sigma_{\phi\phi}$ and σ_{rr} calculated for $\Delta T = 120°C$ and $w_o = 20$ μm and for the concave side, the convex side, and for the membrane case. It shows that the compressive stress in the center on the con-

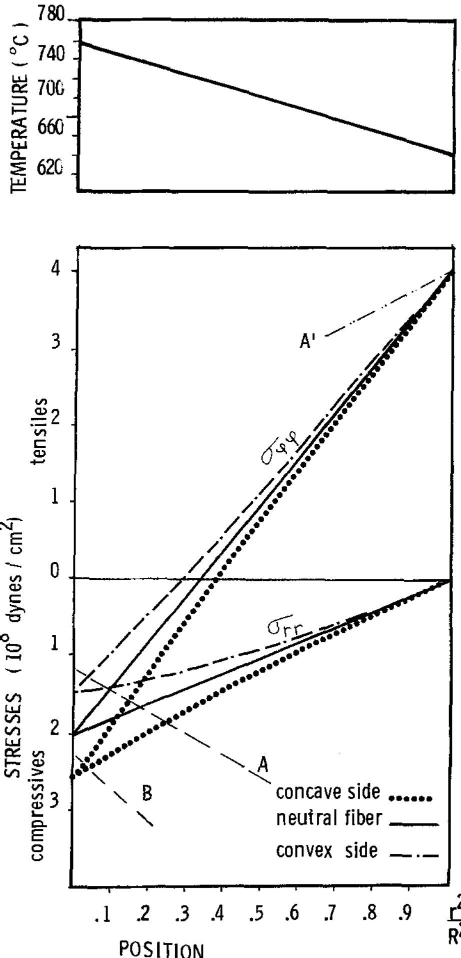

Fig. 14. Distribution of the temperature and of the stresses along a radius of a wafer on the convex and on the concave sides and on the neutral fiber, calculated for an initial bow of 20 μm.

cave side can be increased almost by a factor of 1.5 compared to the convex side whereas at the edge the difference between both sides is negligible. In the center of the wafer the stress on the concave side will always be greater than on the convex side and therefore the dislocation pattern can be expected to be dissymetric. For instance on Fig. 14 we can superimpose a plot of σ_c which is $\sqrt{6}\tau_c$ in the center and $2\tau_c$ at the edge. Also the radial variation of τ_c shown takes into account the temperature distribution assumed for the calculation of the σ's. The AA' τ_c plot corresponds to an oxygen precipitation of 10^{17} at./cm^3. In this case, no slip line will be generated at the edge of the wafer and in the center, the radius of the defective area will be $0.2R$ on the convex side and $0.5R$ on the concave side, *i.e.*, an area 6 times larger, If there is no oxygen precipitation (curve B) dislocations will be generated only on the concave side of the wafer. This result is illustrated by the dislocation pattern of Fig. 3 where the dislocation pattern is larger in the central area on the concave side than on the convex side, and the dislocations are generated in the oxide precipitate rings (see also Fig. 4).

Therefore the stress difference between both sides of the wafer imposed by the elastic bending when the center of the wafer is under compression is also a determining factor to explain the slip patterns. Intuitively the stress enhancement on the concave side compared to the membrane case will depend on the magnitude of the elastic bending which is a function of the temperature differential, the radius, and the thickness of the wafer. From Dyer's equations, this stress enhancement can be calculated as a function of these parameters. If we choose the z axis perpendicular to the wafer surface with its origin in the middle of the wafer thickness, the total stress along the z direction can be written

$$\sigma_{(z)} = \sigma_{(0)} + \Delta\sigma_{(z)}$$

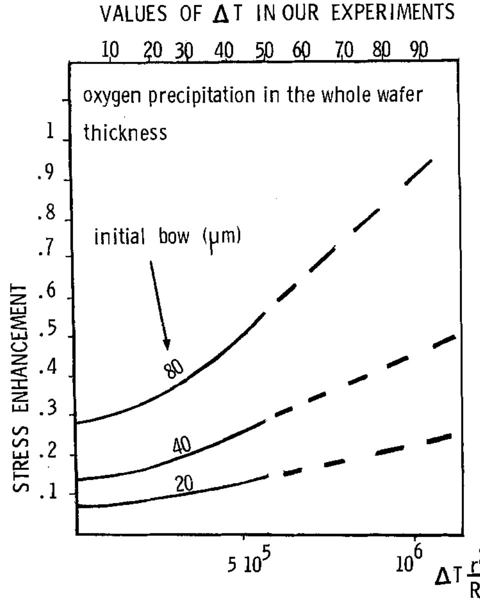
where $\sigma_{(0)}$ is the membrane stress and $\Delta\sigma_{(z)}$ is the stress enhancement due to the bending.

Carrying out the calculations of $\sigma_{(z)}$ and $\Delta\sigma_{(z)}$ from Dyer's solutions shows that these two parameters are a function of z, the radial distance to the center of the wafer r, the initial deflection w_o and a parameter $\Delta T(R^2/h^2)$. It is important to note that σ and $\Delta\sigma$ do not vary with ΔT, R, and h independently but with the product $\Delta T(R^2/h^2)$.

Let us call stress enhancement factor the ratio $Se_{(z)} = \Delta\sigma_{(z)}/\sigma_{(0)}$. The numerical calculations of this factor have been performed as a function of the parameter $\Delta T(R^2/h^2)$ and for different values of w_o and the results are shown in Fig. 15. The development of Dyer is correct if ΔT is not too large (solid line on Fig. 15) and the calculation has been interpolated for larger ΔT values (dashed lines). According to these plots, for our experimental conditions which correspond to $\Delta T(R^2/h^2)$ of the order of $1.3 \cdot 10^6$ one expects to see an impact of the initial deflection on the occurrence of slip for values greater than 40 μm, *i.e.*, a $\Delta\sigma$ due to the bending larger than 20% compared to the case of wafers with initial deflection between 10 and 20 μm. In our experiments the initial deflection was varied by depositing a layer of silicon nitride but the deflection increase thus obtained was probably insufficient to induce a large enough stress enhancement such as to have an effect on the warpage temperature measurement (T_c was measured at $\pm 10°$C). In addition, another factor must be taken into account: the distribution of oxide precipitates in the wafer thickness. The density of precipitates is very high in the middle of the wafer thickness but close to the surface a layer 50-100 μm thick is almost free of precipitates. The result is a higher σ_c close to the surface where the stress enhancement is the largest. The dislocations are generated around oxide precipitates, *i.e.*, at some distance from the surface and therefore only the stress enhancement up to that distance should be considered. The calculation of the stress enhancement factor assuming that the precipitation is uniform only in half of the wafer thickness, *i.e.*, for $-h/4 < z < +h/4$. The stress enhancement at $h/4$ is half its value at $h/2$. In our experiments, ΔT is $\simeq$ 70°-130° when dislocations are emitted, w_c is between 0 and 60 μm and the oxide precipitates are only in the half of the wafer thickness. The stress enhancement is then between 0 and 0.3. When the initial bow varies from 0 to 60 μm, the impact on the critical warpage temperature is the same as an increase of the oxygen precipitation from $3 \cdot 10^{17}$ to $5 \cdot 10^{17}$ at./cm^3. Also one can see that the stress enhancement is larger for larger diameter wafers if we keep ΔT and h constant. This explains why center slip is observed on 57 mm wafers only in cases of very high oxygen precipitation in the center but for smaller oxygen precipitation for the 82.5 mm wafers.

Because of this stress enhancement factor, on Fig. 11, 12, and 13 the stresses on both sides of the wafers should be plotted separately, *i.e.*, higher on the concave side and lower on the convex side at the center of the wafer.

Complete calculation.—Now the experimental plot of Fig. 7 can be calculated from the three factors just described: (*i*) Stresses in the wafers during cooling



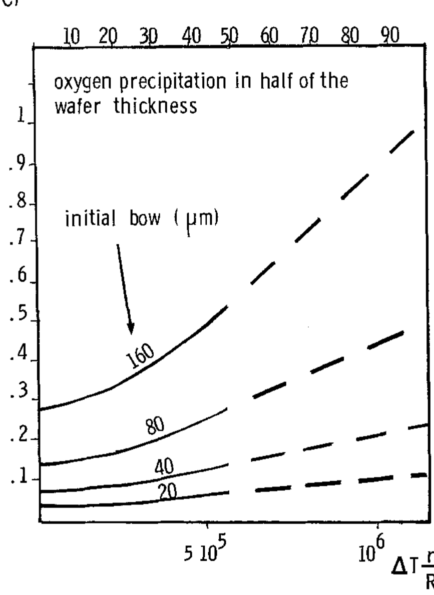


Fig. 15. Stress enhancement in the central area of the wafer, in the part of the thickness where the dislocations are generated.

from different temperatures as shown in Fig. 11 and 12; (*ii*) the relationship between the critical stress, the temperature, and the amount of oxygen precipitated given in Fig. 9; and (*iii*) a stress enhancement at the center of the concave side calculated from Fig. 15 assuming an initial bow between 20 and 30 μm.

Under these conditions the critical temperature is calculated for different amounts of precipitated oxygen and the line joining these points separates two domains: one where the warpage occurs and one without warpage.

This result corresponds to a critical stress obtained in our oxygen precipitation experiments. But for other heat-treatments, where another process of precipitation is involved, σ_c will differ from values of Fig. 9 (19).

Conclusion

Experimental slip patterns have been explained by a model fitting stresses calculated from a temperature distribution across a wafer induced by nonuniform cooling and variations of the critical stress of silicon as a function of the temperature and the amount of precipitated oxygen. The effect of bending explains that for larger diameter over thickness ratio, wafers become more sensitive to warpage, and also that warped wafers show a much larger area affected by slip on the concave side than on the convex side. The model also predicts the critical temperature above which warpage will occur as a function of amount of oxygen precipitated.

Thermodynamic Properties and Subphases of Wustite Field Determined by Means of Thermogravimetric Method in the Temperature Range of 1100°-1300°C

Eiji Takayama and Noboru Kimizuka

National Institute for Researches in Inorganic Materials, Sakuramura, Niiharigun, Ibaraki, Japan 305

ABSTRACT

The composition of the wustite phase field under various oxygen fugacities was determined in great detail by means of the thermogravimetric method in the temperature range of 1100°-1300°C. There is a breaking point, which means a second or possibly higher order transition in the wustite phase, in every isothermal line of oxygen fugacity *vs.* composition of wustite. The phase diagram containing the subphase boundary was obtained. Some thermodynamic functions were also determined and compared with the previously published data.

Darken and Gurry (1, 2) established the equilibrium phase diagram of the Fe-O system in detail at higher temperatures by using controlled oxygen fugacities, and they determined the important thermodynamic values. Since their work, thermogravimetry and the solid-state galvanic cell method have been intensively applied to the study of wustite in order to determine the thermodynamic properties more precisely (the references are listed in the review of Giddings and Gordon (3) and Spencer and Kubaschewsky (4), for instance).

Key words: solids, thermodynamics, stoichiometry, phase transitions.

Vallet and Raccah (5, 6) and Kleman (7) suggested that there are three subphases in the wustite phase field on the basis of thermogravimetry. Their sugges-

tion was supported by Fender and Riley (8) and Carel and Gavarri (9) on the basis of emf measurements, x-ray study, and dilatometry. However, Giddings and Gordon (3, 10) and Hayakawa *et al.* (11) asserted that no positive evidence indicating such subphases could be observed in the available data published so far and concluded that the experimental errors in the data of Vallet and Raccah or Fender and Riley were too large to suggest the existence of subphases.

On the other hand, defect structure analyses of quenched samples of the wustite phase have been made by means of x-ray, neutron, and electron diffraction and they suggest that defect ordering in the wustite phase may be complex (the references are listed in the review of Gavarri *et al.* (12), for instance). But there are gaps and discrepancies among the available data and none support clearly the presence of subphases. These discrepancies may be owing to the fact that perfect quenching of the wustite phase is very difficult because the atoms in wustite, having large amounts of defects, can move too rapidly to be quenched in the process of normal rapid cooling.

A few studies of high temperature x-ray and neutron diffraction of the wustite phase have also been reported (13-15). In these studies, Cheetham *et al.* (13) support the presence of subphases. On the other hand, Hayakawa *et al.* (14, 15) found no evidence for it.

The objective of our present study is to test whether the subphases are present or not. For this purpose, we determined the detailed relationships between equilibrium oxygen fugacity and composition of the wustite phase on the basis of thermogravimetry in the temperature range of 1100°-1300°C. We also determined the thermodynamic functions, relative partial entropies and enthalpies of oxygen, and partial molar free energies, entropies, and enthalpies of formation of the wustite phase.

Experimental

Apparatus.—The experimental apparatus used in this work was made up mainly of three parts; (*i*) a platinum (40% rhodium alloyed) wire wound tubular-type furnace in which a galvanic cell of a stabilized ZrO_2 tube was set up to determine directly the oxygen fugacity around a sample; (*ii*) a gas mixer designed to continuously supply a mixture of hydrogen and carbon dioxide gas in a definite constant proportion; and (*iii*) Mettler H54AR-type balance for measuring the weight of a sample.

The furnace had three independently controllable heating zones and had a central region of about 8 cm in length, where the temperature was distributed within ±0.5°C. In this region, the temperature distribution in the radial direction was also flat in the inner reaction tube, more than 5 mm away from the tube wall. The temperature of the furnace was controlled to be maintained within ±0.5°C at any point for extended periods with a temperature controller (Eurotherm Company Limited, Type 090) and was measured with a Pt-Pt-13%Rh thermocouple which was regularly calibrated at the gold point.

Two kinds of calcia-stabilized zirconia tubes were employed for the galvanic cell (Zr-23 of Degussa Company and Zr-11 of Nippon Kagaku Togyo Company) and the value of the emf did not depend on the kind of tube. Before composing a cell, every tube was evacuated to check for gas tightness. The construction of the galvanic cell was as follows

$$\mathrm{Pt}/(\mathrm{CO_2} + \mathrm{H_2})/\mathrm{ZrO_2(CaO)}/\mathrm{O_2}(1\ \mathrm{atm})/\mathrm{Pt}$$

No paste was used for fixing Pt wire to the tube. Oxygen fugacity of the mixture of CO_2-H_2 in the furnace was evaluated from the emf according to the Nernst equation

$$\mathrm{emf} = RT/4\mathbf{F} \ln[P_{O_2}(1\ \mathrm{atm}\ O_2)/P_{O_2}(CO_2 + H_2)]$$

where R, T, and $\mathbf{F}$ are the gas constant, absolute temperature, and the Faraday constant, respectively, and $P_{O_2}(CO_2 + H_2)$ and $P_{O_2}(1\ \mathrm{atm}\ O_2)$ are oxygen fugacities in both electrodes. The transference number of oxygen ion(II) in the solid electrolyte was reasonably assumed to be unity in the present experimental conditions (16). A potentiometer (Yokogawa Company, Type 2722) was employed for emf measurement.

The gas mixer was similar to that described by Johnston and Walker (17) and Darken and Gurry (1). Two capillaries for CO_2 and H_2 were both calibrated at 0°C in the water-ice system and were maintained all through the experiment at the same temperature in order to avoid any fluctuation of mixing ratio caused by variation of the room temperature.

The oxygen fugacity calculated from thermochemical data for the gases (18) was compared with the one determined by the galvanic cell described above, and the two values were in agreement with each other within ±0.02 (about ±0.2%) above 1100°C and ±0.03 (about ±0.25%) at 1100°C in terms of long P_{O_2} over the whole range of the mixing ratio.

Between the furnace and the balance, there were a marble plate (about 40 mm in thickness) and a water-cooled brass plate in order to shield the heat from the furnace and inhibit convection of air which caused experimental error in weight measurement.

Materials.—High purity grade of Fe_2O_3 powder (99.9%, Kojundo Kagaku Kenkyusho Company) was employed for all starting materials. In addition, Specpure grade of Fe_2O_3 powder (Johnson Matthey Chemicals Limited, detected impurity Mg: 1 ppm) was employed at 1200° and 1300°C. The results obtained from these two materials, however, were in agreement with each other within experimental error.

Commercial high purity grade of hydrogen and carbon dioxide gas (99.99%) which had been purified by passing it over a copper-containing catalyst at 180°C were employed to control the oxygen fugacity in the furnace. Both gases were mixed to the desired ratios by using the gas mixer. After drying over phosphorus pentoxide powder, the mixture was supplied to the furnace.

Procedure.—About 6g of Fe_2O_3 were sintered around a high purity grade thin alumina rod (30 mm in length, 2 mm in diameter, Degussa Company) in a Pt crucible at 1200°C in air. Instead of using a crucible, every sample was suspended in the furnace together with the galvanic cell and the thermocouple so that they might be situated in the even temperature region as close as possible but not in contact with each other, as illustrated in Fig. 1. Since the contact area of iron oxide and the alumina rod was very small, the chemical reaction between two materials could be ignored. Actually, no detectable change was observed in the weight of the alumina rod measured before and after the experimental run. The sample weight was measured immediately after the gas flow in the furnace was stopped, before the oxygen fugacity in the furnace was affected by the effect of thermal diffusion (1).

The experiment was performed in the temperature range of 1100°-1300°C. Since vaporization of the sample could not be ignored at these higher temperatures, correction for the vaporization was indispensable for determining the composition of the wustite phase. For this correction, the weight of the sample under a fixed atmosphere (we selected the CO_2/H_2 mixing ratio of 2.0 at every temperature) was measured every 100 min in the course of each run. Total weight loss by vaporization went up to about 0.12% of the sample weight, at 1250°C for instance. An approximately linear relationship between the weight of the sample at $CO_2/H_2 = 2.0$ and the time was obtained as shown in Fig. 2. From this experimental relationship, we could correct the composition of the

wustite phase for vaporization by recording the time at which the weight of the sample was measured. The correction for the buoyancy with the mixed gas in the furnace was also performed but was not so large.

At 1200°C, the experiment was performed three times (twice with 99.9% starting material and once with Specpure material) and the standard deviation was less than 0.0006 for every x value in FeO_x.

Results and Discussion

The relationships between log P_{O_2} and x in FeO_x.— The relationships between log P_{O_2} and x in FeO_x in the temperature range of 1100°-1300°C are shown in Fig. 3. Each set of isothermal data was at first

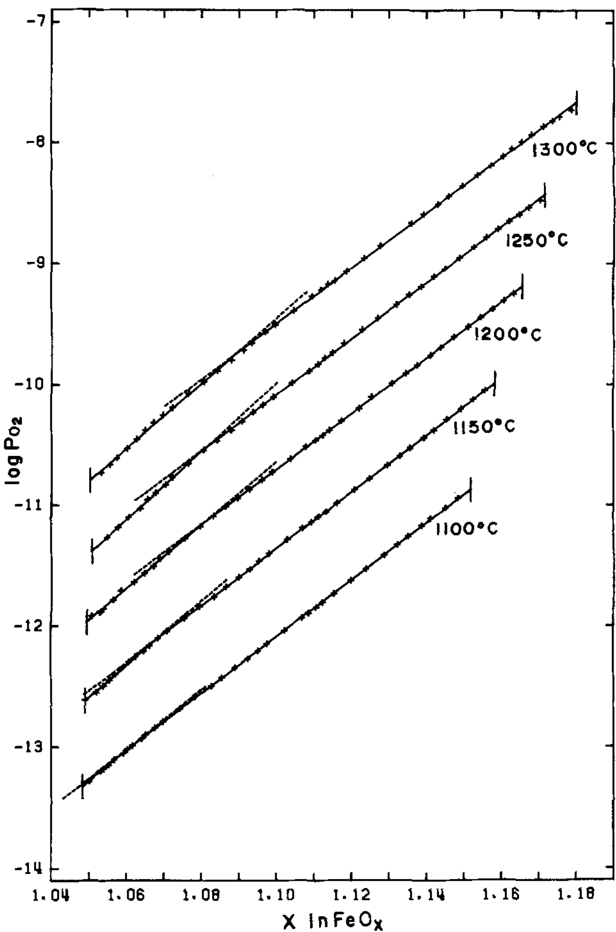

Fig. 3. The relationship between the log P_{O_2} and x in FeO_x. The intersecting lines indicate Eq. [2] and [3] in the text.

approximated by following one linear function

$$\log P_{O_2} = Mx + B \quad [1]$$

where M and B are constants. However, the difference plots, one of which is shown in Fig. 4, reveal that

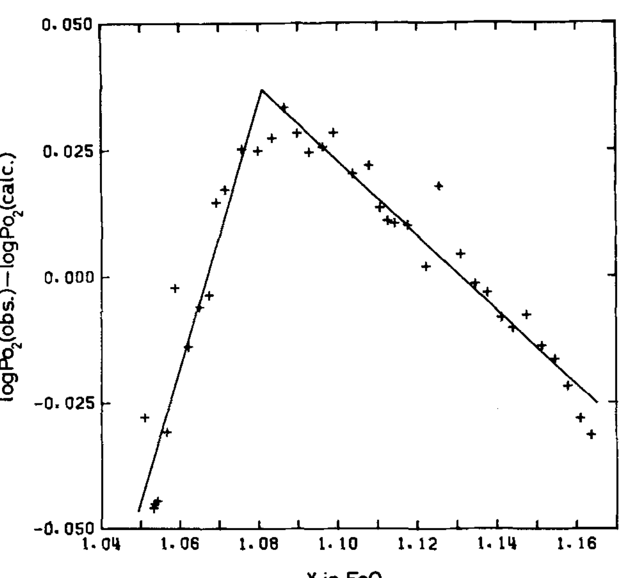

Fig. 4. The difference plot for the data obtained at 1200°C. Calculated oxygen fugacity is based on the following one linear equation (Eq. [1] in the text)

$$\log P_{O_2} = 23.875x - 36.998$$

The lines indicate the difference value of [log P_{O_2} (from Eq. [2] or [3]) — log P_{O_2} (from Eq. [1])].

‡ The values of Giddings and Gordon (3).

this approximation is not appropriate except for the data obtained at 1100°C. The values of [log P_{O_2} (obs.) − log P_{O_2} (calc)] are not distributed randomly around zero, but vary with a certain tendency indicating that the slope of log P_{O_2} *vs.* x changes abruptly near $x = 1.08$. The following two intersecting straight lines were therefore adopted to fit the data in the more oxygen-rich and the less oxygen-rich regions, respectively

$$\log P_{O_2} = M_1 x + B_1 \quad [2]$$

$$\log P_{O_2} = M_2 x + B_2 \quad [3]$$

where M_1, M_2, B_1, and B_2 are constants. These four values were calculated simultaneously by the least squares method, so that the lines might be the best fit for the whole isothermal data. The intersecting lines are drawn in Fig. 3 and 4, and the values of the parameters are listed in Table I. One of the difference plots from the intersecting lines is shown in Fig. 5. These figures indicate clearly that two intersecting straight lines are a better fit than one straight line.

The most important conclusion derived from the facts described above is that the first derivative of the thermodynamic function, namely, $d(\log P_{O_2})/dx$ or $d\Delta\overline{G}_o/dx$ ($\Delta\overline{G}_o$ represents the relative free energy of oxygen in wustite phase), is not a smooth function of x; there is an abrupt change of it near the intersecting point calculated above. This suggests the existence of a second or possibly higher order transition in the wustite phase.

Giddings and Gordon (3) presented a review of the available data on the wustite phase obtained by thermogravimetry and the galvanic cell method and concluded that the relation between log P_{O_2} and x was linear with no breaking point to suggest any phase transitions. Their M and B values are intermediate between M_1 and M_2 or B_1 and B_2 values of the present work as shown in Table I. In order to test their assertion, a few data at 1200°C (6, 19, 20) are replotted together with our own data in Fig. 6. (Since almost all the relationships between log P_{O_2} and x were illustrated in the figures instead of being tabulated, we could not explicitly refer to the data, except a few.) The composite data scatter so widely around the present ones, that it is impossible to conclude definitely whether the relation is linear or not. In the difference plot for the composite data (Fig. 7), however, the data of Bransky and Hed (20) show, though not clearly because of wide scattering, a tendency similar to that shown in Fig. 4. The other two sets of data (6, 19) have too few experimental points to discuss in this respect.

It seems that the data quoted by Giddings and Gordon are in themselves not adequate to conclude definitely whether a breaking point is present or not.

Some physical properties of the wustite phase such as electrical conductivity, Seebeck coefficient (21-24), and work function (25) have been reported and in these physical properties, the change in the sign of the Seebeck coefficient, which means p-to-n transition, is remarkable. This p-to-n transition is situated in the middle of the wustite phase field where the subphase boundary determined in the present work exists at higher temperature (see Fig. 8).

Phase diagram of the wustite region.—The phase boundaries of iron and wustite and wustite and magnetite are in good agreement with those of Darken and Gurry (1) as shown in Fig. 8. The subphase

boundary obtained in this work is shown with a dotted line and apparently disagrees with that of Vallet and Raccah (5, 6) and Kleman (7) or Fender and Riley (8) (see Fig. 9).

The basis of Vallet and Raccah and Kleman for suggesting the three subphases is abrupt changes of the average slopes of $\log P_{O_2}$ *vs.* x with reciprocal of the absolute temperature. Their "semiempirical" analysis, however, does not seem to be appropriate. They detected no breaking point in the isothermal line of $\log P_{O_2}$ *vs.* x above 900°C. In spite of this, they calculated x values of the subphase boundaries

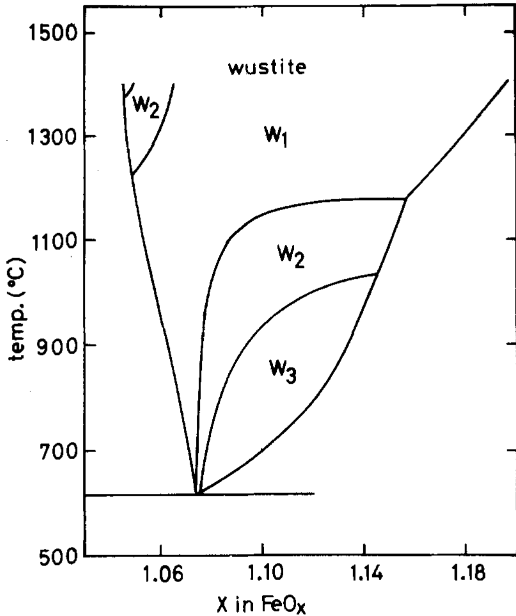

Fig. 9. The phase diagram of wustite after Vallet and Raccah (5)

by using the average slopes of $\log P_{O_2}$ *vs.* x, spanning a range of compositions across the subphase boundaries which would be determined as a result of their calculation. Similarly, the data of Fender and Riley do not seem to be reasonable because of experimental errors, mainly oxygen permeation through the electrolyte as already pointed out by Giddings and Gordon (10). Actually, the phase boundary between wustite and magnetite reported by them (8) is greatly different from that of the present work or Darken and Gurry (1).

Thermodynamic functions.—The relative partial entropies ($\Delta\overline{S}_o$) and enthalpies ($\Delta\overline{H}_o$) of oxygen in the wustite phase were calculated from the following equations

$$\Delta\overline{G}_o = 1/2\, RT \ln P_{O_2} = (2.3026/2)\, RT[M_1(M_2)x + B_1(B_2)]$$

$$\Delta\overline{G}_o = \Delta\overline{H}_o - T\Delta\overline{S}_o$$

by using the least squares method. The calculated values are indicated in Table II in which three values of $\Delta\overline{S}_o$ and $\Delta\overline{H}_o$ are given for $x = 1.07$ and 1.08 at which the isocomposition line traverses the subphase boundary, that is, the mean value spanning the two

‡ At $x = 1.07$ and 1.08, the values parenthesized with ( ) and [ ] were calculated from Eq. [2] and Eq. [3], respectively, and the other was the mean value spanning the subphases (see the explanation in the text).

subphases obtained from Eq. [2] and [3], the value from only Eq. [2], and the value from only Eq. [3].

Since oxygen atoms in the wustite phase form an almost perfect anion sublattice (26), the change of $\Delta\overline{S}_0$ with x is mainly contributed from the change of the vibrational state of the oxygen sublattice. Moreover, since the lattice parameter of the wustite diminishes linearly with increasing x (15), the vibrational entropy of the oxygen sublattice is thought to have a tendency to decrease with increasing x.

In the present data, the $\Delta\overline{S}_0$ value decreases not smoothly with increasing x, but in the oxygen richer region, the slope of $\Delta\overline{S}_0$ *vs.* x becomes smaller than that in the iron richer region. This seems to suggest a structural change of the oxygen sublattice near the breaking point. Similarly, the $\Delta\overline{H}_0$ value does not decrease monotonically with x but has a minimum point. This tendency is in agreement with the data of Darken and Gurry (1), but not in agreement with that of Giddings and Gordon (3). All these facts support the presence of a second or possibly higher order transition in the wustite phase field.

The partial molar free energies ($\Delta\overline{G}^\circ_f$), entropies ($\Delta\overline{S}^\circ_f$), and enthalpies ($\Delta\overline{H}^\circ_f$) of formation of the wustite phase were calculated from the following equations

$$\Delta\overline{G}^\circ_f(FeO_x) = \Delta\overline{G}^\circ_f(FeO_{x0}) + 1/2\,RT \int_{x_0}^{x} \ln P_{O_2} dx$$

$$\Delta\overline{G}^\circ_f = \Delta\overline{H}^\circ_f - T\Delta\overline{S}^\circ_f$$

where $\Delta\overline{G}^\circ_f(FeO_{x0})$ represents the formation free energy of the wustite in equilibrium with iron which was calculated from the equilibrium oxygen fugacity at the phase boundary of wustite and iron. The $\Delta\overline{G}^\circ_f$ values are shown in Fig. 10, and the $\Delta\overline{S}^\circ_f$ and $\Delta\overline{H}^\circ_f$ values are shown in Table III.

Since these values are integrated ones, no abrupt changes with x are detected. The values are in good agreement with those of Darken and Gurry (1) and Giddings and Gordon (3).

Summary

The detailed relationships between the oxygen fugacity and the composition of wustite phase were determined on the basis of thermogravimetry in the temperature range of 1100°-1300°C. There exists a breaking point in every isothermal line of log P_{O_2} *vs.* x in FeO_x, and each side of this point, the relationship can be represented by a linear equation. The existence of the breaking point indicates a second or possibly higher order transition in the wustite phase. Some thermodynamic functions were determined and in these functions, the relative partial entropies and enthalpies of oxygen in wustite phase do not change smoothly with the composition, supporting the transition described above.

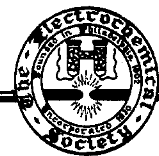
Technical Notes



Electrical Transport Properties of In and Cu-Doped n-Type Epitaxial Thin PbTe Films

A. L. Dawar,[1] O. P. Taneja,[2] K. V. Krishna, and P. C. Mathur

Department of Physics and Astrophysics, University of Delhi, Delhi, 110 007, India

The investigation of transport phenomenon in bulk crystalline materials having low resistivity is often difficult because the resistance of the ohmic contacts may be comparable to or even greater than, the resistance of the bulk material. In such cases, thin films are more suitable for studying the electrical properties due to the higher resistance of the films as compared to that of ohmic contacts. The main drawbacks of using thin films for the study of transport phenomenon are a large number of dislocations present in the films, scattering due to intercrystalline grain boundary barrier potential, and the variation of the charge carrier concentration in the film as it grows. The information about these effects can best be obtained by electrical measurements rather than by optical studies.

Lead telluride is a semiconductor in which the mobility of the charge carriers at low temperatures is mainly limited by phonon scattering rather than by impurity scattering (1). The reason that the ionized impurity scattering is very weak in PbTe is that its static dielectric constant is very high (2, 3) and optical phonon frequency is quite low (4, 5).

Considerable work has been done on the nucleation and growth of epitaxial films of lead telluride (6, 7). While the primary tools in these studies have been electron transmission microscopy and diffraction (8, 9), some workers have also used galvanomagnetic properties of the films (10, 11). The galvanomagnetic properties are very sensitive to the degree of perfection of the films and the concentration of the charge carriers. While high mobility epitaxial films of PbTe have been obtained by many of these workers, not much effort has been made to investigate the variation of grain boundary barrier potential and dislocation density as a function of extrinsic carrier concentration and growth conditions.

In the present work, the results of conductivity and Hall mobility measurements on a few n-type epitaxial films of PbTe have been presented. The effect of In and Cu doping on dislocations and grain boundary scattering have been investigated.

Experimental Details

Films, rectangular in shape (22 × 5 mm), were grown by evaporating stoichiometric (99.999%) PbTe under a high vacuum better than 5×10^{-6} Torr. Film thicknesses are shown in Table I. Freshly cleaved mica was used as substrate, which was kept at 280°C. The rate of growth of the films was controlled by a quartz crystal thickness monitor (12). After growth the films were cooled to room temperature in about 4 hr. Indium and copper were added to the films by coevaporating through a separate boat. Electron micrographs of the films showed the existence of some voids and cracks and the average grain diameter was found to be ~300Å in all the films. High purity silver was evaporated on the films under a high vacuum for making ohmic contacts. The current contacts were spread over the entire width, while the voltage contacts were only dots ~0.5 mm in diameter. Five probe technique, as described by Putley (13), was used to measure the Hall coefficient R_H and d-c conductivity σ. The ohmic nature of the contacts was verified, throughout the temperature range, by the linearity of the *I-V* characteristics. The directions of the current and the magnetic fields ($B \simeq 5$ kg) were reversed so as to eliminate the errors due to the thermomagnetic effects. Geometrical influence of the films on Hall measurements was avoided as the length to width ratio was greater than four. The sign of the Hall voltage showed that all the films were n-type.

Measurement of the Hall coefficient as a function of temperature was found to be reproducible for three to four runs. The Hall coefficient was found to be independent of the magnetic field and the sample current. The overall maximum error in the Hall mobility ($R_H \times \sigma$) is estimated to be about 5%. A copper block with electrical insulation was used to mount the sample which was further kept in a Dewar flask containing liquid nitrogen. A copper constantan thermocouple,

soldered to the copper block, was used to record the temperature.

Results and Discussion

The observed variation of R_H with temperature (log R_H *vs.* $1/T$) for all the films is shown in Fig. 1. It is evident that R_H is practically independent of temperature, which is characteristic of an extrinsic degenerate semiconductor. It is observed that R_H increases with the thickness of the film. The reason for this effect can be formation of an accumulation layer on the surface of the films due to surface states caused by atmospheric oxygen as has been explained by Zemel *et al.* (10). The effect of an accumulation layer, which seems to act as a donor source, will be relatively more significant for thinner films which further explains the observed increase of R_H with the thickness of the films. The value of R_H is found to decrease with the addition of In and Cu but the decrease in R_H is more significant in the case of In. This shows that In impurities in PbTe act as donors. It may be mentioned here that In in PbTe is known to form deep impurity states (14). However, it is also an observed fact that irrespective of the concentration of In, the Hall density of electrons in bulk does not exceed a few units of 10^{18} cm^{-3} (15, 16).

As explained by Rosenberg *et al.* (17), this is due to the fact that a substantial fraction of indium atoms in PbTe enter the octahedral and tetrahedral interstitials of the Te atom sublattice. The observed decrease of R_H in Cu-doped films can either be as a result of the electrostatic shorting of the Hall field due to Cu filaments incorporated between the PbTe crystallites or due to the donor action of Cu. However the Hall field shorting should also be followed by an increase in the mobility, which has been observed in the present case. Cu has less donor electrons per atom than In and therefore the relative effect of In and Cu on R_H is understandable.

The variation of the observed Hall mobility ($R_H \times \sigma$) with temperature for all the films is shown in Fig. 2. The mobility for all the films is found to decrease with the increase of temperature but the rate of decrease of mobility with temperature becomes weaker with increase of carrier concentration in the films. This shows the predominance of some scattering mechanism in which the mobility increases with the temperature as the carrier concentration in the film increases. These scatterings can be due to the presence of intercrystalline grain boundaries, which are well founded for lead chalcogenides films (10). The contribution of grain boundary scattering is independent of temperature for a degenerate material and the corresponding mobility μ_c for the process is given by

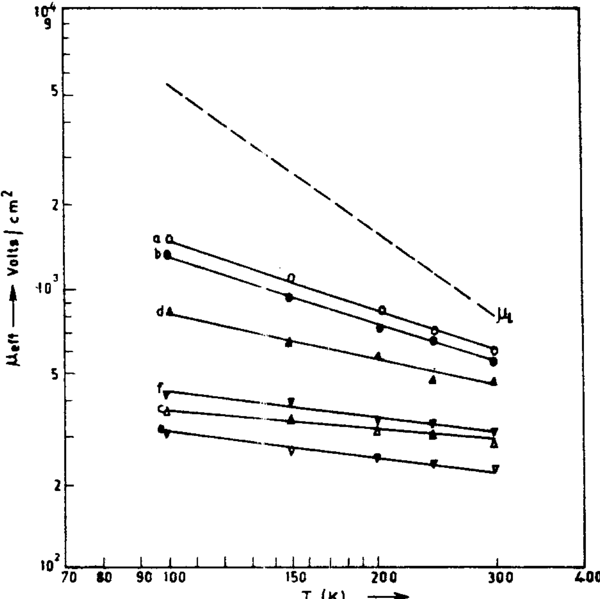

Fig. 2. Variation of observed Hall mobility, with temperature. The dotted line shows the bulk mobility. (a), 1.2 μm; (b), 0.6 μm; (c), 0.4 μm; (d), 0.4 μm, excess of Pb; (e), 0.4 μm, In-doped; (f), 0.4 μm, Cu-doped.

$$\mu_c = \frac{2q}{h} X_c \left(\frac{3n}{\pi}\right)^{-1/3} \quad [1]$$

where X_c is the mean crystallite size, n is the carrier concentration, q is the electronic charge, and h is Planck's constant. In the present work X_c has been determined by electron diffraction micrographs and the calculated values of μ_c using Eq. [1] are shown in Table I.

Using these values of μ_c, the values of μ_D, the mobility (caused by point defects such as vacancies and interstitials) limited by dislocation scattering has been calculated by the well-known relation

$$\frac{1}{\mu_B} = \frac{1}{\mu_i} + \frac{1}{\mu_D} + \frac{1}{\mu_c} \quad [2]$$

where μ_B is the observed mobility and μ_i is the mobility for the bulk material. The data for μ_i has been taken from Zemel *et al.* (10). The calculated values of μ_D as a function of temperature are shown in Fig. 3 for all the films. It is observed that the contribution due to dislocation scattering increases with decrease of the film thickness. It is further observed that the contribution of dislocation scattering also increases with increase of the charge concentration in PbTe films. On the other hand, the addition of In results in significant decrease in the dislocation density. This shows that the dislocation density is very sensitive to the clusters of Pb vacancies, which are filled up by In. While addition of Cu also results in a decrease in the dislocation density, the effect is not as significant as it is in the case of In. A probable reason for this effect is that since the atomic radius of Cu is much less than that of Pb,

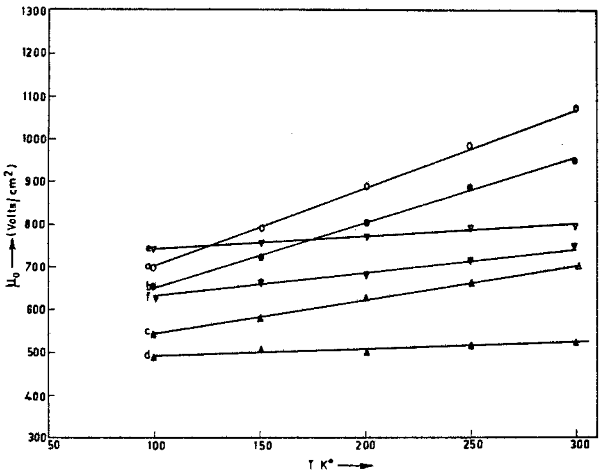

Fig. 3. Calculated values of μ_D as a function of temperature. (a), 1.2 μm; (b), 0.6 μm; (c), 0.4 μm; (d), 0.4 μm, excess of Pb; (e), 0.4 μm; In-doped; (f), 0.4 μm, Cu-doped.

the probability of a Cu atom filling the Pb vacancy is comparatively smaller.

The dislocation density N_D, calculated from the mobility data at 300°K is shown in Table I. The calculations for N_D have been made as follows.

The mobility μ_D due to dislocation scattering is expressed as

$$\mu_D = (q/m^*)\tau_D \quad [3]$$

where τ_D is the relaxation time and m^* is the effective mass of the charge carriers. The value of τ_D is given by (19)

$$\tau_D = \frac{32}{3\pi}\left(\frac{1-\nu}{1-2\nu}\right)^2 \frac{KT\not{n}}{\epsilon^2\lambda^2 N_D} \quad [4]$$

where ϵ is the energy (20) associated with the dislocations and its value is calculated from the temperature dependence of the effective mass bandgap and volume expansion coefficient of PbTe (21); n is the electron density, λ is the unit crystallographic slip distance (22), and ν is the Poisson's ratio.

Using Eq. [3] and [4], the value of N_D is given by

$$N_D = \frac{32}{3\pi}\left(\frac{1-\nu}{1-2\nu}\right)^2 \frac{KT\not{n}q}{\epsilon^2\lambda^2\mu_D m^*} \quad [5]$$

The values of μ_D obtained from Fig. 3 were used to calculate the values of N_D. It is observed from Table I that the value of N_D increases as the carrier concentration in pure PbTe films increases with the addition of In or Cu into the films. The effect of In in reducing the dislocations density is far more pronounced than the effect of Cu. This suggests that the main cause of dislocations in the PbTe lattice is the defect aggregation of Pb vacancies developed during the growth of the films.

A Simple Luminescence Experiment Suggesting Rare Earth Ion Pairing in the Fluorite Structure

G. Blasse and G. J. Dirksen

Physical Laboratory, State University, 3508 TA Utrecht, The Netherlands

It is well known that the luminescence of the Sm^{3+} ion is quenched by cross relaxation in Sm^{3+} pairs ($^4G_{5/2} \rightarrow {}^6F_{9/2}$ and $^6H_{5/2} \rightarrow {}^6F_{9/2}$) (1). It has been shown that the maximum intensity of the $^4G_{5/2}$ luminescence occurs at roughly the same Sm^{3+} concentration in a large number of oxide host lattices, *viz.*, one Sm^{3+} ion per 4600Å^3. We have used this property to demonstrate trivalent rare earth ion clustering in the fluorite lattice (2).

Key words: inorganic, ultraviolet, photoluminescence.

We prepared two series of samples, *viz.*, $NaY_{1-x}Sm_xF_4$ and $Ca_{1-x}Sm_xF_{2+x}$ with $0.01 \leq x \leq 0.08$. In the former the Sm^{3+} ion replaces the Y^{3+} ion substitutionally. We assume that this occurs statistically, since there is not any reason for the opposite in view of the similarity between both ions. These samples show the red Sm^{3+} luminescence from the $^4G_{5/2}$ level with a maximum intensity at about $x = 0.02$. The compound $NaYF_4$ has a hexagonal crystal structure (3). From the crystallographic parameters ($a = 5.967$ and $c = 3.523$Å

and Z = 3/2) it is found that $x = 0.02$ corresponds roughly with one Sm^{3+} ion per 4000Å^3. This is reasonably in line with the results of Van Uitert and Johnson. Our results are not accurate enough to conclude that the Sm^{3+}-Sm^{3+} interaction in fluorides is somewhat weaker than in oxides which were used in the earlier work. These results are consistent with our assumption that the Sm^{3+} ions are randomly distributed among the Y^{3+} sublattice. The value of x was obtained at room temperature, but is not strikingly different at lower temperatures.

Let us now turn to the fluorite samples $Ca_{1-x}Sm_xF_{2+x}$. In view of the sample preparation we may exclude the presence of considerable amounts of oxygen in the lattice. None of these samples showed any Sm^{3+} luminescence at all, independent of the sample temperature. In view of the model developed by Van Uitert and Johnson this suggests that the Sm^{3+} ions occur for the greater part as pairs or even more complicated clusters. There is no obvious reason why an isolated Sm^{3+} ion should not luminescence in this lattice. The absence of luminescence is, therefore, ascribed to cross relaxation in the Sm^{3+} pairs.

Clustering of trivalent rare earth ions in the fluorite lattice has been demonstrated earlier by spectroscopical techniques (4, 5), but none of these was so simple as the present one. Finally it is interesting to note that Andeen *et al.* (6) have found from complex dielectric constant measurements that in Sm^{3+}-doped fluorite samples with x as low as 0.001 cluster formation already occurs.

Experimental

Samples $NaY_{1-x}Sm_xF_4$ were prepared by heating NaF and (Y, Sm)F_3 together with NH_4F. The mixed trifluoride was precipitated from aqueous solution with HF and dried thoroughly. Samples $Ca_{1-x}Sm_xF_{2+x}$ were prepared by heating mixtures of $CaCO_3$ and Sm_2O_3 together with a large excess of NH_4F. All samples were checked by x-ray analysis. If the fluorite samples were heated in air without excess of NH_4F, they showed bright yellowish luminescence under short wavelength ultraviolet excitation. This emission reminds one of that emission in BaFCl which was ascribed to oxygen on fluorine sites (7).

Acknowledgment

The authors are indebted to Dr. J. Schoonman for instructive discussions on the rare earth ion clusters in the fluorite-lattice.

Standardized Terminology for Oxide Charges Associated with Thermally Oxidized Silicon

Bruce E. Deal*

Fairchild Camera and Instrument Corporation, Research and Development Laboratory, Palo Alto, California 94304

MOS transistors were first produced on a commercial basis in the 1963-1964 time period. At the same time various charges associated with the thermally oxidized silicon structure were observed to cause serious yield and reliability problems. Subsequently a number of investigations concerned with oxide charges were started in various laboratories and many have continued to the present time (1). Initially most of the studies were designed to determine the dependence of charge densities on processing parameters so that their adverse effects on device properties could be minimized. More recently efforts have focused on a quantitative understanding of the densities, cross sections, and the nature of oxide charges and traps so that ultimate device performance might be achieved.

During the past 15 years or so, it has been generally established that four general types of charges are associated with the Si-SiO_2 system (2, 3). However, no common set of symbols has been used to designate these four types of charges. This has caused substantial confusion and disagreement during discussions at technical meetings and in interpretation of the large number of publications in the area of semiconductor passivation. This was emphasized by a survey undertaken by the author in 1976 (4).

* Electrochemical Society Active Member.
Key words: charge, semiconductor, interface.

Because of the lack of a common terminology for oxide charges, a committee was established in January 1978 by the Electronics Division of the Electrochemical Society and the IEEE-sponsored Semiconductor Interface Specialists Conference. The names and affiliations of the committee members along with those representing the sponsoring groups are listed below:

Bruce E. Deal (Committee Chairman)	Fairchild Camera and Instrument Corporation Palo Alto, California
W. Murray Bullis	National Bureau of Standards Washington, DC
Sidney R. Butler	Lehigh University Bethlehem, Pennsylvania
Edward H. Nicollian	Bell Laboratories Murray Hill, New Jersey
Donald R. Young	IBM Corporation Yorktown Heights, New York
Arnold Reisman (ECS Electronics Division)	IBM Corporation Yorktown Heights, New York
Al Tasch (IEEE SISC)	Texas Instruments Dallas, Texas

Pieter Balk (Europe representative) Technischen Hochschule Aachen Aachen, West Germany

Takuo Sugano (Japan representative) University of Tokyo Tokyo, Japan

The committee met over a one and one-half year period, during which time a number of specialists in silicon passivation were solicited for opinions and guidance. This was done by personal contact, discussions at technical meetings, and a detailed survey. Several general preferences regarding a standard terminology for oxide charges were evident. These were:

1. Standardization of oxide charge terminology is highly desirable;
2. Such a terminology system should be as simple as possible, *i.e.*, subscripts for symbols should be one letter if possible;
3. The symbols and subscripts should indicate or suggest the nature of the charge type;
4. A symbol representing a given charge should not be easily confused with any of those representing the other charge types;
5. If possible, the symbols selected should not be the same as those used previously by any appreciable segment of semiconductor technologists.

These and other considerations were discussed in considerable detail by the committee. Various sets of symbols were proposed and problems associated with each set were noted. For instance, a symbol subscript which might give rise to confusion would be "i" which stands for both "interface" and "ion." Thus, the single letter "i" should probably not be used as a subscript. Likewise, the use of only "o" or "ox" as subscripts could represent any or all of the charge types and also should not be used.

Finally, at a meeting of the committee in May, 1979, (Spring Meeting of The Electrochemical Society, Boston, Massachusetts) a final terminology was agreed upon. Insofar as practical, the general preferences were observed. Where this turned out not to be possible because of mutually conflicting requirements, the compromise thought to result in the least confusion and ambiguity was selected.

The recommended names for the four types of oxide charges illustrated in Fig. 1 are:

1. Fixed Oxide Charge—Positive charge, due primarily to structural defects (ionized silicon) in the oxide layer less than 25Å from the $Si\text{-}SiO_2$ interface. The density of this charge, whose origin is related to the oxidation process, depends on oxidation ambient and temperature, cooling conditions, and on silicon orientation. Since fixed oxide charge density cannot be determined unambiguously in the presence of moderate densities of interface trapped charge, it is only measured after a low temperature (~450°C) hydrogen treatment which minimizes interface trap density. Fixed oxide charge is not in electrical communication with the underlying silicon.

2. Mobile Ionic Charge—Primarily due to ionic impurities such as Li^+, Na^+, K^+, and possibly H^+. Negative ions and heavy metals may contribute to this charge even though they are not mobile below 500°C.

3. Interface Trapped Charge—Positive or negative charges, due to (*i*) structural, oxidation-induced defects, (*ii*) metal impurities, or (*iii*) other defects caused by radiation or similar bond breaking processes. They are located at the $Si\text{-}SiO_2$ interface. Unlike fixed charge or trapped charge, interface trapped charge is in electrical communication with the underlying silicon and can thus be charged or discharged, depending on the surface potential. Most of the interface trapped charge can be neutralized by low temperature (450°C) hydrogen annealing. This charge type in the past has been called surface states, fast states, interface states, etc.

4. Oxide Trapped Charge—May be positive or negative due to holes or electrons trapped in the bulk of the oxide. Trapping may result from ionizing radiation, avalanche injection, or other similar processes. Unlike fixed charge, oxide trapped charge is generally annealed out by low temperature (<500°C) treatment, although neutral traps may remain.

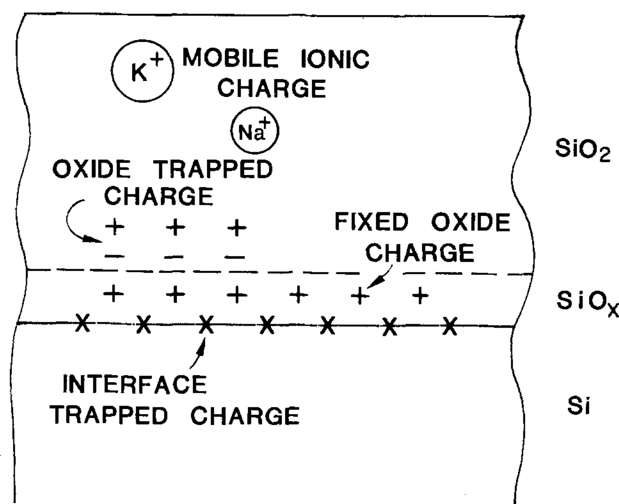

Fig. 1. Names and location of charges in thermally oxidized silicon.

In general, the densities of all of the charges except interface trapped charge may be determined using the high frequency capacitance-voltage (*C-V*) technique. More elaborate measurement procedures such as "quasistatic *C-V* analysis" are required for interface trap charge.

The symbols selected to denote the oxide charges were based on the following assumptions:

Q = Net effective charge per unit area at the $Si\text{-}SiO_2$ interface (C/cm^2).

N = Net number of charges per unit area at the $Si\text{-}SiO_2$ interface (no/cm^2).

Thus, $|Q/q| = N$ where q = electronic charge.

The sign of Q is either positive or negative depending on whether the majority of charge is positive or negative. By definition, however, N is always positive. Also, it should be kept in mind that Q and N are defined as effective net charge at the $Si\text{-}SiO_2$ interface, even though the actual charge density may be considerably larger if the charge is located some distance from that interface. Uncharged trapping centers are not covered by this proposed terminology.

Following are the recommended symbols for the four types of oxide charge:

Fixed Oxide Charge	Q_f, N_f
Mobile Ionic Charge	Q_m, N_m
Interface Trapped Charge	Q_{it}, N_{it}
Oxide Trapped Charge	Q_{ot}, N_{ot}

As indicated above, the charges represented by the above symbols are expressed in terms of density per unit area. In one particular case, that of interface trapped charge, it is common to express its density in terms of unit area and energy in the silicon bandgap. Therefore, a special symbol is recommended:

Interface Trap Density D_{it} ($no./cm^2\text{-}eV$)

The committee strongly urges all scientists and engineers active in silicon oxide work to use the above terminology in oral presentations or written publications. It is recognized that after 15 years of using a particular system, some emotional attachment to some particular nomenclature may exist. However, those persons "brought up" on designating fixed oxide charge as Q_{ss} should remember that others have used, just as diligently, the same symbol for interface traps

(or fast states, or surface states, or interface traps, etc). Likewise, other groups refer to fixed charge as Q_{ox} (or Q_{fc} or N_o or Q_s, etc.). The only way to resolve the difficulties and confusion regarding oxide charge terminology which have persisted for 15 or more years is for everyone to decide that one system should be used and that some compromise in personal feeling on everyones part will be required.

The author wishes to thank the above named committee members for their valuable assistance during the course of these efforts. Also, considerable thanks are due to many individuals who contributed opinions and suggestions to the committee.

Anomalous Boron Profiles Produced by BF_2 Implantation into Silicon

T. W. Sigmon*

Stanford Electronics Laboratories, Stanford, California 94305

and V. R. Deline and C. A. Evans, Jr.

Charles Evans and Associates, San Mateo, California 94402

and W. M. Katz

Department of Chemistry and Materials Research Laboratory, University of Illinois, Urbana, Illinois 61801

It is common practice in the production of low sheet resistance, shallow p-type contacts, such as those used for high frequency Si bipolar transistors, to use BF_2 as the implant species. There are several reasons for this approach: (*i*) to produce a low-energy boron implant distribution while operating at a reasonably high accelerator voltage; (*ii*) the BF_2 molecule is generally the most abundant beam; and (*iii*) the critical dose for amorphous layer production is lowered to reasonable values (1). It is a simple exercise is basic physics to show that for a BF_2 molecular beam of energy, E_o, neglecting the molecular dissociation energy, the ^{11}B possesses (11/49) E_o and the ^{19}F (19/49) E_o. Using secondary ion mass spectrometry (SIMS), we have observed that under certain conditions BF_2 implants can exhibit anomalous ^{11}B profiles. These conditions occur when using BF_2 molecular implants from ion implantation equipment employing preacceleration mass analysis. The following communication demonstrates the problem, proposes and verifies the mechanism, and shows that a solution can be obtained.

The samples were prepared using cleaning procedures and implantation conditions suitable for Si device fabrication. The SIMS in-depth profiles were performed on a CAMECA IMS-3f Ion Micro-analyzer employing oxygen ion bombardment and positive ion spectroscopy. To insure that profiling conditions were identical for the different implants, all samples were run with identical SIMS parameters.

In Fig. 1 we show the SIMS profile for ^{11}B resulting from a BF_2 implant into silicon. Here, the concentration and depth scales have been assigned by fitting the LSS ^{11}B distribution to the SIMS data (2). These results are obtained from unannealed material with implant conditions typical of a high throughput ion implantation process (filament ion source, maximum beam current). A pronounced shoulder on the deep

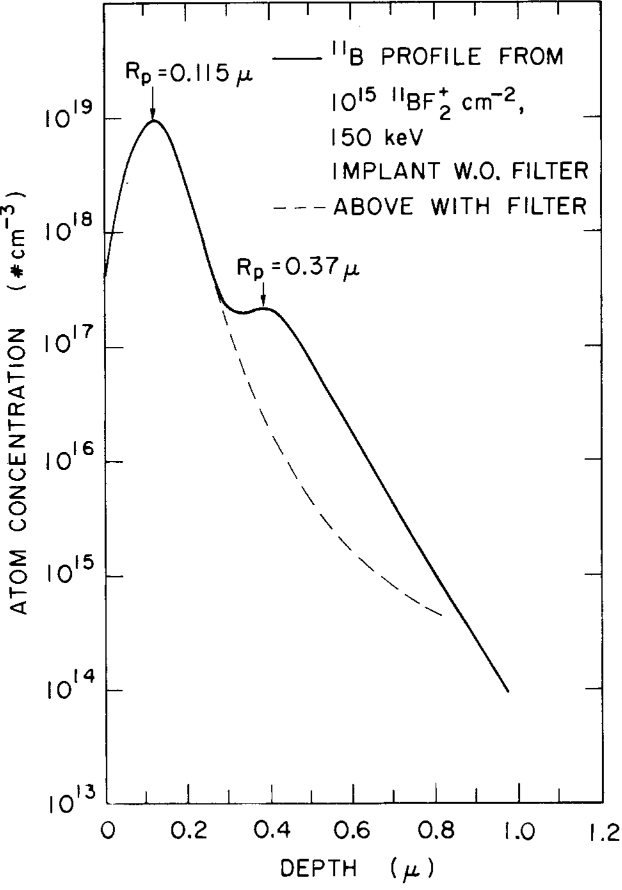

Fig. 1. ^{11}B concentration vs. depth profile resulting from a 10^{15} BF_2/cm^2 150 keV implant, (—) without additional filter, (- -) with additional filter.

* Electrochemical Society Active Member.
Key words: SIMS analysis, boron ion implantation.

side of the ^{11}B profile can be seen in Fig. 1 which results in a significant deviation of the measured and the expected ^{11}B-implanted profile (an ^{11}B concentration increase of over an order of magnitude at $\sim$0.4 μm). The disastrous effect of this shoulder on a shallow base structure is apparent.

We propose that this shoulder results from dissociation of BF_2 molecules which have undergone mass analysis but have not yet obtained the full terminal acceleration of the ion implanter. It is possible, in the low vacuum region between the output of the mass analyzer and the collimation slits, for the BF_2 ions to undergo collisions with other ions or molecules, and fragment into both boron and fluorine ions. These boron ions then take on an energy equal to 11/49's of the preacceleration BF_2 energy plus the full postacceleration energy of the accelerator. For this work, the premass analysis energy of the molecules was 30 keV, while the final terminal acceleration voltage was 120 kV. Thus, this dissociated boron ion will have an energy of approximately 127 keV, resulting in a projected range in the Si target based on this energy, rather than on 11/49 of 150 keV as was initially desired. In Fig. 1, we show the profile of ^{11}B made using BF_2 with a velocity filter located after the normal magnetic analyzer but prior to the final acceleration stage. It can be seen that the high energy shoulder which would result from dissociated BF_2 ions does not exist, suggesting that this is in fact the cause of the anomalous profile.

A further test of this hypothesis can be made by implanting monoatomic boron ions at various energies. The BF_2 implantation with dissociation can be simulated by implanting both 34 keV and 130 keV ^{11}B. The latter implant, representing the boron atoms which have passed through the mass analyzer as a BF_2 molecule, then decompose prior to receiving the full terminal acceleration. In order to identify the mechanism clearly, we have used ^{11}B at 34 keV and ^{10}B at 130 keV, thereby allowing unequivocal identification of the two implants using SIMS. The results of this experiment are shown in Fig. 2, which depicts the SIMS profile of the ^{10}B and ^{11}B ions in Si. The individual implants, shown as the dashed lines, are then combined and result in the composite profile shown as the solid line. It can be seen that the boron profile resulting from the BF_2 implant is reproduced almost exactly by this composite profile resulting from the 34 keV and 130 keV B implants, and each individual implant profile is as expected. The difference in the tails of the profiles is believed to be due to further dissociation of the BF_2 beam during final acceleration. This is supported by the fact that the tails occur only for the BF_2 implants (opposite to what would be expected if this were an ion channeling phenomena), and that the results are reproducible, thereby eliminating SIMS parameter artifacts.

We conclude from these results that, when using molecular ion beams for a source of implant atom, care must be exercised to insure that a significant amount of molecular dissociation (in our case $\sim$0.4%) does not occur in the ion implanter. This dissociation can be reduced by better operating vacuum in the critical regions of the implanter (with an associated loss in beam current), and/or with the use of a second stage of mass analysis prior to the final acceleration stage of the implanter. In this work, we have shown that this effect can be minimized for a preanalysis type implanter (within the sensitivity of our SIMS instrument) by the use of a velocity filter before the final acceleration stage without a large sacrifice of beam current. Moreover, this experiment indicates that the

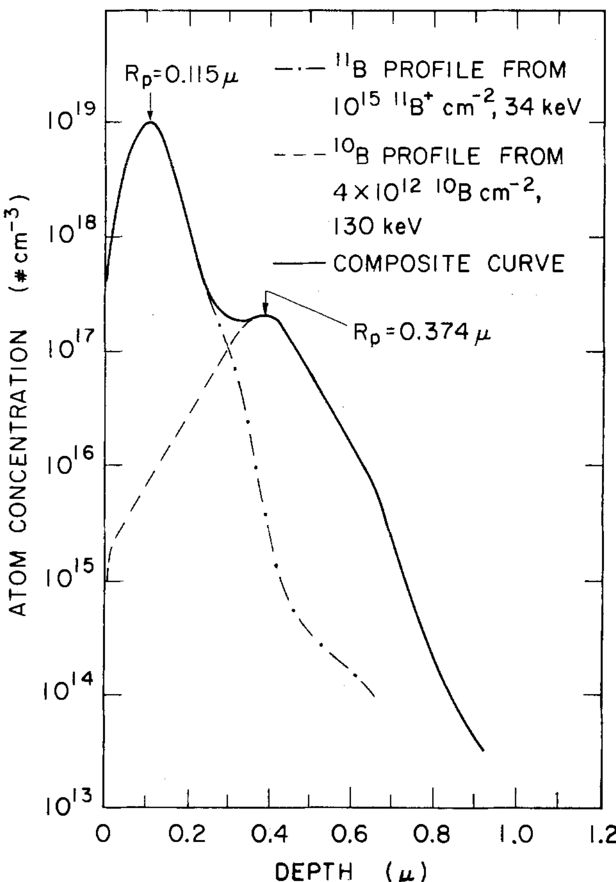

Fig. 2. ^{11}B and ^{10}B concentration vs. depth profiles resulting from a 10^{15} $^{11}B/cm^2$ 34 keV and 4 × 10^{12} $^{10}B/cm^2$ 130 keV implant. The solid line represents the composite profile and should be compared with the solid line in Fig. 1.

majority of the dissociation occurs prior to the exit slits of the magnetic deflection mass analyzer rather than during final acceleration. Should the majority occur during final acceleration, a continuum of boron energies below 130 keV would be produced, resulting in a less well-defined back side shape for the implant profile.

Potential Profiling as a Means to Determine Conductivity Type: Application to ZnSe

G. F. Neumark, B. J. Fitzpatrick,* P. M. Harnack, S. P. Herko, K. Kosai, and R. N. Bhargava

Philips Laboratories, Briarcliff Manor, New York 10510

In characterizing semiconductors it is important to determine whether these materials are n- or p-type. The usual method of determining conductivity type is the Hall effect. However, this measurement cannot be conveniently carried out on high resistivity material. Alternative methods are thus required for this case. In the present paper, we suggest use of Schottky barrier contacts together with potential profiling as an appropriate method. Essentially, this approach gives a large potential drop at the cathode if the material is n-type, and at the anode if the material is p-type. Both the theory and the experimental setup for this profiling method are relatively simple. We are, however, not aware of its prior use to determine conductivity type of semiconductors, and have therefore checked the method with GaP and ZnSe of known conductivity type. The method was then used to characterize high resistivity ZnSe layers. These layers were grown from Bi solution. In an attempt to obtain p-type material, some of these layers were grown with Li, Na, or P as dopants, and/or annealed in Se vapor.

The present method hinges on the use of barrier contacts such that the direction of easy electron transfer across the barrier is known with respect to the voltage polarity. This direction depends on the type of carrier transport which dominates the current: activation over the barrier, or tunneling (1, 2). However, it is known (3-5) that tunneling is not important except for high doping and at low temperature. Now, the aim of our method is measurement at room temperature on high resistance material. We shall thus assume that we are dealing with carrier transport by activation. For this case, under an applied bias the energy band configuration for two symmetric Schottky[1] barriers on an n-type semiconductor (Fig. 1a) changes (1, 3) qualitatively to the situation shown in Fig. 1b, where V_A is the applied voltage. Also indicated on Fig. 1b is a resistive voltage drop (V_R) across the bulk. The corresponding voltage distribution (1, 3) is shown in Fig. 2, which shows that the main voltage drop is at the cathode. An analogous analysis for a p-type semiconductor would show the main voltage drop at the anode.

A more quantitative treatment of the barrier voltages, although not strictly required in the present application of the method, is useful to bring out some sidelights. For ideal[1] reverse-biased Schottky barriers, the voltage distribution is given by (1, 3)

$$V(x) = [4\pi e(N_D - N_A)/\kappa](wx - \tfrac{1}{2} x^2) \quad [1]$$

$$w^2 = [V_B\kappa/2\pi e(N_D - N_A)] \quad [2]$$

where V_B is the voltage drop across the barrier [and where it is assumed that $V_B >> V_O$, with V_O the zero bias barrier height (Fig. 1a)], x is the distance along the field, κ is the dielectric constant, $(N_D - N_A)$ is the net doping density, and w is the barrier width. With use of cgs units in these equations, x is in cm and $(N_D - N_A)$ is in cm^{-3}, which is convenient for resistivity calculations (used below). For these units, $e = 4.8 \times 10^{-10}$ esu, and the voltage is in statvolts, or, for V in volts a value of $V/300$ is used. It is worth noting that $(N_D - N_A)$ can, in principle, be obtained within the barrier region. However, in practice the probing dimensions are inconveniently small except for quite high resistance material. And, of more importance, if the resistance is too high, practical dimensions result in a limitation on the method. Thus, if $(N_D - N_A)$ is very low, the barrier widens appreciably. Since sample sizes, in practice, are limited, this restricts the method. An example will clarify the extent of the limitation. Assume a sample size $\lesssim 1$ cm. It appears desirable to have a barrier width $\lesssim 1/3$ of the sample, so that adequate bulk material is also available. The barrier width can be adjusted through the applied

Key words: semiconductors, ZnSe, conductivity type, potential distribution.

[1] The terminology of what is meant by a Schottky barrier contact is not always clearly defined. In recent literature the term has sometimes been used interchangeably with "metal-semiconductor" barrier contact [see, for example, Rhoderick or Padovani, Ref. (3)]. In earlier literature [see, for example, Henisch, Ref. (1)], a Schottky barrier usually meant a barrier whose width (w) varied with voltage. Here we use the term "ideal" for barriers for which Eq. [1] and [2] are valid.

voltage, but for measurements on high resistance materials the minimum voltage required, in practice, is ~100V (=1/3 statvolts). Assuming $\kappa \approx 10$, the lowest $(N_D - N_A)$ which can be measured is $\sim 10^{10}$ cm^{-3}. To convert this value to resistivity ρ (where $\rho = 1/ne\mu$), one requires a value of mobility μ and the relation between carrier concentration n and $(N_D - N_A)$. For example, for $\mu \approx 100$ cm^2/Vsec and $n \approx (N_D - N_A)$, the corresponding resistivity is 6×10^6 Ω-cm. In practice, one usually has $n < (N_D - N_A)$, so that somewhat higher resistivities should also give satisfactory results, but actual limits cannot be predicted without knowledge of the relation between n and $(N_D - N_A)$.

To carry out the present method, one requires a measurement of potential along a sample. This, in principle, is relatively simple. Using a probe which can be positioned along the sample (*e.g.*, via a micromanipulator), one can measure the voltage at the probe by use of the condition of zero current through the probe. Appropriate circuits are standard. Nevertheless, in practice some difficulties may arise, and it seems worth mentioning some of the problems.

The measurement, as actually carried out, had some usual difficulties due to high sample resistance. The main problem here was the high contact resistance at the probe, leading to poor sensitivity. However, we found that an adequately low contact resistance could generally be obtained by evaporating a pattern of Au dots on the sample, and then moving the probe along a row of such dots. (We used Au since it was convenient—also see below for further discussion on contact aspects.)

Another caution worth mentioning is that the measurement should be done in the dark, in order to avoid photoconductive and/or photovoltaic effects. It is, for instance, known (6) that high resistance p-material can give an n-type photo-Hall effect. This arises when the concentration of the carriers generated by the light is comparable to or higher than the dark concentration, since the conductivity is then dominated by the higher mobility of the electrons.

A further problem is that the present method requires Schottky contacts, and it is not always known which metals and which preparation conditions yield this type of contact. Fortunately, the probing method also yields information on the contact type. Firstly, if the contacts are of the Schottky type, one end of the sample will show a high voltage drop, the other end a lower one (see Fig. 2), and this condition will reverse if the voltage polarity is reversed. Secondly, if the contact resistance is dominated by an intrinsic layer, there will be a potential drop at the contact, but this drop will remain approximately constant with reversal of the polarity. Thirdly, if a contact is ohmic, there are two possible potential profiles (Fig. 3). There may be no extra voltage drop at the contacts, and the voltage distribution will be linear across the sample (dashed line on Fig. 3). The second possibility is a voltage drop at both anode and cathode, approximately equal, giving a symmetric voltage distribution (solid line on Fig. 3). The former case will occur by definition if the contact geometry is such as to give a true one-dimensional situation, *e.g.*, if the contacts extend across the two end faces of a rectangular shaped sample. However, in practice the contacts were usually evaporated on the top surface of a sample. Thus, the current lines can spread downward into the sample (and for point contacts also laterally) leading to a lower resistance away from the contact ends. This is strictly a geometric effect. Various aspects of this problem have frequently been discussed in the literature (7).

Regarding the applications of the profiling method, we first checked it on materials of known conductivity type, namely n-ZnSe, and n- and p-GaP. The method was then applied to several ZnSe layers grown by liquid phase epitaxy from Bi solution. For probing contacts, we used evaporated Au dots for most of the

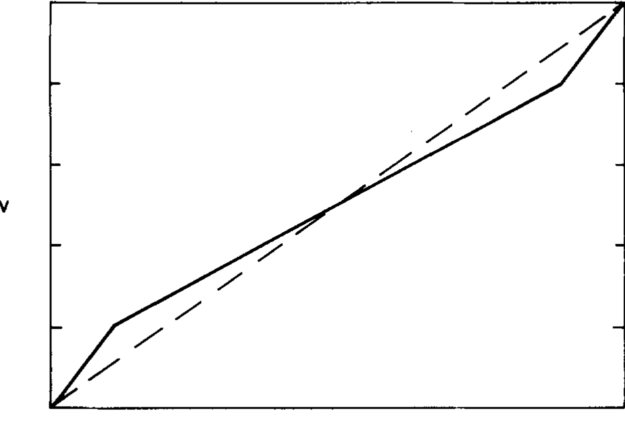

Fig. 3. Potential *vs.* distance for an ohmic contact. The dashed line is the ideal case of even current lines. The solid line shows the case where current lines can spread out from the contact region (see text).

measurements. As discussed earlier, these gave adequately low contact resistance. The one disadvantage of gold is that under certain conditions [*e.g.*, sputtering or heating in H_2 (6, 8)] it may give an ohmic contact to p-ZnSe. However, using a plain evaporation procedure, we obtained sharp contact barriers on a number of high resistance ZnSe layers with p-type characteristics (anode drop—see below).

The profiling method has been carried out on various as-grown layers, both undoped and doped with Li, Na, and P. Also, some of these layers were annealed in Se vapor, since such treatment is expected (9) to result either in better p-type material, or at least in more resistive n-type material. In general, the layers were high resistance, and it was not possible to measure a Hall effect. Probing results showed that some Li and Na doped layers were p-type, and that some undoped layers could be converted to p-type by Se annealing.[2] Results for one typical p-type sample (Na doped) are shown in Fig. 4. The straight lines extending over the bulk part of the sample were obtained by a least squares fit over the measured points.

[2] A more systematic investigation of the conditions which give p-type behavior is presently in progress. However, we believe that a problem in this respect is the role of impurities in providing compensation. See R. N. Bhargava, S. P. Herko, and B. J. Fitzpatrick, *Bull. of the Am. Phys. Soc.*, 24, 402 (1979); and G. F. Neumark, *ibid*, 24, 402 (1979); G. F. Neumark, To be published in *J. Appl. Phys.*, June, 1980.

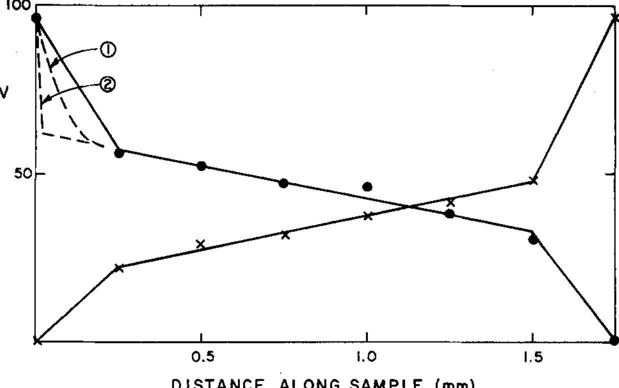

Fig. 4. Potential *vs.* distance along a sample of p-ZnSe(Na doped). The points correspond to a row of Au dots on the sample (0.25 mm apart). The circles denote voltage decreasing to the right, the crosses are for the opposite polarity, and the lines are drawn to connect the points (the actual barrier shape is not known since the doping is not known, see Eq. [1], [2]). The main potential drop is at the anode, denoting p-material. The dashed lines indicate the theoretical barrier shape (Eq. [1], [2]), with curves (1) and (2) for $(N_A - N_D) = 10^{12}$ cm^{-3} and 10^{14} cm^{-3}, respectively.

Similar measurements were also carried out at higher voltages (140, 190V). A least squares fit of current *vs.* bulk voltage gave the resistance between two Au dots as $2 \times 10^9 \Omega$. For an estimated layer thickness of $\sim$10 μm, and since for our Au dots the inter-dot spacing was comparable to the dot diameter, this leads to a resistivity $\sim 2 \times 10^6$ Ω-cm; assuming $\mu \sim 5$ cm²/Vsec, one obtains $p \sim 7 \times 10^{11}$ cm^{-3}. We have also plotted on Fig. 4 (dashed lines) the theoretical relation (Eq. [1], [2]) for $V(x)$ for $(N_A - N_D) = 10^{12}$ cm^{-3} and for $(N_A - N_D) = 10^{14}$ cm^{-3}. As can be seen, any value $(N_A - N_D) \gtrsim 10^{12}$ cm^{-3} fits the observed result—the probing with the present dot distances cannot differentiate. Note that we know only that $(N_A - N_D) \geqq p$, but do not know how much greater, so it may take an appreciable reduction in probing distance to evaluate $(N_A - N_D)$. Due to probing difficulties with smaller dot sizes, this aspect has therefore not been pursued. In any case, the resistivity and the barrier shape results are consistent with each other.

Overall, we have shown that for Schottky contacts the profiling method can be used to differentiate between n- and p-type material. Moreover, it has been successful on high resistance material on which Hall measurements could not be carried out.

Influence of Surface Damage on Stabilization Against Photodecomposition of n-Type GaAs*

Marc J. Madou, Karl W. Frese, Jr.,‡ and S. Roy Morrison

SRI International, Menlo Park, California 94025

Recently noteworthy progress has been made in the development of photoelectrochemical solar cells (1,2,3). However, a major difficulty remains, that is, the photocorrosion of desirable anode materials such as n-GaAs and n-Si. Ultimately, the goal is to make solar cells using polycrystalline materials, (4) and such materials will contain different defects. Simple theory suggests that defective areas of the crystal surface will be more difficult to stabilize. From an experimental point of view, it has not been clear what effects these defects will have on the photoelectrochemical corrosion process. Therefore an important objective of our work is to investigate the effect of dislocations and grain boundaries on the corrosion rate and stabilization efficiency. Before this can be done, however, suitable stabilizing agents must be identified. We report some of our results toward these goals, both the identification of stabilizing agents for GaAs and studies of the influence of defects on the stability of the GaAs. Measurements of conversion efficiencies of radiant energy to electricity and of the influence of surface treatment on those efficiencies are planned for the near future.

A rotating-ring-disc electrode was assembled using a n-GaAs disc and a ring that was made of either amalgamated copper or pure grade gold. The collection efficiency anticipated from the geometric parameters was about 36%. In practice an efficiency of 32% was obtained. This number was independent of rotation speed in a wide range and the most commonly used speed was around 1000 rpm. The etch used for the GaAs disc was H_2SO_4:H_2O_2:H_2O, (3:1:1 v/v) at 80°C. Until now, only the ($\bar{1}\bar{1}\bar{1}$)-face (As) was investigated. The GaAs disc was illuminated with chopped light (at a frequency of 1 Hz) from a 150-W xenon lamp. In the experiments reported, we used an aqueous solution containing $Fe(ClO_4)_2$ in 0.1 M EDTA.

The photoproduced holes coming to the surface of the GaAs disc can oxidize the Fe(II)-EDTA or can corrode the GaAs. The disc potential was always kept in the flat portion of the photocurrent-voltage characteristic (+ 0.8 V versus SCE). The ring voltage was maintained on the saturation portion of the reduction wave at -1.0 versus SCE. Thus Fe(III)-EDTA formed at the disc is reduced at the ring, and its presence is monitored. The stabilization is expressed as the ratio of the hole current that oxidizes Fe(II)-EDTA, i_{ox}, to the total ac hole current i_{photo} through the GaAs disc. The value of i_{ox} is determined by measuring the periodic component of the ring current and dividing by a collection-efficiency factor.

Figure 1 shows the effect of the pH on the percentage stabilization of the etched n-type GaAs for two different concentrations of $Fe(ClO_4)_2$ in 0.1 M EDTA. The pH was adjusted with either $HClO_4$ or NH_4OH. One region below pH = 2.5 is inaccessible because precipitation of EDTA occurs in such a solution. The light intensity was found to influence the percentage stabilization in such a way that higher light intensities gave lower percentage stabilization. Therefore all points given in Figure 1 were taken for the same disc current of about 1 mA/cm^2. Another important observation is that if the percentage stabilization was low, perhaps because of the presence of an oxide film, a cathodic current temporarily passed through the disc could result in the recovery of the initial higher percentage stabilization. The experiments in Figure 1 were always started after the disc had been held cathodic for a few minutes. Both the effect of light intensity and the effect of cathodic pretreatment will be dealt with in greater detail in another publication (5).

From Figure 1 it can be seen that for both concentrations and with the prevailing light intensities the stabilization is complete in the intermediate pH region. Within the accuracy of our apparatus, we concluded the stabilization is > 99% under these conditions. For hole currents of 1 mA/cm^2 the stabilization at both high and low pH

decreases rapidly. We note that the highest stabilization occurs where the oxidation products in Ga are most insoluble (6). This result is completely analogous to the one found in the stabilization of n-GaP with $Fe(CN)_6^{4-}$ (7). Although in this case we found that at lower light intensities in acid solution (e.g., 0.04 M Fe(II)-EDTA, pH = 3, 100% stabilization can be found.

Further investigation is required to fully explain this pH dependence of the percentage stabilization. Possible explanations are (1) a change in redox properties of the solutions with pH [in the case of Fe(II)-EDTA], (2) a shift in energy levels of the n-GaAs relative to the Fe(II)-EDTA level or (3) a change in electrode stability towards holes because of a thin oxide layer on the GaAs surface (8).

Figure 2 shows the effect of surface damage on the stabilization. In the figure we plot percentage stabilization versus concentration curve in 0.1 M EDTA at constant photocurrent and an intermediate pH. Since the disk current was lowered by the introduction of surface damage the light intensity had to be adjusted to maintain a constant photocurrent. Curve (a) was determined using well-etched samples and showed reproducible levels of stabilization as long as fresh solutions and freshly etched (e.g., 10-sec etch) electrodes were used. Curve (b) was determined on specimens etched and subsequently polished with 0.3-μm Al_2O_3 powder for 30 sec. This treatment may be assumed to introduce unspecified surface damage, primarily dislocations. We note that for conditions of constant concentration of Fe(II)-EDTA and photocurrent, the effect of surface damage is to lower the stabilization efficiency. We have also observed several times that if corrosion is allowed to proceed on such a damaged surface, the stabilization will recover with time, reaching a value characteristic of a damage-free surface in about 15 min. Curve (c) shows data taken with a more severely damaged electrode. This surface was prepared for successive polishing with Buehler 4/0 polishing paper, a 6-μm diamond paste, and 1-μm Al_2O_3 and 0.3-μm Al_2O_3 powders. Importantly, the sample was not etched before measurement. The results show that lower stabilization was obtained at all concentrations and that the highest Fe(II)-EDTA concentration was needed to reach values close to 100%. These results demonstrate that damaging single crystal surfaces leads to changes in the competition between oxidation of the redox component in solution and the crystal lattice.

These results show clearly that for well-etched single crystals, Fe(II)-EDTA is a good stabilizing agent for n-GaAs. We concluded that within the limitations of our ring-disc apparatus, the stabilization is > 99%. We observed a very distinct effect of the mechanical damage on the amount of stabilization; that is, the more damaged surfaces had lower percentage stabilization. Finally we observed a dependence of the corrosion on the light intensity and found that a cathodic current passage can produce large positive changes in the amount of stabilization of a semiconductor.

Preferential Etching of Boron-Doped Polysilicon Electrodes for CCD's

H. S. Gamble, N. E. Evans, and S. H. Raza

Department of Electrical and Electronic Engineering,
The Queen's University of Belfast, Belfast BT9 5AH, Ireland

The standard techniques for fabricating charge-coupled devices employ multiple layers of phosphorus doped polycrystalline silicon for the phase electrodes. Several oxidation steps are required and these result in an increase in the grain size of the polysilicon. Fine line structures are difficult to fabricate due to these large grains and the critical etching time of the polysilicon. The faster etch rate of phosphorus doped oxide can lead to problems with undercutting of the fine polysilicon electrodes during etch out of the masking and gate oxides. This problem can be overcome by using a nitride layer as part of the gate dielectric.

To avoid growth of large polysilicon grains and the critical nature of polysilicon etching it was decided to investigate the possibility of fabricating CCD's with boron doped polysilicon. The use of boron doped polysilicon and pyrocatechol etch avoids these problems. Bohg[1] has shown that ethylene diamine-pyrocatechol-water mixture will only etch silicon which has a boron concentration of less 5×10^{19} cm^{-3} and Nicholas et al[2] have used this property for producing fine polysilicon lines.

For polysilicon deposited at 620°C, in a furnace tube at atmospheric pressure and boron doped at 1000°C from a boron nitride wafer source, the maximum sheet resistivity of a 5000 A° layer that was unaffected by the pyrocatechol etch was found to be 65 $\Omega\square^{-1}$.

The effect of impurity type and post diffusion temperature cycles on the resultant grain size of our polysilicon layers was determined by transmission electron microscopy. The results given in Table 1 show that the average grain size of boron doped polysilicon is much smaller than that of phosphorus-doped polysilicon for both low and high temperature processing. All diffusions were carried out at 1000°C for 15 minutes and phosphorus oxychloride was used as the phosphorus source.

One disadvantage, however, of using boron doped polysilicon is the high diffusion rate of boron in SiO_2, especially in water vapour or hydrogen atmospheres.[3] To prevent boron from the first polysilicon layer diffusing through the oxide into the substrate during subsequent oxidation steps, a layer of silicon nitride is used as part of the gate dielectric. As stated above the use of a nitride layer also removes the problems associated with undercutting of the polysilicon.

TABLE I. POLYSILICON GRAIN SIZE

POST DIFFUSION TEMP. CYCLE	IMPURITY TYPE	AVERAGE GRAIN SIZE (A°)
55 min. 1150°C	UNDOPED	1,500
55 min. 1150°C	PHOSPHORUS	4,400
55 min. 1150°C	BORON	1,500
60 min. 1000°C	PHOSPHORUS	2,700
60 min. 1000°C	BORON	1,300

The fabrication sequence for producing four phase CCD's with two polysilicon layers is outlined in Fig 1 a-e. The process steps up to the deposition of the first polysilicon layer are the same as for standard four phase CCD's incorporating phosphorus doped polysilicon electrodes. A masking oxide is thermally grown and subsequently patterned to expose the polysilicon where the phase electrode is required (Fig 1b). The polysilicon is then boron diffused, the masking oxide removed and the wafer immersed in pyrocatechol. The polysilicon remaining is that which was boron diffused and is slightly wider than the original window in the masking oxide due to the lateral diffusion of the boron. (Fig 1c)

An isolating oxide is then thermally grown over the polysilicon electrodes and a second layer of polysilicon deposited. The second layer is patterned using the same techniques as for the first polysilicon

Keywords: Charge-transfer devices, pyrocatechol, silicon nitride, fine geometry structures

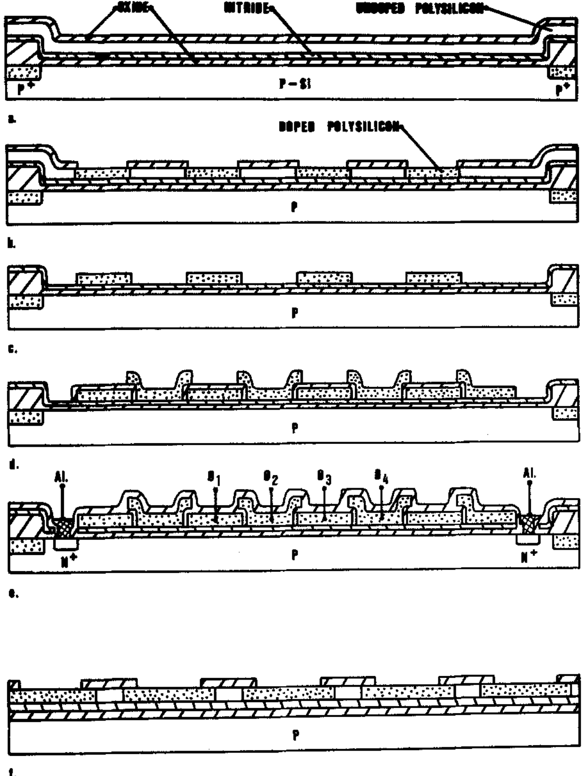

Fig 1. Processing sequence, incorporating a pyrocatechol preferrential etching technique for the fabrication of two layer polysilicon CCD's.

layer. (Fig 1d) It should be noted that since the masking oxide is removed before the second polysilicon layer is etched the isolating oxide covering the first polysilicon layer electrodes is not removed. This reduces the risk of polysilicon to polysilicon shorts at the overlap edges and aids aluminium coverage over polysilicon rails in the field region. The remaining steps in the device processing are as for conventional four phase CCD's. (Fig 1e)

The lateral diffusion of boron can be used to reduce the gap between the phase 1 and phase 3 electrodes of the first polysilicon layer. If the electrode gap on the photographic mask is of minimum dimension then the inclusion of a boron drive in stage, producing significant lateral diffusion, results in a very small electrode gap. (Fig 1g) The second polysilicon layer is patterned as before, without any drive in step, to produce a device with long storage wells under the electrodes of phases 1 and 3 and short transfer regions under the electrodes of phases 2 and 4.

The lateral spread of the polysilicon electrode, after an initial duffusion at 1000°C giving a sheet resistivity of 45 $\Omega\square^{-1}$, was found to have a square root dependence on drive in time and an exponential dependence on drive in temperature. (Fig 2) The etching time of the 5000 A° layer of polysilicon in pyrocatechol at 160°C was 30 seconds and no change was determined in the polysilicon electrode width after 400% over etching.

The resistivity of boron doped polysilicon is a factor of three higher than that of phosphorus doped polysilicon and the work function is increased by approximately one volt. A further increase in the resistivity of boron doped polysilicon is observed after oxidation in a water vapour ambient due to out-diffusion of boron.

Devices have been fabricated as outlined above on P-type <100> substrates of 25-50 Ω-cms. The gate dielectric consists of a 600 A° dry thermal oxide grown at 950°C and covered with a 900 A° layer of silicon nitride deposited at 850°C. The mask dimensions of the electrodes and gaps for the first polysilicon layer were equal at six microns. Various drive in times were then used to fabricate devices with electrode gaps on the first polysilicon layer ranging from one to five microns. The wafers were given a thirty minute hydrogen anneal at 500°C to reduce the fast state density. For a device with input gate and transfer electrodes of 2.5 μm the second harmonic content of the output, for sinewave input by the diode cut-off method, was 55 dB down. This value was obtained for signals of near maximum capacity using four phase double storage clocks of 10 volts.

A transfer region barrier could be provided, for two and pseudo single phase operation, by ion implanting boron through the small gap between the first polysilicon electrodes. (Fig 1g) The use of very short transfer regions enables almost 50% of the total CCD to be used for charge storage. This is particularly important for single phase operation where the charge handling capability is greatly reduced.

A processing sequence for the fabrication of four phase CCD's with boron doped polysilicon electrodes has been determined. It requires no critical etching steps as the fine grain polysilicon electrodes are patterned using a self-stopping etch. Neither gate dielectric nor isolating oxide is required to be etched out so problems associated with undercutting are virtually eliminated. The technique also allows very

short electrodes to be fabricated using standard photolithography for two and single phase CCD's.

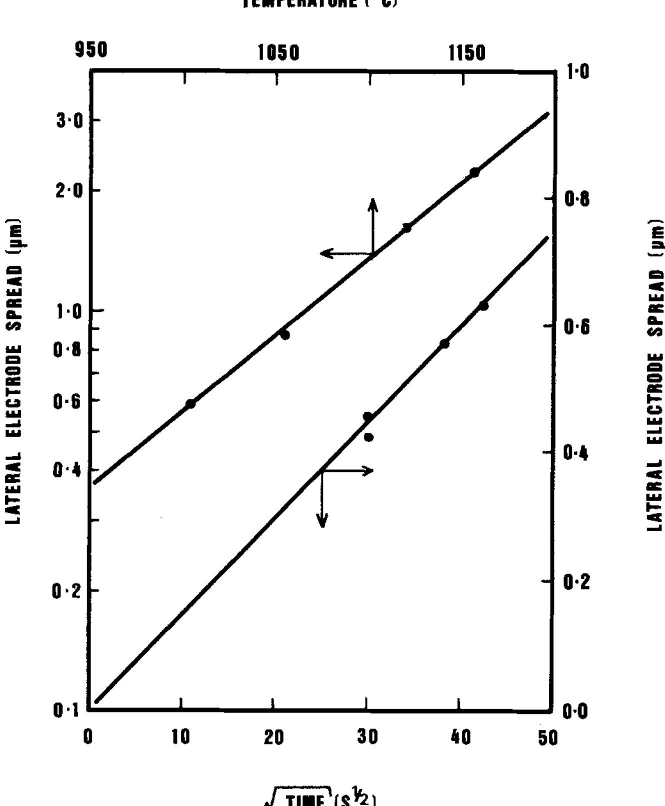

Fig 2. Lateral spread of polysilicon versus boron drive in time and temperature.

Index of Refraction of Steam Grown Oxides on Silicon

E. A. Taft*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

In a recent paper the indices of refraction of oxides grown on silicon in dry oxygen were reported.[1] The index was shown to depend upon the temperature of growth of the oxide. The purpose of this note is to show further results of ellipsometric measurements on a series of oxides grown in 95°C saturated water vapor.

As in the previous work[1] oxide films of about 1200A in thickness were grown on <111> and <100> lightly doped silicon wafers at several temperatures. The index of refraction of each oxide was measured on a Gaertner L119 ellipsometer. The data are shown in Fig. 1. These curves have the same general appearance as those of the oxides grown in dry oxygen. The index for both <111> and <100> decreases with increasing temperature until it reaches the minimum limiting value of 1.462, remaining constant thereafter. This value is the same as that for oxides grown in dry oxygen. This observation is consistent with the previous assumption that this index limit is associated with the properties of fused quartz. However, in the current case of wet oxidation this constant minimum index begins at the lower temperature of about 1025°C rather than the 1140°C found for the dry oxide. (These are the approximate intercept temperatures of the two straight line portions of the curves.) At these intercepts it may also be noted that there is no difference in the indices of oxides grown on either orientation of silicon used. The slopes of the rising index portions of the curves are slightly steeper for the steam-grown oxides than for the dry oxygen oxides; but at ∿750°C the dry oxides still have ∿0.3% higher indices. When a film grown on the low temperature slope of the curves is annealed in nitrogen at a temperature higher than that at which it was formed, it decreases in index (though never below the value for fused silica). The higher the annealing temperature the more rapidly does the index move to lower values. This observation might be compared with the results of Douglas and Isard[2]. Their studies on the density of fused silica give indications of the time constants expected for equilibrium densities to be obtained. More importantly they find the equilibrium density of silica to increase with temperature in the opposite sense to the behavior of our grown oxide films. This fact indicates that the high densities for films grown at lower temperatures are not directly related to the properties of fused silica.

The oxide structure is clearly influenced by the silicon lattice from which it was formed. At the lower temperatures the oxide retains some of this structure. High temperature annealing allows the oxide structure to relax toward fused silica equilibrium properties. The viscosities of vitreous silica have been measured by Hetherington et al.[3] The viscosity is not easily ascertained in silica as, for example, the glass structure changes with temperature and the previous thermal history of the sample must be considered. Metallic impurities and, especially, the water content of the silica are also important. The equilibrium viscosities reported for silicas of very low and of very high hydroxyl content may be viewed with the thought of comparison with the 1140°C and 1025°C temperatures found for our dry and our wet oxides which attain the index of refraction of silica. Hetherington et al.[3] show that IR Vitreosil glass must be heated to 1150°C in order to exhibit

a viscosity of 13.8 poise (near the defined annealing point of glasses), whereas Spectrosil samples need be heated only to 1025°C. These vitreous silicas contain the lowest and the highest hydroxyl amounts, respectively, of all their silicas tested. The Spectrosil appears to contain nearly the saturation value of water in silica[4] so that it would seem reasonable to compare it with our steam oxide. At least the temperature differences in the two cases to obtain the same viscosity is the same as the temperature difference for wet and dry oxides to attain the index of refraction of fused quartz or vitreous silica. The viscosity also seems to be an acceptable value for the growth times involved.

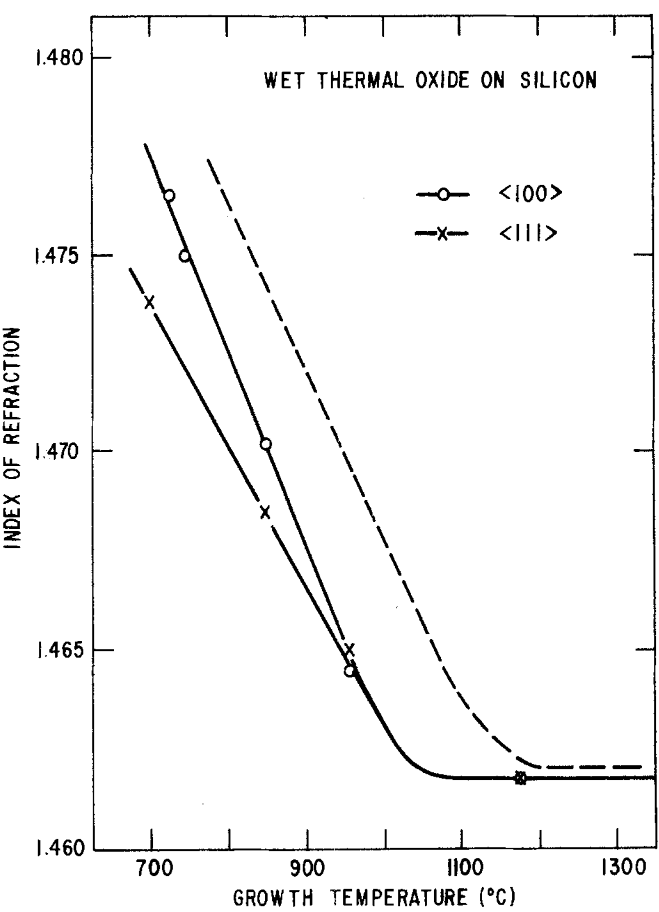

Fig. 1 Index of refraction of steam oxides grown on silicon crystal. The dashed curve is for a dry oxide on <100> silicon (Ref. 1).

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980, Japan

ABSTRACT

The electrochemical behavior of single crystal n-TiO_2 electrodes has been investigated in molten sodium tetrachloroaluminate ($AlCl_3$ + NaCl) at 175°C. The impedance and photoanodic current were measured as functions of electrode potential and of melt acidity specified by pCl(= $-\log a_{Cl^-}$). The flatband potential and the onset potential of photocurrent show pronounced pCl dependence with a variation rate of 2(2.3 kT/e) per unit pCl, and this anomaly has been ascribed to the specific adsorption of Cl^- on TiO_2. Characterization of the melt-oxide interface and the photoelectrochemical oxidation of Cl^- via adsorbed intermediates are discussed on the basis of semiconductor energetics.

Since titanium dioxide received great attention from the viewpoint of the photoassisted electrolysis of water by utilizing solar energy (1), a number of investigations on the photoeffect at various semiconductor electrodes have been reported (2). Naturally, most studies have been concerned with aqueous systems, although some nonaqueous organic solvents have been also used (3). However, there has been little work on the use of molten salt solvents with respect to semiconductor-liquid junctions. Recently, we reported the interfacial behavior of Sb-doped tin oxide electrodes in molten LiCl-KCl eutectic (4, 5) and in $AlCl_3$-NaCl melts (6). There are some advantages in the use of molten salts for studying semiconductor electrodes because of the absence of neutral solvent molecules in the melt systems. The absence of this molecular solvation may lead to reversible reactions, and to a simple double layer structure without a solvent dipole layer oriented on electrode surfaces.

Among a number of molten salt systems, sodium tetrachloroaluminate melts have some salient features; (*i*) noncorrosive, (*ii*) liquidus at relatively low temperature, (*iii*) a relatively wide potential span, and (*iv*) well-established acid-base character. The characterization of the acid-base property of this melt was a recent subject and now we have detailed knowledge on its acid-base chemistry, where tetrachloroaluminate ions, $AlCl_4^-$, act as chloride ion donors yielding Cl^- and $Al_2Cl_7^-$, and the melt acidity is specified by the quantity pCl (= $-\log a_{Cl^-}$) derived from the acid-base equilibrium (7-9). In the present work our effort was mainly focused on characterizing the interfacial property between the melt and oxide. Thus we undertook to measure the photocurrent and differential capacity on single crystal n-TiO_2 electrodes in the melt of various pCl at 175°C. In connection with this study we will also present a photoelectrochemical process in the melt system.

Experimental

The sodium tetrachloroaluminate melt was prepared from the AR grade $AlCl_3$ and NaCl. The melt purification was carried out by employing sublimation, Al-displacement, and preelectrolysis as reported previously (6).

The reference electrode was a coiled Al wire (1 mm diam, 99.99%) immersed in the chloroaluminate melt saturated with NaCl, and the counterelectrode was W foil. Both of them were separated from the bulk of melt with fine fritted disks.

A Ψ-shaped Pyrex cell equipped with an electrode mount at the bottom is illustrated in Fig. 1. The cell assembly was set in a Pyrex container placed in a vertical electric furnace. The bottom of the cell was designed to have a flange with an optically flat surface, to which a disk of single crystal TiO_2 was attached via a Teflon O-ring. Construction details of the mount is shown in Fig. 1(B). An electrical contact to the electrode was made at the back side by alloying indium solder.

The disk of TiO_2 was reduced in a vacuum at 800°C for 1 hr to improve the bulk conductivity, then it was polished to a mirror finish with fine alumina powder (~0.3 μm, Buehler Limited) on a wetted polishing cloth. Before the experiments, the electrode surfaces were chemically etched with CP4.

The assembled cell was evacuated in a container and then the purified melt was transferred into the cell under a dry nitrogen atmosphere. Experimental procedures for capacity measurements and the adjustment of pCl were described elsewhere (6).

In measurements of photocurrent the electrode surfaces were illuminated from the top with a 100W mercury lamp as illustrated in Fig. 1. A Nihon Bunko CT-25N monochromator was used for measurements of photocurrent spectra. All the experiments were carried out at 175° ± 2°C under a dry N_2 atmosphere. Electrode potentials in this work are given with respect to the Al electrode in the melt saturated with NaCl.

Results and Discussion

Background characteristics.—Typical background cyclic traces of a TiO_2 electrode obtained in the melt of pCl = 1.1 in dark is shown in Fig. 2, being compared with the behavior of a SnO_2 electrode reported in the previous work (6). The anodic limit of the melt is

chlorine evolution, which occurs at potentials positive to 2.15V *vs.* Al at 175°C (7). The increase of anodic current at SnO_2 is due to chlorine evolution as described in our comparative study on chlorine evolution at SnO_2 and glassy carbon electrodes (10). In comparison with the SnO_2 electrode, it is noted that the chlorine evolution on the TiO_2 electrode is quite irreversible in dark, no detectable chlorine evolution taking place even at 3.0V *vs.* Al.

Anodic photocurrent.—When electrons at electrode surfaces of TiO_2 are depleted at potentials positive of the flatband potential, illumination of the light with higher photoenergies than the bandgap produces anodic photocurrent induced by the generation of holes. In aqueous solutions this is the case leading to oxygen evolution which was reported by Fujishima and Honda (1). The photoeffect observed at the melt/TiO_2 interface is shown in Fig. 3. The photocurrent begins to increase at a more negative potential than 2.15V which is the thermodynamic reversible potential of Cl^-/Cl_2 at $pCl = 1.1$ (7). The reverse potential scan shows a current peak at 1.5V, which is presumably due to the reduction of the product accumulated at the interface during the anodic photoprocess.

Anodic processes responsible for the photocurrent in this melt containing Cl^- ions are chlorine evolution and/or the decomposition of TiO_2

$$2Cl^- + 2h^+ = Cl_2 \quad [1]$$

$$TiO_2 + 4Cl^- + 4h^+ = TiCl_4 + O_2 \quad [2]$$

Therefore, it is necessary to know whether TiO_2 electrodes in the melt are stable under illumination or not. Many investigators discussed the stability of semiconductors for photodecomposition on the basis of the energetics to semiconductor electrodes (11). According to them, competitive oxidation reactions which are located at potentials negative of the photodecomposition potential ($E°_{decomp}$) can effectively stabilize the semiconductor. In order to check this stabilization effect, we calculated the thermodynamic potential difference between [1] and [2] at 175°C using JANAF Table. Since $E°_{decomp}$ of TiO_2 was shown to be positioned at 0.4V more positive potential than that of [1], the preferable photoprocess must be chlorine evolution which occurs much faster than the photodecomposition. A postulated surface band, which will be described later, can also assist the stability of TiO_2 photoanodes in the melt.

Since the sodium tetrachloroaluminate melt has an excellent optical window with 200 nm cutoff (12), the photocurrent measurement is not disturbed by the bulk adsorption. In our experimental setup, however, the light source was too remote from the electrode surface to supply sufficient light intensity. Thus, we unfortunately failed in having chemical confirmation that the product under illumination was chlorine, because of small photocurrent. However, there were several indications suggesting the chlorine evolution. In the melt saturated with chlorine gas, the reduction wave for chlorine was observed in dark at the same potential region as Fig. 3. It may be noteworthy in this context that the photodecomposition products, $TiCl_4$ and O_2, are not reduced at 1.5V; the reduction potential of $TiCl_4$ is more negative than 1.5V (13) and oxygen seems to be electrochemically inactive. Additionally, the TiO_2 electrodes used in the melt showed no visible attack on the surfaces. Consequently, we

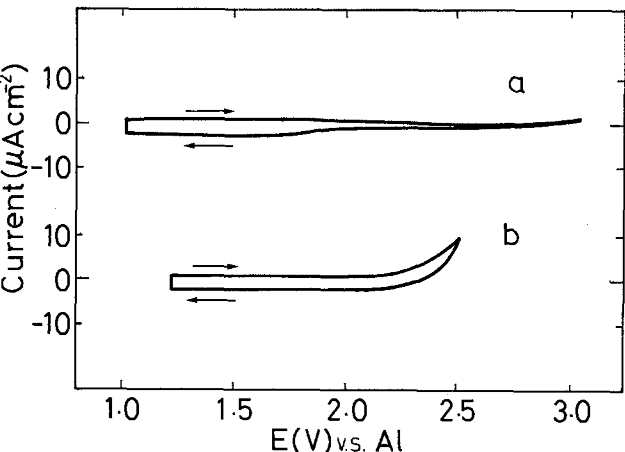

Fig. 2. Background cyclic traces for (curve a) TiO_2, and (curve b) SnO_2 electrodes in molten sodium tetrachloroaluminate ($pCl = 1.1$) at 175°C in dark. $V = 0.02$ V/sec.

believe that the anodic photocurrent is due to chlorine evolution and the cathodic wave is due to the reduction of Cl_2.

The photocurrent spectrum is shown in Fig. 4. Since the light intensity obtained through a monochromator was very weak, we had to use relatively large exit slit (2 mm) of the monochromator to obtain measurable photocurrent. Accordingly, the wavelength accuracy was questionable throughout the spectral region, where the light intensity is shown in Fig. 4c. For convenience' sake, we compared the apparent spectrum obtained in the melt with that in an aqueous 1*N* H_2SO_4 solution (Fig. 4b) where the photoprocess is oxygen evolution. Because both experiments were carried out with an identical condition of illumination by using the same electrochemical cell, the agreement of the spectra indicates that the photoelectrochemical process in the melt has essentially the same wavelength dependence with that in the aqueous solution, suggesting that the photoelectrolysis of the melt proceeds by consuming the photogenerated holes. It is also obvious from Fig. 4 that the process in the melt takes place with a comparable efficiency with the oxygen evolution in the aqueous solution.

The tetrachloroaluminate melts have the acid-base equilibrium expressed by the following equation

$$2AlCl_4^- = Cl^- + Al_2Cl_7^- \quad [3]$$

changing the melt composition therefore results in a change in the activity of Cl^- (7-9). With an analogy to the definition of *p*H, the activity of Cl^- is related to *p*Cl, *i.e.*, $pCl = -\log a_{Cl^-}$; for example, $pCl = 1.1$ in the melt saturated with NaCl (basic melt), $pCl = 2.5$ at equimolar composition (neutral melt), and $pCl > 2.5$ in acidic melt. Figure 5 shows the dependence of the photocurrent on *p*Cl, indicating that the onset potential of photocurrent shifts towards the positive direction with increasing *p*Cl. If the flatband potential does not depend on *p*Cl, the onset potential would be identical regardless of *p*Cl values. Thus the observed dependence strongly suggests that the location of flatband potential shifts towards the positive direction with increasing *p*Cl.

Flatband potential.—It might be necessary to mention briefly the double layer structure in melt systems,

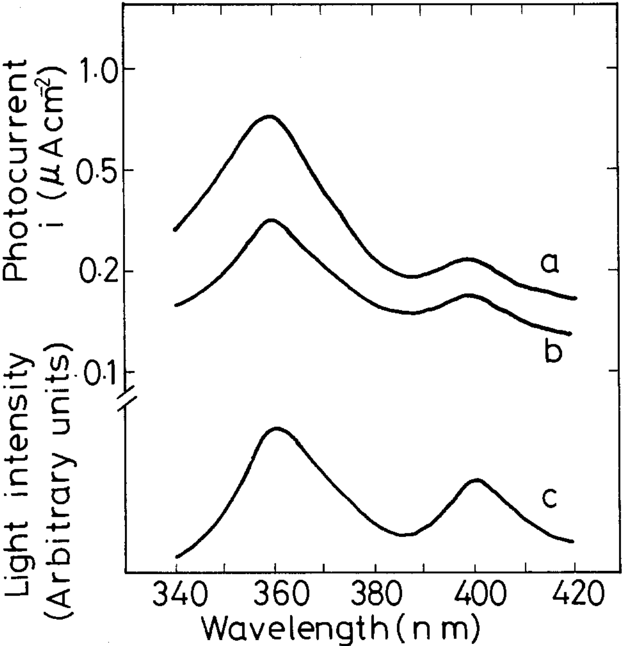

Fig. 4. Photocurrent spectra for TiO_2 electrode at constant potential. Curve a, In molten sodium tetrachloroaluminate ($pCl = 1.1$) at 175°C, $E = 3.0V$ vs. Al; curve b, in 1*N* H_2SO_4 at room temperature, $E = 2.0V$ vs. SCE; curve c, light intensity at the monochromator exit (2 mm slit width).

because our knowledge is rather limited to that in aqueous systems. The potential distribution at the semiconductor/melt interface may be schematized like Fig. 6. The surface potential (ψ_s) is related to the space charge capacity of the electrode side (C_{sc}), which is given by the well-known Mott-Schottky equation (14), while ψ_H is related to the double layer capacity of the melt side (C_H). According to the multilayer model proposed to melt systems (15), the double layer of the melt side is highly compressed because of their high ionic strength. The excess charge is located several ionic layers deep, the layers being alternately negatively and positively charged. Thus ψ_H is regarded as the potential drop across the multilayer where the greater part of the potential drop is imposed on the two charged layers, *i.e.*, the inner layer in contact with the electrode surface and the outer layer at the melt side. In the ordinary sense of the double layer concept, ψ_H is the potential drop inside the compact double layer.

Both capacities, C_{sc} and C_H, are combined in series, where C_H is much larger than C_{sc} as noted in the previous paper (6). Therefore, the measured capacity closely approximates to C_{sc}. The electrode potential (E) is the sum of the interfacial potential differences, and the flatband potential (E_{FB}) is defined as [5] because ψ_s equals zero at the flatband situation

$$E = \psi_s + \psi_H + \text{constant} \quad [4]$$

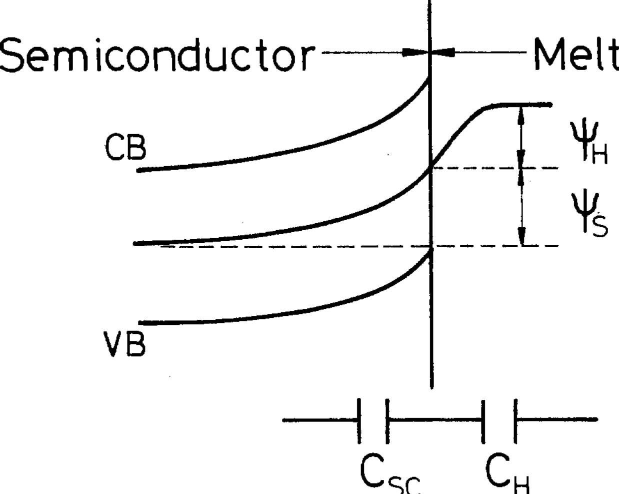

Fig. 6. Potential distribution and equivalent circuit for the semiconductor-melt interface.

$$E_{FB} = \psi_H + \text{constant} \quad [5]$$

If ψ_H is independent of E, ψ_s is replaced with $E - E_{FB}$. This assumption means that the applied potential drops inside the space charge layer. Then the reciprocal square of measured capacity becomes a linear function of electrode potentials which is known as the Mott-Schottky relationship

$$1/C^2 = (2/\epsilon\epsilon_0 e N_d)(E - E_{FB} - kT/e) \quad [6]$$

where e is the electronic charge, N_d the carrier concentration, ϵ the dielectric constant, and ϵ_0 the permittivity of vacuum.

The flatband potential obtained from this relationship has a special meaning; it is the zero charge potential with respect to the electrode. From [5] it is easily shown that a shift of E_{FB} relative to a constant-potential reference electrode is related to a change in the potential distribution of the double layer

$$\Delta E_{FB} = \Delta\psi_H \quad [7]$$

For a given electrode, $\Delta\psi_H$ may be brought about by changing the melt composition, *i.e.*, by changing pCl values.

Mott-Schottky plots for TiO_2 electrodes in the melts with different pCl values were constructed from capacitance data measured at 1 kHz with a phase-sensitive detector. Typical plots at different pCl are shown in Fig. 7, where the capacity is the equivalent series capacity converted from the electrode admittance. In agreement with the shift of the onset potential of photocurrent, the Mott-Schottky plots were found to move towards the positive direction with increasing pCl. Although the plots were observed to deviate from linearity as they approached to E_{FB}, the E_{FB} were determined by extrapolation of the linear parts and the carrier concentrations were obtained from the slope. In the calculation of N_d the dielectric constant of TiO_2 at 175°C is needed, but the exact value is not known. The data of the temperature dependence are available only for sintered polycrystalline rutile (16), indicating that the temperature coefficient is negative at temperatures below 120°C and becomes positive at higher temperatures. Taking into account this temperature dependence (16), it is considered that the ϵ value at 175°C is not considerably different from the ϵ at room temperature (= 172°C). The N_d of this specimen measured in an aqueous 1N H_2SO_4 at room temperature was 3.0×10^{19} cm^{-3}, being in good agreement with the N_d (= 3.8×10^{19} cm^{-3}) calculated from the slope of Fig. 7 and the above ϵ value. Thus there is no inconsistency in our analysis of capacity data based on the Mott-Schottky relationship.

The pCl dependence of E_{FB} is shown in Fig. 8 together with that of the onset potential of photocurrent. The E_{FB} shows a positive shift of 230 mV per unit pCl. Correspondingly, the onset potential of photocurrent moves to the positive direction with a variation rate of about 160 mV per unit pCl. In the case of SnO_2 electrodes in the same system, the variation rate is 170 mV as reported previously (6). Since $2.3(kT/e)$ is 89 mV at 175°C, the observed pCl dependence $(\partial E_{FB}/\partial p\text{Cl})$ is close to two times of $2.3(kT/e)$. It is uncertain whether or not the somewhat large deviation from 178 mV/pCl is real in the case of TiO_2. The deviation appeared to increase in more acidic melts (pCl > 2.5) which may suggest some electrode instability at high pCl or may suggest a change in the type of ions adsorbed on the TiO_2 surface. An interesting feature of the Mott-Schottky plots is that the E_{FB} shifts to negative potentials with increasing the activity of Cl^- and its variation rate is close to $2(2.3\ kT/e)$ per one decade of the activity change. The pCl dependence of the onset potential of photocurrent is regarded as a quantitative confirmation of this feature.

Specific adsorption of Cl^-.—The well-known pH dependence of E_{FB} in aqueous systems, $\partial E_{FB}/\partial p\text{H} = 2.3\ kT/e = 59$ mV, is explained in terms of the change in the potential distribution across the dissociation double layer, which is caused by the acid-base equilibrium between the surface hydroxyl groups and bulk H^+ ions (17). The observed pCl dependence is, however, two times as large as the pH dependence, and cannot be explained quantitatively with the analogous acid-base concept. As suggested in the previous study on SnO_2 electrodes (6), this anomalously large variation rate can be ascribed to the discreteness-of-charge effect of specifically adsorbed Cl^- ions. According to the Esin-Markov effect (18), the point of zero charge (E_{pzc}) shifts towards increasingly negative potentials for anion specific adsorption and varies linearly with the logarithm of the anion concentration.

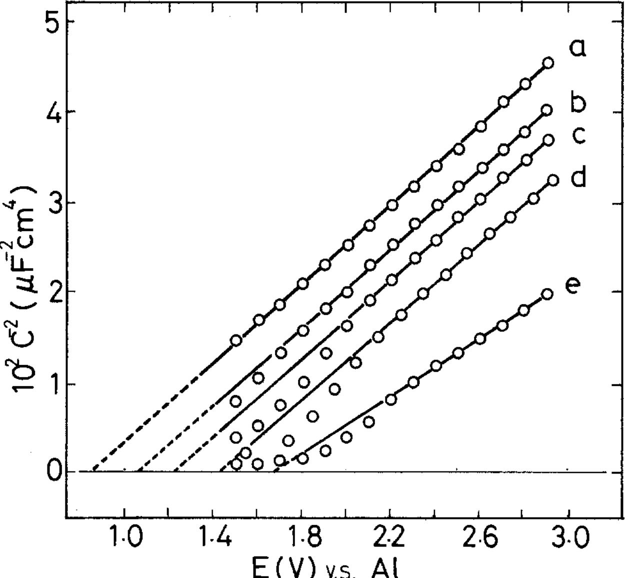

Fig. 7. C^{-2} vs. potential plots for TiO_2 electrode in molten sodium tetrachloroaluminate of various pCl at 175°C. f = 1 kHz. Curve *a*, pCl = 1.1; curve *b*, pCl = 2.0; curve *c*, pCl = 2.7; curve *d*, pCl = 3.5; curve *e*, pCl = 4.1.

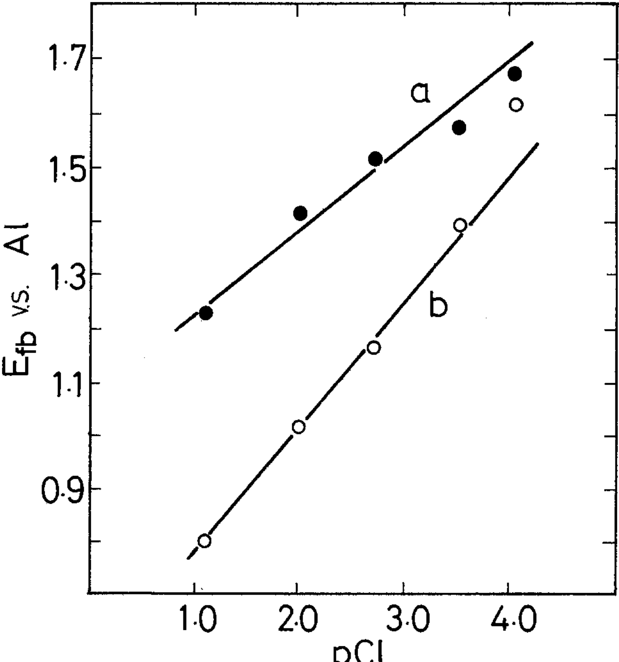

Fig. 8. pCl dependence of (curve *a*) the onset potential of photocurrent, and of (curve *b*) the flatband potential for TiO_2 electrode in molten sodium tetrachloroaluminate at 175°C.

The variation rate is reported to be about 100 mV at room temperature, *i.e.*, $\partial E_{pzc}/\partial \log a_{x^-} \simeq 2(2.3\,kT/e)$ (19).

As discussed in the preceding section, the shift of E_{FB} reflects the change in the potential difference across the compact double layer present at the melt-oxide interface. When the first ionic layer in contact with the oxide surface consists of Cl^- ions, these anions populated on the surface are regarded as specifically adsorbed anions because there is no solvation layer present on the surface in this case. In addition, the original oxide surface which is covered with surface =O (or —OH) groups must be considerably modified with the anions. Considering that $AlCl_4^-$ are oxide ion acceptor (20), the TiO_2 surface may be subjected to the following chemical change

$$TiO_2 \left|\, =O \xrightarrow{Cl^-,\, AlCl_4^-} TiO_2 \,\right| \begin{matrix} -Cl \\ Cl^- \end{matrix} \quad [8]$$

where the surface =O are replaced by chemically bonded —Cl groups, and the specifically adsorbed Cl^- are present at vacant sites available for coordination. It is likely that the first ionic layer takes a hexagonal array, where some of constituents are chemically bonded —Cl and the others are Cl_{ad}^- with negatively charged states. Thus the discreteness-of-charge effect is expected to influence the potential distribution between the first and the second ionic layers, and may result in the anomalous dependence of E_{FB} on pCl. With the analogy to the compact double layer theory developed in aqueous systems (21), the quantity $\partial E_{FB}/\partial p\mathrm{Cl}$ corresponds to the Esin-Markov coefficient at zero surface charge.

Hole transfer at the melt-oxide interface.—As shown in Fig. 3, the product of photo-oxidation is reduced at potentials considerably positive of E_{FB}. It was shown separately that dissolved chlorine in the melt is also reduced at TiO_2 electrodes in dark. The occurrence of reduction at potentials positive of E_{FB} strongly suggests the participation of surface states or an intermediate band in the electron transfer process as discussed by Bard *et al.* (3). Judging from the occurrence, the upper edge of the surface levels extends towards the conduction band, but its exact position is uncertain. The presence of the levels at the middle of bandgap is also suggested by the discrepancy between the onset potential of photocurrent and the flatband position, as noted in Fig. 8. When the band bending is relatively weak, these states must be more effective in the recombination of photogenerated hole-electron pairs, *i.e.*, the back-reaction, rather than in the electron capturing from the melt side species.

Shub *et al.* studied chlorine evolution on TiO_2 photoanodes in aqueous solutions containing Cl^- ions (22), suggesting that the photo-oxidation mechanism consists of two elementary reactions involving adsorbed intermediates; the hole-capturing reaction by adsorbed Cl^- and the following recombination reaction of adsorbed Cl radicals. Taking into account the specific adsorption of Cl^- at the melt-oxide interface, similar reaction scheme can be applicable to this system

$$Cl_{ad}^- + h^+ \rightleftarrows Cl_{ad} \quad [9]$$

$$2Cl_{ad} + 2Cl^-(\text{melt}) \rightarrow 2Cl_{ad}^- + Cl_2 \quad [10]$$

The energy levels of Cl_{ad}^- may be distributed below $E^\circ_{Cl^-/Cl_2}$, while the levels of Cl_{ad} must be positioned above $E^\circ_{Cl^-/Cl_2}$. In the case of strong adsorption the electronic energy levels of adsorbates are practically part of the electron system of the electrodes, and both energy levels will come much closer with increase of the adsorption interaction, approaching the range of the standard potential of the redox couple, as described by Gerischer (23). Thus a surface band consisting of the levels of the intermediates is placed tentatively near $E^\circ_{Cl^-/Cl_2}$ as shown in Fig. 9, which is

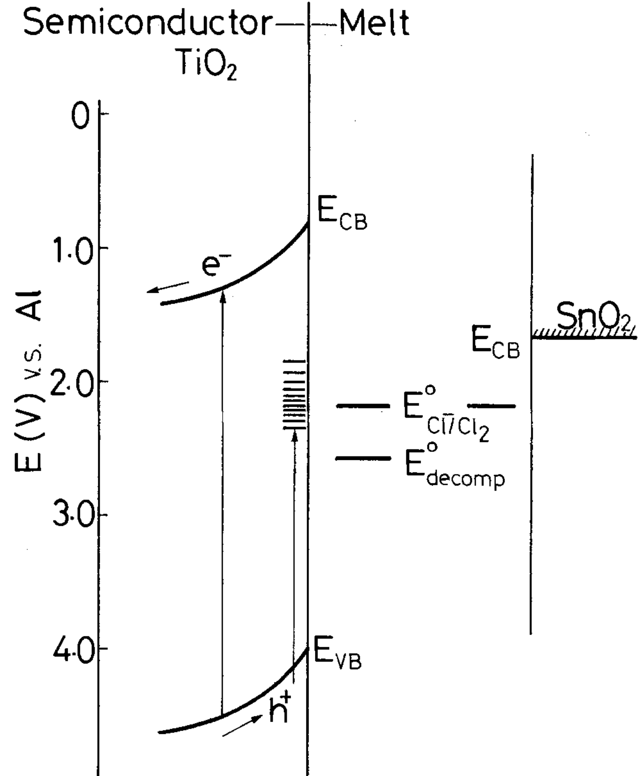

Fig. 9. Schematic energy diagrams for TiO_2 ($N_d = 3 \times 10^{19}$ cm^{-3}), and SnO_2 ($N_d = 7 \times 10^{19}$ cm^{-3}) electrodes in molten sodium tetrachloroaluminate (pCl = 1.1) at 175°C. The flatband position of SnO_2 is presented for comparison.

a schematic representation for the energetic relationship of the melt-TiO_2 interface obtained from the results of pCl = 1.1. The flatband position of n-SnO_2 at the same pCl taken from the previous work (6) is presented for comparison. We feel that the intermediate surface band noticed in the above section is associated with the specific adsorption of Cl^- on TiO_2. The hole transfer under illumination can take place via the surface levels of Cl_{ad}^-, and the yielded radicals either recombine each other or accept the electrons from the melt side Cl^- to evolve chlorine.

Safety Studies on Li/SO_2 Cells

III. Differential Thermal Analysis of Miniature Li/SO_2 Cells

A. N. Dey*

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The differential thermal analysis (DTA) of miniature Li/SO_2 cells made with several design variables including separator material, organic solvent, and electrolyte salts were carried out with fresh, discharged, force-discharged (reversed), and charged cells. The observed thermal transitions were successfully identified by comparing these with the transitions observed in the DTA of cell constituents. The method appears to be a useful tool in studying the thermal runaway process of the Li/SO_2 cells.

Although the state-of-the art hermetically sealed high rate D cells were found to be exceedingly abuse resistant (1-5) we carried out a detailed study in order to gain increased understanding of the thermal runaway process of the Li/SO_2 cells in an effort to make the cells safe under all possible use and abuse conditions. We carried out differential thermal analysis of the cell constituents in order to identify the possible exothermic reactants which could initiate and/or propagate a thermal runaway process in a Li/SO_2 cell and reported earlier (6). In this paper we have attempted to augment the above DTA studies by doing the DTA of the actual Li/SO_2 cells themselves.

We chose to use a miniature spirally wound Li/SO_2 cell instead of the LO26 cells (D size). The design of the miniature cell was such that it reflected the behavior of the larger D size cell insofar as the heat generation characteristics are concerned. The purpose of these DTA studies is to determine the heat generation characteristics of the actual Li/SO_2 cells and compare them with the behavior predicted from the DTA studies of the cell constituents as well as to determine the effect of some of the cell design variables on the heat generation characteristics of the Li/SO_2 cells. The cell design variables studied were: separator material (porous polyethylene and glass), electrolyte salt (LiBr and $LiAsF_6$), and organic solvent (AN and PC + AN). The experimental details and the results are presented here.

Experimental

Miniature Li/SO_2 cell.—The cross-sectional view of the miniature Li/SO_2 cell is shown in Fig. 1. The cell was made in a nickel-plated cold rolled steel can, 0.302 in. diameter and approximately 1.5 in. high. The cell top consists of a G/M seal having a tantalum tube feed through which serves both as the positive terminal and as electrolyte fill port. The G/M seal was welded to the cell can. The cell bottom has a thermocouple well for the measurement of internal temperature. The cell was made with spirally wound electrodes: 1.2 in. × 1.3 in. × 0.012 in. cathode; 1.2 in. × 1.4 in. × 0.005 in. Li anode. The carbon cathode had an expanded aluminum current collector, but the Li anode did not have any current collector. The cells were filled with electrolyte having 70% SO_2 by weight. The fill tube was welded shut after the cell filling. The cells were made with the following variables:

Separator:	porous polypropylene, (celgard) (standard) glass filter paper
Electrolyte salt:	LiBr (standard) $LiAsF_6$
Organic solvent:	AN (standard) PC + AN (1:1)

DTA fixture.—A cross-sectional view of the DTA fixture is shown in Fig. 2. It consists of an aluminum heating block having two cavities for the reference and the sample miniature cells. The differential thermocouples are inserted into the thermocouple wells (of the

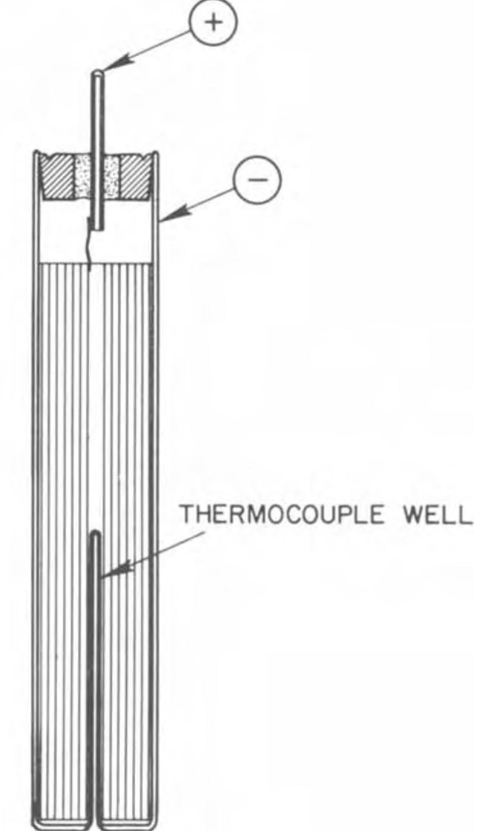

Fig. 1. Cross-sectional view of the miniature Li/SO_2 cell

cells) by means of heat-transfer compounds. The heating elements were wrapped around the aluminum block which was insulated all around by means of fiber glass. The heating block itself served as the negative terminal of the sample cell and the positive terminal was carefully insulated from the aluminum heating block. The DTA runs consisted of heating the aluminum block at a fixed rate from room temperature to a maximum of 250°C and monitoring both the block temperature as well as the differential temperature on a strip chart recorder. The open-circuit voltages of the cells were also monitored during the DTA run. In some experiments the differential temperature of the cell was monitored during discharge, reversal, and charging of a cell.

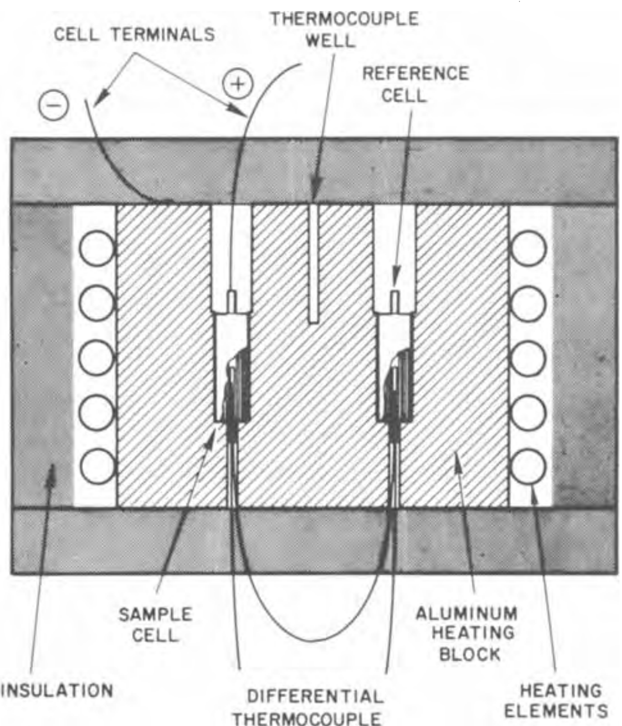

Fig. 2. Fixtures for DTA of miniature cell

Results and Discussion

The miniature cell was designed to reflect the thermal characteristics of the larger LO26S (D size) cells with the exception that the potential explosive energies involved would be substantially lower and hence less destructive of the available DTA fixtures. The electrochemical heat evolved per unit volume, as measured by the current density (i), over voltage (η) and the cell volume, turned out to be 9.1 $(i\eta)_L$ W/cm^3 for the LO26S cells and 11.5 $(i\eta)_S$ W/cm^3 for the miniature cell. Thus, if the cells are discharged at comparable current densities where they would experience comparable overvoltages, the heat evolution per unit volume would be approximately the same for the two cells and so would their thermal excursions under adiabatic conditions.

The miniature cells delivered 227 mA-hr at 1 mA and 180, 210, 180, and 180 mA-hr at 10 mA when discharged at 25°C. At −30°C, the cells delivered 90, 83, and 97 mA-hr at 90 mA to a cutoff voltage of 2.0V. A 90 mA current for the miniature cell corresponds to approximately 2A for the LO26S cells, in terms of equivalent current density.

DTA runs with two empty cell cans and with two cell cans filled with Al_2O_3 showed no transitions as expected. DTA runs with two fresh cells also showed no transitions. Cell cans filled with Al_2O_3 were chosen as a reference for all further DTA runs.

Altogether four different types of cells were tested. These will be referred to as (*i*) standard cells, (*ii*) cells with PC (propylene carbonate), (*iii*) cells with glass filter paper separator, and (*iv*) cells with $LiAsF_6$ electrolyte salt.

Almost all the DTA experiments were done in triplicate and the results were found to be quite reproducible.

Standard cells.—The standard cells contained 0.005 in. thick Li anode, 70% SO_2 + 7% AN (acetonitrile) + 23% LiBr electrolyte, and porous polypropylene (celgard) separator. The stoichiometric ratio of Li:SO_2 was approximately 1:1.3 based on the cell reaction

$$2Li + 2SO_2 \rightarrow Li_2S_2O_4 \quad [1]$$

The cells were discharged at currents of 1, 10, and 90 mA at 25°C and then these were subjected to DTA runs by heating from 25° to 170°C. The differential thermocouple showed one small exothermic transition starting at temperatures of 150°C. A typical thermogram is shown in Fig. 3. There was no significant effect of the discharge current on the size of this exotherm, although the exothermic transition was somewhat smaller for a partially discharged cell. The exothermic transition is attributed to the exothermic decomposition of the discharge product $Li_2S_2O_4$. However the upper limit of the temperature of the DTA run was too low for most of the other exothermic reaction. The sharp lowering of the open-circuit voltage of the cell at temperatures of 140°C was probably due to the formation of shorts in the cell after melting of the polypropylene separator.

Miniature cells were force-discharged to reversal at 25° and −30°C in triplicate. One typical plot of the cell voltage, differential temperature, and the aluminum block temperature during the cell discharge is shown in Fig. 4. The differential temperature increased sharply at the point of the cell polarization. The block temperature was increased only slightly. The cell was at reversal for only 0.75 hr corresponding to a capacity of 67.5 mA-hr. There was no cell

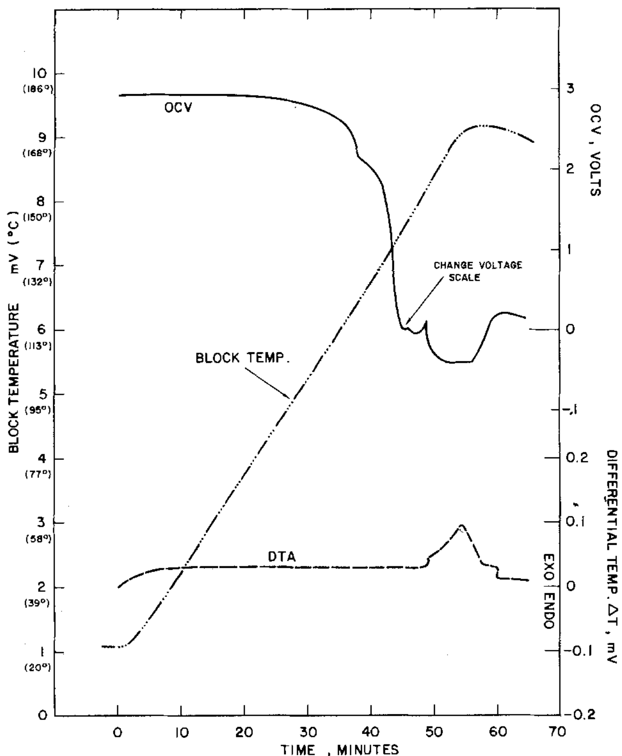

Fig. 3. Thermogram of a discharged miniature Li/SO_2 cell of standard construction. Discharge current 1 mA; discharge capacity 193 mA-hr.

venting or explosion. The cell was then subjected to a DTA run. The thermogram, as shown in Fig. 5, has two strong exothermic peaks very similar to those observed in thermograms of mixtures of powdered Li and $Na_2S_2O_4$ (analogous to $Li_2S_2O_4$). The first exotherm was attributed to the decomposition of $Li_2S_2O_4$ to produce S and the second one was most likely due to the Li + S reaction. Li + AN reaction may also occur simultaneously in view of the lower concentration of SO_2. The similarity of the thermograms of actual cells with that of the synthetic mixtures of chemicals, done earlier, supports our conclusions regarding the identification of chemicals responsible for thermal runaway of Li/SO_2 cells. In the cell, $Li_2S_2O_4$ is formed during discharge and Li is formed during the reversal in the cathode. The presence of Li enhanced the exothermic caloric output of $Li_2S_2O_4$ as observed earlier (6) in DTA experiments with cathodes as well as in synthetic mixtures. A second DTA run with the same cell showed virtually no exothermic transition indicating that the active constituents (Li and $Li_2S_2O_4$) had reacted almost completely during the first DTA run, similar to our observations on $Li/SOCl_2$ cells (7).

The intensity of the exothermic transitions of the cells which were reversed appeared to be independent of the temperature at which the reversal occurred but dependent on the extent of reversal. Prolonged reversal produces more Li in the cathode than a short reversal and this leads to the increased caloric output as observed (6) in the thermograms of mixtures of Li + $Na_2S_2O_4$.

Miniature cells were also charged at 90 mA for 7 hr without any cell explosion. The DTA thermogram of the charged cell is shown in Fig. 6. Note that there is a small endotherm at 180°C most likely indicating the melting of Li. The strong exotherm above 200°C indicates the Li + AN reaction in the presence of excess SO_2 which protects Li from reaction with AN at a lower temperature. Since, the cell was not discharged, there was no strong exotherm corresponding to the decomposition of $Li_2S_2O_4$, although some $Li_2S_2O_4$ may have formed by chemical reaction with the dendritic Li formed on the anode during charging. Again, the thermograms of the cells appeared to be interpretable based on the DTA results of the individual chemicals. A repeat DTA run of the above cell showed considerably reduced exothermic transitions indicating the consumption of the active materials during the first run.

Cells with PC.—These cells have the same size electrodes as the standard cells, only the electrolyte consists of 70% SO_2 + 23% mixture of AN and PC (3:1) + 7% LiBr. The thermogram of a discharged cell, as shown in Fig. 7, was found to be identical to that of the standard cell. Note that the upper limit of the temperature was only 170°C. The voltage and the differen-

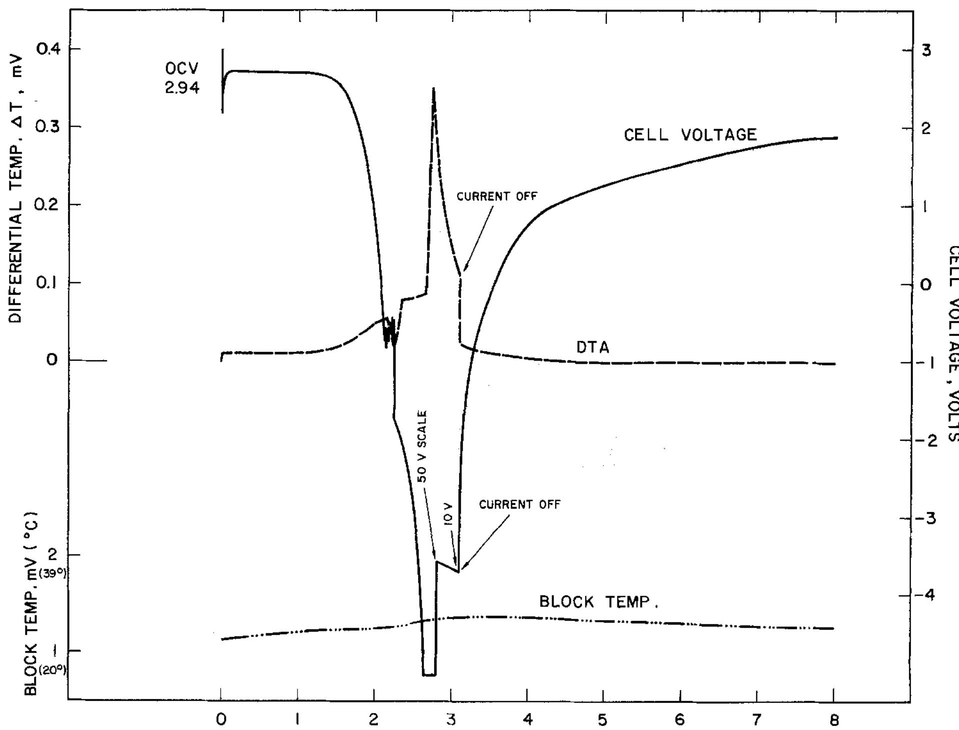

Fig. 4. Voltage, differential temperature, and the block temperature profiles of a Li/SO_2 miniature cell of standard construction during discharge and force-discharge at 25°C at a current of 90 mA.

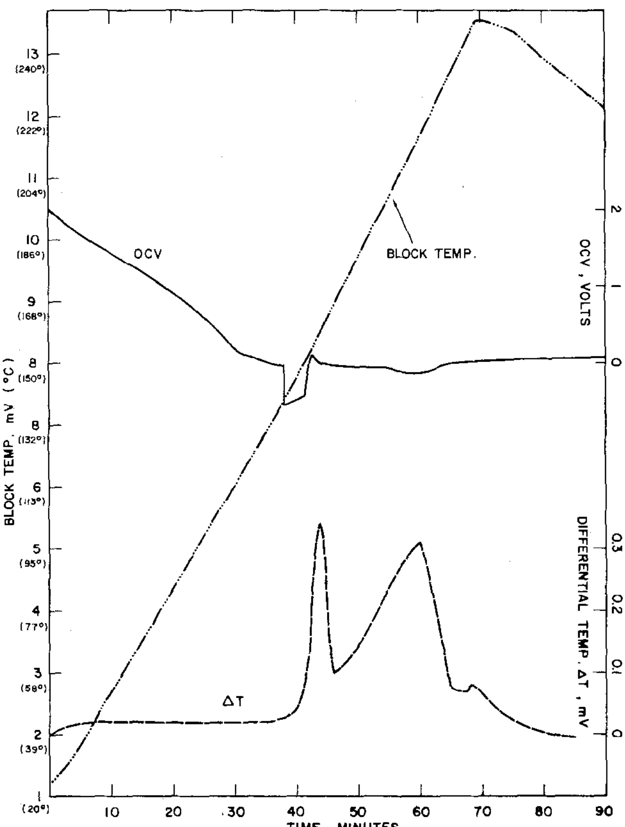

Fig. 5. Thermogram of the force-discharged Li/SO_2 miniature cell of Fig. 4.

tial temperature profile during discharge and reversal at 25°C at 90 mA for 3 hr, as shown in Fig. 8, also are very similar to those of the standard cell. However the DTA thermogram of the above reversed cell, as shown in Fig. 9, is interesting. Note that the upper limit of the temperature was 250°C. It shows three exothermic transitions prior to a very sharp exotherm occurring during the cooling cycle of the DTA. The repeat DTA run shows no significant exotherms. The thermogram of another cell force discharged at −30°C for 3 hr at 90 mA, is shown in Fig. 10. Note that it shows only the three exothermic peaks. But on the repeat run, the fourth strong exothermic peak appears as shown in Fig. 11. The above experiment was repeated and the DTA thermograms were found to be identical to the above. We believe that the three peaks are due to the following three reactions, *viz.*, Li + AN, decomposition of $Li_2S_2O_4$ and Li + PC. The fourth sharp peak in Fig. 9 is most likely due to the Li + S reaction. We found earlier that Li + S reaction produced the sharpest exothermic transitions indicating a very fast reaction.

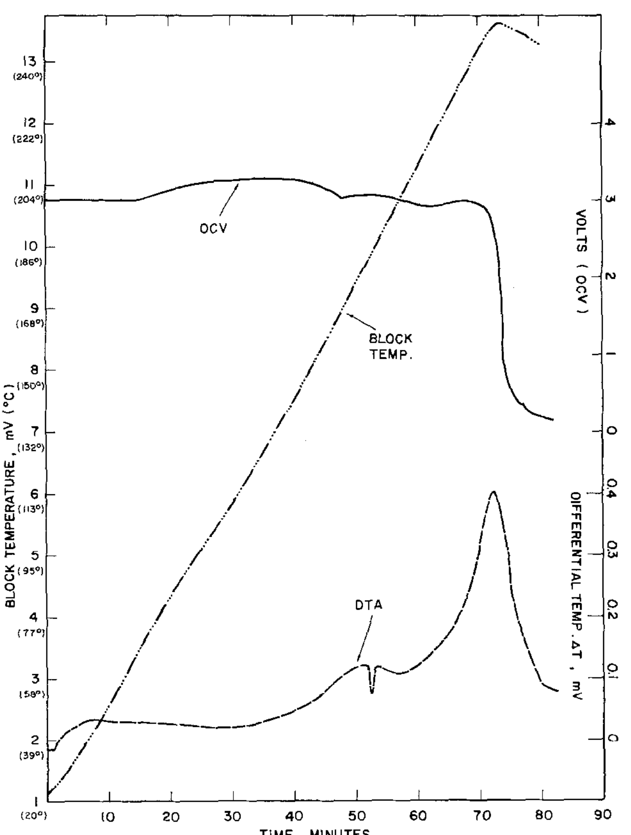

Fig. 6. Thermogram of a miniature Li/SO_2 cell of standard construction after being charged at 25°C for 7 hr at 90 mA.

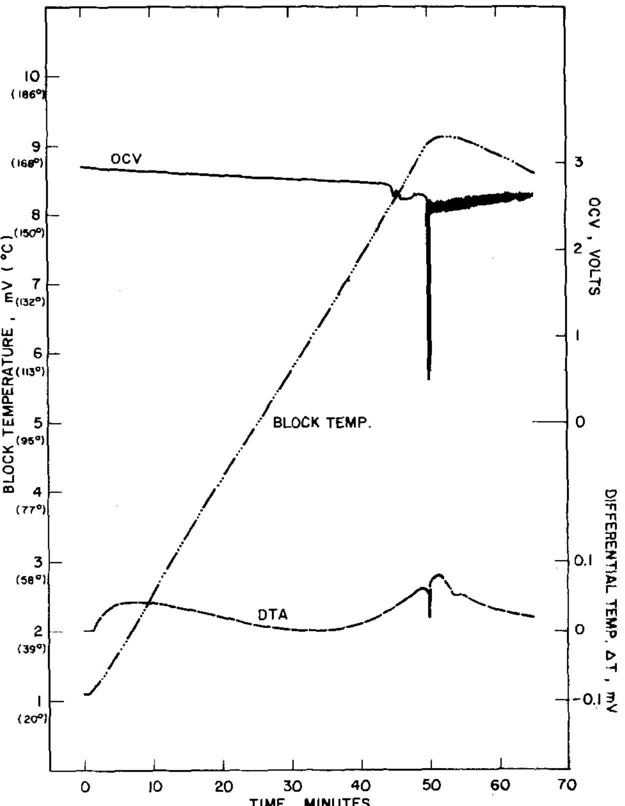

Fig. 7. Thermogram of a discharged minature Li/SO_2 cell with PC in the electrolyte; discharge current, 10 mA; discharge temperature, 25°C.

All the DTA experiments were carried out at least one day after the discharge and reversal of the cells; thus the exothermic transitions reflect reactions of relatively stable species and not transient species.

Cells with glass filter paper separator.—These cells are similar to the standard cells in every respect except the separator is made of glass filter paper. The thermogram of a fresh cell heated to 170°C is shown in Fig. 12. Note that the OCV remained unchanged during the run indicating the absence of shorting that occurred in cells with celgard separator which melts at approximately 140°C causing shorting. Also, there were no significant transitions as expected. The thermogram of a completely discharged cell showed a small exotherm very similar to that of the standard cells, most likely because the upper limit of the temperature was 170°C. Note also that the OCV of the cell did not drop to zero; indicating lack of cell shorting. The repeat run did not show any transition as before.

The DTA thermogram of a cell which was force-discharged at −30°C at 90 mA showed only a small

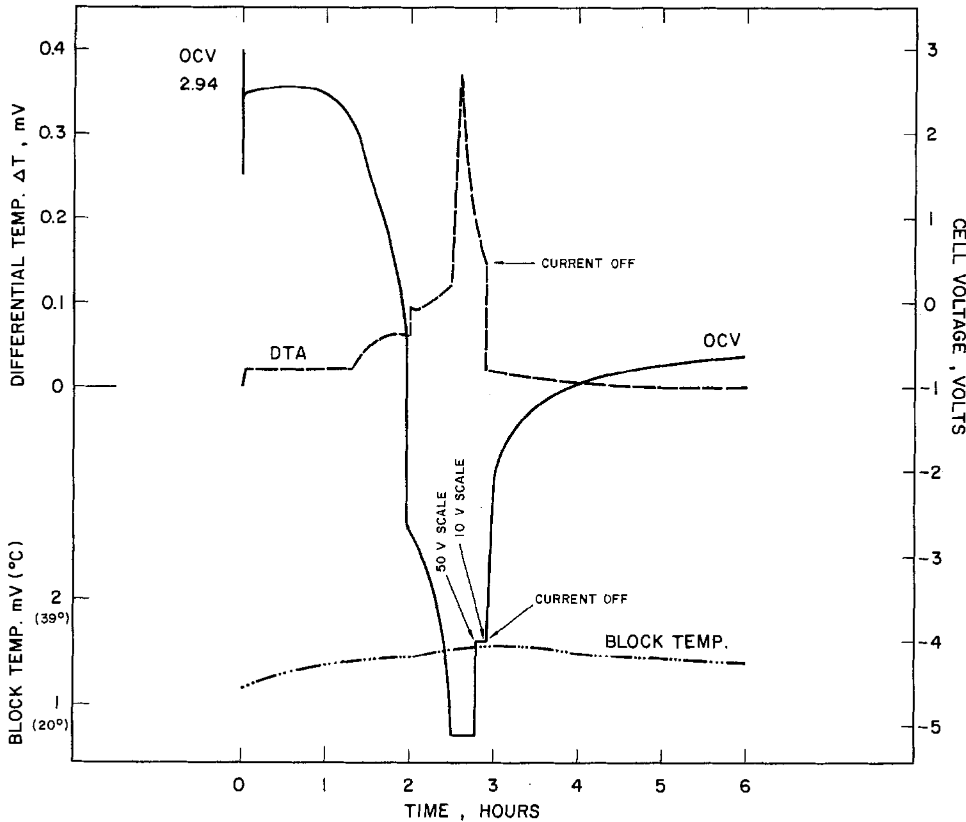

Fig. 8. Voltage, differential temperature, and the block temperature profiles of a Li/SO_2 miniature cell with PC in the electrolyte during discharge and force-discharge at 25°C at a current of 90 mA.

exotherm when the upper limit of the DTA run was kept at 170°C. However, when the upper limit of the DTA temperature was increased to 250°C of a similarly force-discharged cell, stronger exothermic transitions were observed again (Fig. 13) very similar to those of the standard cells.

The efficacy of the glass separator in preventing cells shorting at elevated temperatures is demon-

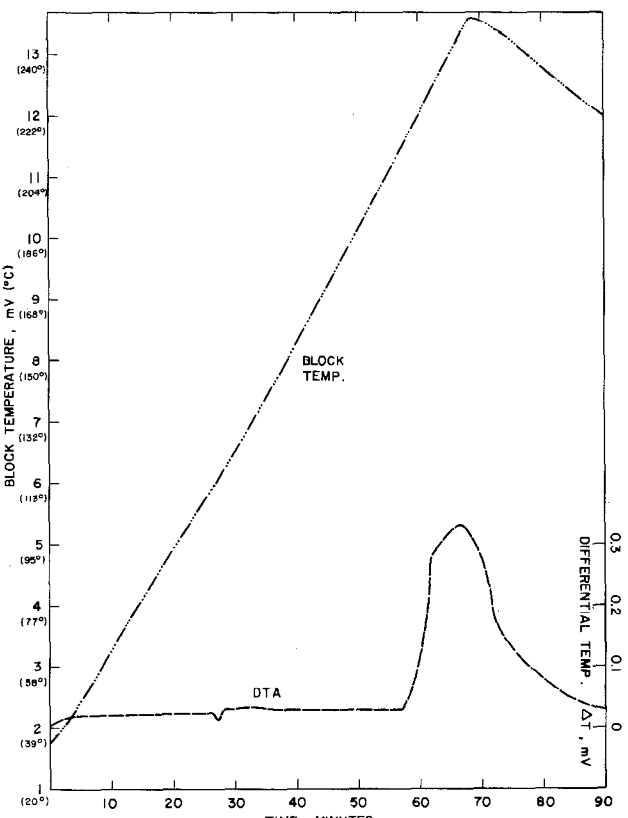

Fig. 11. Thermogram of the repeat DTA run after the one in Fig. 10.

strated from the above experiments. However, the exothermic reactions at 150°C are not thus preventable, as expected.

Cells with $LiAsF_6$ electrolyte salt.—These cells are identical to the standard cells except the electrolyte salt is $LiAsF_6$ instead of LiBr. The electrolyte con-

open-circuit voltage of the cell curiously increased above 132°C from 2.95 to 3.66V. We found this phenomenon to be quite reproducible. There is a small exotherm in the thermogram corresponding to this increase in OCV. Our earlier DTA studies were incomplete insofar as this electrolyte salt is concerned and as such the reason for this increased OCV is not quite clear. The thermogram showed an endotherm corresponding to the melting of Li. Curiously, the cell did not short in spite of the fact that the cell temperature exceeded the melting point of the celgard separator. It is possible that the electrode assembly was not tight enough to create a short when the separator melted. The thermogram then showed a sharp exothermic transition corresponding to the shorting of the cell as indicated by the sudden drop of OCV. This cell did not explode at this point although another cell did in a subsequent run. A repeat run of the same cell showed no significant transitions, indicating complete decomposition of any electrochemically and thermally active materials including $Li_2S_2O_4$ formed during shorting. The temperature of the cell must have been high enough to complete all the thermally active processes discussed earlier.

The thermograms of discharged cells showed relatively smaller exotherms compared to those of a force-discharged cell as observed earlier with the standard cells. The thermogram of a charged cell (Fig. 15) was similar to that of a fresh cell with the exception that the OCV was higher initially (3.44V) and it was reduced to 2.85V prior to shorting which resulted in a very large exotherm corresponding to both electrochemical and chemical heats. Note that the cell shorting occurred after the lithium melted as indicated by the small endotherm prior to the sharp drop of OCV. Repeat run showed no transitions as before.

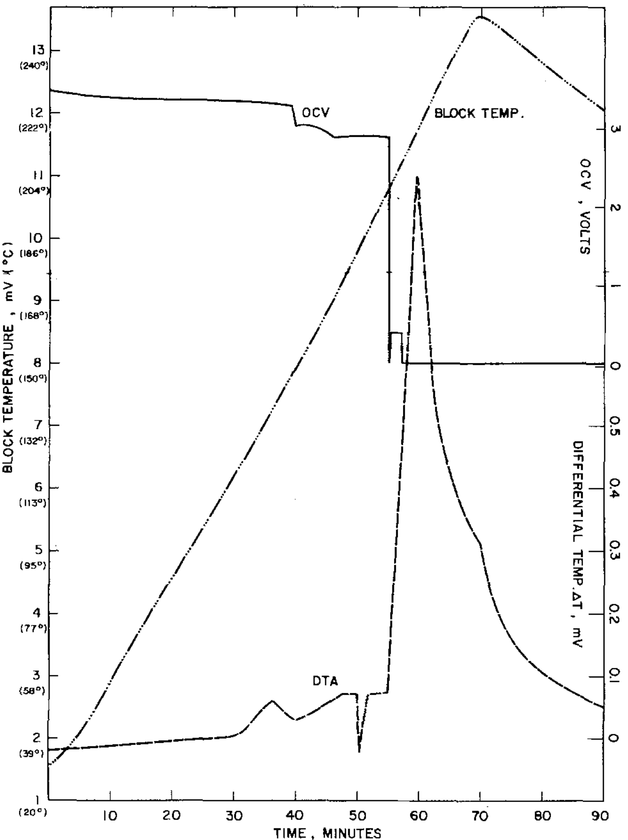

Fig. 15. Thermogram of a Li/SO_2 miniature cell with $LiAsF_6$ electrolyte after charging at 25°C for 7 hr with 90 mA.

The above results demonstrate the applicability of the cell DTA technique, in resolving the chemical processes occurring in cells during thermal excursions, and this method, in conjunction with the DTA of cell constituents, provides a useful tool for studying the thermal runaway processes of Li/SO_2 and other cells.

Conclusions

The differential thermal analysis (DTA) of miniature Li/SO_2 cells was found to be a useful tool in elucidating the chemical processes that occur in a cell during thermal excursions, as in thermal runaways. The DTA data of cell constituents were particularly useful for the identification of the various processes occurring in the cell by comparing the nature of the transitions of the cell with those of synthetic mixtures of cell constituents. The effect of the cell construction variables such as glass filter paper separator on the DTA thermograms of the miniature cells was found to be predictable in most cases based on the DTA data of the cell constituents. The major reactions which contribute to the thermal runaway process are the Li-organic solvent reaction and the decomposition of $Li_2S_2O_4$ as well as the Li + S reaction, where S was produced from $Li_2S_2O_4$. The cell reversal results in stronger exothermic transitions due to the formation of Li in the cathode containing $Li_2S_2O_4$.

The Formation of Ferrous Monosulfide Polymorphs during the Corrosion of Iron by Aqueous Hydrogen Sulfide at 21°C

David W. Shoesmith,* Peter Taylor, M. Grant Bailey, and Derrek G. Owen

Atomic Energy of Canada Limited, Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba, Canada R0E 1L0

ABSTRACT

The initial stages of corrosion of iron by unstirred saturated aqueous H_2S solutions at 21°C and atmospheric pressure have been examined as a function of time, pH (from 2 to 7, adjusted by addition of H_2SO_4 or NaOH), and applied current. Detailed examination of the morphology and phase identity of the corrosion products has led to a qualitative mechanistic understanding of the corrosion reactions. Mackinawite (tetragonal FeS_{1-x}) is formed by both solid-state and precipitation processes. Cubic ferrous sulfide and troilite occur as precipitates between $pH = 3$ and $pH = 5$, subsequent to metal dissolution upon cracking of a mackinawite base layer formed by a solid-state mechanism. The corrosion rate, and the relative amounts of these phases produced, are controlled by pH, applied current, and the degree of convection. The corrosion rate increases with decreasing pH; the quantity of precipitated material peaks near $pH = 4$, below which dissolution becomes the dominant process as the solubilities of the sulfide solids increase. Significant passivation was observed only at $pH = 7$, when the initial mackinawite base layer remained virtually intact. The solid-state conversion of cubic ferrous sulfide to mackinawite at 21°C was monitored by x-ray diffractometry. The resulting kinetics are consistent with the Avrami equation for a nucleation and growth process with a time exponent of 3.

The initial corrosion of iron or carbon steel by hydrogen sulfide saturated water at low temperatures is complex (1-5). There is considerable confusion regarding product identity in the earlier literature (5, 6) but it is now established that the initial corrosion involves the formation of up to three iron monosulfide phases (1-4): mackinawite (tetragonal FeS_{1-x}), cubic ferrous sulfide, and troilite (stoichiometric hexagonal FeS). Solubility measurements (7, 8) and interconversion studies (1, 2, 9) indicate the order of stability troilite > mackinawite > cubic ferrous sulfide. Troilite is a stable phase in the Fe-S system (10), but it is metastable with respect to pyrite in the solutions used in the present study (11). Mackinawite appears to be metastable under all conditions, but it occurs widely both naturally (9, 12) and as a precipitate under a wide range of laboratory conditions (8, 13) as well as in corrosion products. Little is known about cubic ferrous sulfide, other than its occurrence as a corrosion product, and its ease of conversion to mackinawite (1, 2).

Although there is a substantial body of literature describing the occurrence of these phases, no systematic examination of the chemical conditions of their formation on corroding surfaces has hitherto been reported. The purpose of the present study was to make such an examination, and to elucidate the mechanisms whereby the three solid corrosion products are formed. We have therefore examined the sequence of corrosion of iron in unstirred saturated aqueous H_2S at 21°C as a function of pH, reaction time, and applied current.

This work formed part of a study of corrosion and deposition phenomena in Canadian Girdler Sulfide heavy water production plants.

Experimental

Reactions were performed in a standard three-compartment glass cell. Deoxygenated aqueous hydrogen sulfide solutions (about 300 cm^3) of desired pH were prepared *in situ* by purging appropriate NaOH or H_2SO_4 solutions with N_2, and then saturating the solutions with H_2S. A slow H_2S purge was maintained during the experiments, to minimize ingress of oxygen. Experiments were performed at pH values in the range 1.7-7.0, at atmospheric pressure and usually at a temperature of 21°C. (A few experiments were performed at higher temperatures.) The solubilities of mackinawite and troilite, and the concentration of SH^-, under these conditions are given in Table I. Most experiments were not stirred; in some experiments the solution was stirred using a magnetic stirrer bar at the bottom of the cell. Cylindrical iron electrodes (surface area ≃ 5 cm^2) were cut from bar stock (99.95% Fe), and one end of each was polished using 600 grit paper. The electrodes were mounted with the polished surface facing downward. In a few experiments, a more highly polished surface was prepared, using Metadi diamond polishing compound (1 μm). Some experiments were performed with two single crystals of iron, with polished [100] and [110] faces. These were immersed in aqueous H_2S at $pH = 6$ and 7, without electrical connections.

The potential of corroding specimens was monitored with a Dana Model 5330 digital voltmeter connected to a strip-chart recorder. Constant currents were applied using a Hewlett Packard Model 6186B current generator or a PAR Model 173 Galvanostat. All po-

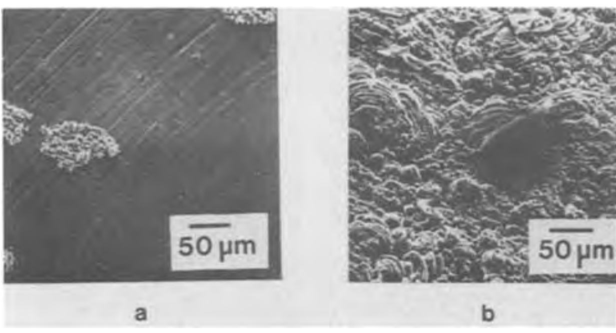

Fig. 1. Iron surfaces exposed to saturated aqueous H_2S solution, pH = 7, for 24 hr at 21°C. (a) Open circuit; (b) applied current, $I = 40\ \mu A \cdot cm^{-2}$.

tentials quoted are on the saturated calomel electrode scale. The reference electrode was an Orion Model 90-02 double-junction silver-silver chloride electrode. The Orion KCl filling solution was of such a concentration that the electrode matched the response of a saturated KCl calomel electrode. It was necessary to use such an electrode because a single-junction electrode was found to degrade in sulfide solution, presumably due to formation of silver sulfide (14).

Corrosion products on the polished electrode surfaces were identified by direct x-ray diffractometry of the surfaces, using a Philips Model PW1050 diffractometer equipped with a diffracted-beam monochromator and using CuK_α radiation. The morphology of corrosion products was examined using a Cambridge Mark IIA Stereoscan scanning electron microscope. Correlation of diffraction data with microscope studies permitted the visual identification of particles of the three iron sulfide phases. Rough quantitative estimates of the three phases were made from the heights of major diffraction peaks, but the accuracy of these estimates was severely limited by the very high absorption coefficient of iron for CuK_α x-rays ($\mu \simeq 10^5\ m^{-1}$ for each phase) and, in the case of mackinawite, by a significant degree of preferred orientation and a tendency to spall from the surface. A few samples of material which had spalled from electrodes were analyzed by x-ray powder photography.

Results

Reaction at pH = 7.—In the experiments performed at pH = 7 for 24 hr, with applied anodic currents, I, of 0, 1, 40, 80, and 130 $\mu A \cdot cm^{-2}$, mackinawite was the only corrosion product observed, with the exception of a trace of cubic ferrous sulfide at $I = 40\ \mu A \cdot cm^{-2}$. Microscopic examination of surfaces after open-circuit reactions ($I = 0$) showed two types of corrosion product: a coherent, featureless base layer, and a loose deposit of precipitated material at a few sites (Fig. 1a). Enhancement of the $hk0$ diffraction peaks of mackinawite indicated a preferred orientation with the sheets of iron atoms in the crystal structure (15) lying perpendicular to the metal surface. The same orientation of the base layer was observed on both [100] and [110] faces of iron single crystals. We associate this preferred orientation with the coherent layer observed microscopically, and suggest that it is formed by a solid-state reaction.

Figure 2a shows the potential of the iron electrode as a function of time and applied current. The positive potential shift indicates that the base layer at least partially passivates the surface. The duration of this shift decreases with increasing anodic current, as the rate of formation of the base layer increases. Cracking of this layer causes local dissolution of iron and precipitation of the loose mackinawite deposit (Fig. 1a). Under applied currents, the enforced increase in corrosion rate results in more rapid and extensive cracking of the base layer, and consequently a much greater amount of precipitated material. The time at which cracking commences is indicated by the sudden negative shift in the potential, Fig. 2, as the electrode surface becomes more active due to the exposure of bare metal. At the higher applied currents, much of the mackinawite spalls from the electrode. This has been used at these laboratories as the basis for a synthesis of mackinawite, using much higher applied currents (4 $mA \cdot cm^{-2}$). At $I = 40\ \mu A \cdot cm^{-2}$, the mackinawite has a layered appearance (Fig. 1b), indicative of successive cracking, repair, and recracking of the base layer.

The initial negative potential excursions in the transients of Fig. 2a at $I = 40\ \mu A \cdot cm^{-2}$, and particularly at $I = 0$, may be due to the removal of an oxide film, resulting in an increased electrode activity. The transients of Fig. 2b show that stirring retards the positive shift of the potential, indicating that a soluble species, presumably Fe^{2+}, is produced concurrently with the film formation.

Reaction at pH = 6.—In the relatively few experiments performed at pH = 6, all under open-circuit conditions, the sole product was again mackinawite, with a high degree of preferred orientation. However, the 001 diffraction peaks were enhanced, indicating orientation with the sheets of iron atoms in the struc-

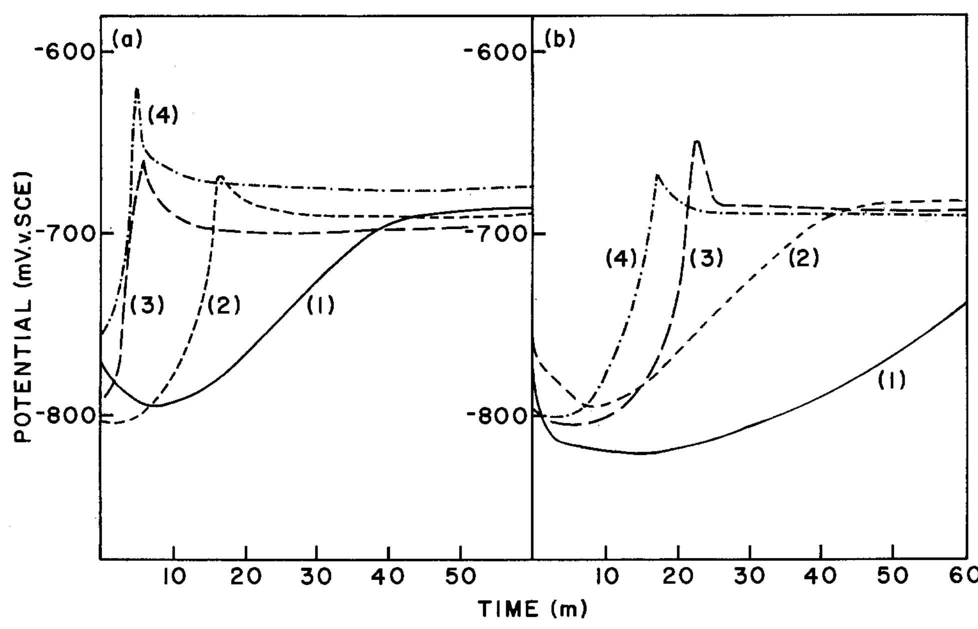

Fig. 2. Potential of iron surfaces exposed to saturated aqueous H_2S solution, pH = 7, at 21°C. (a) Stagnant; (b) stirred. Curve (1) $I = 0$; curve (2) $I = 40$; curve (3) $I = 80$; curve (4) $I = 130\ \mu A \cdot cm^{-2}$.

ture lying parallel to the surface rather than perpendicular as at pH = 7. The intensities of the 001 mackinawite reflections after a given reaction time were enhanced for a more polished surface, which probably reflects a greater degree of perfection of orientation rather than a greater thickness of the layer. Again, the same mackinawite orientations were observed for both [100] and [110] iron crystal faces, although greater enhancement of the 001 reflections was observed for the [100] face. The association of a high degree of preferred orientation of film growth with highly polished surfaces independent of the crystallographic orientation of the substrate, and the phenomenon of changing orientation with changing growth rate, have been discussed by Finch *et al.* (16).

The oriented layer was not sufficiently coherent to passivate the surface. This is indicated by the corrosion potential, which does not show a positive shift, unlike the situation at pH = 7 (Fig. 3). The high corrosion rate resulted in a dense upper layer of very fine-grained, precipitated mackinawite, which covered the surface completely after 24 hr.

Reaction at pH = 5.—All three phases, mackinawite, cubic ferrous sulfide, and troilite, were observed at pH = 5, necessitating a more detailed examination of the reaction. A series of open-circuit experiments was performed over reaction times up to 24 hr, and a series of 24 hr experiments was carried out with applied currents, I, from −50 to +70 $\mu A \cdot cm^{-2}$.

The early stages of natural corrosion at pH = 5 resemble those at pH = 6, but the higher corrosion rate results in earlier cracking of the base layer and associated mackinawite precipitation. The upper layer material covered the surface completely after 9 hr. Both cubic ferrous sulfide and troilite were observed after 16 hr reaction. Both phases occurred as well-developed crystals, evidently grown from solution, scattered over the mackinawite base layer. Cubic ferrous sulfide typically formed large irregular blocks up to 20 μm across, while troilite occurred as pointed needles (up to 10 × 2 μm), of hexagonal cross section.

The appearance of the cubic phase at a comparatively late stage of the reaction, and its known metastability with respect to mackinawite (1, 2), show that the source of iron for its formation is the metal rather than the mackinawite. The dense upper layer of mackinawite obscured any changes in the base layer associated with the formation of cubic ferrous sulfide, but cracking or pitting of the base layer must have resulted in very high local supersaturation. This is demonstrated more clearly by the results obtained at pH = 4.

The relative amounts of cubic ferrous sulfide and troilite were more poorly reproducible at pH = 5 than at pH = 4. When large amounts of troilite were formed, it tended to occur at the expense of cubic ferrous sulfide, reflecting competition for the same source of iron. The greater irreproducibility is reflected in the corrosion potentials as a function of time. A spread of 30 mV was obtained for a series of nominally identical runs at pH = 5, compared with an 8 mV spread at pH = 4. The plot shown in Fig. 3 is for a single experiment which approximated the average behavior at pH = 5. Experiments performed with applied currents are discussed below.

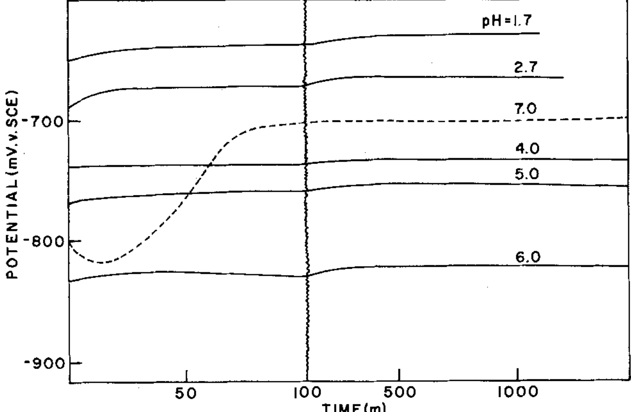

Fig. 3. Potential of iron surfaces exposed to saturated aqueous H_2S solution at 21°C as a function of time and *p*H.

Reaction at pH = 4.—All three phases were again produced at pH = 4. Since results tended to be more reproducible than at pH = 5, the reaction was studied most extensively at this pH. Open-circuit experiments were run from 0.25 to 96 hr, in addition to a series of 24 hr experiments with I ranging from −120 to +120 $\mu A \cdot cm^{-2}$, and a small number of 24 hr, open-circuit runs at temperatures up to 90°C. Figure 4 shows changes in surface morphology with time and Fig. 5 shows the relative amounts of the three phases as a function of time.

After 0.25 hr, a very small quantity of mackinawite was detected. Enhancement of the [001] diffraction peak indicates a significant degree of preferred orientation. The surface film was sufficiently thin that scratch marks from polishing the electrode were still visible on micrographs, and an upper layer of wispy particles was also observed. After 0.5 hr (Fig. 4a), the quantity of mackinawite was greater, the degree of orientation was somewhat lower, and the density of coverage by fine material was higher. However, scratch marks were still visible.

After 1 hr (Fig. 4b), severe blistering was observed, as the coherent base layer peeled from the surface. The blistered material was covered by a dense mass of small crystals, presumably developed by growth of the wispy particles noted after shorter reaction periods. The quantity of mackinawite detected by x-ray diffraction was higher than that after 0.5 hr, but no preferred orientation was apparent, which is consistent with the severe disruption of the base layer. The effect of stirring on the corrosion potential recorded at pH = 7 indicates that some iron dissolution was occurring. This process is more significant at pH = 4, and the fine mackinawite particles seen in these early stages are likely to have precipitated from solution.

After 2 hr, scratch lines were no longer visible and the quantity of mackinawite continued to increase. There was some indication of the redevelopment of preferred orientation with [001] parallel to the surface. This suggests the redevelopment of a coherent base layer below the debris of the original film.

After 4 hr (Fig. 4c) scratch marks were visible once again, indicating that the blistered material had fallen away; the diffraction results showed less mackinawite than at 2 hr, but with a fairly high degree of orientation. The surface was covered with a slightly pitted, dense layer of fine-grained (< 1 μm) mackinawite with larger (*ca.* 5 μm) crystals of cubic ferrous sulfide scattered over the surface. The cubic ferrous sulfide did not display significant preferred orientation in this or any other experiment, nor was any preferred orientation of troilite ever observed. Most of the electrodes displayed a marked [110] preferred orientation of the iron metal, but this did not appear to affect the course of reaction.

In a second 4 hr experiment with a more polished specimen, mackinawite was the sole product. The initial base layer appeared not to have blistered and fallen away, although some cracking had evidently occurred, for much of the surface was covered with fine-grained precipitated mackinawite. This run thus resembled the behavior at pH = 5 with less polished specimens.

Between 4 and 12 hr, cracking and pitting of the second mackinawite base layer occurred, but its thick-

Fig. 4. Scanning electron micrographs of iron surfaces exposed to saturated aqueous H_2S solution at 21°C and pH = 4 for (a) 0.5 hr, (b) 1.0 hr, (c) 4 hr, (d) 12 hr, (e) 16 hr, (f) 24 hr.

ness remained approximately constant (Fig. 4d). The amount of precipitated mackinawite increased somewhat, but much more was seen to spall from the surface. The number and size of cubic ferrous sulfide crystals increased over this period, showing that both nucleation and growth had continued. Crystals of cubic ferrous sulfide tended to be more adherent than those of mackinawite, and only trace quantities were observed in analyses of spalled material.

The only change observed between 12 and 16 hr was the appearance of a small quantity of troilite needles (Fig. 4e). The cubic ferrous sulfide crystals were now up to 15 μm across. A 16 hr experiment with a more polished iron specimen yielded a very similar surface to that obtained with a routinely prepared specimen. Evidently, although rupture of the initial mackinawite base layer was retarded on the more polished surface, the subsequent development of the corrosion sequence was not significantly altered at the high corrosion rates obtained at pH = 4.

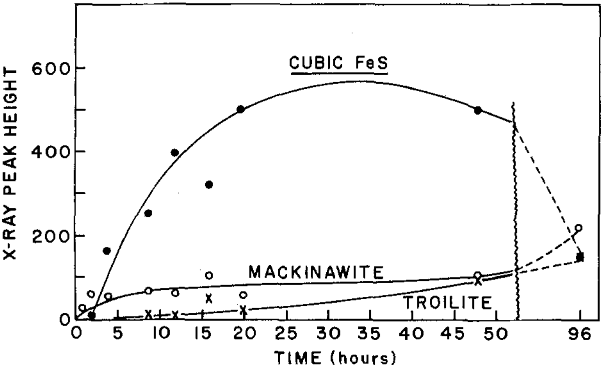

Fig. 5. Relative amounts of ferrous monosulfide phases formed on iron surfaces exposed to saturated aqueous H_2S solution at 21°C and pH = 4 as a function of time.

Surface coverage by cubic ferrous sulfide continued to increase, up to about 80% after 24 hr (Fig. 4f). At longer reaction times, the quantity of the cubic phase fell as it underwent solid-state conversion to mackinawite (1, 2; see below). As at pH = 5, the development of troilite was the least reproducible feature of the experiments. When significant quantities of troilite were formed, it again tended to occur at the expense of cubic ferrous sulfide. Even after 96 hr reaction at pH = 4, troilite was not the preponderant phase, although it was consistently a major component after reaction times $\geqq$ 37 hr.

If the solution was stirred, only a thin base layer of mackinawite was formed after 24 hr, confirming that the upper layer material was precipitated from solution.

As with the open-circuit experiments, behavior under applied currents was more reproducible at pH = 4 than at pH = 5. The relative amounts of the three phases formed as a function of applied current at pH = 4 are shown in Fig. 6.

Even with an applied current of $-120\ \mu A \cdot cm^{-2}$, a small quantity of mackinawite was formed, indicating a substantial corrosion current at pH = 4. The mackinawite had a preferred orientation with [001] perpendicular to the surface, similar to that observed in open-circuit experiments at pH = 7. At $I = 100\ \mu A \cdot cm^{-2}$, the amount of mackinawite had increased, and its orientation had switched to [001] parallel to the surface, characteristic of the higher corrosion rates in open-circuit runs at pH $\leqq$ 6. The quantity of mackinawite did not change greatly over the range $-80 \leqq$

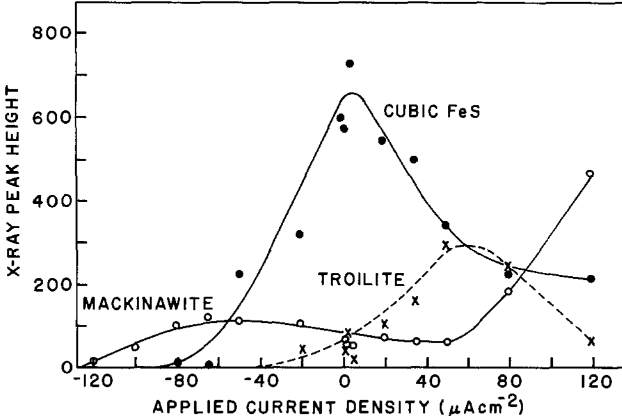

Fig. 6. Relative amounts of ferrous monosulfide phases formed on iron surfaces exposed to saturated aqueous H_2S solution at 21°C and $pH = 4$ for 24 hr as a function of applied current.

$I \leq 0$ $\mu A \cdot cm^{-2}$, except for a gradual increase in precipitated material. The amount of material spalling from the electrode increased as the applied current became less negative, but losses were small in this range. Mackinawite decreased somewhat as I increased to $+50$ $\mu A \cdot cm^{-2}$, then increased massively at still higher applied currents.

Although the amount of mackinawite changed only slightly over the range $-80 \leq I \leq +50$ $\mu A \cdot cm^{-2}$, major changes occurred in the quantities of both troilite and cubic ferrous sulfide. The latter appeared in minor quantities at $I = -80$ $\mu A \cdot cm^{-2}$, was a major product at $I = -50$ $\mu A \cdot cm^{-2}$, increased rapidly to a peak at $I \simeq 0$, then gradually fell to about 30% of its peak value at $I = +120$ $\mu A \cdot cm^{-2}$. Troilite was not observed at $I < -20$ $\mu A \cdot cm^{-2}$, and only became a major product at $I \geq 20$ $\mu A \cdot cm^{-2}$. It peaked at *ca.* $I = 50$ $\mu A \cdot cm^{-2}$, then also gradually fell, concurrently with the increase in mackinawite at $I > 50$ $\mu A \cdot cm^{-2}$.

As noted above, results at $pH = 5$ were generally less reproducible than at $pH = 4$, but similar trends in the quantities of the three phases with changing applied current could be detected.

Figure 7 shows polarization curves obtained at $pH = 4$ and $pH = 5$, constructed from plots of the corrosion potential against time for a given applied current. The corrosion currents at the two pH values were estimated by extrapolating the anodic and cathodic linear regions of these curves to the corrosion potential for $I = 0$. At $pH = 4$, the "initial" ($t = 2$ min) corrosion current density is *ca.* 35 $\mu A \cdot cm^{-2}$, falling to around 30 $\mu A \cdot cm^{-2}$ at 30 min and *ca.* 27 $\mu A \cdot cm^{-2}$ after 24 hr. The slight fall in corrosion rate indicates that none of the corrosion products passivate the surface. At $pH = 5$, the lower corrosion rate of *ca.* 10 $\mu A \cdot cm^{-2}$ is consistent with the reduced amounts of material precipitated, compared with $pH = 4$. These corrosion current densities are only very approximate values. However, they are sufficiently accurate to indicate variations with time and pH.

There is little variation of size or morphology of cubic ferrous sulfide crystals as a function of applied current at $pH = 4$. At lower currents the crystals tend to possess sunken faces (Fig. 8a, $I = -50$ $\mu A \cdot cm^{-2}$), indicative of depletion of iron supply at the growth sites. At higher currents the crystals are better formed, and sometimes nucleate in clumps (Fig. 8b, $I = +35$ $\mu A \cdot cm^{-2}$), reflecting the faster iron supply rate achieved at the higher currents.

Reactions at $pH < 4$.—Only two experiments were performed at pH values below 4, the natural pH of H_2S-saturated water. The pH was lowered by addition of H_2SO_4, and two 24 hr, open-circuit experiments were run at $pH = 1.7$ and $pH = 2.7$. At $pH = 1.7$, the solubilities of all three phases are sufficiently high that no precipitate was observed, but severe attack of the metal surface due to direct dissolution was apparent. At $pH = 2.7$, much of the metal surface was again bare and attacked, but small quantities of cubic ferrous sulfide and precipitated mackinawite were scattered on the surface.

The relative amounts of each phase formed after 24 hr of open-circuit reaction as a function of pH are summarized in Fig. 9. The mackinawite data are less reliable than those for troilite and cubic ferrous sulfide because of the preferred orientation phenomena discussed above, and because of the undetermined quantities of mackinawite which spalled from the electrode.

Reactions at elevated temperature.—A small number of 24 hr, open-circuit experiments were performed in a thermostatted cell at temperatures up to 90°C and $pH = 4$. Reproducibility of results was poor, and ripening of crystals at higher temperatures gave rise to unfamiliar morphologies. However, a few trends could be detected. At 35°C (Fig. 10a) the coverage of the surface by large (20 μm) crystals of cubic ferrous sulfide approached 100% (*cf.* 85% at 21°C), and rather less mackinawite was present than at 21°C. At 50°C, coverage by cubic ferrous sulfide was still close to

100%, but the crystals were only *ca.* 5 µm across (Fig. 10b), indicating a higher nucleation rate. The small amount of precipitated mackinawite was somewhat better formed than that at lower temperatures. At 75°C (Fig. 10c), cubic ferrous sulfide was still present, but covered only about 25% of the surface, on top of a fine-grained mackinawite base layer. Some small blocks *ca.* 1 µm across were tentatively identified as precipitated mackinawite. At 90°C (Fig. 10d), the dominant phase was troilite, but a small amount of the cubic phase still persisted. A fine-grained mackinawite base layer was still visible. In one experiment in which the temperature rose to *ca.* 75°C for *ca.* 1 hr, then was maintained at 35°C for 23 hr, troilite was the major product.

The conversion of cubic ferrous sulfide to mackinawite.—Cubic ferrous sulfide is known to transform spontaneously to mackinawite at room temperature, with reported rates of *ca.* 10% per hour (2) and *ca.* 2% per hour (1). The ease with which the transformation occurs is readily understood in view of the close structural relationship between the phases. The interconversion involves the migration of one-half of the iron atoms between adjacent tetrahedral sites in a cubic close packed sulfide lattice (2, 15).

We have monitored the transformation of cubic ferrous sulfide to mackinawite at 21°C by x-ray diffractometry. Samples were prepared by open-circuit

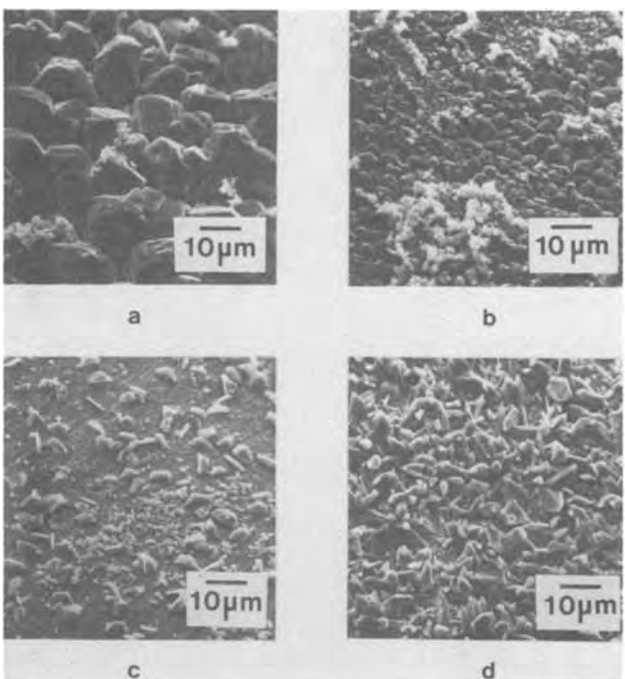

Fig. 10. Scanning electron micrographs of iron surfaces exposed to saturated aqueous H_2S solution at $pH = 4$ for 24 hr at (a) 35°C, (b) 50°C, (c) 75°C, (d) 90°C.

corrosion of iron for 24 hr at $pH = 4$, and the kinetic study was performed on the corrosion products on the metal surface. The intensities of three major diffraction lines of each phase ([001], [101], and [111] of mackinawite; [111], [220], and [311] of cubic ferrous sulfide) were monitored by direct counting. The peaks were scanned at 1° per min, with stationary counting of the background on either side of each peak. Each set of intensity data was scaled using the [110] peak of the iron substrate as a standard, to compensate for long-term fluctuations in the x-ray beam intensity. The relative decrease in the intensity of each cubic ferrous sulfide peak and the relative increase of each mackinawite peak were normalized, and found to follow very similar courses. The decline of the cubic ferrous sulfide intensity was slightly faster for the higher angle reflections; this may be a consequence of strain at the transformation interface. The progress of the summed intensities of the three peaks of each phase is depicted in Fig. 11 (after subtraction of the x-ray intensity due to mackinawite formed directly in the corrosion process). No troilite

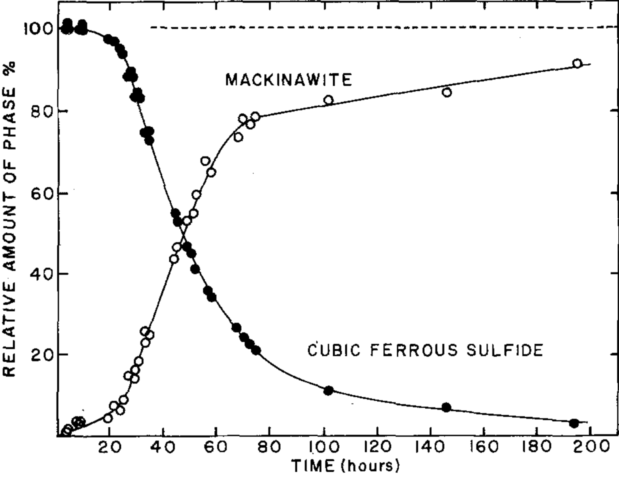

Fig. 11. Relative amounts of cubic ferrous sulfide and mackinawite in the course of their interconversion at 21°C, determined by x-ray diffractometry.

nor any other phase was detected at any stage. The clean interconversion of the two phases is clearly apparent. At longer reaction times the mackinawite intensities were slightly lower than anticipated. This is probably due to slight oxidation concurrent with the interconversion; no effort was made to exclude air from the sample during the diffraction experiment.

Figure 12 shows that the data up to about 60% conversion can be fitted to the Avrami equation [1] (17, 18), with a time exponent of 3

$$X = 1 - \exp(-1/3\, \pi N_v U^3 t^3) \quad [1]$$

where X = extent of conversion, N_v = number of nucleation centers per unit volume, U = linear growth rate of nucleation centers; whence

$$\ln\left(\frac{1}{1-X}\right) = Kt^3 \quad [2]$$

The data are thus reasonably consistent with a constant rate of spherical growth of nuclei, all of which are present at the start of the transformation. The value of K depends on the choice of "zero time." If this is chosen as the point at which the corrosion reaction was terminated, $K \simeq 1.1 \times 10^{-16}$ sec^{-3}. Earlier zero times result in lower values of K; since the cubic ferrous sulfide was formed continuously over a period of about 20 hr, a true zero time does not exist.

Beyond about 60% conversion, the reaction rate becomes slower than that predicted by the Avrami equation. This may reflect a variation in nucleation center density between different crystallites, perhaps between portions precipitated at different stages of the corrosion process. We found that cubic ferrous sulfide prepared at $pH = 5$ underwent considerably faster conversion at 21°C than that obtained at $pH = 4$, and we attribute this also to variation in density of nucleation centers. This may also account for the different rates indicated by the work of de Médicis (2) and Takeno *et al.* (1).

Scanning electron microscopic examination of a corroded carbon steel surface before, during, and after the conversion (Fig. 13) showed no detectable change of morphology of the cubic ferrous sulfide, except for the appearance of cracks in a few crystals. Thus the 14% reduction in crystallographic volume appeared to be accommodated by microscopic voids between mackinawite grains within the original crystallites. Broadening of diffraction peaks of both phases in the course of the experiment indicated that the transformation was accompanied by a substantial reduction in crystallite size. This was not quantified, since it is likely that there was also a substantial lattice strain contribution to the diffraction line broadening.

Discussion

The results of corrosion experiments at all pH values suggest that film growth and metal dissolution occur simultaneously; the relative importance of the two processes varies with pH. At $pH = 7$, where the least precipitation occurs, a dissolution process is suggested by the effect of stirring on the observed potential transient (Fig. 2). The presence of precipitated sulfides in the pH range 2.7-6.0, and the clean but roughened metal surface obtained at $pH = 1.7$ are evidence that the importance of metal dissolution increases with decreasing pH. The results of experiments with stirring at $pH = 4$ confirm that the upper layer of sulfides, comprising mackinawite, cubic ferrous sulfide, and troilite, is precipitated from solution. In the absence of stirring, metal dissolution leads to local supersaturation with Fe^{2+} at the electrode surface and hence sulfide precipitation. However, even in the presence of nominal stirring as used in these experiments, the local Fe^{2+} concentration can be reduced below the levels necessary for precipitation at the electrode surface.

According to Iofa *et al.* (19), SH^- ions chemisorb on iron to form an approximate monolayer. A similar process with OH^- is known to accelerate the anodic process on iron (20). We therefore propose the corrosion of iron in aqueous H_2S to occur by sequential chemisorption [3] and anodic discharge [4] (19) reactions

$$Fe + H_2S + H_2O \rightarrow FeSH_{ads}^- + H_3O^+ \quad [3]$$

$$FeSH_{ads}^- \rightarrow FeSH_{ads}^+ + 2e \quad [4]$$

The hydroxide reaction analogous to [4] is often described as two consecutive electron transfers, the first of which is deemed to be rate determining (20). Subsequent to reaction [4], the species $FeSH_{ads}^+$ may be incorporated directly into a growing layer of mackinawite [5], or it may be hydrolyzed to yield a dissolved species [6]

$$FeSH_{ads}^+ \rightarrow FeS_{1-x} + xSH^- + (1-x)H^+ \quad [5]$$

$$FeSH_{ads}^+ + H_3O^+ \rightarrow Fe^{2+} + H_2S + H_2O \quad [6]$$

If reaction [6] leads to local supersaturation at the electrode surface, then nucleation and growth of one or more of the iron sulfides, mackinawite, cubic ferrous sufide, and troilite occurs.

The fact that the corrosion potential does not vary very much with time in the pH range 1.7-6.0 (Fig. 3), indicates that there is little change in polarization of the anodic and cathodic reactions with time. This is consistent with the presence of a cracked, porous base layer of mackinawite which does not passivate the surface and thereby polarize the electron transfer reactions occurring. This is not the case at $pH = 7$ where an anodic potential shift was observed, indicating that at this pH the anodic reaction (represented by steps [3]-[6]) is inhibited by the presence of the mackinawite base-layer.

Except at pH = 2.7 and 1.7, a solid-state grown film of mackinawite was always observed, indicating that reaction [5] predominates over reaction [6] in the pH range 4-7. This is supported by the very large Tafel slopes ($\gtrsim$ 240 mV) estimated from Fig. 7 at pH values of 4 and 5, which suggest that the anodic reaction and the cathodic reaction

$$2H_2S + 2e \rightarrow H_2 + 2SH^- \quad [7]$$

are both highly polarized when a current is applied, due to the presence of the mackinawite base layer.

The currents, plotted logarithmically in Fig. 7, give an almost linear anodic plot (for current values $\gtrsim +250$ μA) when plotted directly against the potential. This suggests that the anodic reaction is controlled by transport through the base layer of mackinawite at the higher current values. Mass transport of Fe^{2+} and/or H_2S within the pores and cracks in this base layer is the most likely polarizing mechanism, since the anodic reaction, at least, will be occurring on the limited area of exposed metal. A similar observation was made by Hausler *et al.* (21). They also demonstrated that the polarization can be reduced by stirring. This is further evidence for rate control in macroscopic pores and cracks as opposed to transport through the actual mackinawite film.

At the lower pH values (2.7 and 1.7) metal dissolution via reaction [6] predominates and very little iron sulfide is formed. This is due to the increased solubility of the iron sulfide phases at these pH values. Although no major investigation of the effect of pH on corrosion rate was undertaken, the evidence suggests that the rate increases with a decrease in pH. This can be attributed mainly to the effect of increased proton concentration on the cathodic reaction, since the total concentration of H_2S remains constant, and the total sulfide concentration (H_2S + SH^-) decreases, with decreasing pH. At the pH values used here, the concentration of S^{2-} is negligible. The more specific effects of H_2S and SH^- have been investigated by others (22, 23) and will not be discussed here.

Major amounts of precipitated material form only after the base layer of mackinawite cracks and spalls, as illustrated by the electron-micrographs of Fig. 4. A higher degree of surface polishing results in a longer life of the mackinawite film prior to cracking. This suggests that the cracking of the base layer originates primarily at macroscopic irregularities on the metal surface.

Significant passivation of the iron surface occurs only at pH = 7, and even this is incomplete. The survival of the mackinawite base-layer at this pH is mainly due to the much lower corrosion rate than at pH = 4 or 5. Acceleration of the film growth rate by application of an anodic current causes more stress, and more extensive cracking (Fig. 1).

At lower pH values, this film ruptures much earlier, and at pH = 4, it is replaced after 2-4 hr by a second base layer which grows on the metal surface beneath the spalling initial film. This second film appeared to grow to a substantial thickness (Fig. 4). The development of stress appears to have been prevented by a network of cracks and pores, and the film adhered to the surface for the duration of the experiments. These cracks and pores are also sites for high rates of release of soluble iron from the underlying metal. Their persistence up to at least 96 hr accounts for the very slight fall in the corrosion rate observed over this time span.

The nature and amount of precipitated material is strongly dependent on pH (Fig. 9). At pH $\geq$ 6, only mackinawite is precipitated. At pH = 7, the amount is small, but it is localized in clumps at fault sites in the base layer, where iron dissolution is enhanced. Since the solubility of mackinawite is low at pH = 7 [$<10^{-8}$ mole dm^{-3} (7)], its nucleation is local and rapid, leading to the growth of a large number of small particles of ill-defined morphology. At pH = 6, the corrosion rate is higher, and after 24 hr precipitated material covers the surface completely.

In the pH range 2.7-5.0, all three phases were observed, and the total amount of precipitated material reached a maximum at *ca.* pH = 4. The quantity of precipitated material formed is determined by the rate of iron release (reaction [6]), which increases with decreasing pH, and the solubilities of the solid phases, which also increase with acidity (7). For precipitation to occur, the rate of iron release must be sufficient to cause local supersaturation with respect to the precipitating phase. Thus, as the pH decreases from 7 to 4, local supersaturation is easily maintained, and the increase in the iron release rate leads to an increase in the quantity of precipitated sulfides. As the pH decreases below 4, the solubilities of mackinawite and troilite increase above 10^{-3} and 10^{-5} mole · dm^{-3}, respectively (Table I). The solubility of cubic ferrous sulfide has not been determined, but its instability with respect to mackinawite shows that it is the most soluble of the three phases. The increasing solubilities with decreasing pH cause a reduction in the amount of precipitate. Below *ca.* pH = 2.5, all the soluble iron diffuses into solution, and no precipitation occurs.

Application of an anodic current is expected to accelerate reaction [4], with consequent changes in the rates of reactions [5] and [6]. At pH = 4, as the applied current was increased from −80 to +30 $\mu A \cdot cm^{-2}$, the amounts of cubic ferrous sulfide and, less markedly, troilite increased (Fig. 6). The amount of precipitated mackinawite also increased, but most of it spalled from the electrode, and was not readily quantified. Evidently the rate of reaction [6] increases at the expense of reaction [5] with increasingly positive current over this range. However, at large applied anodic currents, >50 $\mu A \cdot cm^{-2}$, the reverse is true, and reaction [5] increases at the expense of [6]. This is demonstrated by the sudden increase in the amount of mackinawite, coincident with a decrease in the quantities of both cubic ferrous sulfide and troilite. At these high applied currents, cracks which form in the base layer are rapidly repaired by the solid-state mechanism, and the release of soluble iron and consequent precipitation are reduced.

Thus the amount of precipitated material is controlled by the rates of cracking and repair of the initial mackinawite base-layer formed by solid-state reaction, and by the rate of release of soluble iron from crack sites. These rates are controlled by both the pH and applied current. The dependence on the nature of the base layer is the chief cause of experimental irreproducibility, which was most marked at pH = 5.

The nature of the precipitated material is also dependent on the experimental conditions. As discussed above, both cubic ferrous sulfide and troilite were observed only at pH < 6, where film cracking is extensive and the rate of iron release (reaction [6]) is high. This is readily understood for cubic ferrous sulfide, which is the most soluble of the three phases and would be expected to form only under conditions of high iron release rate from the underlying metal. However, troilite is the most stable of the three phases under all the experimental conditions, and its formation might reasonably be expected to be ubiquitous.

The general difficulty of troilite formation appears to lie in the nucleation step. Thus, although cubic ferrous sulfide is the first phase formed as the applied current is increased from a minimum of −120 $\mu A \cdot cm^{-2}$ (Fig. 6), once the iron release rate is sufficiently high to cause nucleation of troilite ($I > 0$), its growth occurs at the expense of that of cubic ferrous sulfide. For $I > 50$ $\mu A \cdot cm^{-2}$, further enhancement of troilite yield is suppressed by the accelerated solid-state, film-repair process of mackinawite formation.

The amount of troilite also increases at the expense of cubic ferrous sulfide at temperatures above 50°C, as the troilite nucleation rate increases. In one experiment maintained at 75°C for 1 hr, then 35°C for 23 hr, a major quantity of troilite was produced. This is consistent with a high nucleation rate at the higher temperature, and a subsequent enhanced growth rate at 35°C.

Conclusion

A systematic study of the nature of the corrosion products formed on iron exposed to aqueuos H_2S has led to the qualitative elucidation of the mechanisms of formation of the three ferrous monosulfide phases: mackinawite, troilite, and cubic ferrous sulfide. This mechanistic information is summarized by the reaction scheme shown in Fig. 14, which depicts the corrosion of iron (or carbon steel, which behaves very similarly) in H_2S-saturated water (pH = 4).

Initially a solid-state reaction produces a layer of mackinawite, which readily cracks and spalls from the metal surface (Fig. 4 and 5). This layer is replaced by a second solid-state grown mackinawite layer, which is cracked and pitted. High local release rates of soluble iron from these cracks and pits lead to the precipitation of cubic ferrous sulfide and, to a lesser extent, troilite. Neither the mackinawite base-layer nor the upper layer of precipitated material can passivate the surface, so nucleation and growth of cubic ferrous sulfide continue steadily. Nucleation of troilite, the most stable of the three phases, is evidently difficult, but it comprises a substantial portion of the film after 96 hr. Cubic ferrous sulfide transforms extensively to mackinawite by a solid-state mechanism between 35 and 96 hr.

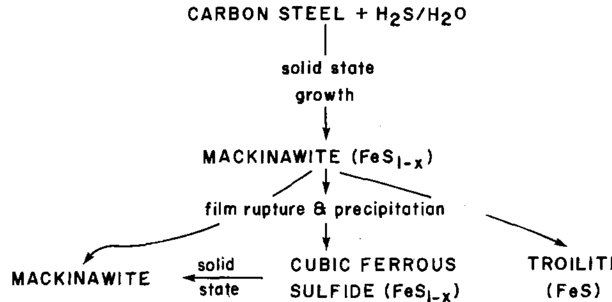

Fig. 14. Schematic reaction sequence representing processes occurring on an iron surface exposed to saturated aqueous H_2S at 21°C and pH = 4.

Kinetics of Growth of Amorphous WO_3 Anodic Films on Tungsten

F. Di Quarto, A. Di Paola, and C. Sunseri

Istituto di Ingegneria Chimica, University of Palermo, Palermo, Italy

ABSTRACT

The kinetics of growth of anodic WO_3 films have been studied in 0.01*N* solutions of H_3PO_4, H_2SO_4, HNO_3, and $HClO_4$ at room temperature. The validity of the relationship $i = A \exp BE$ was verified in the current density range 0.2-16 $mA \cdot cm^{-2}$. Nearly constant B values were found in all investigated solutions. A lower value of dielectric constant was measured for the anodic films grown in phosphoric acid solutions. The effect of phosphate ions incorporation on the breakdown voltage is also discussed. The hypothesis of growth in presence of high space charge is carefully considered.

Although numerous experimental works (1) have been carried out on the anodic behavior of tungsten in aqueous solutions, only a few papers have been concerned with the kinetics of growth of anodic oxide films on tungsten in different acids. Apart from the works of Güntherschulze and Betz (2) and Boosz (3) on the valve-metal behavior of tungsten, the first extensive study on the kinetics was performed by Pitman and Hamby (4) in a wide current-density range (C.D.) but only in 0.1*N* H_2SO_4 solutions at 25°C. In this study the steady-state relationship

$$i = A \exp BE \quad [1]$$

was verified in the C.D. range 0.037-8.6 $mA \cdot cm^{-2}$. In this range the B value was $(5.22 \pm 0.08) \times 10^{-6}$ cm V^{-1}. A film formation current efficiency of 100% was reported above 2 $mA \cdot cm^{-2}$ and a lower efficiency was found below this C.D. value.

The relationship [1] between the C.D., i, and the electric anodizing field E was confirmed by Vas'ko *et al.* (5, 6) in a wide range of temperatures (1.5°-175°C), again in 0.1*N* H_2SO_4. The B value $3.32 \cdot 10^{-6}$ $V \cdot cm^{-1}$ at 25°C reported by these authors differs significantly from that found by Pitman and Hamby.

Ammar and Salim (7) have investigated extensively the growth kinetics of anodic films on tungsten in 1*N* solutions of five different acids in a range of C.D.'s below 1 $mA \cdot cm^{-2}$. Also these authors confirmed the validity of Eq. [1], but they reported electric field intensities and B values which are not in agreement with either the previous ones or the theoretically estimated activation distances.

Recently, Arora and Kelly (8) claimed the valve-metal behavior of tungsten also in an acetic acid-based solution containing 1.0M additional water. Only Ord *et al.* (9, 10) reported a nonlinearity in the plot of ln i *vs.* E in the C.D. range 20-200 $\mu A \cdot cm^{-2}$ both in 0.1M H_2SO_4 and in an acetic acid-based electrolyte which was 2.0M in water. This result was obtained by the analysis of open-circuit transients by assuming that the logs of the C.D. were linearly dependent on the effective electric field (the latter was defined as the product of the applied field and the dielectric constant of the film). The nonlinearity was attributed to the dependence of the dielectric constant of the film on the applied electric field.

As for the nature of the mobile ionic species, mention should be made of the work of Davies *et al.* (11) who reported the transport number of cation was in the range 0.30-0.37, by anodizing tungsten in 0.4M KNO_3 + 0.04M HNO_3 and in the C.D. range 0.1-1 $mA \cdot cm^{-2}$ at 25°C.

Key words: passivity, reflectance, semiconductor, electrode, dielectrics.

As for the composition and morphology of the anodic oxide films on tungsten, all authors agree that in the first instants of anodization there occurs the formation of an amorphous barrier film whose composition is mainly WO_3. To explain the optical behavior of the anodic films, Sarakinos and Spyridelis (12) suggested the formation of a duplex structure involving sulfate ion incorporation, but this claim was not confirmed by Ord *et al.* (10).

In the present work, the influence of different anions on the kinetics of growth of anodic barrier films on tungsten in acid solutions was investigated in a wide range of C.D.'s and at room temperature.

Experimental

Preliminary experiments were performed on different electrodes in order to check the reproducibility of the experimental data. Tungsten foils and rods sealed either directly to glass or to Teflon cylinders with epoxy resins were extensively studied. The best reproducibility was obtained using rods sealed to Teflon hollow cylinders with an insulating mixture of epoxy resins and 1 μm ceramic grains. In the other cases, boundary effects, due to the electrode edges or to a thermally grown oxide, shortened the linear region of the charging curves (see below). All experimental results reported below concern electrodes obtained from spectrographically pure tungsten rods 4 mm diam sealed to Teflon cylinders. The ohmic contact was ensured by a silver paste sealed to the back side of the electrode.

After each measurement at high voltages (80-140V) the electrode surface was freshly prepared by a mechanical polishing with abrasive papers and diamond pastes until 0.1 μm. Afterwards, the electrode was ultrasonically cleaned and then anodized several times in 2M HNO_3 until about 30V; this voltage was much less than the breakdown voltage. The oxide film was removed in 15% (w/v) NaOH, and the bare surface was rinsed with distilled water and dried in a nitrogen stream. At the end of this treatment, a mirror-like surface was obtained which showed even interference colors after anodization.

The galvanostatic measurements were performed using a Keithley Model 227 constant current generator. The cell voltage was monitored with a Keithley Model 610C electrometer and recorded on an Amel Model 862/A x, y, t recorder. A Simpson Model 360 digital multimeter was used in some experiments at high C.D.'s when voltage values higher than 118V were reached.

The reflectance measurements were carried out using a monochromatic light beam obtained by filtering the light from a Bausch & Lomb 150W xenon arc lamp

through a high intensity Bausch & Lomb Model 5 UV-Vis monochromator. The intensity of the reflected light was measured by an RCA Model 5819 photomultiplier tube. Both the cell voltage and the output current from the photomultiplier were recorded, respectively, on the x and y axes of the recorder.

The capacitance of the metal/oxide/electrolyte system was measured by monitoring the 90° out-of-phase component of the a.c. with a PAR Model 128 A lock-in amplifier. The lock-in was equipped with an internal oscillator which drove both an AMEL Model 567 function generator and an AMEL Model 552 potentiostat. The a.c. was obtained by superimposing a 20 mV peak-to-peak a-c voltage on the anodic triangle waveform which modulated the working electrode. The frequency of the a-c voltage was 158 Hz and the sweep of the triangle waveform was 20 $mV \cdot sec^{-1}$.

All the capacitance measurements were performed in 1*N* H_2SO_4 solutions, the counterelectrode was a 10 cm^2 Pt foil and the reference electrode was Hg/Hg_2SO_4 (1*N* H_2SO_4). The electrode surface was 0.1256 cm^2 and the C.D. was calculated on the basis of the apparent area.

The anodizations were carried out in 0.01*N* solutions of H_3PO_4, H_2SO_4, HNO_3, $HClO_4$ in the C.D. range 0.2-16 $mA \cdot cm^{-2}$. Solutions were prepared from distilled water and analytical grade reagents. All experiments were carried out at 25° ± 1°C.

Results and Discussion

Galvanostatic measurements.—As reported in other works (7, 12, 13) the shape of the voltage *vs.* time plots at constant current (charging curves) shows a linear rise until a voltage value is reached at which an inflection appears. This inflection point is preceded or followed, depending on the C.D. and the electrolyte composition, by the occurrence of oscillations in the cell voltage.

The inflection point and the final quasi steady-state value of the voltage can be very different if the anodization is performed at equal C.D. but in different acid solutions. This aspect is more noticeable at the higher than at the lower C.D.'s where it is always present. At a C.D. of 8 $mA \cdot cm^{-2}$, the voltage value at the inflection point is about 135-140V in 0.01*N* H_3PO_4, while it decreases to about 90-95V in 0.01*N* $HClO_4$, HNO_3, and H_2SO_4 solutions. Voltage values found in $HClO_4$ are lower than those in H_2SO_4 and HNO_3.

It is noteworthy to mention that in 1*N* H_3PO_4 solutions, whose resistivity (14) is practically coincident with that of the 0.01*N* H_2SO_4 or HNO_3 solutions employed in our experiments, the inflection point in the charging curves also appears at a voltage value of about 120-125V. Different behavior of tungsten in H_3PO_4 was also found for long times of anodization but this aspect has been widely discussed in another work (13).

In all solutions only a slight influence of the surface finishing on the breakdown voltage was found. For a film growing at constant current, the following relation (15) can be written

$$\frac{dV}{dt} = \frac{dV}{dD} \cdot \frac{dD}{dt} = E_d \frac{i_{ion} M}{z F \rho} \quad [2]$$

where E_d is the differential field strength which corresponds to the applied C.D., i_{ion} is the ionic C.D., *M* the oxide molecular weight, *D* the thickness, ρ the density of the film, and the remaining symbols have their usual meanings.

Equation [2] shows that, by assuming a unitary film formation current efficiency, it is possible to obtain the anodizing electric field from the slope of the charging curves. According to Pitman and Hamby (4) a good agreement between the *E* values obtained from this method and from optical measurements (see below) is found only for $i \geq 2$ $mA \cdot cm^{-2}$. Leakage currents and dissolution processes, which reduce the current efficiency in an unpredictable way, are responsible for the scanty agreement of data obtained from two methods in the experiments performed at low C.D. (≤ 2 $mA \cdot cm^{-2}$). This source of error can significantly affect the electric field values obtained by using Eq. [2] and the *B* values in Eq. [1] (7).

As for the experiments performed in H_3PO_4, it is noteworthy to mention some gravimetric information obtained in 0.01 and 1*N* solutions. In experiments at high C.D. (8 $mA \cdot cm^{-2}$), so that the stay of the electrode in solution was short enough, the growth of the film was stopped in the linear region of the charging curves. The oxide covered electrode (in this case a tungsten foil) was weighed before and after the oxide dissolution in NaOH solution. The ratio between the weight of oxide removed and the weight of WO_3 estimated from the metal loss was larger than unity (1.05) for films formed in 0.01*N* H_3PO_4 and less than unity (0.97) for films formed in 1*N* solutions. The former ratio is in agreement with the hypothesis of phosphate ions incorporation (see also Capacitance Measurements) in the anodic films, the latter seems to indicate a strong dissolving action of H_3PO_4 when it is present in high concentration (13).

Interferometric measurements.—Due to the variable efficiency of film formation current, whose influence is noticeable in the lower C.D. range, an interferometric method was preferred for determining the film thickness and the anodizing electric field in the galvanostatic measurements.

Figure 1 reports typical interference patterns of the light reflected during the growth of oxide films on tungsten at low (0.2 $mA \cdot cm^{-2}$) and high (8 $mA \cdot cm^2$) current density in 0.01 H_3PO_4 solutions.

The thickness of the film can be obtained from the relationship (16)

$$\Delta D = \frac{\lambda}{2(n_1^2 - \sin^2 \phi_o)^{1/2}} \quad [3]$$

where ΔD is the change in film thickness, *D* corresponding to two adjacent maxima or minima in the interference patterns, n_1 is the refractive index of the layer, λ is the vacuum wavelength, and ϕ_o the angle of incidence of the light. The film thickness can be determined by this method if the value of the refractive index n_1 is known at the light wavelength employed.

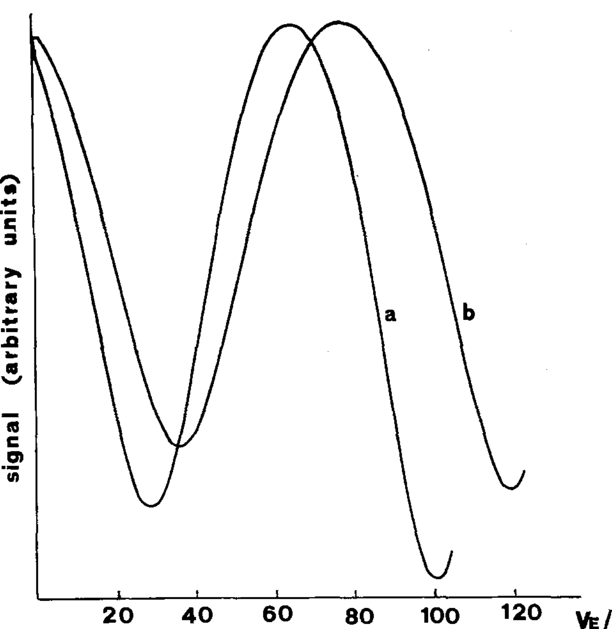

Fig. 1. Interference patterns of the light reflected during the growth of films in 0.01*N* H_3PO_4 solutions. Curve a: $i = 0.2$ $mA \cdot cm^{-2}$; curve b: $i = 8$ $mA \cdot cm^{-2}$. ($\lambda = 6000$Å, $\sin^2 \phi_o = 0.155$).

The choice of the light wavelength was made so that the light absorption within the film was minimized and the number of minima and maxima in the interference pattern were maximized in the range of accessible thicknesses before the breakdown. Both conditions were reasonably fulfilled using monochromatic light at $\lambda = 6000\text{Å}$ ($\lambda\nu < E_g \cong 3.1$ eV).

The n_1 value was calculated by means of Eq. [3], using the value reported by Ord *et al.* (9, 10) for films formed in 0.2*N* H_2SO_4 at $i = 0.2$ mA·cm^{-2} and relative to a wavelength of 6328Å. In fact, assuming a negligible light absorption in the film, from the interference patterns obtained in two separate series of experiments at the same C.D. in 0.2*N* H_2SO_4 at 6000 and 6328Å, respectively, it is possible to write

$$\left(\frac{\Delta D}{\Delta V}\right)^{\text{Min}}_{\text{Max}} = A = \frac{\lambda_1}{4\Delta V_1(n_1^2 - \sin^2\phi_0)^{1/2}} = \frac{\lambda_2}{4\Delta V_2(n_2^2 - \sin^2\phi_0)^{1/2}} \quad [3a]$$

The first member of Eq. [3a] is a quantity experimentally accessible and represents the anodizing ratio *A* which is not dependent on the light wavelength. ΔV_1 and ΔV_2 represent the measurable voltage drops in the interference patterns when the light intensity goes from a minimum to a maximum. The reasonable assumption was made that Eq. [2] still remains valid after the substitution of $\lambda/2$ with $\lambda/4$.

Assuming, according to Ord *et al.* (9, 10), an n_2 value equal to 2.145 at $\lambda = 6328\text{Å}$, a value of 2.162 is obtained for n_1 at $\lambda = 6000\text{Å}$. This last n_1 value was assumed constant in all tested solutions and C.D.'s. To neglect the possible variation of n_1 with the anodizing field (9, 10), gives an error less than 0.5% in the measured thickness.

As Fig. 1 shows, in the measurements performed in 0.01*N* H_3PO_4, in all the C.D. range investigated it was possible to detect a second minimum in the interference patterns before the breakdown phenomenon occurred. In the other solutions, it was impossible to obtain a second minimum before the film breakdown, and the electric field was obtained measuring both the change in the film thickness ΔD corresponding to the adjacent minimum and maximum, and the relative voltage drop. This assumption is supported by the experimental interference patterns in H_3PO_4 (see Fig. 1) which show a voltage drop between two minima almost exactly the double of the minimum-maximum voltage drop.

Figure 1 also shows that at the lower C.D. a decrease of the light intensity is observed in the first instants of anodization at a nearly constant cell voltage. This is in good agreement with the results reported by Ord *et al.* (9) and can be attributed to an initial islandlike growth of the film. When all the metal surface is covered by the oxide, the typical valve-metal behavior begins.

Figures 2 and 3 report the plots of the average anodizing electric field against the logarithm of the corresponding C.D., in the various solutions. A linear relationship between log *i* and *E* can be observed in the C.D. range 0.2-16 mA·cm^{-2}.

The electric field was obtained, as previously reported, by $E = \Delta V/\Delta D$. The accuracy in the measured electric field was estimated to be better than 2%. The agreement with the *E* values obtained from the charging curves was within this value for $i \geqq 2$ mA·cm^{-2}.

In all solutions, the electric field values measured at $i = 0.2$ mA·cm^{-2} do not fall on the straight line but are lower. This is indicative of a true decrease in the film formation current efficiency as previously discussed. The values of the slopes of the ln *i* *vs.* *E* lines are reported in Table I. A little variation in the *B* values is found in the different solutions.

Capacitance measurements.—Capacitance measurements of anodic films grown at different thicknesses

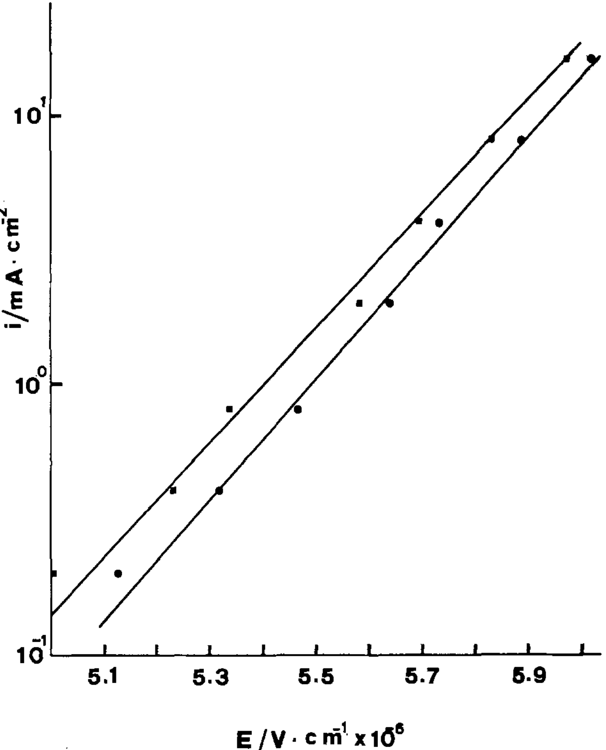

Fig. 2. Dependence of log *i* on electric field *E*. ■ 0.01*N* H_2SO_4; ● 0.01*N* HNO_3.

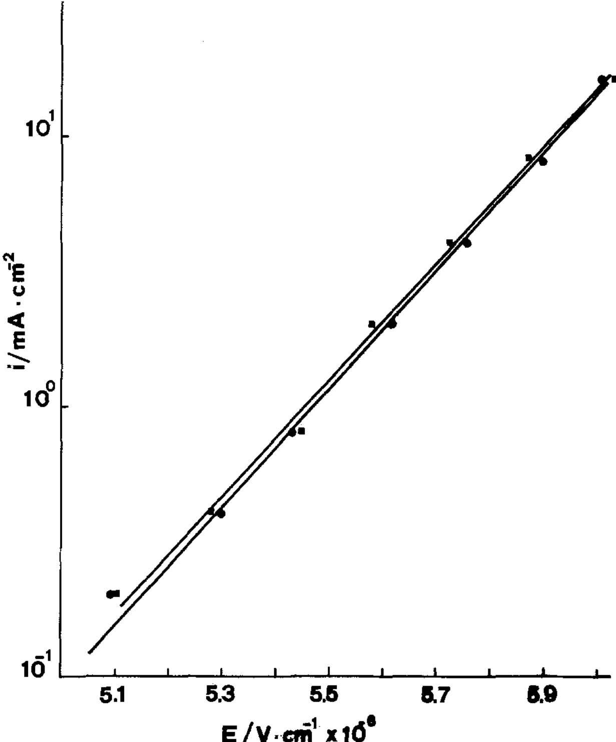

Fig. 3. Dependence of log *i* on electric field *E*. ■ 0.01*N* H_3PO_4; ● 0.01*N* $HClO_4$.

and C.D.'s were carried out in order both to obtain more information on the ion transport controlling process and to detect eventual anion incorporation. The capacitance measurements were performed soon after the interruption of the growth of the films which were obtained by anodization at constant current until the voltage reached a prefixed V_F value. In this way the measured reciprocal capacitance was related to the final voltage and then both to the film thickness and the anodizing electric field. In Fig. 4 the electrode capacitance *C* is plotted *vs.* the electrode

Table I. *B* values obtained from the slopes of Fig. 3 and 4

Electrolyte (0.01*N*)	*B* ($V \cdot cm^{-1}$)
H_3PO_4	4.90×10^{-6}
HNO_3	5.17×10^{-6}
$HClO_4$	5.00×10^{-6}
H_2SO_4	4.90×10^{-6}

potential for two specimens anodized until different final voltages V_F. In the capacitance measurements the maximum value of anodic potential V_E was 3 for V_F values up to 40V, and 5 for V_F values higher than 50V.

Figures 5 and 6 show the plots of the final voltage values V_F against the reciprocal value of the oxide film capacitance at two different C.D.'s. The capacitance values of Fig. 5 and 6 were obtained taking into account the fact that for large anodic polarization—where the space charge layer equals the thickness—the capacity of an n-type semiconductor film with a wide bandgap becomes constant, being a measure both of the thickness and of the dielectric constant (17).

The measured capacitance is given by the relation

$$\frac{1}{C} = \frac{1}{C_{ox}} + \frac{1}{C_H} \cong \frac{1}{C_{ox}} \quad [4]$$

where C_{ox} and C_H are, respectively, the oxide and the Helmholtz double layer capacitances. Since usually $C_H >> C_{ox}$, the measured capacitance corresponds practically to the oxide film capacitance. In Fig. 5 and 6, corrected capacitance values were used for the thinnest films by using a 20 $\mu F \cdot cm^{-2}$ value for C_H.

The excellent linearity in the plots of V_F *vs.* $1/C_{ox}$, found in all solutions and C.D. range seems in agreement with the hypothesis of kinetic control at one of the two metal/oxide or oxide/electrolyte interfaces (18).

A noticeable difference was found in the slopes of the lines in Fig. 5 and 6 for electrodes anodized in

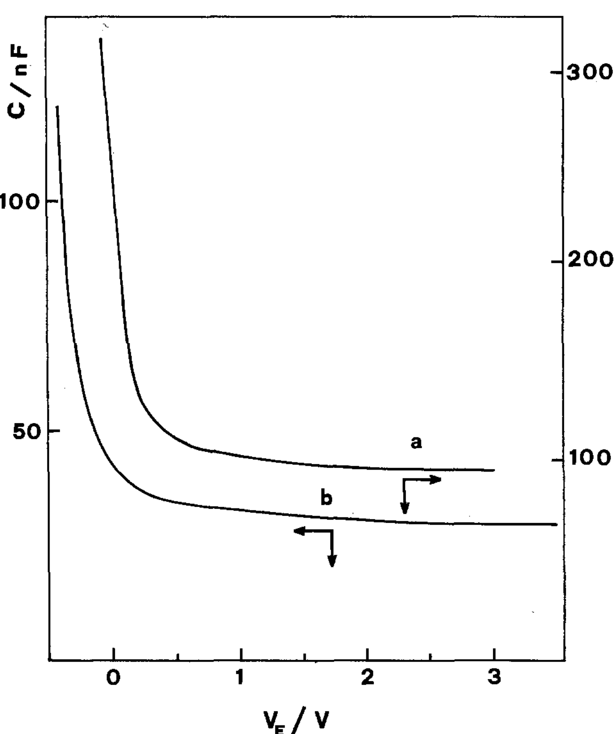

Fig. 4. Electrode capacitance *C* *vs.* electrode potential V_E for electrodes anodized at $i = 8$ $mA \cdot cm^{-2}$ in 0.01*N* H_3PO_4 until different final cell voltages, V_F. Curve a: $V_F = 32V$; curve b: $V_F = 101V$.

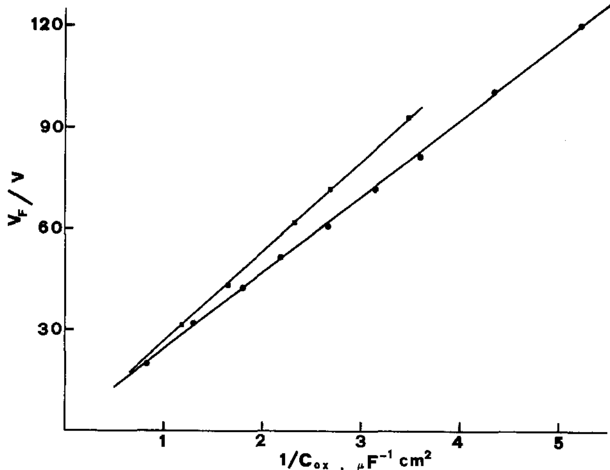

Fig. 5. Final cell voltage V_F *vs.* reciprocal value of oxide film capacitance $1/C_{ox}$ for electrodes anodized at $i = 8$ $mA \cdot cm^{-2}$ in different solutions. ● 0.01*N* H_3PO_4; ■ 0.01*N* HNO_3.

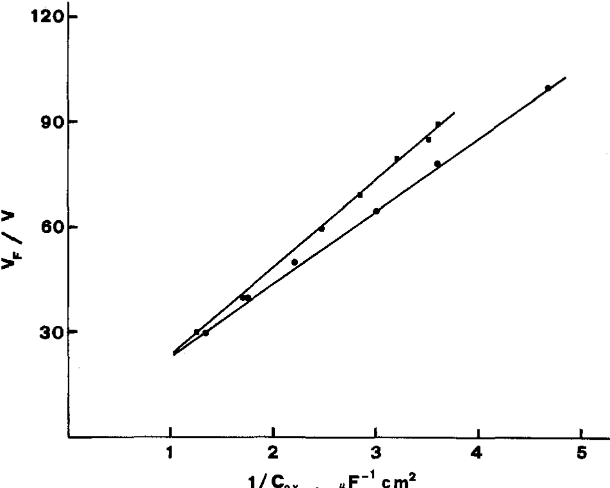

Fig. 6. Final cell voltage V_F *vs.* reciprocal value of oxide film capacitance $1/C_{ox}$ for electrodes anodized at $i = 0.4$ $mA \cdot cm^{-2}$ in different solutions. ● 0.01*N* H_3PO_4; ■ 0.01*N* H_2SO_4.

H_3PO_4 or in the different solutions. In all C.D. ranges, a lower value of the slopes of the lines relative to the measurements in H_3PO_4 was found. Higher, nearly equal, values of the slopes were obtained for the remaining acids (see Table II).

This result can be explained recalling that

$$\left[\frac{\partial V_F}{\partial(1/C_{ox})}\right]_{i,T} = \epsilon_{ox}\epsilon_0 E \quad [5]$$

where *E* is the anodizing field at the chosen C.D., ϵ_{ox} and ϵ_0 are, respectively, the oxide and vacuum dielectric constants and assuming a decrease in the di-

Table II. Dielectric constant values for WO$_3$ oxide films obtained in different solutions and C.D.'s. The ϵ_{ox} values were determined by using Eq. 5.

Electrolyte (0.01*N*)	ϵ_{ox}	*E* ($V \cdot cm^{-1}$)	$\frac{\partial V_F}{\partial(1/C_{ox})}$ ($\mu C \cdot cm^{-2}$)	*i* ($mA \cdot cm^{-2}$)
H_3PO_4	44.3	5.87×10^6	23.0	8.0
	44.0	5.28×10^6	20.5	0.4

	54.0	5.33×10^6	25.5	0.4

electric constant of the films obtained in H_3PO_4. In fact, as shown by Table II, the E values obtained from interferometric measurements are practically equal in all acid solutions at the same C.D. Table II also reports the dielectric constant values of oxide films grown in different solutions and at different C.D.'s. The ϵ_{ox} values were calculated by Eq. [5] using the experimental values of the electric fields and of the slopes of the V_F *vs.* $1/C_{ox}$ lines.

Average dielectric constant values of 43.5 and 54 were obtained for WO_3 anodic films formed respectively in H_3PO_4 or in the different acid solutions. Both these ϵ_{ox} values are in good agreement with the literature data (4, 9); they should be compared to the static and zero electric field ϵ_{ox} values.

Further interesting information was obtained from a detailed analysis of the capacitance measurements at low anodic potentials (19). They concern: (*i*) the noticeable influence of the thickness on the donor concentration N_D in the films. A decrease in N_D was revealed with increasing thickness. A similar result was reported by Heusler *et al.* (20, 21) for Nb_2O_5 anodic films; (*ii*) the existence of a region near the oxide/electrolyte interface with constant donor concentration. In this region, whose thickness is about 60% of the total film thickness, the N_D value may be related to D by the relation $N_D \propto d^{-n}$, with $n = 1.8 \pm 0.2$ (19, 20). A higher donor concentration in the neighboring metal/oxide interface (22) could cause the decreasing slopes measured in the $1/C^2$ *vs.* V_E curves with increasing electrode potential; (*iii*) the absence of any influence of the investigated electrolyte compositions on the above-mentioned properties.

Conclusions

On the basis of the experimental results, it is possible to draw some conclusions on the kinetics of growth of amorphous barrier films on tungsten in weakly acid solutions of different anions.

The most important result concerns the absence of curvature in the plots of ln i against E in the C.D. range 0.2-16 $mA \cdot cm^{-2}$. The disagreement with the results reported by Ord *et al.* (10) could be attributed to a breakdown of Ord's anodic oxidation model in the range of investigated C.D.'s as well as to the fact that experimental information obtained by different measuring techniques cannot be interpreted by the same mathematical relationship (23).

Moreover, in the anodic oxidation of tungsten special attention must be paid to the side parasitic reactions which reduce the film formation current efficiency especially at the lowest C.D.'s.

As for the influence of the anions, they are very significant in determining both the breakdown voltage in the different solutions and the dielectric constant of the anodic oxide films. The lower values of the dielectric constant measured for films grown in H_3PO_4, could be attributed to the incorporation of phosphate ions in the films as reported for other valve-metals (24, 25).

Different breakdown mechanisms can explain the different breakdown voltage values, which in H_2SO_4, $HClO_4$, and HNO_3 are lower than in H_3PO_4 (13). In fact, in the former solutions a mechanical breakdown due to very high internal stresses (a very high Pilling-Bedworth ratio of 3.34 is found for WO_3 films) probably occurs during the anodization process (26). Otherwise, the incorporation of phosphate ions could decrease the internal stresses (27, 28) favoring the achievement of higher thicknesses of the barrier film and the occurrence of an electrical breakdown (29, 30).

As mentioned above, an interfacial barrier kinetic control can be invoked on the basis of the V_F *vs.* $1/C_{ox}$ curves. However, it is noteworthy to mention that an alternative model of growth with kinetic control within the anodic film cannot be discarded *a priori*. In fact, if it is assumed according to the Fromhold theory (31, 32) that the formation of the anodic oxide films on tungsten occurs under very large electric fields and in the presence of high space charge, a very good linearity can be found in the V_F *vs.* D (*i.e.*, $1/C_{ox}$) curves by assuming a space charge screening parameter of about 10Å. This assumption could result in a defect concentration of about $10^{19} \cdot cm^{-3}$ at the injecting interface.

Moreover, if the donors in WO_3 anodic films are identified with the injected defects which are frozen in when the film growth is stopped, two further considerations could support the Fromhold model: (*i*) first is the agreement between the defect concentration mentioned above and the donor concentration value found by extrapolating the $N_D \propto d^{-n}$ relationship (19) at 1V thickness; (*ii*) the second is the qualitative agreement found between the defect concentration profile foreseen by the model and the donor distribution mentioned above (see Capacitance Results). In this frame the kinetics of growth of anodic WO_3 amorphous films would be controlled by the transport within the anodic film of the oxygen vacancies injected at the metal/oxide interface. The nearly equal B values could support this mechanism.

It is noteworthy that a constant electric field with increasing thickness as revealed by the interferometric measurements is partially conflicting with the above-reported model (32).

ABSTRACT

Five different compositions of mixed acidic $PdCl_2/SnCl_2$ catalysts for electroless plating were investigated mainly by electrochemical and x-ray photoelectron spectroscopy measurements, and also by ultraviolet and visible photospectroscopy, transmission electron microscopy, and Auger electron spectroscopy. It is shown that the potential sweep technique using a catalyzed gold electrode in 1M HCl yields voltammograms which depend upon the catalyst activity, and that this technique is applicable for simple diagnosis of the activity of mixed $PdCl_2/SnCl_2$ catalyst systems. It was found by transmission electron microscopy that large colloidal particles are required for high catalytic activities. X-ray photoelectron spectroscopy showed that these colloidal particles consist of a system in which Pd and Sn atoms have an interaction such as in Pd-Sn intermediates or alloys. The ratio of Pd/Sn after acceleration is not constant but depends on the catalyst activity. The accelerator (1M NH_4BF_4 or 1:1 HCl) not only removes Sn(IV) ions from the substrate but also causes coagulation of small particles adsorbed on the substrate, and these actions result in a drastic increase in the activity of low activity catalysts.

The mixed $PdCl_2/SnCl_2$ solution containing hydrochloric acid is most commonly used in electroless plating to make metallic or nonmetallic substrate surfaces catalytically active to initiate the metal deposition. A two-step immersion procedure consisting of sensitization ($SnCl_2$ solution) and activation ($PdCl_2$ solution) was used for many years in the past, while a significant development has been achieved more recently by a single-step mixed $PdCl_2/SnCl_2$ catalyst system, which was first described by Shipley (1). He claims that the catalyst solution contains colloidal particles, and D'Ottavio (2) mentions the presence of uniform stable colloidal particles in the mixed catalyst system which gives active sites on substrates. On the contrary, other investigators in patents claim that the activity results from Pd-Sn solute complexes and not from the colloidal particles (3, 4).

Two groups of investigators have reported on the same catalyst systems as those described in the patent literature cited above. Rantell and Holtzman (5) concluded that the activity of the mixed catalysts is not due to a colloid but to a $SnPd_7Cl_{16}$-type solute complex. de Minjer and Boom (6) showed that the activity results from a Pd-Sn complex containing one Pd atom per two Sn atoms. Feldstein *et al.* (7) also reported that the complex of Pd_3Sn gives the most active sites on substrate surfaces. Joisson and Devand (8) discussed the same Pd_3Sn complex formation by precipitation in acidic Pd(II)/Sn(II) complex solutions.

Contrary to the above proposals involving solute or deposited complexes, Cohen *et al.* (9a, b) concluded by ultracentrifugation, electron microscopy, and Mössbauer spectroscopy that the mixed acidic catalyst systems are colloidal and that the metal deposition is initiated by the formation of a Pd-Sn alloy core with a stabilizing layer of adsorbed Sn(II) ions. Cohen and Meek (9b) reported the ratio of Pd/Sn $\simeq$ 6 for the Pd-Sn alloy core and discussed this result in comparison with other conflicting results. Nagai *et al.* (10) also concluded that the active sites are in the colloidal state. Finally, Matijević *et al.* (11) investigated the various catalysts commercially available and also prepared in their laboratory, and concluded that the catalytic activity is exhibited only by the colloidal

Key words: electroless plating, mixed $PdCl_2/SnCl_2$ catalyst, XPS measurement.

bottom layer obtained by separation using prolonged ultracentrifugation and not by the supernatant liquid.

In the case of selective electroless plating using ultraviolet irradiation, D'Amico *et al.* (12) found that the metal deposition does not initiate when Sn(II) species is photo-oxidized by exposure to ultraviolet light in air. Furthermore, Baylis *et al.* (13) reported that the copper plating does not initiate without ultraviolet irradiation when a Sn(IV) sensitizer-Pd(II) activator is used. Kelly and Vondeling (14) also described the nucleation of Pd on photosensitive TiO_2 by ultraviolet irradiation. Hamilton and Logel (15) concluded by using evaporated Pd that large Pd particles (4 $\sim$ 20 atoms) are required to initiate electroless nickel deposition. Thus, for the two-step immersion procedure, it can be concluded that Pd(O) nuclei on substrate surfaces are the catalytically active sites which initiate electroless plating. In the case of a single-step procedure using mixed $PdCl_2/SnCl_2$ catalyst solution, the active sites consisting of Pd-Sn alloy, Pd_3Sn, or $PdSn_2$ on substrate surfaces have been suggested by Cohen *et al.* (9a, b), Feldstein *et al.* (7) and de Minjer *et al.* (6).

The other important process in the single-step procedure using mixed $PdCl_2/SnCl_2$ catalyst is the acceleration which enhances the activity of the mixed $PdCl_2/SnCl_2$ catalyst. Typical accelerators reported are ammonium fluoborate, ammonium bifluoride, fluoboric acid, hydrochloric acid, sulfuric acid, or sodium hydroxide (5c, 9c).

In this communication, we will investigate the mixed acidic catalysts and also the accelerator effects for the single-step procedure using the mixed $PdCl_2/SnCl_2$ catalyst mainly by means of electrochemical methods. We will also describe an electrochemical method of diagnosing the surface activity and the results of our attempt to find the form of catalytically active palladium using x-ray photoelectron spectroscopy.

Experimental

Preparation of catalysts.—Typical samples, including a commercial one, of mixed acidic $PdCl_2/SnCl_2$ catalysts were chosen and prepared by referring to the patents (1-4) and Matijević's experiments (11). Sample "E" (Hitachi Kasei Company, HS-101B) was used as a typical commercial sample. Preparation procedures and compositions of these catalysts are shown in Table I. All solutions were prepared with reagent grade chemicals and doubly distilled water. A freshly prepared solution of stannous chloride was always used because stannous chloride is easily oxidized by oxygen in air. Samples "A" and "B" contained, respectively, large and small concentrations of $PdCl_2$, sample "C" was an improved Shipley solution containing Na_3SnO_3 which was added as a stabilizing agent for colloidal particles (5b), and sample "D" was prepared by a process which was an improved version of that described in Zeblisky's patent (3a). The surfactant such as $C_2F_{n+1}SO_2Z$ (Z is a hydrophilic group), which in the Zeblisky patent (3b) is claimed to improve "wetness" of substrates, was omitted in this preparation.

Functionality test for electroless plating.—The catalytic activity of mixed acidic $PdCl_2/SnCl_2$ catalysts was tested using an electroless nickel plating bath with the basic composition previously given in Ref. (16) ($NiCl_2 \cdot 6H_2O$ 29.4 g/liter, malonic acid 20 g/liter, DMAB (dimethylamine borane) 3.54 g/liter, pH 9.5 adjusted with NH_4OH, bath temperature 70°C). Glassy epoxy plastic boards (Hitachi Kasei Company, JIS-G10) and copper wires were selected as the substrate to be plated. The redox potential measurement for monitoring the initiation time of plating was performed with copper wire. The process of electroless plating consisted of these steps: (*i*) degrease in ethanol, (*ii*) rinse with water, (*iii*) activate in mixed acidic $PdCl_2/SnCl_2$ catalyst solution (3 min), (*iv*) rinse with water (this step was omitted when 1:1 HCl[1] was used as accelerator), (*v*) immerse in accelerator solution (1M NH_4BF_4 or 1:1 HCl) (3 min), (*vi*) rinse with water, (*vii*) start electroless plating.

Electrochemical measurement.—A gold wire or disk electrode was used as the test electrode, because gold does not have a catalytic activity to initiate electroless plating and also because gold shows a wide double layer region in 1M HCl. The counterelectrode was a gold wire. All potentials were measured against a saturated calomel electrode or a hydrogen electrode, and they are referred to as the saturated calomel electrode (SCE). Potential sweep was applied on the gold electrode after immersing into the activator for 1 min and then into the accelerator for 15 sec. Measurements were performed at 25°C.

Photospectroscopy (u.v. and v.l.), transmission electron microscopy, Auger electron spectroscopy, and x-ray photoelectron spectroscopy.—Ultraviolet and visible spectra of mixed catalyst solutions were measured between 200 and 700 nm with a Shimazu double beam UV-140 spectrophotometer. Sample solutions were prepared by diluting the catalysts with 1M HCl or water. Electron microscope measurements were made using a JEOL JEM-7A instrument with 100 kV electron source. Samples for transmission electron microscopy were prepared by immersing the copper grid coated with collodion film into the catalyst and/or accelerator solutions for 3 min. Auger electron spectroscopy was performed with an Anelva EMAS II instrument, and electroless plated Ni-P sheets (plated by the Sumer method) were used as substrates instead of gold, since the characteristic peaks of gold interfere with the spectra due to surface materials.

[1] 1:1 hydrochloric acid was prepared by diluting 37% HCl with the same volume of water.

* Commercial catalyst marketed by Hitachi Kasei Company.

X-ray photoelectron spectroscopy was carried out on a modified JASCO ESCA I spectrometer (17). Samples for XPS were made by immersing copper plates into sample solutions for *ca.* 3 min, dried under vacuum, and irradiated with Al $K\alpha$ x-ray with energy of 1486.6 eV. Solution samples for the freeze-dry method (FDM) were frozen with Dry Ice on copper plate and dried under vacuum.

Results and Discussion

Functionality test of catalysts for electroless nickel plating.—Electroless nickel plating on glassy epoxy plastic boards for the functionality test of mixed acidic $PdCl_2/SnCl_2$ catalysts was performed for 3 min after pretreatment processes which were described in the experimental section (1:1 HCl was used as accelerator in this case). All samples showed catalytic activities, and especially samples "D" and"E" gave completely uniform nickel films on glassy epoxy plastic boards within the 3 min plating time. Samples "A", "B", and "C" gave patched nickel films, and among the five samples the "C" catalyst gave the worst nickel film on glassy epoxy plastic board.

In order to investigate the functionality of catalysts more precisely, the mixed potential of copper wire in the plating bath was measured after activation and after acceleration (where 1M NH_4BF_4 was used as accelerator instead of 1:1 HCl in order to avoid copper dissolution). Time dependence of the mixed potential is demonstrated in Fig. 1(a) and (b). Figure 1(a) shows the time dependence of mixed potential only with activation (without acceleration). Since the mixed potential changes drastically at the time when a nickel layer covers the copper substrate surface, the initiation time of electroless plating after copper immersion can easily be determined as shown in Fig. 1(a)

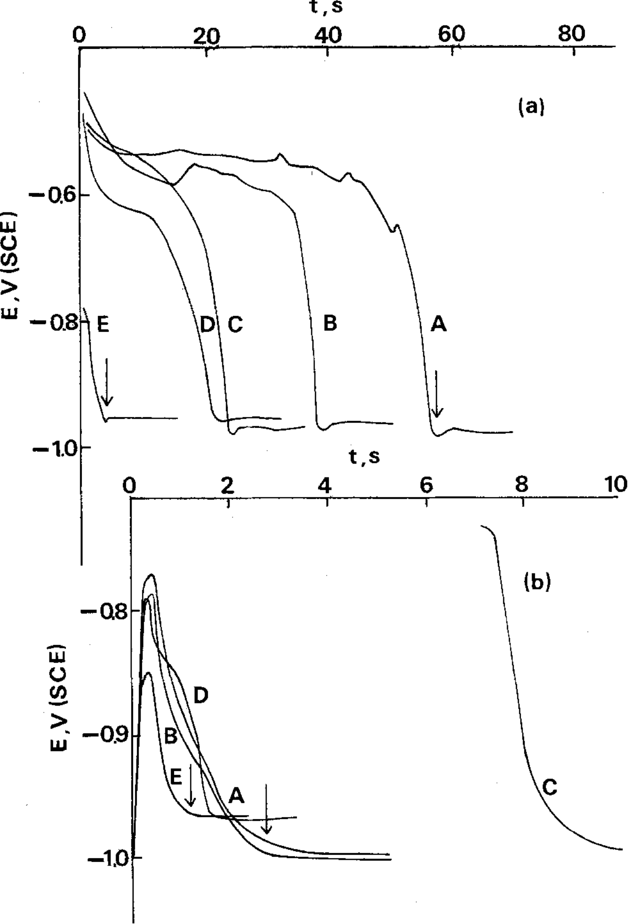

Fig. 1. Functionality test for electroless nickel plating. (a) Time dependence of mixed potentials after activation; (b) time dependence of mixed potentials after acceleration.

(*cf.* the arrows in the figure). This provides the basis for diagnosing the catalyst functionality. The reciprocal order of the induction time corresponds to the order of the catalyst activity; E > D > C > B > A. The time dependence of mixed potential after acceleration procedure shown in Fig. 1(b) demonstrates that the induction times are greatly shortened especially for samples "A" and "B". Sample "C" showed an exceptional behavior or a long induction time after acceleration. This can be explained by the facts that the solution color of sample "C" was more greenish than the other catalyst solutions (*cf.* next section) and that the acceleration effect of removing Sn(IV) ions from substrates was less for this sample because of the presence of sodium stannate for stabilizing Sn(II) ions. Since sample "E", commercial HS-101B, shows the shortest induction time and the most anodic potential after the initiation of plating, this sample is the most active among the five catalysts. Among the samples prepared in our laboratory, sample "D" which showed almost the same catalytic activity as sample "E" in terms of the induction time and catalyst color, was the most active. The results from the actual plating on glassy epoxy plastic board shown above correspond to the information obtained by the redox potential measurements shown in Fig. 1(b).

Spectrophotometric measurement of mixed $PdCl_2/SnCl_2$ in hydrochloric acid solution.—The solution of mixed $PdCl_2/SnCl_2$ in HCl shows green color, which gradually changes to dark brown. A precipitation occurs after keeping the dark brown catalyst solution in air.[2] This precipitate redissolves and finally yields a light yellow solution. Typical absorption spectra of mixed $PdCl_2/SnCl_2$ in 1M HCl at each stage and those of $PdCl_2$ and $SnCl_2$ in HCl solutions are shown in Fig. 2. The Pd(II) ion gives absorption peaks at 280 and 475 nm, while the Sn(II) ion does not give characteristic absorption peaks in the ultraviolet and visible regions though the extinction coefficient of $SnCl_2$ increases with decrease in wavelength in the ultraviolet region. A typical sample of green $PdCl_2/SnCl_2$ (molar ratio 1:10) mixture has three absorption peaks at 280, 330, and 420 nm. Since the characteristics of the absorption spectrum of green catalyst solution neither coincide with that of $PdCl_2$ nor $SnCl_2$, it indicates the formation of a soluble Pd-Sn complex. The absorption spectrum taken after the color change from green to dark brown contains a somewhat wavy linear portion with a high extinction coefficient. In this case the peak at 280 nm due to Pd(II) ions was still observed. However, in the actual samples shown in Fig. 3, only approximately straight lines without the peak at 280 nm were observed. This may be due to the differences in Pd(II)/Sn(II) ratio and in aging of colloidal solutions. According to Nagai *et al.* (10), the first green intermediate complex is $(Pd(II)Sn(II)_mCl_x)^{n-}$ (where $m = 2$ and 6) with various ratios of Pd(II)/Sn(II), and the complex ions are decomposed gradually by the intermolecular redox reaction of Pd(II) with Sn(II) to form free Pd(O) and Sn(IV) and form the second dark brown intermediate of colloidal palladium particles. Cohen *et al.* (9a, b) concluded by their Mössbauer spectroscopy that the solid particles are protective colloids which consist of Pd-Sn alloy core with a stabilizing Sn(II) ion layer and that the precipitation occurs by the oxidation reaction of Sn(II) layer to Sn(IV). In view of the above authors' and Matijević's reports, the spectrum of somewhat wavy linear line with a high extinction coefficient is considered to be the feature of colloidal state. This interpretation was confirmed by the electron microscopy measurement described later.

The absorption spectra of the five catalyst samples are shown in Fig. 3, where the sample solutions were

[2] Contrary to Nagai's report (10), the induction time for the precipitate formation depended upon not only the molar ratio of Sn(II)/Pd(II) but also the Pd(II) concentration.

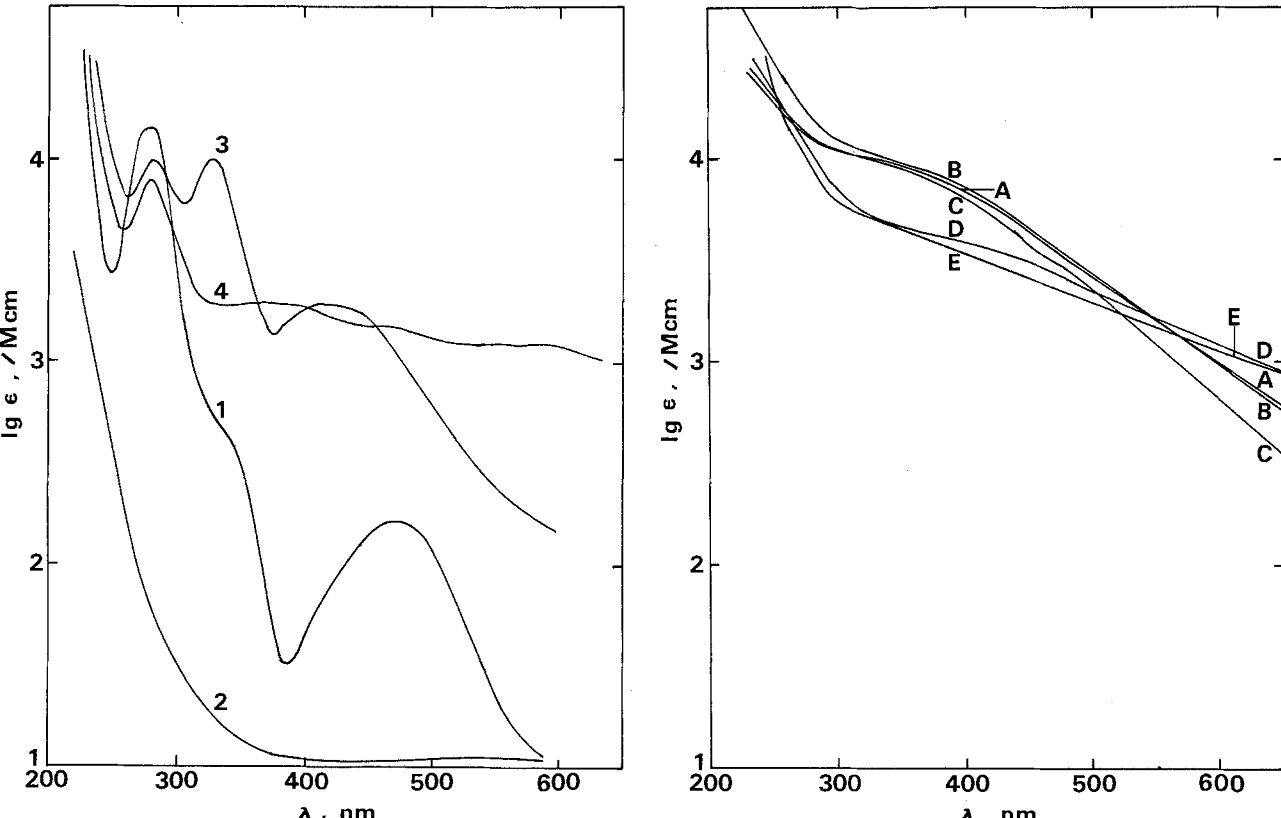

Fig. 2. Absorption spectra of $PdCl_2$, $SnCl_2$ and mixed $PdCl_2/SnCl_2$ catalyst solutions in the ultraviolet and visible regions. Curve 1, $PdCl_2$, curve 2, $SnCl_2$, curve 3, mixed $PdCl_2/SnCl_2$ solution with green color (Pd/Sn = 1/10), curve 4, mixed $PdCl_2/SnCl_2$ solution with dark brown color (Pd/Sn = 1/10).

Fig. 3. Absorption spectra of five samples of mixed $PdCl_2/SnCl_2$ catalyst solutions. Each character in figure shows sample designation.

diluted with water. All spectra show almost the same tendency corresponding to the dark brown solution shown in Fig. 2; this result indicates that the catalyst solutions are in colloidal state. Samples "D" and "E", the most active catalysts, show the best linearity in the visible region.[3]

Since the spectrum of the redissolved solution after precipitation agreed with that of $PdCl_2$ solution, the redissolved solution is considered to consist of $PdCl_2$ containing oxidized Sn(IV) ions. The preparation of catalyst solution in nitrogen atmosphere prevented the precipitate formation, and the precipitation did not take place for a long time when the catalyst solution was stored in a nitrogen atmosphere. Therefore, oxygen produces the precipitate by oxidizing Sn(II) to Sn(IV), and this result supports the contention that Sn(II) ions stabilize the Pd-Sn colloidal particles.

Transmission electron microscopy.—The colloidal particles of catalyst solutions adsorbed on collodion film were observed by the transmission electron microscopy after activation and/or acceleration (see Fig. 4). The particles adsorbed after activation with sample "A" are unevenly distributed and measured several tens of angstroms or less. In the case of sample "D," more uniform distribution was observed as patches measuring 400 ~ 700Å and consisting of small (several tens of angstroms) particles. The commercial sample "E" after activation displayed a uniform, high density distribution of large particles 300 ~ 600Å in diameter. These particles give the most uniform distribution on a collodion film. Therefore, the catalyst solutions are considered to be colloidal, and the catalytic sites formed on substrates after activation consist of colloidal particles. The large size of colloidal particles adsorbed on substrates is required at the activation stage to produce a high catalytic activity. The surface conditions after activation and acceleration are demonstrated in Fig. 4 (a'), (b'), and (c'). In the case of sample "A," there are two kinds of distribution, *i.e.*, the high and low density regions consisting of several tens of angstroms particles. Sample "D" also displays the two kinds of particle distribution; the high density regions consisting of large particles, 400 ~ 700Å, show a relatively uniform distribution, and the low density regions consist of small (several tens of angstroms) particles. The commercial sample "E" was somewhat different from the other two samples. Although there are two types of distribution, the high density regions are almost circular in shape with *ca.* 1000Å in diameter, whereas particles with 100 ~ 200Å in diameter are distributed uniformly in the low density regions. The accelerator is considered to not only remove the Sn(IV) ions but also coagulate the small particles to produce high density particles.[4]

Electrochemical Approaches Using Gold Substrate

Anodic sweep in 1M HCl after activation.—Figure 5 shows current-potential curves obtained on single anodic sweep at a gold electrode in 1M HCl after immersion into the five different catalyst solutions (*i.e.*, after the activation procedure). In the case of the most active catalyst solutions, samples "D" and "E", three distinct anodic peaks were obtained at −0.10 (P1), 0.21 (P2), and 0.43V (P3). With the other three samples each anodic scan gave only two peaks at −0.10 (P1) and 0.20V (P2). This electrochemical technique can be used for rapid diagnosis of the activity of mixed catalysts. In order to identify the cause of each peak in the single anodic sweep after activation, a single anodic sweep was performed after each step in the two-step procedure. Figure 6 shows the anodic sweep in 1M HCl

[3] The data in Fig. 3 were obtained by diluting with distilled water. In the case of dilution with HCl solution, samples "A", "B", and "C" gradually lost the linearity in the absorption spectra, and their spectra became close to that of the first green intermediate complex. A large excess of chloride ions is considered to decompose the colloidal state of the mixed catalyst solutions.

[4] The action to remove the Sn(IV) ions will be discussed later.

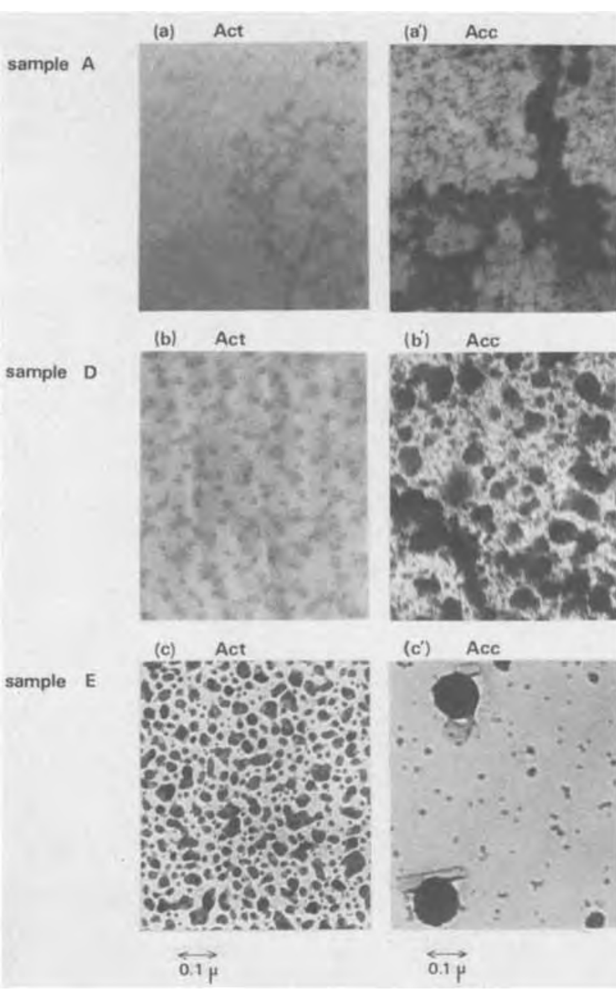

Fig. 4. Transmission electron micrographs of various samples on collodion film after activation or after acceleration. (a), (b), (c): after activation, (a'), (b'), (c'): after acceleration.

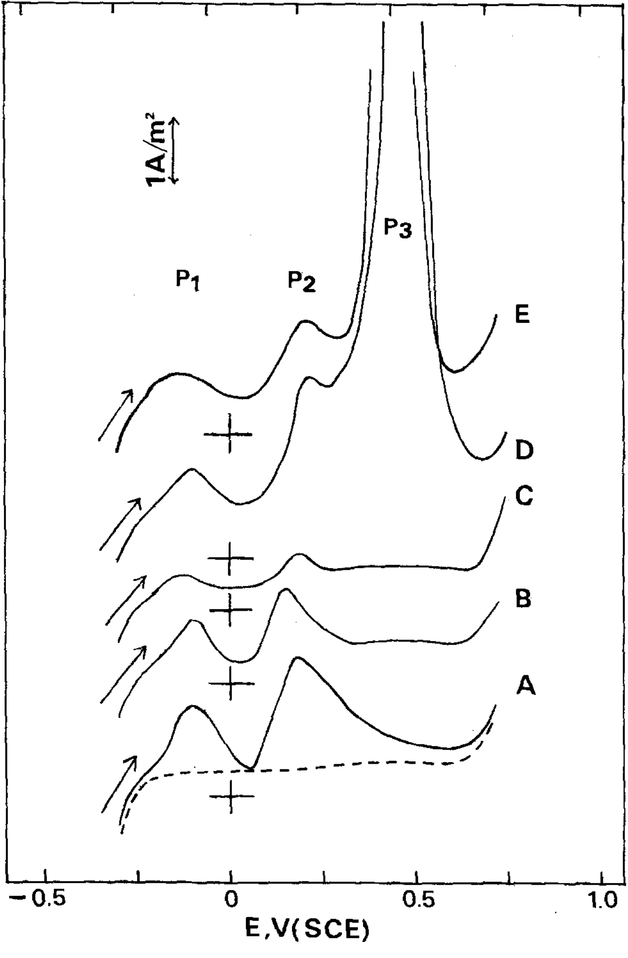

Fig. 5. Voltammograms on Au electrode in 1M HCl. Solid lines: single anodic sweep after activation, dashed line: anodic sweep without activation, sweep rate: 0.1 V/sec. Each character shows sample designation.

after immersion into $SnCl_2$ solution[5] (sensitization), immersion into $SnCl_2$ and $PdCl_2$ solutions[6] (activation), and immersion into $PdCl_2$ solution only. In the case of sensitization, only two peaks appeared corresponding to "P1" and "P2" in Fig. 5. After activation in the two-step procedure, three anodic peaks similar to those of samples "D" and "E" were observed. It is concluded by considering (a) and (b) in Fig. 6 and the more detailed experiments shown later, that the anodic peaks "P1" and "P2" correspond to the desorption of adsorbed $Sn(II)_{ad}$ or $Sn(O)_{ad}$[7] and the oxidation reaction from Sn(II) to Sn(IV), respectively, and that the anodic peak "P3" is caused by the dissolution of Pd. The anodic sweep after immersion only into $PdCl_2$ solution seen in Fig. 6(c) is identical to that obtained without immersion into $PdCl_2$ solution. This result indicates that Pd(O) adsorbed on gold is not produced in the absence of adsorbed Sn(II) formed by the sensitization procedure.

Cyclic voltammograms on gold in 1M HCl containing Sn(II) ions or Pd(II) ions.—In order to obtain further insight into the anodic peak in Fig. 5, cyclic voltammograms were taken in 1M HCl containing $SnCl_2$ or $PdCl_2$. The cyclic voltammograms on gold with various amounts of $SnCl_2$ in 1M HCl are shown in Fig. 7. Two anodic peaks are seen at −0.10 (P4) and 0.20V (P5). It was confirmed by the cyclic voltammograms with changing cathodic scanning potential range that the cathodic peak at −0.10V (P4') corresponds to that of "P4" in the anodic sweep. The anodic and cathodic peaks "P4" and "P4'" give the saturation value of 85.2 $\mu C/cm^2$, while the peak "P5" gradually increases within the concentration of $SnCl_2$. Therefore, it is clear that the peak "P4" or "P4'" is due to the desorption or adsorption of Sn(O) or Sn(II), *i.e.*, the so-called underpotential deposition, and that the peak "P5" is caused by the oxidation reaction $Sn(II) \rightleftharpoons Sn(IV) + 2e$. The peaks "P1" and "P2" in the single anodic sweep after sensitization shown in Fig. 6(a) or activation shown in Fig. 5 or Fig. 6(b) clearly correspond to those of "P4" and "P5" in Fig. 7. Since the cyclic voltammograms on gold in 1M HCl containing Sn(IV) (as $SnCl_4$) ions was approximately the same as that of the blank solution, the cathodic peak "P4'" in Fig. 7 is not due to $Sn(II)_{ad}$ but to the $Sn(O)_{ad}$ adsorption reaction $[Sn(II) + 2e \rightleftharpoons Sn(O)_{ad}]$.[8] When the saturated adsorption value of Sn_{ad} is compared with that of O_{ad} of 395 $\mu C/cm^2$,[9] it is clear that the coverage is very small (1/4 ~ 1/5), and there may be a possibility of co-adsorption of $Sn(II)_{ad}$ without accompanying a charge transfer $[Sn(II) \rightleftharpoons Sn(II)_{ad}]$.

Figure 8 demonstrates cyclic voltammogram on gold in 1M HCl containing $PdCl_2$. The three anodic peaks at −0.20, −0.08, and 0.45V correspond to

[5] $SnCl_2$ solution was prepared by dissolving 90 g/liter $SnCl_2 \cdot 2H_2O$ in 37% HCl in nitrogen atmosphere.

[6] $PdCl_2$ solution was prepared by dissolving 0.5 g/liter in 37% HCl solution.

[7] The possibility of the peak "P1" being due to the desorption of $Sn(II)_{ad}$ or $Sn(O)_{ad}$ will be discussed later.

[8] The observation of the Mössbauer effect by Bowles and Cranshaw (18) showed that the spectra of adsorbed Sn at −0.145V (SCE) (underpotential region) is in fact remarkably similar to those of metallic tin on platinum. The adsorption of Sn(O) may be caused by the starting potential being more cathodic than the rest or open-circuit potential, and at the open-circuit potential the Sn is considered to be in the state of $Sn(II)_{ad}$.

[9] The value of the saturated O_{ad} on polycrystalline gold was determined by the reduction peak. Rand and Woods (19) reported the value of 386 $\mu C/cm^2$ on (100) gold surface.

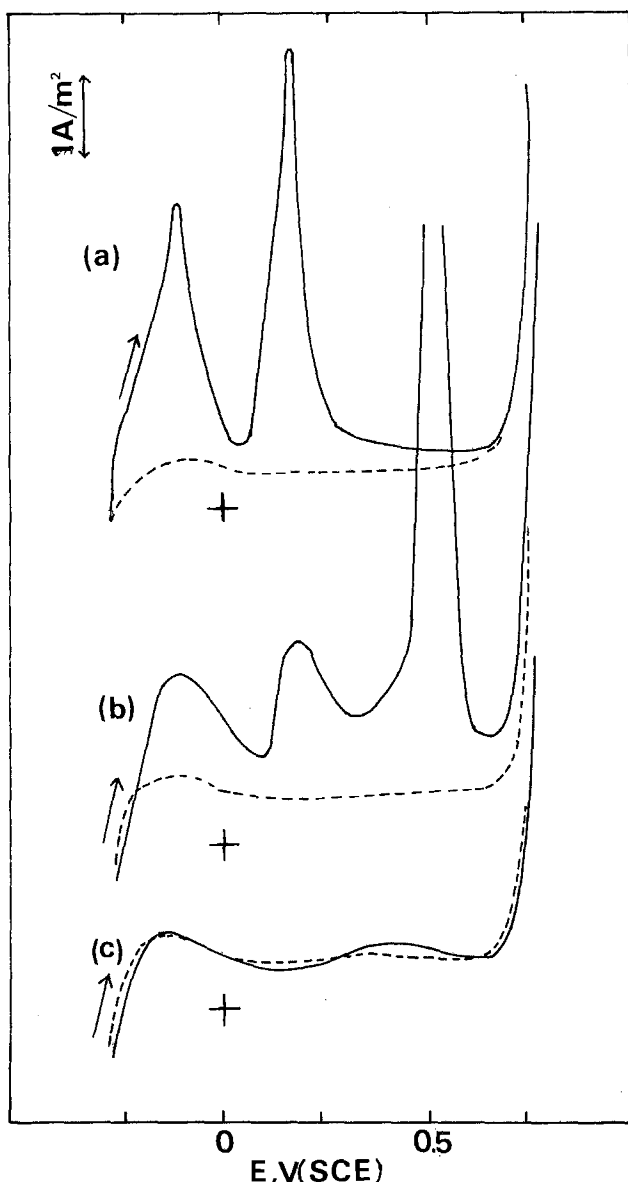

Fig. 6. Voltammograms on Au electrode in 1M HCl in the case of two-step procedure. Dashed lines: anodic sweep without immersion steps, sweep rate: 0.1 V/sec. (a) Single anodic sweep after immersion into $SnCl_2$ solution, (b) single anodic sweep after immersion into $SnCl_2$ solution and $PdCl_2$ solution. (c) single anodic sweep after immersion into only $PdCl_2$ solution.

the three cathodic peaks. From a comparison with the results on palladium deposition (20, 21), the peaks at −0.20, and −0.08V are considered to be the desorption peaks of H_{ad} on Pd deposited on gold. The anodic peak at 0.45V was determined to be the dissolution peak of Pd(O) upon referring to the literature (20, 21). Therefore, the peak "P3" shown in Fig. 5 and Fig. 6(b) is identical with the dissolution peak of palladium in Fig. 8.

Anodic sweep in 1M HCl after acceleration.—As typical accelerators we chose 1M NH_4BF_4 and 1:1 HCl solutions. The hydrochloric acid solution was recommended by Cohen and Meek (9c), because of several advantages, *i.e.*, material cost, simple processing due to the elimination of one-step (water rinse), easier water disposal, and a less toxic material. Figure 9 shows two voltammograms obtained after activation in sample E" and acceleration in 1M NH_4BF_4 or 1:1 HCl. When 1:1 HCl was used as accelerator, the water rinse step after activation was omitted as pointed out by Cohen and Meek (9c). It is interesting that both curves show only one anodic peak of Pd dissolution at 0.45 ~ 0.50V in the single anodic sweep as compared

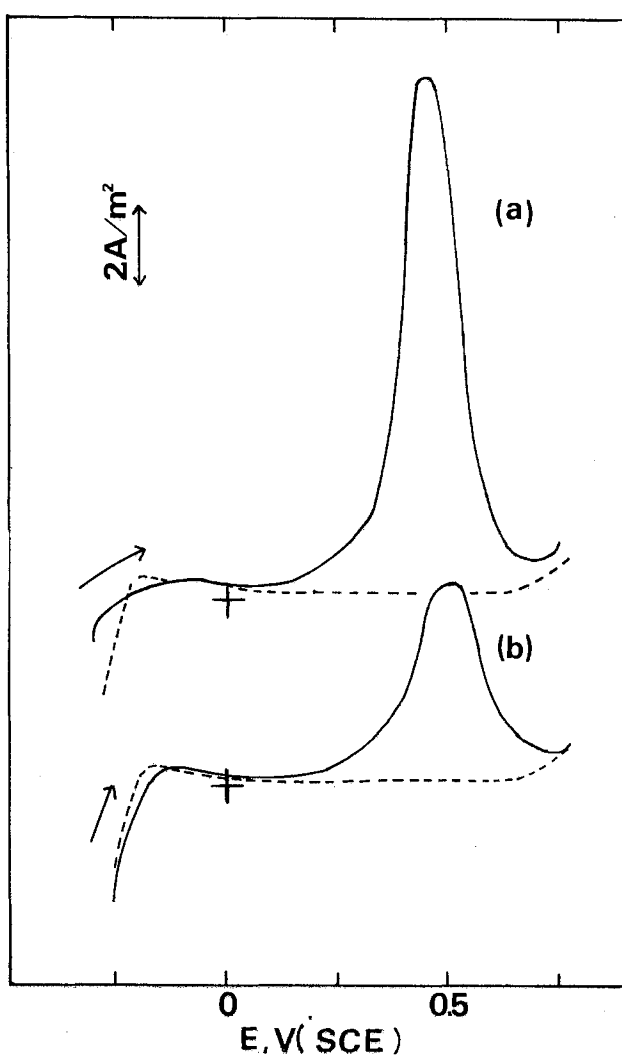

Fig. 9. Voltammograms on Au electrode in 1M HCl after activation and acceleration in the case of sample "E". Solid lines: single anodic sweep after activation and acceleration, dashed lines: anodic sweep without immersion steps, sweep rate: 0.1 V/sec, accelerator: (a) 1M NH_4BF_4, (b) 1:1 HCl.

removes Sn adsorbed on Au, leaving Pd nuclei on gold. The most active catalysts, "D" and "E", gave clearly the dissolution peak of palladium, while the other less active samples, "A", "B", and "C", showed no distinct peak in the single anodic sweep after acceleration. It can be concluded that the active catalyst forms palladium nuclei[10] on gold and that the anodic sweep on gold in HCl solution provides a reliable and simple method of diagnosing the activity of the mixed acidic catalyst. In view of the fact that the induction time before the initiation of metal deposition (cf. Fig. 1) is greatly shortened by the acceleration, it appears that the adsorbed Sn(O), Sn(II), or Sn(IV) ions on substrates formed after the activation mask the catalytic activity of palladium nuclei, and that they are removed in the acceleration step.

Kelly and Vondeling (14) reported that the nucleation reaction of palladium takes place upon u.v. irradiation of photosensitive TiO_2 films in contact with palladium ions and that the photoreaction product consisting of polycrystalline metallic palladium initiates electroless nickel deposition. Hamilton and Logel (15) investigated evaporated palladium deposits and concluded that large palladium particles (4 ~ 20 atoms) are required for nickel deposition. Clearly, metallic palladium particles also provide the catalytic activity. In the mixed $PdCl_2/SnCl_2$ catalytic system, however, several Pd-Sn complexes such as $SnPd_7Cl_6$ (5), $PdSn_2$ (6), and Pd_3Sn (7) have been reported as catalytically active species. In the next section, an attempt will be made, based on XPS (ESCA) measurements, to determine whether the catalytic activity is due to metallic palladium or to some Pd-Sn complexes in the mixed $PdCl_2/SnCl_2$ catalyst system.

[10] It was confirmed by the XPS measurements shown later that the final active sites on substrate are formed not by pure palladium but by the intermediate Pd-Sn system.

Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS) measurements for the $PdCl_2/SnCl_2$ catalysts.—For surveying the surfaces after each step, the AES measurement was done after activation and after acceleration of an electroless plated Ni-P substrate. The AES spectra after activation of Ni-P substrate indicated the peaks of Pd, Sn, O, C, and Cl and the peaks of Ni and P of the substrate were unclear after activation. The peaks of Ni and P after acceleration, however, were clearly observed in the spectra. The carbon is considered to be due to surface contamination. The XPS measurement, which was performed to confirm the chemical states of Pd and Sn on the surfaces, also indicated the presence of Pd, Sn, O, C, Cl, and Cu after activation and after acceleration (where a copper sheet was used as substrate). After acceleration there was a tendency for the Cu peaks to increase, which means that the area of the exposed substrate surface increases with acceleration. Also a tendency of decreasing Pd and Sn was observed except for sample "A" (cf. Table III), which means that the absolute amounts of Pd and Sn on the surface are decreased by the acceleration. Typical examples of XPS spectra are shown in Fig. 10, and the values of measured binding energies and

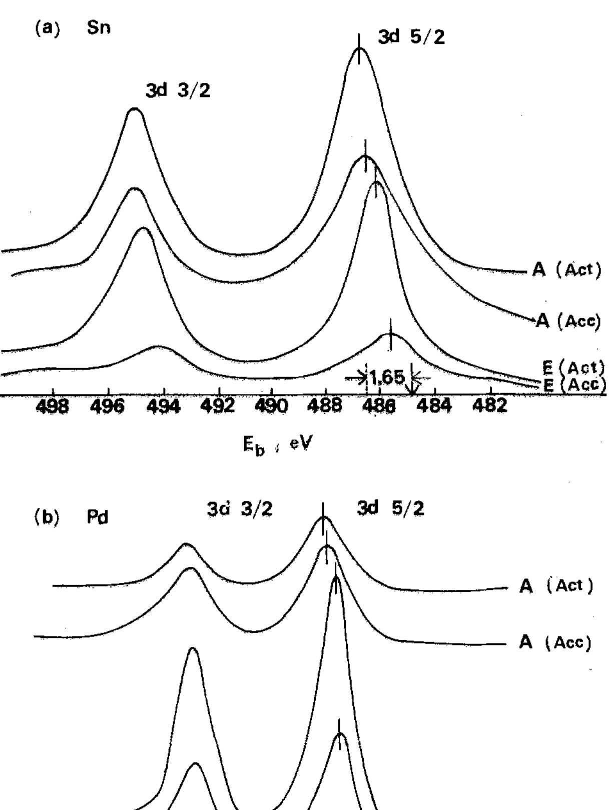

Fig. 10. XPS spectra of sample "A" and "E" for Pd $3d_{5/2}$ and Sn $3d_{5/2}$ levels. (a) Spectra for Sn $3d_{5/2}$, (b) spectra for Pd $3d_{5/2}$. Vertical arrows and dashed lines indicate E_b values for metals and charged species (24, 26), respectively. The numbers between the two markings are the corresponding chemical shifts.

chemical shifts for the Pd $3d_{5/2}$ and Sn $3d_{5/2}$ levels are given in Table II. Three sets of data (after activation, after acceleration, and for freeze-dried catalyst solutions) are tabulated. The binding energies were measured within ± 0.2 eV. The most reasonable values in the literature are considered to be 335.2 eV for Pd metal (22) and 484.9 eV for Sn metal (23) at $3d_{5/2}$ levels. The chemical shift for Pd(II) using $PdCl_2$ was reported to be 2.2 eV (24). The results on the chemical shifts for the Sn $3d_{5/2}$ reported by various investigators (25) disagree with each other, and Lau and Wertheim (26) discussed the above inconsistencies and concluded that the chemical shifts of Sn $3d_{5/2}$ for SnO and SnO_2 are approximately the same. The chemical shift of Sn $3d_{5/2}$ in the direction of higher binding energies against metal was reported to be 1.65 eV for Sn(II) or Sn(IV) (as SnO or SnO_2) by Lau and Wertheim (26). It is interesting that the binding energies of Pd $3d_{5/2}$ level for various samples observed lie between palladium metal and charged palladium (as $PdCl_2$). It is difficult to recognize from the shape of sharp peaks that the peak of Pd $3d_{5/2}$ level for each sample consists of a mixture of Pd(O) and Pd(II).[11] In the step after activation, the correlation between binding energy and catalytic activity is such that the binding energy of a more highly active catalyst becomes close to the low value of palladium metal, and the acceleration procedure causes the binding energy to shift toward lower values than that observed after the activation step. As for the Sn $3d_{5/2}$ level, the tendency similar to the Pd $3d_{5/2}$ level is observed in both cases after activation and after acceleration procedures.[12] The results of the freeze-dry method indicate that the palladium and tin of the colloidal particles in solution are in more highly charged states than those on substrates, and that the more active catalysts also display the lower binding energies in solution similarly to those adsorbed on substrates. There may be also a possibility, however, that the results on the freeze-dried catalysts are caused by the coexistence of original elemental composition and colloidal particles.

It was reported by Masai *et al.* (27) that the Pd 4d state peaks in the XPS spectra for the Pd-Sn alloy system are shifted to higher binding energies with decreasing ratio of Pd/Sn. (The shift of *ca.* 2.2 eV for Pd 4d state was shown from Pd/Sn = ∞ to 0.54.) It may be concluded from the above results on the Pd $3d_{5/2}$ level that the active sites in the final form consist of a Pd-Sn intermediate or alloy system, and that the active site of the more active catalyst is formed by the Pd-Sn alloy containing the larger amount of palladium. The results of the Sn $3d_{5/2}$ level that the ratio of charged states decreases upon acceleration can be explained on the assumption that the accelerator removes mainly Sn(IV) ions from the surfaces. This interpretation agrees well with the results of the electrochemical measurement.

The relative amounts and ratios of Pd and Sn on the surfaces were calculated from the peak area ratios corrected by the photoionization cross section (28) and tabulated in Table III, where the correction for the mean free path and the instrumental factor were ignored because the kinetic energies of the peaks observed are nearly equal. The line shape problems and the presence of satellites were not observed, and there were no problems in the quantification of the relative amounts of Pd and Sn. The value of Pd for sample "E Act" was used as 100 for normalization. The amounts of Pd and Sn on the surface decreased upon acceleration except for the palladium found with sample "A." It is interesting that the final ratio of Pd/Sn after acceleration is not constant but increases with increasing catalyst activity. Meek (9b) showed by the elemental analysis of commercial catalysts (Shipley 9F and MacDermid 9070) using Rutherford ion backscattering technique that the Pd/Sn ratio becomes $\lesssim 1$ after activation and $\simeq 3$ after acceleration and finally $\simeq 6$ at the initial stage of copper plating at which the Pd-Sn alloy core remains. The smaller values of our results for Pd/Sn ratio may be partly due to the difference in catalyst activity.[13] The values obtained by the freeze-dry method were small, which may be due to the original elemental composition. The Pd-Sn alloy particles which constitute active sites on surfaces are considered to consist of a system in which the ratio of Pd/Sn depends on the catalyst activity. Feldstein *et al.* (7) concluded the active sites to consist of Pd_3Sn alloy on the basis of the fact that the lattice parameters determined from the electron diffraction pattern closely matched those of Pd_3Sn in fcc form. Our results (29) of electron diffraction analysis of the catalyst on collodion surfaces after acceleration were also close to those of fcc Pd_3Sn. However, it was difficult to obtain accurate values because of the broad diffraction rings and of each lattice factor deviating somewhat to larger values.[14] Cohen and Meek (9b) discussed the conflicting results by various investigators (5-9) on the catalytic centers

[11] The peak breadth of half-maximum intensity of each sample for Pd $3d_{5/2}$ and Sn $3d_{5/2}$ was nearly equal to that of the metal, respectively, except for "A Acc." in the case of which the peak breadth of half-maximum intensity was somewhat larger.

[12] Since it was reported that Sn(II) can be oxidized to Sn(IV) by the irradiation of u.v. light on photosensitive TiO_2 (12), it was thought probable that a similar reaction might occur upon x-ray irradiation. The above possibility, however, was shown to be nonexistent by the fact that no time dependence of the observed binding energy of Sn $3d_{5/2}$ was found upon x-ray irradiation.

[13] Since the information obtained by XPS technique is assumed to correspond to that of the shallower surface region than that obtained by Rutherford ion backscattering technique, our results for Pd/Sn ratios are also considered to become smaller than those of Meek because of the influence of the residual Sn ion layer on Pd-Sn active center.

[14] Feldstein *et al.* (7) and Rantell *et al.* (5) also reported the slightly larger values of each lattice factor, and it was discussed by Cohen and Meek (9b).

consisting of colloidal particles of Pd-Sn alloy, and concluded that the catalytically active centers would be designated as Pd-Sn alloy, rather than Pd_3Sn. Thus, it is concluded that the final active sites or centers consist of a disordered Pd-Sn alloy system in which the more active catalyst has the higher palladium to tin ratio, and that the actual conditions are such that compounds with various Pd/Sn ratios exist on the surface.

The Effect of Copper and Silver Substrates on the Structure, Internal Stress, and Electrode Potential during the Initial Stages of Gold Electrodeposition

S. T. Rao*,[1] and R. Weil*

Department of Materials and Metallurgical Engineering,

Stevens Institute of Technology, Hoboken, New Jersey 07030

ABSTRACT

The initial stage of epitaxial electrocrystallization of gold from an additive-free, alkaline, sulfite solution on polycrystalline copper and silver substrates was found to be three-dimensional crystallite formation. The crystallites on the copper substrates were laterally considerably smaller than those on silver. This effect is attributed to the larger lattice mismatch between gold and copper. On silver, substrate coverage occurred earlier and was followed by the formation of smaller, secondary crystallites. The internal stress in the gold deposits on silver was initially very small and tensile due to the small lattice mismatch and the large crystallite size. The stress rose to a maximum during secondary crystallite formation. On copper substrates, the stress was initially compressive because of the negative lattice-mismatch component and then changed to tensile when crystallite coalescence became predominant.

Recent studies (1-7) of the early stages of epitaxial electrocrystallization of nickel on copper substrates have shown it to consist of the formation of three-dimensional crystallites all in the size range of 5-8 nm. This uniform size, which was also independent of the presence of addition agents in the plating solution, was attributed (7) to lateral-growth inhibition by basic nickel compounds produced during the deposition reactions. Substrate coverage occurred by the formation of new crystallites between existing ones and their subsequent coalescence. The crystallite nucleation was manifested by a maximum in the magnitude of the cathode potential. The attainment of a steady-state potential was indicative of substrate coverage by the electrodeposit. Crystallite coalescence resulted in the development of dislocations (3) and was the main cause of the internal stress after the initially large, extrinsic component due to the lattice mismatch between substrate and deposit decreased (5).

The purpose of this investigation was to determine whether the relationships of structure, potentials, and internal stress which were found for electrodeposited nickel on copper substrates held for other metals. The intent of this study was also to determine the effect on the internal stress of different lattice mismatches between substrate and deposit. In order that this effect should not be masked, it was necessary to use a plating solution which neither contained or produced substances having a predominant lateral-growth inhibiting effect as was found with nickel.

Gold electrodeposition on copper and silver substrates was selected for this investigation. The substrates can be readily dissolved leaving the gold deposit for transmission-electron-microscopic examination which is necessary to resolve the initial crystallite formation. An alkaline, sulfite solution without addition agents was chosen because deposition therein does not result in the production of lateral-growth-inhibiting substances. As the interatomic distances of gold are only 0.17% smaller than those of silver and 12.8% greater than those of copper, the effects of the sign and magnitude of the lattice mismatch could be determined. This communication reports the result of the investigation of the structures, electrode potentials, and internal stresses during the initial stages of epitaxial electrocrystallization of gold on copper and silver substrates.

Experimental Procedure

The substrates were oxygen-free, high conductivity copper and 99.99% pure silver sheet which had been rolled and recrystallized to produce a texture such that {110} planes were parallel to the surface in most grains. The samples were 55 mm long and 5.5 mm wide. The silver substrates were 125 μm thick; the copper pieces were 25 μm thick. In order that deposition occurred on only one face of the substrate, which was necessary for the stress measurement, two layers of photoresist were applied to one side of the samples. The uninsulated side was electropolished to a mirror-bright finish. The copper substrates were prepared in the same way as those used in the previous study (5) involving nickel electrodeposition. The silver pieces were electropolished in an aqueous solution of 100 g/liter KCN and 100 g/liter $K_4Fe(CN)_6$ and rinsed successively in a 20 g/liter KCN solution, essentially organic-free (5) distilled water, a 5% NaOH solution, and two more times in the distilled water.

The electrodeposition was performed in a proprietary[2] solution from which the usual additives had been omitted. The pH was 9.5 and the temperature 20°C. On the copper substrates the current density was 2.5 mA/cm^2. In order to prevent a replacement reaction from occurring, the copper substrates were either maintained at an anodic current density of 0.5 mA/cm^2 while the necessary adjustments for the stress measurement were made or the concentrate containing the gold ions was added just at the time when plating was desired to start. For deposition on the silver substrates, the current densities were 2.5 and 1.5 mA/cm^2.

The instrumentation for measuring the internal stress and the cathode potential was described in earlier papers (5, 8). Briefly, the stresses were determined from the attempted deflection of the free

[2] BDT 510 solution produced by Oxy-Metal Industries Corporation, Sel-Rex Division, Nutley, New Jersey.

end of the horizontally held substrate strip clamped at the other end, while deposition occurred on only one face. The deflection of the free end was prevented by the application of a force by a null-point electrobalance. As in previous studies (5, 9), the instantaneous stress was determined. Also as was done previously (5, 9), the deposit thicknesses were calculated from the charge densities assuming a uniform layer, 100% plating efficiency, and the same density as the bulk metal.

Samples were plated to a nominal thickness of 100 nm while the stress and cathode potentials *vs.* SCE were monitored. Samples were also plated to thicknesses less than 100 nm at which significant changes in either the stresses or potentials occurred. The very thin gold deposits on copper were backed by a Ni-P film (5) and those on silver by vapor-deposited platinum (10). The copper substrates were dissolved in a solution containing chromic and sulfuric acids (5). The silver substrates were dissolved in nitric acid. The gold deposits, including the thin ones, with their backing films were examined by transmission electron microscopy.

Results

Gold deposits on silver substrates.—Figure 1 shows the cathode potential and the instantaneous stress *vs.* deposit thickness of gold electrodeposits on silver substrates when the current density was 1.5 mA/cm^2. The magnitude of the cathode potential is seen to rise to a maximum at a nominal thickness of about 2 nm. Passing a charge density equivalent to a thickness of 2 nm was found not to have resulted in any gold deposit visible electron microscopically or detectable by electron diffraction. The structure at a nominal thickness of 4 nm, *i.e.*, just after the potential peak is shown in Fig. 2. The larger dark areas are three-dimensional crystallites. The fine dots are the platinum backing. A dark-field electron micrograph of a similar deposit showing the large gold crystallites is Fig. 1a in Ref. (13). A Moiré pattern in Fig. 2 probably resulted from the difference in the lattice dimensions of very thin electrodeposited gold crystallites and the vapor-deposited platinum backing. It does not appear that there is a continuous gold electrodeposit underlying the large three-dimensional crystallites as the Moiré pattern is not visible over the entire sample. The large gold crystallites have an average size of about 60 nm. The electron-diffraction pattern of the gold deposit was that of a single crystal showing that all the crystallites had grown epitaxially on one substrate grain. The majority of the electron-diffraction patterns showed that {110} planes were parallel to the surface, *i.e.*, they had the same texture as the substrates.

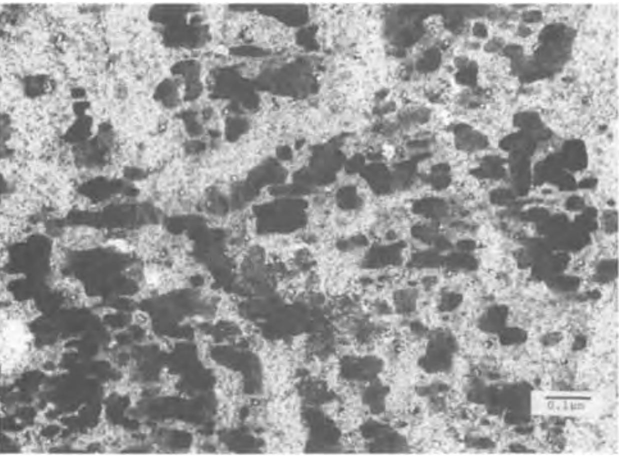

Fig. 2. Transmission electron micrograph showing three-dimensional gold crystallites which grew on silver substrate.

The internal stress shown in Fig. 1 is initially small and tensile when the current density was 1.5 mA/cm^2. The same result was found at a current density of 2.5 mA/cm^2. The stress is seen to rise to a maximum value at a thickness of about 40 nm. The structure at the stress maximum is shown in Fig. 3. This sample did not have a platinum backing and was therefore a continuous film. A continuous gold deposit covered the substrate already at a thickness of 15 nm where the cathode potential attained a steady-state value. The deposit was also continuous at the same thickness when the current density was 2.5 mA/cm^2. In Fig. 3 a number of small hillocks which grew out of the continuous film are indicated by an arrow. These small, secondary crystallites were only observed in the thickness range of the stress maximum. Much larger pyramidal hillocks were found to have developed in thicker deposits.

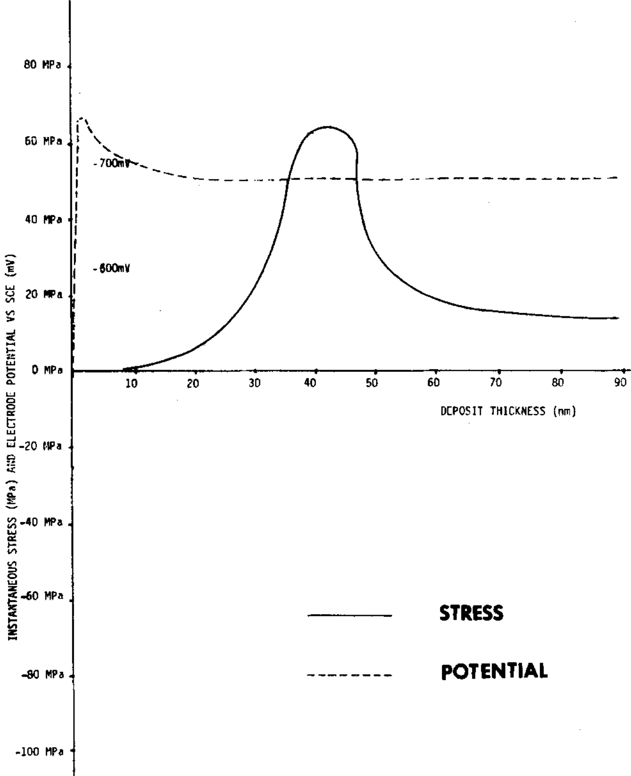

Fig. 1. Graphs of electrode potential and internal stress vs. nominal deposit thickness for gold on silver substrates.

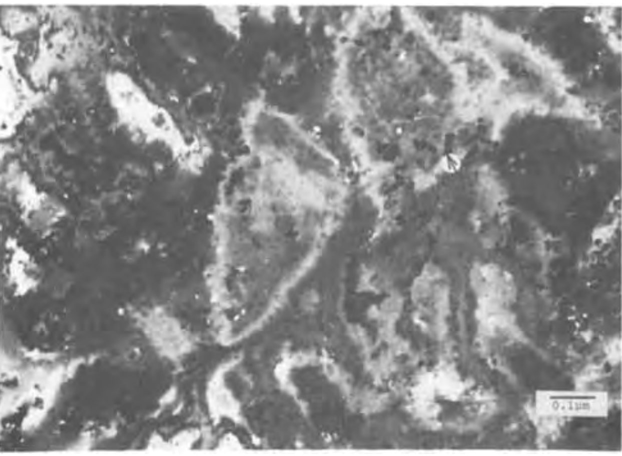

Fig. 3. Transmission electron micrograph of a continuous gold film which had been plated on a silver substrate. Arrow points to secondary crystallites.

Gold deposits on copper substrates.—Cathode potential and instantaneous stress *vs.* thickness curves for gold electrodeposits on copper substrates are shown in Fig. 4. Again the magnitude of the potential is seen to rise to a maximum. However, the nominal thickness or charge density at which the peak occurs is greater than in Fig. 1. Also the magnitude of the potential peak is greater for the deposits on copper. The structure at a nominal thickness of about 20 nm is shown in Fig. 5. Discrete crystallites with an average size of about 20 nm can be seen. The crystallites are considerably thicker than the ones which grew on silver. The effect of substrate-grain orientation is shown in Fig. 6. The deposit on the right, which is almost a complete film, had an electron-diffraction pattern indicative of a {110} plane parallel to the surface. The sparser growth on the left had a {100} plane parallel to the surface. No enhanced crystallite formation on the substrate grain boundary is visible. From an analysis of the crystallographic directions of

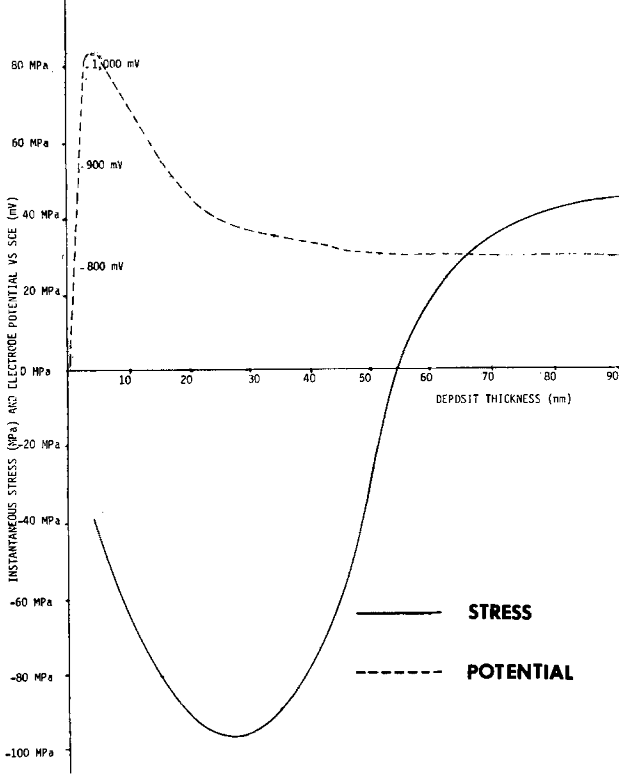

Fig. 4. Graphs of electrode potential and internal stress *vs.* nominal deposit thickness for gold on copper substrates.

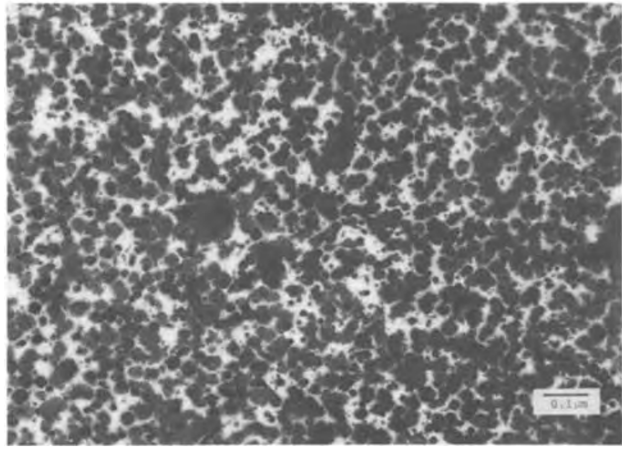

Fig. 5. Transmission electron micrograph showing three-dimensional gold crystallites which grew on copper substrates.

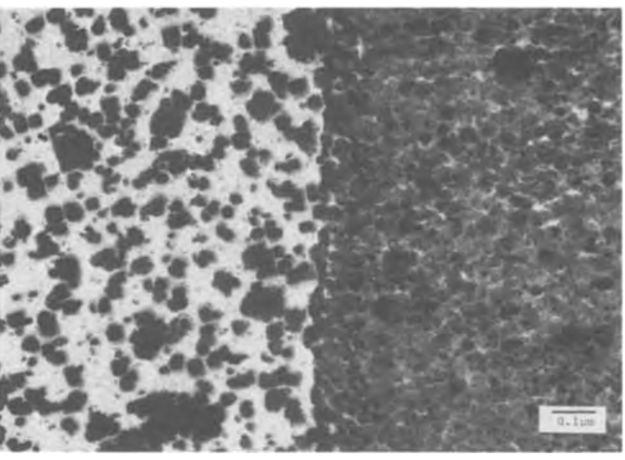

Fig. 6. Transmission electron micrograph showing an almost continuous gold deposit which grew on a {110} copper substrate grain on the right. On the left side discrete crystallites are seen which grew on {100} substrate grain.

the edges of the crystallites such as those in Fig. 5 and 6, it was determined that they were mostly bounded by {110} planes. Substrate coverage by a complete deposit film was found to have been attained at a thickness of about 40 nm, again where the cathode potential leveled off to a steady-state value.

The instantaneous stress shown in Fig. 4 is initially compressive; its magnitude reaches a maximum at a thickness of 27 nm and then increases to become tensile beyond 54 nm. The structure at the thickness where the compressive-stress maximum occurs is the one shown in Fig. 6. No significant structural features were observed in deposits having the thickness where the sign of the stress changed. No secondary crystallization such as seen in Fig. 3 in the deposits on silver was observed in the samples plated on copper substrates. The larger pyramidal hillocks were seen in thicker deposits on copper. No essential differences in the stress *vs.* thickness graphs were observed in samples in which the displacement reaction was prevented by the anodic potential or by the addition of the gold ions just prior to the start of plating. When a displacement reaction was permitted to occur, the first part of the stress graph was not recorded.

Discussion

As was previously found in epitaxial nickel deposits on copper, the initially observed electrocrystallization process of gold on the two substrates of this study was the formation of three-dimensional crystallites. It could not be definitely determined from the results of this study whether in the absence of lateral-growth inhibiting substances, a few monolayers form first and then the crystallites grow on this very thin film as discussed by Matthews, Jackson, and Chambers (11) for vapor deposits. Their analysis of the involved energies indicated that three-dimensional crystallite formation becomes more favorable than a film of uniform thickness with increasing lattice mismatch between deposit and substrate. It is, however, doubtful whether gold deposited as a continuous film even on silver substrates in view of the fact that the Moiré pattern in Fig. 2 is not continuous. Also, Stucki (12) found monolayers to be unstable in underpotential deposition of gold on both copper and silver substrates. The instability was attributed to either three-dimensional-crystallite formation or alloying with the substrate. For the explanation of the results of this study, it appears to be insignificant whether the three-dimensional growth in Fig. 2 and 5 which is clearly discontinuous, developed on a thin continuous layer or not.

The principal effect of the substrate on the initial electrocrystallization process was the size of the crystallites. On the silver substrate, which has the smaller lattice mismatch to gold, the lateral crystallite size is about three times that on copper. The determination of the crystallite size had to be done after depositing at a slightly lower current density than on copper. It was necessary to use the lower current density of 1.5 mA/cm^2 in order to allow sufficient time for removal from the electrolyte of a deposit on the silver substrate which was not yet continuous. It is very unlikely that the crystallite size on silver was significantly smaller when the current density was 2.5 mA/cm^2 as it was found that the deposits were continuous at both current densities after passing approximately the same charge density. Also the electrode potential *vs.* thickness relationships were nearly the same at 2.5 mA/cm^2 as that in Fig. 1. Therefore the difference between the crystallite sizes of gold plated on silver at 1.5 mA/cm^2 and on copper at 2.5 mA/cm^2 should be primarily due to the effect of the substrate.

In another study (13), the crystallite size was found to be nearly the same, *i.e.*, 8-10 nm on both silver and copper substrates, when gold was deposited from a solution containing additions of arsenic, all other conditions having been the same as in this investigation. It is therefore evident that the substrate mismatch affects the crystallite size only in the absence of lateral-growth-inhibiting substances.

As was shown (3, 5, 6) to be the case for nickel deposits, the peak in the magnitude of the cathode potential was associated with the nucleation of three-dimensional crystallites. The larger magnitude of the potential when copper was the substrate was associated with more crystallite nucleation. However, the greater current density used and the potential of copper in the gold electrolyte were also responsible for the greater peak. The presence of an oxide on the copper substrate may also have been a contributing factor. The greater charge density to reach the potential peak where the first crystallites were nucleated on copper may have been due to the need to first reduce the oxide.

The formation of a coherent deposit layer on the copper substrate occurred as it did in the case of nickel (3) by the formation of new crystallites between existing ones. The crystallites, which are still recognizable on the right side of Fig. 6. have a size which is essentially the same as that in Fig. 5. Thus it appears that there is little lateral crystallite growth once a certain size has been attained. This size was probably determined here by the lattice mismatch. Due to the fact that formation of a continuous film on silver substrates occurred after passage of a relatively small charge density and that the crystallites were no longer recognizable then, it was not possible to determine whether the same growth mechanism was operative on silver substrates as on copper.

The thinness of the crystallites on silver substrates probably resulted in relatively few defects such as voids developing during coalescence. The greater number of defects which resulted during coalescence of the crystallites on copper is the likely reason for their being still recognizable in the continuous films. The exposure of the copper substrate to the electrolyte at voids in the deposits probably accounts partly for the magnitude of the steady-state potential in Fig. 4 being greater than that in Fig. 1.

The extrinsic component of the internal stress due to the lattice mismatch between deposit and substrate can be calculated by a formula due to van der Merwe (14). For epitaxial gold on copper this value is about -120 MPa, *i.e.*, compressive, as the deposit has the larger interatomic distance. On silver substrates, the extrinsic stress in the gold deposit is 2 MPa (tensile) which is negligibly small. The intrinsic component of the internal stress is due to the pulling together of crystallites due to surface tension before the spaces between them are completely filled (5, 15). This component is therefore always tensile and varies inversely with the lateral crystallite size. The initial stress of the deposits on silver as seen in Fig. 1 is thus small and tensile because of the large crystallite size and the negligible misfit component. The intrinsic component in the deposits on copper is estimated to be about 50 MPa, which is the value of the stress at 100 nm where the extrinsic one essentially vanishes. The extrinsic stress, which decreases with the reciprocal of the thickness according to the van der Merwe (14) formula when it is relieved by the formation of interfacial dislocations, should be negligibly small at 100 nm. The value of the stress in Fig. 4 at the compressive maximum should therefore be the algebraic sum of the extrinsic component of -120 MPa and the intrinsic one of 50 MPa, *i.e.*, -70 MPa. The agreement with the experimental value of -95 MPa is not bad considering that the reproducibility was about ± 10 MPa. This poor reproducibility was primarily due to uncertainties in the deposit thickness. The greater experimentally determined value of the compressive-stress maximum may also be due to the fact that at the thickness where it occurred there were still a number of crystallites which had not yet coalesced as seen on the left in Fig. 6 resulting in the subtraction of a smaller tensile component.

The variation of the stress with thickness in the gold deposits on copper in Fig. 4 can be explained in terms of the mismatch and crystallite-coalescence components. Initially the compressive, mismatch component predominated. Thus, the magnitude of the stress increased to a compressive maximum. When interfacial dislocations develop, the mismatch stress is relieved and the tensile, coalescence component becomes more dominant. The stress then changes sign and approaches a tensile steady state which, as already discussed, is due essentially only to the intrinsic component.

The stress in the deposits on silver starts very small and tensile as already discussed. The rise to a tensile maximum in Fig. 1 is probably due to the formation and coalescence of the secondary crystallites seen in Fig. 3. As these crystallites are much smaller than the original ones shown in Fig. 2, their coalescence results in a greater intrinsic stress. The maximum stress value of 60 MPa is about the same as the intrinsic stress in deposits on copper substrates, which have about the same crystallite size. The reason for the formation of the secondary crystallites has not been determined. They may be associated with certain crystal defects in the underlying deposit layer. The decrease in the stress beyond the maximum in Fig. 1 probably resulted because there was no observed formation and consequently no coalescence of the small secondary crystallites seen in Fig. 3 except in the one thickness range.

Conclusions

1. The initial structure of the epitaxial gold deposits on silver and copper substrates consists of three-dimensional crystallites.

2. The gold crystallites on the copper substrate are laterally smaller than those on silver, indicating that a larger mismatch results in smaller crystallites.

3. An initial peak in the magnitude of the electrode potential was associated with crystallite nucleation; a steady-state value indicated substrate coverage.

4. The stress in gold deposits on copper was initially compressive due to the predominant extrinsic, mismatch component. With increasing thickness the coalescence component became dominant resulting in a change in the sign of the stress and the development of a tensile stress.

5. The stress in gold deposits on silver were initially small and tensile because of the small lattice mis-

match and large crystallite size. A rise to a stress maximum was due to the formation and coalescence of small, secondary crystallites.

ABSTRACT

The deposition of copper from acid copper sulfate solution in cylindrical holes was studied by potentiostatic and galvanostatic methods. Steady-state plating gave deposits of poor quality and uneven thickness ($S/H > 1$). A pulsed square wave potential resulted in good, coherent deposits. The deposition is discussed in terms of the rate of diffusion to the electrode surface and the rate of diffusion into the pore. For pores of small diameter the latter process limits the plating efficiency under steady-state conditions.

In any plating process, the supply of ions to the electrode surface is often limiting. Thus during the plating of copper under steady-state conditions effects due to the depletion of ions at the cathode (*e.g.*, uneven deposit, hydrogen embrittlement in galvanostatic plating) are often seen (1). Methods involving agitation or air sparging (2) may alleviate these problems by reducing the thickness of the diffusion layer, but pulse techniques (3) have been shown to provide the best possibility of obtaining an even deposit with an efficient use of the current (1, 4, 5). Three methods employing periodically changing currents have been proposed; all are based on an "off" period when the depleted layer of ions at an electrode may be replenished. These use (3) reversed current, d.c. with superimposed a.c., and pulsed current. Potentiostatic methods may have an advantage over galvanostatic methods for two reasons. First, the overall current is an integral of local current densities, which, in the case of galvanostatic plating, may follow an unpredictable pattern and second, the controlled current is used for double layer charging as well as deposition.

* Electrochemical Society Active Member.

Key words: diffusion, mathematical model, through-hole plating.

The charging and discharging of the double layer leads to a smoothing out of the Faradaic wave.

Plating inside pores holds further problems due to the geometry of the system. At constant potential or current the thickness of the deposit inside a pore is less than that of the flat surface and in addition a buildup of copper at the mouth of the pore is observed (6).

In this paper we describe the effect of a pulsed square wave potential and a pulsed square wave current on the deposition of copper in a cylindrical pore such as may be found in printed circuit boards. A mathematical model has been developed to solve the diffusion equations in such a pore. The model gives an insight into the observed difference in plating efficiency inside and outside a pore and may be used to predict optimum plating parameters.

Mathematical Model

Various models of different complexity have been proposed to analyze diffusion in different geometries (4, 7-9). Most recently Popov *et al.* (4) have employed a numerical technique, the central difference method, with the Runge-Kuta method to solve the resulting differential equations.

By taking a sufficiently large mesh and small time intervals an all numeric method [the forward difference method (7)] may be used. This method has the advantages that no differential equations need be solved and it is not necessary to know precisely the nature of the perturbation on the system.

However, a considerable increase in the requirement of computer time and memory results.

The system modeled is shown in Fig. 1. The mesh (200 × 200 points) was taken over $ABCD$, where $AD = 2R$ (R = radius of pore) and $AB = L$ (L = length of pore). The cylindrical axis AB and axis AX allowed calculation of the concentration in all parts of the solution from the value at a point within $ABCXYZ$. The point A was taken as the origin of the cylindrical coordinate system; the electrode surface being $r = R$, $l < L/2$ (XY in Fig. 1) and $r > R$, $l = L/2$ (YZ in Fig. 1). For a volume element which has dimensions sufficiently small relative to the diffusion length $(2\sqrt{D\Delta t})$ the following relations hold

$$C(r + \Delta r,l,t) \simeq C(r,l,t) - \Delta r \partial C/\partial r \quad [1]$$

$$C(r,l + \Delta l,t) \simeq C(r,l,t) - \Delta l \partial C/\partial r \quad [2]$$

$$C(r,l,t + \Delta t) \simeq C(r,l,t) - \Delta t \partial C/\partial t \quad [3]$$

The change in concentration at a mesh point is the change in the number of species within the volume element divided by the volume of that element. Thus for diffusion in an infinite cylinder

$$C(r,l,t + \Delta t) - C(r,l,t) = \frac{\Delta t D}{\Delta r V(r)} \{A(r)(C(r + \Delta r,l,t) - C(r,l,t)) - A(r - \Delta r)(C(r,l,t) - C(r - \Delta r,l,t))\} \quad [4]$$

For the case of a cylindrical hole the effect of diffusion parallel to the axis of the cylinder must be added to Eq. [4]

$$\frac{\Delta t D}{\Delta l^2} \{C(r,l + \Delta l,t) - C(r,l,t) - (C(r,l,t) - C(r,l - \Delta l,t))\} \quad [5]$$

which is

$$\frac{\Delta t D}{\Delta l^2} (C(r,l + \Delta l,t) + C(r,l - \Delta l,t) - 2C(r,l,t)) \quad [6]$$

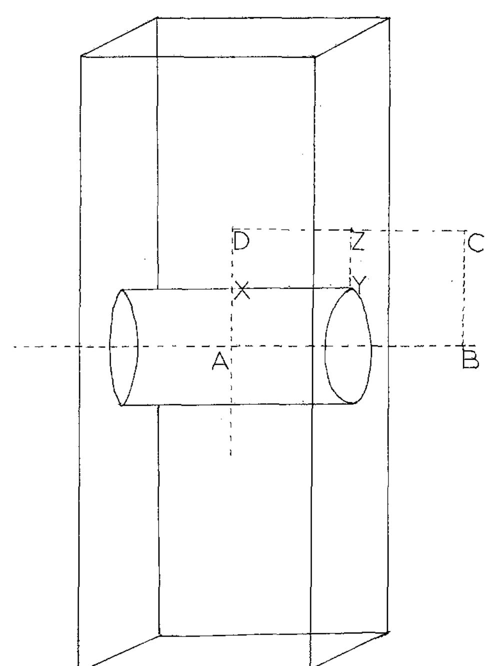

Fig. 1. Diagram of the volume matrix taken for the mathematical model *ABCD*. Origin is at *A*.

The area of a cylindrical element is $A(r) = 2\pi lr$, and the volume element $V(r) = \pi l(r^2 - (r - \Delta r)^2)$. For a plane $A = \Delta l^2$, $V = \Delta l^3$.

There remains the boundary conditions at the electrode which are: electrode surface YZ (Fig. 1) $(\partial C/\partial l) = i/n\mathbf{F}D$ for $r > R$, $l = L/2$; electrode surface XY $(\partial C/\partial r) = i/n\mathbf{F}D$ for $r = R$, $l < L/2$; solution boundary CB for $r < 2R$, $l = L$, $C = C_o$; and solution boundary ZC for $r = 2R$, $l > L/2$, $C = C_o$.

It is assumed that the boundaries CB and ZC are sufficiently distant from the pore not to affect the solution of the diffusion equations in that region.

Therefore in Eq. [4] at $r = R$, $C(r + \Delta r,l,t) - C(r,l,t)$ becomes $i\Delta r/n\mathbf{F}D$ and in Eq. [6] at $l = L/2$, $C(r,l,t) - C(r,l - \Delta l,t)$ becomes $i\Delta l/n\mathbf{F}D$.

In potentiostatic plating the current from an element of electrode area A_e is

$$i = \text{const.} \times C_e \times A_e \quad [7]$$

and for galvanostatic plating

$$i = \text{const.} \quad [8]$$

A periodic pulsed potential was introduced into the model by setting $i = 0$ for the "off" period. No account was taken of double layer charging which therefore limits the viability of the model at high pulse frequencies ($>10^3$ Hz).

Diffusion of Cu^{2+} only was considered (with $D = 5.5 \times 10^{-6}$ cm^2/sec), which was assumed to discharge to copper at the electrode surface. Thus no account was made of the effect of Cu^+. The experimental results show that this is a valid assumption in this case, and work is in progress to model the system containing Cu^+ for other experimental conditions.

The model was used to investigate the depletion of ions within the pore and the buildup of copper at the mouth of the pore for potentiostatic plating (pulsed and steady-state). The ratio of the thickness of the deposit inside and outside the hole was estimated from the integrated current densities at selected areas on the electrode.

The model was implemented on the CDC7600 computer of London University.

Experimental

The deposition of copper was studied by plating on to a brass electrode drilled with holes of different diameters (0.6, 1.0, 1.3, and 1.6 mm). The brass cathode was positioned vertically between two copper anodes (Goodfellow Metals, 99.95%) in a rectangular Perspex tank. For all experiments the electrolyte was a solution of copper sulfate (0.34 mole dm^{-3}) and sulfuric acid (1.76 mole dm^{-3}).

In steady-state deposition a saturated calomel reference electrode was used in a Luggin capillary. A copper wire (Goodfellow Metals 99.99%) was the reference in pulse studies. Provision was made in the cell for air agitation. The potential (or current in galvanostatic experiments) was held constant against the reference electrode by a Chemical Electronics TR40-3A potentiostat. A pulsed current was achieved with a waveform generator (square wave 0.1-10^5 Hz) in conjunction with the potentiostat. The current and voltage were displayed on an oscilloscope.

The brass boards were cleaned in the following sequence (10): (*i*) mechanical polishing, (*ii*) degreasing in trichloroethylene in an ultrasonic bath (5 min), (*iii*) washing in an alkaline bath (NaOH 4%, trisodium phosphate 2%) for 3 min, (*iv*) washing in an acid bath (H_2SO_4 5 volume percent HCl) for 5-10 sec, (*v*) washing in distilled water.

After plating for a time to give a deposit thickness of 0.025 mm (assuming the density of copper to be 8.96 g-cm^{-3}) the brass boards were washed with distilled water and ethanol, dried, weighed, and mounted in acrylic resin for metallurgical sectioning. The sec-

tioned sample was etched in alcoholic ferric chloride (11) and examined under a microscope to measure the thickness of the deposit inside, outside, and at the mouth of the pore. From the increase in weight of the brass board and the charge passed, the current efficiency was determined.

The following plating conditions were studied:

1. Steady-state potentiostatic polarization, with and without air sparging.
2. Steady-state galvanostatic plating.
3. Pulsed galvanostatic plating with $T_{ON} = 1$ sec, $T_{OFF} = 2$ sec, and current densities in the range 34-80 mA cm^{-2}.
4. Pulsed potentiostatic polarization. A range of frequencies (1-7.5 $\times$ 10^5 Hz) was studied with $T_{ON}/T_{OFF} = 1/2$.

Results

Steady-state potentiostatic plating.—Figure 2 shows current-voltage curves for plating with and without air sparging. It is seen that without agitation a limiting current density of 40 mA cm^{-2} is quickly reached. The ratio of the deposit thickness outside to inside the pore (S/H) (6) is plotted as a function of overpotential in Fig. 3 for the unagitated and agitated electrolyte. Although a greater current density is possible with air agitation little effect on S/H is observed. Figure 4 is a micrograph of the cross section of a typical pore under unagitated conditions, when dendritic growths were frequently seen. Agitation reduced these growth to a minimum.

Steady-state galvanostatic plating.—Deposits were essentially similar to those obtained potentiostatically.

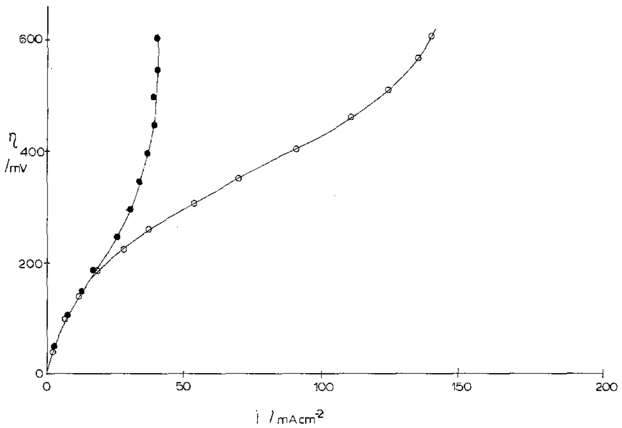

Fig. 2. Current voltage relations for steady-state potentiostatic plating. ● = Without agitation, ○ = with agitation.

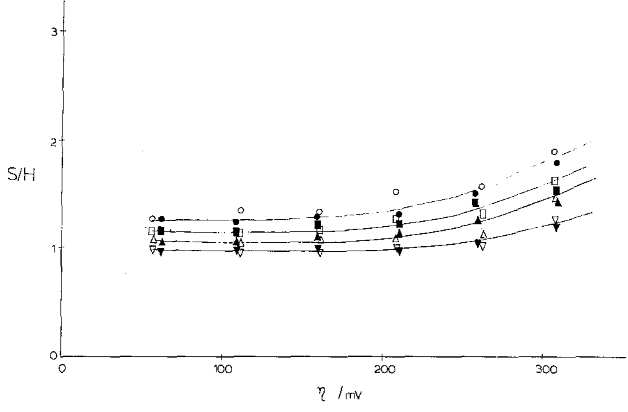

Fig. 3. Ratio of deposit thickness inside and outside the pore (S/H) at different overpotentials (open symbols) and unagitated (filled symbols) steady-state potentiostatic plating. ○, ● = Pore radius 0.6 mm; □, ■ = pore radius 1.3 mm; △, ▲ = pore radius 1.3 mm; ▽, ▼ = pore radius 1.6 mm.

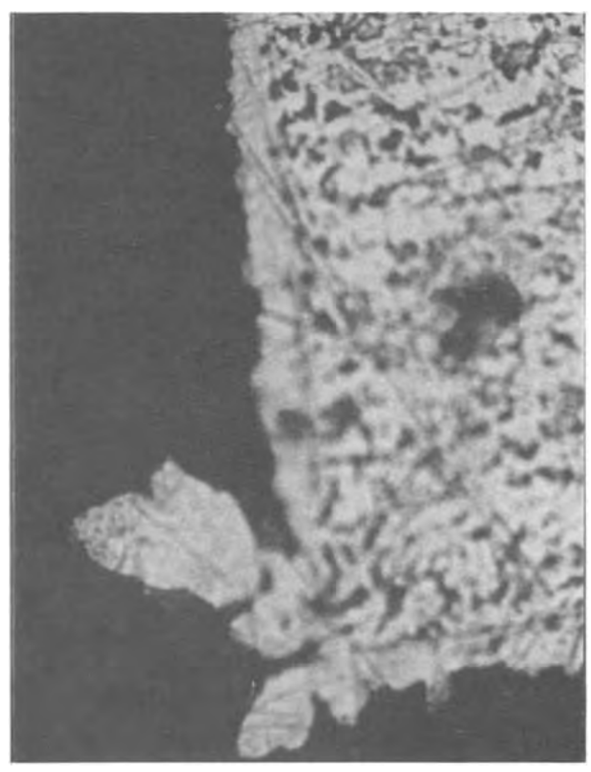

Fig. 4. Copper deposit in 1.6 mm diameter pore after steady-state potentiostatic plating, ζ = 357 mV, without agitation.

However at high current densities S/H was greater for galvanostatic plating (Fig. 5). In addition a thicker deposit at the mouth of the pore was observed (Fig. 6).

Pulsed galvanostatic plating.—With a constant pulse profile $T_{ON} = 1$ sec, $T_{OFF} = 2$ sec, a plot of S/H against current density gave values of S/H near 1 for the larger holes and smaller current densities (Fig. 7). No variations in S/H were found when the period of the pulse was decreased. A smooth copper deposit was found at low current densities ($<$50 mA cm^{-2}) but as the current increased at a constant pulse of $T_{ON} = 1$ sec, $T_{OFF} = 2$ sec, the deposit became rough with pronounced growth at the mouth of the pore (Fig. 8a and b). Increasing the frequency of the pulse gave a smoother deposit at high current density (Fig. 8c). The current efficiency of the deposition was 100 ($\pm$2)% at current densities below 100 mA cm^{-2}. Above this current the efficiency fell linearly to 96% at 150 mA cm^{-2}.

Pulsed potentiostatic plating.—With a constant pulse profile, $T_{ON} = 1$ sec, $T_{OFF} = 2$ sec, S/H approached

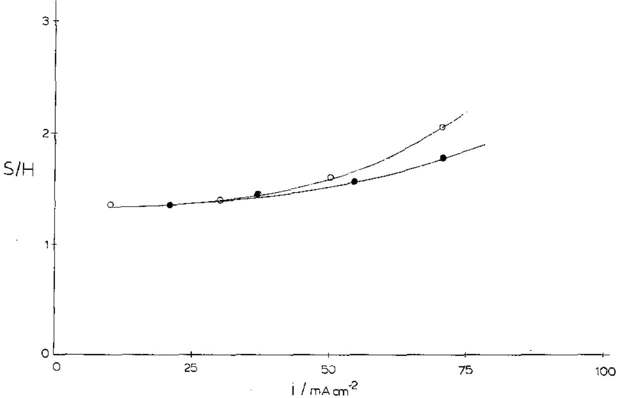

Fig. 5. S/H at different current densities for galvanostatic (○) and potentiostatic (●) steady-state plating. Pore diameter 0.6 mm.

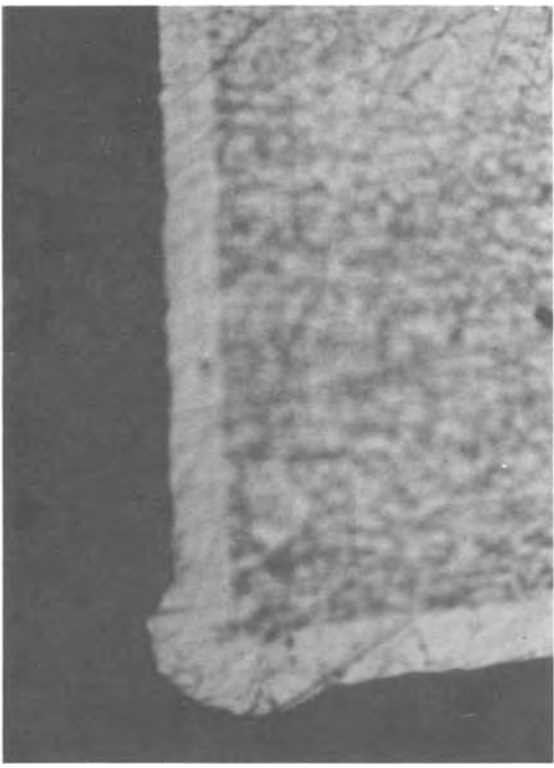

Fig. 6. Copper deposit in 0.6 mm diameter pore after steady-state galvanostatic plating, $i = 50$ mA cm^{-2}, with agitation.

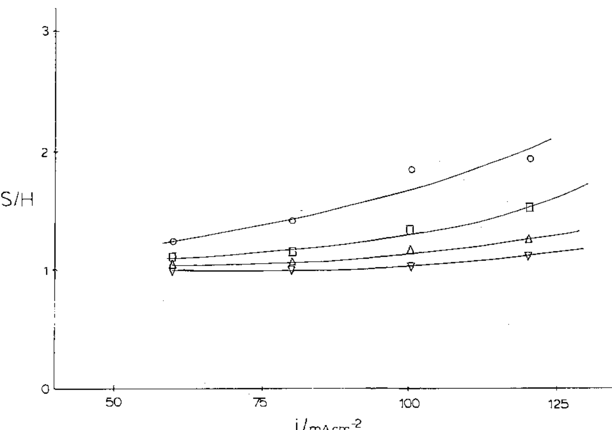

Fig. 7. S/H at different current densities for pulsed galvanostatic plating. $T_{ON} = 1$ sec, $T_{OFF} = 2$ sec. ○ = Pore diameter 0.6 mm, □ = pore diameter 1.0 mm, △ = pore diameter 1.3 mm, ▽ = pore diameter 1.6 mm.

unity for overpotentials less than 300 mV (Fig. 9). As with galvanostatic pulse plating, the frequency of the pulse had no great effect on S/H.

Surface roughness increased with increasing overpotential at constant pulse frequency and decreased with increasing frequency at constant potential (Fig. 10a and b).

The average current densities measured during pulse plating had higher values than the steady-state current densities and the variation of the average current density with pulse frequency at constant overpotential gave a maximum at $\nu = 100$ Hz (Fig. 11).

Mathematical model.—Figure 12a and b show a simulated contour map of the concentration of copper ions near the electrode surface at the mouth of a 1.6 mm diameter pore, after steady-state potentiostatic plating for 0.5 and 5 sec at 455 mV. The graph of current against time is given in Fig. 13. Figures 14 and 15 give corresponding contours and graphs of the same system under a potentiostatic pulsing potential of 455 mV with $T_{ON} = 0.1$ sec, $T_{OFF} = 0.2$ sec. The model parameters were chosen to give a steady-state current of 40 mA cm^{-2} (see Fig. 2). It was noted that for high overpotentials (and currents) and a pulse of $T_{ON} = 0.1$ sec, $T_{OFF} = 0.2$ sec, while the concentration near the electrode surface during the "off" period increased, the boundary of the bulk concentration continued to move away from the electrode.

Discussion

The distribution of copper ions in a pore during plating.—It is known (5, 11), and has been confirmed here, that under steady-state conditions less copper is deposited inside a pore than on a flat electrode. This is obviously due to the deficiency of copper ions at the electrode surface in the pore, but may have two different causes. First, the rate of diffusion inside the pore to the electrode may be less than that to a flat surface by virtue of their different geometries. Second, the ions in the pore may be rapidly consumed with a slow diffusion of ions into the pore from outside. The contour maps of Fig. 12 and current-time graph of Fig. 13 show that at small time intervals after the start of plating (when copper is still present at its bulk concentration in the pore) the difference between the concentration of ions at the electrode in the pore and outside the pore is small. That the concentration is slightly less in the pore is a geometrical effect. However, the difference becomes much greater as more copper is deposited, because the rate of diffusion into the pore is much less than that required to maintain the same concentration gradient as at the flat electrode. This will occur when the boundary of the solution having the bulk concentration reaches the radius of the pore. Therefore, while air agitation and pulse techniques may allow the concentration of copper ions to be maintained in the pore to negate the second effect, the first effect, that of the geometry of the system, will remain.

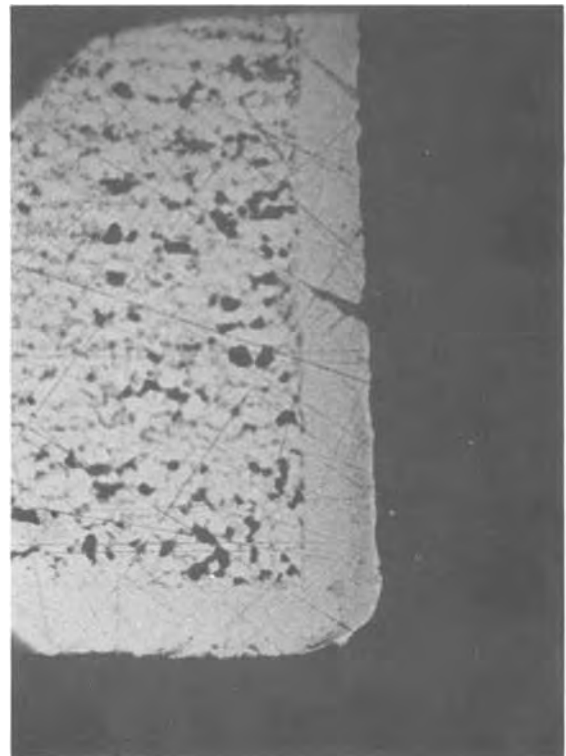
At high current densities a greater S/H may be expected for galvanostatic plating than potentiostatic plating, as was observed in practice, for the following reasons. Under galvanostatic conditions the copper ion concentration within the pore will allow a lower current density than on the flat electrode. To maintain the total current, a higher current density is forced on the outer electrode, leading to a greater S/H. In potentiostatic steady-state plating, the total current falls to accommodate the smaller ion concentration in the pore, and thus there is no exacerbation of the increased S/H.

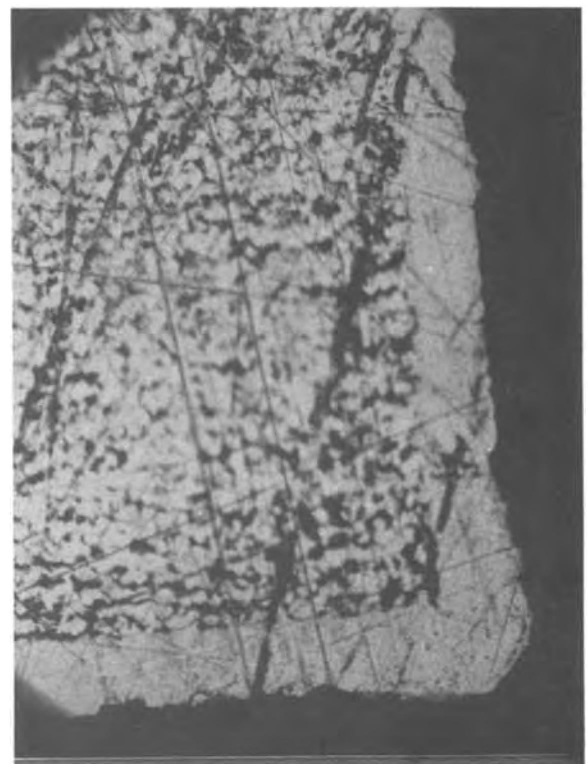
The buildup of copper at the mouth of the pore is a geometrical effect. Here the supply of ions to the edge is much greater than that to a flat electrode or cylindrical pore. It is therefore expected that this phenomenon will be seen when plating reduces the concentration below the bulk concentration. This is the case in steady-state plating, especially in galvanostatic plating (see Fig. 8) and in pulse plating when a high current or potential is held in a long pulse.

The choice of pulse parameters.—The increase in S/H at high current densities suggests that potentiostatic pulsing may be preferred to galvanostatic pulsing, and the following discussion on the optimum plating conditions is concerned with the former technique. It must be noted, however, that monitoring of the overall deposition rate may be more difficult in practical applications of potentiostatic pulse plating.

Four factors must be optimized in plating: (*i*) evenness of deposit ($S/H = 1$) and no increased deposition at the mouth of the pore, (*ii*) surface morphology, (*iii*) current efficiency, and (*iv*) total plating time.

We have shown that the current efficiency is 100% independent of potential and of frequency below 10^3 Hz, when the effect of the disproportionation of Cu^+





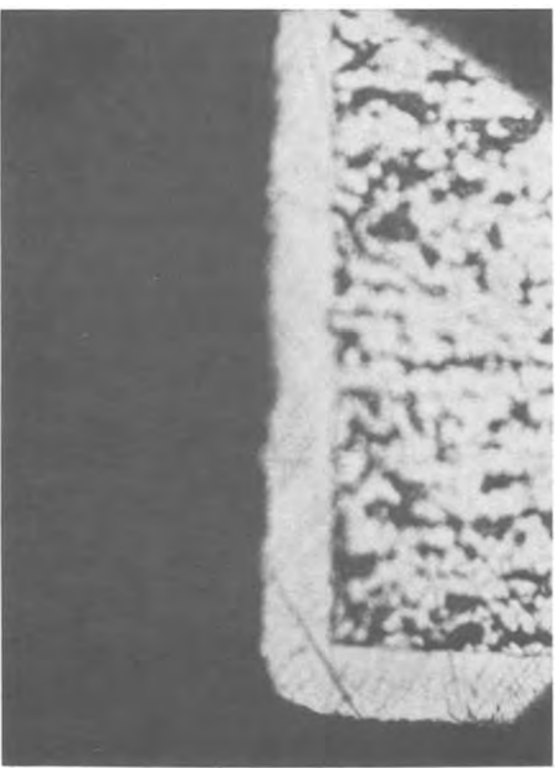


Fig. 8. Copper deposits in 0.6 mm diameter pore after pulse galvanostatic plating with agitation. a (upper left), i = 54.5 mA cm^{-2}, T_{ON} = 1 sec, T_{OFF} = 2 sec; b (upper right), i = 145.5 mA cm^{-2}, T_{ON} = 1 sec, T_{OFF} = 2 sec; c (lower left), i = 145.5 mA cm^{-2}, $T_{ON} = 7 \times 10^{-5}$ sec, $T_{OFF} = 1.4 \times 10^{-4}$ sec.

is seen. This has been reported by Cheh and co-workers for high frequency pulse deposition of copper (14, 15). However for the most part a current efficiency near 100% found here would suggest this mechanism contributes little to the deposition process for our experimental conditions. The total plating time is reduced by increasing the potential and decreasing the "off" time, but both of these factors are limited by the morphology and evenness of the deposit.

The choice of mathematical model.—The model of pulsed deposition described by Despic and Popov (13), assumes the concentration at the electrode surface follows the pulse, falling from C_o to a small value and rising again to C_o. Experimental observation of the current variation during a pulse would suggest that the initial fall in concentration does not recover immediately in the "off" period. A comparison of the diffusion layer thickness predicted by each approach may be made. The diffusion thickness for a pulse of T sec with an equal "off" time has been calculated by Despic and Popov (13). The concentration in the nth "on" period is

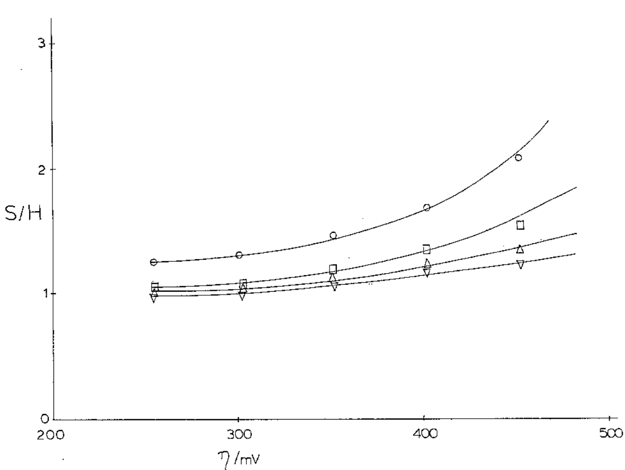

Fig. 9. *S/H* at different overpotentials for pulsed potentiostatic plating. $T_{ON} = 1$ sec, $T_{OFF} = 2$ sec. ○ = Pore diameter 0.6 mm, □ = pore diameter 1.0 mm, △ = pore diameter 1.3 mm, ▽ = pore diameter 1.6 mm.

$$C_{ON} = C(x, (2n+1)T) = \frac{2C_o}{\pi^{1/2}} \left(\int_0^{x/2D^{1/2}[(2n+1)T]^{1/2}} \exp(-u^2)du + \int_{x/2D^{1/2}(2nT)^{1/2}}^{x/2D^{1/2}[(2n-1)T]^{1/2}} \exp(-u^2)du + \ldots + \int_{x/2D^{1/2}(2T)^{1/2}}^{x/2D^{1/2}T^{1/2}} \exp(-u^2)du \right) \quad [9]$$

$$\delta N = \frac{C_o}{(\partial C/\partial x)_{x=0}} = \frac{D^{1/2}\pi^{1/2}T^{1/2}}{a}$$

where

$$a = [(2n+1)^{-1/2} - (2n)^{-1/2} + (2n-1)^{-1/2} - \ldots + 1] \quad [10]$$

We have modified this equation to accommodate a pulse of period P sec and length T sec when the equations become

$$C_{ON} = \frac{2C_o}{\pi^{1/2}} \left(\int_0^{x/2D^{1/2}[nP+T]^{1/2}} \exp(-u^2)du + \int_{x/2D^{1/2}(nP)^{1/2}}^{x/2D^{1/2}[(n-1)P+T]^{1/2}} \exp(-u^2)du + \ldots + \int_{x/2D^{1/2}P^{1/2}}^{x/2D^{1/2}T^{1/2}} \exp(-u^2)du \right) \quad [11]$$

$$\delta N = \frac{D^{1/2}\pi^{1/2}}{b}$$

where

$$b = [(nP+T)^{-1/2} - (nP)^{-1/2} + ((n+1)P+T)^{-1/2} \ldots + T^{-1/2}] \quad [12]$$

For $P = 0.3$ sec, $T = 0.1$ sec, Eq. [12] gives $\delta_N = 1.68 \times 10^{-3}$ cm. From measurements made from Fig. 14b $\delta_N = 3.4 \times 10^{-3}$ cm. At present it is not apparent how the two theories may be distinguished.

Polymer-Metal Composite Thin Films on Electrodes

Karl Doblhofer and Werner Dürr

Fritz-Haber-Institut der Max-Planck-Gesellschaft, D-1000 Berlin 33, Germany

ABSTRACT

The electrocatalytic activity of thin, metal-containing polymer films was studied. The films were prepared on glassy carbon electrodes in a glow-discharge which was established in mixtures of acrylonitrile and metal acetylacetonate vapors at 300°C. The produced films were electronically conductive and solution permeable. It is proposed that electrochemical reactions can proceed not only on the surface but also inside these films at the active sites formed by the incorporated metal. The cathodic dioxygen reduction in acidic and alkaline electrolytes was used as a test reaction for the electrocatalytic activity and stability of the electrodes.

Ultrathin polymer films can be deposited on electrodes with the method of glow-discharge-polymerization (1). Such films adhere well, are chemically stable during electrolysis in liquid electrolytes, and can render inert electrodes catalytically active. Moreover, the catalytic activity can be increased by incorporation of metals in the form of clusters or chelates (2, 3) so that the film-covered electrodes may find practical applications, such as in fuel cells. In this work we discuss basic aspects of such polymer-metal composite films on electrodes and propose a method to prepare such films.

Key words: polymers, films, electrolyte.

The Concept of a Polymer/Metal Electrocatalyst

To be effective in electrochemical processes catalytically active centers in the polymer matrix must be accessible to the electrolyte containing the depolarizer

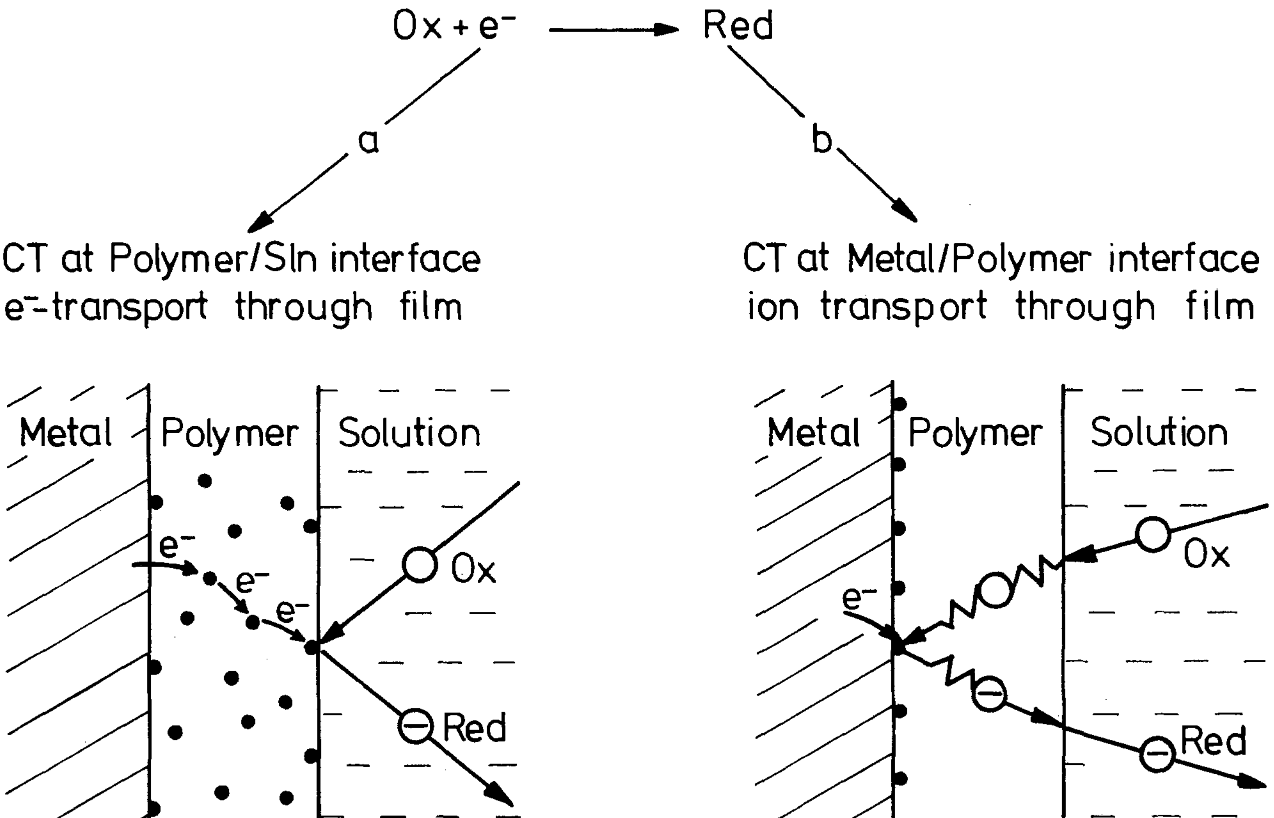

Fig. 1. Two mechanisms of electrochemical charge-transfer (CT) reactions (shown for the reduction step) proceeding on polymer-covered electrodes. The small dots in the polymer are catalytic or electron hopping sites.

species and, secondly, they must be in electrical contact with the conducting support of the polymer film. Both conditions are fulfilled for the two mechanisms (a) and (b) shown schematically in Fig. 1.

(a) The electrochemical process takes place at the interface polymer/electrolyte and the electron is transported through the film. [Note that in the discussion a metallic electrode is assumed as support for the polymer film, and, in fact, many of the experiments have been made with Pt/polymer systems. In practical applications, however, carbon, particularly glassy carbon would be preferable, as discussed in Ref. (1).]

Two steps can be distinguished in this process. Step 1: the electron transfer from (to) the electroactive species in solution to (from) the polymer surface. This process can be discussed on the basis of the accepted interfacial electron transfer theory (4-6). In particular, the predicted strong dependence of the rate of charge transfer on the concentration of the polymer electronic states demonstrated with electrochemical experiments on conducting polymer-covered electrodes (1). Step 2: the electron transport through the polymer film. This process was studied previously, also with metal/polymer/metal sandwich systems (7). From the temperature and field dependence of the film conductivity it was concluded that hopping of electrons along percolation paths was the dominant conduction mechanism.

Mechanism (a) will be favored when the film permeability for the electrolyte solution is low and its electronic conductivity is high. In this case it would be important to introduce the catalytically active (metal) centers on the polymer-surface. Inside the polymer film these centers may contribute to the film conductivity by forming electronic states which participate in the electronic percolation process.

(b) The polymer matrix acts as a membrane permitting the electroactive species and the electrolyte to reach the supporting metal/polymer interface region where the charge-transfer reaction takes place. Glow-discharge polymer films can be prepared to be permeable to electrolyte solutions (8). The permeability is high when the polymer structure interacts with the solvent molecules and when the matrix is not cross-linked (9).

Catalytically active sites in an insulating membrane-type film are expected to be electrocatalytically effective when they are in contact with the metallic support. Such a system could be of considerable practical use to improve the stability of "modified electrodes" (3, 10). It is likely that the decomposition of certain catalytically active compounds, such as chelates or clusters attached to the electrode, is retarded when the compound is imbedded in the polymer matrix.

We propose in the following a third system which is based on a combination of the schemes (a) and (b) of Fig. 1: the polymer matrix of this proposed film is permeable to the solution and electronically conducting. When such a film contains the active sites distributed throughout the matrix an electrocatalytic reaction could proceed at the active centers in a reaction zone inside the polymer film, as schematically shown in Fig. 2. Note, that in this three-dimensional reaction zone a larger number of sites is available for the electrochemical process than on a plane "modified electrode." The electronic current to or from the active sites flows because of an electric field across the film, while the electroactive species (O_2 in Fig. 2) reaches the sites by diffusion. Active centers in the polymer which can transfer electrons reversibly to a redox species are expected to be also electronic states which are energetically accessible for the electrons in the corresponding hopping conduction process, thus increasing the film conductivity. Relatively unstable catalytically active compounds could be stabilized by the polymer matrix and thus rendered usable for electrocatalytic processes, as discussed above.

Depending on the conductivity and permeability properties of an actual, experimental film the reaction zone will deviate in its location and thickness from the idealized picture, Fig. 2. In fact, the situations (a) and (b) of Fig. 1 might be considered to be the limiting cases of the proposed scheme.

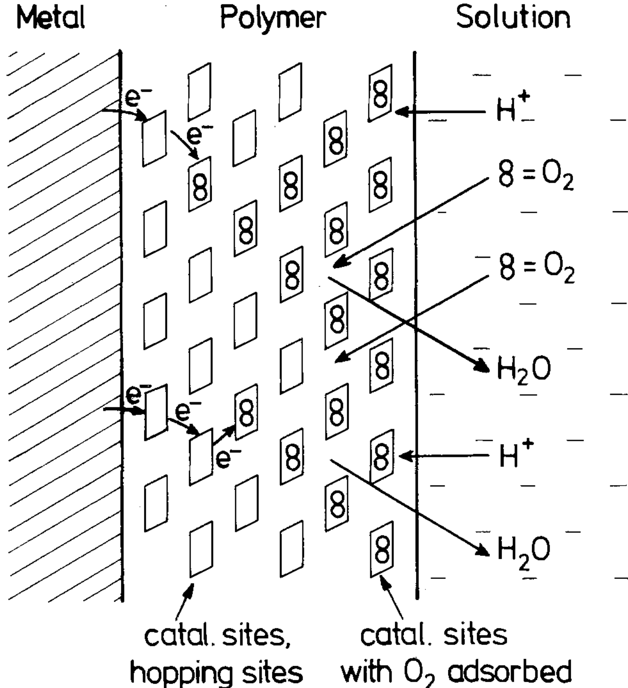

Fig. 2. Model of a solution-permeable, conducting thin polymer film with imbedded active sites, at which the electrochemical O_2 reduction proceeds. O_2 molecules are shown adsorbed on the sites; O_2, H^+, and H_2O as well as electrons (e^-) are mobile in the matrix.

Preparation of the Polymer-Metal Composite Films

The basis of the preparation of the polymer matrix was the cathodic glow-discharge polymerization (GDP) at elevated temperature, as described previously (1). Acrylonitrile was used as the monomer, which had been found to lead to a conducting polymer with a certain solution permeability. At 300°C the nitrile groups of the polyacrylonitrile break up to form an unsaturated, nitrogen-containing ladder polymer. With the nonbonding N-electron pairs, coordinate bonds can be formed with metal ions in the matrix. In fact, it is likely that the ions are complexed by more than one ligand from the polymer matrix. This leads to a chelate-type structure which would protect the metallic central ions in the film from being extracted by the electrolyte solution. Such structures should have a certain catalytic activity, *e.g.*, for the cathodic dioxygen reduction reaction (2).

To introduce the metal into the film, metal-containing volatile species, mainly metal acetylacetonates, were added to the monomer in the GDP reactor during the polymerization process. Acetylacetonates are stable at elevated temperatures and are readily available in high purity for a number of metals. Unfortunately, the necessary vapor pressure is obtained only at temperatures of the order of 150°C. Thus, it was necessary to construct the glow-discharge reactor in such a way that the temperature was nowhere lower, to avoid condensation of the acetylacetonate. A schematic picture of the apparatus is given in Fig. 3. It was built from glass and stainless steel. The temperature of the small vessel at the bottom which contained the acetylacetonate, could be controlled independently. Its temperature was raised to increase the chelate vapor pressure for the polymerization. The process could be continuously monitored with a quadrupole mass-spectrometer attached to the reactor via a narrow nozzle. Electrodes prepared from glassy carbon disks (Sigri Elektrographit GmbH, D-8901 Meitingen, Germany) of diameter 8 mm and thickness 3 mm were used as the substrate for the films. To permit only one face of these disks to be exposed to the solution in the electrochemical experiments, the disks were sealed into glass by melting the ends of

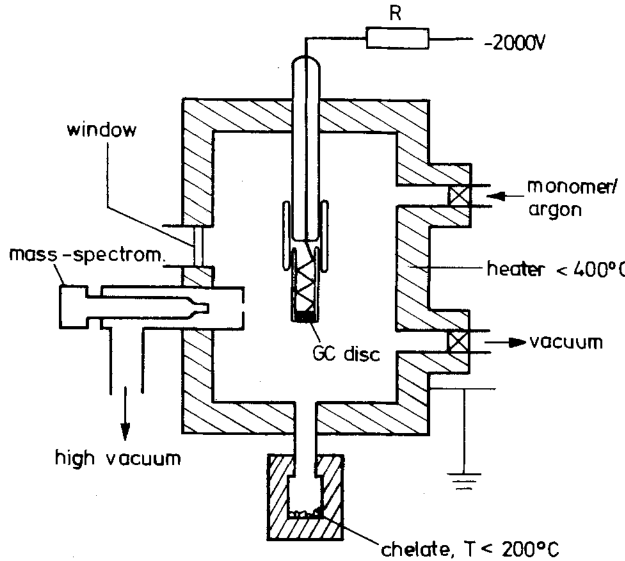

Fig. 3. Glow-discharge polymerization apparatus. The polymer-metal composite film is deposited on the exposed glassy carbon (GC) face of the electrode.

glass tubes around them, and thereafter polishing until a flat surface was obtained. Polymerization was initiated by applying the high voltage to the glow-discharge reactor when the mass-spectrometer indicated the desired vapor composition. To characterize the produced films optical reflection spectra and electrochemical measurements were routinely made. ESCA spectra were taken to estimate the amount of metal incorporated.

Results and Discussion

The properties of the produced films could be varied over a wide range by changing the acetylacetonate, by varying the ratio of the acetylacetonate-acrylonitrile vapor pressures and the polymerization temperature. In the following, a typical film is discussed. It was prepared at 300°C from cobalt(II)-acetylacetonate and acrylonitrile (AN). Vapor composition in the GDP reactor: 0.5 mbar acrylonitrile plus approximately 0.01 mbar acetylacetonate. The latter vapor pressure value can only be estimated, whereas it could be adjusted reproducibly via the acetyl-peak ($m/e = 43$) in the mass spectrum. The cathodic oxygen reduction reaction was used as a test reaction for the electrocatalytic performance of the electrode. Oxygen diffuses well through polymeric structures (11), as do H^+ ions and the produced water; mass transport from the polymer surface to and from the metallic centers was therefore not current limiting.

Figure 4 shows the performance of this electrode (AN + Co) compared with the metal-free (AN) film-covered glassy carbon, the untreated glassy carbon (GC), and a platinum electrode, in acid solution, saturated with oxygen. The curves were obtained from cyclic voltammetry experiments with the electrodes rotated at 40 revolutions per second. The sweeps were slow (5 mV/sec), *i.e.*, the Faradaic currents shown in the figure could be measured under quasi-stationary conditions. Clearly, the catalytic activity of the film with respect to oxygen reduction is significantly enhanced by the incorporated cobalt. ESCA spectra taken after 2 hr of O_2 reduction in acid electrolyte showed a decrease in Co content by approximately one third. After two days of electrolysis no significant amounts of Co could be detected by ESCA, *i.e.*, in the upper 2 nm of the film. The catalytic activity, however, was practically unchanged. Thus, the reaction must have taken place at cobalt centers deep inside the film. This is a strong indication that the electrocatalytic reaction proceeds at this film-covered electrode, according to the mechanism illustrated in Fig. 2.

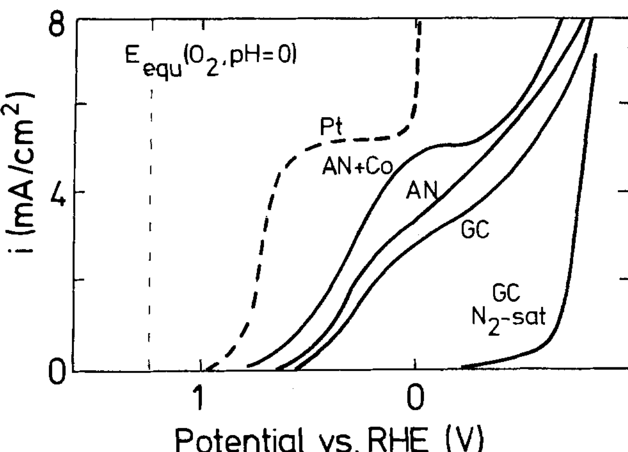

Fig. 4. O_2 reduction in 1M H_2SO_4 on the disk electrodes: glassy carbon (GC), acrylonitrile-polymer on glassy carbon (AN), Co-acetylacetonate/acrylonitrile polymer on glassy carbon (AN + Co), and platinum (Pt). The electrodes were rotated at 40 rps. RHE is the reversible hydrogen electrode in the same electrolyte.

The electrocatalytic activity of the acrylonitrile GDP film was increased by the incorporated cobalt ions also with respect to the O_2 reduction in alkaline solution, as shown in Fig. 5. The stability of the electrodes was at least as high as in acid solution.

With the apparatus shown in Fig. 3 a wide range of different polymer/metal composite films can be prepared on electrodes. The obtained systems are stable, for at least several days when used for electrochemical processes in aqueous electrolytes. One can easily conceive of a large number of metal/polymer combinations which could on this basis, lead to electrodes with desirable electrocatalytic properties, and therefore have practical applications, *e.g.*, in fuel cells.

Electrochemical Synthesis of N-Alkylformamides

Divna Cipris*

Allied Chemical Corporation, Corporate Research Center, Morristown, New Jersey 07960

ABSTRACT

Dimethylformamide, diethylformamide, and other mono- and disubstituted N-alkylformamides are produced from carbon monoxide, methanol, and corresponding alkylamine by electrolysis. The electrolysis is conducted in a one-compartment cell under up to 100 atm of carbon monoxide at 20°-40°C. The reaction is highly electrolyte dependent. The efficiencies exceed 100% (based on 1 **F**/mole of amide). Electrochemical generation and continuous regeneration of catalyst appear responsible for the observed high reaction rates and high yields of formamides. The process is described and the reaction mechanism discussed.

Electrochemical synthesis of N-alkylformamides is a result of our continuing interest in the electrochemical utilization of carbon monoxide in the production of commercially important chemicals. The synthesis of organic carbonates by electrolysis of carbon monoxide and the corresponding alcohol in the presence of a halide electrolyte has been previously reported (1, 2). The process as described here is an alternative to the existing chemical processes, and appears to have some advantages over the latter.

Several processes are described for chemical production of N-alkylformamides, based on various homogeneous and heterogeneous catalysts (3). The most relevant to our work are the processes for the production of N,N-dimethylformamide, described as follows (4-6):

1. By reaction of dimethylamine with methyl formate, according to

$$(CH_3)_2NH + HCOOCH_3 \rightarrow (CH_3)_2NCOH + CH_3OH$$

2. By reaction of dimethylamine with carbon monoxide, in the presence of dissolved alkali metal alcoholate (or $CuCl_2$ and potassium acetate), according to

$$(CH_3)_2NH + CO \xrightarrow[CH_3OH]{CH_3ONa} (CH_3)_2NCOH$$

Since methyl formate can be produced from methanol and carbon monoxide (5), these two processes can be viewed as one, differing only in number of steps.

The main problem in the one-stage commercial synthesis of N,N-dimethylformamide appears to be the plugging of equipment caused by precipitation of salts (sodium alcoholates) (6). This can be apparently avoided by the constant presence of some methyl formate added to the reaction mixture. The reaction is conducted at 90°C, at 175 atm of carbon monoxide. While the residence time of the one-stage process is not specified, methyl formate formation under comparable conditions proceeds apparently at a slow rate (8 days for 84% conversion). The electrochemical synthesis of N-alkylformamides requires ~3 hr for 60-80% conversion (based on amine), and it is conducted at milder conditions (20°-40°C and up to 100 atm of carbon monoxide). No salt precipitation occurs in the course of electrolysis. The syntheses of N,N-dimethylformamide are studied in greatest detail in this work.

Experimental

Constant current electrolysis.—Electrolyses were conducted at constant current, using cell and equipment previously described (1, 7). Graphite anode and stainless steel cathode were used throughout the work unless stated otherwise. Anodic and cathodic chambers were not separated. Commercial chemicals were used without further purification or drying. The temperature was generally maintained in the range of 20°-40°C by cold water circulating coil. In a typical experiment, 200 ml of methanolic alkylamine [25-50 weight percent (w/o)] and 13.0g (0.04 mole) of tetrabutylammonium fluoroborate were charged into the reactor and pressurized with carbon monoxide to 100 atm. A total of 0.45F was usually passed. Product analyses were performed by GC, GC-mass spectrometry, and *IR*. For GC analysis of liquid samples a 5 ft × 1/8 in. stainless steel column packed with POROPAK PS (70 → 730°C/8°/min) was generally used. A Finnigan Model 3300 gas chromatograph/mass spectrometer operated in a chemical ionization mode with methane as the reagent gas was employed.

Potentiodynamic measurements.—The cell used for the potentiodynamic studies was of a conventional type with anolyte and catholyte separated by a fritted glass disk. A graphite rod (~1 cm^2 geometric area) and stainless steel or stainless steel (T316 SS, ~1 cm^2 geometric area) and platinum-clad tantalum were working and auxiliary electrodes, respectively. A saturated calomel electrode served as a reference electrode. Solutions were purged with argon prior to the recording. The electrical equipment used in potentiodynamic measurements consisted of a Function Generator, Model CHF-1 Elscint, a Wenking Potentiostat, and a Hewlett-Packard Autograph Model 7030AM X-Y recorder.

Results

Effect of electrolyte and electrolyte concentration.—The effect of electrolyte employed in the synthesis of various alkylformamides is shown in Table I. These data indicate that the selection of cation plays an essential role in determining the course of the reac-

tion. When tetraalkylammonium or alkali metal cations are substituted by ammonium salts, no formamides are formed. The electrolyte concentration appears to have an effect on reaction efficiencies, with higher yields obtained at lower concentrations (Table II). This, however, may be due to the experimental data scattering caused by *IR* effect (see Discussion).

Effect of current density and electrode material.—The efficient synthesis of formamides was generally carried out in a one-compartment cell on graphite anodes and stainless steel cathodes with current densities of 20 and 200 mA cm^{-2} (geometric area), respectively. When a stainless steel cathode was substituted by graphite, identical results were obtained. Reversing the current densities (200 mA cm^{-2} anode; 20 mA cm^{-2} cathode) has a substantial effect on product efficiency in dimethylformamide formation. Higher yields are obtained invariably with higher cathodic current densities (Table III). Separation of the anolyte and the catholyte (Cation Exchange Membrane Ionics 61 DYG 067) increases the yields at both low and high cathodic current densities. The effect is more pronounced at higher current density (Table III).

Effect of carbon monoxide pressure and temperature.—The effect of carbon monoxide pressure on product efficiencies was studied in the cases of dimethylformamide and diethylformamide formation. Tetrabutylammonium fluoroborate (0.2M) electrolyte and a one-compartment cell were employed in all cases. The reactions were conducted at 20°-40°C. The dependence is illustrated in Fig. 1. These data suggest that in both cases there is at least a 5% yield increase for each 6.8 atm (100 psi) increment of carbon monoxide.

When the reactor is not externally cooled, the temperature rises to 65°-75°C. Some of the experiments were conducted without external cooling. Increased temperature had invariably beneficial effects on product yields. The data of some comparative runs are presented in Table II.

Current-potential data.—Current-potential curves were recorded in methanol solutions with Bu_4NBF_4 and NH_4Br electrolytes in the absence of carbon monoxide. The effect of dimethylamine and diethylamine additions (as well as corresponding formamides) on current-potential profiles of methanolic solutions was studied. The data are summarized in Table IV. As evident, current rise commences at substantially higher negative potentials upon addition of amines than in pure methanol. The reaction is accompanied by gas evolution, as in the case of pure methanol. E_{10} for methanol/NH_4Br compared to methanol/Bu_4NBF_4 solution is 300 mV less negative.[1] In all investigated cases, oxidation of amines takes place at substantially lower potentials than methanol (Bu_4NBF_4 electrolyte). With NH_4Br electrolyte simultaneous oxidation of Br^- and amines appears possible (bromine evolution visible). Some typical cyclic voltammograms are presented in Fig. 2.

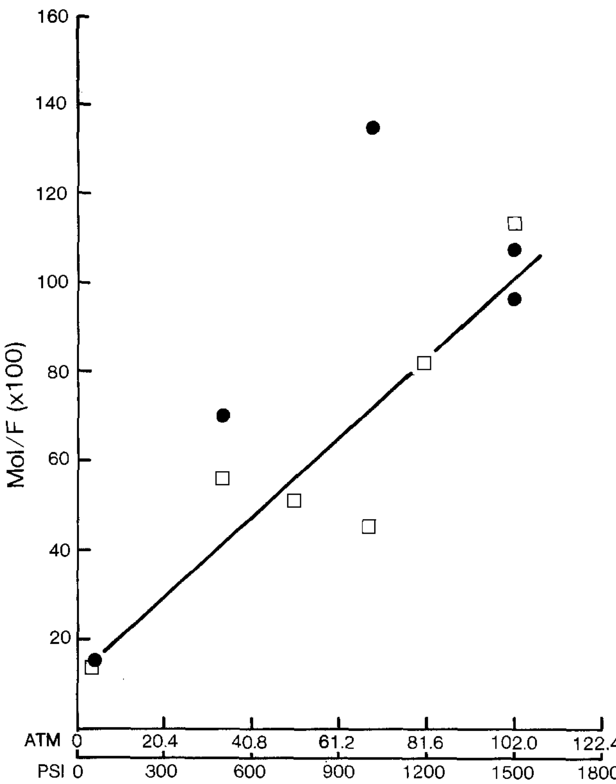

Fig. 1. Effect of CO pressure on efficiency of N,N-alkylformamide formation: □ N,N-dimethylformamide, ● N,N-diethylformamide.

Discussion

The synthesis of N-alkyl amides from carbon monoxide, alkyl amines, and methanol proceeds generally with apparent current efficiency of ≧100% (based on 1 F/mole of amide). Without methanol present, no alkyl amides are formed. In the chemical synthesis of

[1] E_{10} represents the electrode potential at 10 mA cm^{-2}.

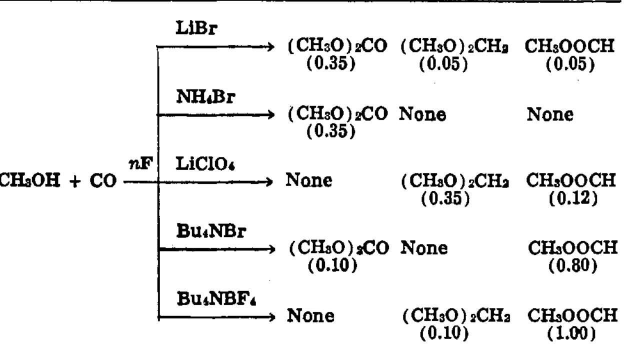
formamide the reaction takes place via methyl formate intermediate and its subsequent reaction with alkyl amines, as already seen. Methyl formate is formed from carbon monoxide and methanol in the presence of sodium alcoholates.

During our studies of electrochemical dimethyl carbonate synthesis from carbon monoxide and methanol, we discovered that methyl formate was formed preferentially when ammonium bromide electrolyte was substituted by tetrabutylammonium bromide (1). Yields of methyl formate indicated a process involving 1 F/mole of ester. Subsequently, the CO/CH_3OH electrolysis was carried out employing tetrabutylammonium fluoroborate; methyl formate was a major product (Table V). The choice of anion, thus, had no essential bearing on the course of the reaction, but catalysis by R_4N^+ cation was clearly implied. When this reaction was carried out in the presence of alkyl amines, the corresponding formamides were formed, as shown in the present work (Table I). This suggests that electrochemical synthesis of formamides proceeds via methyl formate intermediate in much the same way as a chemical one.

The chemical synthesis of methyl formate is catalyzed by sodium methoxide. It requires high temperatures, high pressures of carbon monoxide, and long reaction times (100°-120°C, 160 atm, 8 days for 84% conversion) (5). Chemical synthesis of formamides is, likewise, catalyzed by sodium alcoholates; it is conducted at 90°C and 175 atm, but no residence time was given (6). The electrolysis of CO, methanol, and alkyl amine, in the presence of R_4N^+ or Na^+ salts as electrolytes, converts 60-80% amine to formamide in approximately 1-3 hr at 100 atm. It is believed that the role of electrochemistry is in generation of homogeneous catalyst, R_4N^+ methoxide or Na^+ methoxide. The reaction sequence leading to amides can then be depicted as follows

Table V. Effect of electrolyte on product distribution in carbon monoxide/methanol electrolysis*



$CH_3OH + CO \xrightarrow{nF}$ Electrolyte

SCHEME 1

Cathode:

$$2CH_3OH + 2e \rightarrow 2CH_3O^- + H_2$$

Chemical:

$$CH_3O^- + CO \rightarrow CH_3OCO^-$$

$$CH_3OCO^- \xrightarrow{CH_3OH} HCOOCH_3 + CH_3O^-$$

(the CH_3O^- formed returns to the first step)

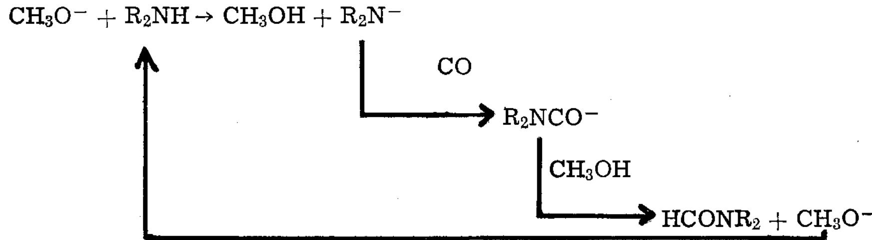
followed by

$$HCOOCH_3 + R_2NH \rightarrow HCONR_2 + CH_3OH$$

In the above scheme, for each mole of hydrogen evolved, two moles of CH_3O^- are formed cathodically. Local concentration of CH_3O^- should thus be sufficiently high to act as catalyst for formate and/or formamide formation. Concentration of R_4N^+ in the cathodic double layer is also expected to be high due to the adsorption phenomena.

An alternative scheme for the chemical reaction of electrochemically generated methoxy ions leading to formamide formation is suggested as follows

SCHEME 2



In the present work no attempt has been made to distinguish between these two possibilities of follow-up chemical reactions.

Anodic reaction in the methanol/amine system will depend on the electrolytic conditions and the concentration of the amine present. In constant current

electrolysis, at low current densities and high amine concentrations, oxidation of amine will take place in preference to methanol (Table IV). As the electrolysis progresses and amine gets depleted, oxidation of methanol will take over (batch-wise operation). It is also possible that oxidation of CH_3O^- (rather than CH_3OH) would compete with amine oxidation. High anodic current densities, even at relatively high amine concentrations, might also change the course of anodic reaction.

We have not attempted (so far) to determine the products of anodic reaction. In the case of methanol (or CH_3O^-) oxidation, formaldehyde is expected as product according to the following reaction (8)

$$CH_3O^- \rightarrow HCHO + 2e + H^+$$

Further oxidation of CH_3O^- to formate (and ultimately CO_2) is possible, but takes place only in the presence of OH^- or H_2O, according to (9)

$$CH_3O^- + 4\,OH^- \rightarrow HCOO^- + 3H_2O + 4e$$

This cannot happen to any substantial degree under our experimental conditions (H_2O concentration below 1%). Small amounts of CO_2 detected in the gas phase may also come from carbon monoxide oxidation. The products derived from amines oxidation are less certain. The literature data (10) suggest that secondary and tertiary aliphatic amines are dialkylated on anodic oxidations in nonaqueous solvents. The data relating directly to dimethylamine or diethylamine oxidation could not, however, be found. The solutions after CH_3OH/amine/CO electrolytes contain small amounts of dark solids, whose nature remains to be determined. It is important to notice that no fouling of the electrodes was ever observed.

With Bu_4NBr electrolyte, in the presence of amine, formation of dimethyl carbonate was observed along with formamide, in agreement with previously observed reactions (Table V). Bromine evolution and subsequent $COBr_2$ formation is postulated in such cases (1). The fact that $(CH_3O)_2CO$ forms in a much lesser degree than either methyl formate or formamide indicates different respective rates of follow-up chemical reactions. With amine present, simultaneous oxidation of amine and Br^- seems possible (Table IV), decreasing the rate of Br_2 generation. Employment of NH_4Br failed to produce any methyl formate or formamide (Tables I and V). In the presence of NH_4Br, hydrogen evolution in methanol takes place at substantially lower potentials than with Bu_4N^+ electrolytes (Table IV). It is quite obvious that, in this case, NH_4^+ serves as a primary proton source, thus diminishing high local concentration of methoxide. Also, NH_4^+ is more acidic than R_4N^+. These two factors can adequately account for the lack of formamide (or methyl formate) formation with NH_4Br electrolyte.

Due to the relatively low conductivity of methanol/amine solutions with Bu_4NBF_4 (and especially $NaBF_4$) and our experimental setup, fairly high *IR* drop is observed, with subsequent generation of heat. Without cooling, the temperature of the reactor would rise to 65°-75°C. In order to reduce the temperature, the reactor was cooled externally (by water circulating coil) to 20°-40°C. It is believed, however, that external cooling could not adequately prevent internal local overheating, so that actual reaction temperature might have been higher than 20°-40°C. The absence of the precise temperature control may account for some of the observed results scattering. The experiments carried out without external cooling were, in general, producing higher yields of amides than the cooled ones (Table II).

Interestingly enough, however, heating by itself (even to the temperature of 100°C) was not sufficient for the continuation of the reaction to any substantial degree once the current flow was discontinued. This is remarkable if we assume that the essential role of electrolysis is indeed the generation of homogeneous catalyst, R_4N^+ or Na^+ alcoholates. Once generated, the reactions would be expected to proceed regardless of the further current flow. Discontinuation of the current should not, therefore, have such a profound effect on the product yield.

The answer for this inconsistency might be found in the possibility that, in the electrochemical synthesis, very high concentration of the catalyst may be generated locally. Concentration of the catalyst in the diffusion electrical double layer (layer adjacent to the electrode) may be many times higher than in the bulk of the solution, influencing thus the rate of the reaction. Such phenomena are known in electrochemistry (11), and it was suggested that it might be the case here (12). The slow rate of the chemical reaction may be thus attributed to the low bulk concentration of the catalyst. Solubility of $NaOCH_3$ in CH_3OH is fairly low. In the chemical process of methyl formate synthesis, difficulties are experienced due to the catalyst precipitation (6). The higher activity of R_4N^+ compared to Na^+ electrolyte in our process may be partially due to the higher solubilities of R_4N^+ salts.[2] Catalysis by metals (leached from the stainless steel container electrode) was ruled out, based on experiments employing both electrodes made of graphite.

Increase in carbon monoxide pressure (one-compartment cell) favors N-alkylformamide formation, as evidenced in Fig. 1. The reaction was not examined at pressures higher than 100 atm.

The observed higher rates (lower residence time) in the electrochemical synthesis of methyl formate (and probably formamides) are thus likely to be due to the higher local concentration of the catalyst, and/or to the continuous catalyst generation. The active catalyst state is continuously regenerated. The direct electrochemical formation of methyl formate is ruled out, even in the one-compartment cell, since it would require fast recombination of cathodic and anodic radical products, preceded (or followed) by chemical reactions, in order to account for the observed 1 **F**/mole efficiency. This unlikely situation can be depicted as follows

SCHEME 3

Cathode: $CH_3OH + e \rightarrow CH_3O^- + H\cdot$; $H\cdot \xrightarrow{CO} HCO\cdot$

Anode: $CH_3O^- \rightarrow CH_3O\cdot + e$

Overall: $CH_3OH + CO \rightarrow CH_3OOCH$

No other direct mechanism can account for the observed 1 **F**/mole efficiency. Preferential oxidation of amines prevents $CH_3O\cdot$ generation, while in the two-compartment cell separation of catholyte and anolyte practically eliminates the possibility of cathodic and anodic products recombination (even if they are both derived from methanol). In either of these two cases, no methyl formate, and consequently formamide, formation could be possible according to the above scheme. In both cases, however, high yields of formamide are formed, eliminating thus even remote credibility of a direct electrochemical mechanism.

Furthermore, separation of catholyte and anolyte (cation exchange membrane) produced DMF with yields highly exceeding 100% (1 mole/**F**) (Table III). This can be explained in terms of further increase in catalyst (R_4N^+ methoxide) concentration in the catholyte. Loss of CH_3O^- is prevented, while R_4N^+ ion con-

[2] It was suggested by one of the reviewers that the higher rates for R_4N^+-containing electrolytes *vs.* Na^+-containing electrolytes probably has most to do with the "nakedness" of the alkoxide ion when the counterion is R_4N^+.

centration gradually increases due to the transfer through the cation exchange membrane. In addition, anodic decomposition of product intermediate(s) which might take place in an undivided cell is also prevented. It is obvious that chemical reaction following the electrochemical catalyst generation (and continuous regeneration) is responsible for the yields exceeding 100% current efficiency.

Acknowledgment

I am highly indebted to Mr. Arthur T. Walsh for conducting the high pressure electrolyses and GC analytical work. I also wish to thank Dr. Miroslav Novotny for useful discussions and the members of the Allied Chemical Physics Department for their contributions: Dr. Danne E. Smith (GC-mass spectrometry) and Mr. James M. Hanrahan (preparative GC and *IR*). Comments provided by Professor E. Gileadi are also greatly appreciated.

Manuscript submitted Sept. 17, 1979; revised manuscript received Nov. 26, 1979. This was Paper 320 presented at the Boston, Massachusetts, Meeting of the Society, May 6-11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Allied Chemical Corporation.

Free-Convective Mass Transfer to a Rod-Shaped Vertical Electrode

J. R. Selman* and J. Tavakoli-Attar

Department of Chemical Engineering, Illinois Institute of Technology, Chicago, Illinois 60616

ABSTRACT

The limiting-current method is used to measure mass transfer rates by free convection to the faces of a rod-shaped electrode as commonly used in molten salts. Mass transfer rates to the horizontal (disk) face and the vertical (curved) face are measured separately and in combination. The two rates are not additive; there is significant interaction caused by leading edge effects at the vertical face and by solution streaming from the horizontal to the vertical face. At the horizontal face a new and unusual but well-characterized type of convective mass transfer, driven by buoyancy, is measured and correlated.

Electrochemical measurements of mass transfer rates and mass transfer coefficients are applied frequently because of their inherent accuracy and convenience. In the present work the limiting current technique (1) is used to investigate mass transfer by free convection at a vertical cylinder of finite length, and its horizontal end face, immersed in a liquid. This problem is of interest to electrochemists active in molten-salt technology.

In molten salts, as in aqueous electrolytic solutions, one prefers to use an electrode of well-defined area and known hydrodynamic characteristics, *e.g.*, a rotating disk electrode. However, the ideal electrode of this type, which has its active area embedded in an insulating surface, is difficult to make and maintain crevice-free for any length of time in common molten salt media such as LiCl-KCl eutectic (mp 625°K) or equimolar Li_2CO_3-K_2CO_3 (mp 778°K). Consequently, one often employs as working electrode a metal or carbon rod partly immersed in the melt.

In a molten salt which contains a minor electroactive component, *e.g.*, a sparingly soluble heavy-metal ion or a dissolved gas, the mass transfer rate to the rod electrode in free convection or in rotation (2) determines the limiting current due to this component.

The mass transfer limiting current to the rod electrode, which consists of a vertical cylinder of finite length with a circular disk as the end face (Fig. 1a), is not as well defined as at a rotating disk electrode (Fig. 1b) or at a vertical electrode by free convection, *e.g.*, at a cylindrical electrode confined between bottom and top of the cell (Fig. 1c). The objective of this work was to measure the mass transfer rate at a rod-shaped electrode in free convection and compare it with rates predicted by classical free-convection correlations for vertical and horizontal surfaces.

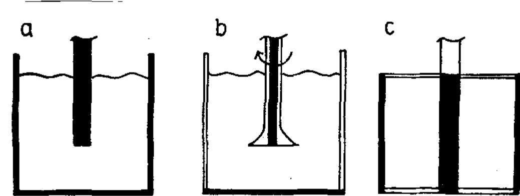

Fig. 1. Cell configurations for: a, vertical rod electrode; b, rotating disk electrode; c, cylindrical electrode confined between bottom and top of the cell. Black surfaces are electrode surfaces; white, insulator.

* Electrochemical Society Active Member.

Key words: free convection, mass transfer, limiting current, molten salt, cylinder, rod, $CuSO_4$.

The mass transfer rates to the vertical, curved surface and to the horizontal, disk face of the cylinder were measured in separate exposures; and, finally, in combined exposure, the mass transfer rate to the entire rod electrode. This was carried out by limiting-current measurements in aqueous solutions. The system used was copper deposition from a $CuSO_4$ solution containing excess H_2SO_4 as supporting electrolyte (1).

It appears justified to apply the results obtained in this aqueous system to the molten-salt solution described above: the major components of the latter, *e.g.*, LiCl-KCl eutectic or equimolar Li_2CO_3-K_2CO_3, besides functioning as ionic solvent, have a high enough conductivity to cause the migration fluxes of minor components to become negligible. Thus there is a nearly complete analogy with a well-supported solution in an electrolytic solvent.

Free Convection at Vertical and Horizontal Electrodes

Free-convective heat transfer at an isothermal vertical surface is one of the classical problems of heat transfer theory (3), solved mathematically by similarity transformation. Wagner (4) first gave an approximate solution for the analogous, but more complicated case of free convection caused by copper deposition in a $CuSO_4$ solution containing H_2SO_4. The limiting current density depends inversely on the 0.25 power of x, the distance from the leading (lower) edge of the electrode. It also depends on the 1.25 power of the bulk $CuSO_4$ concentration.

Wagner's approximate expression for the average limiting current over a distance L may be written in the dimensionless form

$$\mathrm{Sh_L} = \frac{i_{\mathrm{lim}}L}{2\mathbf{F}D_{\mathrm{Cu}^{++}}c_{\mathrm{Cu}^{++}}} = 0.806\left[\frac{gL^3c_{\mathrm{Cu}^{++}}}{\nu D_{\mathrm{Cu}^{++}}}(\alpha_{\mathrm{CuSO_4}} - 0.66\alpha_{\mathrm{H_2SO_4}})\right]^{0.25} \quad [1]$$

Here α_i is the densification coefficient of species i, defined by

$$\alpha_i = \frac{1}{\rho}\left(\frac{\partial\rho}{\partial c_i}\right)_{T,c_{j\neq i}} \quad [2]$$

The negative coefficient of $\alpha_{H_2SO_4}$ in Eq. [1] means that H_2SO_4 accumulates at the cathode by migration, while $CuSO_4$ is depleted. The density difference driving the convection is therefore less than it would be in the case of $CuSO_4$ depletion only.

Accurate estimation of the density difference ($\Delta\rho$) is essential if one wants to use the limiting-current technique to establish free-convection correlations. Such correlations contain the characteristic Grashof number

$$\mathrm{Gr_L} = \frac{gL^3}{\nu^2}\left(\frac{\Delta\rho}{\rho}\right) \quad [3]$$

which is also implicit in Eq. [1]. The density difference $\Delta\rho$ depends obviously on the extent of H^+ ion migration and thus on the ratio of supporting electrolyte (H_2SO_4) to reactant ($CuSO_4$) concentration in the bulk. A constant coefficient of $\alpha_{H_2SO_4}$ as in Eq. [1] is evidently an oversimplification.

Wilke, Eisenberg, and Tobias (5, 6), using an improved, semiquantitative procedure to estimate $\Delta\rho$, obtained for the mass transfer coefficient in free convection at vertical electrodes the correlation

$$\mathrm{Sh_L} = 0.670\,(\mathrm{Gr_LSc})^{0.25} \quad [4]$$

This is in excellent agreement with the theoretical solution for very large Schmidt numbers, characteristic of electrolytic solutions. In the experiments of Wilke *et al.* (5, 6) the vertical plate electrode was bounded on its lower edge, where the convection boundary layer originates, by the bottom of the cell.

The effect of migration on limiting currents was analyzed in more detail by Selman and Newman (7). From their results the accumulation of H_2SO_4 at the electrode may be expressed as a polynomial function of the ratio (supporting electrolyte/total electrolyte), see Table I. This table also presents a coefficient for the ratio of the limiting current in the presence of migration to that expected for pure convective diffusion only. The correlations in Table I are valid for the case of complete dissociation of H_2SO_4, which more closely approximates the chemistry of most experimental solutions than partial dissociation to HSO_4^- (8). The correlations of Table I were used in the present work to calculate $\Delta\rho$ and k.

Free convection at a vertical cylinder differs from that at a flat vertical plate by the effect of transverse curvature; this is the more important as the cylinder (or wire) radius, r, is smaller. Ravoo *et al.* (9) investigated the effect of curvature theoretically and experimentally. They applied a correction function $f(\gamma)$ to the mass transfer correlation

$$\mathrm{Sh_L} = 0.670\,f(\gamma)\,(\mathrm{Gr_LSc})^{0.25} \quad [5]$$

where

$$\gamma = \frac{L}{r}(\mathrm{Gr_LSc})^{-0.25} \quad [6]$$

At high $\mathrm{Gr_LSc}$ combinations or small L/r ratios, γ is $<<1$ and $f(\gamma) \rightarrow 1$. The practical limit for absence of curvature effect is $\gamma = 0.2$; this was not exceeded in the present work.

Germane to free convection at a finite vertical cylinder is free convection at a sphere. Schütz (10) investigated this case and found that between $\mathrm{Gr_dSc}$ numbers of 1.22×10^7 and 1.5×10^{10} mass transfer rates were well correlated by

$$\mathrm{Sh_d} = 2 + 0.590\,(\mathrm{Gr_dSc})^{0.25} \quad [7]$$

where d is the sphere diameter.

Finally it should be noted that free convection at a horizontal surface is possible only if heavier fluid overlies a lighter one (unstable stratification). At a downward facing cathode in a cell as shown in Fig. 2a, deposition of copper from $CuSO_4$ solution will not produce free convection. Conversely, in the cell of Fig. 2b free convection will arise if Jeffreys' criterion (11) is met

$$\mathrm{Gr_hSc} > 1709$$

Here $\mathrm{Gr_h}$ is based on the cell height, h.

Usually $\mathrm{Gr_hSc}$ exceeds 10^7 in electrolytic solutions and a turbulent free-convection regime is established; in this case mass transfer rates are correlated by expressions such as

$$\mathrm{Sh_d} = C(\mathrm{Gr_dSc})^{1/3} \quad [8]$$

If C is a constant, *e.g.*, $C = 0.152$ (12), the mass transfer coefficient is independent of the electrode di-

To the right: schematic concentration profile; (c) unstable stratification leading to nonuniform turbulent free convection. Horizontal arrows: advection of bulk solution.

mension, d. This is evidently the case in Fig. 2b where the current distribution cannot be otherwise than uniform.

However, if the horizontal cathode is embedded, as in Fig. 2c, the coefficient in Eq. [8] depends on the cathode dimensions: bulk electrolyte solution streams slowly toward the cathode from the inert side surfaces. Fenech (13) found for such a case that in Eq. [8] the coefficient is

$$C = 0.122\ \mathrm{Sc}^{1/24}\epsilon \qquad [9]$$

where $\epsilon = 1$ if the plate is bounded by vertical surfaces. (Fig. 2b) and $\epsilon = f(d) > 1$ if it is embedded (13).

In the present study streaming caused by adjacent free convection is found to occur in a different context, as is shown below.

Experimental

The experiments were carried out in a cylindrical Lucite vessel of 16.5 cm diam and 15.9 cm height containing 2.5 liters of electrolytic solution. The working electrode was a stainless steel or OFHC copper cylinder of 0.63-5.08 cm diam; it could be screwed into the spindle of a Pine Instruments Rotator,[1] with which it had been carefully aligned, and was immersed in the center of the electrolytic solution by lowering the arm of the rotator. The counterelectrode was a ⅛ in. thick sheet of OFHC copper, centered and attached to the bottom of the cell. The entire electrolytic cell was immersed in a constant temperature bath maintained at 25.0° ± 0.1°C.

A capillary adjacent to the working electrode was used to connect the bulk solution to the reference electrode compartment, which was filled with the same electrolytic solution as the main cell. A 1/16 in. diam wire of OFHC copper was used as a reference electrode.

The electrolytic solution consisted of approximately 0.05, 0.1, and 0.25M $CuSO_4$ solutions containing 1.5-2.0M H_2SO_4. To some solutions glycerol was added. The concentration of $CuSO_4$ was determined by iodometric titration (14) and the H_2SO_4 concentration by potentiometric titration with NaOH (15). Glycerol was titrated with ceric ion. The solution density, viscosity, and diffusivity at 25°C were found from correlations (Table II) established in earlier work (16).

Table II. Physical property correlations of $CuSO_4$-H_2SO_4-H_2O solutions at 25°C

Before each run the solution was routinely deaerated by sparging nitrogen slowly for 2 hr. The electrodes were carefully polished with grade 0000 emery paper and degreased. If stainless steel electrodes were used, a 2-5 micron thick layer of copper was plated onto the cathode *in situ* while it was rotated at 100-300 rpm, at a constant current density of 3-6 mA/cm².

The limiting current measurement was started after the solution had become completely quiescent and following a visual check to ensure that no bubbles were sticking to the electrode.

The power supply used was a PAR Model 371 Potentiostat/Galvanostat.[2] Limiting current curves were generated by means of a VCF ramp generator (Exact Electronics[3] Model 7030) and recorded on a Houston Instruments[4] Series 2000 Omnigraphic X-Y Recorder.

After each series of experiments the electrode, if it was stainless steel, was first stripped potentiostatically at +300 to +500 mV; the electrode was then rinsed and washed with isopropanol, dried, and prepared for the next run.

In all experiments in which only part of the working electrode was to be exposed to the solution, *e.g.*, the horizontal end face, or a certain length of the cylindrical vertical surface, the nonexposed parts were masked with a thin layer of glyptol paint.

Results and Discussion

Horizontal end face exposed.—As it was expected that no free-convective limiting current would be established in this case (see Fig. 2a), attention was focused on the unsteady-state diffusive process expected to occur at the exposed disk electrode. At a 1.27 cm diam electrode, potential scans were applied with varying scan rates (dV/dt from 2.94 to 50 mV/sec). A typical diffusion-limited process should exhibit a maximum current at aproximately 22 mV (at 298°K) and the peak current should be proportional to the square root of the scan rate a [Sevcik-Randles equation (17)]

$$i_{\max} = -0.6105 c_b n \mathbf{F} (aD)^{1/2} \qquad [10]$$

where

$$a = \frac{n\mathbf{F}}{RT}\frac{dV}{dt} \qquad [11]$$

A typical scan result is shown in Fig. 3. Current maxima were observed at overpotentials ranging between −75 and −160 mV; this is considerably more negative than predicted by the Sevcik-Randles theory, although the copper deposition reaction has an exchange-current density of 0.1-0.5 mA/cm² and is practically diffusion controlled (18).

A similar discrepancy between predicted and observed peak potentials was observed earlier in unsteady-state limiting current measurements at a rotat-

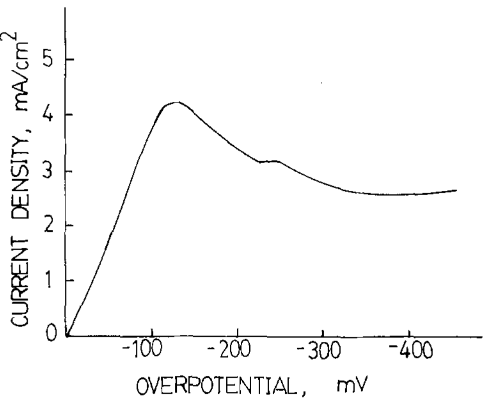

Fig. 3. Typical potential scan at the horizontal electrode surface (1.27 cm diam). Scan rate: 2.94 mV/sec. Solution: 0.05M $CuSO_4$, 1.6M H_2SO_4. Temperature: 25°C.

ing disk electrode (19). Here it was probably caused in part by uncompensated ohmic drop and in part by the presence of convection.

It was evident that, after a lapse of time, convection set in: (*i*) a smaller second peak was observed at −250 mV in almost all cases and (*ii*) the current did not decay to zero but to a small finite value which could be maintained indefinitely by holding the potential at a value between −350 and −400 mV.

Moreover, the peak current densities for the first (Randles-Sevcik) peak were only about 70% of the theoretical prediction, Eq. [10], as shown in Fig. 4. Convection clearly caused an increased supply of $CuSO_4$ to the electrode, thereby lowering the peak current density as well as shifting the peak potential to more negative values (*i.e.*, lower $CuSO_4$ concentration at the electrode when the current peaks).

The steady-state limiting current was subsequently studied at electrodes of various diameters. The limiting current was generated simply by applying a large negative potential, but not so negative as to cause hydrogen evolution; in most cases a potential step of −400 mV was used. Figure 5 shows a typical current response to such a potential step. The limiting current is established after 3-4 min during which the initial oscillations die out. After 5-6 min the current starts increasing slowly due to buildup of surface roughness; if the applied potential was chosen too high, *e.g.*, −500 mV, the current kept on decreasing because hydrogen bubbles forming at the edge of the exposed disk surface slowed down convection.

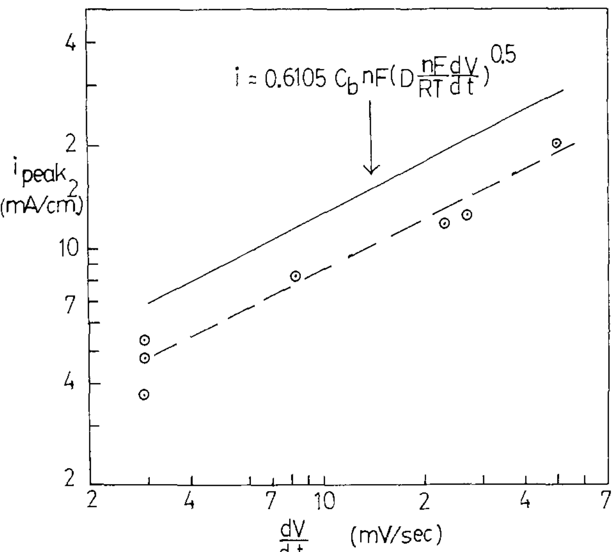

Fig. 4. Correlation of peak currents from potential scans with the scan rate (horizontal electrode surface, 1.27 cm diam). Solution 0.05M $CuSO_4$, 1.6M H_2SO_4 (25°C). Solid: Eq. [10]. Dashed: least squares line through experimental results.

Evidently, the convection responsible for the observed limiting current is caused by upward escape of light solution, depleted in $CuSO_4$, around the edge of the exposed disk surface. The buoyant solution forms a plume around the circumference of the disk and this plume induces a very slow flow of bulk solution up toward the disk, where it is depleted in $CuSO_4$. The depleted solution flows radially outward to the edge of the disk (Fig. 6).

This convection is an example of bulk flow streaming induced by buoyancy (advection) similar to that observed by Fenech (13) and Wragg and co-workers (20) adjacent to a horizontal electrode at which turbulent free convection is taking place.

The mass transfer coefficient corresponding to the present buoyancy-induced convection was found to be inversely proportional to the diameter of the disk surface (Fig. 7). Measurements with various $CuSO_4$ concentrations of approximately equal Sc number (2330 ± 50) yielded the correlation

$$Sh_d = 9.80 Gr_d^{0.167} \qquad [12]$$

with a standard error of 8%.

Measurements with solutions containing 2.97M glycerol (Sc = 9084) yielded the same Gr dependence as Eq. [12] and indicated an approximate Sc dependence of 0.20. This would yield for the overall correlation

$$Sh_d = 2.075 Gr_d^{0.167} Sc^{0.2} \qquad [13]$$

with an error of ±6% (Fig. 8)

Experimental data are given in Table III.

The dependence of Sh_d on $Gr_d^{1/6}$ is quite different from the dependence on $Gr_d^{1/4}$ in free convection at a sphere, Eq. [7], although the two geometries are extreme cases of the same general flow pattern combining free convection with stagnation flow. Whereas

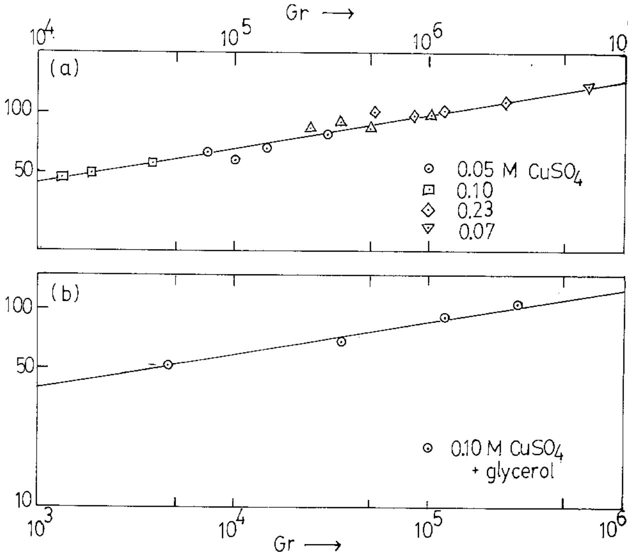

Fig. 7. Correlation of limiting currents at the horizontal electrode surface with Grashof number. (a) Solutions without glycerol. Solid line: Eq. [12]; (b) solutions with glycerol. Solid line: $Sh = 12.79Gr^{0.1667}$.

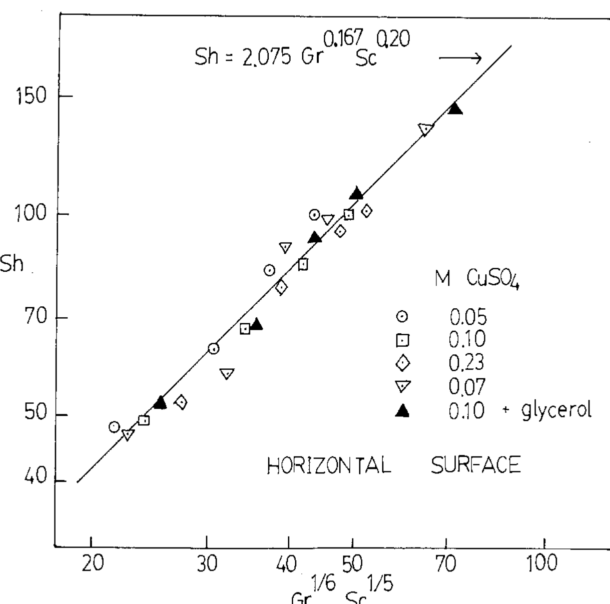

Fig. 8. Overall correlation for mass transfer at the horizontal electrode surface.

free-convection mass transfer dominates at the sphere, in the present case stagnation flow characteristics dominate if the disk is large enough.

Thus the dependence of Sh_d on $Gr_d^{1/6}$ may be explained by considering the streaming toward the disk and the radial outflow as a case of three-dimensional stagnation flow similar to that at a stationary disk perpendicular to a uniform main flow. Matsuda and Yamada (21) found a $d^{-1/2}$ dependence for the mass transfer coefficient at such a disk

$$Sh_d = 0.752Re_d^{0.5}Sc^{0.333} \quad [14]$$

where $Re_d = v_\infty d/\nu$ and v_∞ is the main stream velocity. In this case the main stream velocity v_∞ toward the disk is related to the initial velocity and thickness of the buoyant plume at the edge of the disk.

It is reasonable to assume that the velocity of this plume depends primarily on its buoyancy and on the diffusivity of the reactant species. In the simplest case one would expect from dimensional considerations

* Also 2.97M glycerol.

$$v_\infty \sim (g\alpha\Delta cD)^{1/3} \quad [15]$$

This is similar to the mass transfer velocity associated with turbulent free convection, but larger by a factor of the order of $Sc^{1/3}$.

If Eq. [15] was valid, one would expect Sh_d to depend on $Sc^{1/6}$. Such a dependence does fit the experimental data fairly well

$$Sh_d = 2.715(Gr_dSc)^{0.167} \quad [16]$$

with a slightly larger standard error than Eq. [14]. The experimental data do not allow a meaningful decision between Eq. [14] and [16]. It is possible that the dependence on Sc is not as simple as either of these expressions.

Vertical cylindrical face exposed.—Here, too, one would expect some deviation from the classical free-convection correlation Eq. [4] and this was indeed found to be the case.

Table IV presents experimental data for various exposed lengths at three different bulk concentrations of $CuSO_4$. In Fig. 9 the mass transfer coefficients are compared with Eq. [4]. Almost all the measured values exceed the predictions (indicated in Fig. 9 by lines since Sc does not vary significantly). The largest deviations are systematically found for small lengths L and small concentrations c.

This indicates that the deviation is caused by a leading-edge effect and increases with the thickness

of the free-convective boundary layer, which is inversely proportional with $c_b^{1/4}$.

In the classical boundary-layer model (Fig. 10a) inflow of fresh bulk solution takes place only perpendicular to the surface (y direction), not from below the leading edge (x direction). However, near the leading edge the boundary-layer equations break down and diffusion in the longitudinal (x) direction contributes significantly to the local mass transfer rate; see, *e.g.*, Newman (22).

In many previous free-convection measurements (5, 6, 9) the geometry was that of Fig. 10b; longitudinal diffusion could not contribute to the flux, and inflow of solution necessarily was perpendicular to the electrode. Thus, the conditions for agreement with Eq. [4] were optimal. However, the present geometry (Fig. 10c) allows diffusion over a 270° angle to contribute to the leading-edge flux. From the results of Fig. 9 one can infer also that inflow from below the leading edge takes place, since the leading-edge effect is dependent on c_b and, therefore, on the thickness of the developing diffusion layer.

Combined exposure.—Table V presents the results for mass transfer to the entire surface and Fig. 11 compares these with the summed rates for the separate surfaces. In all cases the total mass transfer rate is less than one would expect if the rates were additive. The difference is especially marked for small electrode lengths. For the larger concentrations the difference appears to approach a constant value as L increases.

	0.2455	1.526	257.7	24.5	286.0

From the results discussed earlier in this section it is evident that the nonadditivity is caused by the streaming of depleted solution around the edge of the horizontal end face into the leading edge of the vertical mass transfer boundary layer. The latter thus suffers an initial depletion, which decreases the overall mass transfer rate by an amount largely independent of the active electrode length.

Conclusions

Mass transfer rates and limiting currents by free convection at a truncated vertical rod electrode are significantly different from those predicted by the well-known correlation for mass transfer at a vertical electrode.

This is due to the development of an unusual but well-characterized limiting current on the horizontal, disk-shaped face of the electrode. It is caused by a buoyancy-driven stagnation flow and its mass transfer rate satisfies the correlation

$$Sh_d = 2.075 Gr_d^{0.167} Sc^{0.2} \qquad [13]$$

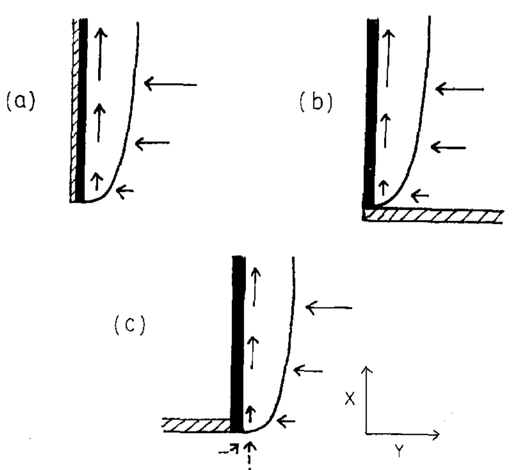

Fig. 10. Leading-edge configurations in free convection at a vertical electrode: (a) idealized boundary layer; (b) electrode extending to the bottom of the cell; (c) immersed electrode. Shaded surfaces are insulators.

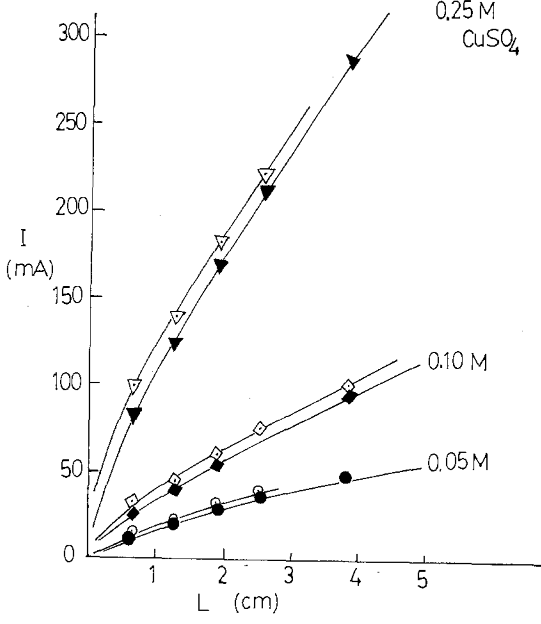

Fig. 11. Total and additive currents for immersed rod electrodes. Open symbols: sum of currents to horizontal and vertical faces; filled symbols: current to both in combined exposure. Electrode diameter = 1.27 cm.

In addition there is a significant leading-edge effect, exceeding 5% for short vertical electrode lengths (<1 cm) and for dilute solutions (<0.1M $CuSO_4$). Mass transfer to the vertical surface alone is increased by diffusion and by inflow of bulk solution at the leading edge. Both act to increase the limiting current.

If the entire electrode surface is accessible, this positive leading-edge effect is overwhelmed by a negative effect: the inflow of depleted solution from the horizontal surface (disk), which causes an overall decrease of the mass transfer rate. The mass transfer rates to the vertical surface and the horizontal electrode, therefore, are not additive.

Free-convection limiting currents at a rod electrode, *e.g.*, in a molten salt, may be estimated with 10-15% accuracy by means of established correlations if positive and negative leading-edge correlations are accounted for.

Semiconductor Electrodes

XXVIII. Rotating Ring-Disk Electrode Studies of Photo-oxidation of Acetate and Iodide at n-TiO_2

Katsuhiko Hirano and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The photo-Kolbe reaction (electro-oxidation of acetate) on TiO_2 in aqueous solution has been studied by means of a rotating ring-disk electrode (RRDE) with a TiO_2 disk and Pt ring. The oxidation of acetate competes very efficiently with water for photogenerated holes on the illuminated n-TiO_2 disk as shown by a decrease in the collection efficiency for oxygen reduction. No oxidation product of acetate was detected on the ring. Competitive oxidation of iodide with acetate and water was also investigated. Equations for determining relative rate constants for competitive reactions are derived and the applicability of the RRDE in studying such systems discussed.

Since the initial studies of the photo-oxidation of water at n-type TiO_2 (rutile) electrodes by Fujishima and Honda (1), investigations of this and many other reactions on this material have been reported. For example, the oxidation of many other substantces (*e.g.*, iodide, bromide, and cyanide ions) can be carried out at n-TiO_2 in competition with water oxidation (2, 3). Of particular recent interest has been the photo-Kolbe reaction in which a carboxylic acid is photo-oxidized (4, 5). For example, previous studies from this laboratory have established that in aqueous solutions containing acetate (Ac^-)/acetic acid (HAc) mixtures irradiation of an n-TiO_2 electrode leads almost exclusively to the oxidation of acetate

$$CH_3CO_2^- + h^+ \rightarrow \tfrac{1}{2}C_2H_6 + CO_2 \quad [1]$$

(where h^+ represents a hole photogenerated at the TiO_2 surface). Photocatalytic decomposition of acetate (predominantly to methane and CO_2) has also been carried out by irradiation of suspensions of platinized TiO_2 (6, 7). While total product yields and current-potential (*i-E*) curves have yielded information about the overall course of the reaction (5) and electron spin resonance spin trapping experiments have established the intermediacy of methyl radicals in the reaction (8), studies of the relative rates of acetate *vs.* water oxidation have not been reported.

We describe here an investigation of acetate oxidation at a TiO_2-disk Pt-ring rotating ring-disk electrode (RRDE). In this research, products generated by photo-oxidation at the n-TiO_2 disk are swept to the Pt ring where they are detected. Relative values of the disk current (i_D) and the ring current (i_R) are then employed to obtain information on reaction rates. Previous photoelectrochemical studies employing the RRDE have proven very useful in elucidating reaction paths, relative reaction rates, and semiconductor stability (2, 9-13). In work closely related to that reported here, a TiO_2 disk RRDE was employed to study photo-oxidation of halide ions and reducing agents (2, 9).

Experimental

Chemicals.—Sodium sulfate, sodium acetate, glacial acetic acid (Fisher Scientific Company), and sodium iodide (Mallinckrodt Chemical Works) were of reagent grade. Triply distilled water was used as a solvent.

Apparatus and procedure.—A Tascussel Electronique Bipotentiostat, Model Bipad 2, was used for all experiments. A Wavetek function generator provided a d-c potential ramp for voltammetric experiments recorded on a Mosley Model 7005A X-Y recorder.

The construction of the RRDE generally followed that described by Fujishima *et al.* (9). The TiO_2 disk electrode was a single crystal, which was prepared by cutting a 1 mm thick slice, 5.5 mm in diameter, from a large single crystal (Fuji Titanium, Japan). This piece was reduced at 750°C under hydrogen for 30 min. The TiO_2 disk and Pt ring electrodes were mounted in a Teflon rod. On the back side of the TiO_2 disk an ohmic contact was made with Ga-In alloy to which a Cu-wire was attached with conducting silver epoxy. The Cu-wire was connected to a brass shaft. The platinum ring electrode had an inner radius (r_2) of 3 mm and an outer radius (r_3) of 6.25 mm. The collection efficiency for this electrode, N_o, defined as $-i_R/i_D$ for a stable system, was calculated to be 0.648 from the geometry (14). The measured value of N_o, determined by reduction of ferricyanide at the TiO_2 in the dark and oxidation of the resulting ferrocyanide at the Pt ring, was 0.65. The electrode was rotated with a Motomatic Model E-550 motor and controller (Electrocraft Corporation, Hopkins, Minnesota). Electrical contact to the shaft was made using two sets of silver graphite brush and leaf assemblies.

A saturated calomel electrode (SCE) was used as a reference and platinum foil served as the counterelectrode. The electrochemical cell had a 4 cm diameter and was 4.5 cm high; a glass basket inside prevented vortex formation at high rotation rates (15). The TiO_2 disk was irradiated through the cell bottom by the focused beam of a 400W xenon lamp. In all experiments, the solution was purged with nitrogen gas for more than 30 min before measurements.

Results

Acetate-free solutions.—The irradiation of the TiO_2 disk electrode immersed in 0.2M Na_2SO_4 solutions produces an anodic disk current and a flux of O_2 and some H_2O_2 to the ring electrode (Fig. 1, curve A) (1, 2, 16). The products are reduced at the ring electrode (Fig. 2, curve A). The ring current, attributed to oxygen (and H_2O_2) reduction, was very dependent upon solution purity. It is well known, see, *e.g.*, Ref. (17), that oxygen reduction at a platinum electrode depends critically on the nature of the electrode surface and the presence of adsorbed impurities. To obtain reproducible ring currents for oxygen reduction, the ring electrode was cycled repeatedly between potentials for hydrogen and oxygen evolution just before the measurement of i_R (17, 18). With this procedure the value of i_R at -0.2V *vs.* SCE divided by the disk photocurrent resulted in a collection efficiency of 0.63

which is quite close to the theoretical and experimental N_o-value (0.65).

Acetate-containing solutions.—The effect of addition of equimolar mixtures of sodium acetate and acetic acid to the 0.2M Na_2SO_4 solution (pH = 4.7) on the disk photocurrent at TiO_2 and the Pt ring current is shown in Fig. 1 and 2. The potential for the onset of the anodic photocurrent at TiO_2 shifts towards more negative values with the addition of acetate (Fig. 1, curves B-D), as found in a previous study (5). The limiting anodic disk current was unchanged by addition of acetate or rotation rate, demonstrating that this current was governed by the rate of generation of holes by light absorption and their flux to the electrode surface. The ring current was reduced by the addition of acetate (Fig. 2, curves B-C). The shape of the i_R-E_R curves was unchanged however by the addition of acetate and no new waves appeared. This demonstrates that the effect of acetate is to compete with water oxidation. Addition of acetate to an oxygen-saturated solution does not affect the limiting current for oxygen reduction at a platinum electrode, so that this decrease cannot be ascribed to this source. No product from the oxidation of acetate at the disk can be detected at the ring. This is in line with expectations, since the acetoxy radical produced by the initial oxidation step decomposes very rapidly to $CH_3\cdot$ and CO_2. The methyl radicals rapidly react to form ethane and neither this species nor CO_2 is reducible at these potentials. Thus the ring current in acetate-containing solutions can only be ascribed to the reduction of products from the oxidation of water that competes with acetate for the photogenerated holes at the TiO_2 disk surface. We might note that the reduction of oxygen occurs on an n-TiO_2 electrode at potentials positive to the flatband potential (5, 18-20). In all of our studies of the collection efficiency, however, the disk potential was fixed at 1.0V *vs.* SCE, which is so positive that no oxygen reduction can occur.

The dependency of the oxygen collection efficiency, N_{O_2} [defined as $-i_R$ (E_R = $-0.2V$)/i_D(E_D = 1.0V) under illumination] upon total acetate concentration is shown in Fig. 3. No effect of electrode rotation rate was found with the concentrations of acetate shown in this figure. At very low concentrations of acetate (less than 1 mM) some effect of electrode angular velocity, ω, was observed however. As shown in Fig. 4, with 0.25 mM acetate the decrease in N_{O_2} was greater at larger ω, showing that at these concentra-

tions the rate of mass transfer of acetate to the disk governs its rate of oxidation.

Iodide solutions.—In the presence of I^-, oxidation of this species competes with water oxidation at the irradiated TiO_2 disk (2, 3). Because concentrations of I^- as low as $10^{-7}M$ suppress the oxygen reduction reaction on platinum, the addition of only small amounts of I^- decrease N_{O_2} to negligible values. To determine the competition between the water and I^--oxidation processes in this case, the ring current due to iodine reduction was determined (Fig. 5) and from this the iodine collection efficiency, N_{I_2} [defined as $-i_R'(E_R = -0.2V)/i_D(E_D = 1.0V)$ in the presence of I^-], was calculated. The variation of N_{I_2}, for solutions in the absence and presence of acetate, as a function of the concentration of sodium iodide is shown in Fig. 6. No effect of ω on N_{I_2} was observed for these concentrations of iodide ion.

Discussion

The reactions which give rise to the different disk and ring currents can be summarized as follows

Disk:

$$\left.\begin{array}{l} 2\,OH^- + 2h^+ \xrightarrow{k_w} \tfrac{1}{2}\,O_2 + H_2O \\ 2\,OH^- + 2h^+ \rightarrow H_2O_2 \end{array}\right\} (i_D)_w$$

$$2I^- + 2h^+ \xrightarrow{k_I} I_2 \quad (i_D)_I$$

$$CH_3CO_2^- + h^+ \xrightarrow{k_{Ac}} CO_2 + CH_3\cdot \rightarrow \tfrac{1}{2}C_2H_6 \quad (i_D)_{Ac}$$

Ring:

$$\left.\begin{array}{l} \tfrac{1}{2}\,O_2 + H_2O + 2e \rightarrow 2\,OH^- \\ H_2O_2 + 2e \rightarrow 2\,OH^- \end{array}\right\} (i_R) \quad \begin{array}{r} [2] \\ [3] \end{array}$$

$$I_2 + 2e \rightarrow 2I^- \quad (i_R') \qquad [4]$$

no reaction [5]

Under conditions where mass transfer rates to the disk surface are unimportant, we assume that the rate of consumption of a given species at the electrode surface is a first-order process (just as most electrochemical reactions) with relative rate constants of k_w, k_I, and k_{Ac} for water, iodide, and acetate, respectively. Under these conditions the total disk current, i_D, can be represented as

$$i_D = (i_D)_w + (i_D)_I + (i_D)_{Ac} \qquad [6]$$

$$i_D = k_w[OH^-] + k_I[I^-] + k_{Ac}[Ac^-] \qquad [7]$$

For solutions of acetate (in the absence of iodide) the ring current for oxygen reduction is

$$-i_R = N_o(i_D)_w = N_o k_w[OH^-] \qquad [8]$$

and the collection efficiency is

$$N_{O_2} = \frac{-i_R}{i_D} = \frac{N_o k_w[OH^-]}{k_w[OH^-] + k_{Ac}[Ac^-]} \qquad [9]$$

This equation can be rearranged to the form

$$(N_o/N_{O_2}) - 1 = (k_{Ac}/k_w[OH^-])[Ac^-] \qquad [10]$$

A plot of $N_o/N_{O_2} - 1$ *vs.* $[Ac^-]$ should be linear with zero intercept and slope $k_{Ac}/k_w[OH^-]$. Such a plot is shown in Fig. 7. From the slope of the line and the solution *pH* (4.7) a value of $k_{Ac}/k_w = 2.0 \times 10^{-8}$ is obtained.

A similar treatment for iodide solutions (in the absence of acetate) yields

$$N_{I_2}/N_o = k_I[I^-]/(k_w[OH^-] + k_I[I^-]) \qquad [11]$$

so that the slope of a plot of $(N_o/N_{I_2}) - 1$ *vs.* the reciprocal of the iodide concentration should yield k_w/k_I. Such a plot at pH = 5.8 (shown in Fig. 8, curve A) yields $k_w/k_I = 8.8 \times 10^5$. The current efficiency for iodide oxidation at illuminated TiO_2 has previously been studied and for a 0.01M iodide solution has been estimated as 60% (3) and 70% (2). From the value of k_w/k_I found here, a current efficiency of 65% is predicted, which is in good agreement with the previous values.

For solutions containing both iodide and acetate, the following equation holds

$$\frac{N_{I_2}}{N_o} = \frac{k_I[I^-]}{k_w[OH^-] + k_I[I^-] + k_{Ac}[Ac^-]} \qquad [12]$$

In this case a plot of $(N_o/N_{I_2}) - 1$ *vs.* $[I^-]^{-1}$ at a constant acetate concentration has a zero intercept and a slope of $(k_w/k_I)[OH^-] + (k_{Ac}/k_I)[Ac^-]$. Such a plot is shown in Fig. 8, curve B, for a 0.5M total acetate solution at pH = 4.7. The experimental slope combined with the value of k_w/k_I determined above yields $k_{Ac}/k_w = 4.5 \times 10^{-8}$ which is in reasonable agreement

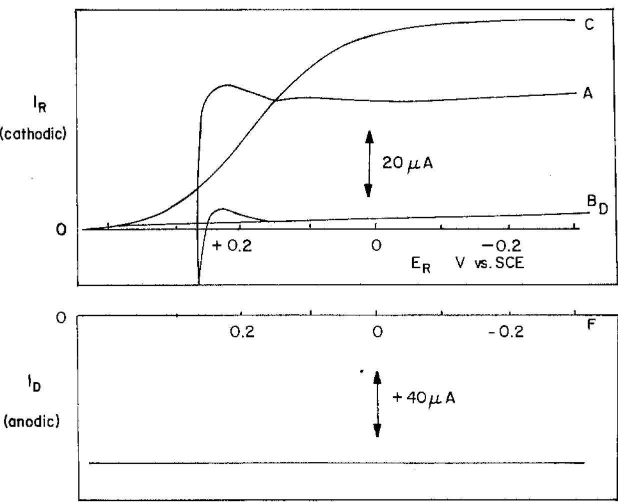

Fig. 5. Current-potential curves for Pt-ring electrode with illuminated n-TiO_2 disk electrode. (Curve A) 0.01M NaI under illumination; (curve B) 0.01M NaI in the dark; (curve C) no NaI under illumination; (curve D) no NaI in the dark; (curve E) 0.01M NaI disk current under illumination; (curve F) 0.01M NaI disk current in the dark. with the value found from Fig. 7. The relatively good agreement of the experimental results with the theoretical equations suggests that there is no direct interaction of the oxidation processes, *i.e.*, that k_w, k_{Ac}, and k_I are independent of the concentrations of acetate and iodide in the solution.

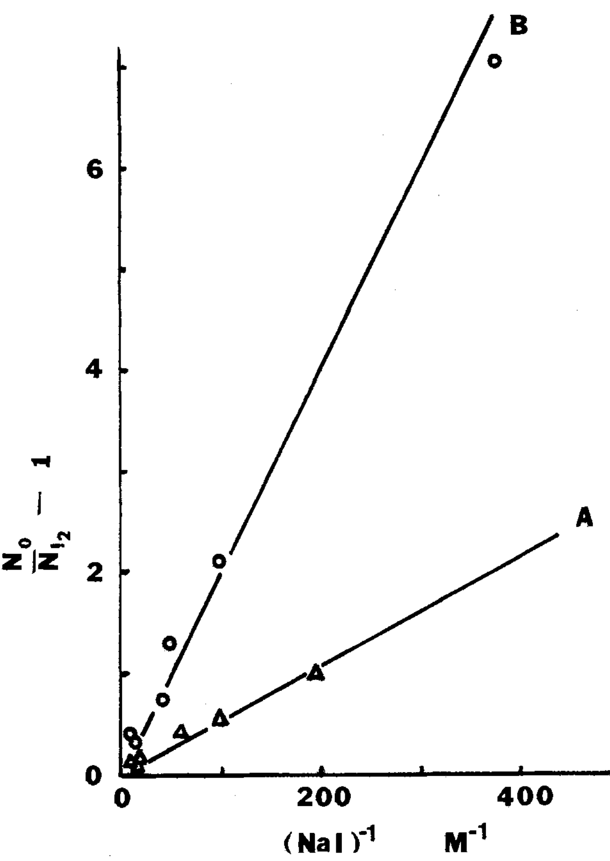

Fig. 8. Reciprocal plot of N_{I_2} and iodide concentration. (Curve A) no acetate; (curve B) 0.5M acetate.

The results above demonstrate the utility of the RRDE technique in determining competitive reaction rates at an illuminated semiconductor, even when, as in the case of acetate above, the product generated is not electroactive at the ring electrode. The method is clearly easier for surveying possible reactions at semiconductors than long-term bulk electrolysis methods, and should also prove useful in the design of heterogeneous photocatalysts (6, 7).

Acknowledgment

The rotating ring-disk electrode was constructed by Dr. G. H. Brilmyer whose assistance is greatly appreciated. We are indebted to Drs. Rolf Hulnhagen, Fu-Ren F. Fan, and Ikuichiro Izumi for their helpful suggestions during the course of this research. The support of this research by the National Science Foundation is gratefully acknowledged.

Influence of Nickel Oxide Transformation Reaction on Oxygen Evolution Kinetics as Ascertained by Temperature Effects

C. R. Davidson*,[1] and S. Srinivasan*

Brookhaven National Laboratory, Department of Energy and Environment, Upton, New York 11973

ABSTRACT

The O_2 evolution reaction and nickel oxide transformation reactions were investigated on Ni electrodes in 50 w/o KOH as a function of temperature using steady-state and cyclic voltammetric techniques, respectively. A change in the valence state of the oxide occurs in the region of oxygen evolution at temperatures above 150°C. The previously reported change in Tafel slope at elevated temperatures is explained on the basis of the role played by the transformation of surface oxides, and its effect on the kinetics of the OER.

The oxygen evolution reaction (OER) was investigated recently on nickel electrodes in 50 weight percent (w/o) KOH as a function of temperature (1). A change in the Tafel slope from 3 $RT/2F$ at temperatures below 208°C to $RT/4F$ at temperatures above this value was reported. The main purpose of the present work was to determine the influence of oxide transformation reactions on the change in Tafel slope and hence on the mechanism of the OER.

The existence of correlations between the activity of heterogeneous catalysts and their magnetic properties has been well documented (2-6). In addition, it has been speculated that magnetic properties influence electrocatalysis as well (7-10). The Neel temperature (antiferromagnetic to paramagnetic transition) of nickel oxide (NiO) is 247°C and the reported change in Tafel slope lends support to the concept of magnetic influences in electrocatalysis. However, as for oxygen evolution on anodized nickel, further experimental evidence now suggests an alternate explanation for the change in mechanism at elevated temperatures. For there to exist a magnetic transformation of the type mentioned on anodized Ni, the surface oxide formed would necessarily be dehydrated NiO with a cubic structure. This condition is considered to be highly unlikely (11). Cyclic voltammetric studies on Ni electrodes have been carried out by a number of workers (12, 13). Although there are some disagreements and ambiguities, it is generally believed that in alkaline solutions, nickel is first oxidized to the hydroxide, $Ni(OH)_2$, and subsequently to the oxyhydroxide, NiOOH; the exact stoichiometry varies around those given, and neither exhibits magnetic transformations.

In the present work, steady-state current-potential measurements were made for the oxygen evolution reaction on nickel from 50% KOH as a function of temperature. In addition, cyclic voltammograms were recorded with the aim of obtaining information on surface oxides in the oxygen evolution potential region.

Experimental

For this study, a stainless steel pressure vessel described in a previous paper (1) was utilized. A Teflon cell containing separate reference and auxiliary electrode compartments was introduced into this pressure vessel. A stainless steel clad Chromel-Alumel thermocouple, sheathed in platinum, was inserted into the electrolyte. The reference electrode was a precalibrated dynamic hydrogen electrode, connected to a 1 mA/cm² power supply. A large cylindrical piece of Ni 200 (99.5% Ni, 0.15% Fe, 0.06% C, 0.05% Cu, 0.25% Mn, nominal) screen was used as the auxiliary electrode. The electrolyte was prepared from Baker analyzed KOH with doubly distilled water and preelectrolyzed for 10-15 hr using Ni screen electrodes. The test electrode was a Ni 200 wire (d = 0.35 cm) of 0.2 cm² total area. The vessel and cell were heated with asbestos wrapped resistance wires; a magnetic stirrer was used to reduce thermal gradients in the cell.

Current density-potential relations were obtained using a steady-potential step technique with a PAR 173 potentiostat. The electrodes were preanodized for a few minutes to ensure an equilibrium coverage of oxide on the surface. The measurements were made from high to low potentials while monitoring the current on a strip chart recorder during the establishment of steady-state conditions. Ohmic losses between the Luggin capillary tip and the test electrode were experimentally measured using the interrupter technique with an Adlake relay and Tektronix 7623A oscilloscope. Ohmic potentials were plotted *vs.* current density to confirm the expected linear relation. Cyclic voltammograms were obtained at the same temperatures as the steady-state measurements, using a PAR 175 voltage programmer in conjunction with the potentiostat. The results were recorded on an HP 7044A X-Y recorder. These experiments are described in greater detail in the following section. In addition, anodic polarization studies on the test electrode were carried out by scanning from the open-circuit potential to potentials well within the oxygen evolution region at a sweep rate of 1 mV/sec.

Results and Discussion

The temperature dependence of the potential, at which the mechanism of oxygen evolution changes, emphasizes the role of oxide films on the kinetics of this reaction. Each experiment at the various temperatures was repeated at least three times to confirm reproducibility. The cyclic voltammogram for Ni at 47°C, shown in Fig. 1, is in agreement with those of other investigators (12-14). The peak before O_2 evolution is believed to correspond to Ni^{2+}/Ni^{3+} oxidation. However, there is evidence in the literature which suggests that this peak represents oxidation to the 4+ state. It is interesting to note that the overpotential for the oxygen evolution reaction at room temperature is high enough that the higher oxide formation peak remains well below the onset of evolution. Both the overpotential and oxide formation potential are temperature dependent. One would expect, however, the oxygen overpotential to have a

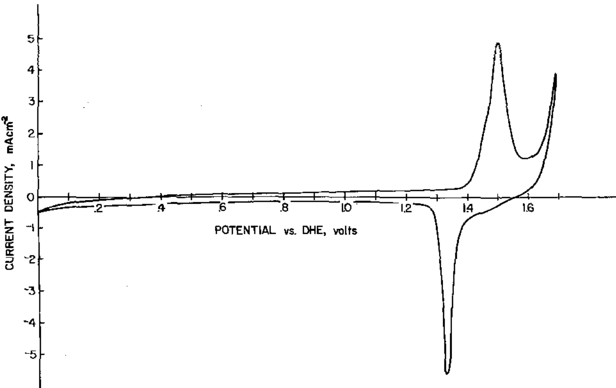

Fig. 1. Cyclic voltammogram for Ni in 50 w/o KOH at 47°C. Sweep rate 50 mV sec^{-1}.

more significant temperature dependency. This is, in fact, observed experimentally. Figure 2 shows a portion of the cyclic voltammogram obtained at 127°C. It is clear that the large oxygen evolution current obscures the higher oxide formation peak. At still higher temperatures, the higher oxide formation peak is totally masked by oxygen evolution, as exemplified in Fig. 3 for a temperature of 183°C. The corresponding reduction peak for this process is not affected by oxygen evolution and this finding can aid in determining the approximate higher oxide formation potential in this region. Cyclic voltammograms were carried out at 50 mV/sec, first sweeping in the anodic direction and then back to the initial potential. If the potential at which the sweep is reversed is not anodic enough for the higher oxide to form, there was no corresponding reduction peak on the cathodic sweep. Upon stepping up the potential of sweep reversal continuously more anodic, a cathodic reduction peak was eventually observed. Since this could only occur if the higher oxide is present, the potential at which this oxide forms can be approximately determined, even though the oxidation peak is completely masked by the oxygen evolution current (Fig. 4). The potentials at which the higher oxide forms were determined in this manner and are shown as a function of temperature in Fig. 5.[2] The line in Fig. 5 represents the least squares fit of these points (coefficient of determination, $r = 0.9580$). The steady-state Tafel plots at selected temperatures are shown in Fig. 6. Below approximately 150°C, only one Tafel region is observed. The transfer coefficient at high overpotentials is again 0.67, while at low overpotentials the transfer coefficient increases with increasing temperature from approximately 1.5 at 150°C to 3.0-4.0 at 275°C. In addition, there is more scatter in the steady-state points in this low overpotential region, even to the extent that in some experiments a true Tafel region could not clearly be defined. It is extremely important to note the potentials at which the Tafel slopes change in the steady-state curves above 150°C.[3] This break potential is plotted *vs.* temperature in Fig. 7. In the same figure, the line corresponding to the higher oxide formation potential is also shown. From this figure, one may conclude that the potential at which a break in the Tafel line occurs when making the measure-

[2] All potentials are with respect to the dynamic hydrogen electrode except those at room temperature, which have been corrected for the overpotential on the DHE. Above 150°C this correction is approximately constant at 30-40 mV (14).

[3] This break potential is defined as being that potential at which the extrapolation of the two Tafel lines intersect.

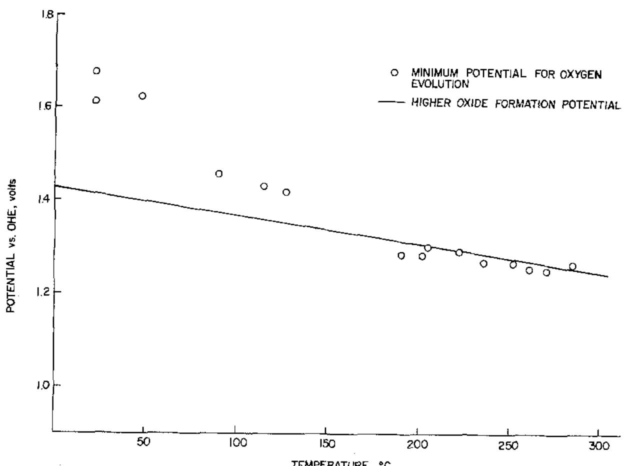

Fig. 9. Higher oxide formation potential, "visible". O_2 evolution potential, and O_2 equilibrium potential vs. temperature.

ments from high to low current density in the steady-state measurements coincides with the potential of the higher oxide formation. To illustrate the importance of this potential, the dependence of current densities on potentials, using the slow sweep technique, were conducted at elevated temperatures to determine the potential required for "visible" oxygen evolution as seen in Fig. 8. These potentials were determined and are shown in Fig. 9. "Visible" oxygen evolution does not apparently occur until the higher oxide is present on the surface. This is direct evidence supporting the arguments made by Tseung (15) concerning the necessity of forming the appropriate oxide for good oxygen evolution electrocatalysts. Evidently the higher oxide is the catalytically active oxide for this reaction.[4] At the lower temperature (*i.e.*, below 150°C), the oxygen overpotential is high enough that oxygen evolution does not occur at significant rates until this higher oxide is formed. As the temperature increases, the overpotenital for this reaction decreases significantly and a two-section Tafel plot is observed, corresponding to oxygen evolution on the partially reduced and higher oxides.

Because "visible" oxygen evolution takes place only on the higher oxide surface as seen from the slow potential scans (Fig. 5), one may suggest a correlation between the higher oxide formation potential and the break in the Tafel line. At high overpotentials, the higher oxide is present and the Tafel lines correspond to a transfer coefficient of 0.67 for the oxygen evolution reaction. Cathodic to the higher oxide formation potential, there is a continuously growing ratio of lower to higher oxide on the surface.[5] It is believed that this may interfere with the surface diffusion or desorption reactions. Transfer coefficients approaching 4.0 are calculated from the Tafel lines at higher temperatures.

Conclusions

The higher oxide formation potential for nickel has been determined as a function of temperature up to 275°C. It has been shown that at elevated temperatures (*i.e.*, >150°C), the kinetics of the oxygen evolution reaction are fast enough that changes in reaction mechanism are observed at this potential. The consequences of reduction of the higher oxide manifests itself as a break in the Tafel slope indicating a recombination or desorption rate-determining step below this critical potential.

An interesting feature of the prerequisite of the higher oxide for the oxygen evolution reaction is a minimum in the overpotential for oxygen evolution *vs.* temperature curve (Fig. 10). Again, Fig. 9 shows the higher oxide formation line, the potential for "visible" oxygen evolution, and the equilibrium potential (16) for the oxygen reaction. The equilibrium potential has a larger temperature dependence than the higher oxide formation potential. Because oxygen is visibly evolved only at this higher potential, a minimum in the oxygen evolution overpotential *vs.*

[4] It should be stated that it is the highest oxide stable with respect to oxygen evolution (as seen from Pourbaix diagrams) which is required.

[5] One may argue that the higher is reduced at potentials more cathodic to the oxidation potential. The present case is not one of bulk reduction, but of a slow increase in the number of lower oxide atoms on the surface between the oxidation and reduction peaks.

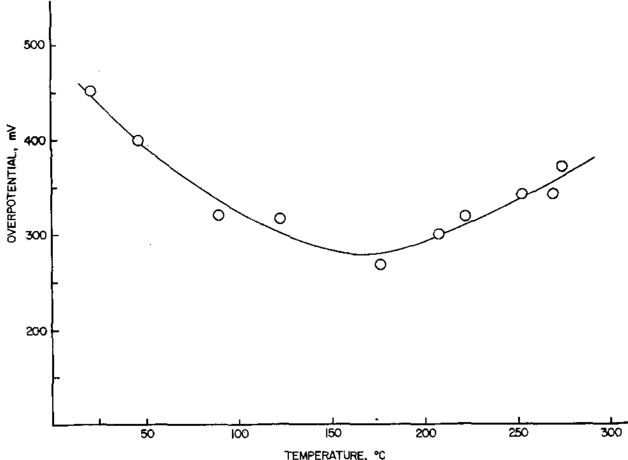

Fig. 10. "Visible" O_2 evolution overpotential on Ni *vs.* temperature

temperature curve results (Fig. 10). It should be realized that although there is a minimum in the overpotential *vs.* temperature plot for "visible" evolution, the potential for oxygen evolution continuously decreases with increasing temperature, although at a much slower rate after the temperature of the minimum than before. This information can be utilized to screen potential oxygen electrocatalyst materials. Oxygen evolution will be catalyzed on the appropriate conducting oxide stable with respect to oxygen. In addition if the temperature dependence of the oxide formation is known (either calculated from existing thermodynamic data or experimentally determined), the overpotential for oxygen evolution can be determined at any temperature. This can then be used to elucidate the activity at elevated temperatures of various electrocatalysts and associated mechanism changes with minimum high temperature experimentation.

The Zn-KOH System: Fragmentation of Dendritic Zinc Clusters on Electrode Cycling

S. Szpak* and C. J. Gabriel

Naval Ocean Systems Center, Electronic Material Sciences Division, San Diego, California 92152

and T. Katan*

Lockheed Palo Alto Research Laboratory, Materials and Structures, Palo Alto, California 94304

ABSTRACT

An *in situ* examination of dendritic clusters in Zn-KOH electrode analogs reveals that fragmentation frequently occurs during cycling. Fragments on the order of 10^{-3} cm or less are formed and are propelled through the bulk electrolyte. Initially the fragments move as though their surfaces are positively charged, but shortly after fragmentation the movement is in accord with a negatively charged surface. Fragments that are larger than ca. 10^{-3} cm are found to exhibit motion principally by displacement, generated by dissolution at one end and deposition at the other. Conditions for fragmentation during cycling are discussed and the relevance is given to zinc electrode operation.

The deleterious effects of the formation of dendrites during the operation of rechargeable systems, particularly those involving zinc electrodes, are well documented. Growing dendrites not only cause internal short circuits but they also contribute to the loss of cell capacity and to the deterioration of cell

Key words: particles, electrode, transport.

performance. The formation of dendritic clusters has been studied rather extensively. Evidently, their growth is controlled by mass transport (1-4) while the initiation of growth may take place by several modes (5-10).

A somewhat different aspect of dendritic behavior, encountered in alkaline zinc batteries, is the subject of the present study, namely, the fragmentation of dendritic structures and their subsequent behavior during the course of electrode cycling. The phenomenon of fragmentation considered here is similar to that described by Vermilyea (11) in studies of the dissolution of whiskers and identical with that described by Wranglen in comments on the behavior of "living crystals," which were first observed at the beginning of this century (12).

The purpose of this communication is to describe the behavior of dendritic clusters during discharge of a zinc electrode analog. In particular, we consider fragmentation of dendritic structures and behavior of the fragments in an electric field associated with the passage of current.

Experimental

The electrolytic cell and associated electronic and optical equipment are shown in Fig. 1 in the form of a block diagram. The electrolytic cell is of the ultrathin type to minimize the development of convective flow usually initiated because of the evolution of hydrogen and localized at dendritic tips. The dimensions of the electrolytic cells, together with the details of their construction and assembly, are displayed in the insert. The working electrodes were made of 99.999% polycrystalline zinc sheet and mounted in plastic holders. Experimental cells were operated in the galvanostatic mode with an electrolyte of saturated zincate in 10M aqueous KOH solution.

The *in situ* examination of the fragmentation of dendritic structures was carried out with the aid of a Zeiss metallurgical microscope equipped with a Nomarski interference objective and a TV camera for monitoring and recording the progress. The post test details of the dendritic structures were viewed with a scanning electron microscope.

The behavior of the metallic zinc fragments that were intentionally placed in an impressed electric field was examined visually. Single crystals of zinc, about 300 μm in size, were placed in a glass capillary tube, 650 μm in diameter, containing the specified electrolyte. Morphological manifestations were examined with a Bausch and Lomb Sterozoom 7 microscope during the passage of a 2.5 mA current through the cell.

Results

An examination of the behavior of dendritic clusters revealed the occurrence of three distinctly different phenomena, aside from the straightforward anodic dissolution: first, a fracturing of dendritic clusters from a parent dendritic stem during the passage of anodic current, yielding fragments of various sizes; second, a motion of the smaller fragments, on the order of 10 μm or less in size, following separation from the parent stem; and, third, over a somewhat longer time, a motion of displacement through bipolar activities of larger fragments.

In particular, Fig. 2a shows the situation immediately after fracturing of a dendritic cluster from its parent stem. A typical trajectory observed for fragments of approximately 5 μm in size, as they are propelled through the electrolyte, is indicated in Fig. 2b. Such a curvilinear trajectory cannot be attributed to a convective flow because no gas evolution occurred during the passage of the anodic current, and any gas bubbles that were generated during the period of dendritic growth remained stationary and retained their shape. Trajectories of fragments were obtained by tracing their motion recorded on video tape. Typically, the velocities were on the order of 5-10 μm sec^{-1}.

The isolated zinc fragments that were placed in capillary cells and subjected to the passage of an electric current of 2.5 mA developed dendrites at their cathodic ends and underwent dissolution at their anodic ends, as indicated in Fig. 3. Initially, however, passive films with particulate residues were formed at the anodic ends. After the passage of current for approximately 20 min, the dendritic mass of clusters forming at the cathodic end of a fragment had grown to fill the transverse cross section of the cell. Subsequently, the dendritic mass appeared to be moving along the capillary tube with a velocity on the order of 0.1 μm sec^{-1}. The motion was clearly by displace-

ment due to dissolution at one end and deposition at the other.

Discussion

The physical motion of the small particles and the apparent motion by electrochemical displacement of the large ones may, in fact, represent two divergent examples of the balance of the electric and hydrodynamic forces acting on isolated zinc particles immersed in an electrolyte. Indeed, the experiments indicate that small fragments are set into motion in a curved path by dominating electrical forces while the viscous forces acting on large fragments limit their velocity thus accentuating the motion by displacement.

To account for these phenomena, we will develop the discussion as follows. First, we will consider the distribution of the current density within the electrolytic cell and within the porous structure of dendritic clusters. We will be primarily interested in clarifying the conditions that lead to anomalous transfer C.D. profiles that may account for fracturing. Following this, we will discuss the motion of small fragments and the bipolar activities of larger particles in the context of the theory of electrophoretic motion (13-15), especially as the theory applies to a corroding system (16). Finally, we will show the relevance of these phenomena to battery technology.

Fragmentation within dendritic clusters.—The *in situ* observation and the post test examination of the growth of dendritic clusters can be summarized as follows. The dendritic clusters originate at the electrode rim and extend into the bulk electrolyte in the form of three dimensional growths. This extension, shown in Fig. 4a, can be viewed as equivalent to a porous structure and as such can be represented by an equivalent electric circuit; a typical one is shown in Fig. 4b. A typical scanning electron microscope (SEM) photograph of a small fraction of the dendritic cluster is shown in Fig. 4c. Evidently, the stems of the dendritic cluster may have various geometrical forms of which two have been selected to illustrate the process of fracturing: those with nonuniform cross section, as indicated in Fig. 4c by arrow A, and those with cross sections being almost uniform, as indicated by arrow B.

The fragmentation of dendritic clusters during the anodic part of the cycle is easy to visualize. When the dendritic stem is of nonuniform cross section, the constricted regions will dissolve first even if the transfer C.D. is relatively uniform throughout. When the dendritic stem is of uniform cross section, an anomalous distribution of the transfer C.D. is required. Such distributions may arise, *e.g.*, because of the formation of localized resistive oxides, shifting the dissolution to areas of lower reaction impedance to generate undercutting and separation. Fragmentation of dendritic structures during their growth is less straightforward, since it requires the reversal of the transfer current within a part of the growing structure.

While the equivalent circuit shown in Fig. 4b provides a convenient visualization of the reaction profile, a more phenomenological description can be obtained from the two-phase model of porous electrodes. The mathematical formulation of this model, when resistivities in both phases may be comparable and complications arising from mass transport may be excluded, is based on (*a*) the application of Ohm's law

$$\nabla u_n + \rho_n i_n = 0 \quad (n = s, m) \qquad [1]$$

(*b*) the conservation of charge

$$\nabla \cdot i_s - j = 0, \quad \nabla \cdot i_m + j = 0 \qquad [2]$$

together with (*c*), the linearized transfer C.D.-overpotential relation

$$Zj + V_{rest} = u_m - u_s \qquad [3]$$

where u is a potential, i is a current density, j is the transfer C.D., ρ is a resistivity, and Z is the reaction impedance. Subscripts s and m denote the solution and metallic phases, respectively.

Within regions of constant parameters, Eq. [1]-[3] can be reduced in number by casting them in the more familiar second-order form (see Appendix)

$$\nabla^2 j - \kappa^2 j = 0 \qquad [4]$$

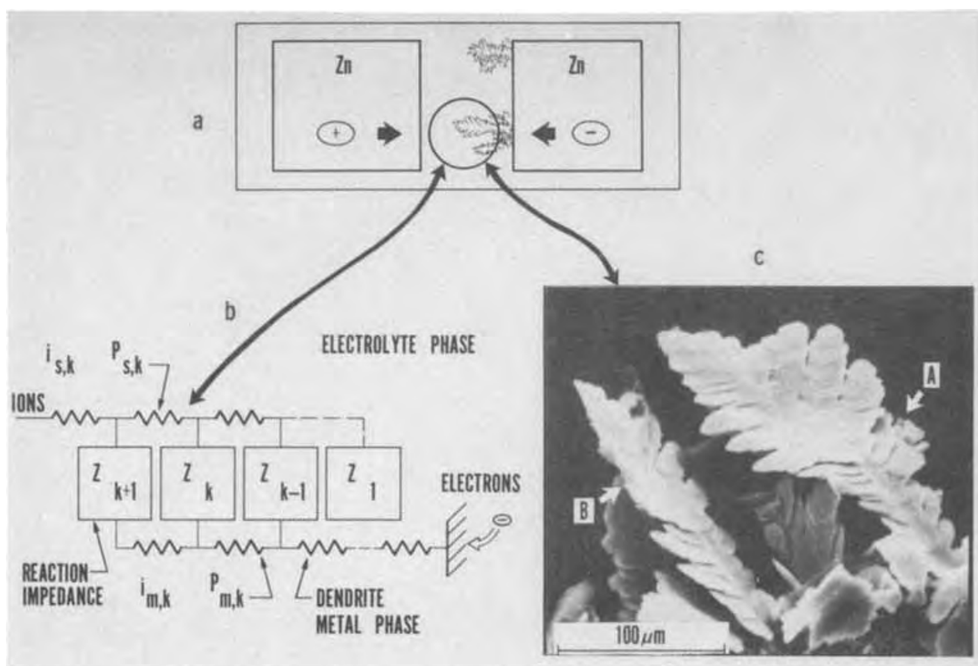

Fig. 4. Dendritic clusters in experimental analog; (a) top view of the cell showing the location of three dimensional clusters; (b) equivalent electric circuit; (c) SEM photograph of representative dendritic forms.

$$\Delta^2\phi = 0 \quad [5]$$

where $\kappa^2 = \rho_s + \rho_m/Z$ and

$$u_s = \phi - \frac{\rho_s}{\kappa^2} j \quad [6]$$

$$u_m = \phi + \frac{\rho_m}{\kappa^2} j + V_{rest} \quad [7]$$

The nonuniformity of cross section of the parent stems, the distribution of localized coverage with resistive oxides, or the variation in electrolyte concentration can be viewed as producing a number of regions characterized by the parameters $\rho_{n,k}$, Z_k, and $V_{rest,k}$, with n = s, m and k = 1, 2, 3 . . . . For simplicity of computation and illustration, we will consider variation of parameters in only one direction.

Examples of computed, one-dimensional transfer C.D. profiles are shown in Fig. 5 and 6. These profiles were generated for dendritic clusters of unit thickness divided into five segments. The length of each segment is arbitrary but the parameters characterizing the

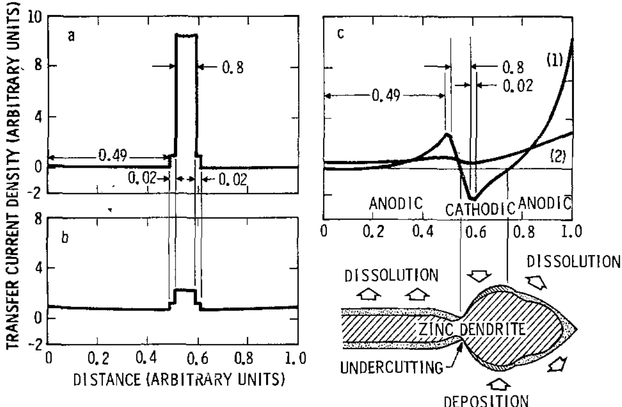

Fig. 5. Calculated anodic transfer C.D. profiles for $J = 1$: a, the effect of changing Z: $\rho_m = \rho_s = 1$, and $V_{rest} = -1$ for all segments, $Z_1 = 10$, $Z_2 = 1$, $Z_3 = 0.1$, $Z_4 = 1$, and $Z_5 = 10$; b, the effect of changing V_{rest}: $\rho_m = \rho_s = Z = 1$ for all segments, $V_{rest,1} = -0.5$, $V_{rest,2} = -1$, $V_{rest,3} = -2$, $V_{rest,4} = -1$, and $V_{rest,5} = -0.5$; c, the effect of changing resistivities; $V_{rest} = -1$ for all segments of all curves. Curve 1, $\rho_{s,1} = 10$, $\rho_{s,2} = 1$, $\rho_{s,3} = 0.1$, $\rho_{s,4} = 1$, and $\rho_{s,5} = 10$; $\rho_{m,1} = 0.1$, $\rho_{m,2} = 1$, $\rho_{m,3} = 10$, $\rho_{m,4} = 1$, and $\rho_{m,5} = 0.1$; $Z = 0.1$ for all segments. Curve 2, same parameters as curve 1, except that $Z = 1$ for all segments.

behavior within each segment were selected to indicate the changing conditions along the dendritic stem/electrolyte interphase. Numerical values that were assigned to these parameters were chosen to exaggerate the desired effect for purposes of illustration.

Transfer C.D. profiles leading to the fragmentation of clusters during the anodic part of the cycle are shown in Fig. 5a-5c. In particular, Fig. 5a illustrates the effect of blocking of the second kind (17), accomplished through changes in the reaction impedance, Z_k. Physically, such a situation should occur at high dissolution rates in zincate-saturated solutions. Figure 5b illustrates the effect of changes in concentration, which are expressed through changes in the value of V_{rest}, on the transfer C.D. profile. Finally, Fig. 5c represents the effect of precipitation in the electrolyte phase as well as the nonuniformity of cross section of the metallic phase, *i.e.*, the combined effect of the blocking of the first kind and morphology of the dendritic growth. This example suggests that in the course of dissolution, we might find segments where the transfer current is reversed. Such reversal is attributed to local variation in resistivities in both phases and is strongly modified by the degree of polarization. Consequently, a smoothing effect of additives, *e.g.*, surfactants, on the fragmentation is anticipated.

Conditions leading to fragmentation of dendritic clusters during their growth period are less obvious, because no insoluble species are generated in the electrolyte phase and no nonconductive material is deposited on the electrode surface during a cathodic period. In the absence of such mechanical factors as vibration or shock, the reversal of the transfer current is the only condition associated with fragmentation. As demonstrated in Fig. 6, the anomalous transfer C.D. profiles arise when a proper ratio of resistivities within the growing cluster is realized, especially when combined with low reaction impedance. These conditions are expected to be fulfilled frequently in the Zn-KOH system because of low overpotentials for the electrodeposition and a particular morphology of growing clusters, consisting of numerous branching and nonuniformity in the cross section of individual stems.

Motion of dendritic fragments.—The motion of particles in the electrolyte arises from the interaction of the interphase region with either phase. The disperse phase may be set in motion by a temperature gradient, by a concentration gradient, or by any number of factors affecting the energetics of the interphase. In electrochemical systems, there is the interaction of the diffuse part of the electric double layer with an externally impressed electric field and their relation to the ensuing hydrodynamic motion.

Upon immersion of a solid particle in an electrolyte, an interphase region of a complex structure is established. A satisfactory theory of electrophoretic motion can be developed using a simple model, that of a capacitor with electrically charged planes, capable of motion relative to each other. The essential features of this simple model are shown in Fig. 7. A charged plane, S_2, is substituted for the diffuse part of the electric double layer. This plane is located outside of the Helmholtz outer layer, *i.e.*, within the region of allowed hydrodynamic activity. The ensuing hydrodynamic flow arising from the interaction between the charge Q^+ and the electric field, E, in the direction parallel to plane S_1 is measured across the plane S_3 placed perpendicular to the direction of flow. The velocity and the direction of flow are proportional to the magnitude and the sign of the excess charge accumulated on the electrode surface, respectively. This simple picture of the interphase region, however, is of doubtful validity when applied to concentrated electrolytes, where the diffuse part of the electric double layer is compressed (15, 18).

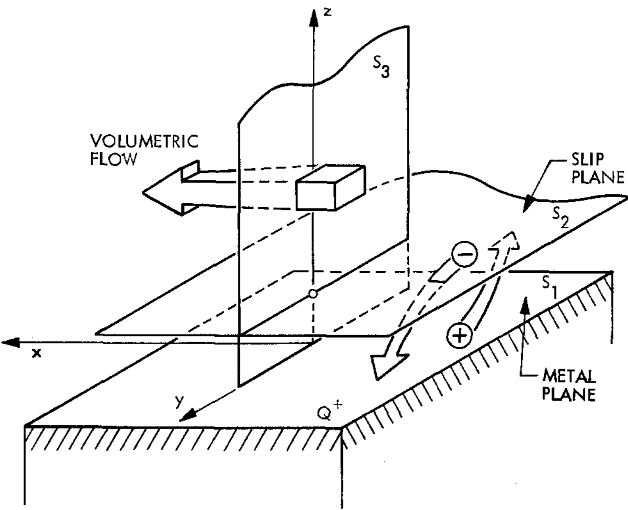

Fig. 7. Capacitor representation of electrophoretic motion: S_1, metal surface; S_2, slip plane parallel to S_1; S_3, reference plane for flow measurements. The volume flow and charge transfer are indicated by arrows.

Prior to fragmentation, the dendritic particle is thermodynamically unstable with respect to the electrolyte phase. This instability is forced by the impressed anodic overpotential which, in turn, results in the establishment of concentration profiles of relevant ionic species in the immediate neighborhood of the dissolving dendrite. At the moment of separation, the instability due to the impressed overpotential is removed and replaced by a thermdynamic driving force leading to the attainment of a steady state.

Qualitatively, the approach to the rest potential following the separation of the fragment can be conveniently studied with the aid of a Pourbaix diagram, part of which is reproduced in Fig. 8. Starting at point A, located within the domain of stability of water, the decaying potential crosses the hydrogen reversible potential, point B, the point of zero charge potential, point C, and slowly approaches its rest potential at E. The rest potential of corroding zinc is very close to the reversible potential (19), as indicated by the dashed line.

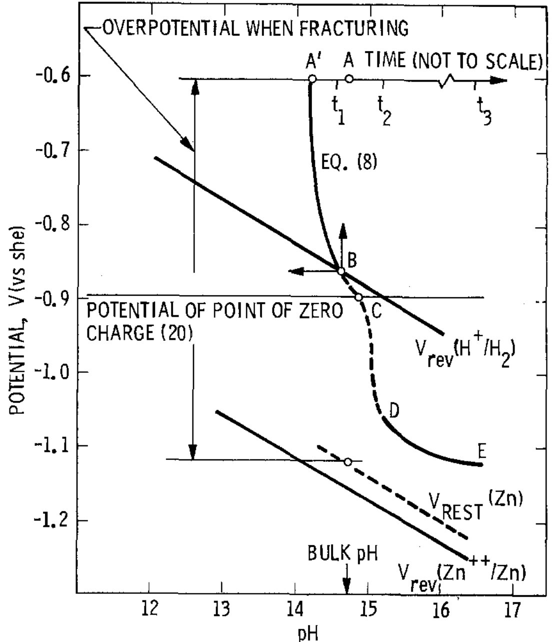

Fig. 8. Schematic representation of the approach to the corrosion potential of fragmented zinc particles.

The potential decay within the first time interval, curve AB, and the approach to the steady state, curve DE, can be treated analytically. Thus, the potential decay within the first time interval, $0 < t < t_1$, can be obtained from the expression of charge conservation

$$i_m = \Sigma_k j_k + d(CV)/dt \qquad (k = 1, 2 \ldots) \qquad [8]$$

where j_k is the participating reaction current density and C and V are the capacitance and potential, respectively, of the electric double layer.

Equation [8] represents the electrode response to perturbations in current or potential. This equation must be substantially modified when it is applied to a fragmented dendrite. First, we set $i_m = 0$ to indicate a complete separation. Additional simplifications may arise from considerations involving the magnitudes of respective j_k. Thus, immediately after separation, within the time interval $0 < t < t_1$, we assume that only the Zn^{2+} ions participate in the potential-determining events and that no other processes affecting the capacitance of the electric double layer, *e.g.*, adsorption or desorption, are involved. Choosing for C the value 100 μF cm^{-2} and assuming the exponential form of the $j(V)$ relation with $j_o = 0.3$ A cm^{-2} (8), $b = 50$ mV/decade, and $V(0) = 0.6$V (an arbitrarily selected value within the stability domain of water), on integration of Eq. [8], we conclude that the initial period of potential decay is completed within milliseconds, *i.e.*, this relaxation would not affect the observation of the particulate motion.

Another time interval, $t_2 < t < t_3$, for which the $V(t)$ curve yields to analytical treatment is the final approach to its steady-state value, from D to E, Fig. 8. The dominating elementary processes within this period is the increase in surface converage by the ZnO film that results from the reaction between the Zn^{2+} ions and OH^- ions. This final approach usually occurs over an extended period of time (20).

Of interest to the present investigation is the period $t_1 < t < t_2$, during which the decaying potential moves away from the hydrogen reversible potential, crosses the potential of point of zero charge, V_{pzc}, located at -0.8 to -0.9V (*vs.* SHE) (19), and approaches the rest potential and during which the curvilinear path, shown in Fig. 2, was observed. As the decaying potential crosses the point of zero charge, the character of the excess charge on the surface also changes, thus accounting for the change in the direction of particle motion, as required by the theory of electrophoretic phenomenon.

The theory of electrophoretic motion is usually developed for insulating or ideally polarized particles. Here, however, a different situation arises: the zinc particle is unstable with respect to the electrolyte. The ideally polarized particle is replaced by a corroding one, *i.e.* a system of local cells on the particle surface, as a result of which electrical charges are being transferred across its double layer, as indicated by arrows in Fig. 7. Under these conditions, a correction term must be included in the expression for the particle velocity, which effectively slows down the motion compared to insulating particles carrying the same excess charge (16).

The velocity of the corroding zinc particle is governed by dissipation due to viscous forces and interfacial charge transfer. As the size of the particle increases, both effects contribute more, and the particle slows down to the point that no motion is observed. Instead, because of the low overpotentials for both cathodic and anodic reactions, a metallic particle placed in an electric field suffers dissolution at one end and deposition at the other, cf. Fig. 3.

This type of behavior can be demonstrated by intentionally placing a zinc particle of considerable size, *e g.*, 300 μm, in a capillary-type cell. The small cell dimensions dampen the development of convective flow,

and the geometrical form of uniform cross section assures a uniform primary current distribution except in the immediate vicinity of the metallic particle. Using this cell design, we created conditions such that the motion by displacement could be demonstrated. The observed velocities were on the order of 0.1 μm sec^{-1}, and depended on the current flow and the capillary diameter. Further discussion of this observation and its relevance to battery technology will be given in a companion paper.

Relevance to battery technology.—One approach to the rational design of battery electrodes is via electrode modeling. It is generally agreed that the concepts and mathematics of the modeling of porous electrodes are well understood and formulated with a sufficient degree of completeness. The application to real systems, however, has not kept pace with the theoretical advances. The principal weakness involving the modeling of the zinc electrode pertains to the transport coefficients associated with the various growth forms when a new phase appears as a result of an electrochemical process. At present, there is little information concerning the rate at which the various elementary processes occur, *i.e.*, on the numerical inputs that govern the computed transfer C.D. profiles. This is probably the reason why there is substantial disagreement between the predicted (21, 22) and observed (23, 24) performances of the Zn-KOH system.

Here, we have elaborated on one aspect not included in modeling, that of the motion and reactivity of metallic zinc particles in an electrolyte during the passage of current. The disengagement of zinc particles from cycled zinc electrodes has, indeed, been observed (24, 25). However, the fact that these particles may experience motion and, moreover, a change in shape has never been included in the source of modeling. The electrophoretic and displacement velocities were found to be of such magnitude that, from the size of the zinc particles, it appears that the dimensions of pores in real electrodes can be breached in just a few cycles.

Particles found in the main body of the electrolyte should affect the primary current distribution, and their effect would magnify with each cycle, causing progressively severe nonuniformities. The migration of these isolated zinc fragments with systematic cycling could contribute to the commonly observed overall change in the zinc electrode's shape. Indeed, a recent postmortem examination conducted on a 10 A-hr silver/zinc cell after 157 cycles, revealed the presence of isolated zinc fragments, *ca.* 10^{-2} cm in size, at numerous locations removed from the zinc electrode, *i.e.*, on the nylon cloth and reprocessed cellophane separator material (26). Although the effects of these fragments could not be determined, their presence lends credence to the importance of the phenomena causing fragment migration in practical battery systems.

Fragmentation of the electrode structure can reduce the cell capacity if the fragments become electrically isolated, and then capacity can be restored only after the dissolution of the fragments and subsequent deposition onto the conductive matrix. In addition, the isolated metallic particles trapped within the electrode pores are likely to affect the current flow in the electrolyte phase, thus producing additional anomalies in the transfer C.D. profile.

The examination of conditions leading to fracturing, especially during the cathodic cycle, suggests the use of additives designed to cause an increase in polarization. Such an increase in polarization would reduce the occurrence of transfer current reversal thus minimizing fragmentation of dendritic clusters.

Conclusions

1. Fragmentation may occur during either the anodic or cathodic part of the cycles. Fracturing during the anodic part of the cycle may result from either an anomalous distribution of the transfer C.D. or from nonuniform cross section of metallic stems. Fracturing during the cathodic part requires a reversal of transfer current.

2. Small fragments, on the order of 10^{-3} cm across in our experiments, exhibit what appears to be an electrophoretic motion with an average velocity of 5-10 μm sec^{-1}. Large particles, longer than *ca.* 10^{-3} cm, placed in an electric field move by displacement with a velocity on the order of 0.1 μm $sec.^{-1}$.

3, The presence and migration of particles in the bulk electrolyte may affect the distribution of the primary current, thus contributing to the electrode shape change with systematic cycling.

4. The addition of surface active agents designed to increase the polarization of the $Zn/Zn^{(2+)}$ reaction may increase the cycle life of the zinc electrode.

APPENDIX

For constant $\rho_{n,k}$ (n = s, m; k = 1, 2, 3 . . .) and Z_k the reduction of Eq. [1]-[3] is as follows. Taking the gradient of Eq. [3] and using Eq. [1] we have

$$Z\nabla j = -\rho_m i_m + \rho_s i_s \quad \text{[A-1]}$$

Taking the divergence of Eq. [A-1] and using Eq. [2] to eliminate i_m and i_s, we obtain Eq. [4].

The divergence of Eq. [1] yields

$$\nabla^2 u_s + \rho_s j = 0 \quad \text{[A-2]}$$

Here, Eq. [2] has been used to eliminate i_m. Taking the gradient of Eq. [A-2] followed by the divergence, we have

$$\nabla^4 u_s - \kappa^2 \nabla^2 u_s = 0 \quad \text{[A-3]}$$

where Eq. [4] and [A-2] have been used to eliminate j. Now, since Eq. [A-3] can be rewritten as either

$$\nabla^2(\nabla^2 u_s - \kappa^2 u_s) = 0 \quad \text{[A-4]}$$

or

$$(\nabla^2 - \kappa^2)\nabla^2 u_s = 0 \quad \text{[A-5]}$$

it follows that there are solutions to Eq. [A-3] of the form

$$u_s = \phi + \psi \quad \text{[A-6]}$$

where

$$\nabla^2 \phi = 0 \quad \text{[A-7]}$$

and

$$\nabla^2 \psi - \kappa^2 \psi = 0 \quad \text{[A-8]}$$

Substituting Eq. [A-6] into Eq. [A-2] and making use of Eq. [A-7] to eliminate ϕ and Eq. [A-8] to evaluate $\nabla^2\psi$, we obtain

$$\psi = -\frac{\rho_s}{\kappa^2} j \quad \text{[A-9]}$$

Thus, Eq. [A-6] becomes Eq. [6], which then combined with Eq. [3], yields Eq. [7].

For the one dimensional case considered here, the solutions to Eq. [4] and Eq. [5] for the kth segment, respectively, of the forms

$$j = A_k e^{\kappa x} + B_k e^{-\kappa x} \quad \text{[A-10]}$$

and

$$\phi = C_k x + D_k \quad \text{[A-11]}$$

At the current collector and at the electrode/solution interface, the current densities are known, this permits the boundary conditions on the current at the collector to be expressed as

$$\frac{dj}{dx} = -\frac{\rho_m}{Z} J \quad [A-12]$$

$$\frac{d\phi}{dx} = -\frac{\rho_s \rho_m}{\rho_s + \rho_m} J \quad [A-13]$$

and at the electrolyte interface as

$$\frac{dj}{dx} = \frac{\rho_s}{Z} J \quad [A-14]$$

$$\frac{d\phi}{dx} = -\frac{\rho_s \rho_m}{\rho_s + \rho_m} J \quad [A-15]$$

where J is total cell current density.

At each intersection of segments of constant parameters $i_s + i_m$, i_s, u_s, and $u_m - u_s$ must be continuous. This provides enough linear equations to find j as a function of J and the other parameters.

The Electrochemical Formation of Au(I) Hydroxide on Gold in Aqueous Potassium Hydroxide

D. W. Kirk,* F. R. Foulkes,* and W. F. Graydon

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Canada M5S 1A4

ABSTRACT

The behavior of gold in aqueous potassium hydroxide was studied using potentiodynamic methods. Three peaks found at potentials more negative than the gold (III) oxide formation region were identified as adsorption reactions. These reactions were shown to depend on the hydroxyl ion in solution. The following reaction was proposed

$$Au + OH^- \rightarrow AuOH_{ads} + e^-$$

Each of the peaks was found to correspond to the formation of only a monolayer of adsorbed species, with each peak being restricted to a particular type of surface site. By means of the work function values and the ease of oxidation of the three most common crystal planes, the peaks at −1.2 to −0.7V *vs.* SCE, −0.7 to −0.3V *vs.* SCE, and −0.3 to +0.3V *vs.* SCE were identified with monolayer hydroxide adsorption on the (110), (100), and (111) crystal faces, respectively.

The gold oxidation process has been the subject of considerable study in the literature, principally for acid media (1-21). Although there are fewer works for alkaline media (22-29), it has been shown that anodization at less than 0.1 A · cm^{-2} does not build up visible oxide films on gold (21, 30-33). The oxide layer has been shown to grow in thickness in the region of oxygen evolution and different oxide structures are reported to form (14, 34).

Although these works provide clear evidence of the formation of the gold (III) oxide at potentials anodic of its theoretical potential ($E°$), the formation of lower valent oxides or hydroxides at less anodic potentials is usually disputed. Hoare has postulated that the formation of AuO might account for the value of the rest potential of gold in acidic solutions (35, 36). The increase of the double layer capacity of gold electrodes when oxygen is introduced into the solution was used as support for this proposal (37). Ellipsometric measurements in alkaline solutions by Sirohi and Genshaw (29) indicated that adsorption of an undeter-

* Electrochemical Society Active Member.

Key words: anode, adsorption, kinetics, gold.

mined nature occurs on gold over a wide potential region (−0.8 to +0.2V[1]) cathodic of the gold (III) oxide region. Difficulty with the interpretation of differential capacitance measurements by Carr and Hampson (38) also led to the suggestion of adsorption phenomena in the region −0.6 to +0.6V. The nature of this adsorption was not made clear.

The lack of reaction of an electrode with electrolyte is a desirable feature for the study of organic reactions, and gold is often recommended as an electrode material because of its wide potential region which is reportedly free of reactions. It is therefore important to determine whether the adsorption phenomena were artifacts of the measurement techniques or represented interactions between gold and the electrolyte. Therefore linear sweep voltammetry (a technique suitable for the detection of electrochemical reactions) was used to study the interactions between gold and aqueous alkaline hydroxide solutions at potentials cathodic of the Au(III) oxide formation.

Experimental

The electrochemical measurements were carried out in a typical electrochemical cell. The details of the cell and electronic equipment may be found in Ref. (39). For fast potential scan measurements a Tektronix storage oscilloscope (Model 5113) was used to record the data. Polycrystalline gold (>99.99% purity) wire (0.0254 cm diam) was used as the working electrode in potential scan measurements because cylindrical geometry is not subject to edge effects, and the positioning of the reference electrode to reduce *IR* drop is not as critical as for the case of planar electrodes. The Luggin capillary was drawn to a 0.1 mm diam (OD) capillary at the tip and was located approximately 0.2 mm from the working electrode. Calculations showed that, under the worst condition ($100\ V \cdot sec^{-1}$), the maximum *IR* drop would be only 1.8 mV. Details of the calculation method may be found in Ref. (40-42).

The solutions, prepared from analytical grade reagent and doubly distilled water, were deoxygenated by bubbling with oxygen-free nitrogen during the experiments. The alkaline solutions were also treated with a preelectrolysis step before being used. This additional precaution was taken because of the sensitivity of the fast linear scan technique to trace impurities. The preelectrolysis was conducted for a minimum of 4 hr using two gold foil electrodes with the potential at one of the electrodes set at −1.8V and a cell potential of 2.61V. Measurements were recorded photographically from the oscilloscope screen and the data taken from the developed prints.

Gold dissolution rates were determined from weight losses and electrode surface areas. The weight loss measurements were accurate to within ±20 μg. The surface area of the electrode was determined from potential scan measurements, using the linear relationship between the current peak height and the square root of the voltage scan rate for the oxidation of $Fe(CN)_6^{-4}$. The relationship given by Nicholson and Shain (43) is

$$\frac{i_p}{nFAC_o\left(D_o\dfrac{nFv}{RT}\right)^{1/2}} = 0.4463$$

where C_o is the concentration of $Fe(CN)_6^{-4}$ ($mole \cdot cm^{-3}$), D_o is the diffusion coefficient of $Fe(CN)_6^{-4}$ ($cm^2 \cdot sec^{-1}$), i_p is the peak current (A), A is the area of the electrode (cm^2), n is the number of electrons transferred in the oxidation, v is the scan rate ($V \cdot sec^{-1}$), and **F**, R, and T have their usual meanings.

A standard pretreatment of the electrode was necessary to achieve reproducibility. The electrode was first heated to redness in air, then etched in hot aqua regia for 5 sec, washed in doubly distilled water, dried, and weighed (in the dissolution measurements). It was immediately given a further treatment consisting of a 5 min reduction period in the electrolyte at −1.2V. This latter procedure was found to improve the reproducibility of the weight loss and potentiodynamic measurements but did not affect the measured weight of the electrode.

[1] All potentials are reported *vs.* a saturated calomel electrode.

Results and Discussion

A typical slow scan potential sweep in 0.01M potassium hydroxide is shown in Fig. 1. Although similar profiles have appeared in the literature for acid media (44) and alkaline media (28, 45) it is useful to review some of the features for an alkaline medium. The slow scan profile has been divided into four regions which correspond to the following main processes (neglecting double layer charging)

region 1: hydrogen evolution ($H_2O + e^- \rightarrow OH^- + \frac{1}{2} H_2$)

region 2: surface oxide reduction

region 3: surface oxide formation

region 4: oxygen evolution ($2\ OH^- \rightarrow H_2O + 2e^- + \frac{1}{2} O_2$) and oxide buildup

From Fig. 1 it can be seen that region 1 is characteristic of a faradaic reaction, that of hydrogen evolution without adsorption. Indeed, unlike other precious metals such as Pt, In, and Pd, gold is known not to display any tendency to adsorb hydrogen (10, 46). The anodic portion of region 2 appears to display only the double layer charging current, but it is shown later that several important reactions take place in this region which are not visible at slow potential sweep rates. The separation observed in Fig. 1 between the oxide formation (region 3) and reduction (region 2) is characteristic of an irreversible surface reaction. Recently it has been shown (44, 47-49) that the oxidation of gold in acid media involves the formation of a surface film which, although initially reversible, undergoes a rearrangement to form an irreversible surface species. In alkaline solutions the oxidation in region 3 has been shown to be complex (34) with the oxide structure dependent on the extent and duration of potential sweep. Figure 2 shows potential scans at much faster sweep rates. It can be seen that there are three peaks cathodic of the the formation of the gold (III) oxide (peak D). These peaks have been designated as peaks A, B, and C. It can be seen that the peaks are easily observed only at higher sweep rates ($>1\ V \cdot sec^{-1}$) which would account for the fact that their existence has not been reported before. At slower sweep rates ($<1\ V \cdot sec^{-1}$), the peaks are difficult to separate from the double layer charging current. Indeed, even at the sweep rate of $10\ V \cdot sec^{-1}$, the complete separation of the peak current and the double layer charging current can only be estimated. (The method of estimation is given later.)

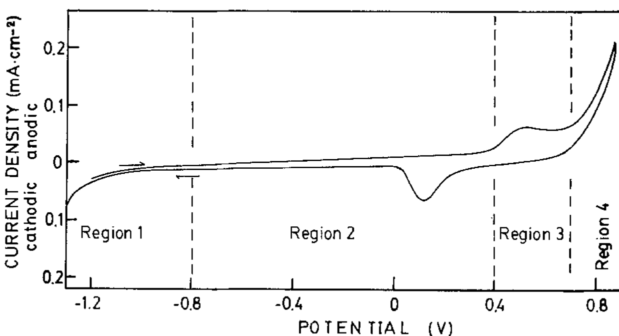

Fig. 1. Potential sweep profile in 0.01M potassium hydroxide electrolyte; sweep rate = 10 mV · sec⁻¹; temperature = 23.0°C. All potentials vs. SCE.

The area under the potential sweep curves may be used to estimate the extent of oxidation of the surface atoms, assuming there is no significant dissolution or ion discharge at the potential in question. Oxygen evolution will not be important cathodic of region 4 (see Fig. 1); however, the anodic dissolution of gold must be considered.

The dissolution rate of gold in highly alkaline solutions has not been reported in the literature and the experimental determination was therefore necessary. The results of the dissolution measurements shown in Table I reveal that no measurable dissolution could be found at potentials less than +0.7V even though the potentials were applied for periods up to 29 hr. Therefore, current which flows in the peak regions cannot result from a dissolution process. Since the three peaks A, B, and C are found at potentials less than +0.7V, the area under the potential sweep curve could be used to calculate the charge on the surface atoms.

Determination of the charge per surface atom for most metals involves comparison of the charge passed in the anodic region and the total charge required for discharge of a monolayer of adsorbed hydrogen. However, because gold does not display any hydrogen adsorption, this method could not be used and it was necessary to measure the surface area of the electrode and estimate the number of gold atoms per unit surface area. The geometric area does not indicate the real area available for a surface reaction; hence the area determination was carried out using an electrochemical method suggested by Nicholson and Shain (43). The electrochemical method gives a better indication of the real surface area because the reaction depends to some extent on the number of active sites.

The nature of the surface structure can also affect the gold (III) oxidation behavior (50-53). For this work the electrodes were assumed to be polycrystalline. Reflection electron diffraction pictures of the electrode after cleaning did not indicate any preferred orientation. In addition, the shape and position of the gold (III) oxidation peak in Fig. 1 is similar to that found for a polycrystalline gold surface by Dickertmann, Schultze, and Vetter (15), who showed that different crystal orientations have unique potential sweep profiles. It was assumed, therefore, that the number of atoms on the surface could be calculated from an average atomic density of the three most prominant crystal faces, (111), (100), and (110), (see Table II). Similar values have been reported in the literature (4).

In order to use the area under the potential sweep profile as an estimate of the extent of reaction, the amount of current corresponding to the double layer charging also must be determined. In a study of reflectance changes on Au and Pt electrodes in acid media, Conway, Angerstein-Kozlowska, and Laliberté (54) showed that double layer charging corrections should be made from the potential of zero charge (pzc) to the potential of monolayer oxide coverage. Changes in the charging current once a complete layer of oxide had been formed were shown to be small. The actual value of the reported pzc of polycrystalline gold in alkaline solutions may be questioned, since the work of Carr and Hampson (38) indicated that the double layer structure was complicated by oxide films or the adsorption of solution species. Their measurements indicated a value of approximately −0.50V in contrast to a value of approximate 0V reported by Gileadi (55), of −0.32V reported by Bode (56), or of −0.16V reported by Lin (57). Regardless of the value, starting the double layer correction from any of these potentials does not seem appropriate in view of the shape of the curves in Fig. 2.

Therefore, the double layer charging current was estimated graphically (see Fig. 2) by drawing a line from the $i = 0$ point to the minimum current between peaks A and B. The area under the line was used as the value of the double layer charging for peak A. From the minimum between peaks A and B, the line was extended through the minimum between peaks B and C and extended past peak C. Since the peak potentials of A, B, and C are well separated (>0.4V), it is unlikely that there is serious overlap of the peaks A, B, and C which would elevate the double layer charging current erroneously. There is, however, overlap between peaks C and D and therefore the measurements for peak C were made up to the peak maximum and then corrected to give the value for full surface coverage by assuming the surface coverage at the peak maximum to be 0.5 of full surface coverage. This type of correction has been shown to be valid for reversible reactions (58). The reversibility of peak C will be established later.

The magnitude of the charging correction depended on the sweep rate. For the data shown in Fig. 2 (10 $V \cdot sec^{-1}$) the corrections for the area under the curve in the peak A, B, and C regions were 9.0×10^{-6}C, 9.9×10^{-6}C, and 9.9×10^{-6}C, respectively.

It is clear that this estimation of the charging current represents the maximum value and thus may bias the value of the surface charge density. A smaller estimate of the double layer charging current would yield larger values of the surface charge density.

Table I. Weight loss measurements in 1.0M KOH electrolyte for potentials less than +0.7V at 23°C

Potential (V)	Time duration (hr)	Measured weight loss (g) (area of electrode = 1.8 cm²)	Dissolution rate** (g · cm⁻² · sec⁻¹)
−0.5	29	N.D.*	≤5 × 10⁻¹¹
−0.23	21.5	N.D.	≤7 × 10⁻¹¹
+0.58	16	N.D.	≤9 × 10⁻¹¹
+0.7	16	N.D.	≤9 × 10⁻¹¹
+1.2	34	3 × 10⁻⁶	8.2 × 10⁻⁹

* N.D. = not detected.
** Dissolution rate calculated from error limits in weighing procedure (±1 × 10⁻⁵g).

Table II. Charge density on individual crystal planes

Crystal plane	Atomic density (atoms · cm⁻²) (calculated)	Charge density* (C · cm⁻²)
(100)	1.2 × 10¹⁵	1.92 × 10⁻⁴
(110)	0.85 × 10¹⁵	1.36 × 10⁻⁴
(111)	1.39 × 10¹⁵	2.22 × 10⁻⁴

The average charge density based on equal proportions of (100), (110), and (111) crystal planes is 1.83 × 10⁻⁴* C · cm⁻².

* Based on 1 electron per gold surface atom.

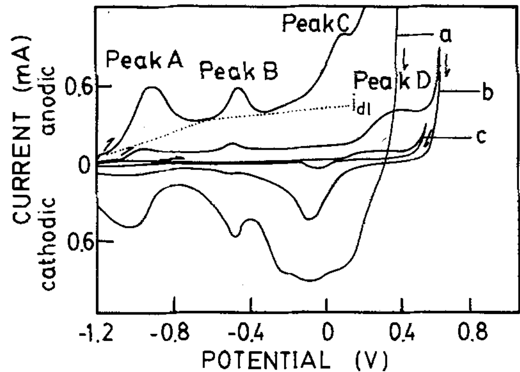

Fig. 2. Potential sweep profiles in 1.0M potassium hydroxide electrolyte at fast sweep rates: a, $v = 10\ V \cdot sec^{-1}$; b, $v = 1.0\ V \cdot sec^{-1}$; c, $v = 0.1\ V \cdot sec^{-1}$; area of electrode = 0.16 cm²; temperature = 23.4°C. All potentials vs. SCE.

Using the above graphical method to correct for the double layer charging contribution, the area under the peaks was measured using a planimeter and the data presented in Table III as the charge accumulated (mC) per surface area of the electrode. It is clear from the table that although the charge accumulated under each peak varies from run to run, the total charge accumulated for the three peaks approaches one electron per surface atom. This suggests that there is only a certain fraction of the surface which will accommodate each of the individual reactions A, B, and C. This view is supported by measurements taken from cyclic potential sweep experiments which are also shown in Table III. The reactions at peak A and peak B gradually disappear after many (>10) cycles, but the reaction at peak C does not. The charge accumulated for peak C in this case is approximately the same as if it had occurred with reactions A and B. Thus the reactions of peak A and peak B are not necessary for peak C to occur. Similarly it can be shown that peak B can be made to appear without peak A, if potential cycling is carried out in the region of peak A before the normal single sweep. It appears, therefore, that the three reactions are independent but restricted to a total accumulated charge of one electron per surface atom. Measurements in 0.1M KOH were found to have lower values for the total accumulated charge (~0.6 e^-/Au), but this was most likely the consequence of smaller peak currents and the greater difficulty in separating the peak currents from the double layer charging at the lower hydroxide concentration.

The effect of sweep rate on peak current for each of the peaks A, B, and C was studied over several orders of magnitude of sweep rate and the results are presented on a log-log plot in Fig. 3. There is good correlation ($r > 0.99$), indicating linearity for the data when plotted as peak current *vs.* sweep rate on rectilinear axes for each of the three peaks. The data do not follow the $i_p \propto v^{1/2}$ behavior observed for diffusion controlled oxidation-reduction reactions and thus the oxidation of electrolyte contaminants may be ruled out. Linearity of the i_p *vs.* v plot is typical for activation-controlled adsorption reactions (41). The adsorption of impurities may also be ruled out because of the concentration (0.02M) of the impurity that would be required to yield the currents observed at sweep rates of 10 V · sec^{-1}. A reaction between the gold and the electrolyte is therefore indicated.

The effect of sweep rate on the peak potential was also determined and the results are shown in Fig. 4. The potential for peak A shifts anodically at the rate of 0.053 V/decade of sweep. The constant shift of potential with sweep rate is characteristic of an irreversible reaction (58). The correlation coefficient was 0.95 and the slope was shown to be statistically significant. Peaks B and C do not shift significantly with sweep rate and are therefore characteristic of a reversible type of reaction (58). It is clear in Fig. 2 that peak B shows features of a reversible reaction with the cathodic peak almost identical in shape and position with the anodic peak. The cathodic peak A representing the reduction of peak A is different in shape from the anodic peak, and the peak potential is shifted cathodically from the anodic peak position. Thus the potential difference between the anodic and cathodic peaks also indicates irreversibility, while the nonsymmetrical shape of the cathodic curve indicates interaction among the surface species involved in the reduction reaction. The effect of interaction on the shape of peaks in simulated potential sweep experiments has been studied by Angerstein-Kozlawska, Klinger, and Conway (59) and indicated for this type of behavior a positive interaction parameter, g, for

peak A. Using the peak width at half the peak current (0.22V) the interaction parameter can be estimated from the theoretical plot of $\Delta V_{1/2}$ vs. g presented in Ref. (59). The value of $N \simeq 5$ found for peak A indicates that there is repulsion within the adsorbed layer. One can speculate that significant repulsion effects could arise in the peak A region on account of the electrode surface charge. The literature values for the potential of zero charge, referred to earlier, indicate that the gold surface may have a negative charge in the region of peak A. Such a charge would tend to repel adsorbing anions, which would have to overcome this surface repulsion effect before adsorption could take place. In addition, repulsion among adsorbed anions would be more significant when combined with the negative surface charge. In contrast, the surface bonding energy would be the dominant energy barrier to overcome in the desorption process. These factors could cause the irreversibility observed in the behavior of peak A.

Once the extent of reversibility of the reaction has been determined for peaks A, B, and C, the slope of the peak current *vs.* sweep rate can be used to estimate the fraction of the surface involved in each of the reactions for the run which generated the data.

Consider the adsorption reaction given below

$$M + A^- \underset{\overleftarrow{k}_1}{\overset{\overrightarrow{k}_1}{\rightleftarrows}} MA_{ads} + e^- \quad [1]$$

where M = the metal and A^- = the anion in solution. If the reaction is activation controlled with no mass transfer limitation and if the species A^- does not undergo any reactions other than by step [1] the following equation may be set up assuming Langmuir-type adsorption

$$i = \overrightarrow{i} - \overleftarrow{i}$$

$$= \overrightarrow{k}_1 \mathbf{F}(1-\theta)[A^-] \exp(\beta \mathbf{F} \Delta\phi/RT) - \overleftarrow{k}_1 \mathbf{F}\theta \exp[-(1-\beta)\mathbf{F}\Delta\phi/RT] \quad [2]$$

where $\mathbf{F}$ = Faraday constant, i = current, $\overrightarrow{i}, \overleftarrow{i}$ = partial currents, $\overrightarrow{k}_1, \overleftarrow{k}_1$ = electrochemical rate constants, R = gas constant, T = temperature, β = symmetry factor for anodic rate-determining step (=0.5), $\Delta\phi$ = electrode potential, and θ = fractional surface coverage of MA_{ads}. For the reversible adsorption case $\overleftarrow{i} = \overrightarrow{i}$, and for the irreversible adsorption case $i \simeq \overrightarrow{i}$.

Using the procedure outlined in Ref. (58), but including the concentration term $[A^-]$ the following relationships can be found

For the reversible case

$$\frac{i_p}{v} = 0.25 \frac{Q\mathbf{F}}{RT}$$

For the irreversible case

$$\frac{i_p}{v} = 0.368 \frac{Q\beta\mathbf{F}}{RT}$$

where i_p = peak current ($A \cdot cm^{-2}$), v = sweep rate ($V \cdot sec^{-1}$), and Q = charge associated with the formation of a monolayer of adsorbed species ($C \cdot cm^{-2}$).

Therefore, from the data in Fig. 3: for peak A, $Q = 8.26 \times 10^{-5}$ $C \cdot cm^{-2}$; for peak B, $Q = 4.36 \times 10^{-5}$ $C \cdot cm^{-2}$; for peak C, $Q = 8.23 \times 10^{-5}$ $C \cdot cm^{-2}$; total $= 2.09 \times 10^{-4} \pm 0.12 \times 10^{-4}$ $C \cdot cm^{-2}$ (95% confidence limits).

The value calculated earlier for a unit charge per surface atom based on an average of the atomic surface density of three crystal planes, (111), (100), and (110), was 1.84×10^{-4} $C \cdot cm^{-2}$. The agreement might be better than indicated if the three crystal structures were not present in equal amounts. The surface charge density, calculated from the data in Fig. 3 and shown above, and the determination of surface charge density from the measurement of total accumulated charge (Table III) both indicate that, after peak C, there is a net charge of approximately one electron per surface atom. No gold dissolution could be measured in this potential region and it is reasonable to conclude that there is an adsorbed surface layer with the gold atoms in the +1 state.

Furthermore, the potentials for the reactions at peaks A, B, and C were found to depend on pH, thus indicating a reaction involving the hydroxyl ion. Figure 5 shows the linear dependence of the potential for the reactions at peaks A, B, and C with the logarithm of the hydroxide concentration. The influence of the sweep rate on peak A was eliminated by plotting $(\Delta\phi p_{Anodic}{}^A + \Delta\phi p_{Cathodic}{}^A)/2$ (60). The potentials for peaks B and C were not affected by sweep rate for the range studied. The data indicate that the peak potentials for the reactions may be written as (*indicates based on 95% confidence limits)

$$\Delta\phi_p{}^A = -1.013(\pm 0.019) - 0.061(\pm 0.02) \log [OH^-] \quad {}^*r = 0.965 \quad [3]$$

$$\Delta\phi_p{}^B = -0.55(\pm 0.04) - 0.058(\pm 0.033) \log [OH^-] \quad {}^*r = 0.926 \quad [4]$$

$$\Delta\phi_p{}^C = +0.113(\pm 0.034) - 0.082(\pm 0.034) \log [OH^-] \quad {}^*r = 0.937 \quad [5]$$

Therefore, the following adsorption reaction is proposed to account for the three reactions of peaks A, B, and C

$$Au + OH^- \rightleftarrows AuOH_{ads} + e^- \quad [6]$$

That three peaks might arise from the adsorption of a

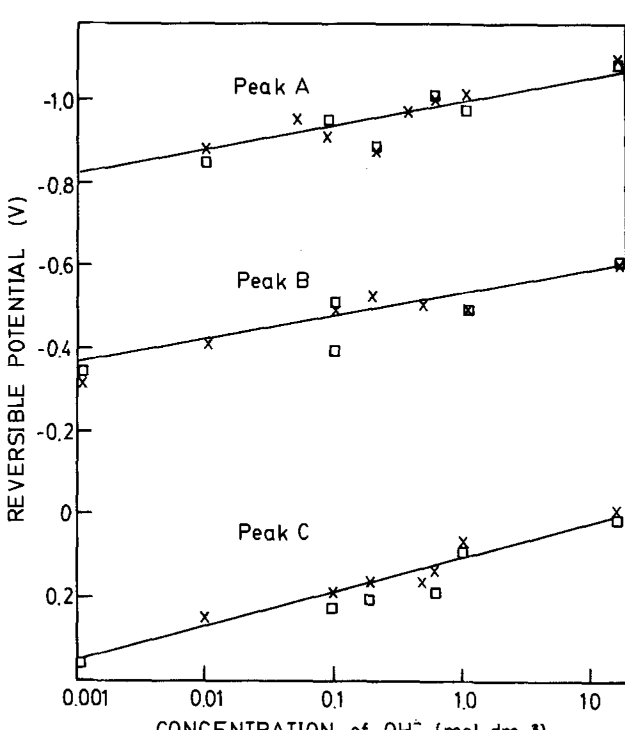

Fig. 5. Effect of hydroxide concentration on reversible potentials of peaks A, B, and C: □, 1.0 V · sec⁻¹; ×, 10 V · sec⁻¹; temperature = 23.0°C. All potentials vs. SCE.

single species is not unexpected in view of the known behavior of gold (III) oxide, for which the crystal structure has been shown to affect the potential of the Au_2O_3 formation (15, 50-53). On a (100) plane in acid media, Dickertmann, Schultze, and Vetter (15) found the oxidation peak to occur at +1.26V, while on the (111) plane, the oxidation peak occurred at +1.46V. Work on desorption of various adsorbed metal ions on gold single crystal substrates by Schultze and Dickertmann (61) has shown that the desorption peaks from different crystal surfaces may be separated by as much as 0.3V. The actual value for the peak separation was found to depend on the particular ion in question and was interpreted as being related to the work function difference between the gold and the solvated adsorbing ionic species. Although the work functions for the crystal planes (111), (100), and (110) of gold have been estimated to be 5.11, 5.01, and 4.80 eV, respectively, (62, 63), the contribution from the solvent and the hydroxide ion is unknown. The work on the formation of Au_2O_3 (15) indicated that the susceptibility of the crystal planes to oxidation followed the sequence (110) > (100) > (111); that is, the crystal plane with the smallest work function being oxidized first, and the crystal plane with the largest work function being oxidized last. This feature was also noted for the desorption of the metal ions of Bi and Pb from gold single crystals by Schultze and Dickertmann (61), although the ions of Sb, Cu, and Tl did not always show the same sequence. In addition, broadened desorption peaks were observed by them on the (110) crystal plane for Bi^{+3}, Pb^{+2}, and Sb^{+3}. This broadening of the peak was said to be the result of repulsion effects between the metal ions. In the present work, this effect was observed for peak A (Fig. 2), and therefore, as a result of this and the work function value, peak A can be associated with a reaction on the crystal face (110). Likewise, because of the theoretical values of the work function for the planes (100) and (111), the reactions at peak B and peak C are assumed to be related to the crystal planes (100) and (111), respectively.

The reason for the variation observed from run to run in Table III is now apparent. A change in the relative proportion of each crystal face would change the relative peak sizes, but the total charge accumulated would always approximate 1 e^-/Au atom.

Previously reported work (64-66) indicated that three peaks might arise in the adsorption of a single species on platinum electrodes as a result of preferred bonding sites. These preferred bonding sites were said to be unrelated to crystal structure but were a consequence of the proximity of neighboring adsorption sites. However, the peak separations resulting from this phenomenon were quite small (<0.1V) and therefore it is unlikely that the peaks A, B, and C found in the present work were caused as a result of the preferred bonding site phenomenon.

It is possible to correct the theoretical value for the unit charge per surface atom by using the relative proportions of each crystal face indicated from the data, rather than the arithmetic mean value used earlier. Thus, for the data in Fig. 3, the relative area for each peak was measured and is recorded in Table IV. The value calculated by this method is 1.91×10^{-4} $C \cdot cm^{-2}$ compared with 1.84×10^{-4} $C \cdot cm^{-2}$ for the mean value calculated assuming equal proportions of the (100), (110), and (111) planes for this case. Thus the correlation between the surface charge calculated from the i_p *vs.* v data in Fig. 3 (2.09×10^{-4} $C \cdot cm^{-2}$) and the surface charge calculated from the relative proportions of each crystal face in Table IV (1.91×10^{-4} $C \cdot cm^{-2}$) is improved. Therefore, if the crystal faces have been correctly assigned to the peaks, the correction applied to the data in Table III should yield a surface charge density which is closer to unity than the previous values. The values calculated are listed in Table V. The average charge per surface atom

Table IV. Unit surface charge density based on the identification of the peaks with distinct crystal planes

Peak	Crystal plane	% of total surface	Calculated unit charge density ($C \cdot cm^{-2}$)	Theoretical charge ($C \cdot cm^{-2}$) for 1 e^-/surface atom
A	(110)	0.291	1.36×10^{-4}	0.40×10^{-4}
B	(100)	0.215	1.92×10^{-4}	0.41×10^{-4}
C	(111)	0.494	2.22×10^{-4}	1.10×10^{-4}
Total charge for 1 e^-/surface atom = 1.91×10^{-4} $C \cdot cm^{-2}$.				

Measurements are for a sweep rate of 1 $V \cdot sec^{-1}$, in 1.0M KOH.

cathodic of peak D is $0.98e^-$ for the measurements in 1.0M KOH.

From Table V it is clear that the value of 1 e^-/surface atom is more closely predicted when the relative proportions of each crystal plane are considered. Thus the identification of peaks A, B, and C, with the crystal planes (110), (100), and (111) is further supported.

The data presented here have demonstrated that adsorption reactions do occur on gold electrodes in alkaline solutions at potentials cathodic of the formation of gold (III) oxide. These adsorption reactions are related to the hydroxyl ion via reaction [6] and are apparently limited to monolayer formation on each crystal plane.

Summary

The oxidation process of gold in alkaline solutions has been studied in detail. The potential regions in which the major electrochemical reactions occur for a gold electrode in alkaline solutions were identified in Fig. 1. No gold dissolution in 1.0M KOH was found cathodic of +0.7V *vs.* SCE [the region of the gold (III) oxidation peak].

At potentials less anodic than the oxidation peak (regions 1 and 2 in Fig. 1), the fast scan potential measurements reveal the presence of three distinct peaks. These peaks could not easily be identified at sweep rates less than 1 $V \cdot sec^{-1}$, which would account for the fact that they have not been reported in the literature. The magnitude of the peaks at sweep rates of 10 and 100 $V \cdot sec^{-1}$ precluded the possibility that the peaks were the result of impurity oxidation. Since the peak current-sweep rate data (Fig. 3) indicated activation rather than diffusion control for each peak, the parameter i_p/v was used to predict the number of coulombs required to achieve complete surface coverage by the species at peaks A, B, and C. The reaction at each peak was found to occupy only a fraction of the available number of surface sites, but the combined fractions approached the value for monolayer coverage of a univalent species. The fraction of surface occupied by each reaction varied from run to run, but the com-

Data from Table III using corrected unit theoretical charge for each crystal plane.

bined total was always ≈1 e^-/surface atom (Table III).

The potentials of the reactions at peaks A, B, and C were found to be linearly dependent on the logarithm of the hydroxide concentration and the involvement of the species OH^- was therefore indicated. Differentiation between the surface sites for the reactions at peaks A, B, and C could therefore only be the result of different bonding energies for the types of bonding sites. Two explanations for different bonding energies on a pure metal electrode had been reported. The first (64) was the result of preferred bonding sites arising from repulsion effects of the adsorbing species. The peak separations found in the potential sweep data (Fig. 2) appear to be too great to be caused by the preferred bonding site phenomenon. The second explanation results from the differences in the work function values between various crystal structures in the metal (63). The peak separations resulting from this effect were much greater. The major crystal faces of a gold electrode have been shown to have different bulk oxide (Au_2O_3) formation potentials (15). Thus the three peaks were identified as hydroxide adsorption reactions on different crystal planes. Based on the work function values for the three most common gold crystal planes, the adsorption peaks A, B, and C were identified with the planes (110), (100), and (111), respectively. Comparison with work on desorption phenomena on gold single crystals (61) revealed that the (110) plane was found to show noticeable interaction effects similar to that found for peak A in the cathodic sweep (Fig. 2), thus supporting the identification of peak A with the (110) crystal plane. Corrections to the data in Table III, based on the identification of the reactions at peaks A, B, and C with the crystal planes (110), (100), and (111), improved the correlation between the total accumulated charge density and the theoretical value of 1 e^-/surface atom cathodic of peak D. From these data and from the variation of peak potential with hydroxide ion concentration, reaction [6] was identified with the reactions at peaks A, B, and C.

Electrochemical Properties of Iron Naphthalocyanine on Carbon Black for O_2 Reduction and Evolution in Alkaline Media and Applicability to Air Cathodes

G. Magner, M. Savy,* and G. Scarbeck

Laboratoire d'Electrochimie Interfaciale du C.N.R.S., 92190 Meudon-Bellevue, France

ABSTRACT

The synthesis, optical spectra, and x-ray pattern of iron naphthalocyanine as the pure powder are reported. The electrochemical properties for O_2 reduction and evolution of this compound loaded on carbon black supports have been determined by ultrathin and rotating ring-disk electrode techniques. While on the carbon black support O_2 reduction occurs through a two electron pathway followed by HO_2^- decomposition, four electron reduction is obtained on the loadings with a high efficiency. Stability tests proved their applicability as useful catalysts as the air cathode in metal-air generators.

While the capacity of monomeric phthalocyanine materials for nearly reversible charge transfer reaction (1) has been demonstrated, the main objection to their use as practical catalysts in metal-air or fuel cell generators has been their lack of stability. However, by synthesizing polymeric materials, high stability (2) during continuous operation in 3M SO_4H_2 for times up to 3000 hr has been obtained. The working potentials of the oxygen electrode remain about 400 mV below the four electron reversible potential. In these types of compounds the effect of the enlargement of the π-electron system on their activity has been emphasized by several groups (3a, b).

One might hope to be able to apply such materials to metal-air systems due to the lower current densities (C.D.) involved. On different types of polymeric iron phthalocyanines (4) spectroscopic and electrochemical investigations have been performed in alkaline media and correlations between the activity and the structural properties have been found. The role of the π-electron delocalization in the optimization of the free energy of oxygen adsorption on the iron sites (due to π-d hybridation) has been confirmed by ESCA techniques (5). In the case of compounds of larger sizes the π-electron delocalization is inhibited due to spin-spin interactions. Such effects upon chemical reactivity have already been noticed in the chemistry of conjugated ring systems (6), the activity decreasing in the order anthracene > naphthalene > benzene.

Besides this π-electron density condition, many factors can affect the electrochemical activity, for example, the junction with the support, the wettability, or the d orbital configuration of the iron which is very critical (2-4). The difficult problem is to meet all these requirements simultaneously. Several types of synthesis have been worked out. A rapid technique for the comparison of the electrochemical activity is the ultrathin electrode (7). The preparations were tested by easy to perform spectroscopic techniques, in order to check the electronic configuration.

In this paper different syntheses of iron napthalocyanine are briefly summarized. Investigation of the samples by optical spectroscopy and x-rays is presented. Then more complete studies of the electrode performances for the electroreduction in 1M alkaline medium are made using the ultrathin electrode technique and the rotating ring-disk electrode (RRDE) to determine the reaction path and the kinetic constants.

Previous investigations have been performed on a type of carbon black formed from CO (8a, b), which gave a life expectancy, as air electrode material, of 1000 to 1500 2 hr cycles. However the oxygen electrode carbon black catalysts have the disadvantage of a strong H_2O_2 generation which perturbs the activity of the metal electrode. By application of the rotating disk technique, investigations can be made of the amount of H_2O_2 formed and of the favored reaction path (9). A diagram of the energies of intermediates involved in the overall process was given by Morcos and Yeager (10).

Experimental

Synthesis and Characterization

The details of the synthesis and EPR investigation of samples are given elsewhere (11). Briefly two syntheses of iron naphthalocyanine have been achieved. Synthesis I corresponds to the reaction of orthodicyanonaphthalene with Fe dipyvalolymethane. Synthesis II is identical to synthesis I with the addition of ammonium paramolybdate under the same experimental conditions. From EPR and ESCA data (11, 12) these molybdenum ions which were added as a probe are partially dispersed in the napthalocyanine structure with valencies 4, 5, and 6.

Instead of 7.3% w/w as theoretically expected, the amount of iron with synthesis I is 5.3%. With synthesis

* Electrochemical Society Active Member.

Key words: battery, carbon, catalysis, chelates.

II only 4.3% w/w iron has been found with approximately 1 Mo atom per iron. The molybdenum ions with valencies 4 or 5 are distributed either substitutionally for the iron in the naphthalocyanine structure or are in the oxide form (10, 11).

X-ray analysis.—Debye-Scherrer patterns on the powder resulting from synthesis I are shown in Fig. 1. The pattern is similar to that shown by the γ-form of phthalocyanines (13). This form involves small size crystallites of some 10 nm or less in diameter as shown by electron microscopy. Further investigations will be conducted in order to determine the structural properties.

Iron naphthalocyanine is difficult to vacuum sublime: at 320°C after 2 hr at 10^{-7} Torr the thickness of the deposited layers is about 160 nm as measured by a Talystep recorder. For a similar deposit of iron phthalocyanine the time required is less than 5 min.

Optical spectroscopy.—The optical transmission absorption spectrum was obtained using a Cary 17 spectrometer in a layer deposited onto a quartz slab. The spectrum in Fig. 2 is similar to that of phthalocyanine compounds (14, 15). It presents the characteristic Soret bands due to charge transfer transitions between the central ion and the ligand. In the visible, the absorption band due to π-π^* and π-d transitions can also be observed.

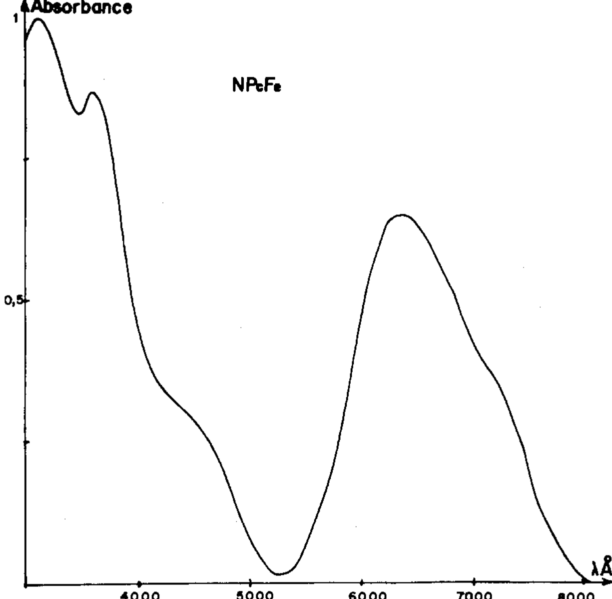

Fig. 2. Optical absorption spectrum by transmission

Electrochemical Investigations

Previous investigations (16) on a phthalocyanine dimer have stressed the role of Fe^{II}/Fe^{III} couple on its electrochemical activity. Due to the action of reducing couples the stoichiometry discrepancy in iron and H_2 may therefore affect the properties of these series of compounds, especially in the range of polarization where the conductivity in the solid phase is the limiting factor. Using different iron donors in the synthesis of naphthalocyanine it is possible to modify the iron content. For example with ferrocene it drops to 2.2% w/w.

Ultrathin electrode.—Preliminary experiments have been conducted using the Lundquist-Vogel ultrathin electrode technique (6) to determine the influence of the stoichiometry on the activity of these samples. The most active samples were investigated using the rotating disk electrode.

1M alkali has been chosen as the medium for the comparison with the dimer. Structural effects of the carbon black support were also found to be an important factor in the activity of the loadings (17). Best performances were obtained with low microporosity materials. For these preliminary tests Vulcan carbon blacks have been chosen as support, with a 10% loading synthesis.

The activity may vary as a function of the charge of the catalyst on the nickel grid or with the grinding. After thorough grinding the activity as a function of the charge presents a plateau value at 0.2 mg cm^{-2}, independent of the applied potential. This value has been chosen, therefore, for all the samples investigated.

As seen in Fig. 3 for synthesis I the activity is noticeably increased with the iron content in the naphthalocyanine structure, depending upon the iron donor used in the synthesis. Between ferrocene (2.2% w/w iron) and iron dipyvaloylmethane (5.3% w/w iron) the zero current potential increases from −100 mV to −72 mV SCE with the corresponding increase in current densities. The use of Mo catalysts (syntheses II) extends the Tafel zone of polarization over almost one decade of current densities.

The activity of high iron content samples can also be compared with that of the phthalocyanine dimer previously investigated (16, 17). For low polarizations the rest potential and current densities are identical. The increase in current obtained at high polarizations is a factor of about 10.

Rotating ring-disk electrode.—Equipment.—The basic experimental equipment has been previously reported (18). In this work a ring disk electrode has been substituted for the disk electrode. Its main interest lies in the wide range of the speeds available from 4 to 500 rps with a stability of 1%. The mechanical accuracy ± 3μ in the rotation plane can be maintained independent of the rotation speed. In addition, within these characteristics several types of disks in different metals or of different diameters can be fitted and provided with rings. The electrode support can be changed without any modification of the initial accuracy of the equipment. This apparatus is represented in Fig. 4 with the modifications required for the present work. In order to avoid any possible contamination, a gold ring has been used for current collection. The disk diameter was 4 mm. Preliminary experiments have been conducted to test the validity of the equipment.

This first condition of the validity of this technique concerns the surface of the metal and of the insulator which should be situated in a plane perpendicular to the rotation axis. A slight deformation of this plane can modify the diffusion layer in such a way that the collection factor does not remain constant but decreases in a noticeable fashion as the rotation speed increases. After thorough polishing and machining of the surface, $5 \cdot 10^{-3}$M $K_3Fe(CN)_6$ in 1M KOH supporting electrolyte gave a constant collection factor

of 0.26 up to 196 rps. If surface defects of the order of 0.05 mm were present a constant collection factor was not observed under the same experimental conditions. In order to work with carbon black powder under similar conditions, a hollow cavity 0.25 mm in depth was made on the disk. Tests of this electrode are described below.

Electrode preparation: binding agent.—Several tests were performed in order to choose appropriate binding agents. Initially, a spectroscopically pure paraffin wax "Uvasol" (19) was used. By mixing with the carbon powder, a plastic paste can be obtained which can be introduced into the disk cavity and which remains adherent. This paste can be smoothed mechanically with a razor blade to meet the above conditions. With this mixture, limiting currents on the disk do not present the classical linear relationship as a function of the square root of the rotation speed. As the diffusion does not appear to be the limiting factor in the overall reaction this assumption was tested by plotting the current densities as a function of the applied scanning voltage velocity v for a rotation speed initially equal to zero. Two domains can be observed for the peak current I_p

$$\text{Domain I} \quad I_p \propto \sqrt{v} \qquad [1]$$

$$\text{Domain II} \quad I_p \propto v \qquad [2]$$

Depending upon the scanning velocity the limiting step is first the diffusion then the adsorption. At 9 rps data are similar but the diffusion domain is smaller, the adsorption domain being extended. Using this type of binding agent the RRDE technique seems to be inappropriate due to slow adsorption kinetics.

In the rest of this study Soreflon[1] has been used as the binding agent. A mixture of carbon black and 40% w/w Soreflon is prepared. A typical preparation was, for example, C 50 mg, Soreflon 0.14 ml of 98 mg/ml solution.

The paste is immediately introduced into the cavity and then smoothed mechanically as above. To avoid any poisoning after the preparation, the electrode is cautiously washed with ethanol. For comparison with "Uvasol," data are presented in Fig. 5.

A pseudo plateau is visible with the Soreflon preparation which is linear as a function of the square root of the rotation speed while the *i-V* slope is steeper. The increase in *C.D.* at − 650 mV SCE is compatible with the reduction of NiO present at high concentration (18%) w/w in the carbon black structure.

Results

Loadings.—The collection factor was determined before and after plotting the *i-V* curves, as described above, using the same solution deaerated with Ar. A constant factor $0.22 < N < 0.26$ was measured over a wide range of rotation speeds.

[1] Societe Francaise des Matières Colorantes.

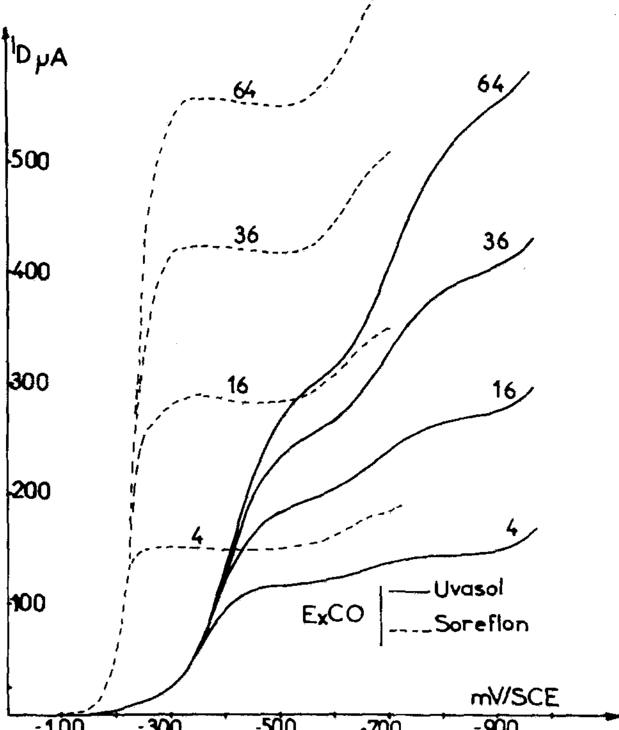

Fig. 5. Effects of the binding agent on the O_2 electroreduction. Continuous line Uvasol, dashed line Soreflon.

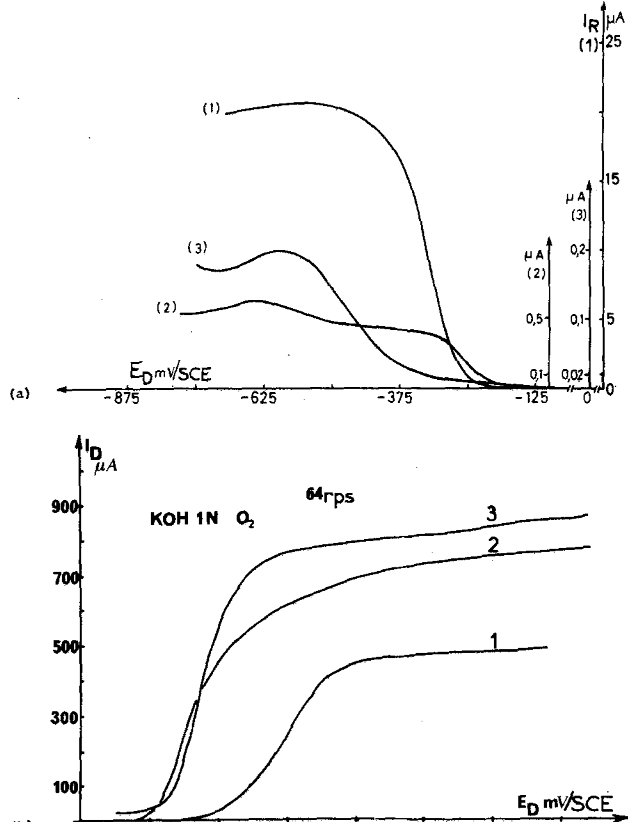
Vulcan support.—A preliminary study has been performed for the reasons stated above on a 10% loading on Vulcan carbon black in order to compare the properties of the phthalocyanine dimer studied previously (4) with those of the iron naphthalocyanine (synthesis I). Data are presented in Fig. 6a, b, c. In Fig. 6a are represented the ring currents obtained on the three types of samples at 64 rps. The drastic drop in H_2O_2 generation from the carbon black support on loading can be seen. In the active range of polarizations (for potentials higher than 375 mV) the ring current remains much lower with the iron naphthalocyanine loading (0.02 µA) than with the dimer (0.45 µA). Correspondingly, in Fig. 6b, which shows the disk current in the region of diffusion limitation, the current densities with the iron naphthalocyanine loading are approximately twice those of the support whereas with the dimer they are less than twice. In the Tafel region, the current densities with the dimer and the iron naphthalocyanine are similar, as observed with the ultrathin electrode technique. In Fig. 6c, the linear relationship as a function of the square root of the rotation speed is obeyed. As in the other figures, in Fig. 6a and b the improved efficiency of the four electron reduction process with the iron naphthalocyanine loading can immediately be seen. The slight deviation from the value 2 in the slope, compared with that on the Vulcan, can be attributed to a decrease of the surface area in the case of this loading.

Ex CO carbon black (holding recycling) support.—In the rest of this work 2.5% loadings on carbon black ex CO have been used. Data on both the loading and the support at 64 rps for the disk and the ring are presented on Fig. 7a and b, respectively.

In Fig. 7a, a hump is visible on both plots at a scanning velocity of 2 mV/sec, which vanishes for the lower rate of 0.1 mV/sec. The plateau domain is better defined with the loading than with the support, an effect which can be due to the presence of nickel. In the Tafel region the slope is about 30 mV per decade with the loading as against 60 mV with the support. Potentials at constant current densities are between 120 and 150 mV more positive with the loading than with the support. In the plateau region, in the presence of the loading, the current densities are twice those of the support alone, as previously found with the Vulcan.

In Fig. 7b, the corresponding ring currents are represented. In the range of useful polarizations they remain below 1 µA on the loaded electrode. In contrast, on the support alone they rise with the disk current, being one and a half orders of magnitude higher. The corresponding efficiencies for H_2O_2 formation are about 57% on the support and 0.45% on the loaded electrode.



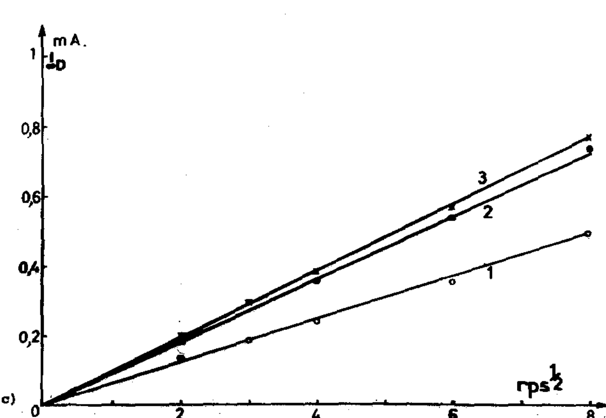


Fig. 6. Comparison Vulcan-dimer-FeNPc on the O_2 electroreduction. (a) Ring currents at 64 rps. Curve 1, Vulcan; curve 2, dimer; curve 3, NPc. (b) Corresponding disk currents. (c) Disk current vs. $(rps)^{1/2}$.

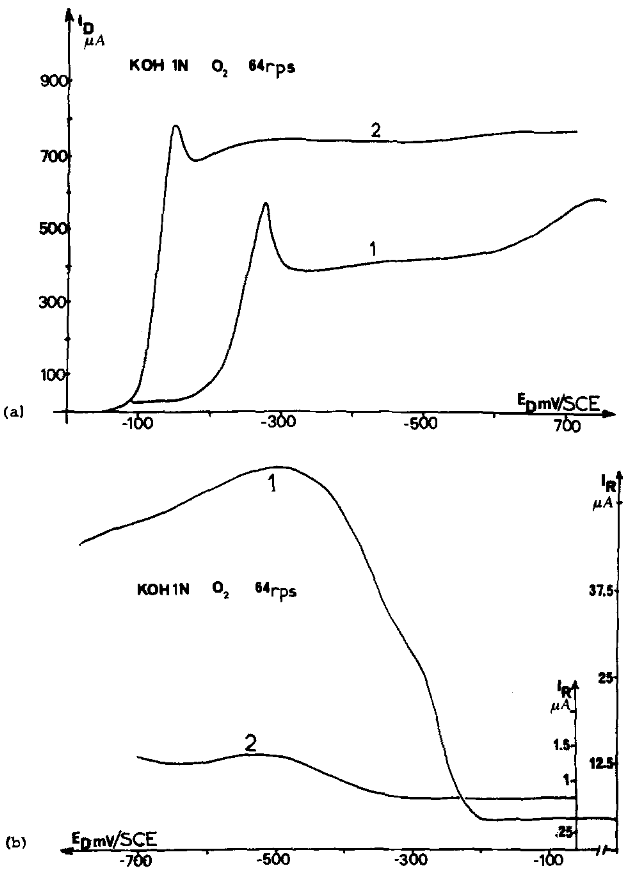

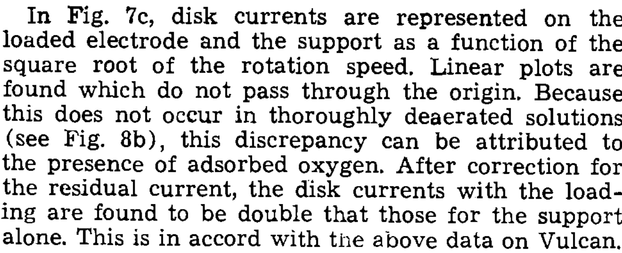

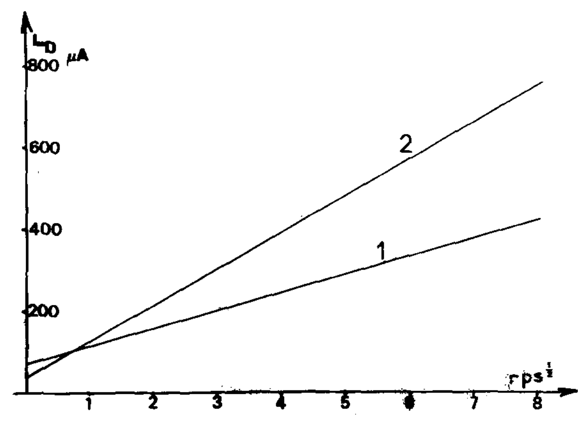

Fig. 7. Comparison with ex CO carbon black (O_2 reduction). (a) Disk current at 64 rps. Curve 1, carbon black support; curve 2, FeNPc (synthesis I, 5.6% iron). (b) Corresponding ring currents (to a), same labels as (a). (c) Disk current vs. $(rps)^{1/2}$, same labels as (a).

In Fig. 7c, disk currents are represented on the loaded electrode and the support as a function of the square root of the rotation speed. Linear plots are found which do not pass through the origin. Because this does not occur in thoroughly deaerated solutions (see Fig. 8b), this discrepancy can be attributed to the presence of adsorbed oxygen. After correction for the residual current, the disk currents with the loading are found to be double that those for the support alone. This is in accord with the above data on Vulcan.

On the anodic side the activity of the loading is increased compared to that of the ex CO carbon black support. The overpotential for O_2 evolution drops initially by approximately 200 mV. Under oxygen the system is relatively stable but under nitrogen the activity tends towards that of the support.

Carbon black ex CO alone.—Disk and ring currents as a function of the square root of the rotation speed under 1 atm of O_2 are shown in Fig. 8a. As the rotation speed increases, the ring current tends towards a limit. The first explanation of this feature may be associated with the roughness of the electrode or the insulation surface. However it has to be pointed out that under thoroughly deaerated solutions, classical disk and ring currents are obtained which are linear functions of the square root of the velocity passing through the origin, similar to the data obtained on the loading. The collection factor with the loading and with deaerated solutions on the support remains constant up to 81 rps. In the presence of O_2 the ring current begins to deviate for rotation speeds higher than 16 rps. If H_2O_2 was decomposed before flowing to the ring, the reverse phenomena would be observed. Nonnegligible recycling of oxygen into the electrochemical reaction coming from the H_2O_2 decomposition would increase the disk current and not yield a factor of about 2 in the current densities between the support and the loading in the plateau region (9). An adsorption limiting step can also be ruled out by investigation of the ring current in the presence of H_2O_2 solution. A Tafel slope is observed which is compatible with charge transfer limiting kinetics without any detection of an adsorption-limiting step.

Stability under recycling conditions.[2]—Thin porous electrodes have been prepared from a mixture of 20% Teflon with carbon black powder with or without a loading of iron naphthalocyanine. The porous electrodes were obtained after compressing the powder at 50 kg/cm² on an expanded nickel grid. Tests were conducted in 6M KOH solutions at ambient temperatures. Potentials were monitored using an automated system between +10 and −10 mA cm^{-2} during 2 hr cycles. The life expectancy for the carbon black support with 10, 5, and 2.5 w/w percent loading synthesis I and II are shown in Fig. 9. The activity increases with the dilution, the greatest activity being obtained for the 2.5% loadings. The enhancement is about 100 cycles with a factor of 2 in dilution. No differences are visible between synthesis I and II (at 2.5% w/w). With the most dilute loadings, up to 375 cycles, the activity on the cathodic side remains higher than that of the support, the drop in activity occurring at 600 cycles.

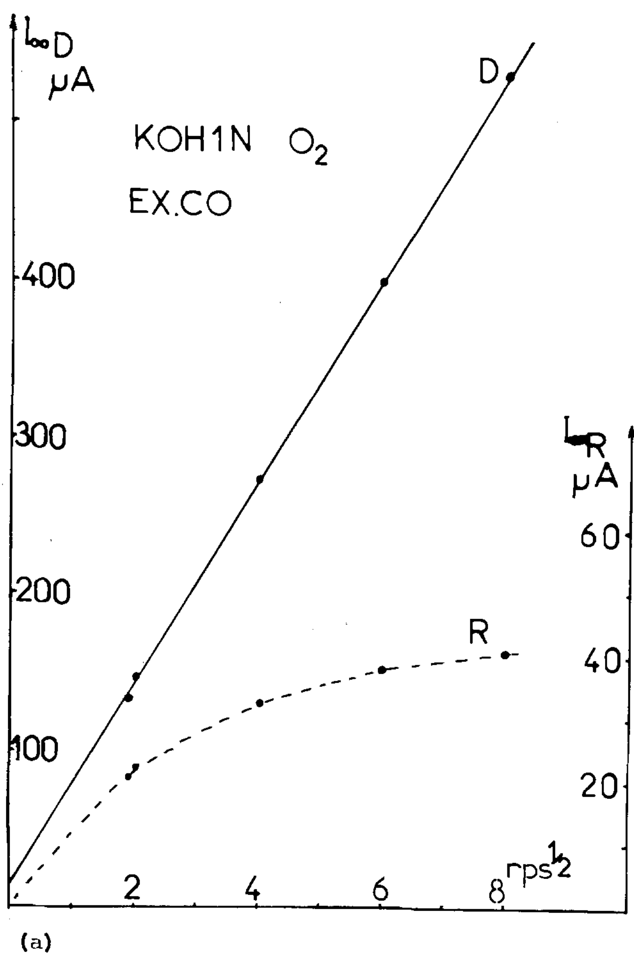
On the carbon black support, by applying cycles at 1 mV/sec, HO_2^- formation can be detected. Voltammetric scans after 300 cycles are presented in Fig. 10. Potentials are measured in this case *vs.* Hg/HgO reference electrode.

While the cathodic currents are comparable, on the anodic side, the gain in potential at 100 mA cm^{-2} is about 100 mV for the loading. The high intensity peak due to HO_2^- visible on the support at 0 mV potential is not present on the loading on which the formation of HO_2^- remains negligible. The reduction peak at 300 mV on the support alone is slightly depleted for the loading. On the support alone as the recycling increases the HO_2^- formation is inhibited while the peak observed in reduction is enlarged.

Discussion

In this section we will discuss first the data obtained on the ex CO carbon black alone. The practical problem is to avoid the H_2O_2 generation and the techniques used may bring some insight on this problem.

[2] We acknowledge Dr. Feuillade and Mr. Dupeyré from CGE Marcoussis who obtained these data.



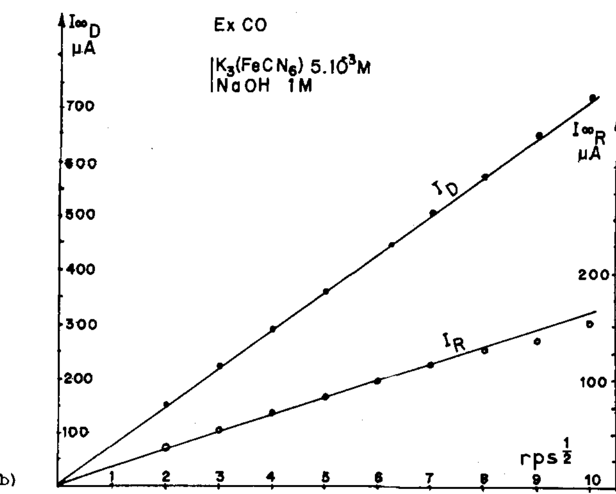


Fig. 8. Ring and disk currents on ex CO carbon black vs. $(rps)^{1/2}$. (a) In presence of O_2: D, disk; R, ring. (b) In ferrocyanide deaerated solutions (same labels).

Ex CO alone (O_2 reduction mechanism).—Damjanovic, Genshaw, and Bockris (20) first established a criterion for the determination of the kinetic parameters of O_2 reduction in using the RRDE. They started from a simple model in which the reaction intermediate can diffuse into the solution or undergo a reducing process. Linear plots of NI_D/I_R (N: collection factor, I_D and I_R disk and ring currents, respectively) as a function of $\omega^{-1/2}$ were obtained on the basis of their assumptions.

More recently Wroblowa *et al.* (21) considered a more general scheme of reaction for O_2 electroreduction. Diagnostic criteria were derived from the shape of the NI_D/I_R plots *vs.* $\omega^{-1/2}$ in accord with the different reaction paths. This type of interpretation can be applied in the case investigated here. Following

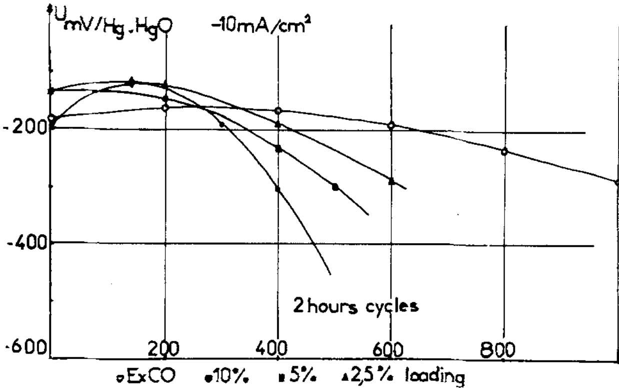

Fig. 9. Potential stability vs. recycling at 10 mA cm^{-2}. ○ carbon black; ● 10% loading; ■ 5% loading; ▲ 2.5 % loading.

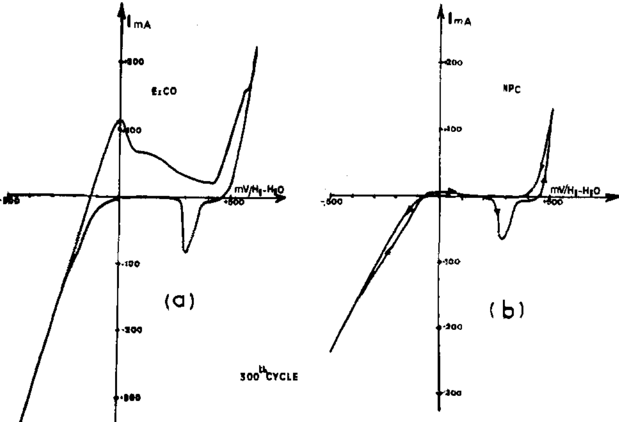

Fig. 10. Voltammetry after 300 cycles. (a) Carbon black (alone). (b) Loading (2.5%).

the latter paper with a desorption controlled ring current, the variation of the slope and intercept of these plots as a function of the applied voltage are not linear *vs.* $\omega^{-1/2}$.

In the present study it is also not possible to obtain such linear plots (NI_D/I_R *vs.* $\omega^{-1/2}$). However linear plots NI_D/I_R *vs.* $\omega^{+1/2}$ were obtained and are represented on Fig. 11b using the original data presented in Fig. 11a. For low applied overvoltage the plots extrapolated to $\omega = 0$ intersect the ordinate axis at $NI_D/I_R = 1$. This ordinate then increases with the overvoltage, the slope of the different plots remaining invariant.

In the case of a desorption controlled ring current the expression NI_D/I_R has been calculated in Ref. (9) as a function of the kinetic parameters taking into account the rate of recycling. The rate of loss of the peroxide from the system is given by

$$k_D[HO_2^- \text{ Sol}] = \vec{k}_5[HO_2^- \text{ ads}] - \overleftarrow{k}_5[HO_2^- \text{ Sol}] \quad [3]$$

where

$$k_D = 0.62\, D^{2/3}\nu^{-1/6}\omega^{1/2} \quad [4]$$

D and ν being the diffusion coefficient for HO_2^- and the kinematic viscosity. $\vec{k}_5$ and $\overleftarrow{k}_5$ are the rate constants for adsorption and desorption respectively.

I_R is given by

$$I_R = 2FN \frac{\vec{k}_5 k_D}{k_D + \overleftarrow{k}_5} [HO_2^- \text{ ads}] \quad [5]$$

writing

$$B = 0.62\, D^{2/3}\nu^{-1/6} \quad [4']$$

and the experimental relationship

$$I_D = B\omega^{1/2} \quad [6]$$

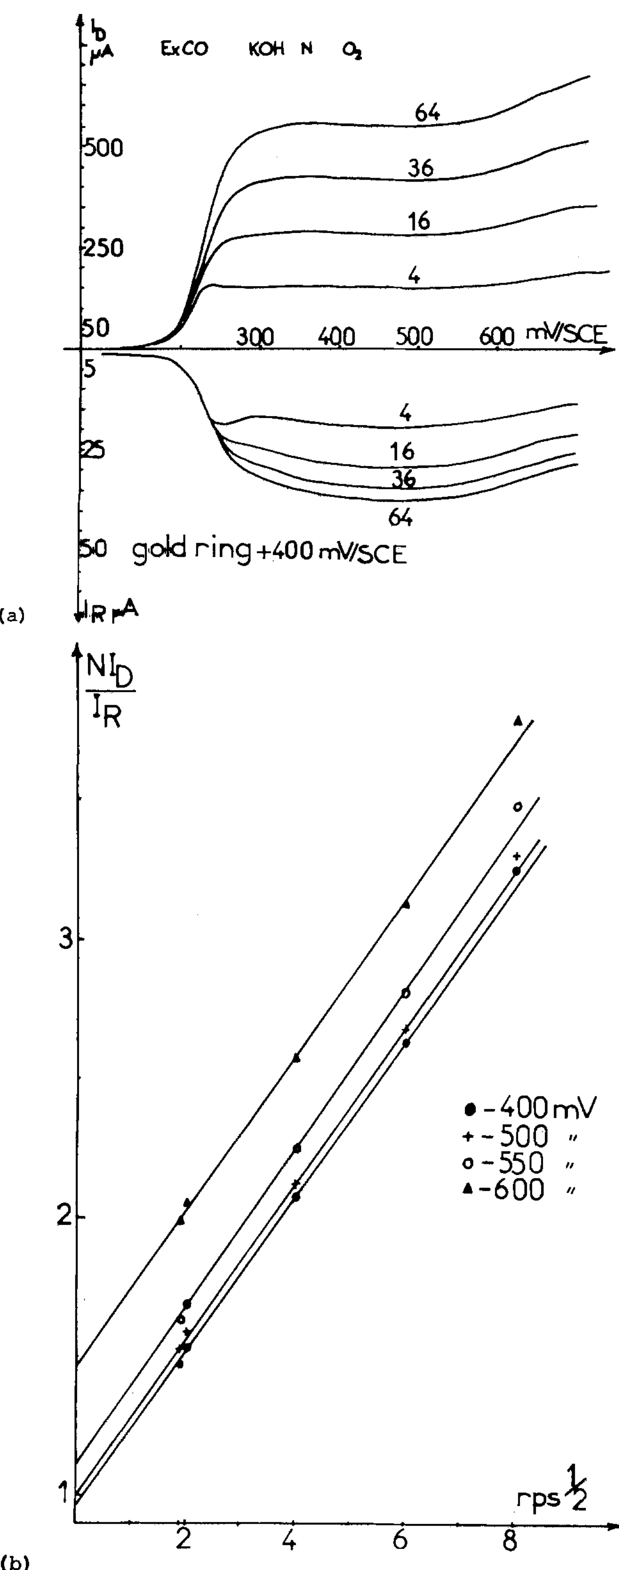

Fig. 11. NI_D/I_R vs. $\omega^{1/2}$ vs. applied potentials. (a) Initial disk and ring currents under oxygen. Data presented on Fig. 8 and 9 have been obtained on another variety of carbon black ex CO than those presented on Fig. 7, 0.1 mV/sec scanning (numbers indicated are rps). (b) Calculated curves from (a) NI_D/I_R plots vs. $\omega^{1/2}$.

A correction is made for the residual current

$$\frac{NI_D}{I_R} = \frac{B\omega^{1/2} + \overleftarrow{k}_5}{\overrightarrow{k}_5} \cdot \frac{1}{[HO_2^- \text{ ads}]} \quad [7]$$

As the overvoltage increases, the near constancy of the slopes implies

$$\overrightarrow{k}_5 [HO_2^- \text{ ads}] = c^{te} \quad [8]$$

or also k_5 and $[HO_2^- \text{ ads}]$ are constant. [9]

In the region (low overvoltages) where I_D is found to be twice as large on the loaded material as for the support alone, it follows that in Eq. [36] of Ref. (9)

$$\overrightarrow{k}_1 \neq \overrightarrow{k}_3 \neq 0 \quad [10]$$

where $\overrightarrow{k}_1$ = kinetic constant for the four electron process reduction, $\overrightarrow{k}_2$ = kinetic constant for the two electron process, $\overrightarrow{k}_3$ = kinetic constant for the HO_2^- reduction process, and k_4 = kinetic constant for HO_2^- decomposition.

From Eq. [36] of Ref. (9) Eq. [10] means

$$\overrightarrow{k}_2 \propto k_4 \quad [10']$$

The velocity of decomposition of HO_2^- is practically equal to its velocity of formation. The reaction path is a two electron process with a totally irreversible desorption limiting step.

Remarks.—The dependence of k_4 upon cathodic polarization can be interpreted as a succession of two electrochemical reactions, cathodic and anodic, in the adsorbed phase.

The cathodic reaction should be the rate-determining step, the anodic reaction being very fast. The data are compatible with the following mechanism

$$S-OO^-H + OH_2 \rightarrow S-OO^-H-O{<}^{H}_{H} \quad [I]$$

(Due to the symmetry considerations (11) the wetting is faster when the water molecule is fixed by the oxygen atom on the surface than the reverse.)

$$e + S-OO^-H-O{<}^{H}_{H} \rightarrow SO + H + 2OH^-$$

rds [II]

$$H \rightarrow H^+ + e \text{ fast} \quad [III]$$

$$OH^- + H^+ \rightleftarrows H_2O$$

$$2SO \rightarrow 2S + O_2 \quad [IV]$$

The rds corresponds to the formation of hydrogenated free radical. In addition, due to the applied potential, step [III] can be fast.

Without any additional hypothesis about the HO_2^- decomposition mechanism this information can be introduced into Eq. [37] of Ref. (9) by considering two cases

1) $k_1 = k_3 = 0$

$$\frac{NI_D}{I_R} = \tau \left[\frac{k_4}{k_D} \frac{\overrightarrow{k}_5}{\overrightarrow{k}_5} + \frac{k_4 + \overrightarrow{k}_5}{\overrightarrow{k}_5} \right] \quad [11]$$

τ being the rate of recycling.

Writing the condition

$$k_4 = \alpha' k_D \quad [12]$$

$$\frac{NI_D}{I_R} = \tau \left[\alpha' \frac{\overleftarrow{k}_5}{\overrightarrow{k}_5} + \frac{\alpha' k_D}{\overrightarrow{k}_5} + 1 \right] \quad [13]$$

For low overvoltages

$$\tau = 1, \text{ i.e., } k_4 < 5\, k_D \quad [14]$$

and also

$$\frac{\overleftarrow{k_5}}{\overrightarrow{k_5}} << 1 \quad [15]$$

The increase of the ordinate at $\omega = 0$ cannot be accounted for only by an increase of τ because from Eq. [13] this would simultaneously increase the slope. Two conditions should be considered; either an increase of $\overleftarrow{k_5}$ or a second condition

$$2) \quad \overrightarrow{k_1} = 0 \quad \overrightarrow{k_3} \neq 0$$

As the current densities on the disk with the loading are less than twice those on the support alone the Eq. [11] becomes

$$\frac{NI_D}{I_R} = 1 + \frac{\overrightarrow{k_3} + \alpha' k_D}{\overrightarrow{k_5}} \quad [17]$$

The increase at $\omega = 0$ with the overvoltage corresponds to an increase of $\overrightarrow{k_3}$ (velocity of reduction of HO_2^-) and is detectable only at high overvoltages above the useful range of polarizations.

It may be concluded that the interpretation of the data obtained on the support alone from the models developed in Ref. (9) and (21) yields kinetics limited by a slow desorption step of HO_2^- produced. At low overvoltages one obtains a two electron reduction process followed by a decomposition of adsorbed HO_2^-. For higher overvoltages the HO_2^- reduction process takes place with a possible increase of the kinetics of desorption which means that the reduction may occur outside the initial reaction zone on the electrode.

Improvements of the carbon support may consist of adding HO_2^- decomposition catalysts which are stable under recycling conditions.

Naphthalocyanine loadings on ex CO carbon black (Improvements for O_2 electroreduction and evolution). —Our search for organic compounds presenting a useful stability and activity to serve as air cathode catalysts in alkaline media for zinc-air or fuel cell generators has led to the fabrication of iron naphthalocyanine. The materials synthesized as the pure powder have an optical absorption spectrum and x-ray pattern similar to those given in literature for the corresponding phthalocyanines.

As loadings on carbon black support, the activity of the samples prepared were investigated by the ultrathin electrode technique and were found to be higher than that of the dimer previously studied. The improvement of the performance is due to the increase of the conductivity of the naphthalocyanine. As with the phthalocyanine dimer, the differences in structure are associated with the existence of noticeable amounts of fixed oxygen which act as a well for π-electrons, a greater density of π-electrons involving (3a, b, 5) a greater activity. This result is in accord with the predictions made in Ref. (6).

As in the case of the phthalocyanine dimer (4), the reaction involves radical formation. Rest potentials and current densities at low polarizations turn out to be highly sensitive to the iron content bound to the structure. The highest iron content corresponds to the best activity. This result agrees with the models of charge transfer complexes investigated in Ref. (16). In these models as previously reported, the conductivity between superimposed molecules takes place with Fe^{II}/Fe^{III} exchange [$D_h \leq 10^{-12}$ cm^2 sec^{-1} (22a, b)] simultaneously with electron hopping on the oxygen covalently bound to the iron sites: H_2/H^+ couples in the solid phase act as reducing agents for Fe^{2+}/Fe^{3+} couples decreasing the density of sites for oxygen activation. Therefore the activity is related to the purity of the samples in Fe and the elimination of any reducing couple which can be introduced during the synthesis or in contact with the support. A possible way to improve the performances would be by doping. Introduction of Mo^{+5} ions enhanced the activity but results in stability are similar for 2.5% loadings w/w.

While the optical spectrum and x-ray pattern are similar, there are important differences in the EPR spectra compared to those of the monomeric iron phthalocyanine. Those concern primary the amount of Fe^{III} which increases with the π-electron density (5). Due to the π-d hybridation requirement for $Fe—O_2$, the electrochemical activity seems therefore to be more dependent upon two species in resonance, one in which the Fe^{II} is covalently bound to oxygen and a second where the Fe^{III} is ionically bound to O_2^-. More excited states of the molecule do not seem to play any important role in the activity.

On the loading surface the kinetics consist mainly of a four electron reduction process with a reaction scheme similar to the one obtained with phthalocyanine dimer type (4). Rotating ring-disk techniques have shown that on the same support, the efficiency of the four electron reduction process is better with the naphthalocyanine material than with the oxygen fixing phthalocyanine dimer, confirming the correlation of activity *vs.* π-electron density. This low rate of HO_2^- formation can present an important advantage for zinc-air generators. Experiments have been conducted on a type of carbon black support holding for more than 1000 2 hr cycles. As above, on naphthalocyanine loadings, on this support RRDE techniques show a rate of HO_2^- formation to be less than 5% of that observed on carbon within the whole range of useful polarizations.

A main cause of the drop in the performance of the loading is generally a modification of the junction properties at the naphthalocyanine-carbon black interface. However, this type of explanation appears to be at variance with the increase of the life expectancy observed with dilution. The above data seem to be better interpreted by seeking a correlation between the overall conduction and the life expectancy; the better is the conduction the better is the life expectancy. Therefore as a working hypothesis one may assume that the development of an electric field inside the layer may involve long-range structural changes which inhibit the catalytic properties. With the aid of EPR (11) and pulse techniques (21) the formation of dipoles within the naphthalocyanine layer has been shown. They are due to the strong difference in mobility between the holes on the iron sites (Fe^{2+}/Fe^{3+} couple) and the electrons associated with the oxygen molecules which can diffuse more rapidly (22b). Due to the low mobility of the positive charges Fe^{3+} or Mo^{V} ions are segregated at the surface. This view seems to be supported by ESCA investigations (12) under progress. One solution for increasing the life expectancy might consist of introducing doping agents into the naphthalocyanine lattice which would decrease the existing initial electric field.

Compared to the support, the most significant feature of Fig. 9 is the blocking of the activity after 600 cycles on loadings corresponding to coverages of naphthalocyanine lower than one monolayer. This result can be interpreted by the fact that active sites for oxygen reduction on the carbon support alone are also active sites for the fixation of the naphthalocyanine layers.

From M. O. symmetry considerations (23) the sites in the naphthalocyanine molecule presenting a high degree of symmetry should play a special role, *i.e.* mainly the iron sites or corresponding sites with an A_4 axial symmetry and the external carbon atoms on the napthalene ring with A_2 axial or planar symmetry. In the first case, of sites A_4, the adherence of the naphthalocyanine deposit would be higher than with the second case, sites A_2, which requires a special spacing be-

tween the sites of the support in order to fit with the distances in the plane of the naphthalocyanine lattice. The relative stability of the loading under both cathodic reduction of oxygen and its evolution would suggest that the first type of fixation should be considered. If according to Yeager (10, 24) the active sites for O_2 reduction on carbon surfaces are the planes possessing π-type of orbitals, symmetry requirements for the fixation of the naphthalocyanine molecules can be encountered in this case, carbon orbitals and high symmetry sites being allowed to combine.

Conclusion

On the ex CO alone this study has shown a kinetic limitation due to a slow desorption of H_2O_2 interpreted using models developed earlier. In the present case linear plots of NI_D/I_R *vs.* $\omega^{+1/2}$ are obtained instead of the usual $\omega^{-1/2}$.

On the naphthalocyanine loadings tests of stability have underlined the absence of H_2O_2 generation. The limitation of the performances due to the conduction in the solid phase has been emphasized.

Using loadings on a suitable carbon black support, iron naphthalocyanine has proved to be a useful catalyst for practical applications in zinc-air generators working in alkaline media. Improvements in activity and stability may consist of a synthesis yielding an iron content as close as possible to the theoretical value and in a parallel the elimination of the reducing couples in the structure. Doping techniques may also be usefully used.

Another point of interest is the illustration of the relationship existing in such compounds between the activity and stability *vs.* oxygen reduction and the density of π-electrons in the conjugated rings as already reported on similar compounds. The search for larger molecules such as the six unit polymer does not take into account electronic interaction between molecules in the crystal lattice which perturbs the π-electron density. With smaller size molecules the highest π-electron densities can be obtained. A major fact seems to be the simultaneous presence of Fe^{3+} with Fe^{II} covalently bounded to oxygen which is always present on active and stable materials, *cf.* ESCA investigations.

Mass Transfer in Packed Bed Electrochemical Cells Having Both Uniform and Mixed Particle Sizes

Richard Alkire,* Brian Gracon, Thomas Grueter, James Marek, and Paul Blackburn*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

An electrochemical method was used to measure the mass transfer coefficient in packed beds containing spherical particles. The electrochemical reaction was reduction of ferricyanide ions on stainless steel ball bearings in the presence of potassium nitrate supporting electrolyte. The correlation found in this study was

$$j_D = 2.944\,\mathrm{Re}^{-0.554}\left(\frac{L}{d_p}\right)^{-0.15}$$

where $1.8 < \mathrm{Re} < 27$, $2.98 < L/d_p < 7.45$, and $\mathrm{Sc} = 1421$. The mass transfer coefficient for randomly packed beds containing up to five different sizes of spheres (0.398-0.952 cm diam) was correlated by the above equation when the average particle diameter was determined by

$$d_{pm} = \frac{1}{\sum_i \frac{x_i}{d_{pi}}}$$

where d_{pi} is the particle diameter of size i, and x_i is the volume (or weight fraction) of particles of size i in the packed bed. It was found that when the bed packing was segregated into two parallel flow zones, each having different particle sizes, then the average mass transfer coefficient was less than the value given by the correlation above.

The design of porous electrode systems usually depends critically upon mass transfer between electrode and fluid. Although convective heat and mass transfer in packed beds has received vigorous attention in the chemical engineering literature, these studies have been primarily carried out at high flow rates and on packing materials of uniform size. Most practical porous electrode systems, however, employ electrode packing material of nonuniform size and shape. The purpose of this investigation is to obtain mass transfer correlations for flow-through porous electrodes containing mixed sizes of spherical particles.

Heat and mass transfer correlations for single phase flow in uniformly packed beds have been collected by Karabelas *et al.* (1), Froment (2), Gupta *et al.* (3), Marivoet *et al.* (4), and Sherwood *et al.* (5). Flow in nonuniform packed beds containing high and low porosity zones has also been studied recently (6), and the flow patterns within such nonuniform beds were found to be complex (7, 8), and to affect adversely the bed contact efficiency (9). The majority of the foregoing work was carried out at high flow rates characteristic of chemical engineering separation processes.

Electrochemical reactors involving porous flow-through electrodes have been studied extensively during the past decade (10). It has been found that optimum operating conditions invariably involve low flow rates, and that flow channeling therefore represents a serious practical limitation on performance. Although electrochemical methods have been used to measure mass transfer rates in packed beds at low flow rates (11-15), studies to date have addressed the more fundamental aspects for which electrodes of uniformly dimensioned packing material, usually spheres or stacks of screens, were most appropriate.

In the present study, the electrochemical limiting current method was used to measure mass transfer coefficients in porous flow-through electrodes having nonuniform properties of two different types. In the first type, different sizes of spherical particles were thoroughly mixed and then dumped to form a porous bed which was nonuniform on a microscopic scale but uniform on a macroscopic scale (16-18). In the second type, different sizes of spherical particles were placed in different parts of a bed to create regions which were each uniformly porous on a microscopic scale but, when taken together, were not uniform on the macroscopic scale (16).

* Electrochemical Society Active Member.

Key words: mass transfer, porous electrode, nonuniform porosity, channeling.

Apparatus

The porous flow-through electrode was fabricated by packing a Plexiglas tube (5.1 cm diam) with spherical metal particles. In all but one series of experiments reported below, Type-440 stainless steel ball bearings (McMaster-Carr, Chicago) were used; eight different sizes of bearings were employed ranging from 0.397 to 0.952 cm diam (5/32-3/8 in.); the machine tolerance on these bearings was 0.0025 cm.

The tube containing the packed bed was 40 cm long. The upstream region (about 23 cm) was packed with glass beads (0.6 cm diam) in order to establish plug flow (19). The packed bed electrode (cathode) was assembled upstream from the anode, and was separated from the anode by a 2.5 cm layer of glass beads. The surface area of the anode was more than twice that of the cathode. Platinum contact wires were inserted into the two electrodes through serum stoppers in the cell wall.

The electrolytic solution used with stainless bearings was 0.95M KNO_3 containing 0.002M of both potassium ferricyanide and potassium ferrocyanide. The ferricyanide ion was reduced at the cathode and was reoxidized at the anode, which was downstream. Solution samples were withdrawn from the downstream side of the working electrode and were analyzed by iodometric titration, accurate to within one percent, to determine the exit concentration of ferricyanide (20). The ferricyanide concentration in the external flow loop was found to remain constant, permitting continuous recirculation of electrolyte to the cell.

Solution was pumped by a magnetic drive "Metl-Less" pump (March Manufacturing, Glenview, Illinois)

and was controlled by needle valves placed downstream from each rotameter. Other than the electrolysis cell, all parts of the flow system were fabricated from glass or leached Tygon tubing. The flow system was blanketed with nitrogen except in the small number of early experiments; in these, appreciable oxygen background currents were present, as described in the discussion of Fig. 2 below.

Polarization curves were obtained with a potentiostatic power supply (Wenking 70TS1) driven by a voltage ramp generator. In the cell, a plastic pipette was used as the capillary tube for a saturated calomel reference electrode; the tip of the capillary was positioned 0.35 cm downstream from the working electrode. Determination of cell current was made with use of a precision resistor.

Procedure

Electrolytic solution was prepared from AR grade chemicals and was deaerated by water-saturated nitrogen (30 liters/hr) for 3 hr prior to initiation of experiments. To prepare for use, the stainless steel bearings were tumbled in a slurry of 80-grit grinding powder, rinsed with deionized water, mildly etched in 1M H_2SO_4 to dislodge final traces of grit, rinsed with deionized water, and dried in warm air.

The electrolysis cell was fabricated by filling the Plexiglas tube with alternate regions of glass beads and ball bearings, taking care at each step to dislodge air bubbles. In particular, the working electrode bed was carefully assembled with forceps to insure that the interface between glass beads and ball bearings was perpendicular to the cell wall. "Type 1" electrodes were prepared by random placement of particles to form an electrode. "Type 2" electrodes were prepared by establishing concentric zones each composed of single-sized particles.

The flow rate was measured both by rotameters and by collecting measured volumes of solution. The needle valve was found to provide steady flow control to within 2% of the mean value reported.

Polarization curves were obtained at various flow rates in order to determine the mass transfer limiting current. Background currents were measured separately by following the above procedure with use of solutions containing only 0.95M KNO_3; limiting current data reported below have been corrected for background current. For over 60% of the data points, background currents were less than 1% of the limiting current; at the highest flow rates, the background currents were at most 10% of the limiting amount. For the data presented in Fig. 2, the background current was neither measured nor corrected for; these data are, therefore, presented for qualitative examination only.

Results and Discussion

Measurement of ferricyanide concentration in the cathodic effluent gave material balances which agreed, after correcting for background current, to within 1% of Faraday's law with $n = 1$. Because the electrolysis rate was limited solely by mass transfer in the catholyte, the mass transfer coefficient was found by measurement of current, inlet concentration, and surface area

$$I_l = n\mathbf{F}C_b(aLA\epsilon)k \quad [1]$$

Table I. Physical properties of solutions studied

Property	Value
ρ, g/cm³	1.058 ± 0.001
μ, g/cm sec	$8.68 \pm 0.07 \times 10^{-3}$

where the surface area for reaction is $(aLA\epsilon)$. In this study, the mass transfer coefficient was correlated by

$$j_D = G\mathrm{Re}^p\left(\frac{L}{d_p}\right)^q \quad [2]$$

where G, p, and q are constants to be found by analysis of experimental data. Combination and rearrangement of Eq. [1] and [2] provides the equation used for correlation of experimental data

$$\frac{I_l\rho\mathrm{Sc}^{2/3}}{\epsilon an\mathbf{F}C_bA\mu} = G\mathrm{Re}^{p'}\left(\frac{L}{d_p}\right)^{q'} \quad [3]$$

where

$$p' = p + 1$$

$$q' = q + 1$$

Uniform particle size results.—Properties of the electrolytic solutions used in this study are compiled in Table I. Geometric properties of the stainless steel ball bearings are listed in Table II. The bed porosity, ϵ_i, was measured by placing a known quantity of uniformly sized bearings into tubes having inside diameters of 3.8, 5.1, and 8.9 cm. A least squares fit of the data indicated that the bed porosity was a weak linear function of bearing diameter

$$\epsilon_i = 0.3754 + 0.04744 d_p \quad [4]$$

Equation [4] was used to compute the bed porosity values given in Table II. The specific surface area, a_i, was defined as surface area per unit volume

$$a_i = \frac{(1-\epsilon_i)\dfrac{S_i}{V_i}}{\epsilon_i} = \frac{6(1-\epsilon_i)}{d_{pi}\epsilon_i} \quad [5]$$

Table III lists the geometric properties of the eleven electrode configurations which comprised the studies on uniform bed particles. The length of the packed bed was calculated by

$$L = \frac{V_b}{A(1-\epsilon)} \quad [6]$$

The volume of the bearings V_b, was determined by counting the number of bearings placed in the bed. The eleven configurations exhibited L/d_p ratios ranging between 2.98 and 7.45.

10	0.873	0.417	2.602	234.4
11	0.873	0.417	6.507	586.1

The value of q was found by plotting the left side of Eq. [3] *vs.* (L/d_p) at constant Re. A least squares analysis of the slope gave a value of 0.83 for Re = 6, and 0.87 for Re = 11. The average value gave $q' = 0.85$, or $q = -0.15$.

The values of p and G were found by analysis of the limiting current data indicated by solid points in Fig. 1. The set of 184 data points was treated by linear regression analysis which gave $p = -0.554$ and $G = 2.944$. That is, the mass transfer correlation was found to be

$$j_D = 2.944\text{Re}^{-0.554}\left(\frac{L}{d_p}\right)^{-0.15} \quad [7]$$

$$1.8 < \text{Re} < 27$$

$$2.98 < \frac{L}{d_p} < 7.45$$

$$\text{Sc} = 1421$$

$$0.397 < d_p < 0.952 \text{ cm}$$

By linear regression analysis, the slopes on either side of Re = 12 in Fig. 1 were found to be statistically different

For Re < 12 (112 data points, 95% confidence level):

$$p = 0.567 \pm 0.005$$

$$G = 3.039 \quad [8]$$

For Re > 12 (72 data points, 95% confidence level):

$$p = 0.533 \pm 0.015$$

$$G = 2.797 \quad [9]$$

Because the confidence bands do not overlap, these results indicate that the linear correlation reported in Eq. [7] is a simplification. Since limiting current data were corrected by subtraction of background current, the difference in slope would not be attributed to a second electrolysis reaction. Indeed, the results of Karabelas, Wegner, and Hanratty (1) indicate that the range of Reynolds numbers used in this study does not lie in a region where a straight-line asymptotic correlation would be expected. Values of j_D calculated by Eq. [7], however, are within 3% and 1% of the values calculated with use of constants in Eq. [8] and [9], respectively.

Glass beads were used in the upstream section of the cell to establish uniform hydrodynamic conditions. The beads were of uniform size for all experiments (0.6 cm) whereas the packing particles ranged in size from 0.398 to 0.952 cm. Therefore, the data may be influenced by modest hydrodynamic rearrangement which accompanies flow into the porous electrode. Also, mass transfer entrance effects may be operative in the shallow beds used in this study, as would be indicated by the results of Fedkiw and Newman (21). Therefore, the weak L/d_p dependence found in Eq. [7] may be the result of various entrance effects which would not be experienced in deeper beds. Whereas these results indicate the need for additional investigation at the fundamental level, the point remains that most industrial porous electrodes are "shallow" (in order to accommodate potential distribution requirements), so that the correlations reported here are therefore useful for practical applications.

Nonuniform particle sizes: microscopic nonuniformity.—Results were obtained for working electrodes having two, three, four, and five different sizes of ball bearings placed randomly in the packed bed. These results are summarized in Table IV.

Eight sets of two-ball mixtures were studied as indicated in part A of Table IV. The upper portion of part A gives the weight fraction and size of each component in the electrode mixture. The average diameter for the mixture material was calculated with the rule

$$d_{pm} = \frac{1}{\sum_i \left(\frac{x_i}{d_{pi}}\right)} \quad [10]$$

This average diameter was then used to calculate values for ϵ_m, a_m, and L in a manner analogous to that

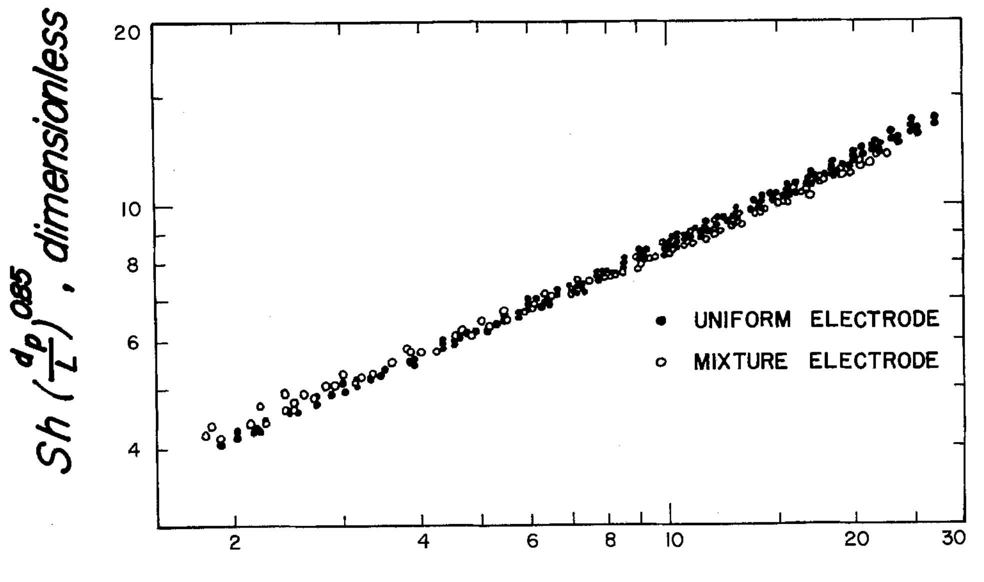

Fig. 1. Mass transfer correlation for packed bed electrochemical cells having both uniform and mixed particles sizes.

used for uniform packing as described previously. Since all bearings had the same density, the weight fraction in Eq. [10] is equivalent to the volume fraction occupied within the bed by each bearing size. The hollow circles in Fig. 1 illustrate how Eq. [7] and [10] correlate data in nonuniform beds.

The lower portion of part A contains examples of results for mixtures of two bearings. It was found that the discontinuity between the high and low flow rate regions centered about Re = 12 was not as distinct as had been the case with uniform packings. Therefore, the overall correlation given in Eq. [7] was used to predict the mass transfer limiting current for the entire range of flow rates studied. The second column in the lower portion of part A of Table IV lists the limiting current predicted by Eq. [7] for one particular example flow rate (V_∞ = 309 ml/min). The third column gives the experimental data measured at that flow rate.

To gain a measure of comparison between data and correlation, it is helpful to determine what the limiting current would have been had the electrode consisted only of the large bearings used in the mixture; in the lower portion of each section of Table IV, column four (labeled "0% smaller balls") lists those values for each run as computed with use of Eq. [7] at a flow rate of 309 ml/min. In a similar manner, column five lists the limiting current which would be expected, at a flow rate of 309 ml/min, had the electrode been constructed from only the smaller bearing size. These results will be used below when comparing experimental data with calculated values.

The last column in the lower portion of part A of Table IV gives the percent error between calculated and observed limiting currents for the two ball mixtures as computed by

$$\% \text{ error} = \frac{100}{N} \sum^{N} \left| \frac{I_{\text{lim, data}} - I_{\text{lim, calc}}}{I_{\text{lim, calc}}} \right| \quad [11]$$

where there are N data points. The percentage error listed in the last column was computed by averaging all data for whch the system was under mass transfer control.

In a similar manner, parts B and C of Table IV provide data and analysis for three, four, and five ball mixtures. The average of all errors for the two, three, four, and five ball mixtures were: 4.4, 2.6, 2.6, and 9.6%, respectively. These results illustrate that, over the range of parameters investigated here, Eq. [10] provides a good method for selecting the average diameter needed for predicting the mass transfer coefficient in porous electrodes fabricated from randomly mixed spherical particles.

Nonuniform particle sizes: macroscopic nonuniformities.—Nonuniform packed beds were also prepared by placing particles in two concentric zones each of which contained particles of a single size. Two different combinations of particle sizes were investigated, as listed in Table V. Different proportions of each pair of particle size were studied, ranging between all small particles and all large particles. The fraction of large and small particles is listed in Table V under headings x_l and x_s, respectively. Also given in Table V is the value of d_{p_m} computed by Eq. [10], and of ϵ_m and a_m computed by Eq. [4] and [5].

When the average geometric properties listed in Table V were used to compare the limiting current by Eq. [7], deviations between calculated values and measured data were found. The nature of these deviations was characterized by the following definition of percentage error

$$E_1 = \left(\frac{I_{\text{measured}}}{I_{\text{Eq. [7]}}} - 1 \right) \times 100 \quad [11a]$$

Figure 2 illustrates how E_1 varied with the fraction of large particles in the bed (x_l) for the two systems studied. As mentioned previously, the early experimental data reported in Fig. 2 were measured under conditions where appreciable background current was present owing to dissolved oxygen. Thus it was ex-

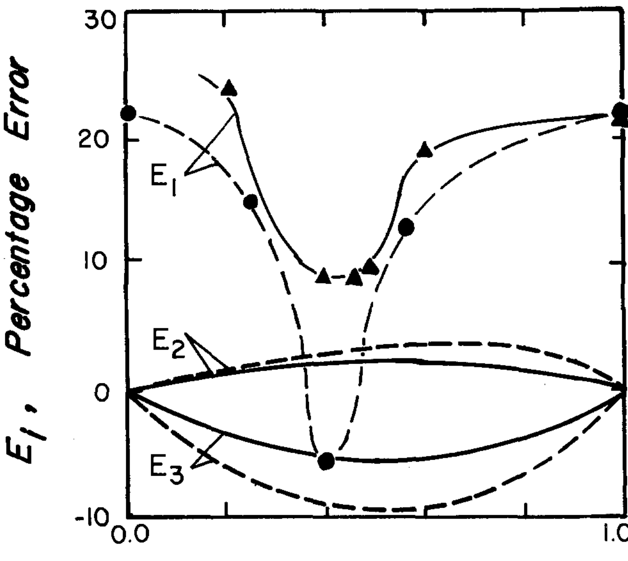

Fig. 2. Deviations from Eq. [7] for macroscopically nonuniform porous electrodes. (———: d_{p_l} = 0.714, d_{p_s} = 0.397; - - - - -: d_{p_l} = 0.873, d_{p_s} = 0.397). Errors defined by Eq. [11]-[13].

pected that positive errors should be observed. It is seen that when the bed consisted of nearly all small, or nearly all large particles, then the experimental data were indeed higher than the value computed by Eq. [7] and this (positive) deviation is attributed to the presence of oxygen. For intermediate ranges of $0.2 < x_l < 0.6$, experimental data dip sharply. Since the correlation illustrated in Fig. 1 served adequately to characterize uniformly dispersed mixtures of particles, it is tentatively concluded that the strong (negative) deviations in Fig. 2 must be the result of the macroscopic nonuniformities present in the packed bed.

Two routes were used to seek improved correlations of experimental data. In the first, it was assumed that fluid passed through the mixed bed at a rate which was everywhere uniform (plug flow). Such a situation would be encountered in practice if the flow resistance external to the packed bed was large and if no rearrangement of flow pattern occurred within the packed bed. The limiting current calculated by this method, $I_{\text{plug flow}}$, was put on the same comparative basis by defining

$$E_2 = \left(\frac{I_{\text{plug flow}}}{I_{\text{Eq. [7]}}} - 1 \right) \times 100 \qquad [12]$$

Results are shown in Fig. 2. It is seen that this method of prediction gives limiting currents which were slightly larger than the values computed by Eq. [7].

In the second method of calculation, it was assumed that the fluid distributed itself between the two portions of the bed such that the pressure drop across each portion was the same, and that no intermixing of fluid occurred between the two portions. By this method, the fluid flow rate was larger in the region having the larger particles since that region had the lower flow resistance. The limiting current calculated by this method, $I_{\Delta p}$, was also put on the same comparative basis by defining

$$E_3 = \left(\frac{I_{\Delta p}}{I_{\text{Eq.[7]}}} - 1 \right) \times 100 \qquad [13]$$

Results are shown in Fig. 2. It is seen that this method of prediction gave limiting currents which were slightly less than the values computed by Eq. [7].

On the basis of results given in Fig. 2, several observations can be made. Since the correlation given by Eq. [7] serves adequately to characterize uniformly dispersed mixtures of particles, it is tentatively concluded that the strong variations seen between $0.2 < x_l < 0.6$ in Fig. 2 are the result of macroscopic nonuniformities present in the packed bed. Calculations based on plug flow (E_2 curves) exhibit incorrect qualitative trends: experimental data (E_1 curves) exhibit deviations which are in the opposite direction from the plug flow results (E_2 curves). On the other hand, the constant pressure drop method gave results (E_3 curves) which are more like experimental data: (*i*) deviations in the negative direction are predicted, (*ii*) the deviations for the dashed lines are greater by a factor of two than the solid line.

Conclusions

Mass transport coefficients have been correlated by Eq. [7] over a range of operating conditions. When the bed is randomly packed with a mixture of up to five different spherical particle sizes, the average particle diameter defined by Eq. [10] may be used in the mass transfer correlation. It may therefore be anticipated that an integral form of Eq. [10] would be useful in situations where the packing material is characterized by a particle size distribution.

When the bed packing is segregated into two parallel flow zones having different particle sizes, then it was found that Eq. [10] may still be used to estimate mass transfer behavior via Eq. [7] although the results may be in error if $0.2 < x_l < 0.6$. Failure of simple correlations thus indicates that flow patterns are undoubtedly complex and are deserving of additional study at the fundamental level. The hydrodynamic studies of Stanek and Szekely (6) represent a fruitful starting position since these authors provide equations for predicting cross-flows in multiple porosity regions of the type investigated here.

The widest disparity between diameters of the largest and smallest sphere in an electrode was a factor of 2.40 in this study. A still greater disparity in size would eventually beget wholly different packing structures (like buckshot in an array of tennis balls) for which the foregoing correlations would not be expected to hold.

The present study has not addressed the role of particle shape on electrode performance. Gamson (22) was evidently the first to use empirical shape factors to correlate heat transfer data for beds containing spheres, cylinders, and various commercial packing materials. Those methods have been actively pursued in the chemical engineering literature and could be applied with relative ease to electrochemical analogues.

Electrochemical Studies of Triethylammonium Dichlorocuprate(I), A Room Temperature Fused Salt

James R. Silkey and John T. Yoke

Department of Chemistry, Oregon State University, Corvallis, Oregon 97331

ABSTRACT

Density, conductivity, and viscosity data are reported in the 25°-50°C range for the neat liquid $Et_3NHCuCl_2$ and for solutions containing CuCl and $CuCl_2$. The Walden product of the room temperature fused salt is not much lower than that of a molten alkali metal halide. A relation proposed by Frenkel, $\mu\Lambda^{(E_\mu^{\ddagger}/E_\Lambda^{\ddagger})}$ = constant, is followed closely by triethylammonium dichlorocuprate (I) and by solutions containing CuCl and $CuCl_2$. The $Cu/Et_3NHCuCl_2$ electrode was found usable as a reference electrode. A solution of $CuCl_2$ in $Et_3NHCuCl_2$ has an absorption maximum at 402 nm ($\epsilon = 2.02 \times 10^3$ liters $mole^{-1}$ cm^{-1}). Spectrophotometric studies in an optically transparent gold minigrid electrode cell are reported. Potentiometric data from this and from a $Cu/Et_3NHCuCl_2/Et_3NHCuCl_2$, $CuCl_2$(M)/Pt cell show approximate Nernstian behavior. Overpotential-current studies permit calculation of the exchange current density at each of the above electrode interfaces. Anodic and cathodic current-voltage plots obtained with a platinum working electrode in neat $Et_3NHCuCl_2$ in the region of the Cu(I)/Cu(II) redox couple have a remarkable appearance. They resemble a conventional cyclic voltammogram of a dilute solution even though the electrode reaction involves a constituent ion of the solvent itself. This is due to formation of a viscous film of the anodic product $CuCl_2$ on the electrode surface. Practical development of galvanic cells based on $Et_3NHCuCl_2$ electrolytes is limited by their high internal resistance.

Dichlorocuprate(I) salts with certain tertiary aliphatic ammonium and phosphonium cations are oils at room temperature and form glasses when cooled. Triethylammonium dichlorocuprate(I), $Et_3NH^+CuCl_2^-$, the prototype of these materials, is formed merely by bringing triethylammonium chloride and copper(I) chloride powders into physical contact. That such liquids truly are salts is proved by observation of the characteristic dichlorocuprate(I) ion frequencies in their infrared and Raman spectra (1). One postulate to explain why these salts are liquid is that a steric effect causes abnormally low lattice energies. A second reason is that a mixture of species is present, resulting in mutual melting point depression. The mixture arises from the operation of such complex anion equilibria as

$$CuCl_2^- + CuCl \rightleftharpoons Cu_2Cl_3^-$$

$$Cu_2Cl_3^- + Cl^- \rightleftharpoons 2CuCl_2^-$$

$$CuCl_2^- + Cl^- \rightleftharpoons CuCl_3^{2-}$$

Key words: fused salts, copper complexes, viscosity.

The existence of such equilibria was demonstrated by the effect of added triethylammonium (or phosphonium) chloride, and of added copper (I) chloride, on the intensities and frequencies of the complex anion vibrations. The electrolytic nature of these neat liquids was also demonstrated (1, 2) by their conductivities, which were, however, several orders of magnitude lower than typical for high temperature molten alkali metal chlorides.

Porterfield and his students at Hampden-Sydney College showed (2) that liquid triethylammonium dichlorocuprate(I) (which has only a light yellow color) is a chloride ion-rich solvent useful for observing the visible spectra of chloro complexes of various transition metals. They also observed the cyclic voltammogram of triethylammonium dichlorocuprate (I) dissolved in acetonitrile, demonstrating oxidation and reduction of the copper(I) in the complex anion. Finally, they showed that a voltaic cell with a potential of 0.85V results from partial electrolysis of neat triethylammonium dichlorocuprate(I) between inert

electrodes. The electrode reactions were taken to be

$$Cu^\circ + 2Cl^- \rightleftharpoons CuCl_2^- + e^-$$

$$CuCl_2 + e^- \rightleftharpoons CuCl_2^-$$

We now report additional electrochemical and related physical studies of systems based on triethylammonium dichlorocuprate(I).

Experimental

Materials.—Reagent Grade chemicals were used. Copper(I) chloride was prepared by the method of Keller and Wycoff (3). Triethylammonium chloride was prepared from freshly distilled triethylamine and 6M hydrochloric acid. The water was evaporated. The residue was recrystallized three times from absolute ethanol, dried at 110°, and ground. It was then finally dried at 110° for 18 hr, as was anhydrous lithium chloride. Copper(II) chloride dihydrate was converted to the anhydrous salt by similar heating.

Inert atmosphere techniques.—The dried chlorides were stored in a stainless steel dry box fitted with an evacuable entry port. The box atmosphere of Prepurified Grade nitrogen was continuously circulated through a tower containing BTS catalytic oxygen remover and through tubes of 4A, 5A, and 13X molecular sieves (4). All fused salt mixtures were prepared and transferred in this box. Mixtures were prepared by accurate weighing of the constituents with the exception of saturated solutions of lithium chloride and of triethylammonium chloride in liquid triethylammonium dichlorocuprate(I). These were prepared by equilibrating the fused salt solvent with an excess of each solid chloride and then filtering the mixture through a medium porosity glass frit. The filtrates were then analyzed for lithium and copper content, respectively. Lithium was determined by flame emission and copper by atomic absorption using an Instrumentation Laboratory 351 AA/AE spectrophotometer. All cells and vessels for physical, spectrophotometric, and electrical measurements were loaded and sealed with appropriate closures under nitrogen in the glove box. In no case was any interaction observed of the fused salt with the materials used for constructing and sealing the cells.

Densities.—These were measured using a specially constructed dilatometer, of approximately 5 ml capacity, whose bulb and graduated stem had been calibrated using a weighed quantity of freshly boiled distilled water (5). Precision was limited by measurement of volume, which was shown to be reproducible to two parts in 10,000; measurements of mass were one order of magnitude more precise. The assembly was then immersed in a bath whose temperature was controlled to ±0.1°.

Viscosities.—A modified Cannon-Fenske viscosimeter was constructed, which could be closed to maintain a dry nitrogen atmosphere. A rubber bulb on the side could be squeezed to pump the liquid into the upper reservoir. The viscosimeter was calibrated using aqueous solutions of glycerol (J. T. Baker Reagent Grade). Temperatures were controlled to ±0.05° and measured with a National Bureau of Standards calibrated thermometer. Calibration reference viscosities, μ, were inferred from solution compositions, which in turn were obtained from densities, ρ, determined using a dilatometer of about 50 ml capacity and calibrated as described previously. Density-composition-viscosity interpolations were made in the extensive "Table of Absolute Viscosities of Glycerol-Water Solutions" given by Segur (6). Solutions of 79, 91, and 96% concentration were measured at 25° and 30°. From the efflux times, t, the viscosimeter constant, k, was calculated, using the equation $\mu = k\rho t$, to be 0.4727 with an accuracy of ±0.2% in the viscosity range 30-200 cp and ±2% in the range 200-440 cp.

Conductivities.—An Industrial Instruments Model RC16 B2 bridge was used. The cell consisted of two parts with a standard taper joint in the middle; the platinized platinum electrodes were sealed in the top and dipped into the test liquid in the bottom part. The cell, whose constant was 0.100 cm^{-1}, was immersed in a bath controlled to ±0.1°. Conductivities were measured at a frequency of 1 kHz.

Electronic spectra.—Spectra of fused salt mixtures in stoppered 1 mm cells were recorded with a Cary 16 spectrophotometer. A Cary 118 spectrophotometer was used with the OTTLE cell, for which a special sample compartment carriage was constructed.

Electrochemical cells.—Copper and platinum wire and foil electrodes were polished with emery cloth and washed with nitric acid and distilled water. Working and auxiliary cell compartments were separated by coarse porosity glass frits. The OTTLE, an optically transparent thin layer electrode cell similar to that described by DeAngelis and Heineman (7), was also used in potentiometric, spectrophotometric, and electrolysis experiments. Microscope slides (Corning No. 2947) were cut in 6 cm lengths and, with the electrodes in place, were sandwiched together using strips of 2 mil adhesive-backed Teflon tape (Dilectrix Corporation Fluorofilm DF 1200) as spacers. The cell sides were glued and sealed with epoxy cement. The reference electrode, a strip of 0.005 in. copper foil, was mounted at the top, partly extending out of the cell. The auxiliary and slightly smaller working electrodes were made of gold minigrid mesh (Buckbee Mears Company) of 100 wires/inch with an optical transmittance of 82%. After the cell had been loaded in the dry box, its ends were sealed with Pyseal black wax (Fisher). External electrical contacts to the protruding gold minigrid leads were made with folded and clamped strips of aluminum foil. The optical pathlength of the OTTLE was calculated to be 0.168 mm from measurement of the absorbance at 426 nm of a potassium chromate solution in it and in a calibrated 1 mm spectrophotometer cell.

Electrochemical instrumentation.—Polarization and electrolysis studies were carried out with a Princeton Applied Research Model 173 potentiostat/galvanostat fitted with a Model 179 digital coulometer. Current and potential data were recorded on a Heath Model SR 204 recorder or read directly from a Fairchild Model 7030 digital voltmeter. Potential-current relationships for various electrode-fused salt interfaces were investigated using a Princeton Applied Research Model 174 polarograph. Current-voltage curves for slow voltage sweep experiments were recorded with a Varian F80A X-Y recorder. EMF measurements on galvanic cells were made using a Leeds and Northrup Student's Potentiometer or with a Fairchild Model 7030 digital voltmeter.

The $Cu/Et_3NHCuCl_2$ reference electrode.—All metal-fused salt interfacial potentials were measured with respect to this electrode. To test the polarizability of the reference electrode, galvanostatic currents were applied to a cell containing copper wire working, auxiliary, and reference electrodes immersed in neat triethylammonium dichlorocuprate(I). A length of glass tubing shielded the reference electrode from most of the bulk electrolyte but allowed electrical contact with the liquid through an open end. The area of the working electrode was about 1 cm^2. The potential of the working electrode was shifted by 1 mV on passage of a 1 μA current for 30 sec, and recovered the equilibrium value in 30 sec. This means that using such a $Cu/Et_3NHCuCl_2$ electrode as a reference with instrumentation of 1 MΩ impedence, a 1V potential could be measured to within an error of 1 mV.

Using the three compartment cell

$$Hg, Hg_2Cl_2, KCl\ (aq\ satd.)/Et_3NHCuCl_2/Et_3NHCuCl_2/Cu$$

the operational potential of the copper reference electrode plus junction potential was found to be −0.241V *vs.* SCE at 25°.

Overpotential measurements.—A two-compartment cell was used. One compartment contained an 18 cm^2 copper foil auxiliary electrode immersed in triethylammonium dichlorocuprate(I). For study of the electrode process

$$CuCl_2^- + e^- \rightleftharpoons Cu^\circ + 2Cl^-$$

the second compartment contained a sheathed copper wire reference electrode and a 1 cm^2 copper foil working electrode mounted orthogonally to the direction of the auxiliary electrode and coated with Apiezon black wax on its back side. The electrodes were immersed in triethylammonium dichlorocuprate(I). Similar platinum wire reference and 1 cm^2 platinum foil working electrodes were used, immersed in a solution of copper(II) chloride in triethylammonium dichlorocuprate(I), for overpotential studies of the electrode process

$$CuCl_2 + e^- \rightleftharpoons CuCl_2^-$$

In both cases, the electrolyte was stirred magnetically.

Results and Discussion

Densities.—Density data for triethylammonium dichlorocuprate(I) and for fused salt mixtures at several temperatures are listed in Table I and permit concentrations to be expressed both on weight and molarity bases. The molar volume of the fused salt exceeds the molar volumes of its solid constituents by 10.9%, corresponding to the expansion taking place during the markedly endothermic reaction

$$CuCl_{(c)} + Et_3NHCl_{(c)} \rightarrow Et_3NHCuCl_{2(l)}$$

The greater densities of copper(I) and copper(II) chlorides than of triethylammonium dichlorocuprate (I) account for the correspondence between increasing concentrations of these salts and the densities of fused salt mixtures containing them.

Spectra.—Pure triethylammonium dichlorocuprate (I) has no absorption maximum in the visible region; its pale yellow color is due to the tail of a u.v. charge-transfer absorption. A solution of copper(II) chloride in triethylammonium dichlorocuprate(I) is green, appearing nearly black if the concentration or path length is large. Such a solution absorbs continuously across the visible region and shows no maximum *vs.* air, but with the neat fused salt solvent in the reference beam it has a well-resolved absorption peak at 402 nm ($\epsilon = 2.02 \times 10^3$ liters $mole^{-1}$ cm^{-1}). These values are typical of various chlorocuprate(II) complexes (8). No special behavior is observed of the "intervalence transfer absorption" type (9-11), common for complexes containing a transition metal in two different oxidation states. Solutions of concentration up to 0.1M copper(II) chloride in triethylammonium dichlorocuprate(I) were found to obey Beer's law.

Electrolysis products.—That the cathodic product of electrolysis of neat triethylammonium dichlorocuprate (I) is metallic copper was determined by visual inspection of the deposit on a graphite electrode. The nature of the anodic product was determined using the OTTLE. The absorption spectrum of the solution in the region of the gold anode after electrolysis was identical to the spectrum of copper(II) chloride in triethylammonium dichlorocuprate(I).

Viscosities and conductivities.—Listed in Table I are viscosity and specific conductivity data at several temperatures for triethylammonium dichlorocuprate(I) and for solutions in it containing added copper(I) and copper(II) chlorides. Addition of either compound markedly increases the viscosity and decreases the conductivity. This was true for other solutes as well. For example, at 25° the specific conductance of a saturated solution of lithium chloride (LiCl mole fraction 0.00747) was 3.68×10^{-3} Ω^{-1} cm^{-1} and of a saturated solution of triethylammonium chloride (total Et_3NHCl mole fraction 0.5098) was 3.74×10^{-3} Ω^{-1} cm^{-1}.

The viscosity times the specific conductance (Walden) product of triethylammonium dichlorocuprate(I) in the 25°-50°C temperature range is compared with data (12) for two molten alkali metal halides in Table II. The Walden product of molten salts over a temperature range is not constant. It is noteworthy, however, that the values of this product for triethylammonium dichlorocuprate(I) near room temperature are not all that different from the values for the much hotter molten alkali metal halides. The lower order of magnitude of the conductivity of the room temperature fused salt relative to an ordinary molten electrolyte can be attributed to the higher order of magnitude of its viscosity. This complements the vibrational spectroscopic evidence that the room temperature liquid is completely made of ions.

The equivalent conductance Λ (Ω^{-1} cm^2 $equiv.^{-1}$) of neat triethylammonium dichlorocuprate(I) was calculated from its equivalent weight, W, density, ρ, and specific conductance, κ, by the equation

$$\Lambda = \kappa W/\rho$$

For the solutions, the same form of equation was used, with the weighted average equivalent weight $\overline{W}$ calculated from

$$\overline{W} = \Sigma f_i W_i$$

where f_i is the fraction of the total equivalents contributed by the ith component of concentration C_i and cation charge Z_i

$$f_i = C_i Z_i / \Sigma C_i Z_i$$

Arrhenius-type behavior was observed for the temperature variation both of the viscosities, μ, and equivalent conductances, Λ, of the neat fused salt as well as of solutions in it. Plots of log μ and log Λ *vs.* $1/T$ had good linearity, in accordance with the functions

$$\mu = A \exp(-E_\mu^{\ddagger}/RT)$$

Table I. Densities, viscosities, and specific conductivities of fused salt mixtures at various temperatures*

Electrolyte composition (mole fraction)			Density (g/cm^3)				Viscosity (cp)				$10^3 \times$ sp. cond. (Ω^{-1} cm^{-1})

* Ref. (12).

and

$$\Lambda = A' \exp(-E_\Lambda^{\ddagger}/RT)$$

The energies of activation for viscous flow ($E_\mu^{\ddagger}$) and for electrolytic conductance ($E_\Lambda^{\ddagger}$) are given in Table III. The $E_\mu^{\ddagger}$ values are in the range generally found for fused salts (13), but the $E_\Lambda^{\ddagger}$ values are about three times larger than usually observed. Values of the empirical function proposed by Frenkel (14)

$$\mu\Lambda^{(E_\mu^{\ddagger}/E_\Lambda^{\ddagger})} = \text{constant}$$

are also given in Table III. It is interesting that these values do indeed show remarkable constancy in the 25°-50°C range for each given composition.

Potentiometry.—Potential measurements were made on galvanic cells of the type

$$Cu/Et_3NHCuCl_2/Et_3NHCuCl_2,\ CuCl_2(M)/Pt$$

in a two-compartment cell and with varying concentrations of copper(II) chloride and corresponding variations in the copper(I) concentration [as dichlorocuprate(I) ion] in the catholyte. Similar measurements were made in the OTTLE cell

$$Cu/Et_3NHCuCl_2/Et_3NHCuCl_2,\ CuCl_2(M)/Au$$

The data were combined in a plot of log [Cu(I)]/[Cu(II)] vs. potential, which was linear at copper(II) concentrations of 0.1M or less with a least squares slope of 55.1 mV/decade. This agrees well with the Nerstian theoretical slope of 59.2 mV/decade at 25°. There was marked deviation at higher copper(II) concentrations.

Overpotential measurements.—The effects of anodic and cathodic polarizing currents were determined for the processes

$$CuCl_2^- + e^- \rightleftharpoons Cu° + 2Cl^-$$

on a copper electrode surface and

$$CuCl_2 + e^- \rightleftharpoons CuCl_2^-$$

on a platinum surface. In the low overpotential region 5 mV ≧ η ≧ −5 mV, plots of current *vs.* overpotential showed no discontinuity at zero potential and indeed were quite linear. The values of $di/d\eta$, which are useful criteria of electrode behavior (15), are given in Table IV. The linearity of these plots is in accord with the simplified form (for a one-electron process with a change transfer rate-determining step) which the Butler-Volmer equation assumes in the limit of low overpotential

$$i = i_o F\eta/RT$$

and permitted determination of the exchange current densities, i_o given in Table IV.

Cyclic voltage sweep studies.—In unstirred neat triethylammonium dichlorocuprate (I), potential scans were carried out, first anodic and then cathodic, with sweep rates of 2-10 mV/sec using a conventional three-electrode potentiostat. The cell had a platinum or glassy carbon working electrode, a copper reference electrode, and a platinum auxiliary electrode. The general features of the current-voltage curves obtained in this way were reproducible, but details depended on the age and history of the electrolyte.

Such curves have a remarkable and unexpected appearance, considering that the anodic process

$$CuCl_2^- \rightarrow CuCl_2 + e^-$$

involves a constituent ion of the solvent itself, with a copper(I) concentration of 5.9M. [Of course, the actual electroactive species may or may not be the dichlorocuprate(I) ion; however, reversible dissociation reactions of chloro complexes of d^{10} copper(I) would be expected to have rapid rates.] A typical scan at 21° is shown in Fig. 1(a), and resembles a cyclic voltammogram of an electroactive species in dilute solution, where the limiting current-voltage relations involve diffusion control.

Qualitatively, current-voltage relations of the type observed here are attributed to blockage of the electrode surface by formation of a poorly conducting

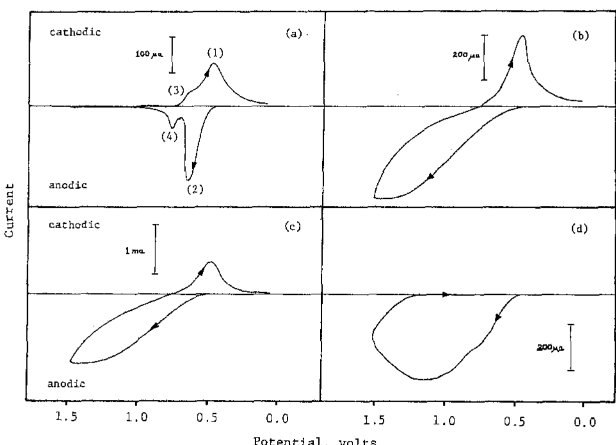

Fig. 1. Effect of temperature on voltammetry curves obtained at a platinum electrode in triethylammonium dichlorocuprate (I): (a), 21°C; (b), 34°C; (c) 51°C; (d), then cooled to 13°C.

film (16). This dark green copper(II) chloride film can be seen on the electrode surface after the anodic portion of the scan and has the same appearance as that electrogenerated in the OTTLE experiments. The previously described physical measurements demonstrated that as the concentration of copper(II) chloride in triethylammonium dichlorocuprate(I) increases, there is a marked increase in viscosity and decrease in conductivity.

Quantitatively, according to the theoretical treatment developed by Calandra and co-workers (17) and supported by their experimental observations in cases of insoluble films of anodic products blocking electrode surfaces, one expects a linear dependence on the square root of the scan rate of both the potential of the peak maximum and of the current at that point. As shown in Fig. 2, this square root dependence is observed in the present work.

The cyclic voltage sweep in Fig. 1(a) provides evidence for two anodic and two cathodic reactions. The larger anodic and cathodic peaks are a combination based on one oxidation-reduction process, and the smaller anodic and cathodic peaks correspond to another. This was proved by carrying out the scan sweep over limited parts of the range. The first anodic reaction commenced at about 0.5V with respect to the copper reference electrode. Following onset of the reaction, a green deposit was observed adhering to the working electrode. That this first anodic product is copper(II) is implied by the resemblance between this potential and appearance of the product to those observed in the OTTLE coulometric experiment. It is not known what the second anodic product is.

The peak shapes are very temperature dependent as shown in Fig. 1(b, c, d). Polarograms at 34° and 51°C, in addition to showing the expected increase in current, lack the definition observed at 21°. The polarogram obtained at 13°C, made following the 51° scan, shows the same lack of anodic peak definition observed at 51°. The cathodic process on reversing the sweep direction has vanished at 13°, indicating some change in the nature of the anodic deposit. The considerable decrease in viscosity of the anodic film on raising the temperature accounts for the changes seen in Fig. 1(b, c). The viscous gel formed by the concentrated film of anodic product on the electrode surface evidentally has become completely rigid on cooling to 13°C, as indicated by the disappearance of the cathodic process on reversing the scan, seen in Fig. 1(d).

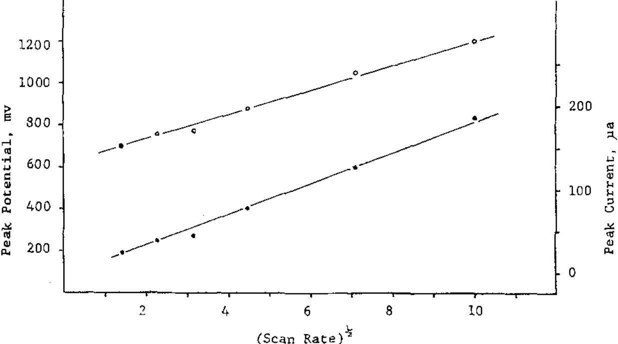

Fig. 2. Dependence of the peak potential (upper line) and peak current (lower line) on the scan rate.

Galvanic cells.—Several types of cells were prepared using copper foil and platinum or graphite (Grafoil) foil electrodes and various separator materials (18). The electrolyte was prepared either by preelectrolysis of neat triethylammonium dichlorocuprate(I) in the cell, or by using various triethylammonium dichlorocuprate(I)-triethylammonium chloride mixtures on the anode side and various triethylammonium dichlorocuprate(I)-copper(II) chloride mixtures as the catholyte. Several current-voltage-time tests of such cells were undertaken (19). Open-circuit voltages of about 0.75V were generally observed. In limited studies, performance of the cells under conditions of sustained discharge was found unsatisfactory due to their high electrolyte viscosity and high internal resistance.

Acknowledgments

We thank the Oregon State University Research Council for funds used in the construction of the OTTLE and other apparatus. Helpful discussions with Professors Harry Freund and Allen B. Scott are acknowledged with thanks.

Manuscript submitted May 28, 1979; revised manuscript received Nov. 11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Theoretical and Experimental Modeling of Surface Leveling in ECM under Primary Current Distribution Conditions

R. Sautebin, H. Froidevaux, and D. Landolt*

Materials Department, Swiss Federal Institute of Technology, Lausanne, Switzerland

ABSTRACT

Finite element (FE) numerical simulation was employed for studying the influence of geometrical factors on the rate of leveling of a triangular surface profile during anodic dissolution in ECM at constant interelectrode gap under conditions of primary current distribution. Theoretical results were verified experimentally with a laboratory ECM apparatus using active dissolution of copper in $NaNO_3$ as model reaction. The experimentally observed decrease with time of profile amplitude corresponds well to that predicted theoretically. At long dissolution times, experimental surface roughness does not reach zero, however, because microroughness develops due to crystallographic etching of the anode.

Electrochemical machining (ECM) is a high rate electrolysis process involving time dependent shape change of the anode. Shape prediction problems in ECM can be divided into two categories: prediction of tool shape necessary to produce a given workpiece, and prediction of the shape evolution of the workpiece during machining with a given tool. Deburring and surface smoothing are ECM operations falling into the second category. They are based on the observation that, upon machining with a flat tool, protruding parts of a rough surface dissolve at a higher rate than receding parts. The degree of preferential dissolution determines how much metal has to be dissolved overall to achieve a desired leveling effect. It will depend on geometrical and on electrochemical parameters.

A study involving theoretical and experimental modeling was initiated at our laboratory with the aim of learning more about the mechanism of surface leveling under ECM conditions and providing guidelines for predicting the memory effect of the anode, *i.e.*, the extent of metal dissolution necessary to change a given anode surface profile into that of the cathode.

Theoretical modeling of surface smoothing requires calculation of the current distribution on the anode and of the resulting change in its shape with time. The problem of current distribution on a time invariant triangular two-dimensional surface profile has been treated analytically by Wagner (1). McGeough (2) has given a solution for the time dependence of the amplitude of a sinusoidal profile during anodic dissolution. For the calculation of complex shape changes the use of numerical rather than analytical procedures is indicated. Riggs (3) has developed a sophisticated computer program for predicting the influence of ECM operating variables on the accuracy of shape reproduction obtained during simple cavity sinking operations. The author used a finite difference method of calculation and was able to take into account local conductivity variations in the gap due to joule heating and to the presence of gas. In recent years the finite element method (FEM) has become increasingly popular in different branches of engineering including structural engineering and heat transfer (4-7). Compared to finite difference methods the FEM requires less elaborate programming and is more easily adaptable to time-dependent geometrical conditions. At the time the present work was initiated no application of FEM to electrochemistry was known to the authors. However, recently an excellent discussion of the relative merits of FEM and finite difference methods for solving electrochemical problems has been published by Alkire and Bergh (8) who used FEM to predict the shape change of the cathode in an electrodeposition cell.

Experimental modeling of the ECM leveling process requires the availability of an anode of well-defined surface profile and knowledge of reaction stoichiometry, kinetics, and mass transport conditions. High rate anodic copper dissolution in KNO_3 solution has been extensively studied in the past (9-11). Copper dissolution in this electrolyte proceeds in the active mode up to a critical current density, the value of which is mass transport controlled and may be many A/cm^2 under ECM flow conditions. The copper-sodium nitrate system was therefore chosen for simulating leveling behavior under active dissolution conditions.

In the present paper, surface leveling under conditions approaching primary current distribution, where geometrical parameters rather than electrode overvoltage are controlling, is investigated. Surface leveling under secondary and tertiary current distribution conditions is being studied at this time in our laboratory and results will be reported at a later date. Original surface roughness is modeled by a two-dimensional triangular wave profile. Shape evolution with dissolution time is computed numerically using FEM based on a general computer program (7). Calculations are tested experimentally in an ECM test rig under conditions of constant interelectrode gap.

Theoretical Simulation by FEM

Fundamental equations.—The two-dimensional model of the interelectrode gap is schematically shown in Fig. 1. Throughout the present calculations, it is assumed that the average interelectrode distance l is much longer than the original surface profile amplitude ϵ_0, $l >> \epsilon_0$. Potential distribution in the interelectrode gap at any time is given by Laplace's equation

$$\nabla^2\phi = 0 \quad [1]$$

It is assumed that local conductivity changes due to joule heating or gas evolution are negligible. The current density i at any point in space is given by Eq. [2] where κ is the specific electrolyte conductivity

$$i = -\kappa\nabla\phi \quad [2]$$

The local anodic dissolution rate v_a (cm/sec) is given by Faraday's law

* Electrochemical Society Active Member.
Key words: dissolution, anode, FEM.

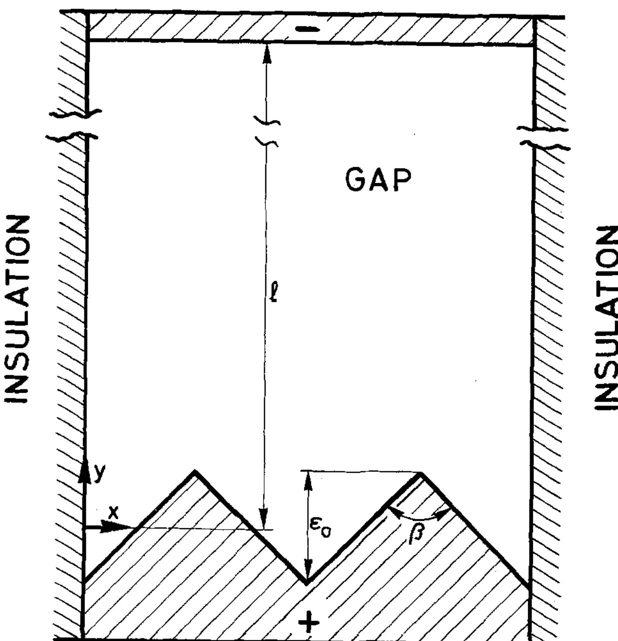

Fig. 1. Electrochemical cell geometry with triangular wave surface profile of the workpiece.

$$v_a = \frac{M\theta i}{n\rho F} \quad [3]$$

Here M is the atomic weight of the metal, θ is the current efficiency for metal dissolution, ρ is the density of the anode metal.

The boundary conditions are the following

at the anode

$$\phi = \phi_A \quad [4]$$

at the cathode

$$\phi = 0 \quad [5]$$

at insulating boundaries (planes of symmetry)

$$\frac{d\phi}{dX} = 0 \quad [6]$$

Equations [1]-[6] allow one to calculate the local dissolution rate on the anode at any given time. To obtain the decrease in amplitude as a function of dissolution time, the calculation is repeated for suitably chosen time intervals using the computed roughness profile of each preceding calculation as the initial condition for the subsequent step.

Method of solution.—The system of Eq. [1]-[6] was solved numerically by FEM using a CDC Cyber 7328 computer. For the theory of FEM the reader is referred to the literature (6, 7). In brief, the method consists in finding a function Φ which minimizes the energy density of the electric field in the interelectrode space and which satisfies the boundary conditions. For this purpose, the interelectrode space is divided into a finite number of small elements, in this case triangles (Fig. 2). Discrete linear potential functions Φ_i are defined for each node i corresponding to the peak of a triangle. The problem of searching the unknown potential ϕ then reduces to solving a system of linear equations expressed by Eq. [7].

$$A\underline{\phi} = \underline{\mathbf{f}} \quad [7]$$

Here $\underline{\phi}$ is a vector $\underline{\phi} = (\phi_1\ \phi_2)$, A is a symmetrical matrix (rigidity matrix) the value of which depends on the triangulation employed, and $\underline{\mathbf{f}}$ is a vector depending only on boundary conditions.

With the FEM, the potential gradient at the nodes is not well defined but it can be approximated using Eq. [8]

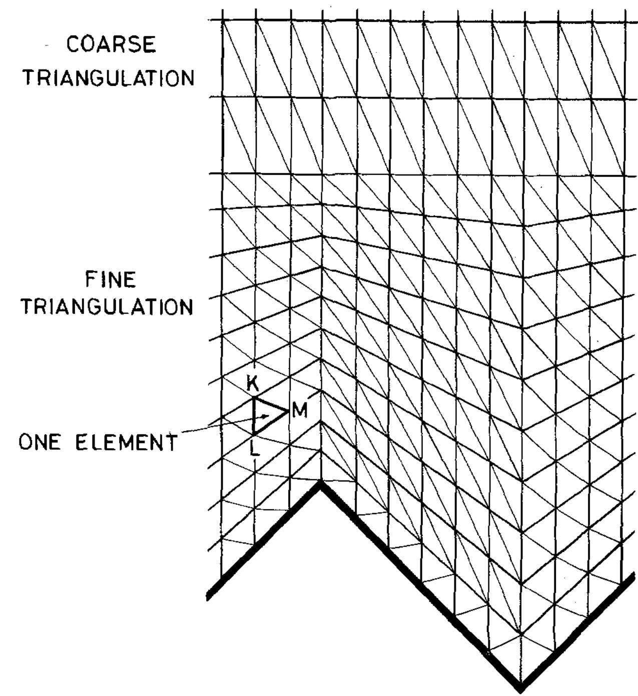

Fig. 2. Division of interelectrode space in finite triangular elements. K, L, M are the nodes of an element.

$$\overline{E}_s = \sum_{i=1}^{k} S_i E_i \Big/ \sum_{i=1}^{k} S_i \quad [8]$$

Here $\overline{E}_s$ is the mean potential gradient at node s, S_i is the area, and E_i the (constant) gradient corresponding to a given triangle i. The summation is made over all k triangles having a common node s. Equation [8] is applicable to the computation of the potential gradient at sharp corners of the profile.

The accuracy of the approximation of the potential distribution depends on the node density which has to be chosen sufficiently high. The FEM allows one to have a higher node density in the region of primary interest, *i.e.*, nearer the anode surface than in the rest of the gap (Fig. 2). For the present computations, it was ascertained that a further increase in node density did not change obtained results significantly.

The numerical calculation involves the following steps:

1. Read data, initial geometry, electrochemical parameters, and boundary conditions;
2. Label triangles in interelectrode space;
3. Compute rigidity matrix A and second member $\underline{\mathbf{f}}$;
4. Solve system of linear equations by overrelaxation;
5. Calculate potential gradients at the anode and the corresponding shape change for a given time interval;
6. Repeat procedures 1-5 until the original profile has disappeared;
7. Print out results of computations in dimensionless form.

Experimental Method and Apparatus

To test theoretical predictions experiments were carried out in a laboratory ECM rig at constant interelectrode gap. The apparatus consists of an electrochemical cell with moving anode through which the thermostated and filtered electrolyte is recirculated by means of a controlled volume two piston pump equipped with an attenuator to dampen flow pulsations. The electrochemical cell is shown in Fig. 3. It consists of two transparent plexiglass bodies (J, K) separated by a Teflon spacer (F) which fixes the dimensions of the rectangular flow channel (0.5 × 3 mm cross section). The flat stainless steel cathode (B) is in a fixed posi-

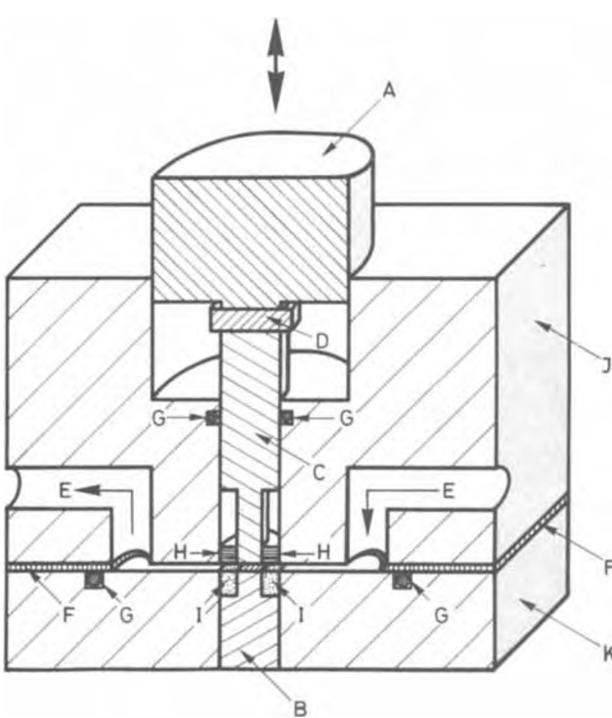

Fig. 3. Flow channel cell with moving anode (schematic): (A) anode support with controlled rate of advance; (B) fixed cathode; (C) moving anode; (D) connecting screw; (E) electrolyte flow; (F) Teflon spacer; (G) O-ring; (H) Teflon joints; (I) araldite mould; (J) fixed plexiglass cell body; (K) detachable plexiglass cell body.

tion flush with the channel wall. The anode (C) is sealed with Teflon joints (H) and O rings (G). It can be advanced continuously towards the cathode at rates varying from 1 μ/min to 6 cm/min. Anode movement is controlled by a stepping motor allowing for precise control of feed rate and position ($\pm$ 1μ). The anode is 99.9% copper, the geometrical surface area exposed to the electrolyte is the same as that of the cathode (0.5 $\times$ 3 mm). The anode surface is machined mechanically to a triangular profile of amplitude $\epsilon_o = 50\mu$ and an opening angle of $\beta = 95.5°$. Real anode surface at the beginning of an experiment is 0.203 cm^2. During the experiments the triangular profile is oriented parallel or perpendicular to the flow direction.

All experiments are performed at a constant linear flow rate of the electrolyte of 20 m/sec corresponding to a Reynolds number of 19,000. A 2M $NaNO_3$ solution prepared from analytical grade chemicals is employed as electrolyte. Electrolyte temperature is 25°C in all experiments. Due to the high flow velocity employed conductivity changes in the electrolyte gap due to joule heating and cathodic gas evolution are negligible.

To simulate leveling experimentally under conditions approaching primary current distribution, operating variables have to be chosen in such a way that electrode polarization and mass transport effects are negligible. In the present study, a current density of 10 A/cm^2 was applied at a linear flow rate of the electrolyte of 20 m/sec. Under these conditions the value of applied current density corresponded to approximately 10% of the value of the critical mass transport controlled current density for the transition from active to transpassive dissolution. Mass transport effects, therefore, should not affect obtained results. The importance of activation polarization for current distribution can be estimated by considering the Wagner number W_a

$$W_a = \left(\frac{d\eta}{di}\right)\frac{\kappa}{L} \quad [9]$$

Here $d\eta/di$ is the slope of the current voltage curve, κ is the electrolyte conductivity, and L is a characteristic length of the system. Primary current distribution prevails if $W_a << 1$, secondary current distribution if $W_a >> 1$. For active copper dissolution Tafel polarization can be assumed (10). The characteristic length L for surface leveling may be taken equal to ϵ_o. Equation [9] then becomes

$$W_a = \frac{b\kappa}{2.3\, i\epsilon_o} \quad [10]$$

Numerical values typical for the present experiments are $b = 40$ mV [Tafel slope for high rate copper dissolution in sulfuric acid (10)], $\kappa = 0.112\ \Omega^{-1}\ cm^{-1}$, $i = 10\ A/cm^2$, $\epsilon_o = 5 \times 10^{-3}$ cm, and the resulting value for the Wagner number is $W_a = 0.04$. The condition for primary current distribution, $W_a << 1$ is therefore well fulfilled.

All experiments were performed at constant current. At the beginning of an experimental run, the anode was positioned flush with the channel wall. Anode feed rate was then adjusted such that the position of the electrode surface with respect to the channel wall remained unchanged during an experiment, *i.e.*, the feed rate was equal to the average dissolution rate. Dissolution experiments were carried out in successive steps. After each step, the surface profile was determined with a mechanical surface tester (Talysurf, Model 10), then the electrode was reintroduced into the electrolysis cell. Some surface profiles were also observed by means of a scanning electron microscope. Figure 4 illustrates the original triangular surface profile of the anode and its shape evolution with increasing dissolution time.

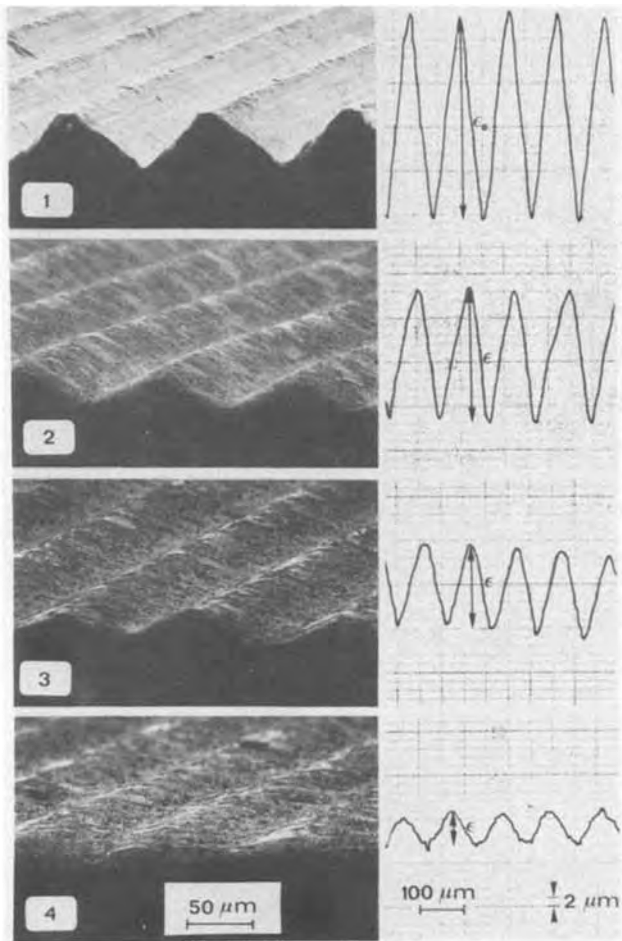

Fig. 4. SEM micrographs and surface tester traces illustrating the time evolution of a triangular profile during leveling. Pictures 1-4 correspond to points marked in Fig. 7.

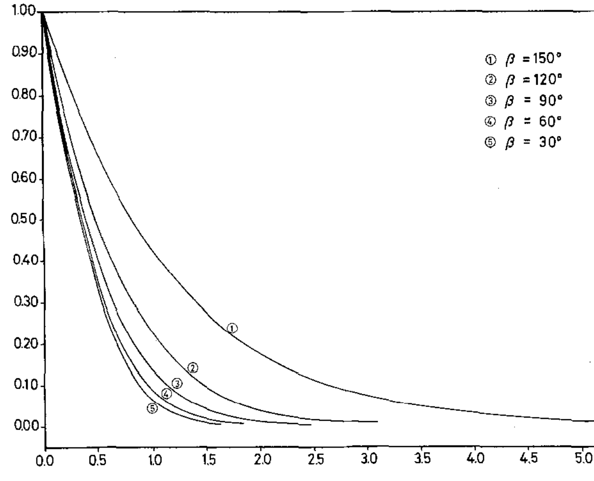

Fig. 5. Computed curves showing the influence of profile angle β, on leveling rate. $\epsilon_0/l = 0.095$.

Results and Discussion

Figures 5 and 6 give results of numerical computations. The decrease in relative amplitude ϵ/ϵ_0 is plotted as a function of the dimensionless dissolution time τ which is defined by Eq. [11]

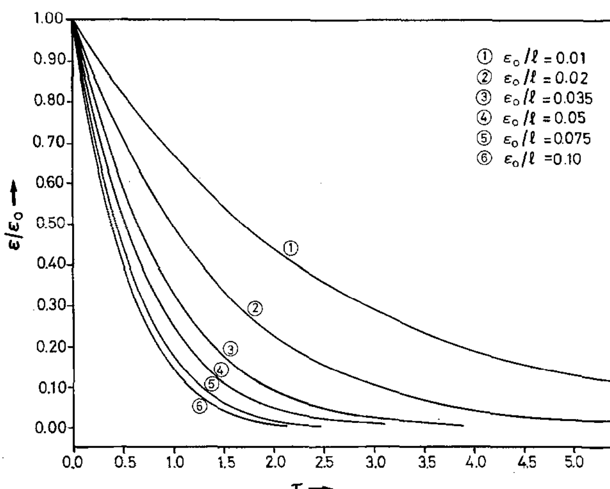

Fig. 6. Computed curves showing the influence of relative rugosity, ϵ_0/l, on the leveling rate, $\beta = 95.5°$.

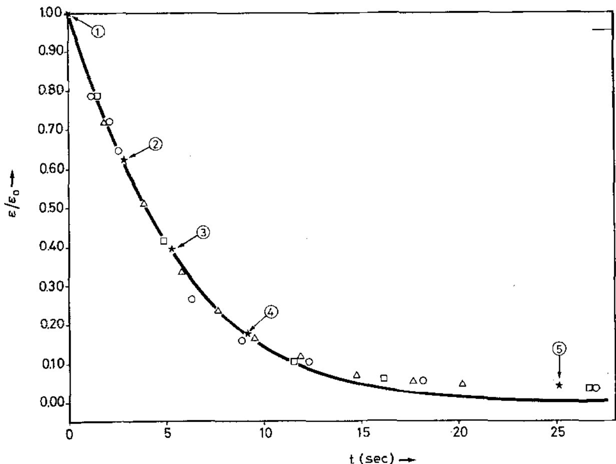

Fig. 7. Theoretical (solid line) and experimental leveling rates as a function of dissolution time, surface profile oriented perpendicular (○, △), and parallel (□) to the flow direction. The symbol (*) designates experimental points shown in Fig. 4 and 8. Profile angle $\beta = 95.5°$.

Fig. 8. SEM micrographs and profilograms illustrating microrugosity resulting at long dissolution times. Experimental conditions correspond to Pt. 5 in Fig. 7.

$$\tau = t \frac{M\theta I}{nF\rho\epsilon_0 A} = \frac{tv}{\epsilon_0} \quad [11]$$

Here I is the applied current, A is the geometrical area of the anode, t is the dissolution time, and v is the average rate of dissolution of the anode which for equilibrium gap conditions is equal to the cathode feed rate.

Figure 5 shows the influence of opening angle β. The larger β, the less efficient is the leveling process, *i.e.*, the longer is the time required to achieve a desired surface smoothness. Decreasing the value of β leads to faster leveling but a limiting value is reached at small angles when dissolution proceeds almost exclusively from the peaks. The influence of the magnitude of the initial amplitude of the surface profile with respect to the electrode distance l is shown in Fig. 6. The smaller the ratio ϵ_0/l, the less efficient is the leveling process. This behavior is intuitively understandable since for small values of ϵ_0/l the potential difference relative to the applied cell voltage between the location of peaks and valleys is smaller.

The rate of mass transport controlled leveling of a sinusoidal surface profile in presence of a stagnant diffusion layer at the anode has been calculated by Wagner (12) who gave an analytical solution of Fick's law for the limiting conditions $\epsilon_0/\delta << 1$, and $\lambda >> \epsilon_0$ where δ is the thickness of the stagnant diffusion layer, and λ the wavelength of the sinusoidal profile. From a mathematical point of view Wagner's solution corresponds to the solution of Laplace's equation given by McGeough (2), with the difference that the characteristic distance is the diffusion layer thickness δ in the first case, and the interelectrode distance l in the second case. It can be shown that present numerical computations applying to triangular profiles of different opening angle β at different interelectrode distance l approach Wagner's limiting solution for very large values of opening angle and of interelectrode distance, *i.e.*, when $\beta \rightarrow 180°$ and $\epsilon_0/l \rightarrow 0$.

Figure 7 shows a comparison between theoretical and experimental results for a ratio $\epsilon_0/l = 0.1$ and an opening angle of $\beta = 95.5°$. The good correspondence of theoretical and experimental data for dissolution times smaller than 15 sec confirms the validity of the numerical computations and experimental procedures used. The experimentally determined rate of leveling is independent of the orientation of the triangular profile with respect to flow direction. This confirms that mass transport effects were indeed absent under the conditions of present experiments. For dissolution times longer than 15 sec or $\epsilon/\epsilon_0 < 0.05$ measured points in Fig. 7 deviate from the calculated curve. This behavior is due to the development of surface microroughness the wavelength of which is independent of the wavelength of the original triangular surface profile. This is evidenced by the SEM micrographs of Fig. 8 which clearly reveal the grain structure of the anode indicating that the development of microroughness is due to the crystallographic nature of the dissolution process. The role of crystallographic factors in high rate anodic copper dissolution in the active potential region has been discussed previously (11).

In principle, under ideal primary current distribution conditions crystallographic factors should play no role since by definition system behavior is governed entirely by geometrical factors. To explain the apparent discrepancy between observed and calculated behavior at long dissolution times, one has to consider the value of the Wagner number W_a. It was shown above that at the beginning of the dissolution experiment $W_a = 0.04$, *i.e.*, $W_a << 1$. However, as the surface profile amplitude decreases the value of W_a increases since one may set now $W_a = b\kappa/2.3i\epsilon$. Indeed, for $\epsilon/\epsilon_0 \approx 0.05$ corresponding to $t \geqq 15$ sec one obtains $W_a \approx 1$, *i.e.*, the condition for primary current distribution, $W_a << 1$, is no longer fulfilled. Electrode polarization, therefore, is no longer negligible and crystallographic factors which introduce local variation of overvoltage on a microscopic scale become significant.

Summary and Conclusions

The present study confirms that FEM is useful for simulating current distribution in electrochemical cells involving electrode shape changes. The influence of geometrical variables on the rate of anode leveling under ECM conditions at constant gap has been modeled for primary current distribution conditions and theoretical results have been verified experimentally. The use of FEM to predict leveling behavior can be extended to include other surface profiles and/or electrochemical kinetics including transpassive behavior. The approach outlined in this paper involving theoretical and experimental modeling, therefore, should eventually contribute to further our present understanding of the mechanisms which determine surface finish resulting from anodic dissolution processes such as ECM and electropolishing.

Dependence of Lithium-Silicon Electrode Potential and Lithium Utilization on Reference Electrode Location

Randall N. Seefurth* and Ram A. Sharma*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

Lithium-silicon electrodes are undergoing development for use as negative electrodes in Li/FeS_2 compact cells (1). Lithium utilizations obtained from Li-Si electrodes having an initial composition of $Li_{15}Si_4$ were reported in a recent publication (2). The measurements were made at current densities between 20 and 1000 mA/cm^2 and at temperatures between 675° and 750°K using a cell similar to the one shown in Fig. 1A. During cycling, the voltages of the Li-Si working electrode were monitored by use of a 40 atomic percent (a/o) Li-Al reference electrode placed behind it. The working electrode was discharged to a 0.5V cutoff voltage with respect to the reference electrode and exhibited three voltage plateaus. The lithium utilizations were then calculated by dividing the plateau(s) capacity obtained during discharge by the theoretical capacity of the corresponding plateau(s).

Normally, in the measurement of overpotential of an electrode, a capillary which is connected through the electrolyte column to a reference electrode is placed in front of the electrode. The design and location of this capillary has been the topic of a number of research papers (3-6). It has been concluded in these papers that the overpotentials of an electrode measured by locating a capillary end at a distance larger than four times the external radius of the capillary from the electrodes face, and correcting for the electrolyte resistance losses, do not involve any appreciable error. It was also pointed out that significant error in overpotential measurements can occur when the capillary is placed on the insulated back side of the electrode.

In the measurement of lithium utilizations reported earlier (2), the capillary reference electrode approach was not adopted because capillary construction material which was compatible with the cell environment was not easily available. It also appeared difficult to avoid shielding of current from the electrode by the use of a capillary in this type of cell.

Due to the above reasons, lithium utilizations were measured placing the Li-Al reference electrode on the back side of the working electrode. The unconventional location of the reference electrode could cause errors in the monitored working electrode voltages, particularly at higher current densities. This was brought to our attention by one of the referees of our paper (2). He pointed out that these voltage errors in turn could lead to errors in the lithium utilizations we reported. Therefore, the present experiments were carried out to determine the variation in the measured value of the working electrode voltage with different locations of the reference electrode, the extent of error in the working electrode voltage when the reference electrode is placed behind it, and subsequently, the magnitude of any errors in the lithium utilizations reported earlier (2).

Experimental

The materials used, electrode preparation, and experimental setup procedures were the same as reported in Ref. (2).

The working electrode was prepared by inserting a 98% porous nickel current collector into a 5 mm long and 25 mm diam stainless steel chamber with one end enclosed by spot-welding a double layer of screens (400 followed by 150 mesh). The electrode was completed by vibration-loading it with 60/100 mesh particle-size Li_2Si and enclosing the open end with screens.

In the present experiments, a liquid lithium counterelectrode was used instead of the Li_2Si-Si counterelectrode, and two 40 a/o Li-Al reference electrodes were used, one behind the working electrode and one beside it (Fig. 1B). Liquid lithium electrode preparation has been reported before (7, 8); this electrode also has been used as a reference electrode (9, 10). However, it is not normally used as a counterelectrode in Li-Si alloy electrode tests because it reacts with the LiCl-KCl electrolyte (11).

The cycling was carried out at various constant current densities at 675°K, and the discharges were terminated at a 1.0V cutoff voltage with respect to the liquid lithium counterelectrode. The working electrode-to-counterelectrode voltages were corrected for electrolyte resistance losses using the electrolyte conductivity value of 1.247 Ω^{-1}-cm^{-1} reported by Van Artsdalen and Yaffe (12), with an electrode separation of 0.5 cm and an area of 5.0 cm^2 for the cell constants. These working electrode voltages with respect to lithium were then converted to those with respect to 40 a/o Li-Al using emf data published earlier (13).

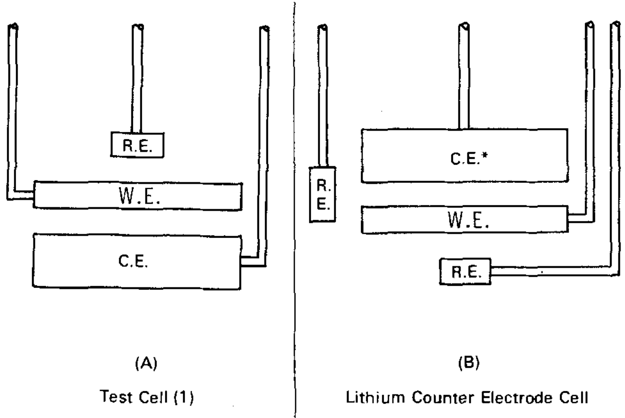

Fig. 1. Schematic representation of electrode placement in the various test cells. Where W.E. = Li-Si alloy working electrode; C.E. = Li_2-Si-Si counterelectrodes; C.E.* = liquid lithium counterelectrode; and R.E. = 40 a/o Li-Al alloy reference electrode.

Results and Discussion

During the charge-discharge cycles, voltages of the $Li_{15}Si_4$ working electrode with respect to the liquid lithium counterelectrode were monitored at current densities of 50, 100, 200, 300, and 400 mA/cm^2. In addition, the voltages were monitored with respect to the two Li-Al reference electrodes; one placed behind the working electrode and the other placed by its side (Fig. 1B). The voltages, with respect to the liquid lithium electrode, were corrected for electrolyte resistance and then converted to potentials *vs.* a 40 a/o Li-Al reference electrode. The voltages, with respect to these reference electrodes, are plotted against capacity density at current densities of 100 and 200 mA/cm^2 in Fig. 2 and 3. The plots at other current densities were similar to these plots. The voltages of the working electrode with respect to these three reference electrodes at three different locations were observed to fall within 50 mV. The calculated voltages of the working electrode with respect to the 40 a/o Li-Al reference electrode (in place of lithium) after correcting for the electrolyte resistance losses should be the most accurate. It was observed that the voltages, with respect to the reference electrode placed on the back side of the working electrode, are within 10 mV of these values at current densities up to 200 mA/cm^2. However, the working electrode voltages, with respect to the back side reference electrode, were ~25 mV lower than the calculated voltages at current densities of 300 and 400 mA/cm^2. This small difference in the two voltage values might indicate that lithium concentration gradients developed in the Li-Si electrodes during discharge at higher current densities. Apparently, under these conditions, an Li-Si compound with a lithium deficiency forms in the front of the electrode while the same Li-Si compound with a lithium excess predominates at the back of the electrode.

The voltages of the $Li_{15}Si_4$ working electrode, with respect to the liquid lithium counterelectrode after correcting for electrolyte resistance losses, are plotted against capacity density at current densities between 50 and 400 mA/cm^2 in Fig. 4. These plots are similar to those obtained with an Li_2Si-Si counterelectrode and a 40 a/o Li-Al reference electrode placed behind the working electrode as reported before (2). In fact, the total cycle lithium utilizations are within 5% of those earlier values at comparable temperatures and current densities (Table I), and the overpotential during cycling determined from current-voltage plots in the regions of the three voltage plateaus were mostly ohmic as observed before (2).

Table I. Total lithium utilizations at different current densities at 675°K

Current density (mA/cm^2)	U_T (%)	U_T* (%)
50	79	84
100	82	83
200	78	80
300	66	—
400	55	—

where U_T = total lithium utilization from $Li_{15}Si_4$ to Si (calculated from the voltages measured with respect to a liquid lithium counterelectrode after correcting for electrolyte resistance losses),

and U_T* = total lithium utilization from $Li_{15}Si_4$ to Si [calculated from the voltages measured with respect to a 40 a/o Li-Al reference electrode placed behind the working electrode (Ref. 2)].

Mixed Potential Analysis of Sulfation of Molten Carbonate Fuel Cells

Dan Townley and Jack Winnick

Georgia Institute of Technology, Atlanta, Georgia 30332

and H. S. Huang

Argonne National Laboratory, Argonne, Illinois

Theory

At the anode of the molten carbonate fuel cell, reducing gas is oxidized to water and CO_2. The reaction proceeds through the intermediacy of carbonate ion as the charge carrier in the electrolyte. At the cathode, oxygen and carbon dioxide are electronated to form carbonate ion

$$1/2\ O_2 + CO_2 + 2e \rightarrow CO_3^{2-}$$

At the anode, hydrogen reduces the carbonate ion to water and carbon dioxide

$$CO_3^{2-} + H_2 \rightarrow H_2O + CO_2 + 2e$$

Recent experiments (1, 2) have shown that low levels of H_2S in the reducing gas at the anode have profound effects on cell performance. The potential drop due to the presence of 10 ppm of H_2S is on the order of 100 mV, indicating that the activity of H_2S may not be equal to its partial pressure. For this model, we assume a linear Henry's law relation between the activity and the partial pressure

$$a_{H_2S} = H^{-1}\,P_{H_2S} \qquad [1]$$

where H^{-1} is experimentally determined.

There are two reactions that may take place at the anode in which H_2S will compete with the desired reaction. In one sulfate ion is formed and in the other sulfide ion is formed. So, on the basis of eight electron transfer, there are three anode reactions to consider

$$4CO_3^{2-} + 4H_2 \rightarrow 4CO_2 + 4H_2O + 8e \qquad [2a]$$

$$H_2S + 5CO_3^{2-} \rightarrow SO_4^{2-} + 5CO_2 + H_2O + 8e \qquad [2b]$$

$$H_2S + 4H_2 + 5CO_3^{2-} \rightarrow S^{2-} + 5CO_2 + 5H_2O + 8e \qquad [2c]$$

If the relative extent of each of these reactions is determined by chemical equilibrium, then each will occur at the same potential as predicted by the Nernst relation

$$E = E_1^\circ - \frac{RT}{8F}\left\{ \ln\left[\frac{a_W^4 a_{CO_2}^4}{a_{CO_3}^4 a_{H_2}^4}\right]_{an} + \ln\left[\frac{a_{CO_3}^4}{a_{CO_2}^4 a_{O_2}^2}\right]_{ca} \right\} \qquad [3a]$$

$$= E_2^\circ - \frac{RT}{8F}\left\{ \ln\left[\frac{a_{SO_4} a_{CO_2}^5 a_W}{a_{CO_3}^5 a_{H_2S}}\right]_{an} + \ln\left[\frac{a_{CO_3}^4}{a_{CO_2}^4 a_{O_2}^2}\right]_{ca} \right\} \qquad [3b]$$

$$= E_3^\circ - \frac{RT}{8F}\left\{ \ln\left[\frac{a_S a_{CO_2}^5 a_W^5}{a_{CO_3}^5 a_{H_2}^4 a_{H_2S}}\right]_{an} + \ln\left[\frac{a_{CO_3}^4}{a_{CO_2}^4 a_{O_2}^2}\right]_{ca} \right\} \qquad [3c]$$

We assume that the activities of all gases except H_2S are equal to the corresponding partial pressures. If we also assume that in the electrolyte melt

$$a_{CO_3} + a_{SO_4} + a_S = 1.0 \qquad [4]$$

then we have five equations in five unknowns. In the experimental determination of H^{-1}, E is known and the five unknowns are H^{-1}, a_{H_2S}, a_{CO_3}, a_{SO_4}, and a_S.

The overall cell reaction corresponding to each of the half-cell reactions in [2a-c] are

$$H_2 + 1/2\ O_2 \rightarrow H_2O \qquad [5a]$$

$$H_2S + 2\ O_2 + M_2CO_3 \rightarrow M_2SO_4 + H_2O + CO_2 \qquad [5b]$$

$$H_2S + 2\ O_2 + 4H_2 + M_2CO_3 \rightarrow M_2S + 5H_2O + CO_2 \qquad [5c]$$

The metal in these equations corresponds to the binary eutectic composition of lithium and potassium carbonates used as the electrolyte in these cells. Equation [5a] gives a standard potential $E_1^\circ = 1.027V$. Data from the Institute of Gas Technology (IGT) (3) show that the free energy change for [6a] is +7.7 and for [6b] is −1.7 kcal/mole.

$$H_2S + M_2CO_3 + 3H_2O \rightleftarrows M_2SO_4 + CO_2 + 4H_2 \qquad [6a]$$

$$H_2S + M_2CO_3 \rightleftarrows M_2S + H_2O + CO_2 \qquad [6b]$$

Combining these equations with

$$4H_2 + 2\ O_2 \rightleftarrows 4H_2O \qquad [7]$$

shows that $E_2^\circ = 0.986$ and $E_3^\circ = 1.037V$.

Calculations

We have six experimental data points relating partial pressure of H_2S in the anode feed and potential drop (Table I). The first two points, taken by United Tech-

Key words: coal gasification, hydrogen sulfide, anode.

Table I. Experimental data points (1, 2)

PT	$P_{H_2S} \times 10^6$ (atm)	Potential drop (mV)	Inlet anode gas composition	Outlet anode gas composition
UTC No. 1	8	100	0.51 H_2 0.105 CO_2	0.057 H_2 0.443 CO_2
UTC No. 2	31	183	0.085 CO 0.286 H_2O	0.477 H_2O
IGT No. 1	10	44	0.572 H_2	0.091 H_2

IGT No. 3	100	154	0.262 H_2O	0.456 H_2O
IGT No. 4	200	169		

nologies Corporation (UTC) are at 650C and a current density of 160 A/ft². The hydrogen utilization is 96% for both data. The other four points were taken by the Institute of Gas Technology (IGT) at the same temperature and current density, in a similar apparatus, but at only 76% hydrogen utilization.

The first point, UTC No. 1, has been used to calculate H^{-1}. This H^{-1} was used to predict the other five points. Using Eq. [3a], we first calculate the Nernst potential at the inlet conditions when no sulfur is present, that is when $a_{CO_3} = 1$. Although the cathode gas composition is not important in this model, we based our calculations on a composition of 0.67 CO_2 and 0.33 O_2. The potential calculated is 1.100V. The observed potential drop of 100 mV is subtracted to give the potential produced by the cell ignoring all overvoltages. Thus, E is set equal to 1.000V in Eq. [3a-c], and these equations along with Eq. [4] are solved for a_{CO_3}, a_{SO_4}, a_S, and a_{H_2S}. Equation [1] then gives $H^{-1} = 1.5 \times 10^4$.

In this model the voltage drop caused by H_2S is presumed to be due entirely to the replacement of carbonate in the electrolyte.

Discussion

If the same H^{-1} is used to calculate the potential drop due to H_2S at the anode outlet, the value is on the order of 150 mV. This value assumes that steady state has been reached at the anode and that no sulfur is absorbed. Allowing for the increased volumetric flow rate at the outlet, P_{H_2S} is decreased by a factor of 1.5 from the inlet value. A different H^{-1} may be calculated using the outlet gas composition for UTC No. 1. Using the same method as before, $H^{-1} = 5.3 \times 10^3$ at the outlet. Using this H^{-1}, the potential drop at the inlet should be in order of 50 mV.

These calculations predict that the effect of H_2S is progressively greater from the inlet to the outlet. This is in agreement with results of the UTC study (3) which showed that the amount of sulfur in the electrolyte increased from inlet to outlet. This means, for example, that for UTC No. 1, η_{H_2S} at the inlet is less than 100 mV and η_{H_2S} at the outlet is greater than 100 mV. The overpotentials not due to H_2S are thus changed and the current density becomes redistributed across the cell. The local current density increases at the inlet and decreases at the outlet. Therefore, the true H^{-1} will be somewhere between 5.3×10^3 and 1.5×10^4. Table II shows the results of using $H^{-1} = 5.3 \times 10^3$ to calculate the activities in the melt and the the potential drops due to H_2S at the outlet.

Figure 1 illustrates the effect of increasing H_2S composition. Note that different curves are predicted

Table II. Predicted anode outlet conditions

PT	$P_{H_2S} \times 10^6$	a_{H_2S}	a_{CO_3}	a_{SO_4}	a_S	η_{H_2S} calc	η_{H_2S} meas
UTC No. 1	5.3	0.0281	0.082	0.887	0.031	(100)	100

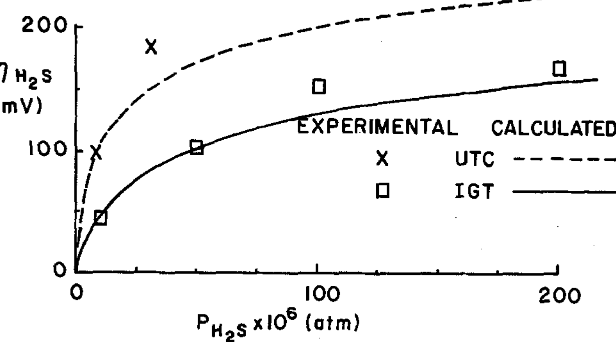

Fig. 1. Effect of H_2S pressure on overvoltage

for the two sets of experiments. This is due to the difference in hydrogen content of the fuel used by the two laboratories. The hydrogen content affects Eq. [3a-c].

Since the H^{-1} we calculate is not the true thermodynamic value, it is only valid for data points with the same electrochemical hydrogen utilization and current density. The effect of the H_2S is greatest at the outlet, where P_{H_2} is low, so our calculated H^{-1} will be greater for a higher utilization. The UTC points are for a utilization of 96% and the IGT points for 76%. If IGT No. 1 is used to calculate H^{-1}, a value of 4.3×10^3 is found, so that the difference is only about 20%.

The mixed potential found disregards differences in the kinetics of the three anodic reactions. The effect of incorporating the true kinetics, when they are available, would be to change the predicted anion compositions as well as the Henry's constant. The calculated η_{H_2S}-P_{H_2S} curve is very insensitive to changes in the potential. However, the compositions are very sensitive to such changes. For example, a change of -0.150V in E^o for Eq. [3b] will have the same effect on the calculated mixed potential as a change by a factor of 5/2 in the exchange current densities of the reactions. This change produces essentially no change in the predicted curve of η_{H_2S} *vs.* P_{H_2S}. Yet, a dramatic shift in compositions is calculated. The sulfate ion activity decreases while the sulfide ion increases. The Henry's constant increases also. Since we have no kinetic data, we must consider our predicted compositions (activities) approximate at best.

UTC (4) ran free-electrolyte experiments with varying ratios of sulfate to carbonate ion in the electrolyte. They found that the voltage produced was qualitatively related to the sulfate content of the electrolyte, in agreement with our predictions.

Although this model is not an entirely accurate representation of the effects of H_2S on fuel cell performance, it is a first attempt to describe these effects based on changes in the electrolyte. The Henry's law constant calculated may include effects other than solubility, such as the kinetics of electrode sulfidation. The kinetics of the reactions will also play a role in a working cell. Although we neglected the Henry's law constant for all gases other than H_2S, the effects of these constants are implicitly included in the overpotentials not due to H_2S. The partial pressures of these gases do not change enough between the two sets of data to have a significant effect on the observed voltages.

The true H^{-1} could be determined from cells run with zero utilization but at the same current density as before. A more exact prediction of η_{H_2S} could then be made using this H^{-1} and the polarization curve for an uncontaminated cell by numerically integrating local current densities across the cell for any utilization.

Conclusion

A simple thermodynamic model has been used to estimate the effect of H_2S on molten carbonate fuel cell performance. One datum was needed to fix the

single floating parameter. Predictions were compared with data from two independent laboratories under somewhat different conditions, with surprisingly good agreement.

The predictions of electrolyte composition are no doubt inaccurate due to the uncertainties involved in the calculation of the Henry's constant.

Synergism in Hydrogen Evolution on Platinized Tungsten Trioxide in Acid Medium

S. A. Abbaro and A. C. C. Tseung*

Department of Chemistry, The City University, London, England

and D. B. Hibbert*

Department of Chemistry, Bedford College, University of London, London, England

Platinum when supported on tungsten trioxide shows synergism towards reactions in acid involving hydrogen atoms. Hobbs and Tseung (1-3) have demonstrated this effect for hydrogen oxidation in sulfuric acid, as have Hibbert *et al.* (4) for the hydrogenation of p-nitrophenol in sulfuric acid. Tungsten trioxide functions as an active support due to the reaction between hydrogen atoms and tungsten trioxide giving a conducting hydrogen tungsten bronze, H_xWO_3 ($0 < x < 1$). For hydrogen oxidation, therefore, two routes may be postulated; a normal route

$$H_2 + 2Pt \rightarrow 2PtH \quad [1]$$

$$PtH \rightarrow Pt + H^+ + e \quad [2]$$

and a bronze route

$$xPtH + WO_3 \rightarrow Pt + H_xWO_3 \quad [3]$$

$$H_xWO_3 \rightarrow xH^+ + xe + WO_3 \quad [4]$$

The rate of reaction, compared to that on pure platinum is thus enhanced if spill-over (Eq. [3]) and the subsequent reaction of tungsten bronze are fast. In this note we report the results of experiments which show synergism for hydrogen evolution in acid solution on platinized tungsten trioxide, and comment on the possible mechanism of the effect.

Experimental

A stock sample of 1 weight percent (w/o) platinum on tungsten trioxide was prepared by freeze-drying (5) chloroplatinic acid on tungsten trioxide followed by reduction in hydrogen (50°C for 30 min, 90°C for 3 hr). By this method, a great dispersion of platinum on the tungsten trioxide substrate is obtained. The specific surface area of the platinum prepared in this manner has been shown to be 35 m^2g^{-1} (1). All other loadings (0.2-0.9 w/o) were prepared by mechanically mixing tungsten trioxide with the stock sample. It is of some importance to ensure that the morphology of the platinum particles remains constant (4), and thus it was not possible to freeze-dry each loading.

Teflon-bonded electrodes were prepared by ultrasonically mixing a 60% P.T.F.E. dispersion with the freeze-dried catalyst in the ratio 3:10 by weight. The mixture was painted onto a carbon plaque, dried, and cured at 300°C for 1 hr. Catalyst loadings were typically 10-15 mg cm^{-2}. A graphite rod was used as the counterelectrode.

Steady-state polarization curves were determined in 2.5M sulfuric acid at 25°C, against a dynamic hydrogen reference electrode. The measured potential was corrected for the *IR* drop between Luggin capillary and electrode by the interruptor technique.

Several determinations were made at temperatures up to 60°C, a fresh electrode being used on each temperature cycle. Atomic adsorption analysis of the electrolyte solution was performed for tungsten.

Results

We define the specific activity of an electrode (J) as the current density at a given overpotential divided by the platinum loading. For a system in which the support plays no part, J is constant with platinum loading.

Figure 1 shows a series of curves of J against platinum loading for electrodes at different overpotentials. Similar results were obtained for many electrodes, the reproducibility being 15% between different electrodes. An electrode prepared from pure tungsten trioxide gave almost no current in the overpotential range studied. The characteristic blue color of hydrogen tungsten bronze was observed on all electrodes.

* Electrochemical Society Active Member.
Key words: synergism, spill-over, hydrogen.

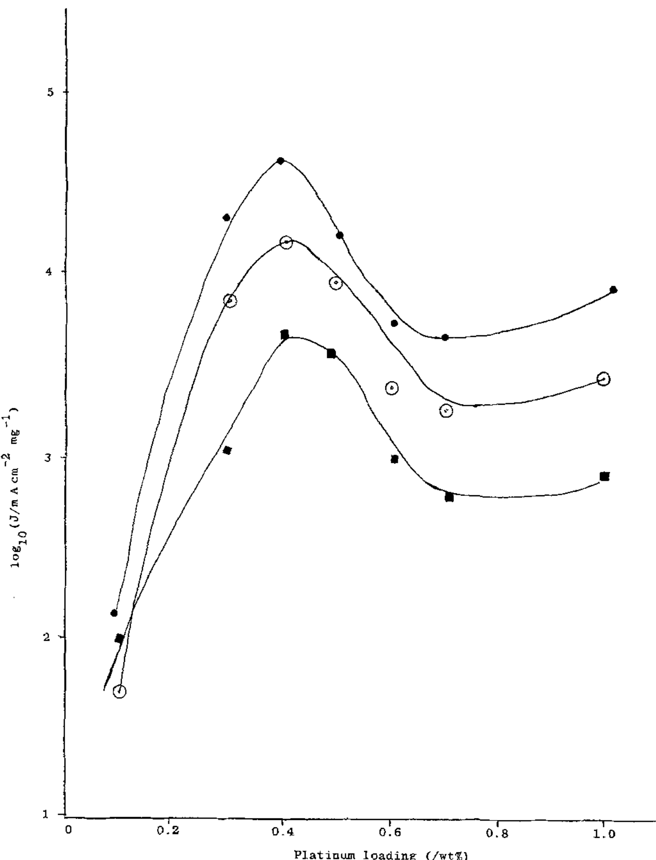

Fig. 1. Variation of specific activity (J) of a platinized tungsten trioxide electrode with platinum loading. ■: $\xi = -10$ mV; ○: $\xi = -30$ mV; ●: $\xi = -80$ mV. 2.5M H_2SO_4, 25°C, IR corrected.

The temperature dependence of the current at $\xi = -30$ mV for an electrode of platinum loading 0.3 w/o is given in Fig. 2. The poor performance at 60°C remained when the electrode was cooled, suggesting some permanent change had occurred. No tungsten was observed in solution. This effect was observed for each platinum loading.

Discussion

The existence of a maximum in the curve of J against platinum loading at 0.4 w/o platinum indicates a synergistic effect. The fall in performance at low platinum loadings may be correlated with the number of particles of platinum and tungsten trioxide. At 0.2 w/o platinum, a simple calculation shows that the number of platinum particles just equals the number of tungsten trioxide particles. Below this loading, tungsten trioxide particles exist which are not in contact with platinum, and thus may not contribute to the activity if the migration of hydrogen atoms between tungsten trioxide particles is slow.

A simple scheme to explain synergism in this system may be postulated in which adsorbed hydrogen atoms on platinum may react immediately to give hydrogen (Eq. [6]) or migrate on to tungsten trioxide to give a tungsten bronze (Eq. [7])

$$Pt + H^+ + e \rightarrow PtH \quad [5]$$

$$2PtH \rightarrow 2Pt + H_2 \quad [6]$$

$$xPtH + WO_3 \rightarrow xPt + H_xWO_3 \quad [7]$$

$$H_xWO_3 \rightarrow x/2H_2 + WO_3 \quad [8]$$

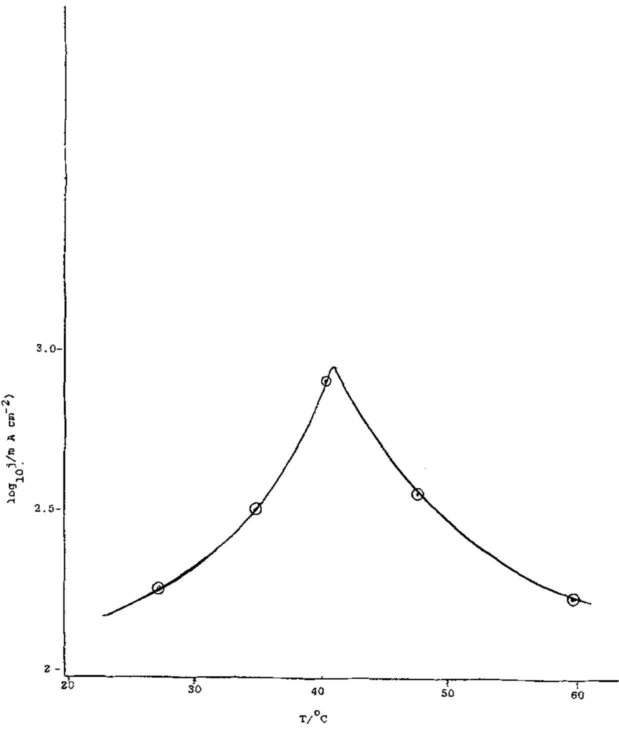

Fig. 2. Variation in the current from a platinized tungsten trioxide electrode (Pt loading 0.3 w/o) with increasing temperature. $\xi = -30$ mV. 2.5M H_2SO_4, IR corrected.

The tungsten bronze may decompose (Eq. [8]) or act as a hydrogen evolution catalyst itself. However, the inactivity of pure tungsten trioxide at low overpotentials, even though the blue color of the bronze was seen, suggests the latter step does not contribute greatly. It has been shown (6) that the rate-determining step of hydrogen evolution on platinum is hydrogen recombination.

Thus, a fractional coverage of hydrogen atoms on platinum of near 1, would allow spill-over to occur easily and thus facilitate synergism.

The initial increase in activity with temperature yields an activation energy of 5 kcal mol^{-1}, which falls close to values in the literature (6, 7). The subsequent permanent fall in activity may be due to dissolution of platinum followed by its reprecipitation, causing a growth in platinum particle size (8).

Volatile Products from Interaction between Steel and H_2O/CO_2 at High Temperatures

Sin-Shong Lin

Army Materials and Mechanics Research Center, Watertown, Massachusetts 02172

ABSTRACT

A combined technique of mass spectrometry and high pressure sampling was used to analyze vapor products emanating from this interaction between steel and H_2O/CO_2. Only metal containing species of $MoO_2(OH)_2$, $MoO_2(OH)$ were identified at 1400°C near the melting point of steel under water atmosphere. These vapor species might be one of the contributing factors to the initiation of high temperature steel erosion.

The ablative and erosive interactions between metal and hot flowing media have been widely investigated (1, 2). Under the extreme conditions near the melting point of steel and subjected to high pressure gases, such as repetitive gun firing, explosion, rocket exhausts, and high temperature flames, the mechanism of corrosion differs significantly from those mechanisms at low and medium temperatures. The dominant causes of material failures at low temperatures, such as mechanical stress rupture, thermal degradation, and chemical deterioration, are no longer distinguishable from each other at high temperature where an evaporation loss of material prevails. And the interaction of all failure mechanisms act simultaneously to the limited useful life of a material. The study reported here is aimed at elucidating the chemical aspect of ablative and erosive interactions under evaporative loss of materials near the melting point of steel. The experiments described in this study have simulated the hostile environment as close as possible within current available technologies. With the novel combined technique of sampling atmospheric gases and mass spectrometric detection, it might be possible to find one of major contributing factors for the initiation of high temperature erosion.

The volatile high temperature vapors originated from the interactions between metals and water have been known (3). The vapor species frequently observed from those metals used in steel are listed in Table I. The vapor pressures as well as thermodynamic properties of these species are well documented (4-15), but the behaviors of each individual species over a molten solution of steel are not well examined. The iron alloys react vigorously with water near the melting point to form iron and other oxides. Thus some vapor species derived from the reaction are similar to that under low pressure oxygen, and they are also listed in the table. A typical iron alloy contains less than 10 weight percent (w/o) of minor elements, and the presence of these minor elements might play a key role in the promotion of high temperature erosion. The situation might be similar to a small concentration of sulfur associated with fuel, which often is a major cause of corrosion in combustion processes.

Key words: corrosion, erosion, steel, gas-solid interaction.

Experimental

The experimental apparatus has been described previously (16, 17). And the schematic diagram of the sampling apparatus is shown on Fig. 1 together with the miniature furnace assembly in Fig. 2. The only modification made from previous arrangements was to locate a water reservoir adjacent to the combustion tube of the furnace. This was accomplished by directly coupling the reservoir to the fitting of the combustion tube. The core of the furnace consisted of a 1/2 in. OD closed-end alumina tube. On the tip of the tube, a 0.005 or 0.010 in. sampling orifice was drilled along the axial direction, and the depth of the orifice varied with the tubes from 0.02 to 0.06 in. The metal samples in the forms of chips, filings, and powders, were loaded in the

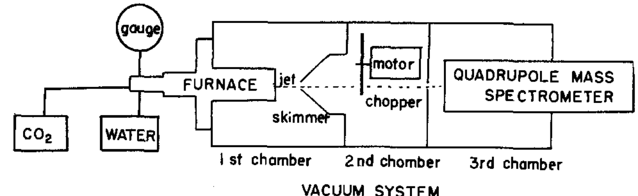

Fig. 1. Schematic diagram of sampling apparatus. The apparatus consists of three chambers differentially evacuated; the first chamber is an expansion chamber where a molecular jet beam is formed through the sampling orifice, the second chamber contains a beam modulation mechanism, and the third chamber houses the quadrupole mass spectrometer for the detection of beam. The furnace is flanged to the wall of the first chamber.

tube within one inch from the tip. For wire samples, a several-fold concentric coil was made so that a maximum surface area could be exposed. The reactor chamber was resistance heated by a molybdenum wire winding covering the orifice area and about 4 in. from the end of the tube. The a-c power input to the heater was regulated by a proportional temperature controller, and the temperature was measured by a Pt/10%Rh-Pt thermocouple protected by a 1/4 in. OD alumina sheathing tube in the 1/2 in. combustion tube. The reacting gases including water vapor were introduced into the reactor through the annular opening of two alumina tubes, and the pressure was recorded by a digital pressure gauge connected to the steel fitting at the open end of the combustion tube. For mass spectrometric detection, the quadrupole mass filter was operated at 40 eV electron ionization energy and at an appropriate resolution throughout the experiments.

After the sample had been loaded into the reactor and good vacuum was obtained in the first chamber of the sampling apparatus, heating began. The temperature of the furnace was raised quickly to a predetermined level up to 1400°C. During this period the reactant gas (H_2O or CO_2) was introduced gradually to a selected setting of not more than 1/2 atm. Often the sampling orifice was found to clog due to a sudden introduction of the gas. To examine vapor species originating from the interaction, the mass spectrometric scans were made repeatedly during the entire heating period. Moreover many experiments had to be repeated several times so that the reproducibility of ion vapor species present in a minute amount could be confirmed. Even at the maximum temperature of 1400°C, the signals of ion vapors observed over steel and Fe samples were so weak that a positive identification was almost impossible. Alternatively a suspected source of pure metal was substituted for a better and clear identification. The identity of an ion peak was established from mass number, isotopic distribution, temperature, pressure and time dependences. A summary of experiments performed is listed in Table II.

Results

Fe.—Extensive search was made to detect metal-containing vapor from the interaction between a high purity Fe and water, CO_2, CO_2/H_2 mixture. In the water reaction, the H_2O^+ intensity diminished considerably at the initial period of heating above 1200°C. Evidently a strong interaction took place between water and Fe. The Fe coil after the heating was a partially molten chunk of black appearance presumably consisting of iron oxides. In the CO_2 reaction, the oxidation of Fe was found to be the only reaction. The sample after heating consisted of iron oxides. No ion vapor species was detected.

No metal-containing vapor species was detected in scan mass spectra except in some spectra obtained at 1400°C and a high H_2O pressure near 1/2 atm. Ion peaks corresponding to masses $Fe(OH)_2$, FeO, and Fe in order of increasing magnitudes were observed. Since their ion intensities were only a few times more than the background noise level which was about 10^{-5} relative to H_2O^+, no identity could be established from their isotopic abundances. Some ions at masses 88, 64, and 44 were frequently detected. These ions were probably hydrocarbons from the preparation of the Fe sample, they were discarded because of their temperature and time dependent behaviors.

Fe_2O_3, Fe_3O_4.—The experiments were performed because these oxides instead of Fe might accelerate the formation of Fe containing vapor species. However only in two mass spectra obtained from the Fe_3O_4 sample, a very weak signal slightly above background noises corresponding to FeO was observed. Since the signal was so weak, no definite conclusion about the existence of FeO could be established. The powder samples after the interaction were partially molten black aggregates.

Steel.—The extensive search was made to identify exotic vapor species effusing from the steel + H_2O interaction up to temperatures of 1400°C. In order to increase surface areas of steel, not only chips but also filings were used for the investigation. After every run, the sample was found to be partially molten and oxidized. In some instances, the melts were found to diffuse into the alumina tubes and they could not be sep-

Table II. Summary of experiments
Metal + H_2O/CO_2 reaction

Sample	Source	Ion vapor species observed	
		H_2O reaction	CO_2/H_2 reaction
Fe	99.9% wire	Yes, not confirmed	None
Fe_2O_3, Fe_3O_4	99.8% powders	None	Not performed
Steel	Gun tube[a]	$MoO_2(OH)_2$ & others	Not performed
Cr	99.9% powders	None	Not performed
Ni	99.9% powders	None	Not performed
Mo	99% wire	$MoO_2(OH)_2$, $MoO_2(OH)$ Mo-O vapors	MoO_2, $MoO_3(MoO_3)_n$ $n = 2,3$

arated from the tubes. Alternatively a ZrO_2 boat was used to avoid the contamination of alumina, but the wetting of melt still existed. Moreover in these ZrO_2 boat runs, more spurious ions were observed in mass spectra. The impurities associated with ZrO_2 might be a cause of these spurious ions, and the presence of these ions in observed spectra made the interpretation of data more tedious and difficult.

No ion peak was detected in the initial period of heating. But after several hours of heating, ion signals slightly above the background level began to emerge. The only signals constantly present in mass spectra and yet reproducible, were at masses 64, 48, and 44 amu plus two broad peaks at masses 140-150 and 155-165 amu. The ions at masses 64 and 48 were found to diminish slowly with the extent of heating, and they were probably SO_3 and SO_2. The ion at mass 44 was presumably SiO or CO_2, and it could not be definitely identified. The two broad peaks were identified later as $MoO_2(OH)_2^+$ and $MoO_2(OH)^+$ ions with the aid of mass spectra obtained from the Mo + H_2O experiments.

Cr.—The purpose of the experiment was to identify Cr-O vapor species which might be evolved from the interaction between Cr and H_2O. Although vapor species such as CrO_3 and $CrO_2(OH)_2$ are reported (7, 8), no trace of these ions was detected in the present experiments.

Ni.—A single run was made with Ni and H_2O to examine Ni-O, or Ni-OH vapor species from the interaction. No ion signal other than those derived from H_2O was detected in mass spectra even at 1400°C and 1/2 atm of water pressure.

Mo.—The Mo and H_2O/CO_2 experiments were performed in order that the broad peaks observed in the steel-water runs could be identified. As one might expect (7) numerous ion species were detected. The relative intensities of these Mo-O species at the highest isotopic peak together with Mo hydroxide ions are listed in Table III. The data were taken directly from scan spectra without corrections for isotopic abundance, ionization cross section, and ion transmission efficiency. The most important species in the water reaction were $MoO_2(OH)_2$ and $MoO_2(OH)$ ions. The mass positions of these ions in the spectra agreed well with those broad peaks observed in the steel-water experiments. Thus the trace amount of ion peaks observed in the steel experiment were identified as those ion peaks of $MoO_2(OH)_2$ and $MoO_2(OH)$.

In addition to these Mo hydroxide ions, a lesser abundant ion $Mo_2O_6 \cdot H_2O$ was also observed in mass spectra taken at 1190°C and 304 mm Hg water pressure. The neutral precursors of two abundant hydroxide ions were not determined from the present experiments. The molecule $MoO_2(OH)_2$ is reported (7, 12) to exist in high temperature vapors. Upon electron impact ionization, $MoO_2(OH)_2$ could produce fragmented ions MoO_2^+ and $MoO_2(OH)^+$ in addition to the parent ion $MoO_2(OH)_2^+$. However the observed intensity ratios of $MoO_2(OH)_2^+$ to $MoO_2(OH)^+$ varied with temperatures and pressures of the system. Therefore the existence of $MoO_2(OH)$ as a neutral molecule is highly probable.

The Mo-O vapors observed in the Mo + CO_2 reaction were very similar to those vapor species observed over Mo oxides. The observed Mo-O species up to Mo_3O_9 in the runs are listed in Table III. The higher polymers of Mo-O ions such as Mo_4O_{12}, Mo_5O_{15} might exist in the system but they were not recorded.

Table III. Vapor species observed in Mo + H_2O/CO_2 reaction

Discussion

The results from the steel-water experiments indicated that Mo hydroxide vapors were only major metal containing species emanating from the interaction. Other vapors such as CO_2, SiO, SO_2, and SO_3 might exist at 1400°C, but the result was not very conclusive. Thus near the melting point, the erosion of steel could be initiated by evolution of these vapors just below partially molten steel surfaces. The absence of the vapors in the initial heating period of the experiments further suggested the reacting gas H_2O, must diffuse into interiors of steel and produced the volatile Mo containing vapors.

The vapor pressures (18, 19) of metals and metal oxides commonly observed in the composition of steel are plotted on reciprocal temperatures in Fig. 3. Iron comprises 90 w/o of the steel composition. At the temperature of 1400°C, the vapor pressures of Fe or FeO are so low as indicated in the figure, that they are not a substantial fraction of evaporation loss. Chromium, the second important element of steel, tends to form a protective compact oxide layer by reaction with water,

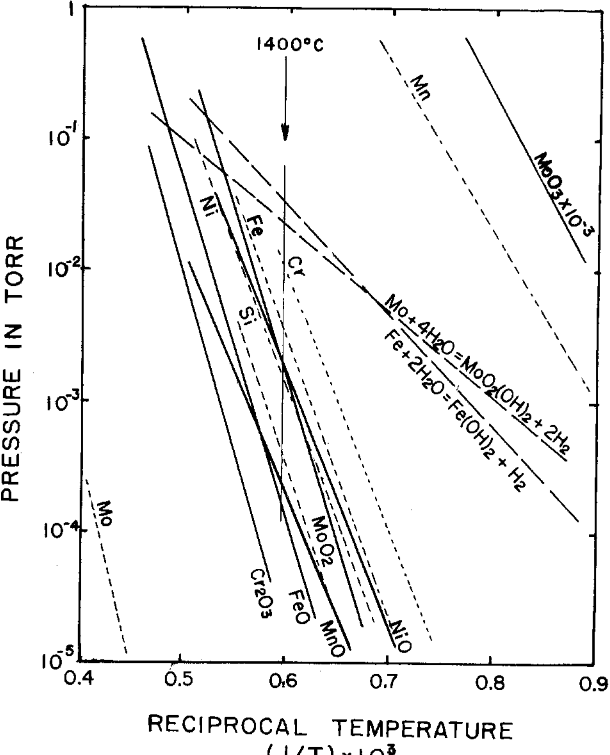

Fig. 3. Vapor pressures of metals, oxides, and hydroxides. Metal in dotted line, oxide in solid line, and hydroxide in dashed line. The pressures of hydroxides are calculated by assuming $P_{H_2O} = P_{H_2}$ = 1/2 atm.

which is well known for oxidation resistance. The vapor pressure of Cr oxides is lower than that of Fe except under a very high oxygen pressure. Consequently the evaporation loss resulting from chromium could be neglected. The third abundant element of steel, nickel, consists of less than 5 w/o of the solid solution. The volatility of Ni is less than that of Fe and there is no stable nickel oxide. The minor constituents of steel such as Mn, Mo, C, Si, and S occupy less than 1 w/o of a steel composition. Manganese had a higher vapor pressure, but Mn oxide is more stable than Fe oxides. Molybdenum could form many volatile vapors MoO_2, MoO_3, and $(MoO_3)_n$ polymers upon oxidation. The evaporation of Mo-O vapors at temperatures far below the melting point of steel is not a major concern because the Mo content in steel is only a few fraction of one percent. Except at a high oxygen pressure near the melting point, they could cause a serious problem of ablation and erosion. Other elements such as sulfur to form SO_2 and SO_3, silicon to form SiO, and carbon to form CO and CO_2, are believed to cause no severe evaporation loss because these elements are present in a minute concentration and exist in the solid solution as stable carbides, sulfides, and silicides.

The formation of Mo-hydroxide vapors appears to be the most important process of steel near the melting point under H_2O atmospheres. In an equilibrium system, the magnitudes of the hydroxide vapors increase drastically with the 3rd and 4th powers of the H_2O pressure as indicated by the equilibrium constants of the reactions

$$Mo(s) + 4H_2O(g) = MoO_2(OH)_2(g) + 3H_2(g) \quad [1]$$

$$Mo(s) + 3H_2O(g) = MoO_2(OH)(g) + 5/2\, H_2(g) \quad [2]$$

In the case of gun and rocket firings, the temperature and the pressure of exploding gases in which H_2O is a major constituent, are up to minima (20) of 2500°K and 20,000 psi, respectively. Thus the evaporation of Mo as hydroxide vapors from steel would be greatly enhanced. This evaporation would provide a recession in steel or a diffusion through fissure which may lead to fracture of the film or loss of protective metal layers. The exact role of Mo hydroxide vapors in the erosion and ablation process is not clear, but they are the first metal containing vapors to escape from molten steel surfaces.

The formation of $Fe(OH)_2$ vapor from the Fe-H_2O interaction seems to be more favorable than that of Fe vapor at high temperatures as shown in the pressure *vs.* temperature diagram of Fig. 3. However $Fe(OH)_2$ vapor from the reaction

$$Fe(s) + 2H_2O(g) = Fe(OH)_2(g) + H_2(g) \quad [3]$$

was not positively identified. The dominant reaction observed in the Fe-H_2O reaction is the formation of iron oxide solids, such as

$$Fe(s) + H_2O(g) = FeO(s) + H_2(g) \quad [4]$$

According to the thermodynamic calculation (4, 12) at various water pressures, the magnitudes of Fe hydroxide vapor in the system should be more than 10^{-6} relative to the H_2O^+ intensity. And at the water and hydrogen pressures of 1/2 atm, both Fe and Mo hydroxide vapors should have a comparable magnitude at the present experimental conditions as shown in Fig. 3. However the Mo hydroxide vapors were found to be much more abundant than $Fe(OH)_2$. The $MoO_2(OH)_2^+$ and $MoO_2(OH)^+$ were observed in a large amount from 10^{-1} to 10^{-5} relative to H_2O^+, but little evidence of $Fe(OH)_2^+$ was obtained. The source of this discrepancy is not clear, but it is likely due to the fact that the gas-solid equilibrium in the Fe system is not established. The gas-solid equilibrium can be easily attained in the Mo system because a large concentration of Mo-O vapors is present at the temperature range of experiments. And the vapor phase reaction of Mo-O vapors and H_2O kinetically promote the completion of the equilibrium.

Work Function and Chemical Diffusion of Nonstoichiometric Oxide Materials

Z. Adamczyk and J. Nowotny

Institute of Catalysis and Surface Chemistry, Polish Academy of Sciences, 30-239 Kraków, Poland

ABSTRACT

A particular solution of Poisson's equation and of Fick's second law leads to the determination of the chemical diffusion coefficient for the near-to-surface layer of nonstoichiometric oxide materials. The proposed method is based on the work function measurements applied to determine the surface reequilibration kinetics. Metal deficient oxide $Me_{1-y}O$ is taken as an object of quantitative considerations.

Application of the work function measurements in studies of kinetics and the mechanism of heterogeneous processes between gaseous oxygen and metal oxide surfaces was the subject of several works (1-5). It has been shown that the work function may be used to monitor the reequilibration kinetics of oxide surfaces involving chemisorption and lattice ionic diffusion. The purpose of the present work is to discuss correlations between surface potential and work function changes accompanying the reequilibration, surface charge in the boundary layer, and concentration of lattice defects in order to determine the chemical diffusion coefficient in the near-to-surface layer.

Both gravimetric and electrical conductivity methods, widely used to determine the reequilibration kinetics and the chemical diffusion coefficient (6-10), may be applied at higher temperatures (above 800°C). The methods provide information about the crystalline bulk. Recently, however, considerable experimental material has been accumulated which is not in accordance with current theories for the typical bulk-controlled mechanism of reequilibration processes. The conflicting data are referred to a "surface reaction" (11-12) which apparently occurs at the surface or in the near-to-surface layer. The diffusion data obtained from the work function measurements may be useful to characterize both transport and structural properties of the surface layer. This layer may differ essentially from the crystalline bulk especially when segregation of lattice components occurs.

Chemical Reactions and Electrical Effects Accompanying Reequilibration Processes in MeO-O_2 Systems

The reequilibration occurs when an initially equilibrated oxide crystal is subjected to a new value of oxygen pressure (or temperature). The reequilibration process involves the propagation of chemical potential gradients from the surface into the bulk until a new equilibrium is achieved.

As an object of our considerations we assume the nonstoichiometric oxide expressed by the general formula $Me_{1-y}O$ showing doubly ionized cation vacancies as predominant ionic lattice defects which are compensated by electron holes. This type of defect structure is represented by such widely investigated oxide materials as NiO, CoO, MnO, and FeO. We also assume that the cation vacancies are the only mobile ionic species, whereas the anion sublattice remains relatively immobile (13). At low concentrations cation vacancies may be considered as an ideal solution in the lattice and thus their concentrations may be considered as activities.

The following equilibria which seem to be most important may be considered at the oxide surface and in the oxide crystal when oxygen pressure is isothermally changed in the ambient gas atmosphere

$$O_{2\,gas} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} O_{2(ads)} \qquad [1]$$

$$O_{2\,ads} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} 2\,O^- + 2h^{\cdot} \qquad [2]$$

$$O^- \underset{k_6}{\overset{k_5}{\rightleftharpoons}} O^{2-} + h^{\cdot} = V_{Me}'' + h \qquad [3]$$

where $O_{2(ads)}$ is a physically adsorbed molecule, O^- is the most stable ionic form of oxygen adsorbed at the surface of transition metal oxides (14), and O^{2-} is the final ionization form which is stable in the crystal field (14-16). Therefore we consider the form O^{2-} as doubly ionized cation vacancy V_{Me}''.

Assuming isothermic conditions of experiment involving admission of a certain oxygen dose over an oxide surface initially equilibrated under low oxygen pressure (10^{-6} Torr) the following relationship may be written for oxygen pressure as a function of the amount of oxygen adsorbed

$$p_{O_2} = p_{O_2}{}^{\circ} - [O_{2(ads)}]\, S\frac{kT}{V} \qquad [4]$$

where $p_{O_2}{}^{\circ}$ = initial oxygen pressure, V = volume of the experimental chamber, $[O_{2(ads)}]$ = surface concentration of oxygen adsorbed, and S = total surface area of the investigated oxide.

As results from recent works (1-5) the work function changes for the metal oxide-oxygen system may be considered regarding experimental conditions applied.

Isobaric conditions.—The experiment occurs isobarically when the following inequality is fulfilled

$$[O_{ads}]\, S\frac{kT}{V} << p_{O_2}{}^{\circ} \qquad [5]$$

The work function changes accompanying oxygen chemisorption in these conditions $\Delta\Phi_t$ is schematically illustrated in Fig. 1, curve 1. As seen $\Delta\Phi_t$ rapidly increases achieving $\Delta\Phi_{eq}$ which refers to a chemisorption equilibrium involving generation of charged oxygen species at the surface (3).

Sorption of small oxygen dose.—When a small oxygen dose equivalent to a fraction of the monolayer coverage is admitted into the reaction chamber p_{O_2} rapidly decreases as a result of the inequality

$$[O_{2(ads)}{}^{\infty}]\, S\frac{kT}{V} >> p_{O_2}{}^{\circ} \qquad [6]$$

Key words: semiconductor, defects, charge, potential.

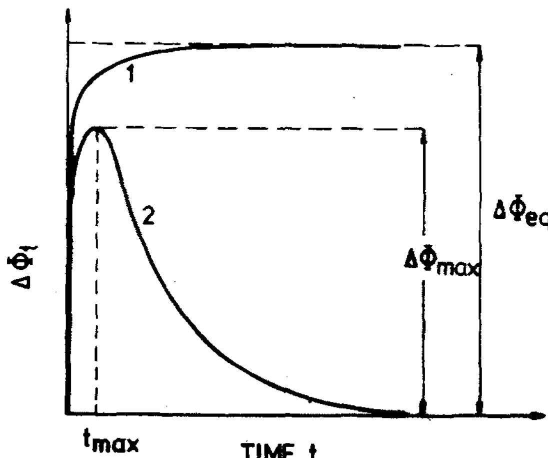

Fig. 1. Schematic plots for the work function changes vs. time accompanying isothermal sorption of oxygen for nonstoichiometric oxide surface. 1, At higher pressures when p_{O_2} = const. and 2, at small oxygen doses equivalent to the fraction of the monolayer coverage.

Accompanying changes Φ_t *vs.* time (Fig. 1, curve 2) show a rapid initial increase due to ionization of adsorbed oxygen, reach maximum $\Delta\Phi_{max}$, and then slowly decrease as a result of diffusion of lattice ionic defects (1, 2).

The following expression may be written for O_2 adsorbed as a result of Eq. [1]

$$\frac{d[O_{2(ads)}]}{dt} = k_1\left\{ p_{O_2}{}^{\circ} - [O_{2(ads)}] S\frac{kT}{V} \right\} \{[O_{2(ads)}{}^{\infty}] - [O_{2(ads)}]\} - k_2 [O_{2(ads)}] - k_3 [O_{2(ads)}] + 4k_4 [O^-][h^{\cdot}] \quad [7]$$

where $[O_{2(ads)}{}^{\infty}]$ is the maximal surface concentration of oxygn adsorbed and k_1, k_2, k_3, and k_4 are rate constants of corresponding processes expressed in Eq. [1] and [2]. Similarly, we can write

$$\frac{d[O^-]}{dt} = k_3[O_{2(ads)}] - 4k_4[O^-][h^{\cdot}] - k_5[O^-] + k_6[V_{Me}{}''][h^{\cdot}] \quad [8]$$

where k_5 and k_6 are appropriate rate constants in Eq. [3]. Finally for cation vacancies we obtain

$$\frac{d[V_{Me}{}'']}{dt} = k_5[O^-] - k_6[V_{Me}{}''][h^{\cdot}] - j_v \quad [9]$$

where j_v denotes the flux of vacancies from the surface into the crystalline bulk. All concentration terms in Eq. [7]-[9] correspond to the surface.

Distribution of Electrical Potential in the Boundary Layer

Shift of Eq. [1], [2], and [3] to the right leads to the formation of doubly ionized cation vacancies localized initially at the surface and to generation of surface charge q_s

$$q_s = -2e [V_{Me}{}''] \quad [10]$$

Consequently, the surface charge causes increase in surface potential and formation of electrical double layer (boundary layer) enriched with electron holes.

In the considerations below we assume that before admission of an oxygen dose, the initial surface potential, with respect to the bulk of the oxide crystal, is negligible comparing its changes accompanying further chemisorption of O_2.

The electrical potential in the boundary layer is related to charge density according to Poisson's equation

$$\frac{d^2\psi}{dx^2} = -\frac{4\pi}{\epsilon}\rho(x) \quad [11]$$

where ψ = surface potential, x = distance from the crystal surface, ϵ = dielectric constant, and $\rho(x)$ = charge density. It is also assumed that ϵ is independent of both x and electric field. $\rho(x)$ may be expressed as

$$\rho(x) = e\{[h^{\cdot}]_b \exp(-e\psi/kT) - [e^-]\exp(e\psi/kT) - 2[V_{Me}{}''] + \sum_i [F_i]z_i\} \quad [12]$$

where $[F_i]$ is the concentration of impurities of effective charge z_i. The Boltzmann distribution of electronic carriers is assumed because of their large mobilities as compared with mobilities of ionic defects. The lattice electroneutrality condition for the crystalline bulk is

$$[h^{\cdot}]_b - [e^-]_b - 2[V_{Me}{}'']_b + \sum_i [F_i]_b z_i = 0 \quad [13]$$

where subscript b refers to the bulk. The concentrations expressed in Eq. [12], [13], and below are considered as volume concentrations in cm^{-3} (contrary to Eq. [7], [8], and [9] where surface concentrations were used). Assuming condition [13] the relation for $\rho(x)$ may be expressed

$$\rho(x) = e\{[h^{\cdot}]_b[\exp(-e\psi/kT) - 1] + [e^-]_b[1 - \exp(e\psi/kT)]\} - 2e\{[V_{Me}{}''] - [V_{Me}{}'']_b\} \quad [14]$$

Therefore, Poisson's equation may be written

$$\frac{d^2\psi}{dx^2} = -\frac{8\pi e[h^{\cdot}]_b}{\epsilon}\frac{1}{2}\left\{[\exp(-e\psi/kT) - 1] + \frac{1}{2}\alpha[1 - \exp(e\psi/kT)] - \frac{[V_{Me}{}''] - [V_{Me}{}'']_b}{[h^{\cdot}]_b}\right\} \quad [15]$$

whre $\alpha = [e^-]_b/[h^{\cdot}]_b$. The boundary conditions for Eq. [15] are

$$\left.\begin{array}{l} \psi = 0 \\ \dfrac{d\psi}{dx} = 0 \end{array}\right\} x \to 0 \quad [16]$$

$$\left(\frac{d\psi}{dx}\right)_0 = \Delta q_s \frac{4\pi}{\epsilon} \quad x = 0 \quad [17]$$

where Δq_s is the surface charge generated due to formation of cation vacancies and localized at the surface.

In order to solve Eq. [15] we have to determine $[V_{Me}{}'']$ (which varies with both x and time t) using the diffusion equation

$$\frac{\partial[V_{Me}]}{\partial t} = \frac{\partial}{\partial x}\left\{D_v\frac{\partial[V_{Me}{}'']}{\partial x} + \frac{2eD_v}{kT}\frac{\partial\psi}{\partial x}[V_{Me}{}'']\right\} \quad [18]$$

where D_v is the diffusion coefficient of cation vacancies.

In further considerations we describe the outward surface diffusion of cation vacancies being formed at $t = 0$ and localized initially at the surface layer of the thickness, a, which in the first approximation is referred to the first monolayer. During the diffusion process the surface concentration of vacancies is assumed to be uniform and independent of surface topography and its energetic state. Therefore, the initial and boundary conditions for Eq. [18] are

$$\left.\begin{array}{ll} [V_{Me}{}'']_s = [V_{Me}{}'']_s{}^{\circ} & \text{for } -a < x < 0 \text{ and } t = 0 \\ [V_{Me}{}''] = [V_{Me}{}'']_b & \text{for } a < x < \infty \text{ and } t = 0 \end{array}\right\} \quad [19]$$

$$\frac{\partial[V_{Me}{}'']_s}{\partial t} = D_v\left\{\frac{\partial[V_{Me}{}'']_s}{\partial x}\right. \text{ for } x = 0 \text{ and } t > 0 \quad [20]$$

and

$$[V_{Me}''] = [V_{Me}'']_s \text{ for } x = 0 \text{ and } t > 0 \quad [21]$$

The schematic diagram in Fig. 2 illustrates the distribution of cation vacancies near the surface at $t = 0$ and at $t > 0$.

Equations [15] and [18], as well as conditions [16] and [17], form a nonlinear partial boundary value problem. Its analytical solution is impossible. Only iterative, numerical methods may be applied.

Equations [7], [8], and [9] should be considered together with Eq. [15] and [18]. However, it results from the experimental data that formation of the surface charge due to ionization of the adsorbed species is much faster than the subsequent discharging of the surface caused by ionic diffusion (1, 2). Therefore, t_{max} (Fig. 1) may here be considered as $t = 0$. We also assume that at $t = 0$ the initial concentration of cation vacancies $[V_{Me}'']_s^o$ refers to the surface layer within $a < x < 0$.

Let us now estimate the term in Eq. [18], responsible for defect migration under potential gradient, regarding the thermal diffusion term

$$b = \frac{D_v \dfrac{\partial [V_{Me}'']}{\partial x}}{D_v \dfrac{2e}{kT} \dfrac{\partial \psi}{\partial x} [V_{Me}'']} = \frac{\dfrac{\Delta [V_{Me}'']}{\Delta d}}{\dfrac{\Delta \psi}{L} [V_{Me}'']} \cdot \frac{kT}{2e} \quad [22]$$

where Δd is the thickness of diffusion layer increasing with time as the concentration gradient propagates inwards and L is the screening depth. According to the experimental conditions we may estimate: $\Delta[V_{Me}''] \cong [V_{Me}'']$; $\Delta d = 10^{-7}$ cm; $\Delta\psi = 200$ mV; $L = 10^{-5}$ cm; $T = 675°K$. Therefore $b = 15$, indicating the thermal diffusion is 15 times faster than migration. For longer times Δd increases but at the same time $\Delta\psi$ decreases. Hence, assuming the thermal diffusion as predominant, Eq. [18] acquires the form

$$\frac{\partial [V_{Me}'']}{\partial t} = D_v \frac{\partial^2 [V_{Me}'']}{\partial x^2} \quad [23]$$

assuming that D_v is independent of defect concentration (16). The term of thermal diffusion involves diffusion of lattice species which occurs within the thermally equilibrated crystal.

Solution of Poisson's Equation

We introduce the following nondimensional variables

$$\tilde{x} = x/L$$

$$\tilde{\psi} = e\psi/kT \quad [24]$$

$$\tilde{q} = \Delta q_s \frac{4\pi e L}{kT}$$

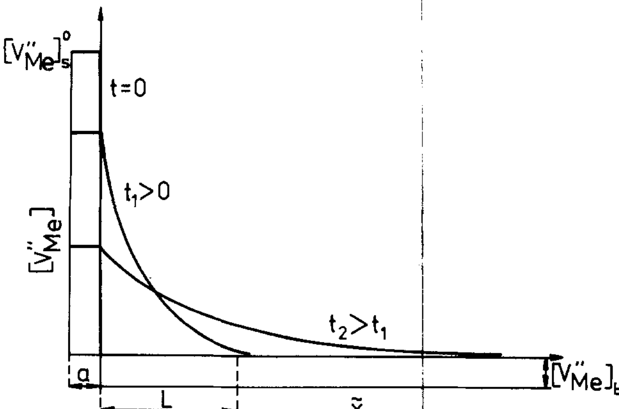

Fig. 2. Schematic distribution of cation vacancies in the boundary layer at different times.

where

$$\frac{1}{L} = \left\{ \frac{8\pi e^2 [h^\cdot]_b}{\epsilon kT} \right\}^{1/2} \quad [25]$$

Taking into account conditions [24], Eq. [15] assumes the form

$$\frac{d^2\tilde{\psi}}{dx^2} = -\rho_o - \frac{1}{2} \exp(-\tilde{\psi}) + \frac{1}{2} \alpha \exp \tilde{\psi} + f \quad [26]$$

where

$$\rho_o = \tfrac{1}{2} (\alpha - 1)$$

$$f = \frac{[V_{Me}''] - [V_{Me}'']_b}{[h^\cdot]_b}$$

This is an inhomogeneous nonlinear differential equation of the second order. Its analytical solution seems impossible at any form of f. Solving Eq. [26] we consider two limiting cases.

The first case concerns $t = 0$ when generated cation vacancies are located at the surface and therefore the term f is negligible. For short times $\tilde{\psi}$ assumes maximal value and then nonlinearity of Eq. [26] is pronounced. Neglecting f Eq. [26] can be integrated

$$\frac{d\tilde{\psi}}{dx} = \{\alpha \exp \tilde{\psi} + \exp(-\tilde{\psi}) + (\alpha - 1)\tilde{\psi} + C\}^{1/2} \quad [27]$$

where C is a constant.

Applying the boundary condition

$$\frac{d\tilde{\psi}}{dx} \to 0 \text{ and } \tilde{\psi} = 0 \text{ when } x \to \infty$$

we receive for $\tilde{q}$

$$\tilde{q} = -\left(\frac{d\tilde{\psi}}{dx}\right)_o = \{\alpha \exp \tilde{\psi}_s + \exp(-\tilde{\psi}_s) + (\alpha - 1)\tilde{\psi}_s - (1 + \alpha)\}^{1/2} \quad [28]$$

where $\tilde{\psi}_s$ is the surface potential.

As seen the relation between $\tilde{\psi}_s$ and $\tilde{q}$ is nonlinear. Let us determine limits of this nonlinearity. By expanding $\exp \tilde{\psi}_s$ and $\exp(-\tilde{\psi}_s)$ in a power series near zero and neglecting terms of the order greater than three we obtain after some rearrangements

$$\tilde{q} = -\tilde{\psi}_s \sqrt{\frac{1+\alpha}{2}} \left\{ 1 + \frac{(\alpha - 1)\tilde{\psi}_s}{(\alpha + 1)3} + \frac{\tilde{\psi}_s^2}{6} + \frac{(\alpha - 1)\tilde{\psi}_s^3}{(\alpha + 1)30} + \ldots \right\}^{1/2} \quad [29]$$

For $\alpha = 0$ and $\tilde{\psi} = 1$ (for NiO refer to $\psi = 70$ mV at 400°C) the deviation from linearity assumes 7%.

The second case refers to small values of $\tilde{\psi}$ for which the expression $\exp(-\tilde{\psi})$ and $\exp \tilde{\psi}$ in Eq. [26] may be substituted by terms $(1 - \tilde{\psi})$ and $(1 + \tilde{\psi})$, respectively. Then Eq. [26] assumes the linear form

$$\frac{d^2\tilde{\psi}}{d\tilde{x}^2} = \beta\tilde{\psi} + f \quad [30]$$

where $\beta = \tfrac{1}{2}(1 + \alpha)$.

This form of Poisson's equation is suitable for describing reconstructions of the surface charge layer for longer times when $[V_{Me}'']_s$ achieves a low value. Ap-

plying Lagrange's indefinite multilayers method we obtain the solution of Eq. [30] in the form

$$\tilde{\psi} = A \exp(-\sqrt{\beta}\tilde{x}) - \frac{1}{2\sqrt{\beta}} \exp \sqrt{\beta}\tilde{x} \int_{\tilde{x}}^{\infty} f \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x} + \frac{1}{2\sqrt{\beta}} \exp(-\sqrt{\beta}\tilde{x}) \int_{\tilde{x}}^{\infty} f \exp(\sqrt{\beta}\tilde{x})\, d\tilde{x} \quad [31]$$

The constant A may be determined from the condition

$$\left(\frac{\partial \tilde{\psi}}{\partial \tilde{x}}\right)_0 = -\tilde{q} \quad [32]$$

Then we obtain

$$\left(\frac{\partial \tilde{\psi}}{\partial \tilde{x}}\right) = -\sqrt{\beta} A \exp(-\sqrt{\beta}\tilde{x}) - \frac{1}{2} \exp(\sqrt{\beta}\tilde{x}) \int_{\tilde{x}}^{\infty} f \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x} - \frac{1}{2} \exp(-\sqrt{\beta}\tilde{x}) \int_{\tilde{x}}^{\infty} f \exp(\sqrt{\beta}\tilde{x})\, d\tilde{x} \quad [33]$$

For $\tilde{x} = 0$ we have

$$\left(\frac{\partial \tilde{\psi}}{\partial \tilde{x}}\right)_s = -\tilde{q} = A\sqrt{\beta} + \frac{1}{2}(\Gamma_1 + \Gamma_2) \quad [34]$$

where

$$\Gamma_1 = \int_0^{\infty} f \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x}$$

$$\Gamma_2 = \int_0^{\infty} f \exp(\sqrt{\beta}\tilde{x})\, d\tilde{x} \quad [35]$$

Combining Eq. [31] and [34] we obtain for surface potential $\tilde{x} = 0$

$$\tilde{\psi}_s = \frac{\tilde{q}}{\sqrt{\beta}} - \Gamma_1 = \frac{1}{\sqrt{\beta}}\tilde{q} - \int_0^{\infty} \frac{[V_{Me}''] - [V_{Me}'']_b}{[h^{\cdot}]_b} \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x} \quad [36]$$

Solution of Fick's Second Law

In order to determine the vacancy concentration we solve Eq. [23]. Let us introduce the following terms

$$[\tilde{V}] = \frac{[V_{Me}'']}{V_{Me_o}}$$

$$\tau = tD_v/L^2$$

$$\tilde{x} = x/L$$

Accordingly Eq. [23] assumes the form

$$\frac{\partial[\tilde{V}]}{\partial \tau} = \frac{\partial^2[\tilde{V}]}{\partial \tilde{x}^2} \quad [37]$$

Equation [37] may be solved applying Laplace's transformations. Its final solution assumes the form

$$[V_{Me}''] = \{[V_{Me}'']_s^o - [V_{Me}'']_b\} \exp(r\tilde{x} + r^2\tilde{x}) \operatorname{erfc}\left(\frac{\tilde{x}}{2\sqrt{\tau}} + r\sqrt{\tau}\right) + [V_{Me}'']_b \quad [38]$$

where $r = L/a$. In our case $r >> 1$.

Substituting the expression for $[V_{Me}'']$ into Eq. [36] we obtain

$$\tilde{\psi}_s = \frac{\tilde{q}}{\sqrt{\beta}} - \int_0^{\infty} \frac{[V_{Me}'']_s^o - [V_{Me}'']_b}{[h^{\cdot}]_b} \exp(r\tilde{x} + r^2\tau) \operatorname{erfc}\left(\frac{\tilde{x}}{2\sqrt{\tau}} + r\sqrt{\tau}\right) \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x} \quad [39]$$

Taking into account that

$$\tilde{q} = \frac{q_s 4\pi e L}{\epsilon k T} = -\frac{8\pi e^2 L a}{\epsilon k T}\{[V_{Me}'']_s - [V_{Me}'']_b\} = \frac{[V_{Me}'']_s - [V_{Me}'']_b}{[h^{\cdot}]_b r} \quad [40]$$

and considering that

$$[V_{Me}''] = \frac{[V_{Me}'']_s^o - [V_{Me}'']_b}{r} \exp\left(-\frac{\tilde{x}^2}{4\tau}\right) \quad \text{for } r\sqrt{\tau} >> 1 \quad [41]$$

we obtain for $\tilde{\psi}_s$

$$\tilde{\psi}_s = \frac{1}{r\sqrt{\beta}[h^{\cdot}]_b}\left\{\Delta[V_{Me}'']_s + \frac{\sqrt{\beta}}{\sqrt{\pi\tau}} \int_0^{\infty} \{[V_{Me}'']_s^o - [V_{Me}'']_b\} \exp\left(-\frac{\tilde{x}^2}{4\tau}\right) \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x}\right\} \quad [42]$$

where

$$[V_{Me}'']_s = \{V_{Me}'']_s - [V_{Me}'']_b = \frac{1}{r\sqrt{\pi\tau}}\{[V_{Me}'']_s^o - [V_{Me}'']_b\} \quad [43]$$

Finally Eq. [42] may be transformed into

$$\tilde{\psi}_s = \frac{[V_{Me}'']_s^o - [V_{Me}'']_b}{r[h^{\cdot}]_b}\left\{\frac{1}{r} + \sqrt{\beta} \int_0^{\infty} \exp\left(-\frac{\tilde{x}^2}{4\tau}\right) \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x}\right\} \quad [44]$$

As seen from Eq. [44] the term related to surface charge $1/r$ has a negligible effect on $\tilde{\psi}_s$ when $\tau > r^2$. For longer times we can write

$$\sqrt{\beta} \int_0^{\infty} \exp\left(-\frac{\tilde{x}^2}{4\tau}\right) \exp(-\sqrt{\beta}\tilde{x})\, d\tilde{x} = 1 \quad [45]$$

and consequently

$$\tilde{\psi}_s = -\frac{[V_{Me}'']_s^o - [V_{Me}'']_b}{r\sqrt{\beta}[h^{\cdot}]_b} \quad [46]$$

For $\tau = 0$ surface potential assumes maximum

$$\tilde{\psi}_{max} = \frac{[V_{Me}'']_s^o - [V_{Me}'']_b}{r[h^{\cdot}]_b} \quad [47]$$

Then we obtain final relation between D_v, ψ_s, and ψ_{max}

$$\frac{\psi_s}{\psi_{max}} = \frac{1}{\sqrt{\beta\pi\tau}} = \frac{L}{\sqrt{\beta\pi D_v t}} \quad [48]$$

We assume that the surface potential in Eq. [48] refers to work function changes

$$e\psi_s = \Delta\Phi_t$$

$$e\psi_{max} = \Delta\Phi_{max} \quad [49]$$

For calculations we also assume $t_{max} = 0$.

Combining Eq. [48] and [25] we obtain

$$D_v = \frac{10^{-2}\epsilon kT}{2.4\pi^2 e^2 [h^\cdot]_b \{1 + [e^-]_b/[h^\cdot]_b\} tg^2\gamma} \quad [50]$$

where $tg\gamma$ is the slope of the linear part of the relation $\Delta\Phi_t/\Delta\Phi_{max}$ *vs.* $1/\sqrt{t}$.

Taking into account relation between chemical diffusion coefficient and diffusion coefficient of defects

$$\tilde{D} = (1 + Z) D_v \quad [51]$$

and assuming $z = 2$ and $[h^\cdot]_b >> [e^-]_b$, we finally obtain

$$\tilde{D} = \frac{10^{-2}\epsilon kT}{0.8\pi^2 e^2 [h^\cdot]_b \, tg^2\gamma} \quad [52]$$

The presented quantitative considerations and the proposed particular solution of Fick's second law for near surface layer enables the calculation of the chemical diffusion coefficient for this layer. Therefore, for $\tilde{D}$ in Eq. [52] we may write

$$\tilde{D} = \tilde{D}_{SL}$$

Determination of $\tilde{D}_{SL}$ leads to a possibility of a quantitative analysis of transport properties for near surface layer of oxide materials and also of other nonstoichiometric compounds. $\tilde{D}_{SL}$ and $\tilde{D}_{bulk}$ may differ essentially if segregation of lattice components occurs. Independent determination of $\tilde{D}_{SL}$ and $\tilde{D}_{bulk}$ is therefore especially important for appropriate characterization of compounds and their surface properties at elevated temperatures after segregation. Data of $\tilde{D}_{SL}$ may be especially useful for understanding and correct interpretation of several technological processes as standardization of semiconducting materials, sintering of ceramic materials, reduction of ores in metallurgy, and heterogeneous catalytic reactions.

Conclusions

It has been found that the dependence between surface potential and surface charge obeys a linear relationship at higher reequilibration times when discharging of the oxide surface is produced mainly by thermal diffusion. Appropriate solution of Fick's second law leads to chemical diffusion coefficient for near-to-surface layer of oxide materials. The described method of measuring $\tilde{D}_{SL}$ from the work function data creates a possibility of studying transport properties of the outer surface layer independently of the bulk. It should be emphasized that both structure and diffusion parameters for the bulk and the surface layer may differ essentially, especially for oxide solid solutions exhibiting the effect of segregation of lattice components.

Surface-controlled mechanism in heterogeneous reequilibration processes for oxide-oxygen systems may find an explanation in investigations of $\tilde{D}_{SL}$ and $\tilde{D}_{bulk}$, independently.

Near-Surface and Bulk Chemical Diffusion of Undoped NiO

Z. Adamczyk and J. Nowotny

Institute of Catalysis and Surface Chemistry, Polish Academy of Sciences, 30-239 Kraków, Poland

ABSTRACT

Work function is applied to monitor the reequilibration kinetics at the NiO surface after sorption of small oxygen doses. Using appropriate solution of Fick's second law and of Poisson's equation the chemical diffusion coefficient for the near-to-surface layer of undoped NiO was calculated in the range 300°-425°C

$$\tilde{D}_{SL} = 4 \cdot 10^{-5} \exp [(-21{,}000 \pm 2{,}100)/RT] \quad [\text{cm}^2\,\text{sec}^{-1}]$$

The obtained results are discussed regarding the available diffusion data for NiO obtained at high temperatures.

Chemical diffusion coefficients for nonstoichiometric oxide materials may be calculated from the reequilibration kinetic data. The reequilibration kinetics may be followed directly by measuring changes in crystal nonstoichiometry *vs.* time. The gravimetrical method is applicable when changes in crystal composition are sufficiently high (1-3). However, for compounds showing a small deviation from stoichiometry, the electrical conductivity method is more convenient (4). Both methods refer to the crystalline bulk and therefore may be applied at sufficiently high temperatures at which equilibrium in a gas-solid system may be reached relatively fast. On the other hand, the method based on the work function data leads to chemical diffusion coefficient $\tilde{D}_{SL}$ for the near-to-surface layer of the oxide crystals (5).

The purpose of the present work is to determine the surface reequilibration kinetics and to calculate $\tilde{D}_{SL}$ for undoped NiO. NiO is a convenient object for diffusion investigations exhibiting a very small concentration of defects which may be considered to form an ideal solution in the crystal. The available data of $\tilde{D}$ for this oxide material (4, 6-12) may serve as a comparative material to discuss the results obtained from the work function measurements.

Discussion of Chemical Diffusion Data for NiO

The available data of chemical diffusion for NiO differ considerably concerning the absolute values and the reported activation energies (4, 6-12). The electrical conductivity method applied in most cases is a very accurate one (13). The differences seem to consist in crystal geometry. Also concentration of impurities may have an essential effect on the measured values of reequilibration kinetic data, especially when segregation of lattice components occurs (14). Then a surface-controlling mechanism may be observed (1, 2).

Table I illustrates available data of both the chemical diffusion coefficient $\tilde{D}$ and the diffusion coefficient of defects D_v. Both are correlated according to the expression

$$\tilde{D} = (1 + Z)D_v \qquad [1]$$

On one side, data of Wagner *et al.* (4, 9), of Koel and Gellings (8), and of Nowotny and Sadowski (12, 13) show an excellent agreement as concerns the activation energy varying between 21 and 24 kcal · mole^{-1}. Another group of data shows high values of the activation energy ranging from 31 to 37 kcal·mole^{-1} (6, 7, 10, 11).

Key words: work function, semiconductor, defects, potential.

Several experimental details are important to determine $\tilde{D}$ correctly. First, the oxide sample should be well equilibrated with the gas phase. It is also important to determine ranges of the equilibration kinetics for which appropriate equations (logarithmic and parabolic) are fulfilled. The calculated diffusion data are self-consistent when calculations according to both parabolic and logarithmic equations (at appropriate ranges) lead to identical values (13). Several papers do not involve any experimental details which could answer these questions (6, 7, 11). The results of Ikeda and Nii (10) show different reduction and oxidation kinetics, which are not in accordance with the bulk diffusion mechanism found for NiO (12, 13). Also impurity concentration required for critical analysis of conflicting results is lacking in several cases (6, 10).

As it results from experimental work of Sadowski (13) crystal geometry has no effect on the measured activation energy of $\tilde{D}$ but as a strong effect on the calculated value of $\tilde{D}$ as a consequence of concentration profiles during the reequilibration.

In the present studies the work function is used to follow the reequilibration kinetics at the surface of NiO crystal and appropriate solution of Fick's second law (5) is utilized to calculate $\tilde{D}_{SL}$.

Comparison of the results obtained presently and those from the electrical conductivity method may bring further arguments concerning diffusion data for NiO.

Experimental

An undoped, polycrystalline NiO sample was taken for investigation. The sample was prepared by calcination of nickel carbonate at 1000°C for 4 hr in air. The specific surface area was 0.42 m^2 g^{-1}. Average particle size was 0.05 mm. Results of spectral analysis for impurity concentrations are given in Table II.

The work function was measured using the dynamic capacitor method (15). The compact polycrystalline sample was located on the stainless steel plate of the dynamic condenser. The chemisorption system is able either to maintain p_{O_2} = const. in the measuring system or to admit the required oxygen dose in it. The electronic device made it possible to monitor fast changes of the work function in time (15, 16). Before measurements the sample was standardized at 400°C for 1 hr under 10 Torr and then outgassed in vacuo referring to $p_{O_2} = 10^{-6}$ Torr. After the standardization the temperature was set on the experimental level and the sample was equilibrated at given conditions of T and p_{O_2} until a constant value of the work function Φ_t

Table I. Data of $\tilde{D}$ and D_v for NiO

No.	Authors	p_{O_2} range (atm)	T range (°C)	Concentration of mono- and three-valent impurities (ppm)	$\tilde{D}$ or D_v vs. T ($cm^2 sec^{-1}$)	Remarks

vs. time t was reached. Then the required oxygen dose was admitted into the measuring system and at that moment both $\Delta\Phi_t$ and Δp_{O_2} were measured isothermally in time. The amount of the NiO sample taken for each experiment was always equal to 0.31g. Two different oxygen doses (indicated as A_1 and A_2) were used. Table III gives their amount and corresponding fraction of monolayer coverage at $t = 0$.

Results and Discussion

The data of $\Delta\Phi_t$ *vs.* t taken after admission of an O_2 dose show a nonmonotonous character involving rapid initial increase and then slower decrease (16). The increase of Φ_t is produced by chemisorption of O_2 and the subsequent decrease refers to ionic diffusion and leads to building up of new lattice elements. Accordingly the work function assumes the initial value. It has been found that p_{O_2} rapidly decreases (after admission of an O_2 dose) from the initial value listed in Table II and achieves vacuum (below 10^{-6} Torr) before $\Delta\Phi_t$ reaches maximum ($\Delta\Phi_{max}$). We assume then that Φ_t changes at time higher than t_{max} (corresponding to $\Delta\Phi_{max}$) are determined only by transfer of ionic species from the surface into the crystalline bulk. The experimental data of $\Delta\Phi_t$ correspuonding to discharging the surface are plotted as a function of $\Delta\Phi_t/\Delta\Phi_{max}$ *vs.* $1/\sqrt{t}$ in Fig. 1. Data of $\Delta\Phi_t$ *vs.* t are presented elsewhere (16). The times when $\Delta\Phi_t \cong 0$ correspond to diffusion within several outer layers only, however relatively small amounts of O_2 used experimentally (16) lead to the negligible final $\Delta\Phi_t$ value after relatively short times. The chemical diffusion coefficient was calculated according to the following equation which is a solution of Fick's second law (5)

$$D_{SL} = (1 + Z) \frac{L^2}{60\pi\beta t g^2\gamma[h^\cdot](1 + [e^-]/[h^\cdot])} \quad [2]$$

where: ϵ = dielectric constant (for NiO, $\epsilon = 10$), Z = effective charge of diffusing defects, L = the screening depth expressed by the formula, $\beta = \frac{1}{2}$, and $[e^-]$ and $[h^\cdot]$ are concentrations of quasifree electrons and electron holes, respectively

$$L = \sqrt{\frac{\epsilon kT}{8\pi e^2([h^\cdot] + [e^-])}} \quad [3]$$

$Tg\gamma$ is the slope of the linear part of the dependence $\Delta\Phi_t/\Delta\Phi_{max}$ *vs.* $1/\sqrt{t}$ in the range of higher reequilibration times where Poisson's equation holds linearity. It has been found that $tg\gamma$ is independent of the amount of oxygen used experimentally, Fig. 2.

As results from quantitative considerations (5), Eq. [2] is valid only for longer reequilibration times when the surface potential can be sufficiently low and the migration term in the diffusion process may be neglected as compared to the thermal diffusion term. This is the reason that the linearity of $\Delta\Phi_t/\Delta\Phi_{max}$ *vs.* $1/\sqrt{t}$ dependence (Fig. 1 and 2) is fulfilled only at higher equilibration times. At lower times the surface potential acquires highest values, the migration term becomes comparable to the thermal diffusion term, and as a result a marked deviation from the linearity is observed. In the experimental conditions applied we may assume doubly ionized cation vacancies and electron holes to be predominant NiO lattice defects (16,

Table III. Experimental O_2 doses

Oxygen dose	Amount (moles)	Fraction of the monolayer coverage (%)	Initial oxygen pressure (Torr)
A_1	$4.23 \cdot 10^{-8}$	4.1	$9.2 \cdot 10^{-4}$
A_2	$1.24 \cdot 10^{-7}$	12.0	$2.7 \cdot 10^{-3}$

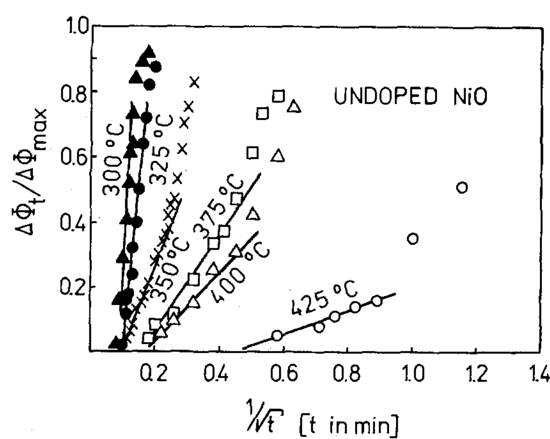

Fig. 1. Experimental work function data for NiO plotted as $\Delta\Phi_t/\Delta\Phi_{max}$ vs. $1/\sqrt{t}$ for oxygen dose A_1.

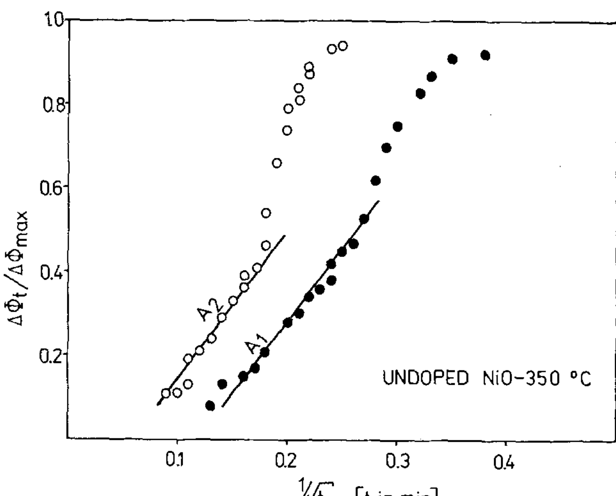

Fig. 2. Work function data for NiO plotted as $\Delta\Phi_t/\Delta\Phi_{max}$ vs. $1/\sqrt{t}$ for oxygen doses A_1 and A_2 at 350°C.

17). Therefore, Eq. [2] and [3] may be expressed in simpler forms

$$D_{SL} = (1 + Z) \frac{\epsilon L^2}{60\pi\beta tg^2\gamma[h^\cdot]} \quad [4]$$

$$L = \sqrt{\frac{\epsilon kT}{8\pi e^2[h^\cdot]}} \quad [5]$$

The concentration of electron holes was assumed to fulfill the electroneutrality condition

$$[h^\cdot] = 2[V_{Ni}''] \quad [6]$$

where $[V_{Ni}'']$ was calculated according to high temperature data of Mitoff (18)

$$[V_{Ni}''] = 11p_{O_2}^{1/6} \exp\left(-\frac{1/3\,\Delta H_f}{RT}\right) \quad [7]$$

where ΔH_f is the activation enthalpy of formation of cation vacancies equal to 54 kcal · mole^{-1} (13, 18). Assuming condition [6] we neglect the effect of impurities on $[h^\cdot]$. Using the work function data (Fig. 1) and applying relations [4], [6], and [7] we obtain

$$\tilde{D}_{SL} = 4 \cdot 10^{-5} \exp[(-21{,}000 \pm 2{,}100)/RT] \quad [8]$$

Table IV shows data of both $\tilde{D}_{SL}$ and L calculated according to Eq. [4] and [5], respectively. Figure 3 illustrates the present results as well as the high temperature data of Price and Wagner (4) and of Nowotny and Sadowski (12) extrapolated to the temperature range 300°-425°C. Taking into account the two different methods applied, two different states of the samples used (single and polycrystalline), and different temperature ranges, there is surprising agreement concerning the activation energy values. Moreover, it should be emphasized that the electrical conductivity method applicable at high temperatures refers to the

Table IV. Values of L, $tg\gamma$, and $\tilde{D}_{SL}$ at different temperatures

Temp (°C)	L (cm)	$tg\gamma$	$\tilde{D}_{SL}$ (cm²/sec⁻¹)
300	$4.56 \cdot 10^{-5}$	11.2	$5.1 \cdot 10^{-13}$
325	$3.36 \cdot 10^{-5}$	7.4	$6.6 \cdot 10^{-13}$
350	$2.55 \cdot 10^{-5}$	3.2	$2.04 \cdot 10^{-12}$
375	$1.97 \cdot 10^{-5}$	2.0	$3.0 \cdot 10^{-12}$
400	$1.55 \cdot 10^{-5}$	1.25	$4.8 \cdot 10^{-12}$
425	$1.24 \cdot 10^{-5}$	0.69	$1.02 \cdot 10^{-11}$

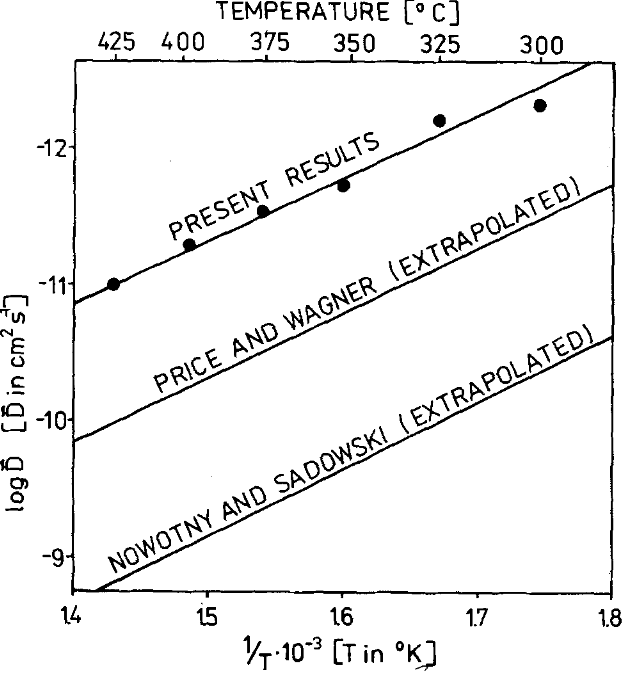

Fig. 3. Arrhenius plots of chemical diffusion coefficient calculated from the work function data (present results) and extrapolated high temperature data of Price and Wagner (4) and of Nowotny and Sadowski (12).

bulk of the crystal, whereas the work function method applied presently concerns the near-to-surface layer which is limited mainly to several outer crystal layers.

Specific surface interactions, resulting, *e.g.*, from segregation of lattice components, may have an essential effect on the measured value of $\tilde{D}_{SL}$ from the work function data. There is, however, some evidence indicating that the segregation effect does not occur for undoped NiO crystal (13, 14). Therefore, the observed agreement between the diffusion coefficient determined from Eq. [3] and high temperature diffusion data is understandable.

The observed differences in absolute values of $\tilde{D}$ in Fig. 3 are apparently connected with several assumptions and approximations introduced to solve Poisson's equation (5).

Conclusions

Appropriate solution of Fick's second law and of Poisson's equation leads to the determination of the chemical diffusion coefficient from the work function data accompanying reequilibration of NiO surface. The determination of $\tilde{D}_{SL}$ is possible at higher reequilibration times when the migration under electrical potential becomes negligible and the dependence $\Delta\Phi_t/\Delta\Phi_{max}$ *vs.* $1/\sqrt{t}$ holds linearity. The data of $\tilde{D}(T)$ obtained for undoped NiO from the work function measurements show excellent agreement, concerning the activation energy term, with the high temperature data of Wagner and co-workers (4, 9) and of Sadowski (13). The agreement indicates the negligible effect of the segregation of lattice components in undoped NiO crystal.

Preparation of Molybdenum Silicide Films by Reactive Sputtering

S. Yanagisawa and T. Fukuyama

Cooperative Laboratories, VLSI Technology Research Association, Takatsu-ku, Kawasaki, 213 Japan

ABSTRACT

A new deposition technique for molybdenum silicide films is presented whereby the films are deposited by magnetron-d-c-reactive sputtering using a Mo target in a silane argon atmosphere. The influence of sputtering conditions upon the film properties was investigated by utilizing mass spectroscopy, Auger electron spectroscopy, and x-ray diffractometry. Films with various Si/Mo atomic ratios up to 1.9 were obtained by controlling the sputtering power and the silane partial pressure. The crystal structures were found to be continuously transformed from Mo-rich silicides to Si-rich ones, including Mo_3Si, Mo_5Si_3, and $MoSi_2$, with increasing Si/Mo atomic ratio.

Studies toward the production of high density, high speed MOSLSI have explored the use of refractory metals such as Mo and W as gate and interconnection materials to replace conventional polysilicon (1-4). The refractory metals are much more conductive than polysilicon, and can withstand high temperature processing. However, these metals have poor resistance to the chemical reagents and oxidizing ambients used in MOS fabrication process, as compared with polysilicon (5, 6). This may limit the use of refractory metals. In order to overcome these disadvantages, the refractory metal silicides such as $MoSi_2$ and WSi_2, have been examined because of their oxidation resistance (7-9). Several deposition techniques of the silicide films were used, including sputtering and coevaporation of the elements with a dual electron beam evaporation unit.

This paper presents a new deposition method for molybdenum silicide films whereby the films are deposited by reactive sputtering using silane as a reactive gas. This method can easily provide the silicide films, *i.e.*, Mo_3Si, Mo_5Si_3, and $MoSi_2$, by adjusting sputtering conditions. The film properties are investigated by Auger electron analysis and x-ray analysis. The sputtering mechanism is also discussed, based upon these experimental results.

Experimental

The apparatus used is a magnetron-d-c-sputtering system (Varian S-Gun), as shown schematically in Fig. 1. Substrates are thermally oxidized silicon wafers of 3 in. diam and were mounted by spring clamps on a spherical rotating planetary substrate fixture. The Mo target is a 5 in. diam water-cooled circular conical

Key words: molybdenum, magnetron sputtering, silane, crystal structure.

cathode (99.99% pure). The system was pumped down to 2×10^{-6} Torr, and then backfilled to the sputtering pressure by introducing argon and silane. The substrates were preheated to about 200°C by radiation emitted from quartz lamp heaters. In this system, their heating during sputtering is negligible (10). Initially, the silane was admitted into the reaction chamber, followed by argon, until the total sputtering pressure reached 3×10^{-3} Torr. The silane partial pressure was varied up to 1.8×10^{-3} Torr. The film composition can be controlled by changing the silane partial pressure. Another method uses a mixture of argon and silane. In this case, the reproducibility of the film composition is superior to that of the first method. The sputtering pressure was measured by an ionization gauge within the high vacuum range prior to backfill. After backfill, a Schulz gauge which withstands corrosion in silane environments was used. After applying power, the sputtering pressure was found to rise higher than that before, indicating an increase of hydrogen due to the decomposition of silane in the argon plasma, as described later. During sputtering, a quartz crystal rate monitor was used to monitor the film thickness and the deposition rate. Since the change in frequency of the quartz crystal is dependent upon the density of the deposited film, the monitor was adjusted for each sputtering condition by which the film composition is determined. After deposition, the thickness was determined using Talystep. The nominal thickness of all the films deposited was 3000Å. The deposition rate was found to be nearly constant under constant sputtering power, within the silane partial pressure range used.

The decomposed products of silane were detected by a quadrupole mass spectrometer. The detector was positioned sufficiently far from the discharge region, as shown schematically in Fig. 1, and was protected from direct impingement by the particles sputtered from the target. Therefore, the species detected are considered to include only the neutral gas species which diffuse from the discharge region. Auger electron spectroscopy was used together with Ar sputtering to investigate the relative amounts of Si incorporated within the films. The electrical resistivity of the films was determined by the usual four-point probe technique in conjunction with thickness measurements using Talystep. The crystal structure of the film was investigated by x-ray diffraction using Cu-Kα radiation.

Results and Discussion

Sputtering procedure and film composition.—The sputtering power dependence of product species at an initial silane partial pressure of 6×10^{-4} Torr is shown in Fig. 2. The signals correspond to the ion currents in the mass spectrometer. The decomposition of silane is marked by a rise in the H_2 signal and a simultaneous fall in each of the Si, SiH_n (n = 1 to 4) signals. The initial Si and SiH_n signals could be attributed to the fragmentation of silane in the mass spectrometer ion source. The increase of molecular hydrogen H_2 as a decomposed product is consistent with the overall decomposition reaction

$$SiH_4 \rightarrow Si + 2H_2$$

As seen in Fig. 2, as the sputtering power was increased, all signals varied by an order of magnitude and then became constant, indicating that most of the silane is decomposed at powers greater than 0.6 kW. Figure 3 shows in-depth profiles for Si and Mo in the deposited film of 3000Å thickness. The profiles were measured by an Auger electron spectrometer. The sputtering power and the silane partial pressure were 2 kW and 1.2×10^{-3} Torr, respectively. Si was found to be uniformly distributed in the film. Si/Mo atomic ratios in the films, which were evaluated from the Auger electron signals, are plotted as a function of silane partial pressure for two levels of sputtering power, as shown in Fig. 4. The Si/Mo ratio was found

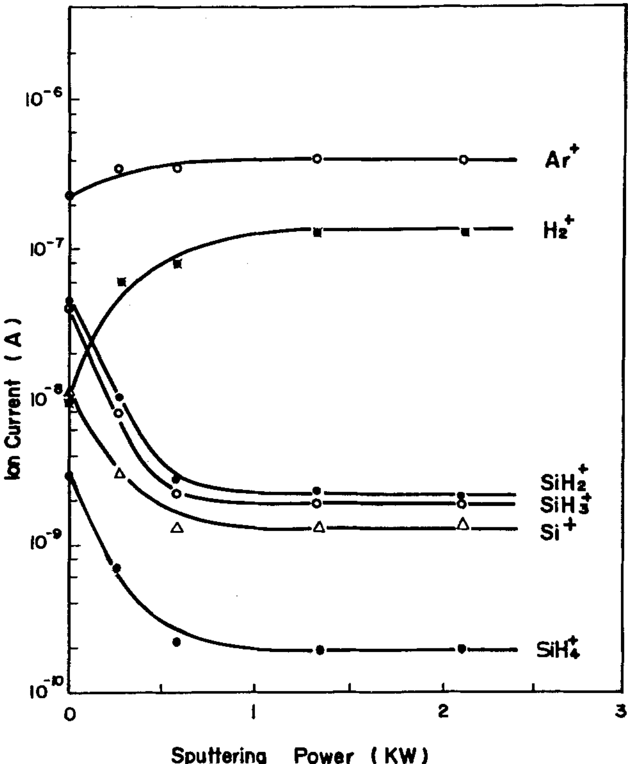

Fig. 2. Decomposed silane species as a function of sputtering power. Silane partial pressure is 6×10^{-4} Torr.

to increase superlinearly with the silane partial pressure and decrease inversely to the power.

In the magnetron sputtering system used here, most of the silane is decomposed within the intense argon plasma region which is sustained close to the target (10). The resulting Si atoms would be mostly adsorbed on a target surface (11). Because the substrate is positioned sufficiently far from the discharge region, it is improbable that Si atoms originating from the silane decomposed in the discharge region, would directly impinge on it. The main process for Si impinging on

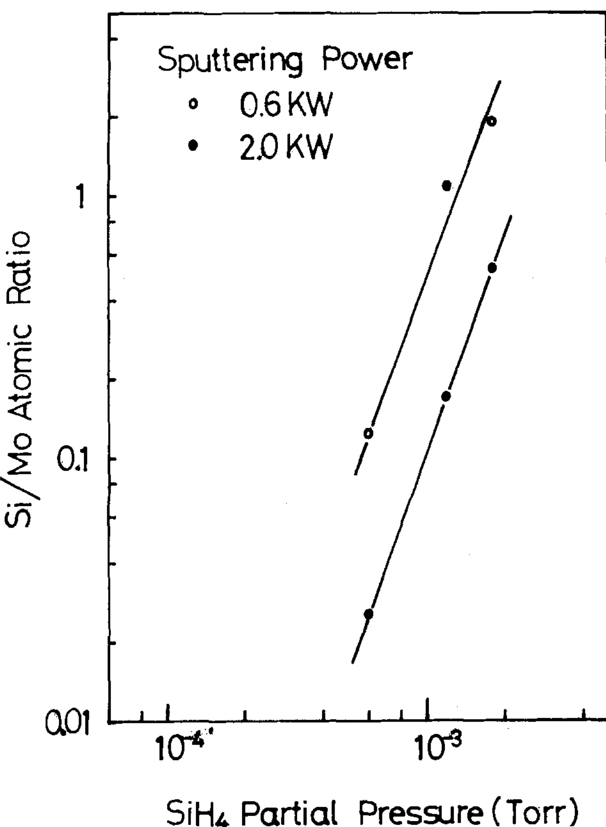

Fig. 4. Si/Mo atomic ratio of the film as a function of silane partial pressure using sputtering power as a parameter. The system pressure is 3×10^{-3} Torr.

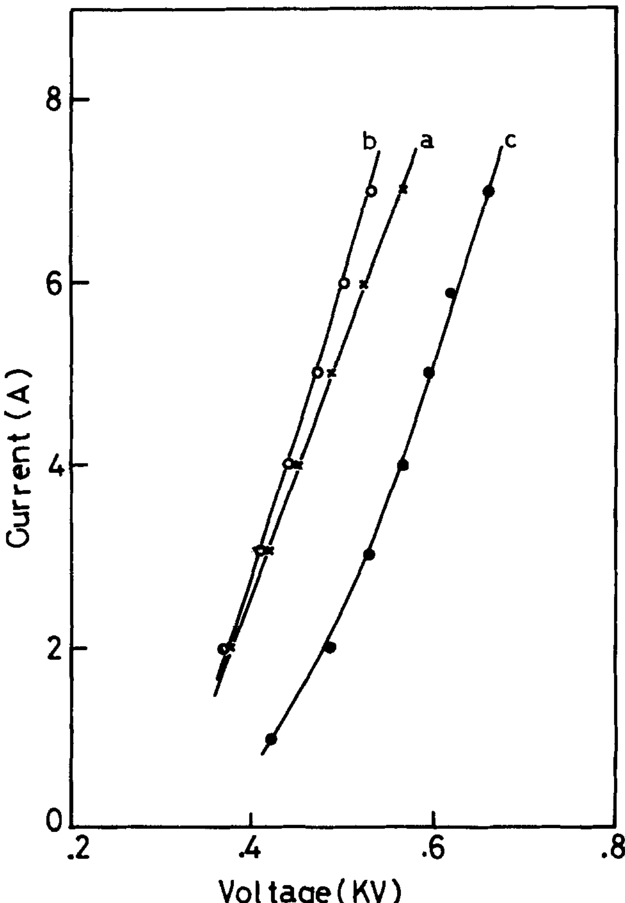

Fig. 5. Target current-voltage relationship for three different sputtering gases. Curve a, pure argon (P_{Ar}: 1.8×10^{-3} Torr); curve b, silane-argon mixture (P_{SiH_4}: 1.2×10^{-3} Torr, P_{Ar}: 1.8×10^{-3} Torr); curve c, nitrogen-argon mixture (P_{N_2}: 1.2×10^{-3} Torr, P_{Ar}: 1.8×10^{-3} Torr).

the substrate may be the bombardment, by Ar ions, of a target surface which has adsorbed a layer of Si. From such an adsorption model, the influence of silane partial pressure on the film composition may be qualitatively understood as follows.

If the silane partial pressure is low enough that the surface coverage is much less than unity, the sputtering yield of the Mo target is little affected by the silane partial pressure. In this case, a linear dependence of the Si/Mo ratio on the silane partial pressure may be expected, because the surface coverage increases linearly with the silane partial pressure (11, 12). However, when the silane partial pressure becomes high enough that the surface coverage is comparable to unity, the sputtering yield of the Mo target is considerably reduced when the silane partial pressure is increased, and sputtering of the adsorbed layer increases. In this case, there may be a deviation from a linear dependence of the film composition on the silane partial pressure, as shown in Fig. 4. With respect to the effect of the sputtering power on the film composition, the amount of Mo deposited on a substrate increases linearly with the power, while that of Si is constant. This is because the decomposed silane species are invariant at powers greater than 0.6 kW, as shown in Fig. 2. As a result, the Si/Mo ratio is inversely proportional to the power (12).

The deposition rate has been known to decrease as the reactive gas partial pressure is increased, that is, if oxygen or nitrogen is used as the reactive gas (11, 13). This is believed to be due to the decrease of sputtering of the nitride or oxide layer synthesized on the target material. However, the deposition rate observed here was found to hold nearly constant when the silane partial pressure was varied. In order to investigate this discrepancy, the effect of reactive gas on the target current-voltage relationship was measured as shown in Fig. 5. Three different gases were used as the sputtering gases: pure argon for curve a, a silane-argon mixture for curve b, and a nitrogen-argon mixture for curve c. The current increased when silane was added to the pure argon sputtering gas, but decreased when nitrogen was added. This result suggests that electrons supplied by the decomposed silane remain within the discharge region, thereby contributing to ionizing collisions with argon gas molecules. Such a mechanism may result in an increase of the target current and thereby compensate the decrease of the sputtering of the adsorbed layer on the target surface. It appears that the decomposition of nitrogen gas does not supply electrons.

Crystal structure.—The crystal structures were investigated by x-ray diffraction. As-deposited films, except for the pure Mo film, were found to be amorphous and to change to a polycrystalline structure after heat-treatment. The continuous transformation from Mo-rich to Si-rich silicides, including Mo_3Si, Mo_5Si_3, and $MoSi_2$, was observed as the Si/Mo ratio was increased up to 1.9. Figures 6(a)-(d) show x-ray diffractometer traces of films within the range $28° \leq 2\theta \leq 51°$, where each film was about 3000Å thick. Films with various Si/Mo ratios were annealed in an N_2 atmosphere for 30 min at temperatures from 600° to 1200°C. For the film with a Si/Mo ratio of 0.17, as shown in Fig. 6(a), the Mo(110) reflection is the only detectable peak when the annealing temperatures were blow 1000°C. Mo_3Si appears with the preferred reflection (210) at temperatures higher than 1000°C. The structure shows a mixture of Mo with Mo_3Si. In Fig. 6(b) for the Si/Mo ratio of 0.54, the Mo(110) reflection was not observed in any temperature range. The film was changed to single phase Mo_3Si with the preferred reflection (200) at temperatures over 800°C. Further addition of Si leads to mixtures of Mo_5Si_3 and $MoSi_2$ at temperatures over 800°C, as shown in Fig. 6(c). In Fig. 6(d)

Fig. 6. X-ray diffractometer traces from the films annealed for 30 min at various temperatures. Si/Mo ratios of the films are (a) 0.17, (b) 0.54, (c) 1.2, (d) 1.9.

for the Si/Mo ratio of 1.9, the hexagonal $MoSi_2$ appears at 600°C, and is continuously transformed to the tetragonal $MoSi_2$ as the temperature is increased over 800°C.

Resistivity.—The effect of the Si/Mo atomic ratio on the film resistivity was evaluated as shown in Fig. 7. Each film thickness is about 3000Å. The resistivity of the as-deposited films was quite high for a relatively large Si/Mo ratio. When the films were annealed for 30 min at 1000°C in N_2 atmosphere, a significant decrease in resistivity is observed for films with larger Si/Mo ratios. The amount of hydrogen incorporated within the film during sputtering results in an additional increase in as-deposited film resistivity. This hydrogen may be removed by high temperature annealing (14). This may cause a significant decrease in resistivity as a function of the annealing temperature for the larger Si/Mo ratio films. Furthermore, as shown by x-ray analysis, the recrystallization temperatures differ from each other depending upon the film composition. This also may explain the differences in temperature dependence of resistivity among the films having the various Si/Mo ratios.

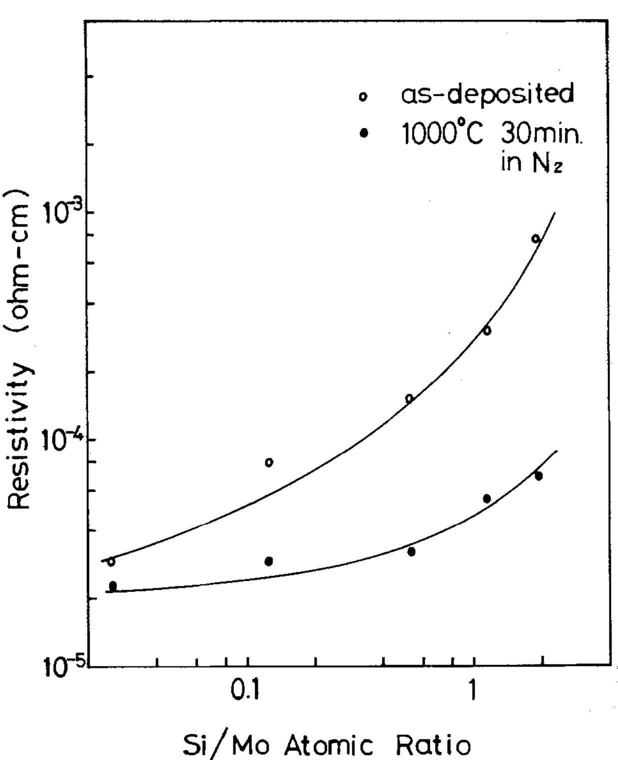

Fig. 7. Resistivity as a function of Si/Mo ratio for the as-deposited films and the films annealed for 30 min at 1000°C in N_2 atmosphere.

Conclusion

Molybdenum silicide films were prepared by magnetron-d-c-reactive sputtering within an argon-silane atmosphere. Most of the silane is decomposed within the intense argon plasma close to the target, resulting in the silicon being adsorbed on the target surface. The silicon within the film is considered to originate from the adsorbed Si layer on the target surface. This mechanism is qualitatively consistent with the measured results concerning dependence of the Si/Mo

atomic ratio of the film upon the sputtering parameters. Corresponding to the Si/Mo ratio, the various silicide structures such as Mo_3Si, Mo_5Si_3, and $MoSi_2$ were observed by using x-ray analysis. The crystal structures were found to be continuously transformed from Mo-rich to Si-rich silicides, as the Si/Mo atomic ratio was increased. This result enables us to obtain the various silicides by controlling the sputtering power and the silane partial pressure. The reactive sputtering technique reported here may be applicable for the preparation of other metal silicide films as well.

Interdiffusion Studies of Au/Ni and Au/Ni-P

A. van Wijngaarden, M. Schlesinger,* N. E. Hedgecock, and B. K. W. Baylis

Department of Physics, University of Windsor, Windsor, Ontario, Canada N9B 3P4

ABSTRACT

A comparative study is presented of the interdiffusion properties of Au/Ni and Au/Ni-P. Anomalous diffusion of gold through nickel is described. It is concluded that electrolessly deposited nickel (Ni-P) could be used to inhibit substrate contamination by gold contacts.

In a recent article (1) we described the use of proton backscattering to determine the surface concentration of palladium present on a catalyzed glass slide. Proton backscattering can also be used to determine concentrations at different depths (2) and can, therefore, be used to follow diffusion of one thin film into another. Nickel is often used as a diffusion barrier between integrated circuitry and gold contacts, for example, see Ref. (3). Therefore, diffusion of Au into Ni and Ni-P, as well as the diffusion of Ni from Ni and Ni-P into Au, was studied. Because Au, Ni, and P are very different in atomic number, the proton backscattering peaks are sufficiently separated to allow the identification of contributions to the spectrum from these three elements at various depths. Unfortunately, the interdiffusion of Ni and Cu cannot be studied by proton backscattering because Cu and Ni are too close in atomic number.

Backscatter techniques, especially involving MeV He^+ projectiles, have been used to study interdiffusion of vacuum-evaporated thin films. For examples involving Ni/Au interdiffusion, see Ref. (4-5). The films studied in this work include Ni-P deposited from an electroless plating bath. Although the attendant impurities complicate the interpretation of the diffusion results, these films should nonetheless be studied because they are used industrially and have particular characteristics that make them preferable to vacuum-deposited films for certain applications. Empirical diffusion data should be helpful, even if the theory on diffusion involving highly disordered or amorphous films is not sufficiently well developed (6) to allow any detailed interpretation.

In the present study keV protons were used to determine surface and near-surface concentrations of diffused matter. Furthermore, the phosphorus concentration in the Ni-P deposited from our pH 5.3 solution (7) was determined, and good agreement was found with results obtained by other methods (8).

Apparatus and Experimental Procedure

Sample preparation.—Thin Ni-P films were deposited electrolessly on quartz substrates using the conventional sensitizing and activating catalytic process in conjunction with a pH = 5.3 nickel metallizing bath, as described by Marton and Schlesinger (7). For comparison pure Ni films were also vacuum deposited on quartz. The vacuum facility used for metal deposition and for heat-treatment was liquid-N_2 baffled, and the pressure in the system was brought to 1×10^{-6} Torr prior to either film deposition or heat-treatment. Both Ni-P and Ni samples were then coated with thin Au films, subjected to proton backscatter analysis, heated under vacuum to around 650°K, and reanalyzed.

In order to assure identical heat-treatment procedures, samples were made with both Ni and Ni-P on the same quartz slide. First, the entire surface of the slide was metallized in a Ni-P bath. A layer of Ni was evaporated on a part of the Ni-P covered surface, then the whole surface was coated with a thin layer

* Electrochemical Society Active Member.

Key words: diffusion, diffusion barrier, electroless nickel, backscatter.

of gold. Therefore, the gold layer thickness on the Ni and Ni-P films was the same. This thickness was controlled during evaporation by monitoring the decrease in electrical resistance as the gold film was built up. This, however, proved to be only partially reliable as we found that the resistance is a function of not only the instantaneous film thickness, but also of the deposition rate. If deposition is rapid, the film contains more vacancies than if it is slow. After the cessation of film deposition a further decrease in resistance is observed as vacancies diffuse from the bulk to the surface, improving film continuity. Similar effects in gold were observed by others (9). It should be noted that no such effect was observed after deposition of nickel films; *i.e.*, once deposited their resistance remained constant.

Heat-treatment.—The samples were heated in a vacuum of 10^{-6} Torr inside a thick-walled cylindrical copper furnace. This form was chosen to assure a uniform temperature throughout the sample. It proved important to control not only the length of time the sample was at the elevated temperature, but also the lengths of time needed for raising and lowering the temperature of the sample. About an hour was needed to raise the temperature to 650°K. (Heat-treatments were performed at temperatures of from 615° to 723°K, see Table I.) The temperature inside the furnace was maintained for various lengths of time (2-24 hr) and then the samples were allowed to cool under vacuum. About an hour was required for cooling to a temperature of about 500°K. The samples were nonetheless left in vacuum until they had cooled to room temperature, a process which took several hours. This was necessary to prevent any possible reactions in air, for example, oxidation of Ni.

Proton backscattering.—The detailed setups (Fig. 1) for the proton backscattering experiments have been described previously (2). Some modifications have been introduced to improve the solid angle of observation and to eliminate errors arising from ion beam fluctuations. Briefly, the magnetically analyzed beam of protons has fixed energy to within one part in 700 of about 90 keV.

We use in our experiments a beam current density of 5×10^{-5} A/cm^2. Thin film targets are mounted in an evacuated system which is made entirely free of pump oil vapors. The target film is scanned by moving it across the path of the proton beam. The energy distribution spectrum of protons scattered through a laboratory angle of $\theta_L = 154°$ is analyzed with a cylindrical electrostatic field sector of $\pi/2$ radians with radius $r = 19.05$ cm. The widths of the entrance and exit slits (S_1 and S_2, respectively, in Fig. 1) are set with a view to achieving an energy resolving power R sufficient for a surface depth resolution of about 10Å in either Au or Ni. The energy resolving power is given by

$$R = \frac{E}{\delta E} = \frac{r}{(S_1 + S_2)} = 175 \qquad [1]$$

The channeltron detector is used in conjunction with standard counting equipment and the resulting counts are electronically normalized to a constant beam current. This is done (10) by monitoring the total backscatter current yield on the collector, which in turn is connected to a current to frequency (C to F) converter. The C to F converted signals serve as the time standard for the length of the counting periods. Information about the atomic composition of the surface region is obtained from the analysis of the energy distribution spectrum of the backscattered projectiles. A thorough analysis of backscattering from thin films, especially as applied to He^+ projectiles, is given in Ref. (11).

The disadvantage of depth profiling by protons, rather than by He^+ ions, is that the mass resolution is small due to the correspondingly small recoil energy of the target atom. At energies below 100 keV, however, we found that the straggling in the energy loss with He^+ is appreciably larger [see for example Ref. (11), section 2.6] than for protons. At these energies it is only with protons that the desired depth resolution of 10Å can be achieved.

Table I. Relative Ni surface concentration after diffusion through Au

x_0* (Å)	Time (hr)	T (°K) 615	623	675	723	Ratios Ni-P/Ni
182	22.5		0.13† 0.09			1.4
192	5			0.11† 0.06		1.7
235	2				0.15† 0.10	1.5
244	24	0.10† 0.06				1.7 1.5
254	4.75			0.14† 0.10		1.4
320	2				0.14† 0.09	1.5
520	3				0.13† 0.08	1.6 1.4

* Gold film thickness.
† Values with a dagger refer to the diffusion of Ni through Au from an Ni-P medium. Those without a dagger refer to the diffusion of Ni through Au from a pure Ni medium.

Results and Discussion

Phosphorus concentration in Ni-P films.—Thin Ni-P films plated from an acidic solution were analyzed for P content. A typical backscatter energy distribution for a film of 1100Å thickness bombarded by a proton beam of 90.72 keV is shown in Fig. 2. The backscatter yield on the high energy end of the curve on Fig. 2 is due to Ni atoms; the step at 80 keV is due to P atoms at the surface; and the yield below 57 keV arises from scattering off the substrate.

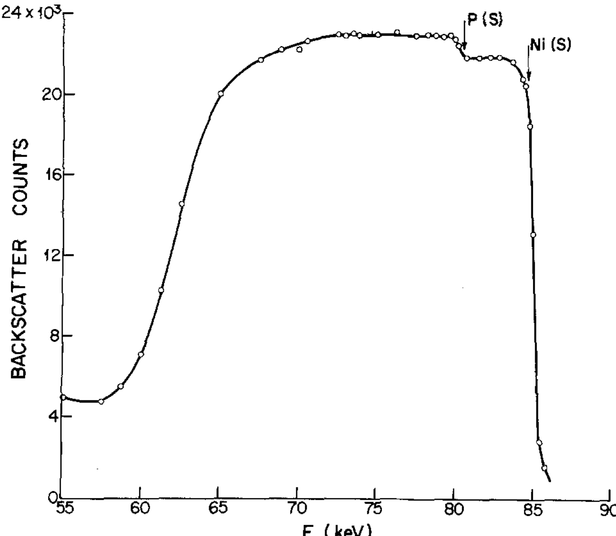

Fig. 2. The energy distribution of 90.7 keV protons backscattered off an Au/Ni film system. (a) Before heating (dotted curve); Ni film with an (S).

Since the backscatter yield, B, from a given atomic species is proportional to the square of its atomic number, Z, the atomic phosphorus concentration is

$$C_p = \frac{B_p/Z_p^2}{\frac{B_{Ni}}{Z_{Ni}^2} + \frac{B_p}{Z_p^2}} \times 100\% \quad [2]$$

The average C_p for several samples was 15.1 ± 0.7%. This value is in agreement with Marton (8) who obtained, for Ni-P films grown under the same conditions, a value $C_p = 16.6 \pm 0.8\%$ from neutron activation analysis. The stopping cross section needed to calculate the film thickness from the observed energy loss data was estimated using the cross-section tabulation by Andersen (12).

Au/Ni film system.—The energy distribution spectrum of backscattered protons from a double layer Au/Ni thin film is shown by the dashed curve in Fig. 3. The sample consists of a 170Å thick Au film vacuum deposited onto a 455Å thick Ni film, itself vacuum deposited onto a quartz substrate. The solid curve represents the backscatter energy distribution spectrum after heat-treatment for 8 hr at 748°K in a vacuum of 10^{-6} Torr. Only minor changes were noted upon completion of a further 8 hr long heat-treatment: the Au concentration near the substrate increased slightly at the expense of the surface gold concentration, while the shoulder representing nickel at the surface developed into a small peak.

Figure 3 illustrates the tendency of Au to diffuse through the Ni layer rather than to remain dissolved in it. This behavior can readily be explained by considering the miscibility gap in the Au/Ni phase diagram (13). During cooling, the reduced solubility of Au in Ni (and vice versa) causes these elements to separate out into layers.

A sample with an 810Å thick Ni film and a slightly thinner Au film was treated in the same way. After 5 hr at 730°K the backscatter energy spectrum shown in Fig. 4 was obtained. In this case, the buildup of Au at the substrate is even more pronounced and very little Au remains at the surface. This anomalous behavior would be understood if a "sink" for Au were present at the substrate surface or a "sink" for Ni at the sample surface. [See Ref. (4, 5, 14) for examples of "sinks."] Au does not react with or dissolve in quartz: heating samples of gold on quartz did not give any broadening of the backscatter curve, indicating that the Au does not diffuse into the quartz. It is possible that the small quantity of oxygen present during heat-treatment could react with the Ni arriving at the surface, creating a Ni sink. Certainly if samples were still warm (about 470°K) when brought into contact with air, the Ni film was observed to boil up to the surface.

In some samples (see Fig. 4), the Ni plateau in the backscattering spectrum showed small irregular peaks and valleys. This was especially noticeable in a few samples which were rapidly cooled after annealing by admitting Ar gas into the vacuum chamber. This effect was not very reproducible, and it probably is due to the precipitation of gold in the nickel layer, arising from the large miscibility gap in the Au/Ni system. Similar effects have been observed in Au/Ni in an x-ray study (15) and a surface diffusion study (16). It is possible that the phenomenon is related to spinodal decomposition. [See Ref. (13) for a description of spinodal decomposition.] These features of the backscatter spectrum could be explained if there were a tendency for the islands of gold to accumulate in layers about 200Å apart in the nickel. In this work, only variations in the concentration gradients at different depths can in principle be seen. The large size of the beam (1 mm²) prevents the measurement of possible concentration gradients in the plane of the film.

Diffusion between Au and Ni-P.—The backscatter energy spectrum after heat-treatment of a composite film where Ni-P replaced Ni, did not show this anoma-

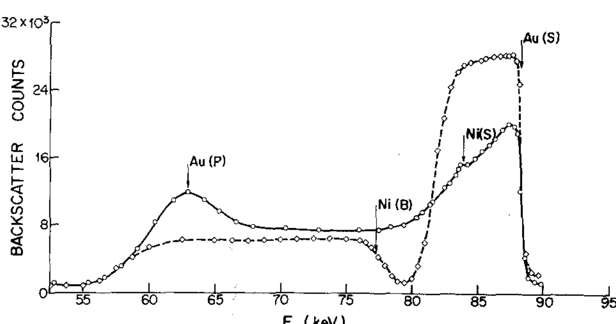

Fig. 3. The energy distribution of 90.2 keV protons backscattered off an Au/Ni film system. (a) Before heating (dotted curve); Ni film 455Å thick; Au film 170Å. (b) After heat-treatment for 8 hr at 748°K (solid curve). (S) refers to surface atoms; (B) refers to atoms immediately beneath the Au layer; and (P) refers to atoms that have penetrated through the Ni layer to the quartz.

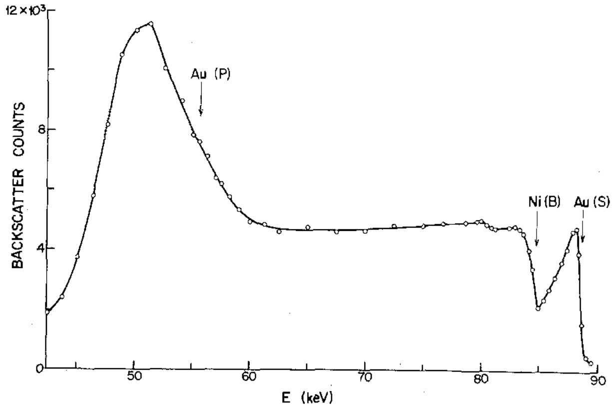

Fig. 4. The energy distribution of 90.2 keV protons backscattered off an Au/Ni film system after heat-treatment at 730°K for 5 hr. The initial Ni film thickness was 810Å; the Au film thickness was slightly less than 170Å. (S) refers to surface atoms; (B) refers to atoms immediately beneath the Au layer, and (P) refers to atoms that have penetrated through the Ni layer to the quartz.

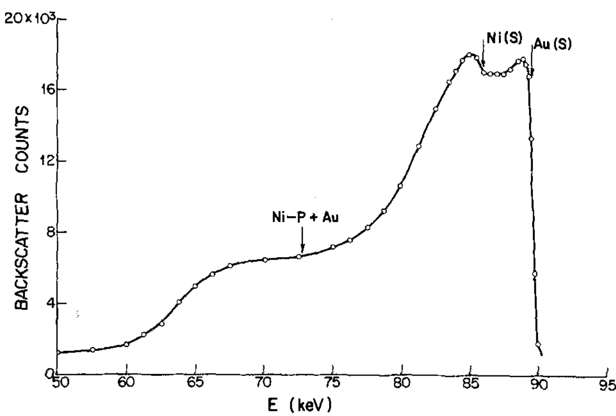

Fig. 5. A representative energy distribution curve of 91.3 keV protons backscattered off an Au/Ni-P film system after heat-treatment to 748°K for 5 hr. Initial Au film thickness was 138Å. (S) refers to surface atoms.

lous migration. The results for a 138Å thick Au film on Ni-P are shown in Fig. 5. It appears in this case that "normal" diffusion has occurred: Au into the Ni-P layer and Ni into the Au layer. Although many samples with Au on Ni-P were heat-treated none showed the anomalous behavior reported above. In fact, for samples in which the Ni was evaporated onto a Ni-P layer rather than directly onto quartz, the Au layer diffused into the Ni layer but showed no tendency to accumulate at either the Ni/Ni-P interface or the Ni-P/quartz interface. Hence, Au appears to diffuse "normally" through Ni-P, with the establishment of a concentration gradient. This suggests that the ternary Au-Ni-P system may lack a miscibility gap. Nonetheless, from a purely practical point of view, this behavior indicates that Ni-P is a better barrier with respect to penetration by Au than Ni is.

Interpretation of these observations is complicated by the fact that during the heat-treatment used to study the diffusion process, a change in the Ni-P structure also occurs. Above 590°K, the initially amorphous Ni-P transforms into a two-component system of Ni and Ni_3P, with small amounts of free P (17). Hence, any discussion of a detailed diffusion mechanism becomes highly speculative.

Ni/Au interdiffusion.—Samples were prepared consisting of quartz covered with Ni-P, then half-covered with evaporated Ni. The whole sample was then covered with Au and analyzed before and after heat-treatment. (See section on Sample preparation for details.) Figures 6 and 7 show the backscatter energy spectra for such a sample: in Fig. 6 the Au is on Ni

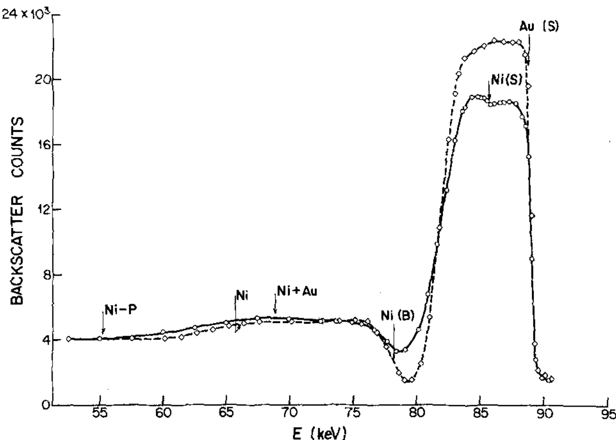

Fig. 6. The energy distribution of protons backscattered off an Au/Ni film system. (a) Before heating (dotted curve); Au film thickness was 182Å. (b) After heat-treatment for 22.5 hr at 623°K (solid curve). (S) refers to surface atoms.

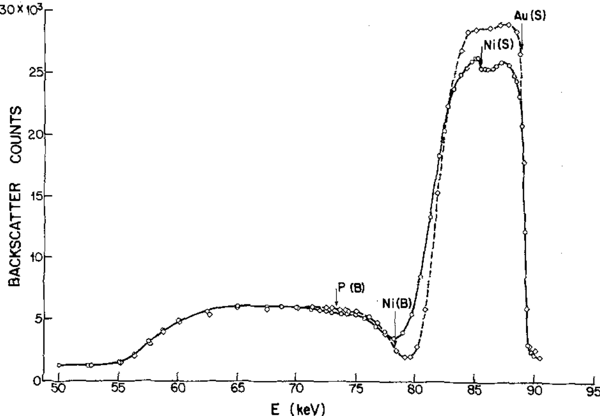

Fig. 7. The energy distribution of protons backscattered off an Au/Ni-P film system. (a) Before heating (dotted curve); Au film thickness was 182Å. (b) After heat-treatment for 22.5 hr at 623°K (solid curve). (S) refers to surface atoms; (B) refers to atoms immediately beneath the Au layer.

(which is on Ni-P); in Fig. 7 the Au is directly on Ni-P. It can be seen on Fig. 6 that the backscatter yield decreases as the projectiles pass from Ni into Ni-P. This is a result of the fact that in the Ni-P medium the concentration of the heavier Ni atoms is lower than in the pure Ni medium. The phosphorus "step" on the Ni-P plateau in Fig. 7 is not very well defined as a result of energy straggling of the protons having passed through the Au film twice.

As noted in the section on Diffusion between Au and Ni-P, the small peaks at 85 keV in Fig. 6 and 7 represent Ni that has migrated to the surface of the Au. The heights of these peaks above the Au baseline were measured for several samples. The ratios of the peak height to the plateau height of the main Ni layers are recorded in Table I. These ratios represent the surface density of diffused Ni relative to that for a pure Ni surface. The plateau heights used for the main Ni-P layers have been adjusted to account for the fact that these layers contain only 85% Ni.

It can be seen from Table I that Ni migrates into Au from Ni-P more readily than from Ni. The ratio between the amount of diffused Ni from Ni-P *vs.* from Ni remains 1.5 $\pm$ 0.2, independent of temperature, heating time, and film thickness. This behavior might be attributable to the influence on grain boundary diffusion by differences in structure between Ni and Ni-P. Furthermore, the structure of the Au layer deposited on polycrystalline Ni might well differ from that of Au deposited on amorphous Ni-P. However, the equipment for properly determining structures of films of these thicknesses being unavailable to us, no determinations of grain sizes, etc., could be made.

The amount of Au diffusing into the Ni (or Ni-P) films can, in principle, be estimated by comparing the backscatter spectra before and after heating. The valley in the spectrum between the Au and Ni peaks fills in as gold travels into the Ni layer. This region of the curve cannot be unfolded unequivocally, but a rough estimate of the amount of Au in the Ni layer could be made. This amount of Au was only about one-fifth as much as the amount of Ni that had traveled into the Au layer. This is in agreement with data for the Au-Ni system obtained by Ziegler (4). It is also consistent with our previously mentioned resistivity data, which show that freshly deposited Au has more vacancies than Ni.

Summary

From the above analyses of the effect of heat-treatment on Au/Ni and Au/Ni-P interdiffusion, the following observations can be made.

1. If the conditions of heat-treatment in vacuum are the same for both samples, the amount of Ni diffusing from a Ni-P film into an Au film is 1.5 $\pm$ 0.2 times that

diffusing from a vacuum-evaporated Ni film. Various conditions were studied: temperature, from 615° to 732°K; times of heat-treatment, from 2 to 24 hr; and Au film thickness, 182-520Å.

2. Roughly five times more Ni atoms diffuse into Au than Au atoms diffuse into Ni.

3. If the sample is not allowed to cool very slowly under vacuum, the gold may leave the Ni surface and accumulate at the Ni/quartz interface. The phenomenon is only observed with Ni; never with Ni-P or with Ni on Ni-P.

4. Observation 3 suggests that Ni-P is useful in preventing contamination of a substrate by a gold contact.

Acknowledgments

It is a pleasure to acknowledge the skillful technical assistance of Mr. Tim Scholl and very useful discussions with Dr. W. E. Baylis and G. W. F. Drake of our Department, and Dr. D. F. Watt of the Engineering Materials Department. This research was supported by the Natural Sciences and Engineering Research Council of Canada.

Manuscript submitted June 27, 1979; revised manuscript received Nov. 26, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by the University of Windsor.

Characterization of Thin Film Molybdenum Silicide Oxide

T. Mochizuki and M. Kashiwagi

NEC-Toshiba Information Systems Incorporated, 72, Horikawa-cho, Saiwai-ku, Kawasaki, Japan 210

ABSTRACT

Dielectric properties and growth kinetics of oxide film of molybdenum silicide ($MoSi_2$) on SiO_2 have been investigated. The oxide of $MoSi_2$ is composed of SiO_2, and the oxidation rate of $MoSi_2$ is described by the same general relationship as of the crystalline silicon. The molybdenum in $MoSi_2$ is partly vaporized through the oxide and is partly piled up at the oxide-$MoSi_2$ interface during oxidation. The ratio of $MoSi_2$ thickness to corresponding thickness of oxide produced from $MoSi_2$ decreases from 0.48 to 0.3 with increasing oxide thickness due to increasing piled-up molybdenum. The dielectric constant and the dielectric breakdown strength of $MoSi_2$-oxide are very close to those of n^+-poly-Si oxide. The $MoSi_2$ oxide shows the self-healing breakdown, more frequently than the n^+-poly-Si oxide, which is due to the interface roughness induced by the pile-up of molybdenum. The dielectric breakdown strength is improved at higher oxidation temperatures.

In very large scale integrated circuits (VLSI) the electrical conductivity of poly-crystalline silicon (poly-Si) for interconnection and gate electrode ($\sim 10^{-3}$ Ω-cm) is one of the major limitations on circuit performance. Studies of refractory metals having low resistivity of $\sim 10^{-5}$ Ω-cm, such as tungsten (W) and molybdenum (Mo), have been made to replace poly-Si (1-3). However, they frequently show poor abilities to withstand chemical reagents and oxidizing ambients especially at high temperatures. An alternative approach is to utilize refractory metal silicides such as $MoSi_2$ and WSi_2, which also show relatively low resistivity ($\sim 10^{-4}$ Ω-cm) and good abilities to withstand chemical reagents (4, 5). For the application to VLSI's, it is generally required to cover the electrode with its own oxide layer for better stability and controllability as in the case of silicon gate technology. $MoSi_2$ and WSi_2 exactly meet this requirement. Therefore, the studies of oxidation mechanism of the silicides and dielectric properties of the oxide are of

Key words: molybdenum silicide, gate electrode, oxidation, oxide.

practical importance to establish the silicide process as one of the VLSI technologies.

Since the earlier works of molybdenum silicide oxidation, it has been recognized that the high oxidation resistance of $MoSi_2$ is due to the protective silicon dioxide layer formation (6). The oxidation products of molybdenum silicides have been comprehensively investigated by Berkowitz-Mattuck *et al.* (7). The kinetics of $MoSi_2$ has been discussed by Chang where the oxidation follows the parabolic law (8). However, the interest of previous works stayed in the refractory behavior relating to heater coating material for resistance furnace. Therefore, the detailed oxidation mechanism and the grown oxide properties of the refractory metal silicide have not been carried out yet.

More recently, studies on the oxidation of WSi_2 and $MoSi_2$ as gate electrodes of MOS devices have been reported (9, 10). The authors have briefly reported the oxidation kinetics of $MoSi_2$ film and the dielectric properties of the oxide grown on $MoSi_2$ previously (10). In this paper, the thermal oxidation kinetics of $MoSi_2$ film and microscopic oxide-$MoSi_2$ interface morphology are described in detail, and the oxide formed on $MoSi_2$ is proved to have good dielectric properties.

Experimental Procedures

Molybdenum silicide films were deposited on oxidized Si wafers by means of planar magnetron type d-c sputtering at the power of 700W. The $MoSi_2$ film thickness was approximately 3000Å. The oxidation was carried out in dry oxygen (dry O_2) ambients at 900°, 1000°, and 1100°C. The oxide thickness on $MoSi_2$ was measured by Talystep after the oxide was selectively removed by buffered or diluted HF. Silicon nitride films were employed as oxidation masks for selective molybdenum silicide oxidation. The composition of molybdenum silicide or the oxide formed on the surface, and microscopic oxide-silicide interface or oxide surface morphologies were investigated with Auger electron spectroscopy (AES), scanning electron microscopy (SEM), and transmission electron microscopy (TEM).

Diodes with the structure of $Al/SiO_2/MoSi_2$ were fabricated in order to evaluate the leakage current and dielectric breakdown strength of the oxide formed by the oxidation of $MoSi_2$ which will be called as $MoSi_2$-oxide in the remainder of this paper. The upper aluminum electrodes were successively deposited on $MoSi_2$-oxide by electron beam evaporator. The oxide and aluminum were measured approximately a thickness of 1100 and 2000Å, respectively. The aluminum electrodes of 640 $\mu m\phi$, were patterned by the usual photolithography. The diodes were annealed for 30 min in forming gas at 450°C.

The phosphorus-doped polycrystalline silicon (n^+-poly-Si), as a reference, was employed in order to compare with the oxidation behavior and dielectric properties of the $MoSi_2$-oxide.

Experimental Results

The oxidation of $MoSi_2$.—Oxidation rate.—The thermal oxidation of $MoSi_2$, as is described above, results in the silicon dioxide (SiO_2) formation on the $MoSi_2$ surface. Figure 1 shows the thickness of $MoSi_2$-oxide *vs.* oxidation time in dry oxygen at 900°, 1000°, and 1100°C. As references, results from (100) crystalline silicon and phosphorus-doped poly-Si are illustrated by broken lines. The oxidation rates of $MoSi_2$-oxide are similar to the rate of single crystalline silicon. Therefore, the general relationship for silicon oxidation, given by

$$Xo^2 + AXo = B(t + \tau) \quad [1\text{-A}]$$

or

$$Xo/A/2 = \sqrt{1 + \frac{t+\tau}{A^2/4B}} - 1 \quad [1\text{-B}]$$

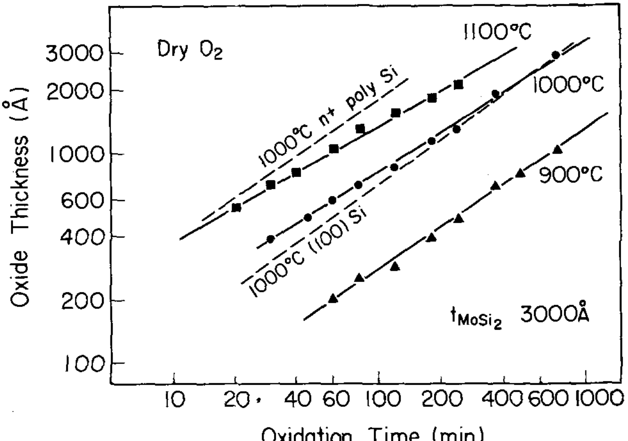

Fig. 1. Growth rates of $MoSi_2$-oxide in dry oxygen at 900°, 1000°, and 1100°C.

is applicable to the oxidation of $MoSi_2$ (11). Figure 2 shows the fitting of the experimental results shown in Fig. 1 with the curve derived from the general relationship for silicon oxidation. As is clearly indicated in Fig. 2, the experimental results show excellent agreement with the crystalline silicon oxidation model. As oxidation proceeds, the oxidation kinetics continuously changes from the so-called reaction-controlled region ($Xo = B/A\ (t + \tau)$) to the diffusion-controlled region (limited by $Xo^2 = B(t + \tau)$). Figure 3 shows the Arrhenius plots of the parabolic rate constant B and linear rate constant B/A which are derived from Fig. 1. The activation energies of B and B/A are estimated to be E_a, (parabolic) = 1.6 eV and E_a, (linear) = 1.9 eV, respectively. The former is two times larger than the value reported by Chang, which was derived from the consumed oxygen during oxidation by monitoring the amount of oxygen at the inlet and the outlet of the furnace (8). Taking account of the deviation of the published results for silicon oxidation where E_a, (parabolic) and (linear) are 1.2 to 2.2 and 1.5 to 2.2 eV, respectively, these activation energies of $MoSi_2$ oxidation are very close to the respective activation energies of silicon oxidation (12). Thus, the experimental results indicate that the oxidation of $MoSi_2$ eventually follows the same oxidation mechanism as crystalline silicon as far as the oxide growth rate is concerned.

Etching rate.—The $MoSi_2$-oxide grown at 900°, 1000°, and 1100°C in dry oxygen shows the same etch rate of 3Å/sec as the thermal silicon dioxide grown under the same conditions in the thickness range of 500-2000Å with 5% HF.

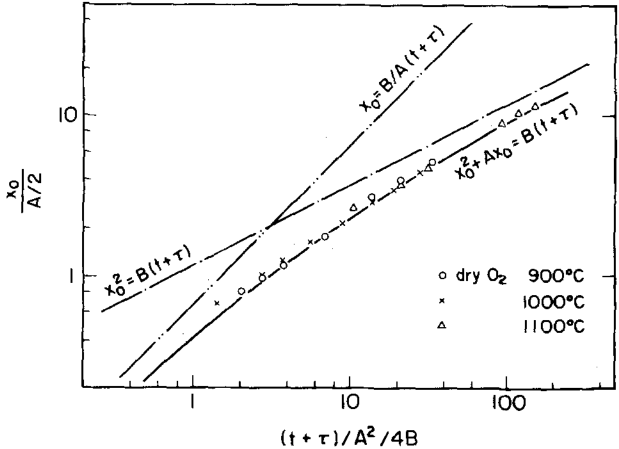

Fig. 2. Relationship for the oxide growth rate of $MoSi_2$ film showing the linear and parabolic region.

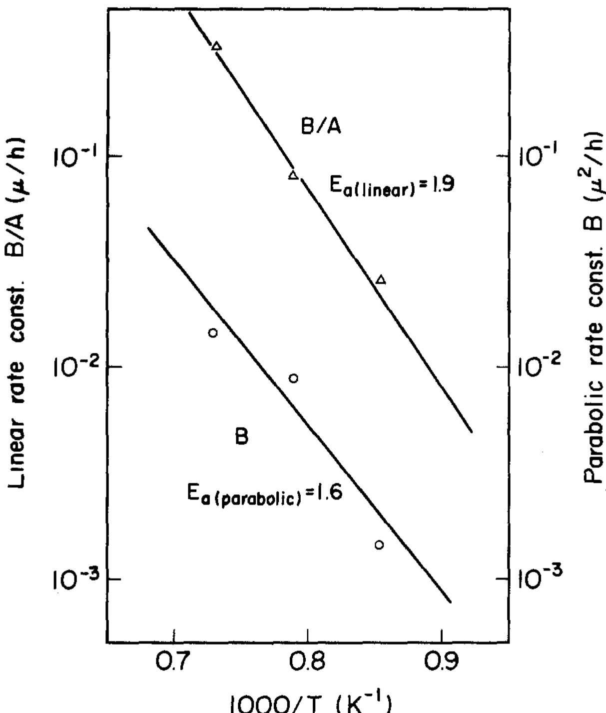

Fig. 3. The Arrhenius plots of the parabolic rate constant B and linear rate constant B/A.

Thickness ratio.—The ratio of $MoSi_2$ thickness (t_m) to the corresponding thickness of $MoSi_2$-oxide produced from the $MoSi_2$ (t_s), $R_o = t_m/t_s$, was measured as a function of grown oxide thickness, which is shown in Fig. 4. t_m was estimated from the difference in height between the initial and the oxide removed surface as shown in Fig. 4. The error bars are mostly attributed to the asperities of the oxidized $MoSi_2$-oxide/$MoSi_2$ interface as described later. The ratio, R_o for silicon oxidation is well known as 0.44. On the other hand, that of $MoSi_2$ oxidation decreases with increasing oxide thickness. At the earlier oxidation stages, the thin oxide layer is less protective for oxidation, so that both silicon and molybdenum in $MoSi_2$ are oxidized, and the most of molybdenum oxide should be vaporized completely through the thin silicon dioxide layer because of its low sublimation temperature.

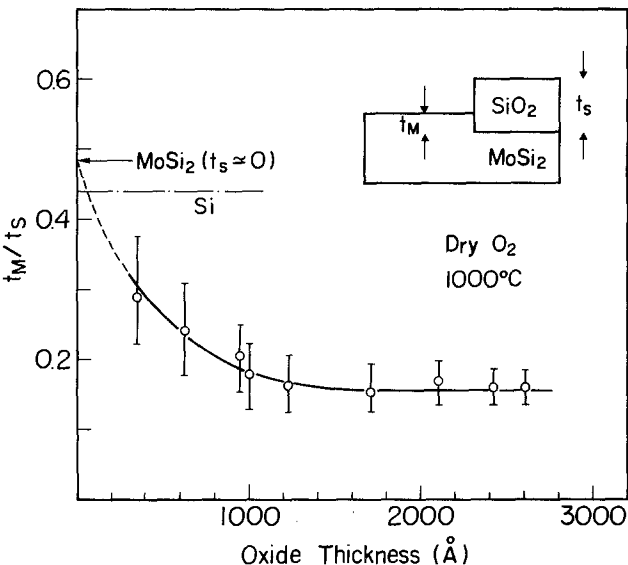

Fig. 4. Change in thickness ratios of the consumed $MoSi_2$ film to the grown SiO_2 layer during oxidation in dry O_2 at 1000°C. The ratio decreases with increasing thickness of $MoSi_2$-oxide.

This means the $MoSi_2$-oxide will not contain molybdenum, thus the ratio should be described as

$$R_o = t_m/t_s = \frac{\rho_s}{\rho_m} \frac{W_{Si/SiO_2}}{W_{Si/MoSi_2}} \quad [2]$$

where W_{Si/SiO_2} and $W_{Si/MoSi_2}$ are the atomic weight ratios of silicon in SiO_2 and $MoSi_2$, ρ_s and ρ_m are the densities of silicon and molybdenum, respectively. By simple calculation, Eq. [2] leads to the constant 0.48.

Dielectric properties of $MoSi_2$-oxide.—Dielectric constant.—The dielectric constant of $MoSi_2$-oxide, ϵ, was estimated to be 3.1 by measurements of oxide capacitance and thickness of $MoSi_2$-oxide with aluminum/$MoSi_2$-oxide/$MoSi_2$ structure diode. This is smaller than that of thermal silicon dioxide, 3.9, but is close to that of n^+-poly-Si oxide, 3.4.

Dark current and breakdown.—Figure 5 shows the dark current of aluminum (Al)/$MoSi_2$-oxide/$MoSi_2$ diode and along with those of Al/n^+-poly-Si oxide/n^+-poly-Si diode. The both signs denote the Al electrode polarities and the arrows show the so-called shorting breakdown (final breakdown). The $MoSi_2$-oxide shows the so-called self-healing breakdown, especially, in the case of positively biased Al electrode. In spite of this, the $MoSi_2$-oxide shows low dark current compared with that of n^+-poly-Si oxide.

Figure 6 shows breakdown probabilities of both $MoSi_2$ and n^+-poly-Si oxides as a function of the electric field (Al^+). The initial breakdown is defined by the voltage when the leakage current exceeds 5×10^{-7} A/cm^2, or the voltage when the initial self-healing breakdown takes place. Both types of breakdown were successively measured with the same ramp voltage sweep. The most of the initial breakdown of $MoSi_2$ and

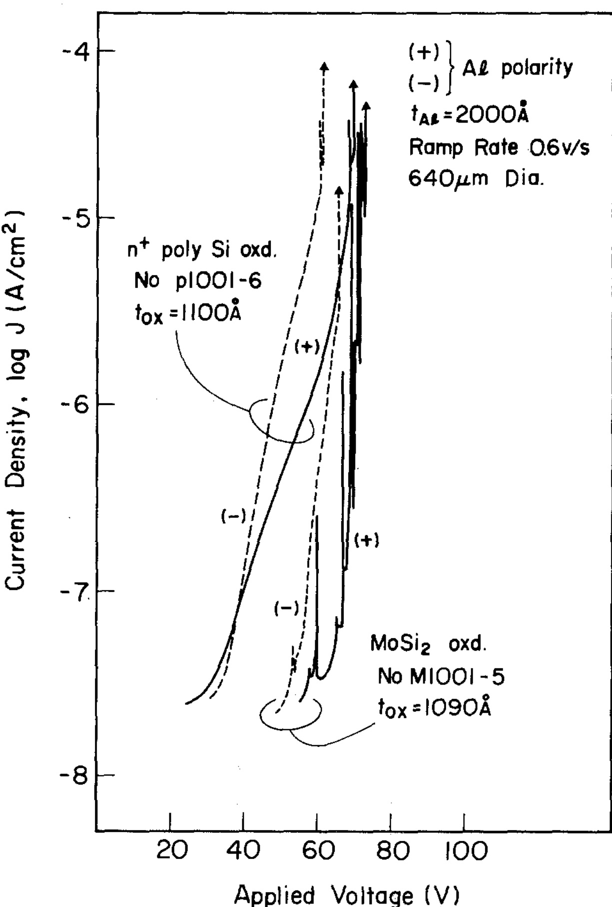

Fig. 5. The dark current densities of Al/$MoSi_2$-oxide/$MoSi_2$ diode, as references, those on n^+-poly-Si oxide are plotted. The arrows show the so-called shorting breakdown. The signs, (+) and (−), denote Al polarities.

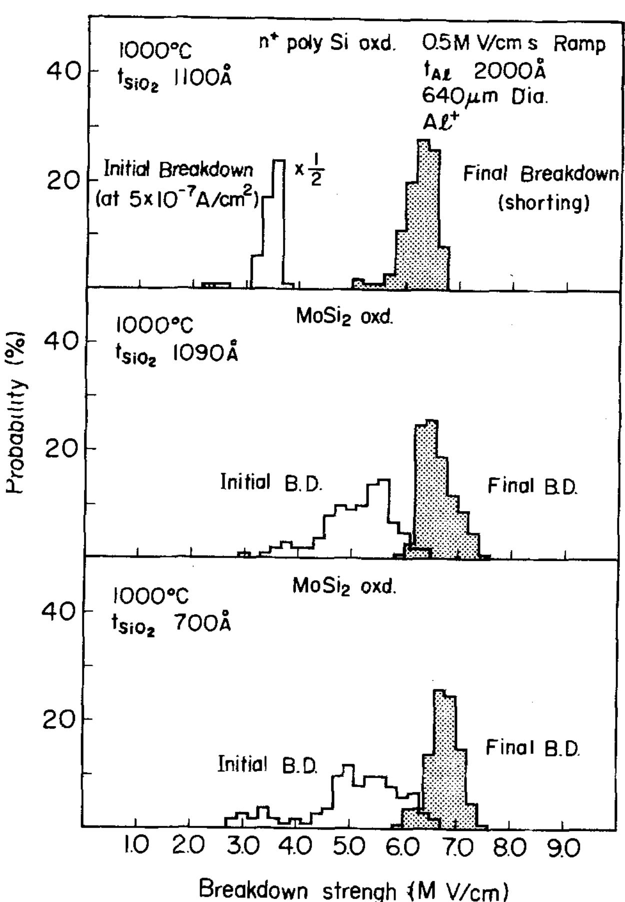

Fig. 6. The breakdown probabilities of the n^+-poly-Si oxide, 1100Å in thickness (upper); the $MoSi_2$-oxide, 1090Å in thickness (middle); and the $MoSi_2$-oxide, 700Å in thickness (bottom). The initial breakdown is defined as the voltage when the current density exceeds to 5×10^{-7} A/cm^2.

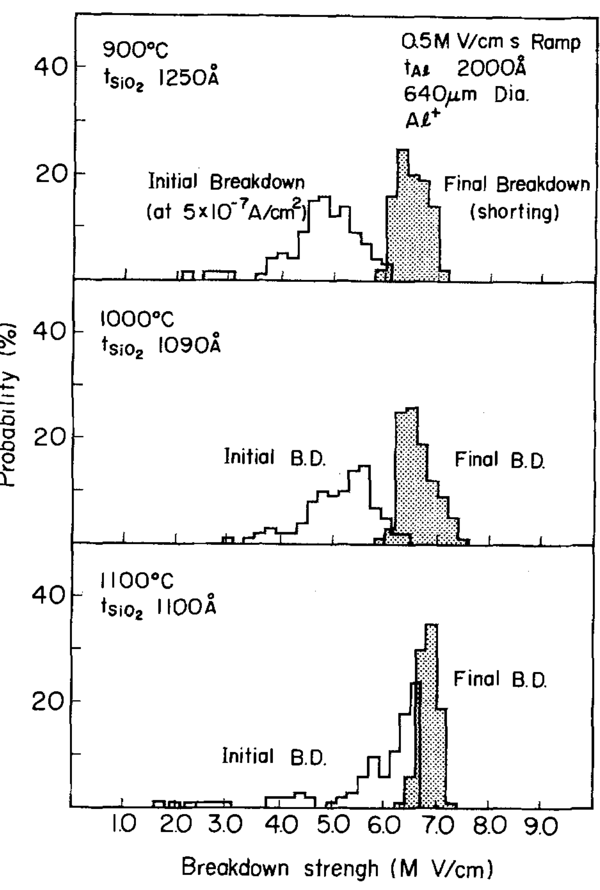

Fig. 7. The breakdown probabilities of $MoSi_2$-oxide oxidized at 900°C (upper), 1000°C (middle), and 1100°C (bottom).

n^+-poly-Si oxide are determined by the self-healing breakdown and the dark current, respectively. There are no $MoSi_2$-oxide thickness dependence for breakdown fields of both initial and final breakdown.

Figure 7 shows the breakdown probabilities of the $MoSi_2$-oxides made at various oxidation temperatures. As is clearly indicated from the figure, the higher temperature oxidation gives rise to the higher initial breakdown strength and less fluctuation in the final breakdown strength.

Discussion

Molybdenum pile-up and vaporization.—The oxidation (oxide growth rate) of $MoSi_2$, as is described, follows nearly the same oxidation mechanism as that of crystalline silicon. In other words, the molybdenum within $MoSi_2$ takes no part in the silicon dioxide formation rate. However, the oxidation shows the different behavior such as $R_o (= t_m/t_s)$. It is important to consider the behavior of molybdenum during oxidation. Figure 8 (a), (b) and (c) show Auger in-depth profiles of $MoSi_2$-oxides made at various oxidation temperatures. As is clearly seen in the figures, the silicon dioxide is formed on the $MoSi_2$ surface during the oxidation. This is also confirmed by backscattering analysis with He^+. The molybdenum in the oxide is less than the Auger electron detection limits which is a few percent in concentration. Figure 8 also shows a peak in molybdenum concentration at the $MoSi_2$-oxide/$MoSi_2$ interface. The molybdenum pile-up region increased in concentration and in depth with increasing oxidation (10), which indicates the preferential oxidation of silicon in $MoSi_2$ because of the difference in the oxide formation energies between silicon and molybdenum in $MoSi_2$.

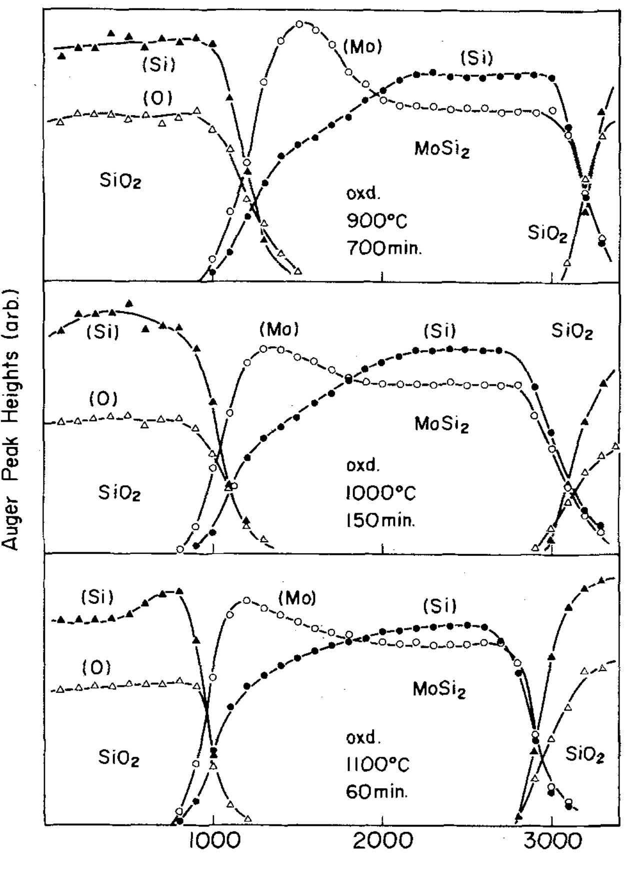

Fig. 8. The Auger in-depth profiles of the $MoSi_2$ film oxidized at 900°C for 700 min (upper), 1000°C for 150 min (middle), and 1100°C for 60 min (bottom).

In order to investigate the structure and composition of the high molybdenum concentration layer, the oxidized $MoSi_2$ film was examined with transmission electron diffraction and the diffraction pattern was obtained as shown in Fig. 9 where the $MoSi_2$ film was 1500Å and was oxidized in dry oxygen for 5 hr at 1000°C. The diffraction lines are assigned to be those of the higher molybdenum silicide Mo_3Si and the elemental molybdenum with ASTM cards No. 4-0811. In addition, the intensity of the diffraction lines suggests that the elemental molybdenum is dominant in this film. This is in agreement with the previous work which identified the molybdenum rich layer as α-molybdenum solution (7).

During the $MoSi_2$ oxidation the white particles were deposited in the cold gas trap. The ESCA spectra of the deposit revealed that the deposit was mostly composed of molybdenum trioxide (MoO_3). It is reasonable to assume the vaporization of MoO_3 can occur because of its low sublimation temperature, 790°C.

According to the above results, the oxidation of $MoSi_2$ is accompanied by the silicon dioxide formation with nearly the same growth rate as that of silicon and the piled-up molybdenum. The negative oxide formation energies of silicon and molybdenum, ΔH_{Si} and ΔH_M, were reported to be -77.2 and -35.5 kcal/g-atom at 1000°C, respectively (13). This means that the silicon oxide is stable compared with molybdenum oxide. The oxidation reaction subsequent to thick oxide growth will be controlled by the diffusion of oxidant through the oxide, and the oxidant concentration will be reduced to the lower levels at the interface at which the oxidation reaction takes place. The ratio of reaction products of silicon-oxidant system to molybdenum-oxidant system, γ, will be given by

$$\gamma = \exp\left((-\Delta H_{Si} + \Delta H_M)/KT\right) \quad [3]$$

The value γ is 4×10^4 at 1000°C, which means the oxidation of silicon is dominantly carried out in $MoSi_2$. Thus, unoxidized molybdenum will be piled up at the $MoSi_2$-oxide/$MoSi_2$ interface. However, a part of piled-up molybdenum is actually oxidized and therefore vaporizes as molybdenum oxide even in the diffusion-controlled region because of the decrease of silicon atom to form the silicon dioxide. On the other hand, analysis for the reaction-controlled region is difficult due to lack of knowledge of the reaction rate process. However, when we consider that vaporization of molybdenum oxide through a thin $MoSi_2$-oxide layer will take place at the earlier oxidation stage, the molybdenum silicide oxidation system will be described by

$$MoSi_2 + \frac{7}{2}O_2 \rightarrow 2SiO_2 + MoO_3 \quad [4\text{-A}]$$

$$MoSi_2 + 2O_2 \rightarrow 2SiO_2 + Mo \quad [4\text{-B}]$$

At the initial oxidation stage and at a further oxidation stage after thick oxide formation, $MoSi_2$ oxidation will follow the reaction and diffusion-controlled oxidation rules, which correspond to Eq. [4-A] and [4-B], respectively. However, at the intermediate stage the oxidation of $MoSi_2$ will be described by a hybridization of [4-A] and [4-B].

The experimental results in Fig. 2 suggest that the higher temperature oxidation rapidly reaches to the diffusion-controlled region. Therefore, piled-up molybdenum will be expected at higher temperature oxidation. However, this is not the case as shown in Fig. 8, where the pile-up of molybdenum is remarkable at lower oxidation temperature. It should be due to the fact that the reaction ratio γ increases with decreasing temperature. Thus, the $MoSi_2$-oxide growth rate will be close to that of crystalline silicon oxidation as long as the silicon reacting with oxidant in the molybdenum rich region is high enough in concentration to form the silicon dioxide.

Thickness ratio.—The thickness ratio, R, will be rewritten and given by

$$R = (t_m - t_{mo})/t_s = R_o - t_{mo}/t_s \quad [5\text{-A}]$$

where

$$t_{mo} = \alpha \frac{\rho_s}{\rho_{mo}} W_{Mo/MoSi_2} \cdot t_m \quad [5\text{-B}]$$

Here $W_{Mo/MoSi_2}$ and t_{mo} are the atomic weight ratio of molybdenum in $MoSi_2$ and the thickness of the piled-up molybdenum layer, respectively. The notation α is defined as the ratio of piled-up molybdenum to the total amount of molybdenum at the interface. From Eq. [2], [5-A] and [5-B], the ratio is given by

$$R = 0.48 - 0.18\,\alpha \quad [5\text{-C}]$$

The ratio R, for instance, is estimated to be $R = 0.3$ when molybdenum in the consumed $MoSi_2$ completely piles up (*i.e.*, $\alpha = 1$). This value is larger than the experimental results as shown in Fig. 2. The experimental results may involve certain errors due to the surface asperities. However, the ratio obtained from Fig. 10 (c) is $R = 0.25$, which is rather close to the calculated value. Thus, the value of R decreases with increasing oxide thickness due to the existence of piled-up molybdenum.

Morphologies.—The morphologies of the $MoSi_2$-oxide and the $MoSi_2$-oxide/$MoSi_2$ interface after the oxidation were investigated with SEM observation. Figures 10 (a), (b), and (c) show the SEM photographs of the $MoSi_2$ surface annealed in nitrogen at 1000°C for 30 min, the $MoSi_2$-oxide surface and $MoSi_2$-oxide/$MoSi_2$ interface oxidized in oxygen at 1000°C for 3 hr, and the cross-sectional view of the selectively oxidized $MoSi_2$ covered with $MoSi_2$ on the oxide and silicon nitride as an oxidation mask. The $MoSi_2$-oxide shows the flat surface and roughened interface. The white and small grains at the concave of the $MoSi_2$ surface, shown in Fig. 11 (b), are assumed to be elemental molybdenum. The average grain sizes are 500 and 2000Å in diameter for annealed and oxidized $MoSi_2$, respectively, while the as-deposited $MoSi_2$ film has an amorphous state. The localization of the elemental molybdenum in the $MoSi_2$-oxide/$MoSi_2$ interface suggests the nonuniform oxidation of $MoSi_2$. In other words, the preferential silicon oxidation simultaneously induces nonuniform pile-up of molybdenum at the interface as shown in Fig. 10 (b). The additional oxidation should cause the oxidation of the piled-up molybdenum and at the same

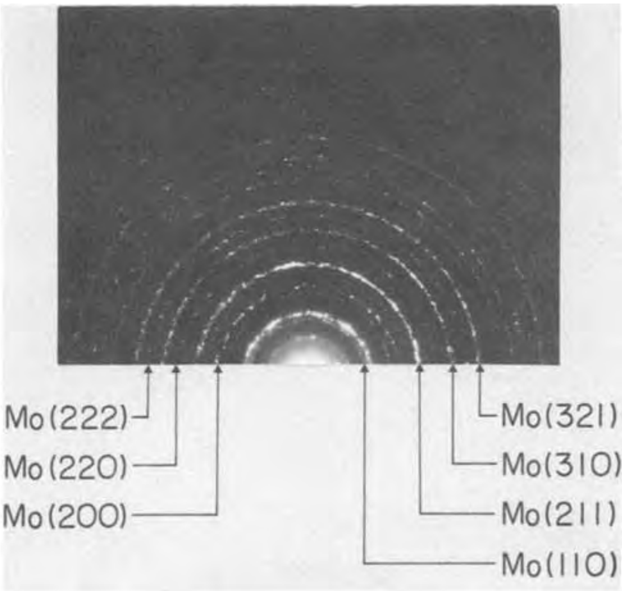

Fig. 9. Diffraction pattern of $MoSi_2$ oxidized in dry O_2 at 1000°C for 5 hr.

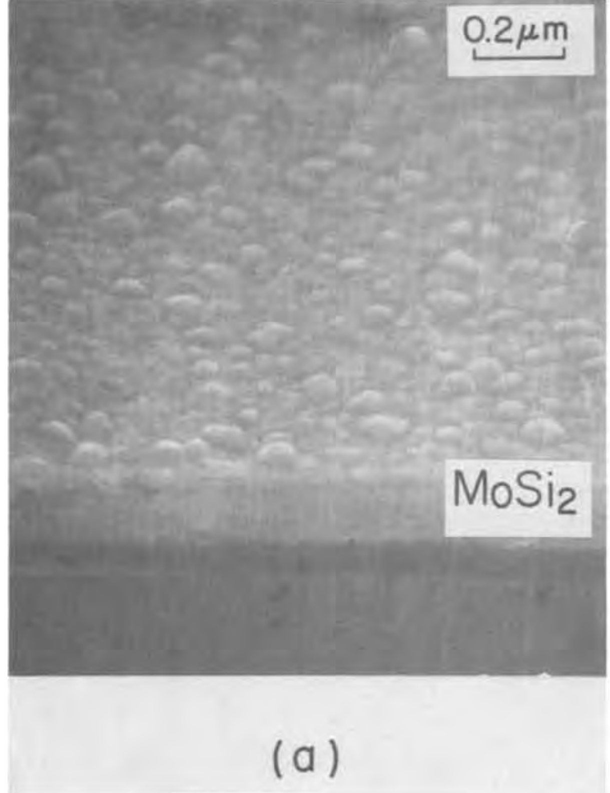

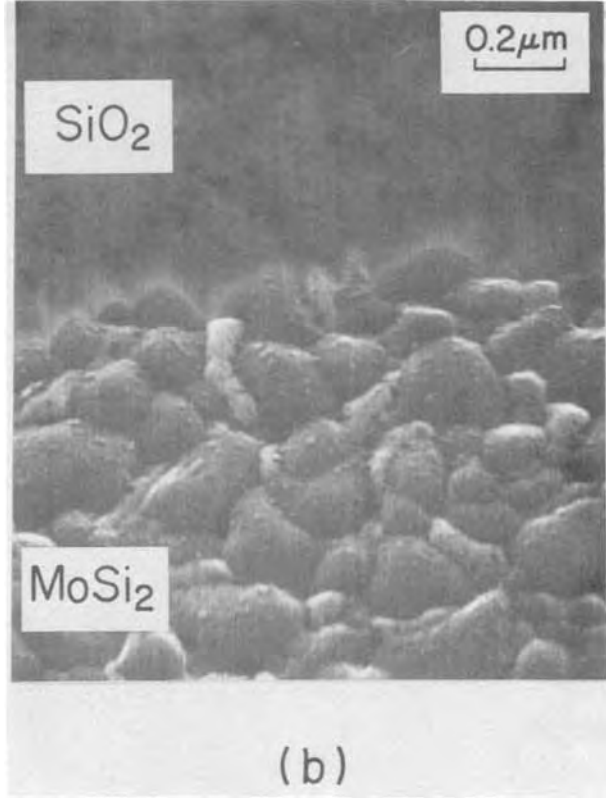

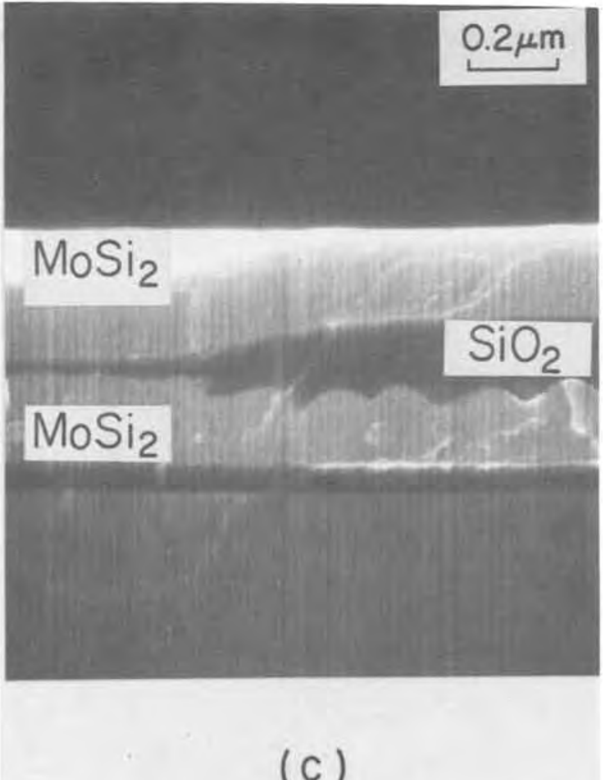

Fig. 10. The $MoSi_2$ surface annealed in N_2 at 1000°C for 30 min (a). $MoSi_2$ surface oxidized in dry O_2 at 1000°C for 2.5 hr (b). Cross-sectional view of the $MoSi_2$/$MoSi_2$-oxide/$MoSi_2$ structure (c). The $MoSi_2$ layer (upper) was deposited on Si_3N_4 and SiO_2 layer after the $MoSi_2$ oxidation at 1000°C for 7 hr.

time another pile-up of molybdenum around the $MoSi_2$ grain could occur.

Dielectric properties.—There is no notable difference between both types of oxides as far as the shorting breakdown is concerned. However, the dark current and the initial breakdown show a remarkably different behavior. The low initial breakdown of poly-Si oxide comes from the high dark current due to the high trap densities in the oxide (14). The $MoSi_2$-oxide shows the low dark current, so that the initial breakdown of $MoSi_2$-oxide is limited by the self-healing breakdown which is generally attributed to the defects in the oxide, such as molybdenum in the $MoSi_2$-oxide smaller than Auger detectability. At higher oxidation temperature, more molybdenum vaporizes as oxide leaving less molybdenum in the $MoSi_2$-oxide which will lead to improvement on the self-healing breakdown. Furthermore, it is likely to consider that the $MoSi_2$-oxide has high pin hole densities because of the vaporization of molybdenum oxide through the $MoSi_2$-oxide. Actually, the pin holes are sometimes observed in the $MoSi_2$-oxide formed in wet oxygen. The rapid oxidation such as in wet oxygen may cause the explosive vaporization through the $MoSi_2$-oxide. Therefore, such a kind of pin

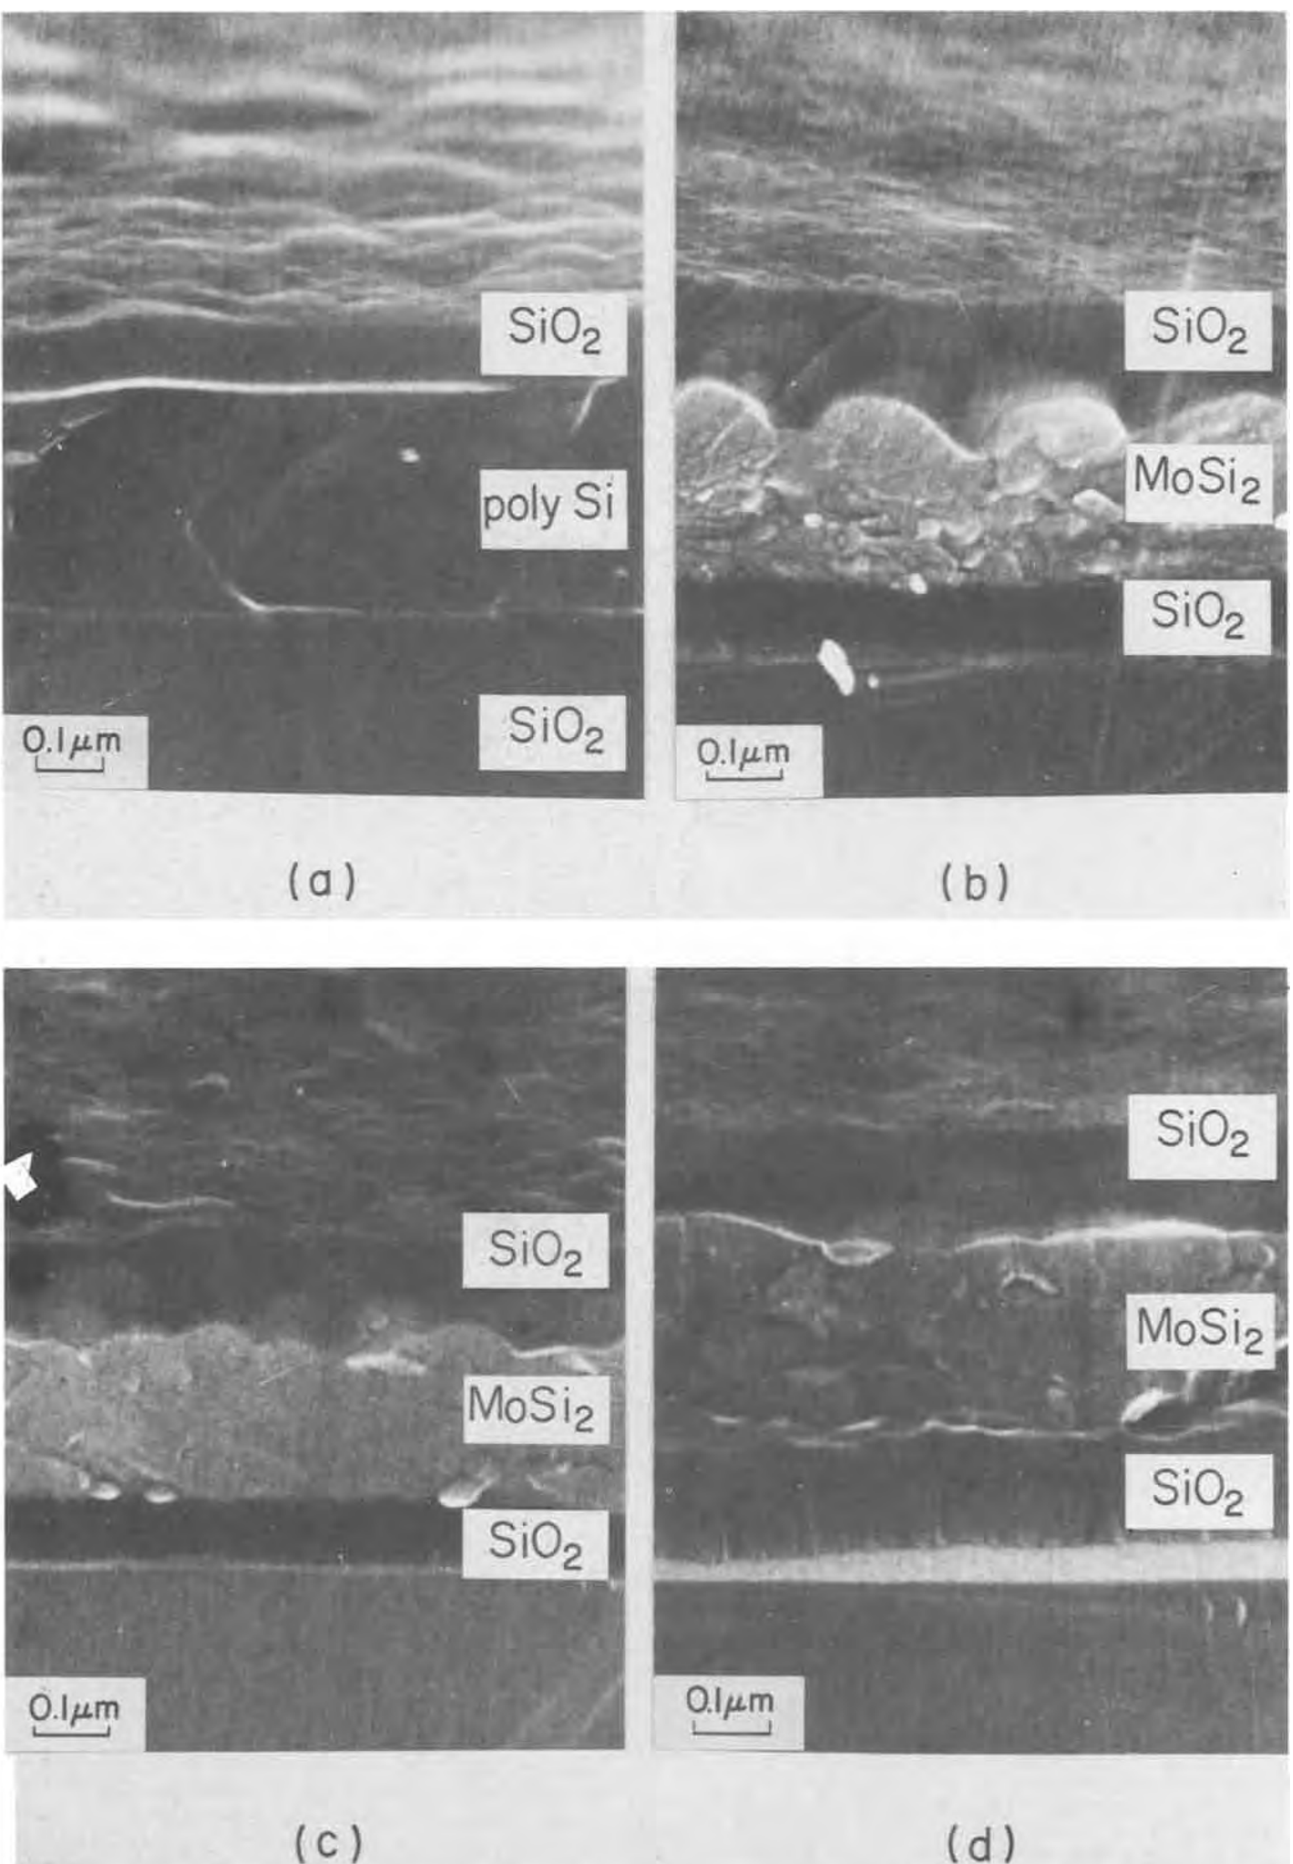

Fig. 11. Cross sectional view of n^+-poly-Si oxidized at 1000°C (a) and those of $MoSi_2$ oxidized at 900°C (b), 1000°C (c), and 1100°C (d). Their oxide layers were 1100, 1250, 1090, and 1100Å thick, respectively.

hole could be formed even in the $MoSi_2$-oxide formed in dry oxygen as far as the oxidation temperature is high enough. The experimental results derived in Fig. 8 indicate that higher temperature oxidation induces low molybdenum pile-up, resulting from high molybdenum vaporization compared with that of low temperature oxidation. Therefore, the pin-hole density in high temperature oxidized $MoSi_2$-oxide would be large. However, Fig. 7 shows that the higher temperature oxidation improves the self-healing breakdown strength. Therefore, the vaporization of molybdenum through the $MoSi_2$-oxide will have no notable influence on the oxide breakdown.

Figures 11 (a) to (c) show the SEM photographs of the cross-sectional view of n^+-poly-Si oxide and the $MoSi_2$-oxide formed at 900°, 1000°, and 1100°C, respectively. As is clearly indicated in the figures, the $MoSi_2$-oxides have the roughened interfaces compared with that of n^+-poly-Si. This is more remarkable at lower temperatures which is qualitatively in agreement with the experimental fiindings on the breakdown strength, *i.e.*, with increasing interface asperities, the probability of the self-healing breakdown at low supply field increases. The remarkable self-healing breakdown when the Al electrode is positively biased, as shown in Fig. 5, will be caused by the electron emission from the convex $MoSi_2$ (or molybdenum) into the $MoSi_2$-oxide, and the electrons emitted into the oxide will increase the electric field in the $MoSi_2$-oxide near the Al/oxide interface up to the oxide breakdown strength. Thus, the self-healing breakdown frequently occurs in the $MoSi_2$-oxide formed at low temperature even at the low supply field, while, the high temperature oxidation improves the breakdown strength because of less pile-up of molybdenum.

Conclusions

The growth rate and the composition of the oxide formed by oxidation of molybdenum silicide are investigated in comparison with those of single crystal silicon. The oxidation rate of $MoSi_2$ can be well described by the same general relationship as of single crystal silicon. The activation energies of the parabolic and linear rate constant of $MoSi_2$ oxidation are estimated to be 1.6 and 1.9 eV, respectively, which are also close to those of crystalline silicon. A part of molybdenum in the consumed $MoSi_2$ is vaporized through the oxide in a form of MoO_3 during the oxidation. The $MoSi_2$ oxidation is governed by preferential silicon dioxide formation, in particular, in the diffusion-controlled oxidation region. The pile-up of molybdenum at the $MoSi_2$-oxide/$MoSi_2$ interface occurs as a result of oxidation of silicon in $MoSi_2$, which depends on the oxidation temperature. The ratio of $MoSi_2$ thickness to the corresponding thickness of oxide produced from $MoSi_2$ decreases with increasing oxide thickness due to the pile-up of molybdenum at the interface. The interface asperities of $MoSi_2$-oxide are attributed to the local oxidation of $MoSi_2$ induced by molybdenum pile-up.

The dielectric constant of $MoSi_2$-oxide is estimated to be 3.1. The final breakdown strength of $MoSi_2$-oxide is close to that of n^+-poly-Si oxide. The $MoSi_2$-oxide frequently showed the self-healing breakdown due to the interface asperities. The higher temperature oxidation decreases the interface asperities of the $MoSi_2$-oxide due to less pile-up of molybdenum, and hence, it results in higher breakdown field.

Process-Induced Effects on Carrier Lifetime and Defects in Float Zone Silicon

A. Rohatgi and P. Rai-Choudhury*

Westinghouse Research and Development Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

The effects of cooling rate, oxidation temperature, back surface damage gettering, and HCl oxidation on the generation lifetime and defects in float zone silicon have been investigated. Silicon used in this study does not show stacking faults after the oxidation; instead, dominant oxidation-induced defects are saucers. The combination of back surface damage gettering and HCl oxidation reduces the oxidation-induced saucer density by three orders of magnitude. Lifetime of a fast-cooled sample is always low and bears no relationship with the saucer density, while the lifetime of slow-cooled samples shows an inverse relationship with the saucer density. High temperature HCl oxidation, with back surface damage and slow cool, is a very effective process which gives lifetimes of the order of 2 msec. Oxidation-induced saucer density is not the only reason for low lifetime, *e.g.*, impurities and/or decorated saucers may play an important role.

The oxidation-induced defects and their deleterious effects on the electrical performance of the devices have been an area of major concern. It is important to understand what defects degrade the device performance and how to minimize them by selecting the right process. Several investigators (1-4) have discussed the conditions for the initiation of oxidation-induced stacking faults and the methods (5-7) of suppressing them by various gettering techniques, *e.g.*, preoxidation gettering (3), HCl gettering (7,19), and high temperature anneal in inert ambient (8). It has been shown (5, 17) that reduction of stacking fault density improves the carrier lifetime. Some investigators (9, 10) believe that oxidation-induced saucers are indicative of metallic contaminants and may also degrade the device performance. Generation lifetime is a good and sensitive indicator of the device performance and has been utilized in this work to study the process-induced effects on device performance and defects in silicon. This paper discusses the effects of process variables, such as cooling rate after the oxidation, oxidation temperature, back surface damage (BSD) gettering, and HCl oxidation on float zone silicon.

Experimental Procedure

Studies were conducted on 4-8 Ω-cm, n-type, (100) float zone silicon. MOS capacitors were fabricated to evaluate the process-induced effects on lifetime and defects. Cleaning involved organic solvents to degrease, a hot sulfuric-nitric acid mix, a detergent to remove lapping residues, and a preoxidation peroxide treatment. In order to keep the oxidation-induced stacking faults to a minimum, no HF treatment was given to the wafers prior to the oxidation (12). Oxidation time was selected to obtain approximately 1500Å thick oxide. These samples were annealed for 20 min in N_2 at the oxidation temperature after the oxidation and prior to cooling. The oxidation was carried out in a quartz furnace and 50 mil diameter aluminum electrodes were evaporated on the oxide.

Generation lifetime in the bulk silicon was determined by the pulse MOS-C technique, which is well documented in the literature (10, 18). In this technique the capacitor is pulsed into deep depletion and the capacitance is recorded as a function of time as it recovers from the deep depletion to its equilibrium state of inversion. Modified Zerbst analysis was used to calculate the lifetime. A simple approximation can be used to obtain the generation lifetime (τ_g) if the surface-state effects are small and the capacitor is pulsed from inversion into the deep depletion. This approximation has been discussed in detail by Schroder (13) and is given by

$$\tau_g = \frac{n_i}{8N_D}\frac{C_F}{C_o}t_F\left(1+\frac{C_i}{C_F}\right)^2 \qquad [1]$$

where N_D is the doping density, C_o is the oxide capacitance, C_i is the initial capacitance in deep depletion, C_F is the inversion capacitance, and t_F is the time it takes to recover from deep depletion to the inversion. In order to keep the surface generation small, the capacitors were sintered at 425°C for 1 hr in H_2. An average of 10 or more data points, near the central region of the wafer, was used to obtain the lifetime.

In selected instances, oxidation-induced defects in silicon were delineated by first removing the metal and the oxide and then preferentially etching ~3 μm silicon with Secco etch (20). The 3 μm region lies within the active area of the device during the lifetime measurement since the deep depletion width was ~5 μm. The oxidation-induced defects on the etched surface were observed with the help of an optical microscope. An average of 10 or more data points was taken to obtain the defect density on a wafer.

The effect of cooling rate after oxidation was studied by either quenching or slow cooling the samples. Quenching was done by rapidly removing the sample to room temperature after the 20 min N_2 anneal. Slow cooling was performed at a rate of 1°C/min in N_2 until a temperature of 600°C was reached and then the sample was removed to room temperature. The effect of oxidation temperature was investigated by varying the temperature in the range of 900°-1200°C. The influence of back surface damage gettering was evaluated by lapping the back side of the wafer with 60 μm Al_2O_3 powder prior to the oxidation. The effect of HCl oxidation was studied by oxidizing the wafers in ambients containing mixtures of HCl and O_2 gases. HCl concentration was varied in the range of 1-6% of the total gas flow during the oxidation. The first 100Å of oxide was grown in dry oxygen and the remaining oxide was grown in the HCl/O_2 mixture.

Results

Float zone silicon used in this study did not show stacking faults after the oxidation (Fig. 1). In a few instances stacking fault density was at most 25 cm^{-2}. The dislocation density was also quite small, less than 100 cm^{-2}. The dominant defects were saucers. Saucers

* Electrochemical Society Active Member.

Key words: oxidation, saucers, impurities, gettering.

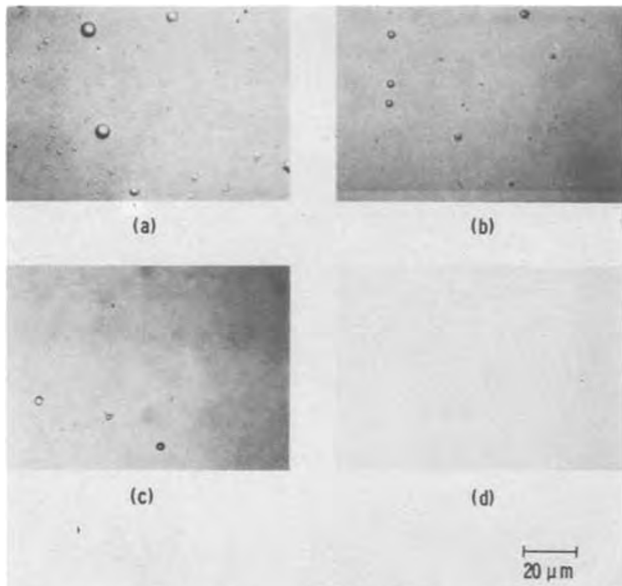

Fig. 1. Effect of back surface damage gettering and HCl oxidation on saucer defects (a) 0% HCl oxidation without back surface damage, ~1 × 10^6 saucers/cm², (b) 1% HCl oxidation without back surface damage, ~1 × 10^5 saucers/cm², (c) 0% HCl oxidation with back surface damage, 1 × 10^4 saucers/cm², (d) 1% HCl oxidation with back surface damage, ~1 × 10^3 saucers/cm².

are small, circular, shallow and flat-bottomed pits (Fig. 1).

Table I shows the effects of cooling rate, damage gettering, and HCl oxidation on the lifetime and defects for 1100°C oxidation. The data show that when a sample is quenched after the oxidation, the lifetime is very small, ~20 μsec, regardless of damage gettering and/or HCl oxidation. Figure 1 and Table I show that the damage gettering reduces the oxidation-induced saucer density by two orders of magnitude, $10^6 \rightarrow 10^4$ cm^{-2}, that HCl oxidation reduces the saucer density by an order of magnitude, $10^6 \rightarrow 10^5$ cm^{-2}, and that a combination of the two brings down the saucer density to ~10^3 cm^{-2}. The saucer density on the starting wafer was in the range of 500-1000 cm^{-2}. Slow cooling, without damage and HCl gettering, gives somewhat higher lifetime (~100 μsec) but the saucer density remains in the range 1-5 × 10^6 cm^{-2}. Introducing back surface damage gives a substantial increase in the lifetime, ~500 μsec, if the sample is slow cooled. One percent HCl oxidation with damage and slow cool gives lifetime of the order of 2 msec. Increasing the HCl concentration from 1 to 6% has very little effect on the lifetime and saucer density.

Figure 2 shows the effect of oxidation temperature on the lifetime. When a sample is quenched after oxidation, the lifetime is very low and relatively insensitive to the oxidation temperature. Slow cool without back surface damage gives somewhat higher lifetime which does not depend strongly on the oxidation temperature. Slow cool with damage gettering gives a substantial increase in the lifetime which is also not a strong function of the oxidation temperature. HCl oxidation with back surface damage and slow cool gives high lifetime which increases monotonically with the increase in oxidation temperature. Increasing the HCl concentration from 1 to 6% has no appreciable effect on lifetime. This is in agreement with Wang *et al.* (16). Table II shows that the saucer density remains unchanged, despite the systematic increase in lifetime, with increasing HCl oxidation temperature.

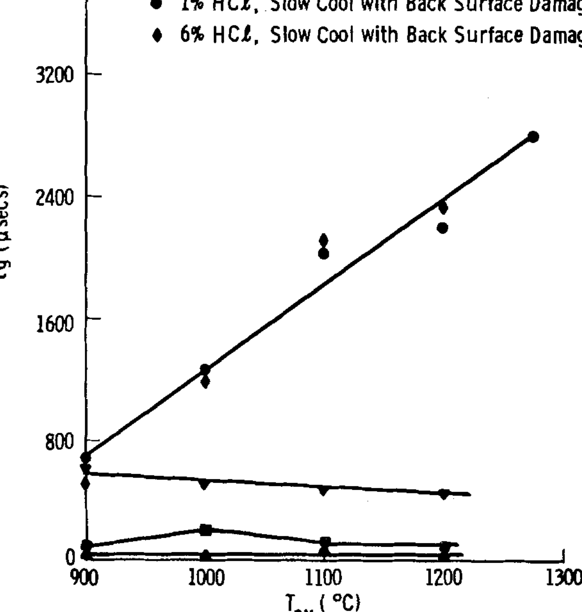

Fig. 2. Minority carrier lifetime as a function of oxidation temperature for different oxidation conditions.

Table I. Effect of cooling rate, back surface damage gettering, and HCl oxidation on lifetime and defects in FZ silicon

Process	Lifetime (μsec)	Saucer density (cm^{-2})
No BSD 0% HCl quench	20	10^6 – 5 × 10^6
BSD 0% HCl quench	20	10^4 – 5 × 10^4
BSD 1% HCl quench	20	10^3 – 5 × 10^3
No BSD 0% HCl slow cool	100	10^6 – 5 × 10^6
No BSD 1% HCl slow cool	200	10^5 – 5 × 10^5
BSD 0% HCl slow cool	500	10^4 – 5 × 10^4
BSD 1% HCl slow cool	2000	10^3 – 5 × 10^3
BSD 6% HCl slow cool	2100	10^3 – 5 × 10^3

Oxidation temperature 1100°C.

Discussion

The data showed that quenching after oxidation is very detrimental to device lifetime, regardless of back damage and HCl gettering. It has been shown by Wang (16) that quenching gives rise to recombination centers, at E_c – 0.26 eV and E_c – 0.49 eV, which may result from the dissolved impurities quenched in the interstitial sites. Thus, in quenched samples, lifetime is probably controlled by these centers and has no relationship with the saucer density (Table I). On the other hand, in the slow-cooled samples, the lifetime is inversely related to the saucer density. During slow cooling, the dissolved impurities get enough time to migrate, precipitate, and become electrically inactive, therefore, they do not seem to limit the lifetime as in the case of quenched samples. Moreover, according to

Table II. Effect of HCl oxidation temperature on lifetime and defects in FZ silicon

Oxidation temperature (°C)	Lifetime (μsec)	Saucer density (cm^{-2})
900	660	10^3 – 5 × 10^3
1000	1275	10^3 – 5 × 10^3
1100	2000	10^3 – 5 × 10^3
1200	2200	10^3 – 5 × 10^3

1% HCl oxidation with back surface damage and slow cool.

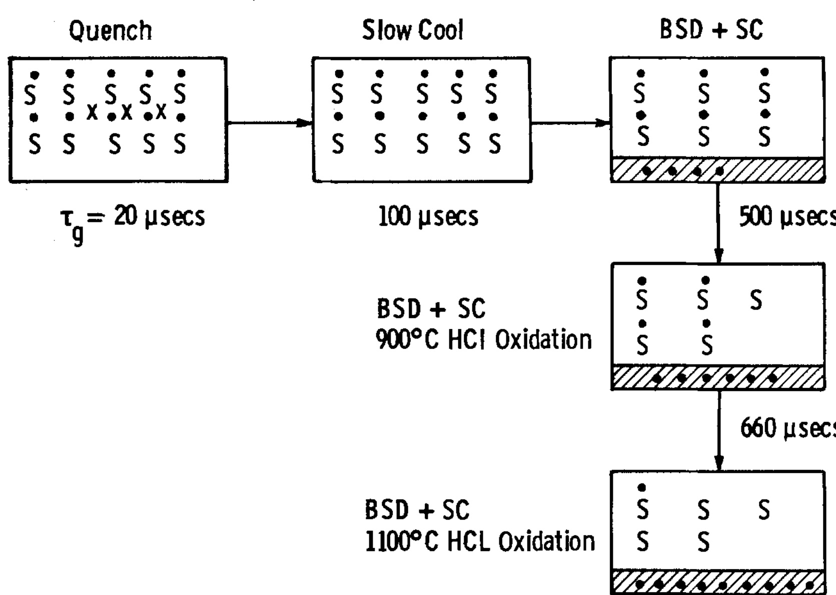

Fig. 3. Schematic representation of process-induced effects on lifetime and defects.

Pearce *et al.* (9), the oxidation-induced saucers can be generated from heavy metals incorporated during handling, cleaning, and processing of the wafer. They found that saucers are the result of a dislocation loop formed by heavy metal precipitates, although no satisfactory model has yet been proposed to account for their behavior. These saucers, being indicative of metallic contaminant, can reduce lifetime. Therefore, in the absence of other lifetime limiting sources, the lifetime is expected to vary inversely with the saucer density (Table I).

Table II showed that the HCl oxidation with the damage and slow cool is a very effective process for achieving high lifetime. The lifetime increases monotonically with the increase in the HCl oxidation temperature, however, the saucer density remains unchanged indicating that this systematic increase in lifetime cannot be attributed to the saucer density alone. Several investigators (8, 17) have pointed out that the defects should be decorated with impurities in order to be detrimental to the device performance. It appears from the data that higher HCl oxidation temperature cleans the bulk silicon more effectively either by extracting the impurities and/or by preventing them from getting into the bulk during the oxidation. Therefore, the concentration of the decorated saucers diminishes with higher HCl oxidation temperature, which may account for the monotonic increase in the lifetime, in spite of a constant saucer density.

The model in Fig. 3 illustrates these process-induced effects on lifetime and defects. It shows that when a sample is quenched, after the oxidation. the lifetime is very low primarily due to the dissolved impurities in the silicon lattice. When a sample is slow cooled, some of the dissolved impurities are able to precipitate and become electrically inactive, resulting in an increase in the lifetime. Slow cooling by itself has no effect on the saucer density. However, slow cooling with back surface damage reduces the saucer density by two orders of magnitude because the damage provides a sink for the point defects and fast diffusing impurities. This results in a substantial increase in the lifetime. HCl oxidation reduces the saucer density by an order of magnitude resulting in some additional increase in the lifetime. Increasing the HCl oxidation temperature has no appreciable effect on the net saucer density but it decreases the concentration of the decorated saucers to improve the lifetime further. Thus, by selecting the right process the lifetime can be increased from 20 μsec to 2 msec.

Conclusions

Quenching of devices after the oxidation results in very low lifetime (~20 μsec), regardless of damage or HCl gettering. The lifetime of quenched samples bears no relationship to the saucer density. Slow cooling has no effect on the saucer density but it gives somewhat higher lifetime (~100 μsec). Slow cooling with back surface damage gives a substantial improvement in the lifetime (~500 μsec). HCl oxidation with damage and slow cool is a very effective process which can give lifetimes of the order of 2 msec. Higher HCl oxidation temperature is more important than the HCl concentration for achieving better lifetimes. Back surface damage reduces the oxidation-induced saucer density by two orders of magnitude and the HCl oxidation reduces the density by an order of magnitude. The saucer density is not always the only reason for low lifetime, *e.g.*, dissolved impurities and/or decorated saucer density play an important role.

Inhomogeneities in Silicon Crystals Grown from the Melt

Gene F. Wakefield*[,1]

Texas Instruments Incorporated, Dallas, Texas 75265

ABSTRACT

A brief review is given of some of the methods used to describe incorporation of impurities into silicon crystals grown from the melt. It is concluded that the concept that allows the equilibrium segregation coefficient to vary to an "effective" segregation coefficient is misleading and disguises the actual solid/liquid dynamics. Impurity concentration is controlled in crystals by their actual (changing) concentration at the interface and their equilibrium (essentially constant) segregation coefficient. This paper presents calculations on the effect of growth rate on impurity incorporation. Growth rate fluctuations lead to solute nonuniformities on a microscale with dopant, carbon, and metals concentrated into areas of a silicon slice separate from oxygen-rich "swirl" bands. The measured fluctuation in dopant concentration across a slice can be used to estimate other impurity concentration variations. Discrepancies between experimentally determined and the calculated values are considered to result primarily from lack of an appropriate value of boundary layer thickness.

The subject of chemical inhomogeneities in semiconductor crystals has received considerable attention, with the major focus on dopant and oxygen nonuniformities. Several crystal growth models (1-6, 8, 9) have been proposed which have aided understanding of the cause of the microscale variations prevalent in crystals. A critical analysis of the models reveals that though each covers certain aspects, the silicon crystal from large commercial Czochralski pullers is not as well described as desired.

Silicon crystals are now grown as long, cylindrical ingots which are sliced into thin wafers for semiconductor device manufacture. During growth of a silicon crystal, constant thermal and chemical changes occur within the crystal puller which cause each individual wafer to differ in content and distribution of impurities from every other wafer. A macroscale longitudinal variation is inherent in batch growth due to concentration of impurities into a decreasing melt volume. Also, thermal convection causes microscopic growth rate fluctuations to occur in the interface dynamics, and introduces inhomogeneities on a microscale. Since the interface shape is usually a curved surface, nonuniform bands reflecting the instantaneous melt-solid interface shape are frozen into the crystal. These nonuniformities have been shown to be bands which have different solute concentration from the interband silicon. As each planar wafer may intersect several of the curved interface shapes, each wafer then also varies across its surface on a microscale basis as illustrated in Fig. 1. Compounding these nonuniformities within a crystal, each crystal is somewhat unique in quality because of the nature of any batch process, the variations in pullers, and the variations in starting polysilicon quality.

Microscale fluctuations are now recognized to result primarily from thermal convection currents within the melt (1-5). These currents periodically disturb the microscopic growth rate of the crystal. The magnitude and nature of the convection currents also varies as the melt aspect (melt height to diameter) ratio is decreased as a crystal is grown. The major source of the convection currents is clearly the temperature gradient (4) which exists due to a high heat input through the crucible walls which must then be lost from the top and bottom of the melt.

The microscale conditions of the solid-liquid interface of a growing crystal include solute rejection (for a solute with a segregation coefficient, $K < 1$) just ahead of the advancing solid, increasing the solute concentration at this interface. Between the solid and the well mixed (bulk) liquid is a 100-500 μm "boundary layer" of liquid, consisting of a momentum and solute concentration gradient. The excess solute moves from the interface against a silicon solution flowing normal to the interface, and with the radial flowing solution. A precise definition of solute boundary layer

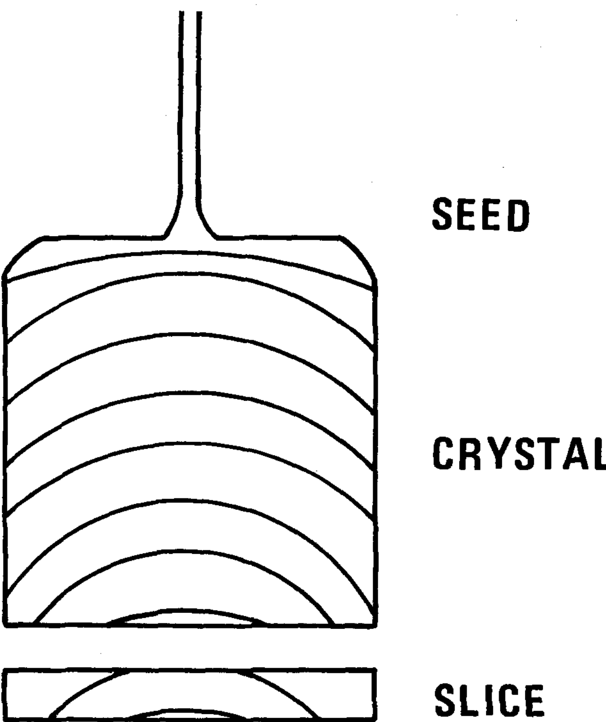

Fig. 1. Schematic illustration of a silicon crystal cross section containing curved melt interface surfaces which result in inhomogeneities on a slice surface.

thickness would be the distance from the solid into the melt at which concentration level becomes constant and equal to the bulk melt composition.

It is preferred to assume that the segregation coefficient is unchanged within the small range of the revelant silicon-impurity phase diagram, since it is a thermodynamic parameter relating the activity of the impurity in the solid and liquid. A crystal growth description which treats K as a variable parameter, such as K_{eff}, masks a true understanding of the interface dynamics since microscale concentration variations are caused by concentration changes occurring at the interface, not by a variation in K.

The purpose of this paper is to present calculations on relationships of solute nonuniformities in a silicon crystal and to suggest a method to use measured dopant variations to predict variations in other impurities. This analysis is based on the two assumptions: (*i*) the segregation coefficient is a constant; and (*ii*) the boundary layer thickness is defined by physical parameters (both are unchanged by growth rate).

Background

The Burton, Prim, Slichter (BPS) description of crystal growth relates variations in impurity incorporation into the solid by varying the equilibrium segregation coefficient K to an effective $K(K_{eff})$ value (6). The main equation of the BPS model is

$$K_{eff} = \frac{K_o}{K_o + (1 - K_o)e^{-f\delta/D}} \quad [1]$$

using the Cochran (7) definition of boundary layer thickness

$$\delta = 1.6\, D^{1/3}\nu^{1/6}\omega^{-1/2} \quad [2]$$

where f is the growth rate solid, δ is the boundary layer thickness, D is the diffusion coefficient of the solute in the melt, ν is the kinematic viscosity of the liquid, and ω is the angular velocity of crystal rotation. The K_{eff} equation is applicable to a (at least instantaneous) steady-state condition and can be used to relate the concentration in the solid to the bulk liquid concentration. Variation in K is used to account for solute concentration changes occurring at the solid-liquid interface. The application of this model is usually done by fitting solute concentration profiles in crystals grown at various macroscopic growth rates using δ/D as a parameter, and subsequent calculation of K_{eff}. This technique has been used to derive a consistent description of a macroscopic situation and also has been the major technique used to obtain values for diffusivities (7).

A description of solute bulidup in zone refining was given by Tiller, Jackson, Rutter, and Chalmers (8). The main equation describing buildup is

$$C_T = \frac{C_s}{K} = C_o \left\{ \left[\frac{1-K}{K}\right] \left[1 - \exp\left(-K\frac{R}{D}x\right)\right] + 1 \right\} \quad [3]$$

where C_T is the solute concentration at the growing interface, C_s the solid, C_o the initial concentration in the melt, R rate of advance of the interface, and x the distance the interface has traveled. This description applies to a constant and limited melt volume, melt replenishment of C_o concentration, and no melt stirring, *i.e.*, only diffusion of the excess solute away from the interface. The approach has the attraction of focusing on impurity buildup and gives a valid macroscopic view of zone refining. Nonmonotonic solute incorporation into the solid, "banding," is briefly ascribed to changes in heat input to the liquid. The description has limited application to a Czochralski configuration with a large and varying, stirred, melt volume.

A modification of the BPS description was used by Hall (9) to correlate the effect of varying growth rate on incorporation of multiple impurity dopants in germanium crystals. The equation was

$$K_{eff} = K \exp\,(V/V_d) \quad [4]$$

where V is the growth velocity and V_d a characteristic growth parameter which depended upon the degree of stirring and diffusion in the melt. The technique was used to develop a process for the growth of crystals having a series of p-n junctions, using gallium and antimony dopants, by varying the growth rate. The important interplay between segregation, growth rate, and melt stirring are included in this model, but emphasis is placed on a K_{eff}, rather than interface concentration.

The development of a technique (10) to determine the microscopic growth rate in a Czochralski puller enabled analysis of actual interface dynamics. The measured dopant variations were found to follow the general shape of the microscopic growth rate curve. Analysis of the data was done using the form of the BPS model

$$C_s = K_{eff}C_L = \frac{KC_L}{K + (1 - K)\exp\,(-V\delta/D)} \quad [5]$$

where C_L is the solute concentration in the bulk liquid and V is the microscopic growth rate obtained from the constant time marks. Crystal dopant levels and microscopic growth rate data were used to obtain the value of δ/D as a parametric fit to Eq. [5] and then the best fit δ/D used to calculate the expected dopant concentration. A value of δ/D of 133.3 sec/cm was obtained which led to a boundary layer thickness of 266 μm taking $D = 2 \times 10^{-4}$ cm²/sec. The value of D was originally obtained (11) by a similar treatment using the BPS model. An independent evaluation of D would be preferred.

The technique of determining microscopic growth rate aided significantly to understanding actual Czochralski crystal growth. Several works (4, 11, 12) support the concept that microscopic growth rate changes are caused by thermal convection currents within the melt.

Analysis and Discussion

Thermal fluctuations which disturb the rate of crystal growth change the rate of solute rejection. The limitation of diffusion of the solute through the boundary layer causes the interface solute concentration to continually change. This is illustrated in Fig. 2 (a and b) where (a) depicts the solute concentration as the microscopic growth rate increases and (b) depicts the solute concentration as the microscopic growth rate decreases. Periodic thermal convection currents cause fluctuations in growth rate, especially during crystal growth from melts having a height-to-diameter (h/d) aspect ratio $> 1/2$. As the volume of remaining melt is decreased, h/d decreases and the microscopic growth rate may at times be negative, *i.e.*, remelting of the crystal may occur.

Crystal growth without remelt.—During periods of increasing microscopic growth rate, solutes with $K < 1$ will be enriched at the solid-liquid interface, and solute diffusivity is insufficient to avoid increasing concentration at the interface. For solutes with $K > 1$ such as oxygen, the concentration at the solid-liquid interface will be depleted and a decreasing amount of these solutes will be incorporated into the crystal.

During periods of decreasing microscopic growth rate, solutes with $K < 1$ will have greater time for diffusion away from the solid-liquid interface and the interface concentration will be decreasing. Solutes with $K > 1$ will have more time for concentration replenishment to the melt-liquid interface and thus will show increasing concentration in the solid.

When microscopic growth is at a minimum positive value, interface solute concentrations closer to the bulk melt concentration result. As the microscopic growth rate then begins to increase, the maximum concentration of oxygen (KC_L) can be incorporated into the crystal. This is consistent with the observations that oxygen is at a maximum on the melt side of growth striation (12). Correspondingly, the initial acceleration period after a pause will incorporate the minimum of components with $K < 1$ and this minimum approaches KC_L. Table I summarizes the solute changes as the microscopic growth rate varies and the limits in impurity concentrations that can conclude from this approach.

When the microscopic growth rate reaches a maximum, the minimum of solutes with $K > 1$ are incorporated into the crystal at some value of $<KC_L$. The maximum in microscopic growth rate corresponds to the maximum in solute incorporation for $K < 1$, and the maximum may be $>>KC_L$ for these solutes.

Crystal growth with extensive remelt.—Crystal growth at conditions where extensive remelt is occurring, such as at low melt aspect ratios, is less well characterized since the microscopic growth rate determination technique is not applicable. The previous discussion showed that as microscopic growth rate decreases, diffusion through the boundary layer decreases the concentration of solutes with $K < 1$ at the solid-liquid interface. If a portion of the crystal is remelted, a further decrease in solute concentration at the interface occurs, since concentration in the melting crystal was less than the interface concentration. Depending upon the amount and speed of remelting, as the crystal begins to refreeze, a reduced concentration of $K < 1$ solutes may result. For solutes with $K > 1$, remelting of the crystal causes the interface concentration to increase. As the crystal begins to refreeze, the concentration of these solutes in the solid is likely similar to the remelted crystal. Lacking detailed information on the dynamics occurring during such remelting periods, limits on the solute concentration in the solid cannot be established.

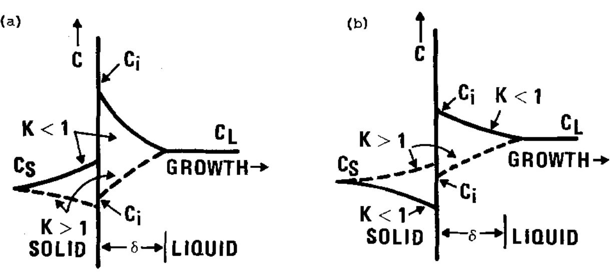

Fig. 2. Schematic of solute profile at solid-liquid interface during growth. (a) Increasing microscopic growth rate. (b) Decreasing microscopic growth rate.

Table I. Summary of solute concentration dynamics during crystal growth

Microscopic growth rate	$K < 1$			$K > 1$		
	C_i	C_S	C_δ	C_i	C_S	C_δ
Increasing	$>>C_L$, inc.	$>KC_L$, inc.	$>C_L$	$<C_L$, dec.	$<KC_L$ dec.	$<C_L$
Decreasing	$>C_L$, dec.	$>KC_L$, dec.	$>C_L$	$<C_L$, inc.	$<KC_L$, ins.	$<C_L$
Pause	$\rightarrow C_L$	$\rightarrow KC_L$	$\rightarrow C_L$	$\rightarrow C_L$	$\rightarrow KC_L$	$\rightarrow C_L$
Negative (remelting)	dec.	—	dec.	inc.	—	inc.

Note: Maximum C_S for any $K > 1 = KC_L$
Minimum C_S for any $K < 1 = KC_L$

$\rightarrow$ = approaches
inc. = increasing
dec. = decreasing

Float zone crystal growth.—The growth mechanism perspective which focuses on solute buildup at the interface is consistent with the occurrence of solute concentrations in float zone crystals. It was shown (13) that carbon concentration bands occur on the seed side of melt striae (as they most likely also do in Czochralski crystals). Correspondingly then, associated with the carbon banding will be higher concentrations of metallic impurities and dopant since the striae are also caused by thermal convection current disturbance of the microscopic growth rate.

Investigation of the impurity striation in float zone crystals having various carbon levels showed that at an average carbon level of 8×10^{16} atoms/cm^3, significant banding of carbon occurred (14). Associated with the maxima and minima of carbon across a wafer surface, correspondingly were maxima and minima of the phosphorous dopant. Subsequent diffusion of gold into the high carbon, striated wafers resulted in gold preferentially distributed into carbon and phosphorous-rich areas and performance of power devices made on this material was substantially degraded.

Impurity distribution calculation.—The impurity concentration of the solid is related to the interface concentration $C_s = KC_i$. The fractional change in C_i with varying (microscopic) growth rates can be calculated from

$$\Delta C_i = \frac{C_i - C_L}{C_L} = \frac{(1 - K)(1 - e^{-\Delta})}{K + (1 - K)e^{-\Delta}}$$

where $\Delta = f\delta/D$.

This equation for ΔC_i was used to calculate the expected changes in concentration for several common impurities. The Cochran (15) derivation of boundary layer thickness was used since it was judged that a more consistent alternative was not available. A kinematic viscosity of 0.0106, as calculated by Kodera (7), was also chosen. The magnitude, but not the trends, in ΔC_i would be slightly sensitive to other selected values. Growth rates of 25, 50, and 75 μm/sec and rotation rates of 10, 15, and 20 rpm were selected to represent typical values for silicon crystal production.

* Assumed values.

The calculated values for ΔC_i are given in Table II along with the values used for K and D. Two calculations were made for carbon using an assumed value for D of 1×10^{-4} cm²/sec [this value was used in Fig. 3(b)], and also a measured value of 0.485×10^{-4} cm²/sec (16). The latter value was determined by an independent method and differs significantly from many of the other D values. The ΔC_i values are plotted in Fig. 3.

The large calculated increases in interface concentration for carbon and antimony are consistent with the tendency for single crystal growth breakdown even at C_L concentrations substantially less than equilibrium liquid solubility values. The expectation of improved uniformity of boron over phosphorous-doped crystals is also consistent with observations.

This approach can be used to predict impurity concentration variations by measurement of dopant variations. Data (1) on antimony variations at minimum (8 μm/sec) and maximum (26 μm/sec) microscopic growth rates indicated a ΔC_i of 0.11 and 0.40, respectively, for a fitted parameter boundary layer thickness of 266 μm. This compares to calculations based on the assumptions of this paper which predict a ΔC_i for antimony of 0.33 and 1.45 for the two growth rates and also ΔC_S of −0.08 and −0.15 for oxygen, 0.42 and 1.91 for carbon, 0.27 and 1.16 for iron for the respective growth rates. Selection of a thinner boundary layer value would reduce these predicted values. However, the areas of higher antimony concentration (fast growth rate) will have relatively lower oxygen, higher carbon and iron.

Deficiencies in calculations.—The discrepancies between the experimental data and the calculated values are likely influenced most from inaccuracy in the appropriate boundary layer thickness and to a lesser extent in the accuracy of the impurity diffusion coefficients and the viscosity of liquid silicon.

The Cochran (7) calculation for the momentum boundary layer was derived for liquid flow normal to the interface. Within the boundary layer adjacent to the crystal, radial velocity significantly exceeds normal

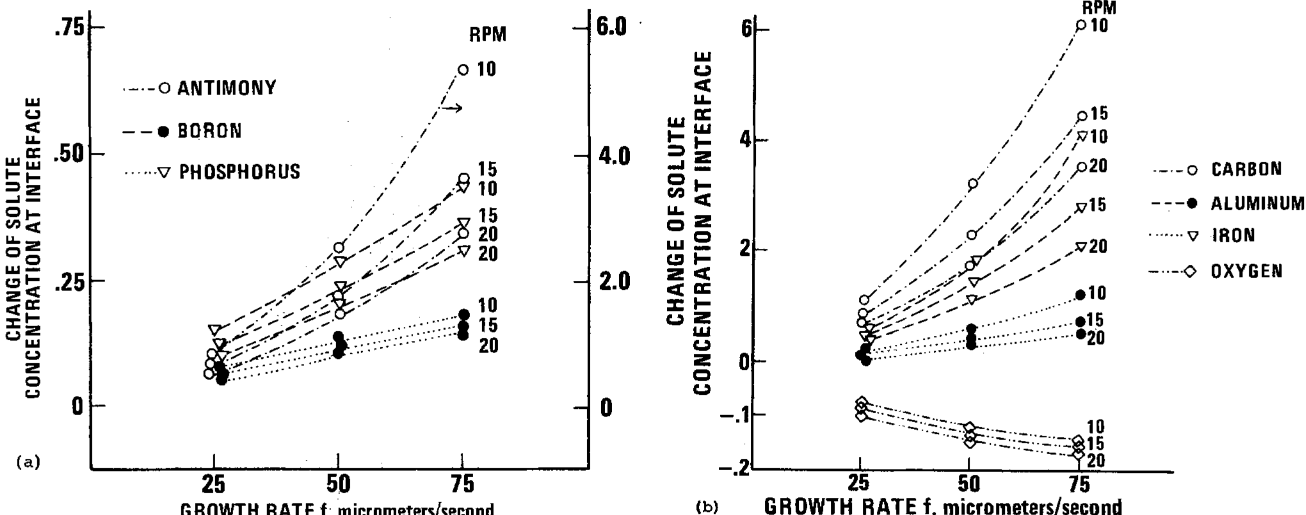

Fig. 3. Calculated change in impurity concentration at solid-liquid interface. (a) Common dopants, (b) impurities

velocity. Accurate calculations require a boundary layer thickness which relates the concentration, rather than momentum, boundary layer thickness established due to diffusion and physical mixing. Estimates of diffusion coefficients have usually been derived from solid concentration values at varying growth rate using a boundary layer value calculated by the Cochran analysis. Later use of such diffusion numbers and adjusting the boundary layer thickness to fit experimental data is a rather questionable, circular procedure. Independent measurement of diffusion coefficients is required.

The one independent check on carbon diffusion (16) in a nonstirred melt (assumed equivalent to silicon self-diffusion) was self-consistent with experimental results and less than one-half most commonly used diffusion values. It would seem consistent to speculate that diffusion coefficients for all impurities should approach the value for silicon self-diffusion. To assume that a weak impurity/silicon bonding (short-range ordering) could occur within the liquid state to allow deviation from silicon self-diffusion values would likely require consideration of impurity/impurity bonding also.

An error in the values for kinematic viscosity of silicon 0.0106 (calculated) (7) and 2.9×10^{-3} (experimental) (17) could lead to a small error in model calculations. However, viscosity enters only into the boundary layer thickness equation to the one-sixth power, so this is of less concern than accuracy of diffusivity or boundary layer thickness values.

Conclusions

Several conclusions can be obtained from this approach. (*i*) Treating K as a constant and focusing on solute concentration at the interface allows additional information to be gained regarding microscale distribution of oxygen, carbon, and other impurities. Both Czochralski and float zone distributions are consistently explained. (*ii*) Microscale dynamics of the growth interface have critical impacts on inhomogeneities in the crystal and some limits on concentrations can be elucidated, at least in the portion of crystal grown without extensive remelt. (*iii*) Silicon crystals with reduced microscale and macroscale inhomogeneities could be obtained from crystal pullers designed with minimum temperature gradients in the melt. A steady-state growth condition from a constant melt volume would aid in stabilizing the microscopic growth rate.

To capitalize on this approach a new mathematical model needs to be developed which defines both the dynamics of the chemical environment at the interface and the transient thermal effects. Additional experimental efforts are needed to quantify the microscale nonuniformities, and relate their impact on device fabrication and performance.

ABSTRACT

Temperature significantly modifies the efficiencies of luminescence and photocurrent in an n-type, single crystal, CdS:Te-based photoelectrochemical cell (PEC) employing aqueous polyselenide electrolyte. Between 20° and 100°C photocurrent (quantum yield Φ_x) from ultrabandgap 501.7 nm excitation increases modestly by $\lesssim$ 20%, whereas photocurrent from bandgap edge 514.5 nm excitation increases by about an order of magnitude, reaching 50-100% of the 20°C 501.7 nm photocurrent. Undoped CdS exhibits a similar photocurrent-temperature profile. Higher temperatures thus extend the wavelength response of CdS- and CdS:Te-based PEC's. In contrast to the increase in photocurrent, emissive efficiency (quantum yield Φ_r) of CdS:Te drops by a factor of ~10-20 over the same temperature range; this decline is relatively insensitive to potential and excitation wavelength (501.7 or 514.5 nm). Little change in the spectral distribution of emission ($\lambda_{max} \sim$ 600 nm) is observed with temperature. A dependence of emission intensity on potential is observed for the first time with 514.5 nm excitation in the high temperature regime. These results are interpreted in terms of band bending, optical penetration depth, the known red-shift of the CdS bandgap edge with temperature, and the competitive nature of emission and photocurrent. Relationships among Φ_x, Φ_r, and Φ_{r_0}/Φ_r (out-of-circuit to in-circuit emission intensity) are discussed.

We recently reported that n-type, tellurium-doped CdS (CdS:Te) serves as a luminescent photoelectrode in photoelectrochemical cells (PEC's) used to convert optical energy to electricity (1). In this manner CdS:Te permits determination of the effect of PEC parameters such as incident excitation wavelength, electrolyte, and potential upon the various deactivation routes of the semiconductor electrode excited state. In particular, luminescence is a probe of electron-hole recombination processes which compete with electron-hole separation leading to photocurrent.

In the course of our studies, we noted that the emission intensity and, in some instances, the photocurrent of CdS:Te-based PEC's were temperature dependent. We demonstrate herein that temperature may be used to significantly modify the relative efficiencies of excited state deactivation pathways in a manner which underscores the competitive nature of luminescence and photocurrent. In addition, higher temperatures extend the wavelength response of both CdS- and CdS:Te-based PEC's.

Theory

The bandgap of undoped CdS, E_{BG}, is ~2.4 eV at 298°K (2). Although CdS:Te has a low energy tail in its absorption spectrum which masks the bandgap, the highest absorptivities (>10^4 cm^{-1}) occur at $\lambda \lesssim$ 500 nm in both undoped CdS and CdS:Te (2-6). Ultrabandgap wavelengths are therefore taken as those with $\lambda \lesssim$ 500 nm; absorption occurs within ~0.1-1μ of the surface, a distance typically corresponding to the depletion region. This zone is characterized by maximum band bending and is conducive to ready separation of photogenerated electron-hole ($e^- - h^+$) pairs leading to maximum photocurrent (7).

Longer excitation wavelengths penetrate farther into the crystal, and the diminished band bending favors $e^- - h^+$ recombination at the expense of separation. Luminescent CdS:Te-based PEC's exhibit more emission and less photocurrent with bandgap edge 514.5 nm than with ultrabandgap 501.7 nm excitation, for example (1).

Figure 1(a) illustrates the interrelationship of penetration depth and band bending at these wavelengths. The dashed line represents the discrete states involved in the emissive process which are introduced by the Te dopant; holes trapped at Te sites (Te presumably substitutes for S in the lattice) may coulombically bind an electron in or near the conduction band to form an exciton whose subsequent radiative collapse leads to luminescence (3-6).

Our chief guide for predicting thermal effects in the PEC was the known optical bandgap temperature coefficient, dE_{BG}/dT, for undoped CdS. This coefficient has a value of -5.2×10^{-4} eV/°K between 90° and 400°K (8). To the extent that CdS:Te resembles CdS, this relationship predicts that the bandgap edge red shifts with increasing temperature; at a sufficiently high temperature 514.5 nm will become an ultraband gap wavelength like 501.7 nm, for example. Figures 1(b) and (c) illustrate the anticipated effect of increased temperature on the band diagram and absorption spectrum. The decline of E_{BG} with increasing temperature has been interpreted as arising from two effects: lattice dilation and energy level broadening at the edges of the bandgap due to collisions between electrons and phonons (9).

Implicit in the comparison of Fig. 1(a) and (b) is the relative insensitivity of the depletion region width, W, to temperature. The expression for W is given by Eq. [1] where

$$W = (2\epsilon\epsilon_0 V_B/qN)^{1/2} \quad [1]$$

N is the charge carrier density in the semiconductor, q is the electronic charge, ϵ_0 is the permittivity of free space, ϵ is the semiconductor dielectric constant, and V_B is the amount of band bending in the depletion region (10). For a given electrolyte we do not expect W to change drastically over the 20°-100°C temperature range investigated. That is, we are assuming variations in ϵ, N, and V_B to be small. We note that ϵ changes by less than 15% between −196° and 25°C for undoped

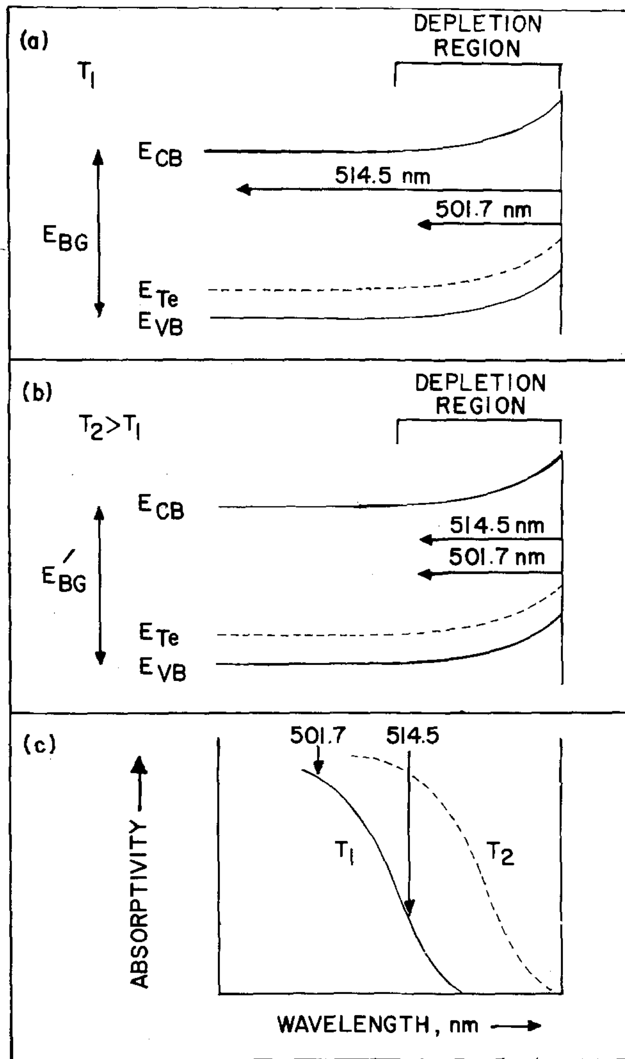

Fig. 1. (a) Comparison of penetration depths for bandgap edge (514.5 nm) and ultrabandgap (501.7 nm) excitation relative to the width of the depletion region at temperature T_1 for CdS:Te (not to scale). E_{CB} and E_{VB} refer to the conduction and valence band energies. Doping CdS with Te is believed to introduce discrete states at energy E_{Te}. E_{BG} is the bandgap energy at T_1; (b) at temperature $T_2 > T_1$ the bandgap is expected to shrink, $E_{BG}' < E_{BG}$; as a consequence, the penetration depth of 514.5 nm light would be reduced; (c) the expected effect on the CdS:Te absorption spectrum caused by an increase in temperature. Solid and dashed lines represent the spectra at T_1 and T_2, respectively (curves are crude approximations and not drawn to scale).

CdS (11) and that donors in 50 ppm CdS:Te are $\gtrsim 90\%$ ionized at room temperature (Hall measurements) (5). The maximum value of V_B is controlled by the relative energies of the semiconductor Fermi level and the electrolyte redox potential, E_{redox} (7, 10). While the explicit temperature dependence of V_B is not known for the electrolyte employed, our results are consistent with small changes in V_B and W. We emphasize that these are assumptions, however, and that a rigorous analysis requires knowledge of the depletion width. With this in mind, we will treat Fig. 1 as an approximation whose validity can be qualitatively probed by the PEC of Fig. 2.

The PEC consisted of an n-type, single crystal, 100 ppm CdS:Te working electrode, a 2.0 × 0.8 cm Pt foil counterelectrode, an Ag pseudoreference electrode (PRE), and an aqueous polyselenide electrolyte of approximate composition 5M OH^-/0.1M Se^{2-}/0.001M Se_2^{2-}. Temperature control was achieved with resistive heating, as sketched in Fig. 2. Emission and photocurrent could be monitored simultaneously by placing the

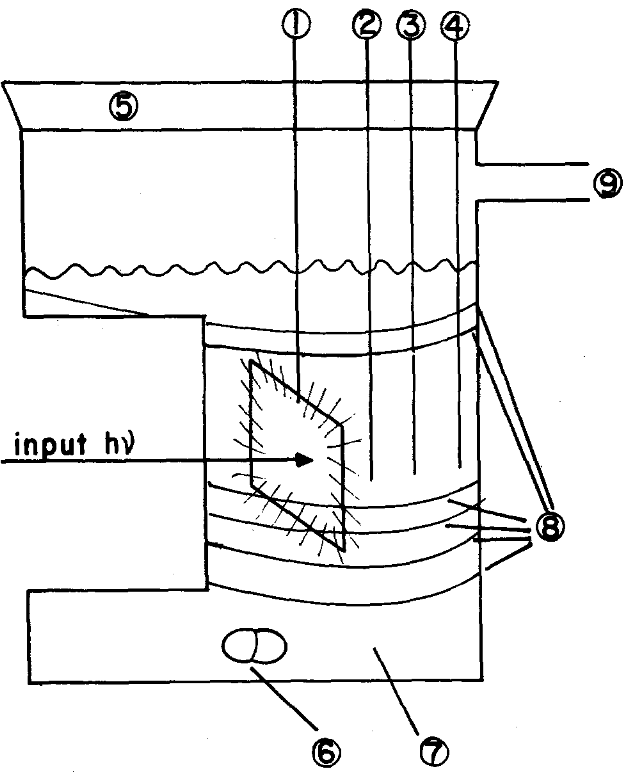

Fig. 2. Components of the CdS:Te-based variable temperature PEC: (1) n-type CdS:Te photoelectrode, site of polyselenide oxidation; (2) thermometer; (3) Pt foil counterelectrode, site of polyselenide reduction; (4) Ag pseudoreference electrode (PRE); (5) rubber stopper, positioned loosely enough to serve as a vent, through which (1)-(4) are inserted; (6) magnetic stir bar; (7) aqueous polyselenide electrolyte; (8) Nichrome wire wound outside the cell for resistive heating; (9) N_2 inlet, the N_2 passing first through an aqueous reservoir. Components (1), (3), and (4) are connected to a potentiostat.

PEC inside an emission spectrometer and inclining the electrode at ~45° with respect to both the Ar ion laser excitation beam and the emission detection optics; the laser beam was expanded and masked to fill the electrode surface. The electrochemistry occurring corresponds to oxidation of polyselenide electrolyte at the photoanode and the reduction of polyselenide at the counterelectrode (12). No net change occurs in the electrolyte under these conditions, thus permitting sustained conversion of optical energy to electricity, while inhibiting the competitive photoanodic dissolution process, Eq. [2] (12)

$$CdS \xrightarrow{h\nu} Cd^{+2} + S + 2e^- \quad [2]$$

Polyselenide electrolyte is also an advantageous choice because of its relative transparency to the excitation wavelengths employed (12).

Results and Discussion

Emissive properties.—While $E_{BG} = |E_{CB} - E_{VB}|$ is expected to vary inversely with temperature, the temperature dependence of the CdS:Te emission spectrum will hinge on the relative positions of E_{Te}, E_{CB}, and E_{VB}. We and others have found that at 77°K the emission maximum blue shifts slightly from its 298°K ~600 nm value; the spectrum also sharpens and increases in intensity dramatically (1, 3-6). As the photoelectrode in a PEC, CdS:Te shows little change in the emitted spectral distribution (bandwidth ~5 nm; 540-800 nm) over the ~20°-100°C temperature range investigated in polyselenide electrolyte. A few samples displayed a modest red shift of λ_{max} (~10 nm) and/or more of a low energy tail at the high temperature extreme. Typical spectra obtained at open circuit are shown in Fig. 3. In

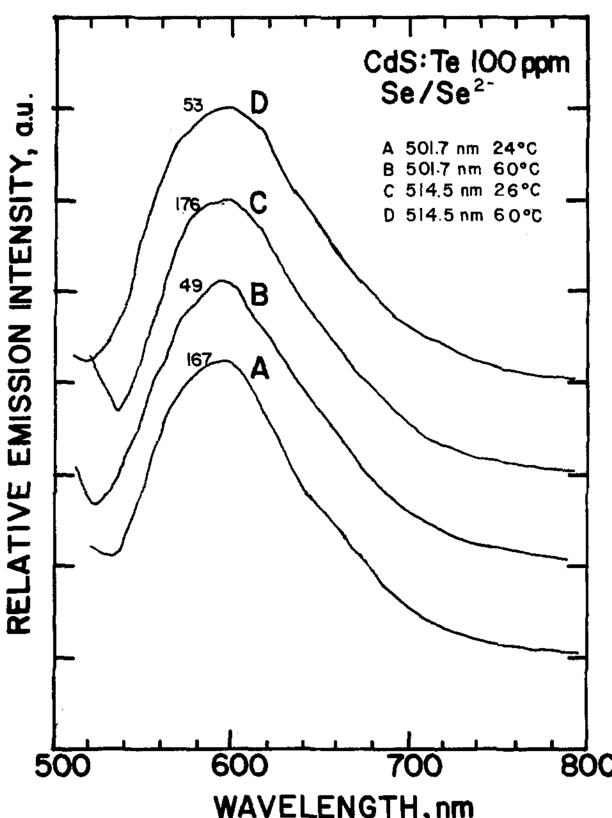

Fig. 3. Uncorrected emission spectra at open circuit of a CdS:Te electrode in 5M OH^-/0.09M Se^{2-}/0.001M $Se_2{}^{2-}$ electrolyte. Temperature and excitation wavelength employed for each curve are identified in the figure. Although the curves have all been normalized to the same intensity at λ_{max} ~600 nm, the number above each curve gives the actual intensity before normalization. A filter solution was used to eliminate the exciting light (see Experimental) and is responsible for the deviations from baseline at the short wavelength extreme.

agreement with our earlier studies, the spectral distribution is independent of whether 501.7 or 514.5 nm excitation is used and independent of electrode potential between +0.7V *vs.* Ag (PRE) and the onset of cathodic current. Changes in potential alter the degree of band bending in an n-type semiconductor: negative bias diminishes and positive bias augments band bending (7). If the Te state energies were not affected by potential in the same manner as the conduction and valence bands, we would expect to see potential dependent spectral distributions. This not being the case, we show E_{Te} bent in parallel with E_{CB} and E_{VB} in Fig. 1(a) and (b).

Another noteworthy feature of Fig. 3 is the considerable decline in CdS:Te emission intensity with increasing temperature. The effect is reversible; luminescence reappears with reproducible intensity upon cooling. A more quantitative measure of this effect is provided by Fig. 4(a) which displays the open-circuit emission intensity monitored at λ_{max}(~600 nm) *vs.* temperature for both excitation wavelengths in polyselenide electrolyte. Earlier studies of CdS:Te in the absence of electrolyte show analogous thermal quenching; plots of ln $(I_o/I_T - 1)$ *vs.* T^{-1} (I_o is the maximum emission intensity observed at low temperature; I_T is the emission intensity at temperature T) yielded straight lines over the range of $150° \lesssim T \lesssim 300°K$ and activation energies, corresponding to the exciton binding energy, of ~0.2 eV (3-5, 13). The radiative efficiency is expected to decline from its maximum value, I_o, with increasing temperature, as progressively more thermal energy becomes available to ionize Te-bound holes. We find the rates of decline in emission to be comparable for 514.5 and 501.7 nm excitation. Because emission from the latter is generally weaker (1b, d), the data in Fig. 4(a) were obtained with 501.7 nm excitation of ~6 times the 514.5 nm intensity in order to match incipient luminescence intensity at room temperature. Note that both curves fall by a factor of ~10-20 over the 75°C interval. This factor is comparable to literature data obtained in the absence of electrolyte and with excitation sources consisting of ultrabandgap light (3b, 5), electron beams (4), and α particles (13).

We also wished to determine whether the decline in emission intensity with temperature was potential dependent. Figures 4(b) and (c) present emission-temperature curves for equivalent numbers of 514.5 and 501.7 nm photons, respectively, at three potentials: open-circuit, 0.0V, and 0.7V *vs.* Ag (PRE). The irradiated CdS:Te electrode emits more intensely with the longer excitation wavelength so that "100" on Fig. 4(b) represents ~5 times the intensity of "100" on Fig. 4(c). To a first approximation the rate of decline in both figures is independent of potential. This is seen more clearly with 514.5 nm excitation where there is very little dependence of emission intensity on potential until high temperatures are reached (*vide infra*). However, even with the more potential dependent emission intensity from 501.7 nm excitation, the rates of decline are similar as evidenced by the parallel shapes of the three curves. As a unit, Fig. 4 indicates that the decline of CdS:Te emission intensity with temperature is relatively insensitive to both penetration depth (501.7 and 514.5 nm) and potential (+0.7V *vs.* Ag to the onset of cathodic current).

iLV curves.—Simultaneous measurement of current, luminescence, and voltage (*iLV* curves) as a function of temperature is facilitated by the cell of Fig. 2. The emission intensity is conveniently monitored by sitting at a single wavelength, generally λ_{max}. Our previous observations regarding *iLV* curves for CdS:Te-based PEC's at 298°K in aqueous (poly)chalcogenide electrolytes may be summarized as follows: for ultrabandgap wavelengths (*e.g.*, 501.7 nm), we observe high quantum efficiencies for electron flow, Φ_x, and potential dependent emissive quantum efficiencies, Φ_r; in general Φ_r and Φ_x vary inversely as a function of potential. For bandgap edge (*e.g.*, 514.5 nm) excitation we observe lower values of Φ_x and higher values of Φ_r; however, Φ_r is largely independent of potential (1).

The ratio of open-circuit to in-circuit emission intensity, Φ_{r_o}/Φ_r, is a useful expression of the potential dependence with the in-circuit value taken at a potential where saturation of photocurrent is evident. For bandgap edge excitation Φ_{r_o}/Φ_r is roughly unity, whereas with ultrabandgap light we have observed ratios from ~1.2 to as high as 15. To some extent Φ_{r_o}/Φ_r correlates with Φ_x which is invariably low (<0.1) for bandgap edge excitation. Ultrabandgap light often gives $0.5 < \Phi_x < 1.0$. By pulsing the electrode between potentials corresponding to open circuit and maximum photocurrent, the discrepancy of Φ_{r_o}/Φ_r from unity is visibly apparent. The same effect may be observed at different potential sweep rates including point-by-point. We have so frequently observed this phenomenon that we have come to regard it as jointly diagnostic of ultrabandgap excitation and a high value of Φ_x.

The prediction afforded by Fig. 1 is that increasing the temperature will increase Φ_x for 514.5 nm excitation. Should this occur we would also predict that Φ_{r_o}/Φ_r will exceed unity. In Fig. 5(a) we present plots of photocurrent *vs.* temperature for 501.7 and 514.5 nm excitation (equal photons/sec) of CdS:Te in aqueous polyselenide electrolyte. The photocurrent at the former wavelength increases by less than 20% over the thermal excursion, but rises by a factor of ~10 with 514.5 nm excitation. In most cases this increase is sufficient to either match the 501.7 nm photocurrent or produce a large fraction ($\gtrsim$ 50%) of it. Since 501.7 nm photocurrent is relatively insensitive to tempera-

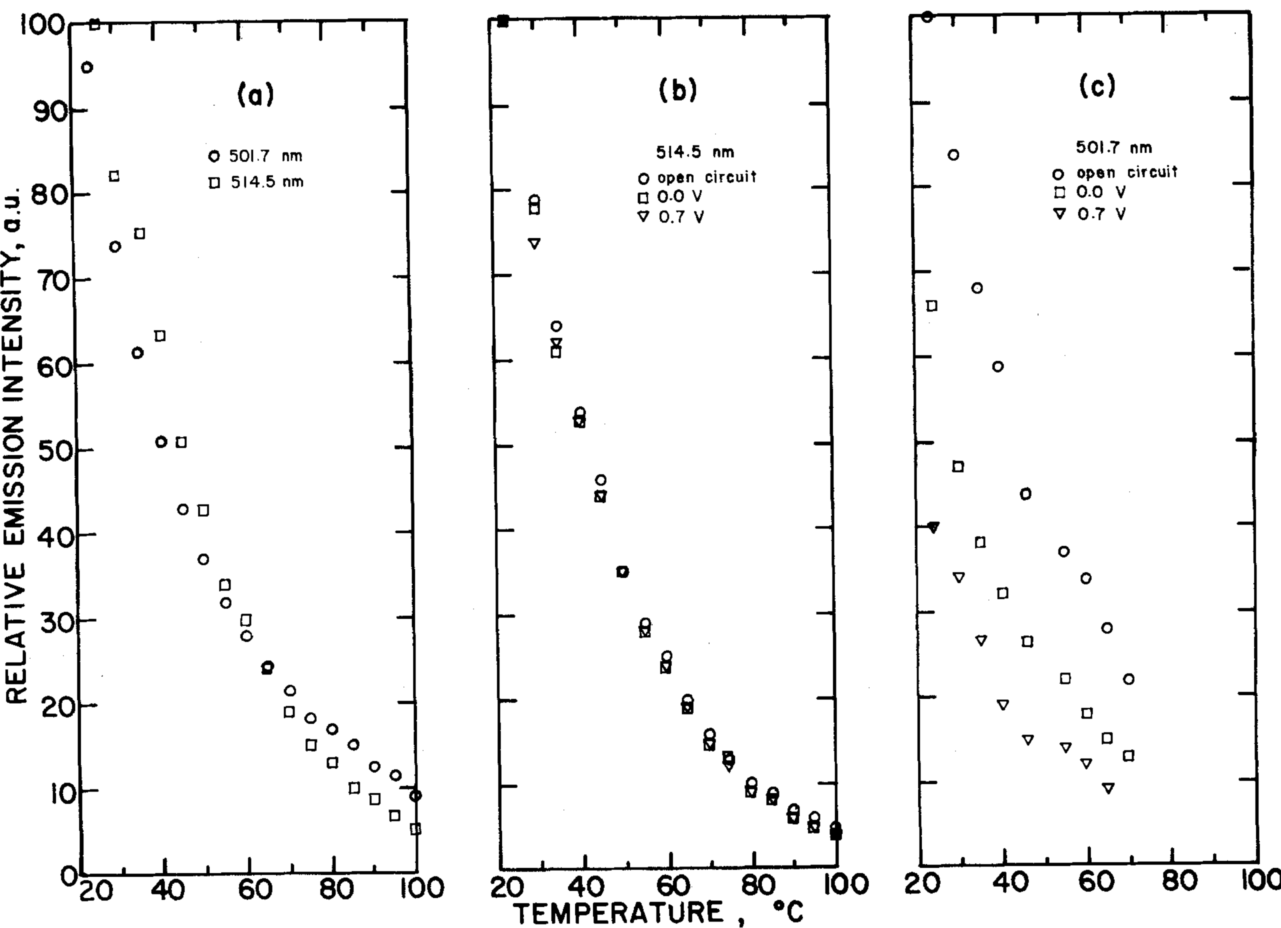

Fig. 4. (a) Relative emission intensity monitored at 600 nm vs. temperature in polyselenide electrolyte (5M OH^-/0.09M Se^{2-}/0.001M Se_2^{2-}) of CdS:Te excited at open circuit with 501.7 nm (circles) and 514.5 nm (squares) light. The excitation intensity at 501.7 nm is 6× that at 514.5 nm in order to approximately match emission intensity at room temperature; (b) relative emission intensity vs. temperature for 514.5 nm excitation of a CdS:Te electrode [different sample than in (a)] in polyselenide electrolyte (5M OH^-/0.02M Se^{2-}/0.001M Se_2^{2-}) at three potentials. Circles, squares, and triangles correspond to open circuit, 0.0V, and 0.7V vs. Ag(PRE), respectively; (c) relative emission intensity vs. temperature for the same electrode and geometric configuration as in (b), but now excited with an equivalent number of 501.7 nm photons as in (b). The point "100" on the emission scale is ~one-fifth the corresponding point in (b). The symbols in (c) have the same significance in terms of potential as in (b). Typical photocurrent behavior at 0.7V accompanying the emission changes shown in (b) and (c) is given in Fig. 5(a).

ture in this range and is not substantially exceeded with shorter wavelength excitation (*e.g.*, 457.9 nm), we regard it as a saturation photocurrent.

Perhaps not surprisingly, undoped CdS yields a similar photocurrent-temperature plot, Fig. 5(b). Because both undoped CdS and 100 ppm CdS:Te have about the same absorptivity for 514.5 nm light (6), it is difficult to determine what role, if any, the low energy absorption tail of CdS:Te plays in the photocurrent-temperature profile. Longer excitation wavelengths should be helpful in resolving this question. We can say that the rate at which 514.5 nm photocurrent approaches 501.7 nm photocurrent in Fig. 5 is in qualitative agreement with the bandgap temperature dependence (*vide supra*). This calculation is made by noting that the two wavelengths differ by ~0.061 eV. predicting a temperature range of ~120°C for matching penetration depths from the model and assumptions described above.

Full *iLV* curves for a CdS:Te-based PEC employing polyselenide electrolyte are presented in Fig. 6. Equivalent intensities (photons/sec) of 501.7 and 514.5 nm excitation were used at both room temperature and elevated temperature (49°C for 501.7 nm; 86°C for 514.5 nm). These plots succinctly summarize many of the properties described previously: photocurrent at 23°C is ~18 times greater for 501.7 nm excitation (curve A *vs.* curve B) and emission intensity at open circuit is ~5 times smaller (curve A′ *vs.* curve B′). The value of Φ_{r_0}/Φ_r is unity for 514.5 nm (curve B′) and 3.5 for 501.7 nm light (curve A′). At 49°C photocurrent with 501.7 nm excitation only increased by ~15% (curve C) but has dramatically increased at 86°C with 514.5 nm light by a factor of almost 8 (curve D). Emission intensity has dropped by more than a factor of 2 with 501.7 nm light while retaining a similar value of Φ_{r_0}/Φ_r of 3.4 (curve C′); for the first time and despite its lower absolute intensity, emission from 514.5 nm excitation has resulted in a nonunity value of $\Phi_{r_0}/\Phi_r = 1.27$ (curve D′, note tenfold scale expansion). We visually confirmed the discrepancy from unity by pulsing the electrode between the extreme voltages shown on curve D′. As mentioned above, this phenomenon is characteristic of larger values of Φ_x. All of the aforementioned changes were reversible simply by returning to the lower temperature. Similar photocurrent and emissive trends were also observed in OH^-/S^{2-} electrolyte.

Energy conversion efficiency.—Another feature of Fig. 6 worth noting is the enhancement of optical to electrical energy conversion efficiency at higher temperature with 514.5 nm excitation. The efficiency, η, is given by Eq. 3 for bandgap energy excitation

$$\eta = \frac{\Phi_x E_V}{E_{BG}} \qquad [3]$$

E_V is the output voltage; extraction of this value from *i-V* curves has been described (12).

In Table I we present a summary of the energy conversion parameters for both undoped CdS- and CdS:

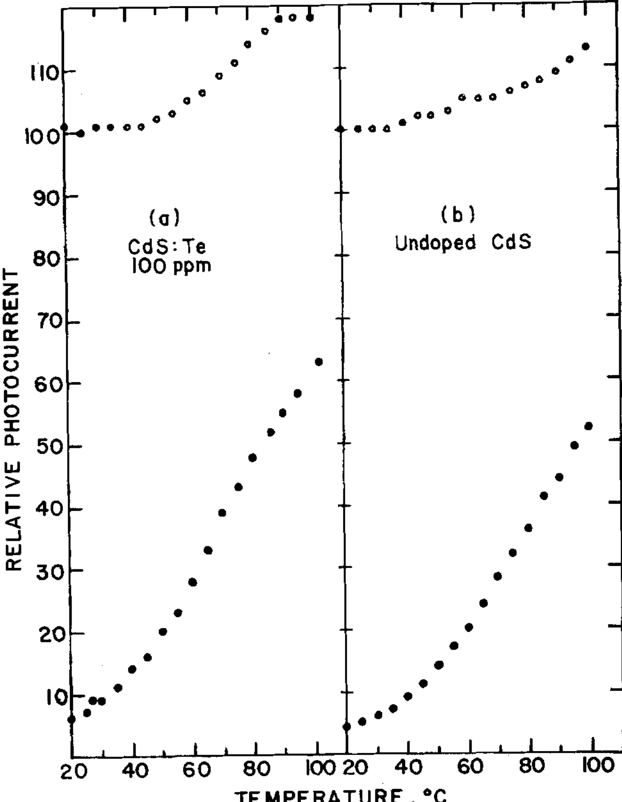

Fig. 5. (a) Relative photocurrent vs. temperature for a CdS:Te electrode in aqueous polyselenide electrolyte (5M OH^-/0.02M Se^{2-}/ 0.001M Se_2^{2-}) excited with equivalent photons of 514.5 nm (filled circles) or 501.7 nm (open circles) light at 0.7V vs. Ag(PRE). The scale is such that the photocurrent at 25°C from 501.7 nm excitation has been arbitrarily set at 100 and corresponds to a current density of ~0.36 mA/cm² and a quantum yield for electron flow, Φ_x, of ~0.50; (b) relative photocurrent vs. temperature for an undoped CdS electrode in the same electrolyte as in (a), excited with an equivalent photon flux of 514.5 nm (filled circles) and 501.7 nm (open circles) light. Again, "100" has been arbitrarily set as the 25°C photocurrent from 501.7 nm excitation and represents a current density of ~0.44 mA/cm² and a Φ_x of ~0.60.

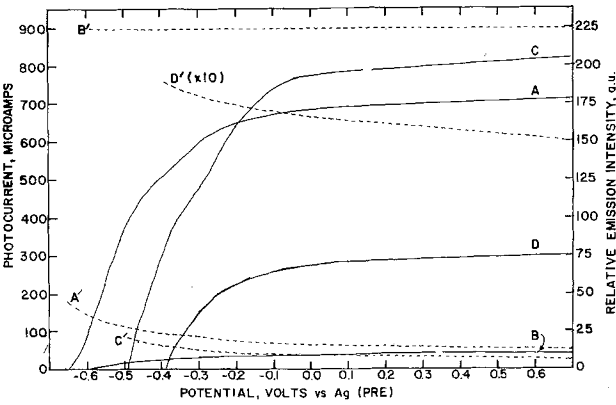

Fig. 6. Current-luminescence-voltage (*iLV*) curves for a CdS:Te electrode in polyselenide electrolyte. Unprimed, solid line curves are photocurrent (left-hand scale) and primed, dotted line curves are luminescence intensity (right-hand scale) monitored at λ_{max}, ~600 nm. Curves A and A′ were obtained from excitation at 501.7 nm, 23°C; curves B and B′ from 514.5 nm, 23°C; curves C and C′ from 501.7 nm, 49°C; curves D and D′ from 514.5 nm and 86°C. Note that the ordinate of curve D′ has been expanded by a factor of 10. Equivalent numbers of 501.7 and 514.5 nm photons were used in identical PEC geometric configurations. The exposed electrode area is ~0.41 cm² and the estimated value of Φ_x for 501.7 nm excitation at 23°C and 0.7V vs. Ag(PRE) is ~0.50, uncorrected for reflection losses and solution absorbance.

Table I. Optical to electrical energy conversion parameters[a]

Electrode	T, °C	$\lambda_{exc.}$	η_{max}, %[b]	E_V, V[c]	Φ_x at η_{max}[d]	$\Phi_{x_{max}}$[e]
CdS:Te	23°	501.7	5.6	0.32	0.44	0.75
		514.5	0.23	0.28	0.02	0.04
	73°	501.7	3.8	0.21	0.44	0.74
		514.5	1.0	0.18	0.14	0.26
CdS	24°	501.7	5.0	0.27	0.46	0.68
		514.5	0.21	0.27	0.02	0.03

		514.5	0.90	0.24	0.09	0.20

[a] The indicated crystal served as the photoanode in a PEC similar to that shown in Fig. 2, but with only two electrodes (Pt counterelectrode and photoanode). Electrolyte composition is 5M OH^-/0.3M Se^{2-}/0.001M Se_2^{2-}. Table entries represent typical values.
[b] (Maximum electrical power out divided by input optical power) × 100.
[c] Output voltage at η_{max}.
[d] Quantum efficiency for e^- flow at η_{max} (±15%), uncorrected for reflection losses and electrolyte absorption.
[e] Maximum quantum efficiency (±15%) for e^- flow, measured at ~0.7V vs. Ag(PRE), uncorrected for reflection losses and electrolyte absorption.

Te-based PEC's employing polyselenide electrolyte and a two electrode configuration (photoanode and Pt counterelectrode). The great improvement in η with temperature for 514.5 nm excitation is readily traced to an increase in Φ_x. At higher temperatures η from 514.5 nm excitation begins to rival that obtainable with 501.7 nm light for both electrodes. We do see a decline in output voltage at the higher temperatures; in general the *i-V* curves shift ~50-200 mV anodic between 20° and 100°C. This may indicate, as noted earlier, some difference in the relative energetic positions of the semiconductor Fermi level and E_{redox} with temperature.

While the enhanced red response is certainly desirable from the standpoint of solar energy conversion, we also wished to determine the extent to which it could be sustained. We found that photocurrent from 514.5 nm excitation of CdS:Te at 78° ± 5°C declined at a respectably slow rate of 3%/hr over 9 hr at a current density of 0.56 mA/cm² at 0.08V vs. Ag(PRE). The emission spectrum was unaffected but for its 25% decline in intensity over this period. Neither the optical density of the electrolyte nor its redox potential changed noticeably during the experiment.

Implications regarding excited state decay routes.— The striking inverse dependence of photocurrent and emission intensity on temperature depicted in Fig. 4-6 highlights their roles as competitive deactivation processes for the CdS:Te electrode excited state. While photocurrent is a unique probe of $e^- - h^+$ pair separation, emission is the minor product of $e^- - h^+$ pair recombination. Nonradiative recombination, (quantum yield Φ_{nr}) leading to heat is the dominant recombination process; room temperature emissive efficiencies for 100 ppm CdS:Te are at best only ~1% (1, 3-6).

Our intent has been to probe the manner in which input optical energy is partitioned among the three deactivation paths as a function of PEC parameters. In steady-state experiments such as these, the redistribution of energy is determined using measures of quantum efficiency, Φ_i. Our analysis is necessarily limited because we have only been able to obtain absolute numbers for Φ_x and relative values for Φ_r. We lack measures of Φ_{nr} entirely except insofar as they can be determined by difference, although photothermal spectroscopy has recently been used to provide quantitative information on nonradiative recombination (14). Despite these limitations, several important features do emerge from the thermal perturbation studies.

First, the ratio of Φ_x to Φ_r can be tuned over many orders of magnitude by a combination of excitation wavelength, electrode potential, and temperature. Previous work established the relative insensitivity to potential of Φ_r during excursions where Φ_x was varied

from zero (open circuit) to ~0.1 with 514.5 nm excitation (1). Figures 4-6 demonstrate for 501.7 nm excitation that changes in temperature leave Φ_x relatively constant while Φ_r varies by a factor of up to 20.

Recasting these observations, a given value of Φ_x does not affix unique values to Φ_r and Φ_{nr}. Besides the example just cited, consider Fig. 6 in more detail. At room temperature equivalent Φ_x can be achieved with 514.5 nm excitation at +0.7V or with 501.7 nm excitation at ~ −0.62V *vs.* Ag(PRE). Yet the emission intensity, Φ_r, corresponding to these two conditions is quite different. In a similar vein, a value of Φ_x attained at −0.52V *vs.* Ag(PRE) with 501.7 nm excitation at room temperature can be matched at 0.7V with 514.5 nm excitation at 86°C, each condition accompanied by a different Φ_r. These differences can be ascribed to variations in optical penetration depth, band bending, and efficiencies of excited state deactivation processes.

Second, there is now additional evidence linking Φ_x with Φ_{r_0}/Φ_r: (*i*) ratios exceeding unity for 514.5 nm excitation appear only at elevated temperatures where Φ_x has increased dramatically [Fig. 4(b) and 6]; (*ii*) neither Φ_x nor Φ_{r_0}/Φ_r changed appreciably for 501.7 nm excitation as a function of temperature even though Φ_{r_0} and Φ_r both changed drastically [Fig. 4(c) and 6]. A simplistic model correlating Φ_x with Φ_{r_0}/Φ_r can be constructed with the assumption that the ratio of Φ_r to Φ_{nr} is independent of potential (band bending). The ratio Φ_r/Φ_{nr} is, of course, dependent on temperature and optical penetration depth. For the purposes of the model, any recombining $e^- - h^+$ pairs are subject to the Φ_r/Φ_{nr} ratio appropriate for the experimental conditions. Photocurrent serves to divert $e^- - h^+$ pairs from recombining by separating them; at open circuit it plays no role in the excited state description. In passing from a given potential to open circuit, changes in photocurrent are changes in Φ_x and determine how many more $e^- - h^+$ pairs are returned to recombination. The significant quantity is the magnitude of this change relative to how many pairs were recombining before the change, $\Phi_x/(1 - \Phi_x)$. This represents the fractional increase expected in Φ_r, Eq. [4]

$$\frac{\Phi_{r_0}}{\Phi_r} - 1 = \frac{\Phi_x}{1 - \Phi_x} \quad [4]$$

Table II lists typical values of Φ_{r_0}/Φ_r and Φ_x derived from [4]. The same logic predicts that Φ_x and Φ_r at any two potentials will be related by [5] for a constant, monochromatic excitation wavelength and temperature

$$\frac{1 - \Phi_{x2}}{1 - \Phi_{x1}} = \frac{\Phi_{r2}}{\Phi_{r1}} \quad [5]$$

While Eq. [4] and [5] have been approximately satisfied by several combinations of luminescent electrodes, electrolytes, excitation wavelengths, and temperatures (1, 15, 16), they are still oversimplifications. Under certain conditions a nearly mirror image relationship between photocurrent and emission intensity in an *iLV* curve has been observed with ZnO photoelectrodes and a derivation presented to account for it (16). A rigorous model, however, will need to incorporate the following features: (*i*) nonexponential emission lifetimes (1, 3-6); (*ii*) nonlinear intensity effects on Φ_x and Φ_r (1, 6); (*iii*) local traps, surface imperfections, surface states, grain boundaries, impurity states, etc., all of which can alter Φ_i; (*iv*) electroabsorption (dependence of absorptivity on potential) which mixes optical penetration and band bending effects (17); (*v*) conditions leading to humps or plateaus in the luminescence portion of *iLV* curves: in these regions Φ_r and Φ_x are decidedly not inversely related (1d). Studies designed to construct a more realistic model are currently in progress.

Table II. Relationship between Φ_x and Φ_{r_0}/Φ_r[a]

Φ_x	Φ_{r_0}/Φ_r
0.001	1.00
0.01	1.01
0.05	1.05
0.10	1.11
0.20	1.25
0.30	1.43
0.40	1.67
0.50	2.00
0.60	2.50
0.70	3.33
0.80	5.00
0.90	10.00
1.00	∞

[a] Calculated from Eq. [4]. Φ_x is the quantum yield for e^- flow in the external circuit (photocurrent), and Φ_{r_0}/Φ_r is the ratio of the emission quantum yield between open circuit ($\Phi_x = 0$) and the potential where Φ_x was measured.

Experimental

All experiments were performed with ~5 × 5 × 1 mm plates of single crystal, 100 ppm CdS:Te or undoped CdS obtained from Cleveland Crystals, Cleveland, Ohio. The ~5 × 5 mm face is oriented perpendicular to the c-axis and sample resistivities are ~2 Ω-cm. Crystals were etched with Br_2/MeOH (1:10 v/v) before use. Electrode and polyselenide electrolyte preparation has been described previously (1d).

The basic PEC configuration, illustrated in Fig. 2, was assembled inside an Aminco-Bowman SPF-2 Spectrophotofluorometer when emission data were desired; the photoelectrode was inclined at ~45° to both the incident Coherent Radiation CR-12 Ar ion laser beam (501.7 or 514.5 nm) and the emission detection optics. The ~3 mm diam beam was 10× expanded and masked to fill the electrode surface. A 0.03M $Na_2Cr_2O_7$ solution was placed in front of the detection optics to filter the exciting light. In experiments where only current-voltage data were obtained, the PEC was simply set on a stir plate and the electrode irradiated "head-on." The electrochemical instrumentation has been described previously (1d).

Temperatures in the PEC were maintained by resistive heating employing a Nichrome wire and a Sepco variable transformer. A thermometer accurate to ±1°C was calibrated by measuring melting points of several solids; adjustment of its immersion depth into the electrolyte indicated that significant thermal gradients were absent.

Changes in electrolyte absorption over the thermal excursion were probed by single beam experiments using the 501.7 and 514.5 nm laser lines and found to be small (<5% change in %T in a 1 mm pathlength). Light intensity in this and other experiments was measured with a Tektronix J16 radiometer equipped with a J6502 probe head.

The suitability of the 25 × 0.5 mm diam Ag wire as a PRE was checked by measuring its potential *vs.* that of a 2.0 × 0.8 cm Pt foil electrode with a high impedance Data Precision 1450 multimeter. Between 20° and 100°C potential only varied from 100 to 123 mV and was stable for minutes at a time at temperatures in this range. Moreover, *i-V* curves run at several temperatures with an Ag(PRE) or an SCE were practically superimposable. Energy conversion efficiencies at all temperatures were derived using a two electrode PEC (semiconductor and Pt counterelectrode; reference and counterelectrode leads from the potentiostat were shorted) whose *i-V* curves also matched those obtained with an Ag(PRE) or SCE three-electrode PEC. The Pt electrode exhibited good reversibility for the polyselenide redox couple over the entire temperature range.

Curves of photocurrent and emission intensity (monitored at ~600 nm) *vs.* temperature were obtained by heating from 20°-100°C over a span of 80 min with readings taken ~ every 5°. Reproducibility of the data upon cooling was generally better than ±10%. The

procedure and equipment involved in the sustained PEC experiment have been described (1d).

ABSTRACT

The reaction between Mo thin films and single crystal Si (100) substrates has been studied as a function of various heat-treatments. In the temperature range between 520° and 550°C, $MoSi_2$ has been observed to grow linearly with time and with an activation energy of about 4.1 eV. X-ray diffraction indicates that the hexagonal phase of $MoSi_2$ changes continuously to the tetragonal phase as the temperature increases from 600° to 800°C. In contrast, the presence of native oxide prohibits formation of any silicide phases in the above temperature range and leads to the formation of a Mo_3Si phase at temperatures near 1000°C. The formation of $MoSi_2$ results in large compressive strains in the $MoSi_2$ layer and in strains of the opposite sign in the underlying Si. In limited reaction areas the corresponding stresses were found to be sufficient to cause the nucleation and propagation of dislocations in the Si substrates. The dislocations are propagated for considerable distances away from the reaction areas. An anomalous growth of silicide occurs at the edges of the reaction areas. These phenomena are shown to result from cumulative stress effects. Stresses enhance the formation of $MoSi_2$ layers, and thereby modify the kinetic laws of growth.

Mo has been considered as a suitable material for gates and interconnections in MOS-LSI technology because of its ability to withstand high temperature processing (1-6). The physical properties of Mo films, such as electrical resistivity, stress, and MOS characteristics have been extensively studied (7-9). Because it controls the electrical and metallurgical characteristics of the contacts, the reaction between Si and Mo films is quite significant. The reaction is known to occur at temperatures considerably below the eutectic temperature; this may impose restrictions of time and temperature on fabrication processes subsequent to metallization. Several papers on the formation of the disilicide of Mo have been published. Oertel et al. (10), using x-ray diffraction, have observed the growth of the tetragonal form of $MoSi_2$ with a square root of time dependence. Bower *et al.* (11) used the backscattering of He ions to determine the thickness of the silicide layers; they found that at relatively high temperatures (1200°C) $MoSi_2$ grows linearly with time. Aleksandrov *et al.* (12) reported that $MoSi_2$ grows according to a square root of time law in the temperature range of 525° ~ 600°C. They determined the thickness of the silicide layers from the quantity of electricity consumed in anodic dissolution. Guivarc'h *et al.* (13) found that the hexagonal phase of $MoSi_2$ grows linearly as a function of the square of the time with an activation energy of 2.4 eV. They used 800Å thick Mo films and investigated the temperature range from 475° to 550°C. The measurement methods and the experimental conditions were different in each case, which might explain the diversity of these results. However, infor-

Key words: molybdenum, molybdenum silicide, stress, strain, dislocation.

mation sufficient to explain the different growth kinetics is still missing. It is necessary to understand the factors affecting the laws of silicide formation, so that through the control of these factors stable contacts might be obtained. It is well known that the reaction being studied is quite sensitive to cleaning of the Si surface. Guivarc'h *et al.* (13) observed that the growth kinetics varied as a function of Mo film thickness. They suggested that stresses might play a dominant role but offered no supporting experimental evidence. Stresses could be important not only with respect to the growth kinetics but also to the metallurgical stability of the contacts. In this paper we present the results of our investigation of the reaction between Mo and single crystal (100) Si in the temperature range between 520° and 800°C, with emphasis on understanding the effect of stresses on the kinetics of silicide formation.

Experimental Procedures

The substrates were 3 in. diam wafers of p-type Si of (100) orientation, doped with boron to 1 Ω-cm resistivity. The Si wafer was etched in dilute HF solution, rinsed in H_2O, and then dried in an N_2 atmosphere just before mounting in a vacuum system. A magnetron d-c sputtering system (Varian S-Gun) was used to deposit Mo films onto Si substrates. The Mo target was a 5 in. diam water-cooled circular conical cathode (99.99% pure). The system was pumped down to 2×10^{-6} Torr, and then backfilled to a sputtering pressure of 3×10^{-3} Torr by introducing argon gas. The substrates were preheated to about 200°C by radiation emitted from quartz lamp heaters. In all runs, the Mo films were deposited at a rate of 180 Å/min to a thickness of 3000Å. In some cases, to confirm the effect of native oxide on silicide formation, the Mo films were deposited on n^+ (100) Si substrates by using the rf sputtering system. Then, the samples were annealed in a flowing nitrogen tube furnace at various temperatures and times. The thicknesses of Mo and silicides were measured by using Talystep after step-etching. Dilute nitric acid was used to etch the Mo films, and $HNO_3:NH_4F:H_2O$ = 10:1:30 etchant was used for silicides. With the second etchant, the Si substrate and the silicide layer near the silicon-silicide interface were etched simultaneously. However, the etching end point was determined easily by utilizing the fact that silicon repels water and silicide does not.

The measurement error was estimated to be on the order of 200Å. This value is probably larger than that obtainable with other methods such as He^+ ion backscattering and x-ray analysis. However, the accuracy of thickness measurements actually depends on the surface roughness of the silicide layer, which becomes more pronounced as the reaction progresses. This decreases the effective depth resolution of these methods by which average thicknesses can usually be detected within a range of several square millimeters or square centimeters on Si substrates. Thus, when measuring silicide thicknesses above several thousand angstroms, the etching method used here may be more reliable than the other methods because the space resolution is only limited by the probe diameter of 10 μm.

In order to evaluate the stress in the silicide layer, the deflection profile of Si substrate over which the silicide was grown was measured by using a laser-scanning flatness tester (Canon LSF-500) where the operating principle was reported earlier (14). The bowing of the Si substrate was then obtained from the deflection profile. The difference h in a bowing between a bare silicon wafer and one from which the residual Mo has been removed after annealing is directly proportional to the product of silicide stress σ and thickness d by

$$\sigma d = \frac{4Es}{3(1 - \nu_s)} \cdot \frac{d_s^2 h}{D^2}$$

where Es is Young's modulus for the Si substrate, ν_s is its Poisson's ratio, and d_s and D are the thickness and diameter of the Si substrate, respectively. The sense of h is a direct indication of the kind of stress in the silicide. An upward-curved h indicates compressive stress, and a downward curve indicates tensile stress. In order to determine the stress accurately, substrates with deflection profiles that were symmetrical with respect to the center were chosen. The measurements were made at room temperature.

The silicide phases were investigated by x-ray diffraction analysis where CuKα radiation was used. A scanning electron microscope was used to observe the silicide textures.

Results

Homogeneous reaction.—Figure 1 shows the silicide thickness as a function of annealing time at a temperature of 540°C. The difference in the Mo film thickness before and after the heat-treatment, which denotes the Mo transformed to the silicide, are also plotted. The thickness of the silicide was found to be about 2.7 times that of consumed Mo. As shown in the figure, the silicide formation follows a linear-growth time dependence. This indicates that the reaction being studied is not diffusion-limited. Figure 2 shows the thicknesses of the silicide and the Mo transformed to the silicide as a function of annealing temperature. The samples were annealed for 30 min. The measured points fall on straight lines with the same slope, indicating an activation energy of about 4.1 eV. This value is significantly larger than those previously reported.

The phases of the formed silicides were identified by x-ray analysis. To confirm the phase transformation, the samples were annealed in a higher temperature range as follows. After being annealed for 30 min at 550°C, the residual Mo films were removed by chemical etching. The silicide thickness was estimated to be about 5000Å. Then, the samples were annealed further for 30 min at various temperatures over 600°C. The above two-step annealing was necessary to avoid film failure arising from excessive silicide formation. Figure

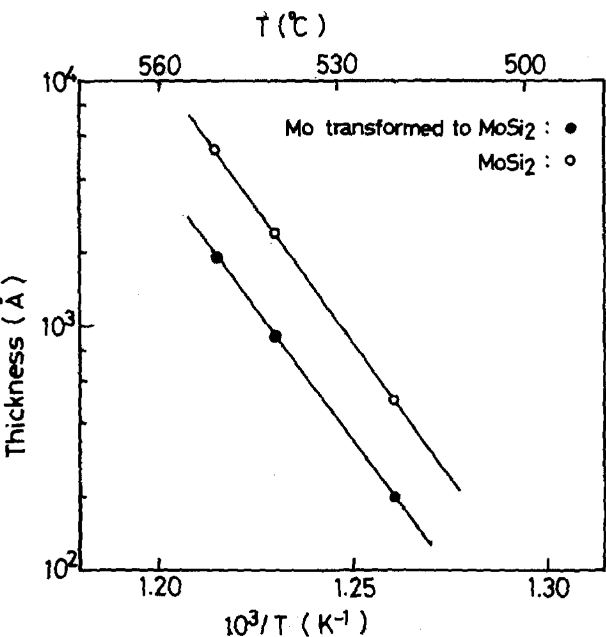

Fig. 2. The thicknesses of $MoSi_2$ (○) and Mo transformed to $MoSi_2$ (●) as a function of reciprocal annealing temperature. Annealing time was held at 30 min.

3 shows x-ray diffractometer traces for samples annealed at three different temperatures. These results clearly indicate that the hexagonal phase of $MoSi_2$ changes continuously to the tetragonal phase as the temperature increases from 600° to 800°C. At an intermediate temperature of 750°C, these phases coexist. The x-ray diffractometer traces showed no direct evidence of the presence of other silicide phases even before the removal of Mo film. It is possible that other phases did exist, but in quantity too small to be detected by x-ray analysis (13).

Silicide formation on the heavily doped Si substrates was found to be quite different from that presented above. When n^+ (100) Si substrates doped with phosphorous to 1×10^{20} cm^{-3} were used, silicides did not form at temperatures below about 800°C; no amount of silicide was detected by the x-ray analysis. However, annealing at higher temperatures was found to lead to formation of Mo_3Si. Figure 4 shows a typical x-ray diffractometer trace for an n^+ sample annealed at 1000°C for 30 min. The occurrence of Mo_3Si and the presence of residual Mo were shown in the figure, although the amount of Mo_3Si was found to differ even between samples annealed under the same conditions. In some samples, Mo_3Si and $MoSi_2$ were found to have formed simultaneously. The native oxide existing between the Mo and the Si substrate may play an important role in these results. The chemical cleaning used here is usually ineffective in removing the native oxide because the Si surface is exposed to air just before Mo deposition (15). In addition, the heavily doped Si generally shows a greater growth rate of native oxide than that which is lightly doped (16). This may result in a pronounced effect of native oxide on the formation of silicide on the heavily doped Si. The effects of surface cleaning on silicide formation were examined by using n^+ silicon prepared by sputter etching on which the native oxide was considered to be completely removed. The results were found to be similar to those shown in Fig. 1 and Fig. 2, only the $MoSi_2$ phase was observed. This suggests that the effect of native oxide is negligible for the lightly doped Si, even after chemical cleaning.

Figure 5 shows the product of silicide stress σ and thickness d as a function of silicide thickness d. Silicides of various thicknesses were obtained from the samples annealed for 30 min in the range of 525° ~

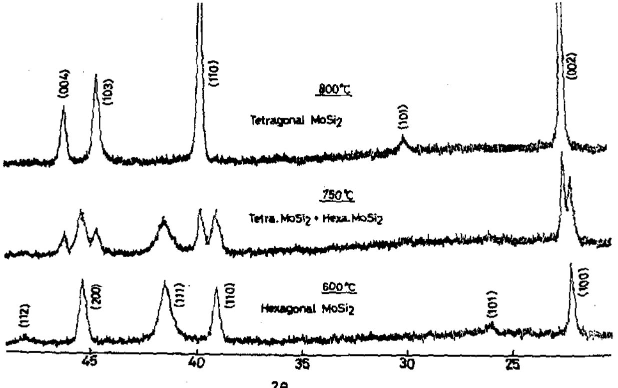

Fig. 3. X-ray diffractometer traces of silicide layers. After the silicides were formed to a thickness of about 5000Å, further heat-treatments were performed at 600°, 750°, and 800°C for 30 min.

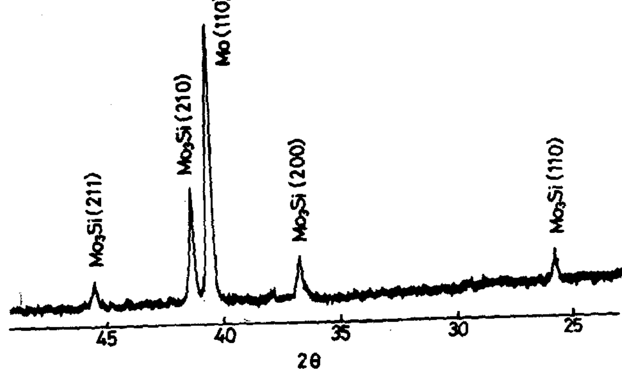

Fig. 4. X-ray diffractometer trace of silicide formed on n^+ Si substrate. The sample was annealed for 30 min at 1000°C.

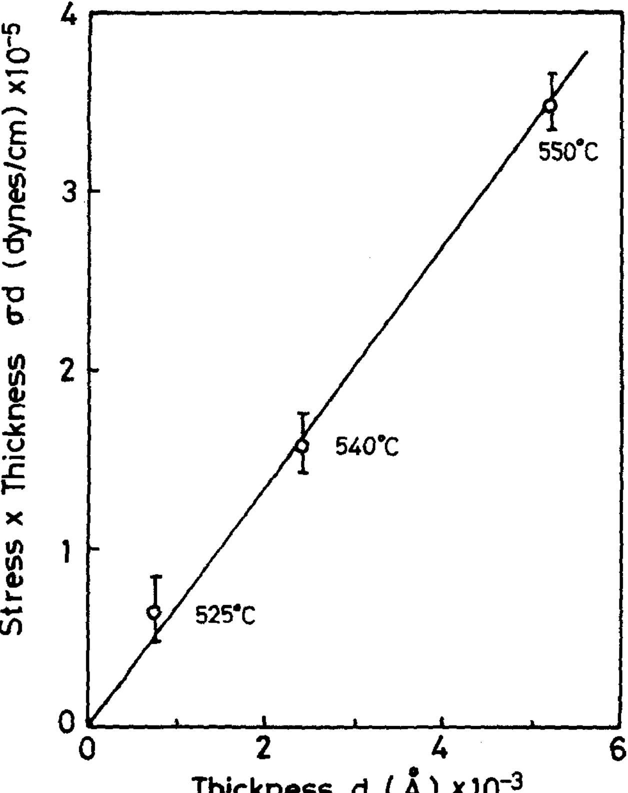

Fig. 5. The product of silicide stress σ and thickness d as a function of silicide thickness d. The annealing temperatures which correspond to the different thicknesses are indicated on the figure.

550°C. The temperatures which correspond to the different thicknesses are shown in the figure. σd is linearly dependent on d through the zero point, indicating that the stress has almost no temperature dependence in the range of 525° ~ 550°C. The stress was found to be compressive and was evaluated to be about 7×10^9 dyn/cm^2. The measured stress σ consists of two components, an intrinsic component σ_i at reaction temperature, and a thermal component σ_{th} caused by the difference between the thermal expansion coefficients of $MoSi_2$ and Si on cooling from the reaction temperature (T_R) to room temperature (T_o): $\sigma = \sigma_{th} + \sigma_i$. σ_{th} is approximately estimated by

$$\sigma_{th} = \frac{E'}{1 - \nu'} (\alpha' - \alpha) \cdot (T_R - T_o)$$

where E' is the Young's modulus for the $MoSi_2$, ν' is its Poisson's ratio, and α' and α are the thermal expansion coefficients of $MoSi_2$ and Si, respectively. Here, E' and ν' are 3.8×10^{12} dyn/cm^2 and 0.165, α' and α are 8.1×10^{-6}/°C and 2.5×10^{-6}/°C at room temperature, respectively (17). Using these values, the thermal stress σ_{th} was found to be tensile and was calculated to be about 6×10^9 dyn/cm^2 in the above temperature range. This leads to the compressive stress of about 1.3×10^{10} dyn/cm^2 for the intrinsic stress σ_i in the range of 525° ~ 550°C. On the other hand, it can be concluded from lattice parameters on the hexagonal $MoSi_2$ (3 molecules in a unit cell volume of 120.699 Å^3) (18) that this formation involves about a 27% decrease in volume with respect to the components Mo and Si. This result suggests that the intrinsic stress would be tensile. However, it should be noted that Si is the dominant diffusing species (18); the reaction progresses by its insertion into the molybdenum lattice. Therefore, $MoSi_2$ formation is accompanied by a volume expansion of the deposited Mo film, resulting in the compressive stress in the $MoSi_2$ and, simultaneously, a void accumulation at the $MoSi_2$-Si interface.

As previously mentioned, the silicide surface becomes rougher as the reaction progresses. In the course of our experiments, the silicide layers were often observed to fail when they grew to more than about 6000Å. Figure 6 shows the surface texture of the sample annealed for 10 min at 600°C. This annealing condition may lead to a silicide thickness of about 6000Å, as estimated from extrapolations of the data shown in Fig. 1 and 2, that is, if the reaction continues uniformly over the entire substrate. As clearly observable in the figure, excessive silicide formation results both in blistering and cracking of the formed silicide. This is probably attributable to the two different stresses; the blistering may be due to the compressive stress during $MoSi_2$ formation, and the cracking may be due to the tensile stress on cooling from the reaction temperature to room temperature. Furthermore, the void accumulation which can occur at the $MoSi_2$-Si interface, might also lead to poor silicide adhesion and rough surface texture. In contrast, when the reaction area was limited to within a range of several tenth μm^2 on the Si substrate, no film failure was observed in any annealing condition. This is described more fully in the next section.

Localized reaction.—Mo film was deposited to a thickness of 3000Å on an Si substrate covered with SiO_2 film which was selectively etched to expose regions of bare silicon. Heat-treatment then permits $MoSi_2$ to form in a limited silicon region. Such $MoSi_2$ formation was found to generate dislocations outside the reaction region, suggesting that the strain field which the $MoSi_2$ formation exerts on the surrounding silicon lattice is relieved through the formation of dislocations. This probably prevents silicide failure in the contact region. The nucleation and propagation of dislocations and their relationship to $MoSi_2$ formation were investigated in some detail, as follows. The samples annealed were etched for 20 sec in Sirtl etch after the residual Mo and SiO_2 films were removed. This etching produces etch pits at the sites of dislocations. Figure 7 shows the dislocation patterns on those samples annealed for 10 min at 560° and 600°C, respectively. The dislocation patterns near the reaction regions of various areas are shown in Fig. 8 where the sample's annealing temperature and time were 600°C and 10 min, respectively. In both figures, the contact edges are along <110> direction. The dislocations extend more laterally outside of the reaction region into the silicon, by increasing the layer thickness and the reaction area. Figure 9 shows the distribution of dislocations on sample whose contact edges are inclined by 45° to <110> direction. The annealing temperature and time were 600°C and 10 min, respectively. A comparison of the dislocation patterns shown in Fig. 7-9 indicates that the disloca-

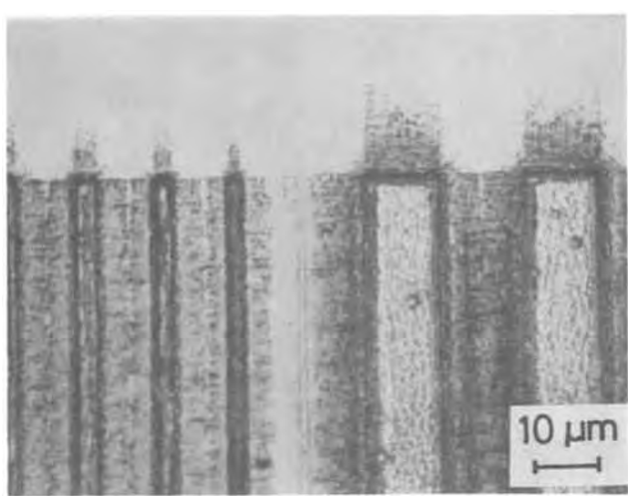

Fig. 8. Dislocation patterns around reaction regions of various areas on the wafer annealed for 10 min at 600°C. The contact edges are along <110> direction.

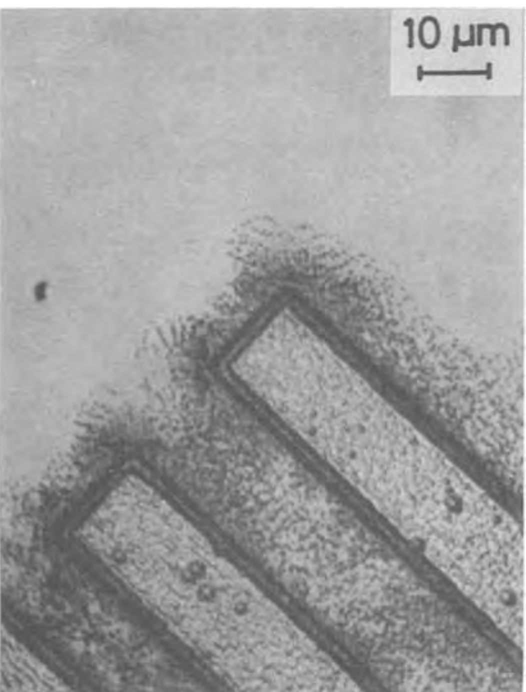

Fig. 9. Dislocation distributions around reaction regions on the wafer annealed for 10 min at 600°C. The contact edges are inclined by 45° to <110> direction.

tions propagate along <110> direction. In addition, as observed in Fig. 10, the dislocations were found to extend for considerable distances perpendicularly down into the silicon substrate. In this sample, the vertical cross section was etched through silicide layers of various widths for 5 sec in Sirtl etch. The dislocations glide on the inclined (111) plane. The dislocation density seems to be greatest at the contact edge, indicating cumulative strain. Corresponding to the above observations, an anomalous growth of the $MoSi_2$ layer was observed near the edge of the reaction region. Figure 11 shows SEM photographs of the vertical cross sections through the edges of $MoSi_2$ layers where the samples were annealed at 550°C for 10 min and 60 min, respectively. The reaction tends to become nonuniform near the edge, as the thickness of $MoSi_2$ layer increases. Figure 12(a) shows a similar observation for $MoSi_2$ layers of various widths. The sample was annealed for 10 min at 600°C. This observation suggests that strain exerted on Si substrates by $MoSi_2$ layers of the nar-

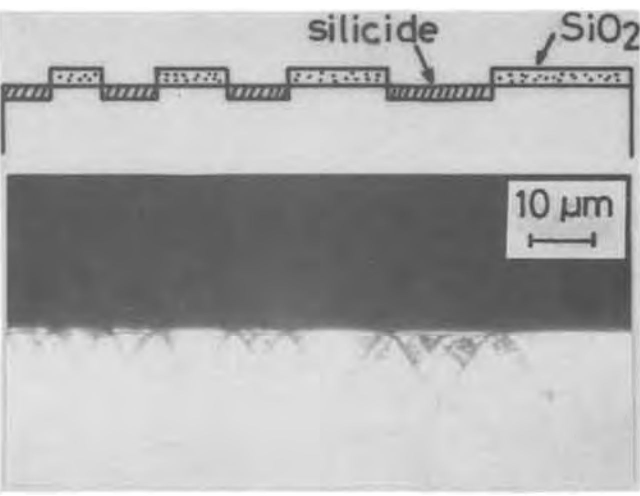

Fig. 10. Dislocation distributions around vertical cross section through the reaction regions on the wafer annealed for 10 min at 600°C.

rower widths is less uniform and results in less uniform growth. The sample for which the width of $MoSi_2$ layer is comparable to its thickness clearly confirms this. Figure 12(b) is an enlarged photograph of a $MoSi_2$ layer with a width of 2 μm. The fiber structured $MoSi_2$ layer is seen to be split at the center of reaction region. Figure 13(a) shows the vertical cross section of the $MoSi_2$ layer edge and Fig. 13(b) shows an inclined view. The surface of $MoSi_2$ layer lies below the level of the original silicon surface, indicating that the reaction is enhanced near the edge. It is interesting to note, as shown by Fig. 11 and 13, that the behavior of $MoSi_2$ near the edge is different even among samples for which the $MoSi_2$ layer is of the same thickness; the anomalous growth of the $MoSi_2$ layer is more enhanced for the sample annealed at the higher temperature. This suggests that the effect of stress on the growth of $MoSi_2$ becomes more pronounced at higher temperatures.

Discussion

Marker experiments show that Si is the dominant diffusing species in $MoSi_2$ formation (18, 19). Thus, one may expect that the diffusion of Si through the growing $MoSi_2$ layer is the rate-limiting factor and that the reaction therefore obeys the parabolic growth-time law. But, the results obtained here, such as those indicating linear-growth time dependence, abnormally high activation energy, and anomalous formation of $MoSi_2$ at the contact edge, would rule out such a simple diffusion model. Bower *et al.* (11) have observed two types of behavior in the formation of silicide contacts; one where the reaction is self-limited to the exposed contact area, and the other where the reaction continues beyond the contact region. Further, they pointed out that these two types of behavior correlate with reaction kinetics; the thickness of the silicide increases with parabolic-time dependence in the first case, and linearly with time in the second case. The $MoSi_2$ formation studied here corresponds to the second case. Although it is difficult at this time to establish a firm model to explain such phenomena, a discussion of the possible contributory mechanism follows.

Silicide formation is significantly delayed due to the native oxide, which acts as a barrier against the diffusion of Si. In addition, the native oxide clearly leads to the formation of Mo-rich silicide, *i.e.*, Mo_3Si. This indicates that the growth mechanism is different for the cases with and without the native oxide. The formation of Mo_3Si may be due to an insufficient supply of Si to the Mo-silicide interface. However, as previously mentioned, extremely thin oxide was found not to affect the growth kinetics of $MoSi_2$.

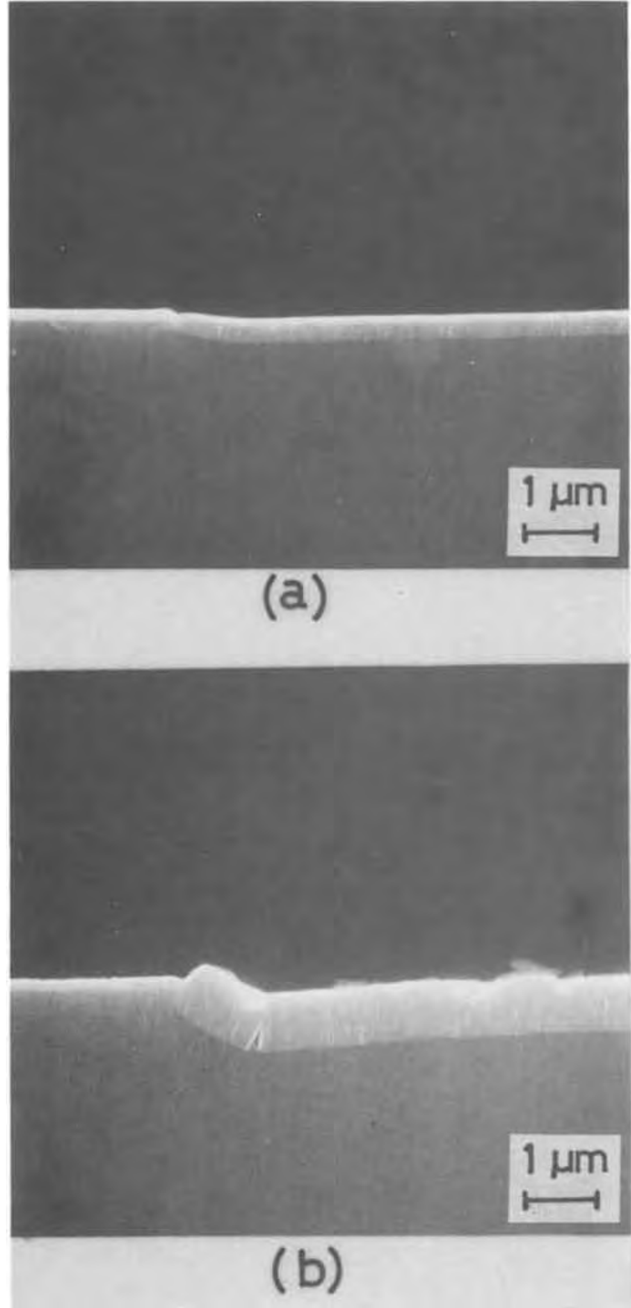

Fig. 11. SEM photographs of the vertical cross sections through the $MoSi_2$ layer edges on the wafer annealed at 550°C for 10 min for (a) and for 60 min for (b), respectively.

Stress seems to be a more important influence on the growth kinetics of $MoSi_2$. The generation of dislocations and the corresponding anomalous growth of $MoSi_2$ appear to correlate closely with the stress in the growing $MoSi_2$ layer. It may be reasonable to consider that such stress weakens the covalent bonds in the substrate and dissolves silicon atoms from their lattice more easily. This may increase the supply of Si to the Mo-$MoSi_2$ interface, enhancing $MoSi_2$ formation. This assumption may be confirmed by the anomalous growth of $MoSi_2$ which corresponds to the cumulative strain at the contact edge. In this case, it is apparent that the reaction is not confined to the exposed silicon region because the strain field extends outward from the reaction region. The variety of data for $MoSi_2$ formation can be qualitatively accounted for by the stress-enhanced reaction mechanism proposed here. The strain increases with the thickness of $MoSi_2$ layer and results in more pronounced growth-time dependence, that is, from a parabolic law to a linear one. The overall stress originates from the bilayer which consists of the formed

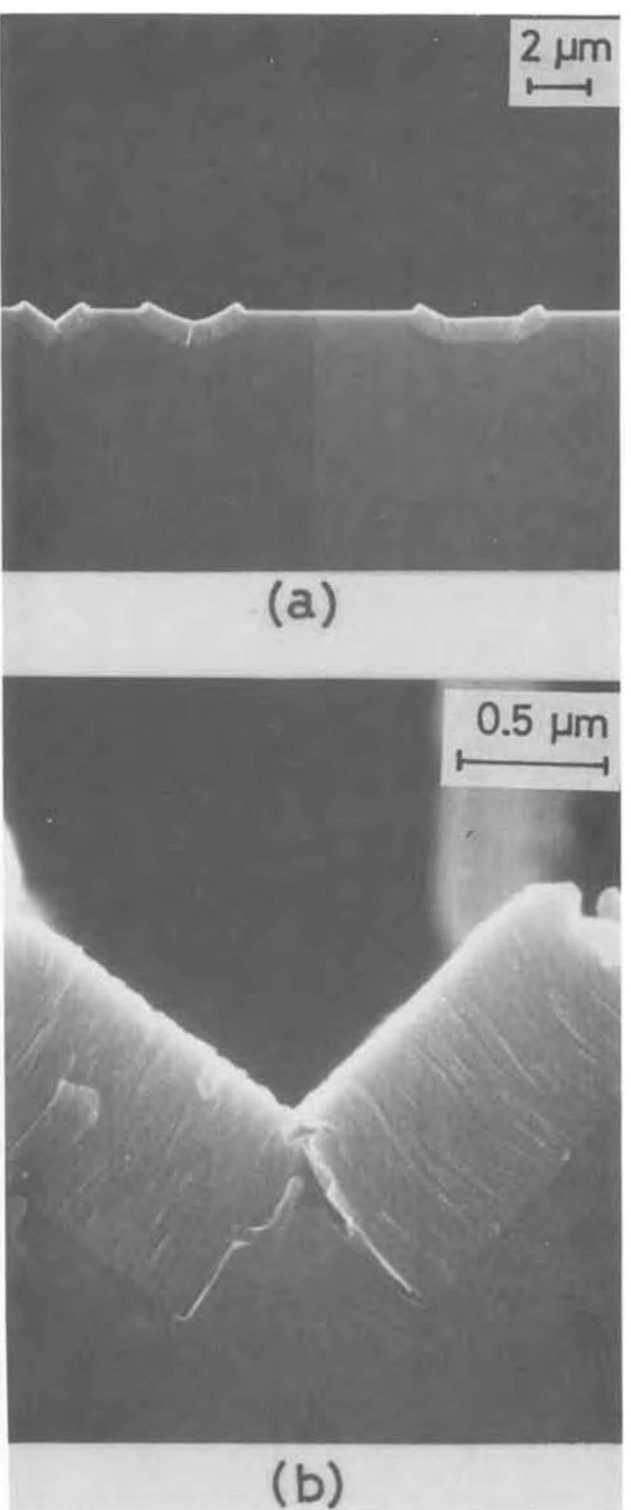

Fig. 12. (a) SEM photograph of the vertical cross sections through $MoSi_2$ layers of various widths. (b) An enlarged photograph of (a). The annealing temperature and time were 600°C and 10 min, respectively.

$MoSi_2$ and the residual Mo. Therefore, the stress in the Mo, which has been shown to be significantly dependent on the deposition condition (20), might also affect the growth kinetics. Considering that the stress in the Mo is on the same order of magnitude and of the opposite sign to that in the silicide under normal deposition condition (21), the overall stress is smaller for samples with the thicker Mo films and may thereby suppress the growth rate. This appears to agree with the results reported by Guivarc'h *et al.* (13) where they observed a linear-growth time dependence for 1500Å Mo film, and a square-growth time for 800Å Mo

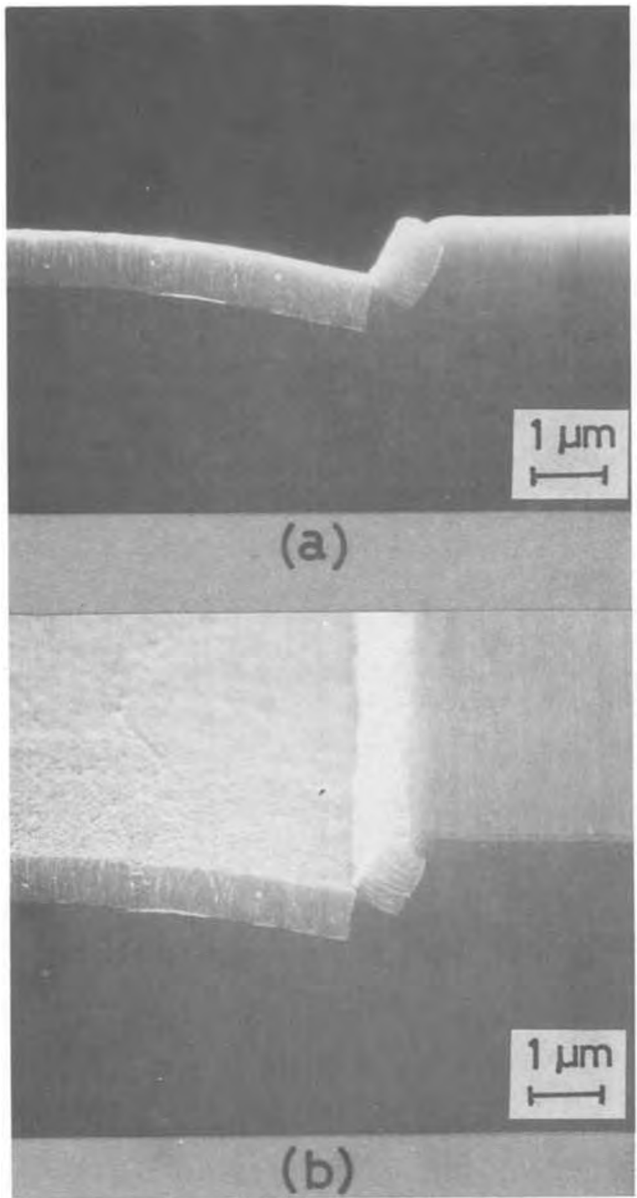

Fig. 13. (a) SEM photograph of the vertical cross section of the $MoSi_2$ layer edge on the wafer annealed for 30 min at 650°C. (b) An inclined view of (a).

film. Furthermore they showed that when 800Å Mo film was coated with an Si layer of about 4000Å thick before annealing, the silicide formation was delayed and followed a linear-growth time dependence. It is worth considering if a coating film might change the overall stress and thus modify the growth time dependence. As previously described, as the growth temperature of $MoSi_2$ becomes higher, the strain field may increase. This also may enhance the reaction, resulting in the high activation energy observed. Thus, it is possible that the growth kinetics of $MoSi_2$ are modified due mainly to the differences in the stress existing under various experimental conditions.

From a practical point of view, it is anticipated from the results presented here that the stress associated with the Mo-Si reaction will result in potentially detrimental effects on the mechanical and electrical characteristics of the devices. To avoid these disadvantages, it is necessary to suppress the dissolution of Si into the Mo film. This consideration may lead to the possibility of using the Mo-Si compound film (22). Further investigation is required to clarify these problems.

Conclusion

It was found that the stress generated in $MoSi_2$ layers enhanced $MoSi_2$ formation. The stress is affected by various factors such as the properties of the deposited Mo film and the annealing temperature range. This suggests that the stress-enhanced reaction mechanism may play an important role in accounting for the differences in data on growth kinetics presented by us and other investigators.

The presence of native oxide also modifies the growth kinetics, but in a different way, as suggested by the formation of Mo_3Si but not of $MoSi_2$.

ABSTRACT

An electrode potential study of the liquid Ga-Ge-Zn system has been conducted with the cell

$$Zn|Zn^{2+} \text{ in LiCl} + KCl|Zn\text{-}Ga\text{-}Ge$$

in the temperature range 623°-1123°K. Zinc partial mixing functions were determined for 22 alloys. These measurements allow us to give the surface corresponding to zinc partial free energy at 1233°K and a large part of the liquidus surface of this system.

In the course of the thermodynamic study carried out by our laboratory at the Université de Provence concerning ternary systems formed by adding to gallium-germanium alloys another metal of group II or III Al (1), In (2), Sn (2), we have measured, by potentiometry, the zinc activity in a number of gallium-germanium-zinc liquid alloys over a large temperature range. The thermodynamic functions and the phase diagram of this ternary system have not been previously studied.

The three limiting binary systems: Ga-Ge, Ga-Zn, and Ge-Zn, the phase diagrams of which are shown in Fig. 1, have the same characteristics: each eutectic composition is very near the most fusible element and terminal solid solutions are small.

Gallium-germanium system.—The eutectic point practically coincides with the melting point of pure gallium ($x_{Ge} = 5 \cdot 10^{-7}$) (3, 4). Greiner (5) suggested a retrograde solidus curve exhibiting a maximum solubility of gallium in germanium ($x_{Ga} = 0.026$) at 1053°K. Trumbore (6) confirmed the shape of this solidus limit and found a maximal solubility at 923°K ($x_{Ga} = 0.011$). Thermodynamic functions for Ga-Ge liquid alloys were determined by Predel (7) at 1273°, by Bergman (8) at 1270°, by Eslami (1) at 1241°, and by Batalin at 1240°K (9).

Gallium-zinc system.—The eutectic point coordinates (T_e, x_e) have been proposed by several authors (10-13) ($298.15 \leq T_e \leq 298.55$ and $0.037 \leq x_{Ga} \leq 0.050$). The maximal molar fraction of gallium in solid zinc would be 0.0195 (14) or 0.009 (13). The solid solubility of zinc in gallium corresponds to $x_{Zn} = 0.085$ (13). Mixing enthalpy was measured calorimetrically at 723°K by Kleppa (15) and Gambino (16); at 978°K Predel (17) obtained activities using a comparative vapor pressure method. The galvanic cell measurements of Genta, 723°-818°K (18); Kleppa 850°K (19), Svirbely 693°-793°K (20); Gerasimenko, 723°-823°K (21); Ryabov, 933°-1033°K (22); and Moser 714°-877°K (23) have yielded partial molar functions of zinc in Ga-Zn system. The last author, Moser, thinks emf measurements are unsatisfactory with such a binary alloy since the components are close together in the electropotential series; he recommends a vapor pressure method. These two kinds of measures will be compared in the Results section.

Germanium-zinc system.—The liquidus curve has been reported by Gebhart (24) and Thurmond (4). The eutectic point coordinates are: $T_e = 671.15$°K for $x_{Ge} = 0.055$ (24), or $x_{Ge} = 0.044$ (4). The maximal solubility of zinc in solid germanium corresponds to $x_{Zn} = 7.2 \cdot 10^{-5}$ at 1032°K (6). Emf measurements performed by Kleppa, 850°K (19); Batalin, 950°-1230°K (25); and Predel, 1000°K (26) have yielded the thermodynamic functions of this binary system. At 687°, 708°, and 739°K Voronin (27) determined zinc activities using an effusion method.

In this paper we report experimental values of zinc activity in some Ga-Zn and Ge-Zn alloys, and partial mixing entropy and free energy of zinc in 22 Ga-Ge-Zn alloys.

Key words: free energy, Ga-Zn, Ge-Zn, Ga-Ge-Zn, liquidus.

Theory

The formation of a binary (or ternary) alloy by a reaction of the type

$$Zn + Zn_aGe_b \rightarrow Zn_{(a+1)}Ge_b \ (T,p)$$

may be investigated by a concentration cell represented schematically by: $Zn|Zn^{2+}$ in molten LiCl-KCl|Zn in Ga-, or in Ge-, or in Ga-Ge- (T, p). Electric conduction

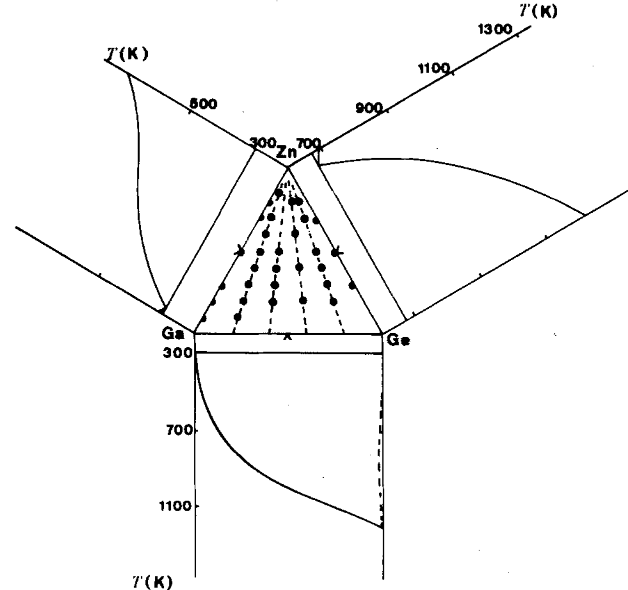

Fig. 1. Phase diagrams of the three limiting binary systems and studied ternary alloys compositions. The temperature scale is larger for the Ge-Zn system than for the two other binary systems.

is due to ions Zn^{2+} because this metal is more electropositive than gallium and germanium. In effect, standard electrode potentials (ϵ°) for zinc and gallium in molten LiCl-KCl eutectic mixture at 723°K: Zn(II) – Zn(0); $\epsilon^\circ_{Zn} = -1.566V$; Ga (III) – Ga(0); $\epsilon^\circ_{Ga} = -0.84V$ have been investigated by Laitinen and Liu (28). These authors have not measured standard potential for germanium; however, from the values of free energy of formation of gallium, germanium, and zinc chlorides (29) listed in Table I, we can deduce that germanium is the least electropositive of these three metals. The differences between the standard free energies of formation of gallium, germanium, zinc, lithium, and potassium chlorides are large enough to avoid exchange reactions at experimental temperatures.

From the knowledge of the emf value (E) at temperature T, partial free energy and activity of zinc in an alloy may be calculated using the following equation

$$-z\mathbf{F}E = \Delta_{mix}G_{Zn} = RT \ln a_{Zn}$$

since we have

$$\Delta_{mix}G_{Zn} = \Delta_{mix}H_{Zn} - T\Delta_{mix}S_{Zn}$$

the determination of $\Delta_{mix}S_{Zn}$ and $\Delta_{mix}H_{Zn}$ requires the measurement of the change in E with temperature

$$\Delta_{mix}S_{Zn} = z\mathbf{F}\left(\frac{\partial E}{\partial T}\right)_P$$

$$\Delta_{mix}H_{Zn} = -z\mathbf{F}\left(E - T\frac{\partial E}{\partial T}\right)$$

If the emf of the cell is a linear function of T ($E = A + BT$), then molar partial enthalpy and molar partial entropy of zinc do not vary perceptibly with temperature: they are proportional to the coefficients A and B.

Experimental

Apparatus.—We have developed the apparatus previously described by Massart (30) and shown in Fig. 2. The large external crucible (I), the lead wire sheath (D), and the thermocouple sheath (E) are of alumina. The pure zinc and alloys are also contained in pure alumina crucibles (A). The electrode crucibles are wedged in place on the bottom of the crucible (I) by several alumina tubes (C). Each cell contains ten electrodes: two with pure zinc and the others with alloys. The tantalum lead wires (D) for the electrodes and Pt-Pt 10% Rh thermocouple (E) are aligned by two covers (G and H). In the cover (G) suitable fittings permit a flowing argon.

The cell is heated by a cylindrical vertical furnace with two kanthal resistors; one of which is connected to a-c supply and the other to an electronic regulator. A more uniform temperature distribution along the electrodes is obtained by enclosing the cell inside the furnace in a concentric refractory steel cylinder (K) which also acts as an electric shield.

Emf values are measured with a digital millivoltmeter (Tacussel Aries 20,000) with a large input impedance ($10^{12}\Omega$).

Materials.—99.9999 gallium was donated by Alusuisse France S.A., and 99.999 germanium and 99.9998 zinc were supplied by Koch-Light Company. Lithium, potassium, and zinc chlorides were analytical grade salts (Prolabo and Merck). The cell was supplied with pure argon (grade U-Air liquide Company).

Table I. Standard free energies of formation at two temperatures of five chlorides (29).

Reaction	$\Delta_f G^\circ$ (kcal$_{th}$ mole^{-1}) T = 500°K	T = 1000°K

Cell preparation.—The molten electrolyte has to be carefully prepared to avoid considerable problems in experiments. Eutectic mixture of lithium and potassium chlorides (55.8 weight percent (w/o) LiCl; T_{fus} = 623°K) was dried at 523°K for 24 hr under dynamic vacuum and molten under flowing argon. After addition of 5 w/o zinc chloride, kept under vacuum at 383°K, the decanted mixture of salts is transferred to the cell after putting metals in the crucibles. The cell is heated until about 1100°K and held for 2 hr at this temperature to stabilize. Potentials are then measured at intervals of about 30°K after stabilization of the cell.

Accuracy.—It is difficult to make a correct evaluation of emf measurement errors. Careful attention has been paid to the experiments preparation but the major problem is knowing if values correspond well to one reversible reaction. During experiments we took the following precautions: (*i*) attainment of equilibrium by alloys after each change in temperature was verified by observing the course of emf over a period of time; (*ii*) the emf between two reference electrodes was always lower than 0.0002V at moderate temperatures and lower than 0.0003V at upper temperatures; (*iii*) since zinc vapor pressure becomes important

above 900°K (p = 10132 Pa at 991°K), all measurements were repeated on the next day to check that measured voltages were constant during this period; (*iv*) for each composition, three independent experiments were carried out; (*v*) Ga-Zn and Ge-Zn binary alloys were studied in the same cells as ternary alloys. Results were compared with published data to verify the smooth working of the cells; (*vi*) at fusion of reference metal (M) the slope change of $E = f\ (T)$ diagrams is proportional to metal fusion enthalpy

$$\Delta_{fus}H_m(\mathrm{M}) = zT_{fus}\mathbf{F}\left[\left(\frac{\partial E}{\partial T}\right)(\mathrm{M},s) - \left(\frac{\partial E}{\partial T}\right)(\mathrm{M},1)\right]$$

In our case, however, it was difficult to determine accurately the slope $(\partial E/\partial T)$ (M,s) because melting points of zinc and the salt mixture are close. We have seen that there is no correlation between the difference calculated value, generally accepted value (1750 $\mathrm{cal_{th}}$ $\mathrm{mole^{-1}}$), and zinc concentration.

Experimental Results

Limiting binary systems.—Ga-Zn system.—Six alloys (x_{Zn} = 0.1; 0.2; 0.3; 0.5; 0.7; 0.8) were studied. In Table II are reported equations $E = f(T)$ calculated from emf experimental measurements of Genta (18), Kleppa (19), Svirbely (20), Gerasimenko (21), Moser (23), and Ryabov (22)

Using these equations we calculated zinc activity at 850° and 978°K; resulting values are compared in Table III.

Results proposed by Kleppa, Svirbely, and Moser are in good agreement: the maximal discrepancy is about 4% at 978°K for x_{Zn} = 0.6. Comparing our values with the mean of those found by these three authors, we find a maximal deviation of 4.7% for the alloy x_{Zn} = 0.1 at 978°K; at 850°K this deviation was lower than 3%. We have also reported in this table results from a comparative vapor pressure method used at 978°K by Predel (17). The difference between his values and the same mean values is about 1.5%, except for the alloy x_{Zn} = 0.5 for which it is about 5%, which is very satisfactory for two such different methods. Consequently, although Genta, Gerasimenko, and Ryabov give somewhat different values, the potentiometric method seems well reproducible and as reliable as the vapor pressure method.

Ge-Zn system.—In Table IV are reported experimental results found by Kleppa (19), Batalin (25), and Predel (26) with the potentiometric method, and Voronin's (27) obtained by an effusion method.

Table V, giving zinc activity values calculated at 739° and 1000°K from the data of Table IV, shows that the deviation between values of Kleppa and Batalin increases with germanium molar fraction from 1% (x_{Ga} = 0.1) to 11% (x_{Ge} = 0.7). The maximal difference between these values and Predel's is 4%. Our results are very near to those of Kleppa (maximal difference 1%). At 739°K, values calculated from Kleppa's and Batalin's data are coherent but not in good agreement with Voronin's results. This discrepancy probably reflects the method used by Voronin.

Emf values *vs.* temperature for different Ge-Zn alloys, which are plotted in Fig. 3, vary linearly across the one-phase field as expected from equilibrium considerations. $E = f(T)$ curves exhibit sharp discontinuities at the phase boundaries. Liquidus temperatures so obtained agree well with those found by Kleppa and with the phase diagram published by Hansen (14).

Ga-Ge-Zn system.—In Fig. 4-7 are reported $E = f(T)$ curves for 22 alloys disposed along four sections,

x_{Ga}/x_{Ge} = constant, of the Ga-Ge-Zn phase diagram. The compositions of the investigated ternary alloys are

$$\frac{x_{Ga}}{x_{Ge}} = 4;\ x_{Zn} = 0.1; 0.2; 0.3; 0.4; 0.5; 0.6; 0.7; 0.85$$

$$\frac{x_{Ga}}{x_{Ge}} = \frac{3}{2};\ x_{Zn} = 0.2; 0.3; 0.4; 0.5$$

$$\frac{x_{Ga}}{x_{Ge}} = \frac{2}{3};\ x_{Zn} = 0.2; 0.4; 0.6; 0.8$$

$$\frac{x_{Ga}}{x_{Ge}} = \frac{1}{4};\ x_{Zn} = 0.2; 0.3; 0.4; 0.5; 0.7; 0.8$$

For an alloy containing a large amount of germanium, the plot of E *vs.* T is a straight line at upper temperatures and a curved line at moderate temperatures; this part is interrupted by a break point at 693°K, the melting temperature of zinc. For an alloy containing a large amount of gallium or zinc, the curved part is very short or absent. These results may be easily explained: the straight line corresponds to one liquid phase equilibrium; therefore, the partial mixing enthalpy and entropy of zinc, deduced from the zero abscissa ordinate and the slope, vary very little or not at all with temperature changes. Analytical equations of these straight lines and partial functions of zinc are listed in Table VI.

For all the studied alloys, from the partial mixing enthalpy and entropy of zinc, we have calculated $\Delta_{mix}G_{Zn}$ at 1233°K, the temperature at which the Ga-Ge-Zn system is always composed of one liquid phase: corresponding values are reported in Table VII, and Fig 8 gives the general shape of the $\Delta_{mix}G_{Zn}$ function over all the concentration range.

The curved line of each $E = f(T)$ diagram corresponds to a two-phase equilibrium (liquid-solid) with a sharp discontinuity when the liquidus surface is reached. Liquidus temperatures so determined are listed in Table VIII and plotted in Fig. 9. We can compare these results with those recently obtained by Fornaris (31) using a high temperature Calvet type microcalorimeter: we notice small deviations which are not significant.

For the ternary alloy: $x_{Ga}/x_{Ge} = 1/4$, $x_{Zn} = 0.8$, the $E = f(T)$ curve shows a third break point at 738°K, the temperature at which the emf value is near to zero.

Thus, solid zinc appears and this temperature is probably the upper limit of the three-phase zone [liquid + Ge(s) + Zn(s)].

For the alloy $x_{Ga}/x_{Ge} = 4/1$, $x_{Zn} = 0.85$, when $E = 0$ solid zinc is in equilibrium with liquid solution; the equilibrium temperature may be calculated from the following simplified equation (32)

$$T = \frac{\Delta_{mix}H_{Zn(l)} - \Delta_{fus}H_m(\text{Zn})}{\Delta_{mix}S_{Zn(l)} - \Delta_{fus}H_m(\text{Zn})/T_{fus}(\text{Zn})}$$

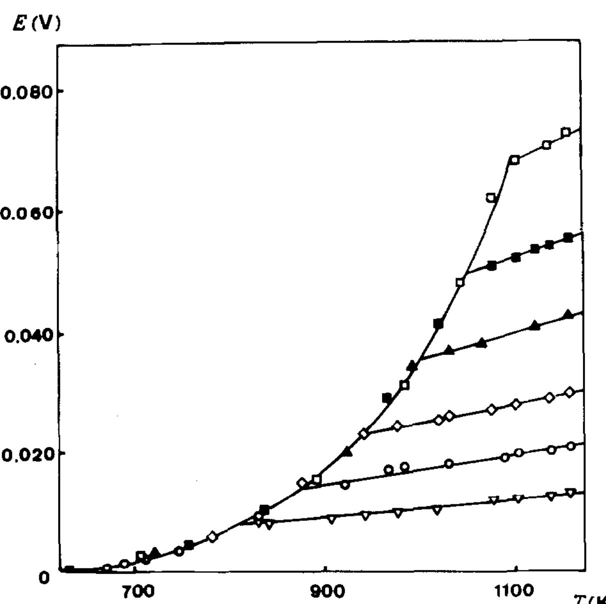

Fig. 3. Experimental values of emf plotted against temperature for 6 alloys of the Ge-Zn system: $x_{Zn} = 0.3$ (□); 0.4 (■); 0.5 (▲); 0.6 (◇); 0.7 (○); 0.8 (▽).

Conclusion

The activities of zinc measured in 22 Ga-Ge-Zn alloys between 623° and 1123°K allowed us to propose partial molar mixing entropy and free energy of zinc. From the shape of the $E = f(T)$ plot we have deduced a large part of the liquidus surface of the ternary system.

The Effects of Titanium Impurities in N⁺/P Silicon Solar Cells

A. M. Salama* and L. J. Cheng*

California Institute of Technology, Jet Propulsion Laboratory, Pasadena, California 91103

ABSTRACT

To understand the degradation mechanisms associated with the presence of titanium impurities of concentration level 3.6 × 10^{14} atoms/cm^3 in silicon solar cells, microscopic and electrical measurements were performed on these cells. The measurements included x-ray topography, transmission electron microscopy, and deep level transient spectroscopy, before and after processing. The results indicated the presence of TiO_2 precipitates, the density of which increased after phosphorus diffusion. A majority carrier trapping level located at $E_v + 0.27$ eV was observed in the wafers before processing. Two additional majority carrier trapping levels located at $E_v + 0.20$ eV and $E_v + 0.40$ eV and a minority carrier level at $E_c - 0.24$ eV were observed at the junction after phosphorus diffusion. It was concluded that about 10% of the Ti in the N^+/P silicon solar cells formed electrically active centers which caused degradation of the cell junction. About 14% of the remaining Ti precipitated out as TiO_2, forming electrically active defects, which also caused junction degradation. The details of the degradation mechanisms are given.

Titanium is one of the impurities of concern in metallurgical grade silicon. Therefore, this work was performed to determine its effect on solar cell performance, in order to establish a definition of low cost solar grade silicon.

From previously reported investigations (1, 2), it was found that deliberate titanium doping in N^+/P silicon solar cells caused degradation in the cell conversion efficiency to about 61% of that of the undoped baseline silicon solar cells.

During deep level transient spectroscopy studies (DLTS) (3), a majority (hole) carrier trap at $E_v +$ 0.29 eV was observed in the as-grown titanium-doped silicon wafers. A minority (electron) carrier trap, at energy level $E_c - 0.24$ eV, was also seen for titanium in p-type silicon diodes. The electrically active concentration of the minority trap was estimated to be 1.5 × 10^{13}/cm^3, and the hole trap concentration was 1.35 × 10^{13}/cm^3.

By means of electron spin resonance measurements, titanium was found (4) to have occupied interstitial sites in silicon. It was also reported (5) that diffused titanium in silicon acted as a donor at the level $E_c - 0.24$ eV.

In addition, titanium is known to have a high affinity to react with oxygen and form a wide range of titanium oxides (6). Therefore, one expects a great tendency for the titanium to react with the oxygen in the Czochralski-grown ingots or wafers, during growth or annealing, thus forming titanium-oxygen complexes.

To understand the mechanism of the titanium-doped solar cell degradation, a series of microscopic and electrical measurements were performed on these cells, before and after phosphorus diffusion and solar cell fabrication. By comparing the results of these measurements, it was possible to track the critical step for defect generation and determine the defects that caused the junction degradation.

Description of the Silicon Wafers and Cells under Investigation

The 0.025 cm thick, 3.12 cm diam silicon wafers were cut from ingots with <111> growth axes, prepared by Czochralski techniques (3). The titanium was added to the ingots during the melting process at ~1412°C. The seed silicon material was boron-doped to a concentration of ~10^{16} atoms/cm^3. The titanium doping level was 3.6 × 10^{14} atoms/cm^3, as determined by neutron activation analysis (3). The ingot was pulled out of the furnace at a rate of 7.5 cm/hr, then rapidly cooled. Some of these wafers were characterized before and after processing, and the results are included in this paper.

The diffusion process was performed at 825°C using standard solar cell fabrication techniques with $POCl_3$ as the phosphorus source. Thin films of Ti/Pd/Ag metallization were evaporated on the diffused wafers to form the contacts of the solar cells.

Devices for capacitance studies were prepared as follows: (*i*) titanium Schottky barrier diodes on silicon wafers, (*ii*) mesa structure diodes etched from solar cells, and (*iii*) diodes made by the usual integrated circuit techniques.

Experiments and Results

Microscopic Evaluation of the Silicon Wafers

Transmission x-ray topography on the as-grown wafers.—Wafers of <111> crystal orientation were examined using the Lang transmission method. A Rigaku-Denki camera and MoK_α radiation from a Jarrell-Ash microfocus x-ray generator were used. All exposures were recorded on Ilford K-5, 50 μm nuclear plates. Three Ti-doped silicon wafers of each ingot were examined, and topographs of both the (111) and (220) crystal reflections from those wafers were taken.

Figure 1 shows a typical (220) topograph of a titanium-doped silicon wafer before processing. The dislocation density of this wafer was 700 d/cm^2, and the precipitates, shown as bright spots, had a density of 1.9 × 10^2 p/cm^2.

Transmission x-ray topography on wafers after phosphorus diffusion.—After the x-ray topography examination, the same wafers were processed for p-n junction formation by phosphorus diffusion. The back sides of those wafers were etched off as done for standard solar cell fabrication. Then they were examined again by the nondestructive transmission x-ray topography technique.

Figure 2 shows a typical (220) topograph of the same wafer as in Fig. 1, after the phosphorus diffusion. The topograph indicated that there were new precipitates at the central part of the wafer at A. The dislocation density had changed slightly to 800 d/cm^2, whereas the precipitate density had increased significantly to 4 × 10^2 p/cm^2.

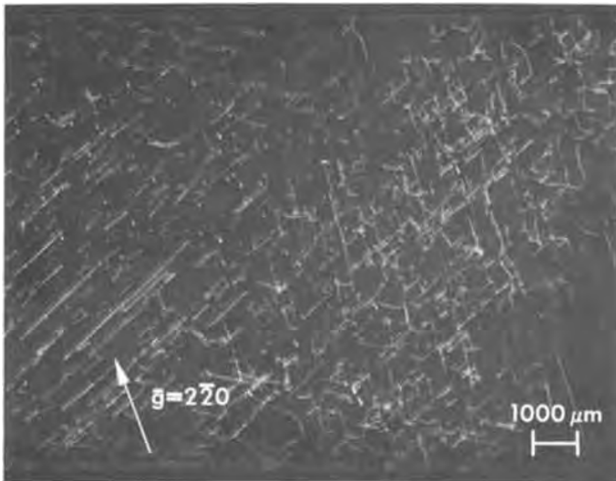

Fig. 1. A (220) x-ray topograph of a Ti-doped silicon wafer before processing.

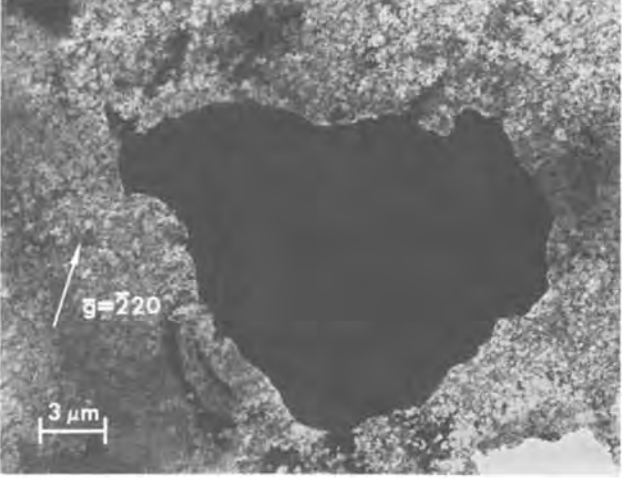

Fig. 3. A TEM micrograph showing a large precipitate particle in the bright field.

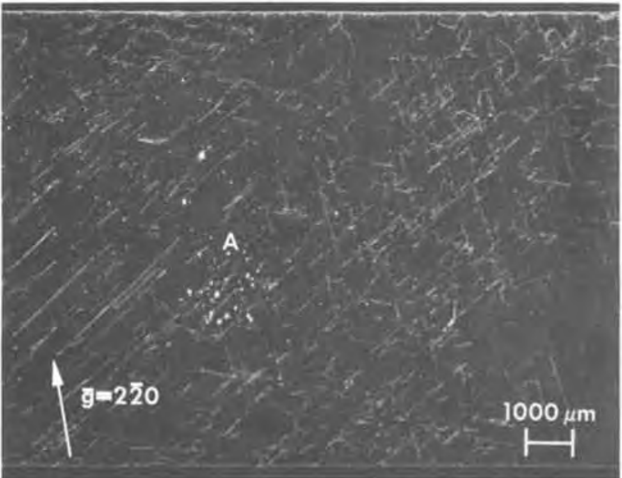

Fig. 2. A (220) x-ray topograph of the same wafer as in Fig. 1, after processing.

Fig. 4. A TEM micrograph of the same large particle as in Fig. 3, in the dark field.

From the two figures, it was found that the precipitate concentration increased from 2.6×10^{13} atoms/cm^3 to 4.9×10^{13} atoms/cm^3 after the diffusion process. Some of these precipitates were associated with dislocations.

Transmission electron microscopy (TEM).—Titanium-doped silicon specimens were cut from the previously examined wafers, around the areas that showed precipitates in the x-ray topographs (area A in Fig. 2). Thin foils were prepared chemically using HF, HNO_3, CH_3COOH, and iodine, in an ice bath, then examined by Siemens' Elmiscope TEM at 100 keV. The foils were examined in the (111) plane. Other results (not included here) were obtained for foils tilted in the (110) and (100) planes. Selected area diffraction (SAD) patterns were taken, both for the silicon material and the precipitate particles in the silicon.

Figures 3 and 4 show a large precipitate particle in bright and dark fields, respectively, and Fig. 5 shows the selected area diffraction pattern for the precipitate particle. The average size of the precipitate particles was 1.2×10^{-12} cm^3. The diffraction spots correspond to the precipitate interplanar spacings of 1.8907, 1.343, and 1.044Å for the ($\bar{2}00$), ($\bar{2}20$), and ($\bar{3}2\bar{1}$) reflections, respectively. By comparing the obtained lattice spacings with those of the ASTM index cards, it was determined that the precipitate is the tetragonal titanium dioxide, TiO_2 (anatase).

Physical and Electrical Evaluation of the Solar Cells

Physical evaluation.—Scanning electron microscopy (SEM) using the electron beam induced current

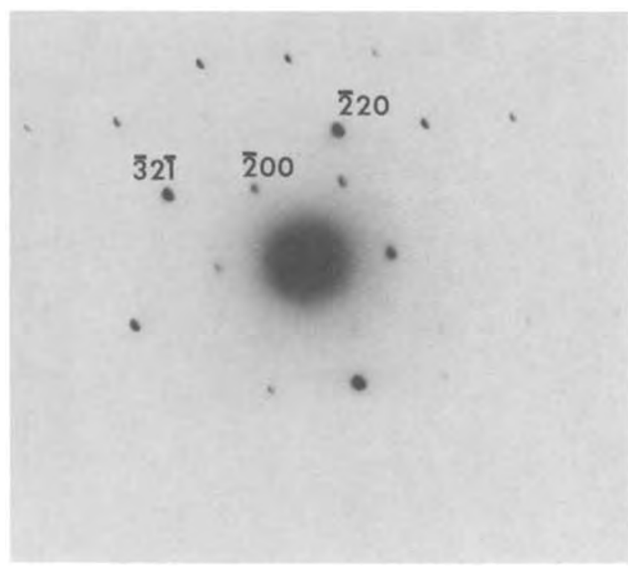

Fig. 5. Selected area diffraction pattern for the precipitate particle in Fig. 3 and 4.

(EBIC) mode was employed on solar cells incorporating the titanium impurities of interest. A Cambridge S-410 scanning electron microscope was used. At ~10 keV, the electron beam penetration depth is ~0.5 μm, which gives an image of the p-n junction depletion region. The junction depth, as determined by the incremental sheet resistance technique (3), is 0.3-0.4 μm. Figure 6 shows an EBIC micrograph at 10 keV. A precipitate clump is shown in the center of a hole-like region. It is believed that these defects are the TiO_2 precipitates found in the TEM experiments.

Electrical evaluation.—Deep level transient spectroscopy (DLTS) method used to measure the carrier trapping centers is similar to the deep level transient spectroscopy method reported by Lang (7, 8). The measured activation energies for carrier emission are accurate to about ±0.02 eV.

The samples used were in the form of Schottky diodes or diffused diodes. They were prepared from wafers of Czochralski ingots grown from the melt as described previously. The Schottky barrier was prepared by titanium evaporation on freshly etched wafers.

Figure 7 shows typical DLTS spectra of the Ti-doped samples, in which the upper spectrum is that obtained from the Schottky diodes made of as-grown materials, and the other two spectra are measured from the two diffused diodes. These two diodes were prepared from the same Ti-doped material fabricated as previously described. It should be mentioned that one kind of the diffused diodes (cell-s) was prepared by mesa etching of solar cells, while the other (cell-W) was made by etching and photolithographic techniques. Four DLTS peaks were observed, corresponding to three majority carrier trapping levels and one minority carrier trapping level.

The temperature dependence of carrier emission rate of each level was measured as shown in Fig. 8. The activation energies for the emission process of the levels estimated from those data revealed their locations in the forbidden gap. They were $E_v + 0.18$ eV, $E_v + 0.27$ eV, and $E_v + 0.38$ eV for the majority carrier trapping levels and $E_c - 0.24$ eV for the minority carrier trapping level.

The $E_v + 0.27$ eV level was the only majority carrier trapping level in the as-grown samples. The measured concentration was about 5-6 × $10^{13}/cm^3$, which is much lower than the total concentration of titanium determined by neutron activation analysis. The $E_v + 0.27$ eV level was also observed in the diffused samples but with lower concentrations, ~1 × $10^{13}/cm^3$, indicating the existence of some diffusion-induced effect.

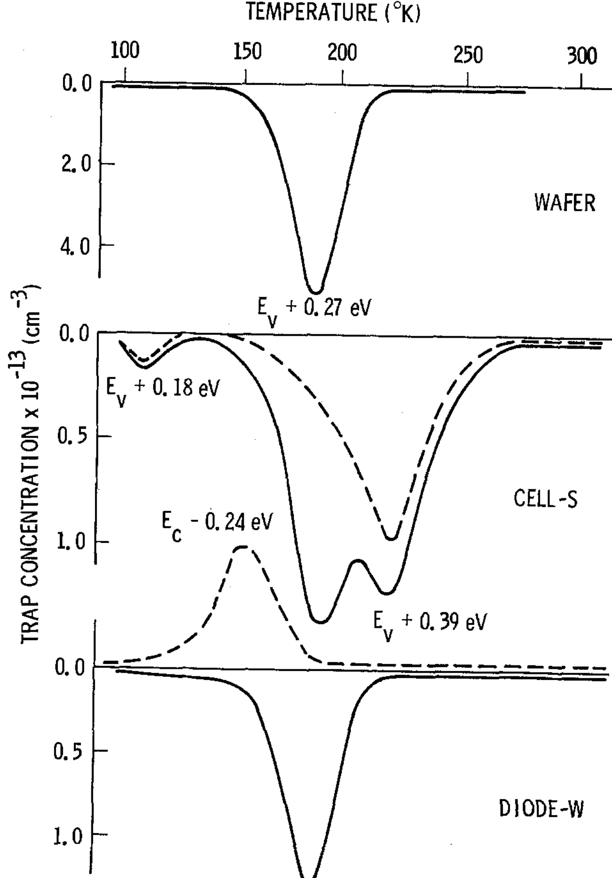

Fig. 7. Typical DLTS spectra of Ti-doped samples. The upper one corresponds to that of as-grown materials, and the other two are for the two types of diffused diodes. The solid curves were taken without carrier injection and the dashed curves with carrier injection.

In order to explore the effect further, the diffused layer of the wafer was removed by etching off 10-30 μm. Then, several Schottky diodes were made. The DLTS measurements on these Schottky diodes revealed that the concentration of the $E_v + 0.27$ eV level in the etched wafer is about 5 × $10^{13}/cm^3$, being the same as that in the as-grown material.

Discussion

The effect of titanium in silicon.—Titanium was found to have diffused interstitially in silicon (4). In the presence of a high concentration of oxygen of ~7.8 × 10^{17} atoms/cm^3 in the Czochralski crystals (3), it reacts very rapidly with oxygen, forming Ti-O complexes and consequently precipitates out as TiO_2 (anatase). If the precipitates' molar volume is greater

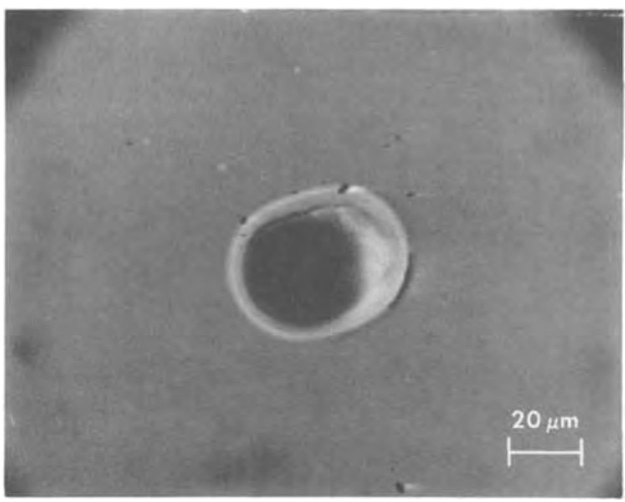

Fig. 6. An SEM/EBIC micrograph of a defect in the Ti-doped silicon solar cell junction depletion region.

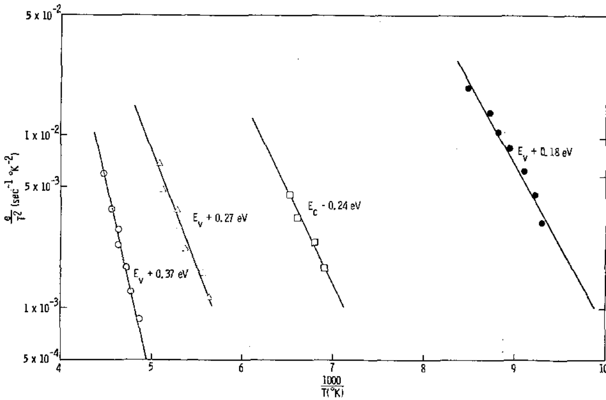

Fig. 8. Arrhenius plot of the carrier emission rate of the levels observed by DLTS.

than the molar volume of the matrix as in the case of TiO_2, interstitials or dislocations are introduced to relax the stress field which will develop. The x-ray topographs in the present work indicated the presence of a high density of dislocations due to this effect. It is known that impurities segregate to the dislocations. If the titanium interstitial impurities act as donors, this means that a p-n junction forms around each dislocation, degrading the solar-cell quality.

Gettering of titanium during the solar cell processing.—X-ray topography showed that more precipitates are formed during the diffusion process, which was supported by the deep level transient spectroscopy measurement results. It was found that about 10% of the titanium in the N^+/P silicon solar cells is electrically active centers. About 14% of the remaining titanium precipitated out. It is therefore believed that the remaining titanium was either gettered out during the solar cell fabrication process or cannot be detected by these techniques.

The DLTS results also indicated a reduction in the concentration of the $E_v + 0.27$ eV level, in the depletion region of the diffused diodes. This reduction can be attributed to the diffusion of titanium in the n^+ region (gettering effect) or the transformation of titanium into other complexes such as titanium oxide TiO_2 or the occurrence of both effects simultaneously.

Also, the observation of additional DLTS peaks corresponding to $E_v + 0.18$ eV, $E_v + 0.38$ eV, and $E_c - 0.24$ eV levels and the TEM results which indicated the presence of TiO_2 precipitates could serve as an indication of formation of titanium oxide complexes in the depletion region during the diffusion process. The $E_c - 0.24$ eV level may correspond to the $E_c - 0.24$ eV level found earlier (5) for a titanium donor level in a diffused titanium sample.

Moreover, the titanium oxide precipitates, which were not associated with dislocations, were electrically active defects as was revealed by the SEM/EBIC results. Therefore, the presence of these defects in the solar-cell depletion region causes further degradation of the solar-cell conversion efficiency.

Conclusion

For titanium-doped silicon solar cells of concentration level 3.6×10^{14} atoms/cm^3, the mechanism of the significant degradation is attributed to the presence of electrically active titanium or titanium oxide complexes in the junction depletion region. In spite of the fact that the active trapping center concentration was reduced during the phosphorus diffusion process, due either to the increase in the TiO_2 precipitate density or to the gettering of titanium to the n^+ region, the TiO_2 (anatase) precipitate particles were also active in the depletion region when not associated with dislocations. However, dislocations act as recombination centers in the depletion region. The precipitates or impurity atoms segregate to the dislocations and probably degrade the junction. This is consistent with the findings of other investigators that diffused titanium forms a donor level at $E_c - 0.24$ eV. The DLTS and x-ray topography measurements strongly suggest that titanium diffuses during the processing steps. However, the rate of titanium diffusion in silicon is slow compared to that of other metals such as copper.

Acknowledgments

The authors wish to thank JPL and Materials Research Incorporated staff for the use of the facilities and the services performed during the course of this evaluation. Special thanks are extended to Danny Leung for the DLTS measurements and to Mary McGough of the Photolab for her excellent efforts in reproducing the photographs.

Liquid Phase Epitaxial Silicon Diodes: N-Epitaxial Layers on Boron-Doped Substrates

B. Jayant Baliga*

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

It is demonstrated that both abrupt and graded junction diodes can be fabricated by the growth of n-type epitaxial layers on heavily boron-doped substrates by using silicon liquid phase epitaxy with tin as the solvent. It is found that the breakdown voltage is enhanced by the presence of the graded p-type region at the epi-substrate interface when the layers are grown with meltback prior to growth. In spite of a high measured tin concentration in the epitaxial layers, the diodes exhibit characteristics which are in good agreement with theoretically calculated values based upon bulk silicon properties. In addition a high minority carrier lifetime has been measured in the epitaxial layers, indicating that the incorporation of tin does not introduce a large density of recombination centers in silicon.

The growth of epitaxial layers of silicon by liquid phase epitaxy offers an interesting alternative to the presently used vapor phase epitaxial deposition techniques. Early reports on silicon liquid phase epitaxy have been directed towards reducing epitaxial layer defects (1) and for the formation of ohmic pedestal contacts to planar-diffused diodes (2). More recently, Girault *et al.* (3) and Sumner and Foley (4) have reported on the growth and electrical properties of silicon epitaxial layers grown from gallium and aluminum melts. Since both gallium and aluminum exhibit shallow acceptor levels in silicon and are readily incorporated into the epitaxial layer, these layers were found to be p-type with carrier concentrations above 10^{18} cm^{-3} and to have a short minority carrier lifetime. The growth of high resistivity epitaxial layers with high lifetime, therefore, requires that the solvent used for the silicon must not introduce active centers in the silicon lattice. Since tin lies in the same column as silicon in the periodic table, its incorporation in the silicon lattice is not expected to introduce either shallow dopant levels or deep lying recombination levels in the silicon energy gap. It has been previously shown that specular films can be grown at reasonable growth rates by silicon liquid phase epitaxy with tin as a solvent (5-7). More recently, measurements of the doping profiles in these epitaxial layers has also been reported (8). These measurements have demonstrated that in spite of a tin concentration in excess of 10^{19} per cm^3 in the epitaxial layers, carrier concentrations in the range of 1×10^{15} cm^{-3} to 1×10^{16} cm^{-3} could be achieved. In addition, it was shown that meltback prior to epitaxial growth had a strong influence on the doping profile of these n-type epitaxial layers when grown on heavily boron-doped substrates. Although an abrupt doping interface was observed between the epitaxial layer and the substrate in the absence of meltback, a graded p-type layer was produced at the substrate interface in the presence of meltback.

The quality of junctions fabricated using silicon liquid phase epitaxy with tin as the solvent is of importance in evaluating its potential for device applications. The incorporation of a high concentration of tin in these layers has been found by electron microprobe analysis. The presence of this high tin concentration may be expected to have an influence on the junction characteristics, particularly, since some studies have implied that the tin introduces deep recombination levels in silicon (9). In addition, meltback prior to epitaxial growth is expected to improve the crystalline quality of the epitaxial growth because it provides an *in situ* substrate surface cleaning prior to growth. However, it has been found that meltback cannot be used for the growth of n-type layers on heavily boron-doped substrates if an abrupt interface is required (8). The objective of this paper is to examine the quality of junctions fabricated by silicon liquid phase epitaxy on heavily boron-doped substrates both with and without meltback. It is shown here that in spite of the high tin concentration in the epitaxial layers, the junction characteristics are in agreement with theoretical calculations based upon bulk silicon parameters.

Experimental Procedure

The technique used for the growth of the epitaxial layers in this study has been reported in detail in a previous paper (5). Briefly, the layers were grown by using the dipping technique with tin as a solvent for the silicon. The tin melt was maintained at the growth temperature in a quartz crucible within a hydrogen ambient. In order to grow the epitaxial layers, the melt was first saturated with silicon at 950°C. The saturation was done with phosphorus-doped, float zone wafers having resistivities in excess of 100 Ω-cm. The carrier concentration in the epitaxial layers was found to be independent of the phosphorus concentration in the saturation wafers, thus indicating the presence of an n-type contaminant in the high purity tin (five nines purity) used as the melt. After saturation, (111) oriented, boron-doped substrate wafers with a resistivity of 0.01 Ω-cm were introduced into the melt and the temperature of the melt was reduced at known cooling rates to initiate the epitaxial growth.

After epitaxial growth, the wafers were etched in aqua regia to remove any tin that may have adhered to the wafer surface. A piece of each wafer was then used for spreading resistance measurements using an ASR100 spreading resistance probe to obtain the doping profile. An abrupt doping profile was observed between the epitaxial layer and the substrate in the absence of meltback. However, in the presence of meltback prior to growth,[1] a graded p-type layer was observed at the interface between the epitaxial layer and the substrate. The origin of this graded profile has been discussed in detail in an earlier paper, and it has been shown that the doping concentration decreases exponentially with distance away from the epi-substrate interface (8). To examine the effect of this graded profile upon the junction characteristics, diodes were fabricated from these wafers. The diode fabrication procedure consisted of first performing a phos-

* Electrochemical Society Active Member.
Key words: silicon, liquid phase epitaxy, junctions, diodes.

[1] The meltback was caused by raising the temperature of the melt by 1° to 5°C after saturation as described in Ref. (8).

phorus diffusion into the epitaxial layer to obtain a good ohmic contact. This diffusion was performed well below the growth temperature for a short duration to avoid any impurity redistribution in the epitaxial layers. Aluminum was then evaporated on both sides of the wafers, and sintered at 400°C for 30 min. The wafers were then scribed apart into 60 × 60 mil chips and mounted on TO-5 headers. After bonding a gold lead to the top surface, the edges of the chips were etched in a freon plasma just prior to passivation. A polyimid passivant similar to that described in Ref. (13) was used here. This method of mounting and passivation has been found to be successful in reducing the surface electric field to an extent that allows observation of bulk diode characteristics.

For this study, the diodes were fabricated from epitaxial layers grown at various cooling rates ranging from 0.2°C/min to 7°C/min. In addition, some of these layers were grown with meltback prior to epitaxial growth to allow examination of the influence of the graded p-type region upon diode characteristics. The avalanche breakdown voltage of many diodes was measured both at room temperature and at 77°K for each of the wafers. Table I lists some of the diode breakdown data together with the growth conditions and the diode doping profile in the order of increasing exponent factor. This exponent factor (α) is a measure of the gradient of the junction and is described analytically in the next section. It should be noted that the diode breakdown voltage at 77°K is lower than the value at room temperature. This is an indication that bulk avalanche breakdown is being observed during these measurements. In addition it can be seen that the breakdown voltage decreases with increasing exponent factor, α, and is not sensitive to the cooling rate used during epitaxial growth.

In addition to the breakdown characteristics, the capacitance of these diodes was also measured as a function of the reverse applied voltage. The C-V characteristics of four typical diodes are shown in Fig. 1. The broken lines in this figure have been drawn to indicate the shape of the curves for an abrupt junction diode (C proportional to $V^{-1/2}$) and a linearly graded junction diode (C proportional to $V^{-1/3}$). It can be seen that the curves for diodes with large exponent factors (α) approach the abrupt junction case while those for diodes with smaller exponent factors (α) approach the linearly graded case.

Analysis

Electron microprobe measurements of the epitaxial layers grown in this study indicate that the layers contain tin concentrations in excess of 10^{19} per cm^3. This incorporation of tin in the layers may be expected to degrade the quality of the junctions being discussed in this paper. To assess the influence of tin on the junction characteristics, it is, therefore, necessary to obtain a comparison with theoretically calculated values of the breakdown voltage based upon bulk silicon properties. As shown in a previous paper, the doping profile in the epitaxial layers can be described as (8)

$$N_A = N_D \exp(-\alpha x) \quad [1]$$

Table I. Diode breakdown voltage data

Experimental data					
Sample number	Cooling rate (°C/min)	Exponent factor (α) (cm^{-1})	N_D (cm^{-3})	Breakdown voltage 77°K (volts)	Breakdown voltage RT (volts)
GBG-21	0.2	1×10^3	6×10^{15}	120	150
GBG-26	2	1.5×10^3	3×10^{15}	100	120

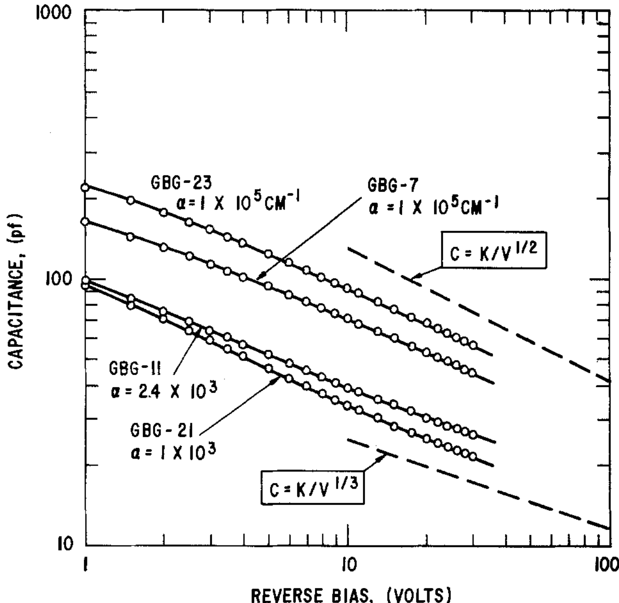

Fig. 1. Capacitance-voltage characteristics of diodes fabricated with abrupt and exponentially graded junctions using silicon liquid phase epitaxy.

where N_A is the acceptor concentration (boron), and N_D is the background donor concentration in the epitaxial layer in the absence of meltback. This doping profile and the electric field distribution are indicated in the inset of Fig. 2. The electric field distribution is described by Poisson's equation

$$\frac{d^2V}{dx^2} = -\frac{dE}{ax} = -\frac{\rho(x)}{\epsilon} = -\frac{qN_D}{\epsilon}[1 - \exp(-\alpha x)] \quad [2]$$

where $\rho(x)$ is the charge distribution in the junction depletion layer. Integration of this equation provides the electric field distribution

$$E(x) = \frac{qN_D}{\epsilon}\left[\frac{\exp(-\alpha x)}{\alpha} - W_N - \frac{\exp(-\alpha W_N)}{\alpha} + x\right] \quad [3]$$

where W_N is the depletion layer width on the n-type side of the junction. This depletion width is related to the applied junction voltage

$$V_A = \frac{qN_D}{\epsilon}(W_P + W_N)\left[\left(\frac{W_P + W_N}{2}\right) - \frac{1}{\alpha} + \frac{\exp(-\alpha W_N)}{\alpha}\right] \quad [4]$$

with

$$W_N + \frac{\exp(-\alpha W_N)}{\alpha} = \frac{\exp(\alpha W_P)}{\alpha} - W_P \quad [5]$$

where W_P is the depletion layer width on the p-type side of the junction. In addition, if avalanche breakdown is assumed to occur when the peak electric field in the junction reaches a critical value (E_C), then at breakdown

$$W_N + \frac{\exp(-\alpha W_N)}{\alpha} = \frac{1}{\alpha} + \frac{\epsilon E_c}{qN_D} \quad [6]$$

From the last equation, the depletion layer widths at breakdown, as well as the breakdown voltage, can be calculated as a function of the background doping (N_D) and the exponent factor (α). Using the critical electric field values given by Sze and Gibbons (10), the depletion layer widths on both sides of the junc-

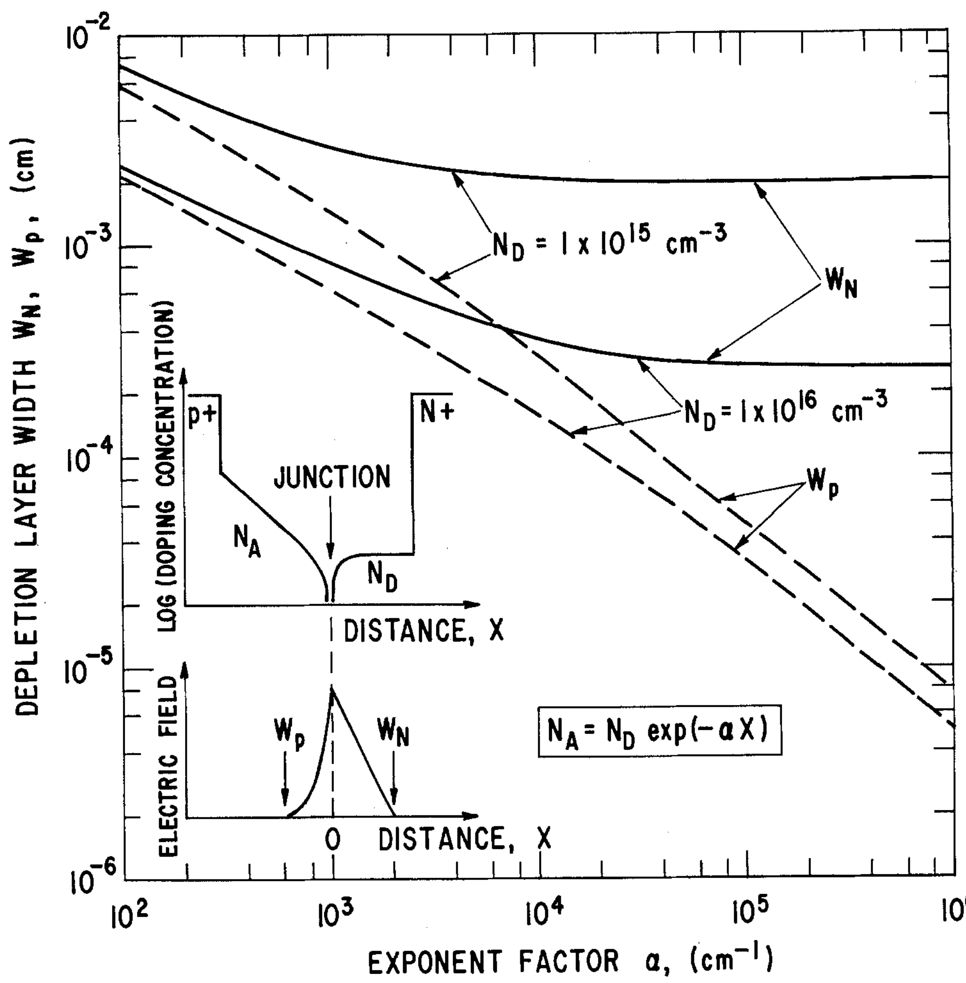

Fig. 2. Variation of depletion layer widths on the p-side (W_P) and n-side (W_N) of the junctions with exponent factor. (The inset shows the doping profile and the electric field distribution.)

tion and the breakdown voltage have been calculated over a selected range of background doping and exponent factor values and are plotted in Fig. 2 and Fig. 3. It can be seen that when the exponent factor (α) exceeds 10^5 cm^{-1}, the breakdown voltage and the depletion layer width on the n-type side of the junction become independent of α, and the depletion layer width on the p-type side of the junction becomes far smaller than that on the n-side. Consequently, at these large exponent factor values, the diodes will essentially have an abrupt junction characteristic. Similarly, at small values of the exponent factor ($\alpha < 10^2$ cm^{-1}), the depletion layer widths on both sides of the junction become nearly equal, indicating that the junction is now approaching the linearly graded case.

A comparison of these theoretically calculated values can now be made with the measured values listed in Table I. For the wafers with large values for the exponent factor (GBG-7 and GBG-23), the breakdown voltage is within 10% of the calculated values. This indicates that in spite of the junction being located at the epi-substrate interface and in spite of the high tin concentration in the layers, good diode breakdown characteristics can be achieved with this liquid phase epitaxial growth process for making abrupt junctions. This is of particular significance to the fabrication of devices which require an abrupt transition in doping between the epitaxial layer and the substrate. The achievement of good diode breakdown characteristics in the absence of meltback prior to epitaxial growth is also of significance to the fabrication of buried grid regions (11). However, the quality of the diodes grown in the presence of meltback is also of interest because the junction is now located within the epitaxial layer and away from the epi-substrate interface. In addition, Fig. 3 shows that the grading of the doping concentration on the p-type side of the junction enhances the breakdown voltage. The measured breakdown voltage of the diodes with exponent factors of 2×10^3 cm^{-1} (GBG-14) are indeed about three times larger than those with exponent factors of 10^5 cm^{-1} (GBG-7), in reasonable agreement with the calculated values. It is also worth pointing out that the breakdown voltages of the diodes listed in Table I are essentially controlled by the magnitude of the exponent factor (α) and are insensitive to the cooling rate (and hence the growth rate) at which the epitaxial layers were grown. Thus, although a high cooling rate has been found to cause a deterioration in the surface quality of the films (6), it does not cause any significant degradation in the breakdown characteristics.

In addition to obtaining a comparison between the experimental breakdown data and the theoretical values determined using bulk silicon parameters, it is also interesting to examine the capacitance voltage characteristics of these diodes. The theoretical ca-

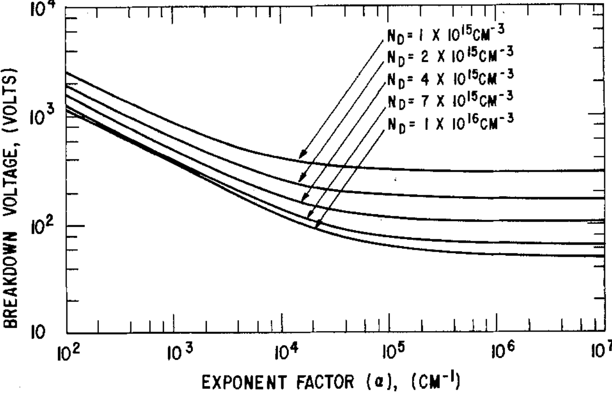

Fig. 3. Theoretical plots of junction breakdown voltage as a function of the exponent factor and the background doping level.

pacitance per unit area can be determined from the calculated depletion layer widths at each applied bias by using the relationship

$$\frac{C}{A} = \frac{\epsilon}{(W_P + W_N)} \qquad [7]$$

where A is the area of the diode. Using this relationship with Eq. [4] and [5], the capacitance per unit area has been calculated for diodes with background carrier concentration of 2×10^{15} cm^{-3} on the n-type side of the junction. These calculated curves are shown as a function of reverse bias in Fig. 4 using the exponent factor as a parameter. From this figure, it can be concluded that when the exponent factor exceeds 10^6 cm^{-1}, the capacitance varies inversely as the square root of the reverse bias. Even at lower exponent factors in the range of 10^5 cm^{-1}, the curves asymptotically approach the curve for $\alpha = 10^6$ cm^{-1} at the larger reverse bias voltages. This theoretically predicted behavior can be observed to occur in the C-V curves of diodes made from wafers GBG-23 and GBG-7 as shown in Fig. 1. In contrast, the curves in Fig. 4 for small values of the exponent factor (less than 10^3) approach the linearly graded case where the capacitance varies inversely as the cube root of the reverse bias voltage. This can be observed in the experimental data obtained for the diodes fabricated from wafers GBG-11 and GBG-21 at the larger reverse bias voltages (see Fig. 1). In addition to this, the theoretical calculations predict an increase in capacitance with increasing values of the exponent factor (α). In spite of some expected variation in the diode area due to the sample preparation technique used in this study, it can be seen from Fig. 1 that a roughly threefold increase in capacitance occurs when the exponent factor increases from 1×10^3 to 1×10^5 cm^{-1} in agreement with the theoretical calculations.

Discussion and Conclusions

The analysis presented in the previous section demonstrates that diodes, which are fabricated by the growth of n-type layers using silicon liquid phase epitaxy on heavily boron-doped substrates, have the breakdown and C-V characteristics that is expected of bulk silicon diodes. However, it is possible that the presence of tin in the epitaxial layers may cause the introduction of deep levels in the silicon energy gap in spite of tin being in the same column as silicon in the periodic table. Schulz (9) has reported that when tin is introduced in silicon by ion implantation several deep levels are observed even after annealing. If these levels were due to the tin incorporation and were not associated with any residual defects after the implantation and annealing procedures, then the lifetime in the epitaxial layers grown in this study should be very low because the tin concentration in the layers exceeds 10^{19} per cm^3. To evaluate the lifetime, reverse recovery measurements (12) were made using the diodes fabricated in this study. It was found that the minority carrier lifetime was in the neighborhood of 2-10 μsec at room temperature. The observation of these reasonably high lifetime values is another indication that the tin is inactive in the silicon lattice, and that the lifetime is controlled by some other impurity or defect center. An idea of the location of this deep level which is controlling the lifetime may be obtained by measuring the lifetime as a function of ambient temperature. Typical results of such measurements are shown for three diodes in Fig. 5. These data show an increase in lifetime with increasing temperature. This indicates that the dominant recombination center lies below midgap. At present, the nature of the defect center responsible for this recombination level is not known.

In conclusion, it has been determined that both abrupt and exponentially graded junction diodes can be fabricated by the growth of n-type layers on heavily boron-doped substrates by using silicon liquid phase epitaxy with tin as the solvent. In spite of a high tin concentration in the layers, the diode break-

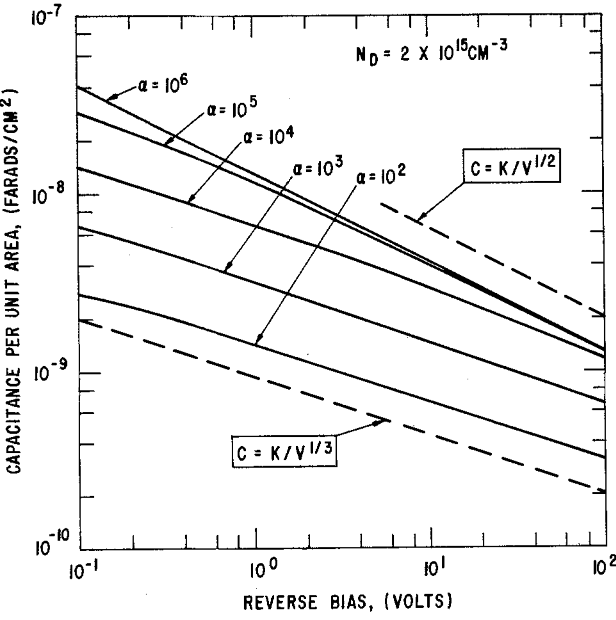

Fig. 4. Theoretical capacitance-voltage characteristics of diodes with various exponent factors.

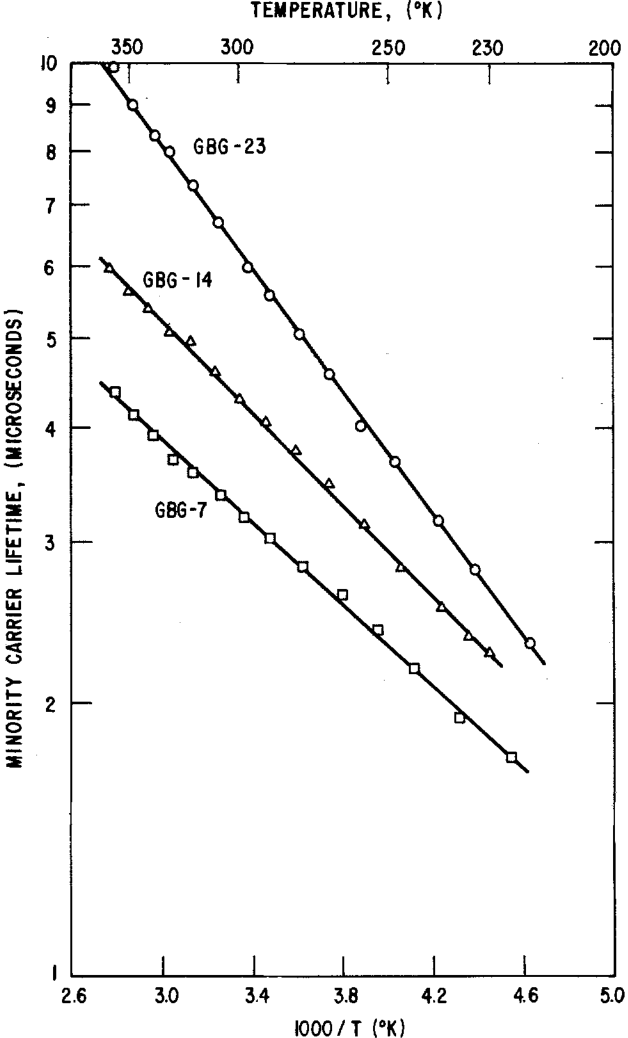

Fig. 5. Variation of the minority carrier lifetime with ambient temperature.

down and capacitance-voltage characteristics are in agreement with the theoretically calculated values using bulk silicon properties. Although good breakdown characteristics are observed even for diodes made with an abrupt junction (without meltback), the breakdown voltage can be increased by creating the graded junction (using meltback prior to growth). In addition, these diodes have been used to measure the lifetime in the epitaxial layers. The reasonably high lifetime values observed in this study are an indication that the tin in the layers does not introduce a high concentration of recombination levels in the silicon energy gap. The results, thus, indicate that the fabrication of junctions by silicon liquid phase epitaxy using tin as a solvent is a promising technique for device applications.

Distinction Between Clean and Decorated Oxidation-Induced Stacking Faults by Chemical Etching

Motonobu Futagami

Sony Corporation Research Center, Hodogaya-ku, Yokohama 240, Japan

ABSTRACT

Decorated stacking faults in (100) silicon were distinguished from clean faults by Sirtl etch at any etching stage. The decorated faults were delineated as hillocks, while the clean faults were delineated as flat and geometric pit-features by Sirtl etch. These observations were confirmed by transmission electron microscopy. The formation of the different etch features of the faults can be explained in terms of the solution etch rate and the activity of the etch agent on the decorating precipitates.

There is considerable interest in oxidation-induced stacking faults (OSF's) (1-7) in semiconductor manufacturing. These faults which form during a high temperature thermal oxidation of silicon wafers are extrinsic in nature and are bounded by Frank partial dislocations (2). The presence of such faults is well known to have a deleterious effect on device performance (8-11). A number of techniques have been applied to eliminate the formation of OSF's (12-17). None of the methods, however, has been found to be effective in completely eliminating the formation of OSF's in actual devices. The electrically active OSF's are decorated with impurity precipitates and the electrical activity differs with varying degrees of impurity decoration on OSF's (9, 10). This fact suggests that the clean OSF's which are free of precipitates will be electrically nearly inactive. The development of a simple and reliable method to distinguish them is therefore highly desirable.

Rozgonyi and Kushner (18) have reported that there are differences in etch pit features by Secco etching (19) between OSF's due to varying amounts of decoration and electrical activity. The Secco etch, however, is not satisfactory to precisely distinguish the faults with small amounts of decoration from the faults without decoration. A suitable or an improved preferential etch is now expected to be developed for this purpose.

Key words: preferential etch, precipitation, gettering.

In this paper it is demonstrated that decorated faults frequently induced during oxidation of silicon wafers were clearly distinguished by the Sirtl etch (20) from clean faults obtained by the subsequent gettering treatment using boron diffusion on the backside of the wafer. Etch features of clean and decorated faults are compared using the Secco and the Wright (21) etches as well as the Sirtl etch. It was found that the Sirtl etch is superior in distinguishing them. These observations were confirmed by transmission electron microscopy (TEM).

Experimental

Silicon wafers used in this work were prepared from boron-doped p-type dislocation-free Czochralski-grown crystals with a (100) surface plane. They were 5 cm diam, 300 μm thick wafers with resistivities ranging from 40 to 60 Ωcm and mirror polished on one side. The front side (polished side) of the wafers was used to study OSF's. The wafers were cleaned using a standard cleaning procedure prior to oxidation. The oxidation was carried out in steam at 1100°C for 2 hr (giving -0.85 μm of oxide) to enable OSF's to grow to a microscopically visible size. Some of the oxidized wafers were boron-diffusion gettered at their back surfaces to extract impurity precipitates from the OSF's. In these cases a control was built into each sample. This was accomplished by the

following method. Conventional photolithographic procedures were used on these oxidized wafers to strip the oxide from the half of the back-side while the oxide layers were retained on the front. Boron was then diffused into the exposed half of the wafer at 1000°C for 15 min from a BBr_3 source. A 0.85 μm thick SiO_2 layer was sufficient to mask the silicon underneath against the diffusing boron atoms.

Regardless of any test sample processing prior to defect examination all samples were stripped of oxide in concentrated hydrofluoric acid solution. The etchants used to delineate the OSF's were those due to Sirtl, Secco, and Wright. The samples were etched with manual agitation for a desired length of time in each etch solution. The etched samples were rinsed, dried, and examined with the optical microscope, if necessary, using differential interference contrast.

After stripping of oxide the sample was waxed onto a flat stainless steel plate and thinned by chemical etching from the back surface to a thickness of about 1 μm using a $HF:HNO_3:CH_3COOH$ mixture. Specimens thinned in this manner were examined using a JEOL JEM 200A TEM operated at an accelerating voltage of 200 kV.

Results

Decorated Fault Delineation

Surface stacking faults which were in the uniform size of about 20 μm in length were formed during thermal oxidation on mirror polished wafers. They were uniformly distributed in the entire area of the wafer with a typical density of 5×10^3 cm^{-2}. The transmission electron micrograph of a typical OSF is shown in Fig. 1. The partial dislocations bounding a fault were decorated with impurity precipitates while the faulted regions were free of precipitates. The presence of impurity precipitates around the partial dislocations will be demonstrated in detail in the following section.

A comparison of stacking fault delineation after preferential etching is shown in Fig. 2. Portions of an oxidized wafer were etched using the following etch solutions: (a) Sirtl etch, (b) Secco etch, and (c) Wright etch. The etching time for each etch was 5 min, which was long enough to reveal entire features of OSF's. The most well-defined stacking fault etch pits were produced by the Wright etch. It was found that the Sirtl etch produced OSF etch hillocks while the Secco etch produced deep OSF etch pits. These observations were confirmed by the following examinations of OSF's on the cleavage face.

Figures 3(a) and (b) show the Sirtl-etched (100) surface and the subsequently cleaved (110) surface, respectively. It can be seen that both ends of the fault located at the edge of the (100) surface present hillocks

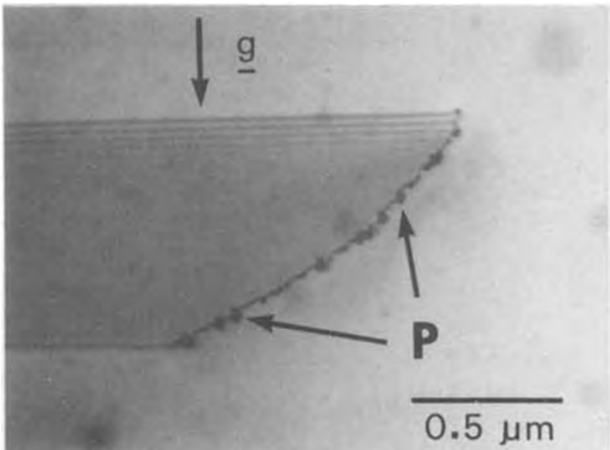

Fig. 1. Bright field transmission electron micrograph of a typical oxidation-induced stacking fault. Note the impurity precipitates (P) around the partial dislocations.

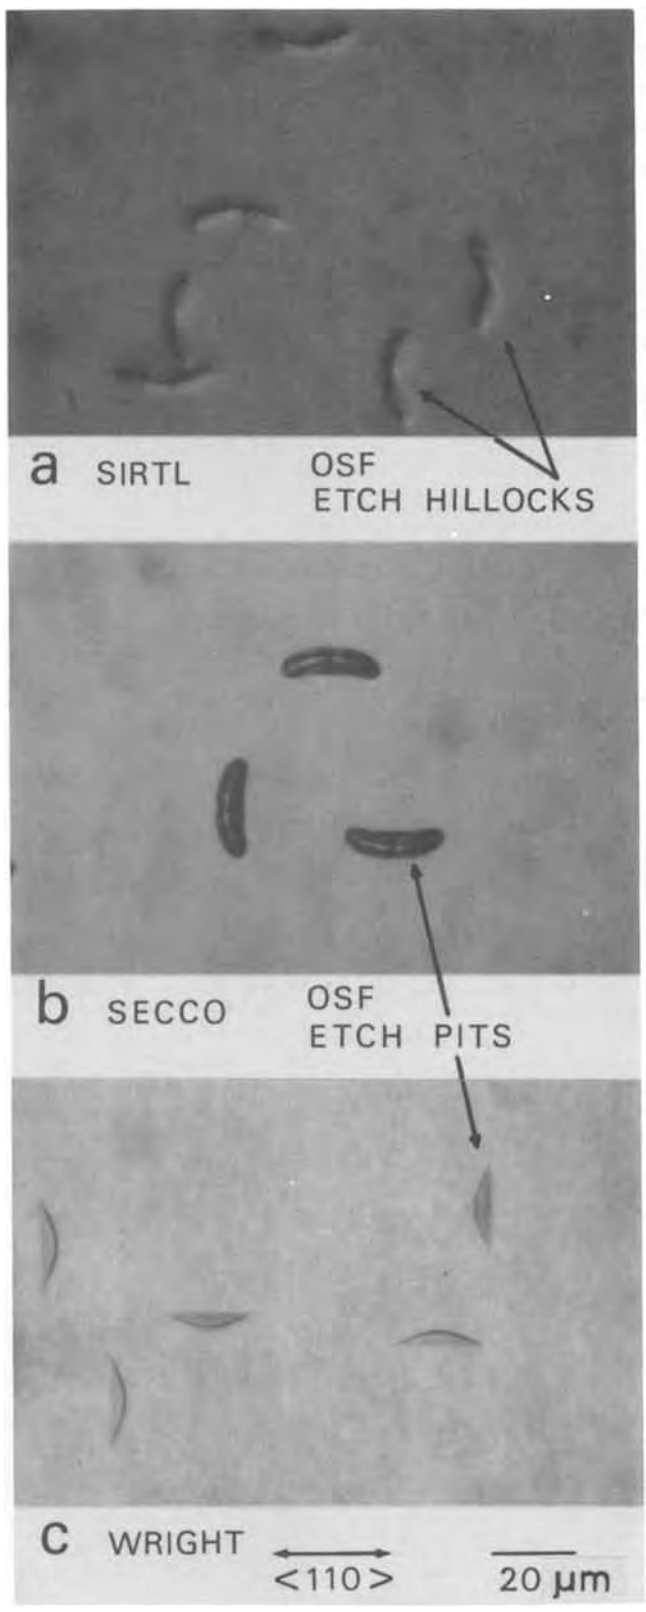

Fig. 2. A comparison of stacking fault delineation of a (100) oriented wafer after oxidation and preferential etching. (a) Sirtl etch, 5 min:interference contrast; (b) Secco etch; 5 min; (c) Wright etch, 5 min.

as shown in Fig. 3. Figure 4 shows the similar examination by the Secco etch at the intersection of the cleavage edge and the stacking fault. In this case, the stacking fault was delineated as the deep pit. By microstructural examination of the pit in Fig. 4 the bounding dislocation had a deeper profile in depth than the faulted region.

Comparison of Clean and Decorated Faults

Detailed TEM studies of impurity precipitates.—Diffraction-contrast experimental results proving the presence or absence of impurity precipitates on stacking faults are demonstrated in Fig. 5. Figures 5(a) and (c) are bright field micrographs of stacking faults in the ungettered (controlled) and gettered regions, respectively. These micrographs were obtained under two-beam dynamical conditions (diffracting vector g = [220], Bragg deviation parameter Sg > 0). In Fig. 5(a), it is observed that the partial dislocation is decorated with impurity precipitates. In Fig. 5(c), precipitates are not observed both at the partial dislocation and in the faulted region. To confirm the presence or absence of precipitates, further diffraction-contrast experiments were performed. As a result it was confirmed that the precipitates were present on the faults which were in the ungettered region and the precipitates were absent on the faults which were in the gettered region. These results are demonstrated in Fig. 5(b) and (d). Figures 5(b) and (d) were obtained under quasikinematical conditions. Figure 5(b) is the bright field micrograph of the same stacking fault as shown in Fig. 5(a), and Fig. 5(d) is that of the same stacking fault as shown in Fig. 5(c). In Fig. 5(b), the array of grain-contrast images is observed around the defective area defined by the partial dislocation. Based on the dynamical theory of electron diffraction [*e.g.*, Ref. (22) and (23)], this shows the presence of impurity precipitates around the partial dislocation. In Fig. 5(d), no grain-contrast image is observed in the defective area defined by the fault and bounding partial dislocation. This shows that the fault and bounding partial dislocation are free of precipitates.

A selective area diffraction pattern analysis was performed to characterize the precipitates. However, the extra spots due to the precipitates could not be observed because of too small amounts of precipitates.

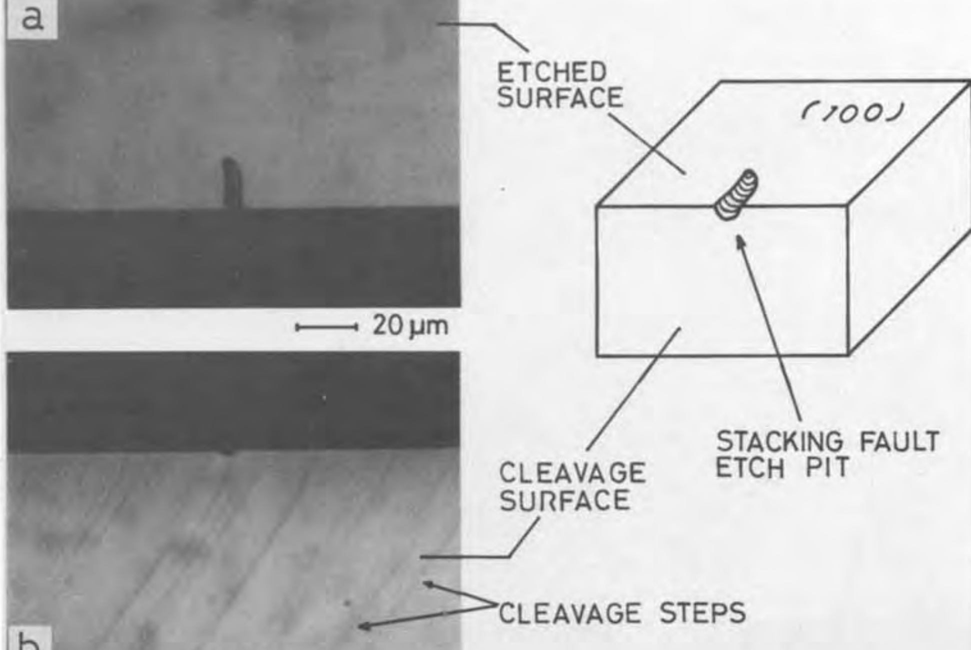

Fig. 4. Optical micrographs of (a) Secco-etched (100) and (b) subsequently cleaved adjacent (110) surface of the oxidized wafer showing extension of the OSF etch pit. Etching period 5 min.

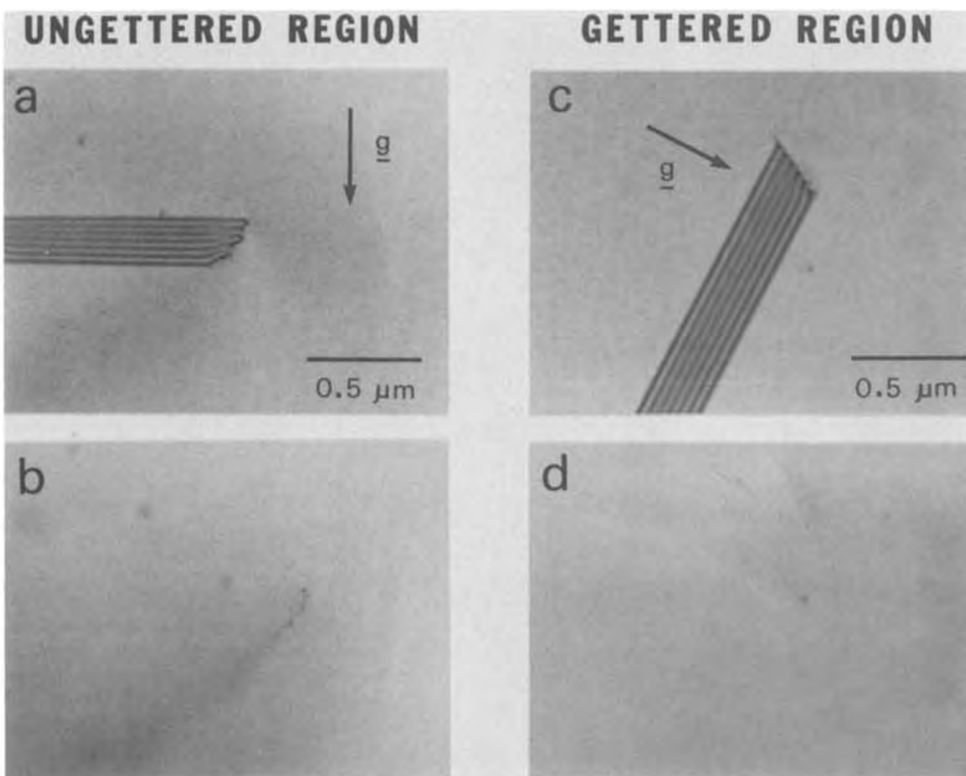

Fig. 5. Bright field TEM micrographs of stacking faults in (a and b) ungettered and (c and d) gettered regions. (a) and (b) show the presence of impurity precipitates around the bounding partial dislocations. (c) and (d) show the absence of precipitates on the fault and the bounding partial dislocations. (a) and (c): two-beam dynamical conditions, g = [220], and $S_g > 0$. (b) and (d): quasikinematical conditions, no Bragg reflection strongly excited.

Sirtl etch results.—The difference in Sirtl etch features between clean and decorated OSF's is shown in the optical micrographs using differential interference contrast in Fig. 6. In the early stages of etching, the decorated OSF's, top left in Fig. 6, were delineated as pairs of etch hillocks at both ends of each fault, where the bounding dislocations intersect the silicon surface. The clean OSF's, top right in Fig. 6, however, were delineated as the very shallow etch grooves which show intersections between fault planes and the (100) silicon surface. On further etching, pairs of etch hillocks of the decorated faults became more pronounced. The morphology of the faults became an oxbow-like hillock as shown in the bottom left in Fig. 6. The appearance of these oxbows, similar to those shown in Fig. 2(a), can be interpreted as the etching-out of the decorated partial dislocations bounding the faults. On the other hand, the shallow grooves of clean faults broaden but not deepen on extended etching. The morphology of the faults, which is shown in the bottom right in Fig. 6, was geometrically similar to the images of stacking faults obtained with the TEM and also similar to the Wright etch figures of OSF's [see Fig. 2(c)].

The above results show that decorated OSF's are distinguished from clean OSF's at any etching stage by using the Sirtl etch. The Sirtl etch, however, produced a rough surface, which is the well-known drawback for (100) silicon. Care should be taken in optical microscopic observation, since the clean stacking fault etch grooves or pits produced by Sirtl etching are so shallow that they cannot be observed clearly without using interference contrast. No interference contrast may lead to a wrong conclusion; one may conclude that no stacking faults are present in this area.

Secco and Wright etch results.—The Secco and Wright etch results are shown in Fig. 7 and Fig. 8. No remarkable difference in etch features between clean and decorated OSF's was observed except that the decorated OSF etch pit appeared prior to the clean OSF etch pit appearance, when Secco or Wright etched lightly. Both the Secco and Wright etches produced clear OSF etch grooves in the early stages of the etching at both the gettered and ungettered regions. With extended etching, familiar OSF etch pits which are peculiar to the respective etching were produced in the both regions. The etch features observed in the bottom left and right in Fig. 7 and those in Fig. 8 were

the same as the etch features in Fig. 2(b) and (c), respectively.

Discussion

The Sirtl etch features of OSF's which have been presented by many workers are similar to those observed in the oxidized wafers in the present work. This suggests that the OSF's generated during the usual oxidation are generally decorated with impurities around the partial dislocations, in some degree. When the degree of decoration on OSF's is large, precipitates exist not only around the partial dislocations but on the faulted regions (9). Rozgonyi and Kushner have showed in an actual device that there are differences in Secco etch pit features between decorated faults from a heavily swirled wafer and clean faults from a "POGO" treated wafer (18). No remarkable difference in etch features by the Secco etch, however, was observed in the present study. This is believed to be related to the degree of decoration and the difference in precipitated materials on the faults between Rozgonyi and Kushner's samples and the present samples, though they did not show the details about precipitates.

The defect delineation can be described as follows (24). The chemical etching of silicon results from an oxidation of the silicon followed by removal of the oxide by HF. In order to delineate a crystal defect as an etch pit, the defect area must be oxidized and removed at a faster rate than the surrounding area. If HF, which removes the oxide immediately, is in excess in the etching solution, the delineation of the defect will be determined by the oxidation rate differential, *i.e.*, etch rate differential, between the defect and surrounding areas. This etch rate differential is accentuated by the slowing down of the solution etch rate.

The reason for the occurrence of the remarkable difference in Sirtl etch features between clean and decorated faults can be explained as follows.

The Sirtl etchant has much oxidizing agent and a higher solution etch rate compared with the Secco and Wright etchants. The etch rates of the Sirtl, Secco, and Wright etches are about 3, 1.5, and 1 μm/min, respectively (19-21, 24). If the etch rate of the defect area is denoted by R_D and that of the surrounding area by R_S, the relationship as $R_D \approx R_S$ will be given in the Sirtl etch because of the higher solution etch rate. This corresponds to the experimental result that the Sirtl etch pits of the clean faults are very shallow and cannot be observed clearly without using interference contrast.

If precipitates on the defect resist the etching, the situation $R_D < R_S$ will be realized easily in the Sirtl etching. The decorated partial dislocations are etched at a slower rate than the surrounding area and consequently, remain as the hillocks. Lawrence has reported that copper precipitates in silicon resist the Sirtl etching (25). The present precipitates are thought to be fast diffusing metallic impurities, such as Cu, Fe, and Au, because the precipitates could be gettered at a lower temperature (1000°C) and for a short period (15 min). Therefore, it is reasonable to assume that the precipitates around the partial dislocations resist the Sirtl etching and affect to slow down the etch rate at the partial dislocations. If the partial dislocation of the fault is free of precipitates, the faulted plane and the partial dislocation will be etched at approximately the same rate, producing a flat figure. On the other hand, both the Secco and Wright etches have a relatively slow solution etch rate, thus $R_D >> R_S$. In addition, it is believed that the precipitates are dissolved

and removed readily with $K_2Cr_2O_7$, a strong oxidizing agent, in the Secco etch formulation. Similarly, HNO_3 in the Wright etchant is considered to act also as a solvent for the precipitates. These are reasons why clear and relatively deep etch pits of both the clean and decorated faults were formed by the Secco and the Wright etches.

The observations that the decorated OSF etch pit appeared prior to the clean OSF etch pit appearance when Secco or Wright etched lightly, can be interpreted that the decorated partial dislocations are etched at a rather higher rate than the clean dislocations.

Schimmel has showed that the Sirtl etch reveals fewer dislocation etch pits and saucer pits, and produces some mounds in virgin and/or oxidized (100) wafers compared to the Secco etch (24). These facts can be explained by the relationship between defect appearance and effects of Sirtl etch on the impurity decoration of the defects in (100) silicon discussed above.

The Sirtl etch produces a rough surface and gives rise to loss of details for the very small stacking faults. An improved or modified Sirtl etch formulation with minimum surface roughness and with good (deep) definition of the clean faults is expected to be developed for the present purpose.

Conclusions

Decorated faults could be distinguished from clean faults by the Sirtl etching at any etching period. The decorated faults were delineated as hillocks, while the clean faults were delineated as flat and geometric pit-features by the Sirtl etch. It was found that the Sirtl etch was more effective in delineating decorated stacking faults than the Secco and the Wright etches.

The Dissolution Kinetics of GaAs in Undersaturated Isothermal Solutions in the Ga-Al-As System

M. B. Small, R. Ghez,* R. M. Potemski, and W. Reuter

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Experiments are described which demonstrate that during the isothermal dissolution of GaAs wafers into undersaturated Ga-Al-As solutions a graded layer of the alloy (GaAl)As is present on the surface. Such a layer can only be formed by solid diffusion. A kinetic analysis of the situation using a value of 5×10^{-12} cm^2 sec^{-1} for the diffusion coefficient of Al in the solid gives a good agreement with the experimental results. The fact that a layer is formed during dissolution is counter to a number of recent publications on the subject, while the measured diffusion coefficient is very different from that measured in bulk MBE material. The significance of obtaining an understanding of this situation is relevant to the formation of all heterojunctions by near-equilibrium processes.

When a GaAs wafer is exposed to an isothermal, undersaturated solution in the Ga-Al-As system, the surface dissolves and a layer of (GaAl)As forms on the surface. This situation has been encountered when determining the phase diagram of the system (1) and in the fabrication of solar cells (2). In both these cases the kinetics have been assumed to involve dissolution, in order to saturate the solution, followed

* Electrochemical Society Active Member.
Key words: kinetics, dissolution, GaAs.

by regrowth to form the layer. A recent analysis of experimental results by Kordos *et al.* (3) has been based on the same assumption. On the other hand, our kinetic analysis (4) suggests that dissolution should be continuous and that Al enters the dissolving solid by diffusion.

This paper describes experiments designed to test which of two models of the process is correct. In order to do this, the solid and liquid phases have been allowed to interact for a range of times about the diffusion relaxation time, t_R (see below), for the liquid. In this time the liquid would become essentially uniformly saturated and if there were any change in the behavior of the interface (such as a reversal of its direction of motion), then it may occur at about that time. Measurements were made of the amounts dissolved from these samples and of the profiles of Al concentration into the solid. Particular attention has been paid to the measurement of the Al concentration at the surface of the solid. If a dissolution-regrowth model was correct, then one would expect some change in the surface concentration between these two states, while our analysis predicts that the surface concentration should be essentially constant. Also, if dissolution is shown to be continuous with time, while at the same time the thickness of a surface layer containing Al becomes greater, then this must disprove the dissolution-regrowth model. Our model suggests that the Al enters the dissolving solid by diffusion, and the measurements enable the coefficient of diffusion under these conditions to be calculated.

The import of obtaining a correct understanding of the process is neither limited to this crystal system nor to the process for fabricating solar cells. The liquid phase epitaxy (LPE) process is used to make a number of heterostructure devices in a variety of crystal systems. It is vital, therefore, to have a satisfactory understanding of the chemical physics of heterostructure formation and a reliable model of the kinetic processes which occur.

Experimental

GaAs wafers were prepared for LPE using a normal combination of chemical-mechanical polishing and chemical etching. The LPE process was performed using an apparatus which has been described elsewhere (5), but the essence of which is a graphite crucible in which a number of solutions may be presented to a wafer in sequence. Two solutions were used for each of the experiments described here. The purpose of the first was to grow a layer of approximately 20 μm of GaAs onto the wafer to present a clean surface to the second solution. The first solution was originally saturated and the layer was produced by cooling the system by 23° to 835°C. The cooling program was then stopped for a period of 15 min after which time the system had reached a stable temperature for the isothermal part of the experiment.

The second solution was made up to contain 1.41g of Ga and 20.5 mg of Al. The geometry of the well containing the solution defined the depth, L, to be 1.5 mm. Using the measured value for the diffusion coefficient, D_{As}, of As in a Ga solution at this temperature, 5×10^{-5} cm^2 sec^{-1} (6, 7), one can calculate the diffusion relaxation time, $t_R = L^2/D_{As}$, of the solution to be 450 sec and then define dimensionless time $\tau = t/t_R$. The experiment was repeated with the exposure times of the wafers to the solutions being fixed at $t = 45$, 180, 720, and 2790 sec, or $\tau = 0.1$, 0.4, 1.6, and 6.2. By exposing only part of the area of the wafer to this second solution, the remainder served as a reference plane from which the amount dissolved could be measured. If, following the processing of a wafer, any drops of solution were left on parts of the surface, these areas were cleaved away.

It can be seen, both from the simulation and the experimental results, that for $\tau \leq 1$ the process was dominated by large changes in the compositions of the solutions as they become saturated. For longer times the driving force is for the bulk solid to tend towards equilibrium; this is a very much slower process limited by solid diffusion. Thus the dissolution rate becomes very small for $\tau > 1$, Fig. 2; and, consequently, during this phase of the process the experiment becomes very sensitive to both temporal and spatial thermal variations. We calculate, for example, that a layer as thick as that formed on the sample exposed for $\tau = 1.6$ would be either dissolved or as much grown if the temperature fluctuated by 0.5°C in the time interval between this and $\tau = 6.2$. For this reason we have only used the latter experiment to demonstrate that dissolution was taking place when the first three samples were removed from their solutions.

The amount dissolved from each surface was determined using the calibrated focusing mechanism of a microscope to measure the displacement of the surface exposed to the second solution compared to the reference surface. Since this involved traversing the sample from one region to another, checks were made that the traversing plane was normal to the measurement direction by rotating the sample. There was considerable roughness on the dissolved surfaces, which both precluded some alternate methods of measurement and produced a larger error than is inherent in this method. One form of surface roughness was on the scale of the sides of the solution well and was thought to be due to solutal convection during rapid dissolution. Figure 1 shows two finer scaled morphologies. One of these has a spacing of the order of 20 μm and may be similar to those observed by Nishinaga *et al.* (8) on dissolved surfaces of InP. The closed loops shown in the figure were unusual, but the same spacing was normally present in a linear array. Also shown in the figure is a finer structure, which does not appear to have been remarked upon before. Although one of these patterns might be explicable in terms of the constitutional variations which occur on a perturbed interface, and the resulting two-dimensional transport effects in the two phases (9), it is difficult to associate both with such a mechanism. The uncertainties in the measurements shown in Fig. 2 are a result of a combination of these morphologies. Of these, the contribution due to the larger features shown in Fig. 1 could be as great as 1 μm. In sputter etching these surfaces, it has been assumed that the rate of removal was uniform over the surface.

Secondary ion mass spectroscopy (SIMS) was used to determine the profiles of Al into the dissolved surfaces. The secondary ion mass spectrometer is

Fig. 1. A Nomarski interference contrast micrograph of a dissolved surface illustrating the two finer scale morphologies which occur. The longer side of the figure represents 680 μm.

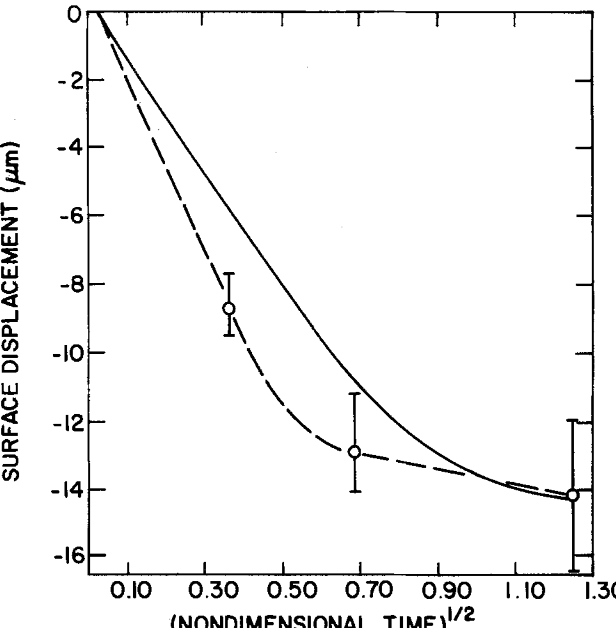

Fig. 2. This illustrates the amounts dissolved from the surfaces as a function of $\tau^{1/2} = (D_{As}t)^{1/2}/L$. The data points may be compared with the results (solid line) of the computer simulation.

an integral part of a surface analysis system including Auger and photoemission spectroscopy. A detailed description of this system will appear shortly elsewhere. Primary ion beams of reactive or inert gases are produced in an ion gun built by Atomike Technische Physik, GmbH, Munich, which is discussed by Wittmaack (10). In this study we used a 12 and 6 keV O_2^+ beam mass analyzed by a Wien filter and focused to about 20 μm onto the target with an Einzel lens. The beam was raster scanned to cover an area of 750 $\times$ 950 μm, but the scaler was gated to count only during the central 5% of the scanned area. Secondary ions emitted from the target are first energy analyzed by an energy filter (11) before mass separation by a quadrupole mass spectrometer. This filter was set to transmit positive ions of approximately 10 eV and the energy distribution was scanned by variation of the bias potential of the target. For the data presented here we used a fixed bias potential corresponding to the peak in the energy distribution of the secondary ions $^{27}Al^+$ and $^{69}Ga^+$.

This analytical technique is generally utilized to measure the relative concentrations of components which are present in the host lattice at low concentrations, such that one would not expect the secondary ion yield to vary as material was removed. In this instance the components of interest constitute a substantial proportion of the lattice. A separate experiment was carried out to investigate this. The $^{27}Al^+$ concentration was measured through a heterostructure laser grown by LPE in which the compositional ratio between the active region and the clad layers was known, from the phase diagram (12) and growth conditions, to be 3.5. The measured ratio was 3.2. Because the active layer was thin ($\sim$0.2 μm), the measured concentration in this layer was likely to be high tending to reduce the measured ratio. Thus, the change in secondary ion yield is less than 10% in this range. This calibration is sufficiently accurate for our present purpose, which is to demonstrate constant surface composition during dissolution and obtain an estimate for the diffusion coefficient of Al in the solid.

Results and Analyses

The three data points in Fig. 2 are the displacements of the interface of the three samples processed for the shortest times. They are plotted against $\tau^{1/2}$. The additional data point mentioned earlier was -16.8 μm at $\tau = 6.2$ and this is cited to demonstrate continuous dissolution for the first three samples.

The data points in Fig. 3 illustrate the Al concentrations as functions of depth into the solid as measured using SIMS. For each sample the data set is representative of a number of repeated measurements which showed no significant differences. Absolute measures of concentration are not possible using this technique so these are expressed in terms of the numbers of counts. Some samples were profiled using different sputtering current densities and these have been normalized to the same value. Manual adjustments were made to maintain a constant sputtering current. The corresponding changes in the numbers of counts can be seen as noise on the data set for the sample with the smallest change in Al concentration. At the end of the sputtering process the depths of a number of craters between 1 and 2 μm deep in relatively smooth regions of the surface were measured using a Talysurf to transform a time scale into a depth scale.

The data in Fig. 2 and 3 show quite clearly that there is an Al-containing layer of finite thickness on the surfaces of the samples which were dissolving when withdrawn from their solutions. Also, it can be seen that the sharpest profile occurs at the fastest dissolution rate, as one would expect for a diffusive process.

An important test of our kinetic analysis is that it predicts an essentially constant surface concentration for all components in all phases (4). We have access to that concentration frozen into the solid. The dissolution-regrowth model (3), on the other hand, does not attempt to provide a consistent model for the whole of the process, but assumes dissolution to a point where the solution is supersaturated, as a whole, and hence regrowth must follow from this assumption. Because there has been no attempt to describe the dissolution process, our only argument against this model must be based upon our interpretation of it. We assume that if the direction of motion of the interfaces changes, then this must be reflected in a change in the surface concentrations; otherwise there would be no driving force for such a change since the phases "sense" one another at the interface. We have used two methods for determining the surface concentration. First, the data points in Fig. 3 have been fitted to polynomial forms (see below) to allow us to extrapolate to the values at the surface. These are the points shown, as open symbols, on the

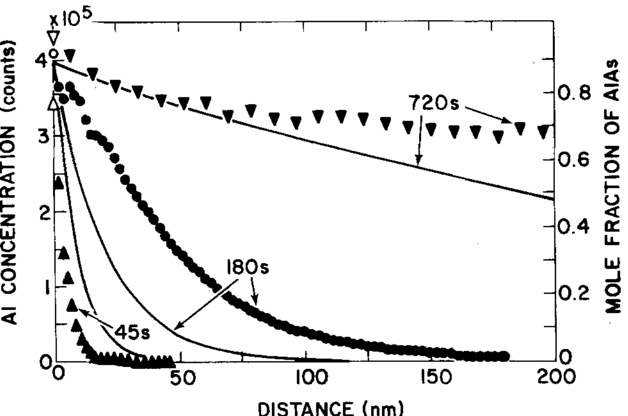

Fig. 3. This illustrates the $^{27}Al^+$ concentrations as functions of depth from the solid surface. The data points were measured under the conditions described in the text while the open symbols show the extrapolated values at the surface for the three profiles shown. The full lines are profiles produced by the computer simulation and refer to the scale on the right. The two scales were matched at the surface of the crystal.

origin of the spatial axis. It can be seen that they are the same within the reproducibility of SIMS measurements, $\pm 10\%$.

The above procedure may be subject to doubt, particularly for the sample $\tau = 0.1$ which was only in contact with the melt for 45 sec and hence exhibits a very steep decline in the $^{27}Al^+$ signal near the surface. For this reason we have repeated the SIMS experiment using only 50 msec counting time, increasing the scanned area to 800×800 μm, and reducing the primary ion current to 50 nA operating at 12 keV. For these conditions we estimate a removal rate of 0.06 Å sec^{-1} from Talysurf measurements made at 500 nA but otherwise identical conditions. The results are shown in Fig. 4. The upper six curves show the $\log_{10}$ intensity of $^{27}Al^+$ and $^{69}Ga^+$ for each of the three samples sputtered for 1000 sec corresponding to the removal of about 60Å of material. In the early phase of the sputtering process both signals increase, probably due to the removal of a hydrocarbon contamination layer (see below) from the surface. Note that the rate of increase during this early phase is much higher for Al than for Ga. This can be attributed to the preferred sputtering of the lower atomic weight component as discussed by Kelly (13) and studied in detail also by Liau *et al.* (14) and Ho *et al.* (15). More difficult to understand is the appearance of a maximum in the $^{69}Ga^+$ emission near the surface, which recovers in intensity after about 300 sec of sputtering time. This effect is reminiscent of a similar observation by Anderson (16) when bombarding Al with O^{2+} ions. Anderson attributed the initial peak to the presence of a thin Al_2O_3 layer on Al and the final recovery of the Al intensity later in the sputtering process due to the conversion of the Al to an Al_2O_3 film under O_2 bombardment at a depth corresponding to the range of the primary projectile. Implantation of oxygen, which is more electronegative than arsenic, may indeed explain the initial intensity variation in the $^{69}Ga^+$ signal. Note that the transient features in the sputtering process can be discussed without invoking, but not necessarily excluding, the possibility of compositional variations near the surface. After about 300 sec a steady state is reached, when the value for the intensity ratio of $^{27}Al^+$ to $^{69}Ga^+$ is constant within 5% for the samples $\tau = 0.4$ and $\tau = 1.6$. This indicates an identical composition of both samples after the removal of about 20Å. For the sample $\tau = 0.1$, which is of primary interest in this study, we find the concentration of Al already decreasing when steady-state conditions are attained. In the lower part of Fig. 4 we have plotted the $^{27}Al^+$ signal on a linear scale as a

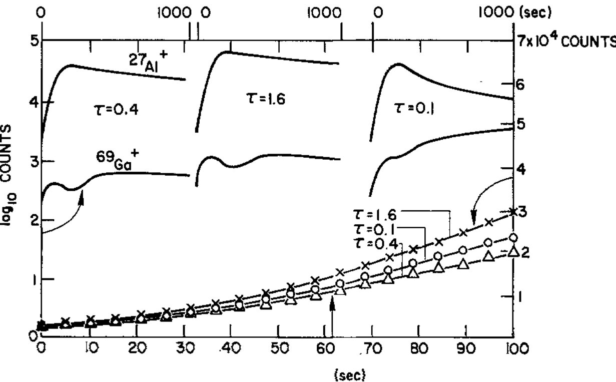

Fig. 4. The intensity of $^{27}Al^+$ and $^{69}Ga^+$ as a function of time raster scanning a 12 keV O_2^+ beam of 50 nA over an area of 800×800 μm gating 5% of the central portion of the scanned area and counting each isotope for 50 msec. The upper six curves show the $\log_{10}$ intensity of $^{69}Ga^+$ and $^{27}Al^+$, sputtering each sample for 1000 sec (~60Å), whereas the three lower curves show the counts for $^{27}Al^+$ on a linear scale in the first 100 sec of each run.

function of time for the first 100 sec of the sputtering process, thus removing only a few monolayers of the targets. Extrapolation of the $^{27}Al^+$ signal to the start of the experiment clearly demonstrates that within the experimental error of $\pm 10\%$ the composition is identical for all samples at the surface.

We now fit these data to our model (4). Specifically, we seek an estimate of the diffusion coefficient D_s of Al in the solid, and a reasonable description of the Al concentration profiles. For short times we expect our analytic solution to hold. With minor changes in notation, Eq. [3.6] and [3.7c] of Ref. (4) for the amount dissolved, h, and the local mole fraction x of Al in the solid are

$$h = 2\beta(D_s t)^{1/2} \quad [1]$$

$$\frac{x - x_\infty}{x_0 - x_\infty} = \frac{\operatorname{erfc}(|z|/2(D_s t)^{1/2} - \beta)}{\operatorname{erfc}(-\beta)} \quad [2]$$

Here, $|z|$ is the distance measured from the actual interface into the solid, x_∞ is the initial composition of the substrate ($x_\infty = 0$ for these experiments), x_0 is the surface composition (approximately equal to the equilibrium value, 0.85), and β is a constant that describes the growth rate. For long times one expects β to be a slowly varying function of time, as is clear from Fig. 2. Now, for small values of $|z|/2\sqrt{D_s t}$ one can expand the function [2] to get

$$\frac{x - x_\infty}{x_0 - x_\infty} = 1 - \frac{|z|}{(D_s t)^{1/2}} \frac{1}{\operatorname{experfc}(-\beta)} - \frac{|z|^2}{2D_s t} \frac{\beta}{\operatorname{experfc}(-\beta)} + \ldots \quad [3]$$

where

experfc (.) stands for the abbreviation

$$\operatorname{experfc}(-\beta) = \pi^{1/2} \exp(\beta^2) \operatorname{erfc}(-\beta) \quad [4]$$

and is asymptotically equal to $(-\beta)^{-1}$ for large negative values of β, as will be the case. The polynomial approximation [3] is compared to a polynomial representation of the 45 sec data of Fig. 3, namely

$$C = C_0(1 + a_1|z| + a_2|z|^2) \quad [5]$$

where C is the number of counts. Least squares fitting yields the values

$$\left.\begin{aligned} C_0 &= 3.46 \times 10^5 \\ C_0 a_1 &= -9.22 \times 10^{11} (\text{cm}^{-1}) \\ C_0 a_2 &= 8.99 \times 10^{17} (\text{cm}^{-2}) \end{aligned}\right\} \quad [6]$$

With these values, the first data point of Fig. 2, namely $h = -8.7$ μm at $t = 45$ sec, and the above formulas, we find $\beta = -34.05$, hence, $D_s = 3.6 \times 10^{-12}$ cm² sec⁻¹.

A value for D_s of 5×10^{-12} $cm^2\ sec^{-1}$ was then used for our simulation. The diffusion coefficient D_{Al} of Al in the liquid was assumed equal to D_{As} (a tenfold change in D_{Al}/D_{As} produced no significant changes in the kinetics). The methods are described in Ref. (4). Briefly, we generate an analytic solution for $\tau = 0.04$, and march this forward in time by finite-difference methods. The results are displayed in Fig. 2, 3, 5, and 6. Figures 5 and 6 show the profiles of As and Al in the solution, assumed stagnant, at $\tau = 0.04$ (the analytic solution) and at those times at which samples were removed from the solutions. It can be seen that there are very steep gradients at short times and that the solution is essentially uniform at $\tau = 1.6$. Also calculated was the dissolution, h, as a function of time; this is compared with the data points in Fig. 2. It can be seen that there is excellent agreement at $\tau = 1.6$. This is to be expected because the solution is then saturated and the amount of dissolution necessary to achieve this is simply determined by the phase diagram. The fact that at short times the dissolution was more than predicted is further

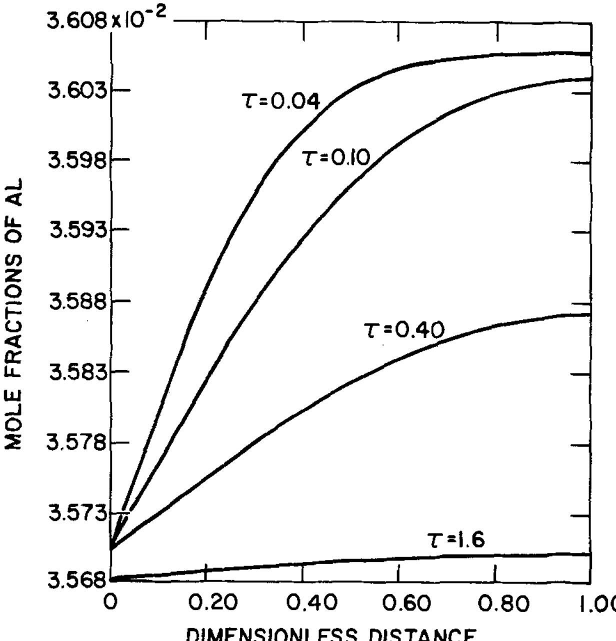

Fig. 5. Showing the concentration profiles of Al in the solutions, as calculated by computer simulation, at a series of times including those when the substrates were withdrawn.

evidence for the fact that the large solutal gradients produced convection in the solutions. The simulation also calculates the Al profiles in the solid and these are compared with the data points in Fig. 3. The measured concentrations were not absolute and so have been scaled to have the same surface concentration as the calculated profiles. The correspondence between theory and experiment is good except for the profile at the intermediate time. In this case, because of the assumed convection, the actual dissolution rate was substantially less than the predictions and this would tend to produce a deeper diffusion profile as the results show.

Two points should be made here concerning the diffusion of Al into the solid. First, the full profile at $\tau = 1.6$, of which only a part is shown, has an inflection point deeper in the material than is shown in the figure. This implies that the diffusion coefficient is not a constant. Secondly, earlier measurements (17, 18) of the diffusion coefficient of Al in (GaAl)As super-lattice structures grown by MBE gives a value of $\sim 10^{-18}$ cm^2 sec^{-1} for the diffusion coefficient at this temperature. Although one may argue that LPE material has a higher concentration of arsenic vacancies (19) and that the diffusion process could involve such vacancies acting in a ring mechanism, the fact that LPE may be used to grow heterostructures in this system with very thin layers (20) indicates that it is not simply a difference between these two materials that accounts for this large effect. It would appear, therefore, that the diffusion coefficient is larger in dissolving than in growing material.

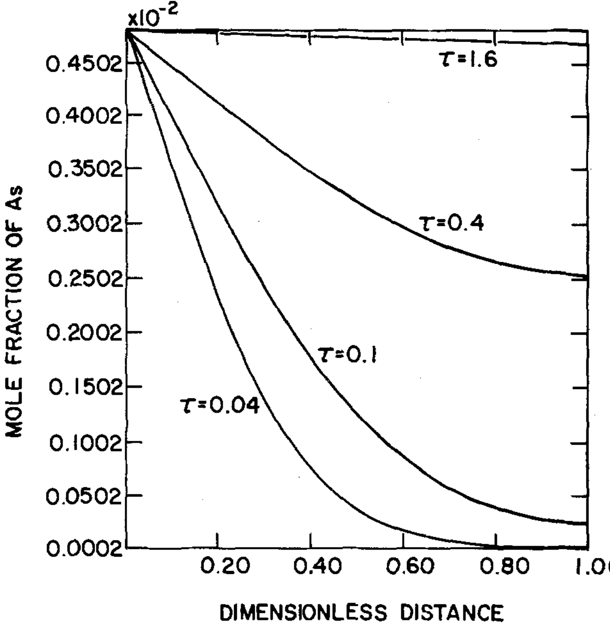

Fig. 6. Showing the As profiles in solution corresponding to those for Al in Fig. 5. Both figures show the initially very large gradient and that the solutions are essentially uniform at $\tau = 1.6$.

Summary and Conclusions

These experiments have demonstrated the following:

1. That GaAs wafers withdrawn from isothermal Ga-Al-As solutions while they were dissolving had layers of finite thicknesses of (GaAl)As on their surfaces.
2. That the surface compositions of these layers are constant, within the accuracy of our measurement technique. This also discounts suggestions that the process occurs in two stages.
3. That data fitting between theory and experiment for a time when the liquid was essentially semi-infinite gave a value of $\approx 5 \times 10^{-12}$ cm^2 sec^{-1} for the diffusion coefficient of Al in the solid close to the surface. (It has also been noted that the diffusion coefficient is a function of either concentration or distance from the surface.)
4. A reasonably good fit has been obtained, when using the above value, for D_s, between a computer simulation and the measured concentration profiles and amounts dissolved.

Thus, it has been demonstrated that our kinetic model of the process is certainly correct inasmuch as these layers are not produced by regrowth. The diffusion coefficient for Al in the solid necessary to explain these results is larger than one would expect. It is obviously of interest to pursue this matter further.

Microdistribution of Oxygen in Silicon

A. Murgai,*[,1] J. Y. Chi, and H. C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The microdistribution of oxygen in Czochralski-grown, p-type silicon crystals (75 mm in diameter and with a resistivity of 10 Ω-cm) was determined by using the SEM in the EBIC mode in conjunction with spreading resistance measurements. The crystals were heat-treated at 450°C to activate oxygen donors. When the conductivity remained p-type, (the oxygen donor concentration did not exceed the dopant concentration), bands of contrast were observed in the EBIC image which were found to correspond to maxima in resistivity, *i.e.*, to dopant compensation maxima and hence, to maxima in oxygen concentration. When at the oxygen concentration maxima the oxygen donor concentration exceeded (locally) the p-type dopant concentration, an inversion of the conductivity occurred. It resulted in the formation of p-n junctions in a striated configuration and the local inversion of the EBIC image contrast. A chemical etching procedure was developed, in conjunction with phase contrast microscopy, to delineate the n-type oxygen striations. By heat-treating silicon at 1000°C prior to the activation of oxygen donors, some silicon-oxygen micro-precipitates were observed in the EBIC image within the striated oxygen concentration maxima.

Variations in oxygen thermal donor concentration, activated by 450°C heat-treatment have been observed in Si (1-3) and determined by spreading resistance measurements (4, 5). The thermal donor concentration is proportional to the oxygen concentration and provides direct information on the microdistribution of oxygen. Such measurements, however, do not provide direct knowledge of the overall state of oxygen, *e.g.*, on the morphology of oxygen concentration variations, on oxygen clusters (6), and on precipitates (7-9). X-ray topography (10) has also been employed for the observation of oxygen concentration variations. This technique is at best qualitative in nature, as no quantitative relationship between topographic contrast and oxygen concentration is as yet available. In addition, the resolution of inhomogeneities by this technique is rather limited.

The electron beam induced current (EBIC) mode of scanning electron microscopy offers several advantages over the above characterization techniques. Dopant striations (11, 12), impurity precipitates (13), and other electrically active defects (14) can be simultaneously observed in the EBIC image with a relatively high resolution. Recently, the EBIC technique has been applied to the quantitative determination of dopant concentration variations (15), and employed in the study of impurity segregation (16). In addition, basic electronic parameters, such as minority carrier diffusion length, lifetime, and their variations (15, 16) can be readily determined with the EBIC technique.

In the present investigation, the EBIC technique has been applied to the study of microscale variations in oxygen concentration and their effects on p-type silicon crystals.

Experimental Procedure

Dislocation-free silicon crystals 75 mm in diameter and boron-doped to a level of about $5 \times 10^{14}/cm^3$ were pulled in the (100) direction from the melt. They were grown with a seed rotation of 5 rpm and a pulling rate of 75 mm/hr. The average oxygen concentration in the crystals, as determined from *IR* measurements (17). was found to be $1.8 \times 10^{18}/cm^3$.

All measurements were made on (100) longitudinal slices, 0.5 mm thick. The slices were heat-treated at 450°C for 50 hr, lapped, and polished with Syton HT. After cleaning with an organic solvent and etching in $HF + HNO_3 + CH_3COOH$, a 0.5 μm Al layer (2 × 2 cm) was deposited on these slices to obtain a semiconductor-metal Schottky barrier (collecting field).

Impact traces of spreading resistance probes were introduced (at 5 or 25 μm intervals) on the Schottky diode to serve as location markers (see also below). EBIC measurements were subsequently conducted in the region of the impact traces with an electron beam accelerating voltage of 35 kV. At the above accelerating voltage the electron range, *R*, lies outside the depletion width of the Schottky barrier for 10 Ω-cm Si (18). The experimental arrangement for the EBIC measurements and imaging is indicated schematically in Fig. 1.

Following EBIC measurements, the metal layer was stripped from the slice with concentrated HCl. Longitudinal variations in the thermally activated donor concentration (introduced by the 450°C heat-treatment) were determined from spreading resistance measurements (at 5 μm intervals) carried out near and parallel to the impact traces introduced earlier, the traces were still present after the metal layer was stripped. The spreading resistance measurements were made employing both polarities of the d-c bias between the two probes. From such measurements, the presence of any

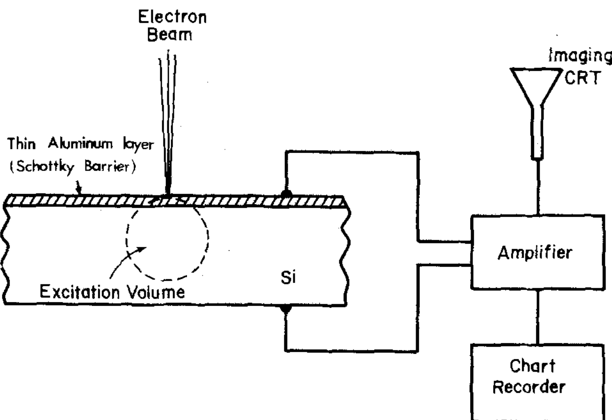

Fig. 1. Schematic diagram of experimental arrangement for EBIC measurements.

p-n junctions formed during the 450°C heat-treatment was readily determined.

The slices were subsequently heat-treated at 700°C for 1 hr to eliminate the oxygen thermal donors (1-3); following this heat-treatment EBIC and spreading resistance measurements were repeated in the identical regions using the impact traces of the spreading resistance probe as reference.

In certain instances, the slices were heat-treated at 1000°C for 12 hr in ultrahigh purity argon prior to the 450°C heat-treatment. The 1000°C heat-treatment induces some form of silicon-oxygen precipitation in the slices as confirmed by *IR* measurements.

Results and Discussion

Oxygen striations—compensation.—Following the 450°C heat-treatment, the presence of oxygen striations is seen in Fig. 2 for a longitudinal slice cut 0.5 mm from the periphery of a typical 75 mm diam. The oxygen striations are seen in the EBIC image [Fig. 2(a)] as bright bands and the corresponding variations in the normalized EBIC and resistivity (as determined from spreading resistance measurements at 5 μm intervals) are shown in Fig. 2(a) and (b), respectively.

As can be seen from Fig. 2(a) and (b), there is direct spatial correspondence of the variations in the normalized EBIC and resistivity; the large variations (exceeding a factor of 10) in resistivity following the 450°C heat-treatment reflect corresponding variations in the oxygen thermal donor concentration (and, hence, in the oxygen concentration), since variations in the boron acceptor concentration are less than 12% (see below); the oxygen striations in the EBIC image, Fig. 2(a), manifested as bright bands, correspond to the maxima in resistivity [Fig. 2(b)] which in turn correspond to oxygen concentration maxima. Maxima in resistivity are expected to coincide with maxima in oxygen thermal donors, since the higher the concentration of the thermal donors, the higher the compensation of the p-type dopant and hence the higher the resistivity (provided the concentration of thermal donors does not exceed the concentration of the acceptors).

In the regions of maximum resistivity, the space charge region (depletion width) of the Schottky diode is significantly increased. For resistivities of about 200 Ω-cm the depletion width is several microns but well within the excitation volume of a 35 keV electron beam. Accordingly, the collection efficiency of the excess carriers is enhanced in these regions of the oxygen concentration maxima and consequently appear as bright bands in the EBIC image.

As seen in Fig. 2(a) and 2(b), the width of the EBIC maxima (*e.g.*, the width at half the maximum value) is larger than that of the resistivity maxima. This result is apparently due to interference effects of the electric fields resulting from the resistivity variations.

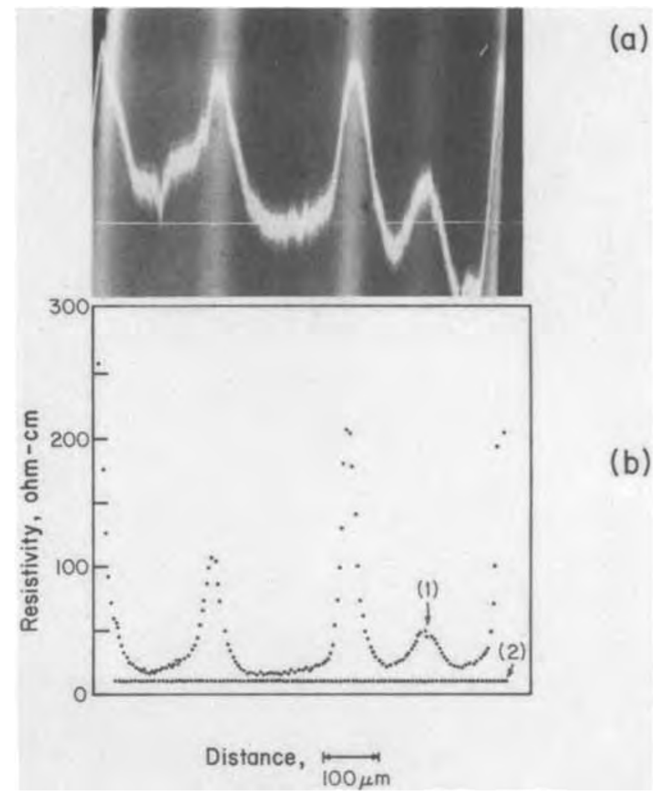

Fig. 2. (a) EBIC image and superimposed EBIC tracing taken along indicated line on a sample cut near crystal periphery (see text). (b) Resistivity profile as determined by spreading resistance measurements at 5 μm intervals along the line indicated in EBIC image after 450°C heat-treatment, curve 1; profile taken prior to 450°C heat-treatment, curve 2; small variations of boron concentration are not visible on this scale.

Since the spacing of the spreading resistance impact traces in the EBIC image is 5 μm, it is seen from a comparison of the resistivity and the normalized EBIC that the linear resolution attained by the EBIC technique in the present case is about 10 μm.

It has been found that heat-treatment of Si at 700°C eliminates oxygen thermal donors (1-3). Consistent with this finding, after heat-treatment of the slices studied above at 700°C for 1 hr, their EBIC images exhibited no bands. The normalized EBIC and resistivity measurements carried out in the same regions as discussed above exhibited small variations.

These variations are due to B-dopant fluctuations which in 10 Ω-cm Si are about 12% [Fig. 2(b)]. These B-dopant fluctuations are not resolved in the EBIC image.

Oxygen striations and overcompensation.—Longitudinal slices cut 1 cm from the crystal periphery were also investigated. They were also treated at 450°C for 50 hr and prepared for EBIC and spreading resistance measurements as discussed above.

The EBIC image of one of these slices is shown in Fig. 3(a). Spreading resistance measurements were carried out at 5 μm intervals, 20 μm below the horizontal impact trace markers which are spaced 25 μm apart and are clearly shown in the EBIC image. Dark bands are seen in the EBIC image which correspond to resistance minima in Fig. 3(b). These dark bands (regions of low collection efficiency of excess carriers) correspond to oxygen striations in which the donor concentration exceeds the concentration of the p-type dopant forming striated n-type regions (see below). Since the donor concentration is a direct function of the oxygen concentration (2), the presence of n-type regions only in the slices cut 1 cm away from the periphery shows that the mean oxygen concentration is higher

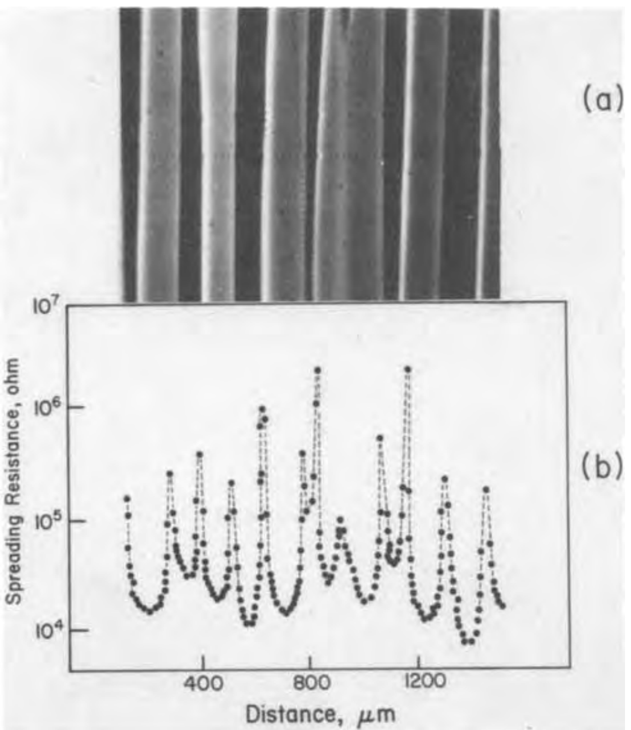

Fig. 3. (a) EBIC image on sample cut away from crystal periphery. Reference impact traces are clearly visible. (b) Spreading resistance profile taken at 5 μm intervals, 20 μm below horizontal line of reference tracers.

away from the periphery than near the periphery of the crystals. The bright bands (adjacent to the dark bands) in Fig. 3(a) correspond to regions of maxima in compensation as in the case of Fig. 2(a) but not to maxima in oxygen concentration.

The conductivity type within the dark bands was determined as follows: employing a two-probe spreading resistance measurement arrangement, measurements were carried out at 5 μm intervals with one of the probes positioned at all times on a dark band as shown in Fig. 4(a). As shown in Fig. 4(b) with the probe on the dark band having a negative polarity the measured resistance was about $8 \times 10^5 \Omega$. When the bias was reversed the resistance increased by about three orders of magnitude. Thus, there is a p-n junction at the boundary of each dark band and the adjacent bright band; the dark band is n-type and corresponds to a region overcompensated by thermal oxygen donors. After a 700°C heat-treatment (which eliminates the thermal oxygen donors) no dark bands in the EBIC image nor pronounced variations in resistance were present; this result confirms that the n-type regions (dark bands) are the result of oxygen donors.

Chemical etching.—It was found that oxygen striations can be conveniently revealed by chemical etching when they form n-type regions in p-type silicon. The etchant found suitable for this purpose is 20 parts $CH_3COOH + 3HNO_3 + 1HF$. An interference contrast photomicrograph of the slice etched for 20 min (after the metal layer was removed) is shown in Fig. 5. The area depicted in this figure is identical to that in the EBIC image of Fig. 3(a). It is seen that the striations in Fig. 5 correspond exactly to the dark band in Fig. 3(a). The bright bands (region of compensation maxima) could not be revealed by etching. Thus, a bright band in location D of Fig. 3(a) does not appear in Fig. 5; similarly, no oxygen striations could be revealed by etching on slices cut near the crystal periphery which correspond to oxygen concentration maxima but lead to maxima in compensation as in the case shown in Fig. 2(a).

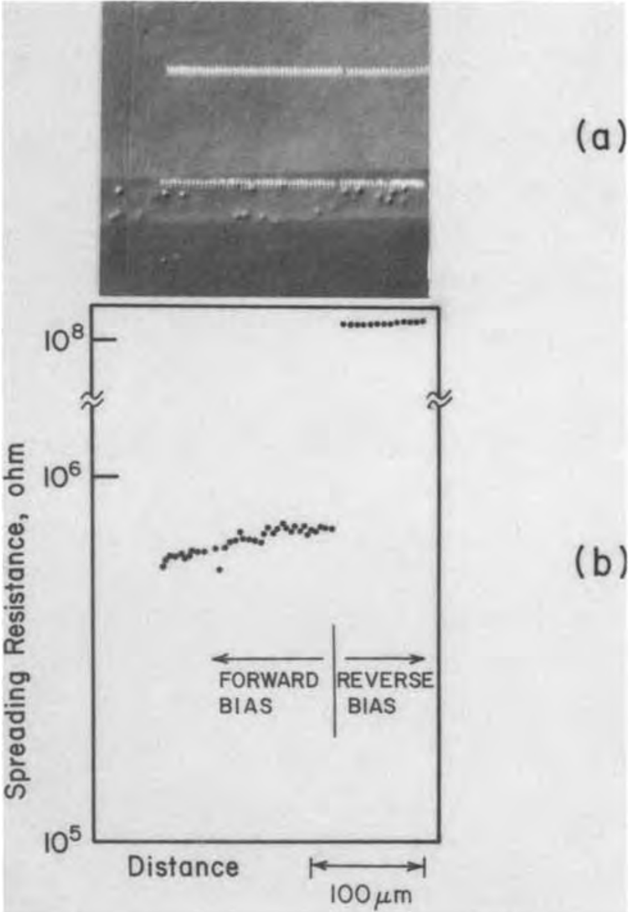

Fig. 4. (a) Optical photomicrograph of chemically etched surface (see text) showing impact traces of two-probe spreading resistance measurements. Traces of one probe are within dark band measurements of EPIC image (Fig. 2) while traces of other probe are outside dark band (for convenience the dark band is shown in the horizontal position). (b) Spreading resistance measured with both polarities of the d-c bias. Polarity was reversed at the discontinuity of the impact traces.

SiO_2 precipitation.—Silicon slices heat-treated at 1000°C for 12 hr prior to heat-treatment at 450°C (for activating thermal donors) exhibited silicon-oxygen precipitation (19). An EBIC image of a slice cut from near the periphery of the crystal is shown in Fig. 6(a). It is seen that within the bright bands [corresponding to maxima in resistivity, Fig. 6(b); compare also with Fig. 2] there are dark spots with low excess carrier

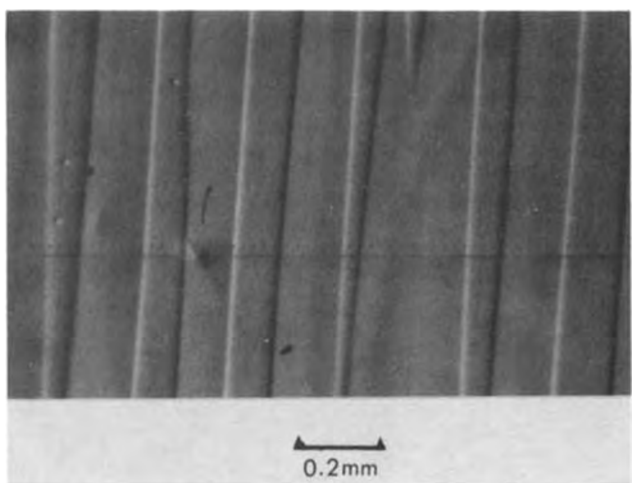

Fig. 5. Optical photomicrograph of chemically etched sample showing the identical region as EBIC image of Fig. 3(a).

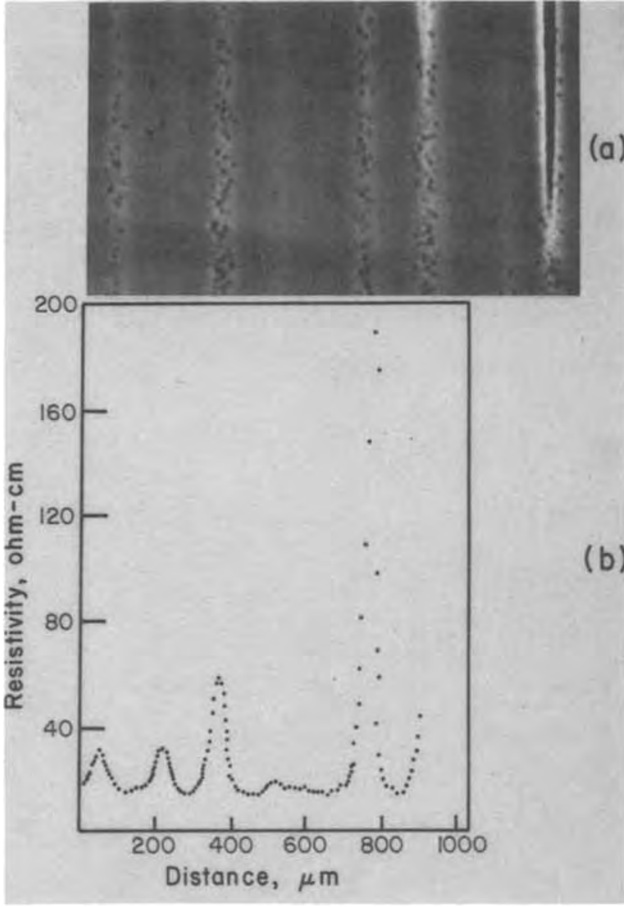

Fig. 6. (a) EBIC image of sample heat-treated at 1000°C prior to a 450°C heat-treatment. (b) Resistivity as determined from spreading resistance measurements.

collection efficiency which are associated with microprecipitates (and related loops and stacking faults). On the right-hand side of the EBIC image there are two dark bands, corresponding to overcompensated, n-type regions, which also contain microprecipitates. Apparently, the 12 hr 1000°C heat-treatment causes only partial precipitation of oxygen, since a subsequent 450°C heat-treatment leads to the formation of thermal oxygen donor striations (bright and dark bands in the EBIC image). The fact that the microprecipitates are associated with oxygen was confirmed by *IR* transmission measurements which showed that after the 1000°C, and prior to the 450°C, heat-treatment the interstitial oxygen content in Si was reduced.

As in the cases discussed earlier, heat-treatment at 700°C eliminates the oxygen donor striations, however, the microprecipitates can still be seen (Fig. 7).

Although the detailed nature of the micro-defects generated by these precipitates will not be discussed in the present communication, it should be pointed out that the morphology of the etch pits, revealed by the Sirtl etchant, was found to correspond to that associated with stacking faults as discussed in the literature.

Summary and Conclusions

The distribution of oxygen in Czochralski-grown p-type silicon was studied by scanning electron microscopy in the EBIC mode in conjunction with spreading resistance measurements. A linear resolution of about 10 μm was achieved in the determination of oxygen distribution. Through generation of thermal oxygen donors (by heat-treating at 450°C) it was found that oxygen is distributed in a striated pattern. At the oxygen concentration maxima, maxima in dopant compensation occur, provided the thermal donor concentration does not exceed the p-type dopant concentration. These compensation maxima appear as bright bands in the EBIC images (high collection efficiency regions of excess carriers) and exhibit high resistivity as determined by spreading resistance measurements. If at the oxygen concentration maxima the thermal donor concentration exceeds that of the p-type dopant, then dopant overcompensation takes place. These regions become n-type and appear as dark bands (low collection efficiency regions of excess carriers) adjacent to bright bands (highly compensated regions). The boundaries of these regions constitute p-n junctions which could be individually characterized with a two-probe spreading resistance arrangement.

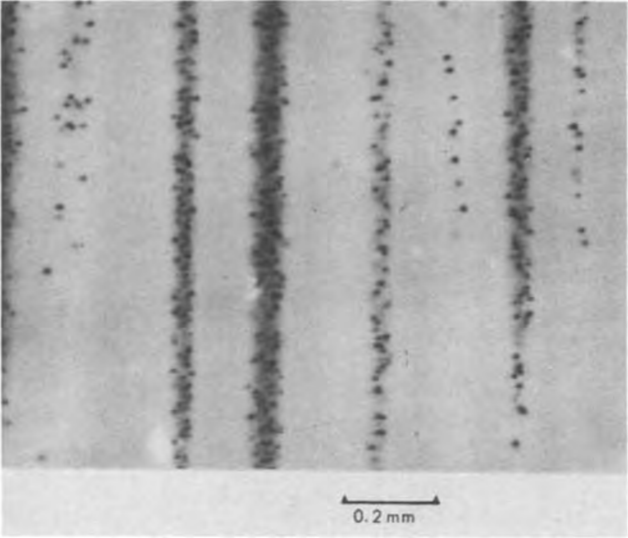

Fig. 7. EBIC image of sample heat-treated at 700°C after heat-treatments at 1000° and 450°C.

Oxygen precipitates resulting from a heat-treatment at 1000°C were found to be distributed in a striated pattern and within the regions of oxygen concentration maxima. Unlike the thermal oxygen donors the precipitates were not eliminated by prolonged heat-treatment at 700°C.

Etching with a mixture of 20 parts CH_3COOH + $3HNO_3$ + 1HF was found to delineate conveniently and accurately the oxygen striations in the cases where the oxygen donors overcompensate the p-type dopant (dark bands in the EBIC image); this etchant also revealed oxygen precipitates. However, the oxygen striations could not be revealed by etching in the cases where the oxygen donors do not overcompensate the p-type dopant.

The EBIC technique employed in the present study, in conjunction with spreading resistance measurements, is well suited for quantitative study of the microsegregation of oxygen in silicon and its quantitative interactions with electronic phenomena and defect structure. It should be finally noted that controlled formation of p-n patterns through controlled incorporation of oxygen in silicon could be advantageously employed for photovoltaic cell and other device applications.

The Influence of Preparation on Semiconducting Rutile (TiO_2)

L. A. Harris and R. Schumacher

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Three processes for doping rutile crystals, vacuum reduction, hydrogen reduction, and electrochemical hydrogen loading are considered. The mechanisms by which n-type conductivity is produced, the relative disorder in the crystal, and the effects on photoelectrochemical behavior are compared for these different processes.

Rutile has received a great deal of attention as an electrode in photoelectrochemical studies. It is usually made conducting by some form of reduction such as heating in vacuum, in hydrogen, or by introducing an appropriate impurity such as fluorine. More recently it has been shown that conductivity can be induced by electrochemically charging the TiO_2 with hydrogen at room temperature (1, 2). It is the purpose of this note to suggest that the materials produced by these doping processes have different chemical and physical structures that influence their electronic behavior as photoelectrochemical electrodes.

Vacuum Reduction

To produce conductivity in a TiO_2 crystal by vacuum treatment, temperatures exceeding about 700°C are required (3). It has been established that the crystal loses weight during this treatment due to the loss of water and oxygen (4, 5). The oxygen vacancies so formed leave some of the Ti atoms in the 3+ state and these can readily act as donors, providing electrons to the conduction band. Relatively high temperatures are required because bonds between an O atom and the remainder of the lattice must be broken so that O can diffuse out of the crystal.

Some disorder is introduced by this reduction process, and interstitial Ti atoms have been detected by channeling experiments (6). As oxygen content is decreased the crystal rearranges itself to accommodate the various Magneli phases by introducing shear planes or grain boundaries where extra titanium atoms are located (7-9).

The disorder in the crystal manifests itself in the photoelectrochemical characteristics. The poor response to longer wavelengths of light which are absorbed deep in the crystal and the low quantum efficiency are indicative of short hole diffusion lengths due to a high density of bulk recombination sites (3).

Vacuum reduction appears to be the only process by which hydrogen, evidenced by OH absorption peaks in the infrared spectrum, can be removed from these crystals (10, 11).

Hydrogen Reduction

If rutile is heated in hydrogen, conductivity can be induced at temperatures roughly 200°C lower than those required to induce comparable conductivities by heating in vacuum (3). The presence of hydrogen in the crystal is shown by the appearance of OH absorption peaks, indicating that the hydrogen is bound to O atoms of the lattice. There are usually two peaks, one at 3276 cm^{-1} and a smaller one at 3323 cm^{-1} (10, 11). One might speculate that the peak at 3276 cm^{-1} is due to H bonded between two lattice O atoms (10) and that the peak at 3323 cm^{-1} is due to H bonded to a single lattice O atom. These peaks are not to be confused with those due to surface-adsorbed OH which occur at 3620 and 3680 cm^{-1} (12). This interpretation is consistent with the appearance of a third peak at 3345 cm^{-1} in samples etched in molten NaOH (Fig. 1). This third peak, attributable to interstitial OH groups is removed by heating in H_2 but not by heating in O_2.

Recent observations of the diffusion of tritium in TiO_2 agree with computed values under the assumption that the tritium is bonded to lattice O atoms (13, 14). In contrast to the vacuum reduced case no O atoms need be lost from the crystal and the crystal order is not so seriously disturbed. We may think of the conductivity as being produced by the change of divalent O ions to monovalent OH ions, thus leaving Ti^{3+} ions

Key words: semiconductor electrodes, photoelectrochemistry, hydrogen, doping.

to act as donors, without leaving their central positions in the surrounding octahedra of O atoms. This process is analogous to doping with fluorine, in which divalent O is replaced by monovalent F, leaving an extra electron on the Ti atom (15).

To produce an OH group, one of the oxygen bonds must be switched from a Ti to an H atom. The activation energy for this process must be less than that to simply break O-Ti bonds, without reestablishing them, so that O vacancies can be produced, hence the lower temperatures required for reduction in hydrogen than in vacuum. Hydrogen reduction at higher temperatures can result in the production of both OH groups and oxygen vacancies with the attendant crystal disorder.

The photoelectrochemical behavior of electrodes reduced in hydrogen at the relatively low temperatures of 550°-650°C are consistent with a high degree of order, hence longer hole lifetimes and fewer bulk recombination centers. The observed quantum efficiencies are higher than for vacuum reduced samples, particularly in the long wavelength region approaching the edge of the absorption band (3).

Electrochemical Loading

It has been demonstrated that the density of donors in a lightly doped rutile electrode can be enormously, but temporarily, increased by operating the electrode cathodically so as to generate hydrogen at its surface. The original doping of the crystal, necessary to operate it as an electrode, can be done either in hydrogen or in vacuum. The extra conductivity induced by the generation of hydrogen is attributed to the diffusion of H atoms into the crystal where they donate their electrons to the conduction band, leaving interstitial protons (2).

There are several indications that the protons are not bound to the crystal lattice. This form of doping is much more temporary than the higher temperature processes. The increased donor density induced by electrochemical loading disappears in the course of a few hours if the crystal is just left standing, either in electrolyte or in air. The capacitance of the depletion layer, which reflects the donor density, decreases more rapidly as the field strength in the depletion layer is increased, suggesting the presence of mobile positive charges (2). Recent measurements indicate that the

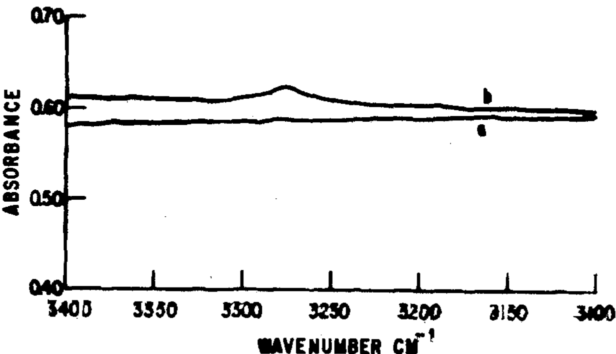

Fig. 2. Infrared absorption of a vacuum reduced crystal: (a) after vacuum reduction; (b) same crystal after hydrogen loading.

hydrogen, which usually leaves the crystal as it entered as neutral H atoms, leaves as protons if the surface field exceeds the critical value of about 10^6 V/cm (16).

Vacuum reduced TiO_2 crystals can be heavily loaded electrochemically with hydrogen, enough to give the crystal a temporarily bluish cast, yet the infrared absorption spectrum taken promptly after loading does not show an appreciable density of OH groups (Fig. 2). Thus the hydrogen introduced electrochemically cannot be bound to the lattice, except possibly where some O atoms had dangling bonds due to the original vacuum reduction.

As might be expected, the photoelectrochemical properties of rutile electrodes charged with hydrogen at room temperature are similar to those of well-ordered hydrogen-reduced crystals previously annealed in oxygen. The quantum efficiencies are relatively high and the short wavelength response is improved by the loading (2). There is some decrease in long wavelength response near the absorption edge. This decrease at heavy loadings can be shown to result from the decrease in depletion layer width. In this case most long wavelength photons are absorbed well beyond the depletion layer and in a field-free region where the collection efficiency of holes is somewhat reduced. These electrode properties are of only academic interest in this case, because in normal operation the hydrogen soon leaves the crystal.

This brief review of some of the properties of semiconducting rutile is far from complete, neglecting as it does, possible changes in band structure, the results of ESR studies, and other components of the extensive literature on TiO_2. Nevertheless, the viewpoint offered here, it is hoped, may be helpful to others in clarifying some of the controversies regarding the nature of donor species produced by different preparatory treatments.

Acknowledgment

ABSTRACT

The arsenic concentration (C_{As}) in polycrystalline silicon (poly-Si) deposited under various deposition conditions in the deposition temperature range 670°-760°C using SiH_4-H_2-AsH_3 gas system has been determined by neutron activation analysis. From the experimental results, it was found that C_{As} increases with decreasing deposition temperature and with increasing partial pressure of AsH_3 in the gas introduced into the reactor ($P_{AsH_3}{}^{(i)}$), and that for lower $P_{AsH_3}{}^{(i)}$ region, C_{As} decreases with decreasing gas velocity and with increasing deposition rate, and for higher $P_{AsH_3}{}^{(i)}$ region, C_{As} is independent of gas velocity and deposition rate. From the analyses of the experimental data, it was suggested that (*i*) for lower $P_{AsH_3}{}^{(i)}$ region, C_{As} is limited by the diffusion of As-containing species, such as As molecule, As_2 molecule, and As_4 molecule, in the stagnant layer formed by gas stream, and for higher $P_{AsH_3}{}^{(i)}$ region, C_{As} is controlled by the surface reaction; (*ii*) monatomic As existing at wafer surface is incorporated in poly-Si in accordance with Henry's law; (*iii*) the transfer coefficient of As atoms in gas phase increases slightly with increasing deposition temperature and gas velocity; (*iv*) the segregation coefficient of monatomic As between gas phase and poly-Si (m) is approximated by $m = 1.5 \times 10^8 \exp(-71.5 \text{ kcal/mole}/RT)$; (*v*) the energy of As-Si bond is 44.5 kcal/mole.

Arsenic-doped polycrystalline silicon (As-doped poly-Si) is an important material as a diffusion source for the emitters of microwave transistors (1, 2) and as a gate electrode of MOSLSI's (3). In the fabrication process of fine pattern silicon devices, the deposition temperature of As-doped poly-Si has been selected in the range between 650° and 800°C, taking account of grain size (4-6). The deposition rate, structure, and resistivity of As-doped poly-Si have been investigated by many workers (5-7), however, little has been known about As doping mechanism of chemical vapor deposited poly-Si at deposition temperature between 650° and 800°C, which is a basic knowledge for using As-doped poly-Si.

In the present work, the As concentration (C_{As}) in poly-Si deposited under various deposition conditions in the deposition temperature range 670°-760°C using the SiH_4-H_2-AsH_3 gas system was obtained by neutron activation analysis. From the experimental results, it was suggested that, for lower $P_{AsH_3}{}^{(i)}$ region, C_{As} is limited by the diffusion of As-containing species in the stagnant layer (8) formed by gas stream, and for higher $P_{AsH_3}{}^{(i)}$ region, C_{As} is controlled by the surface reaction, and that monatomic As existed at wafer surface is incorporated in poly-Si in accordance with Henry's law. The temperature dependences of the transfer coefficient of As atoms in H_2 and the segregation coefficient of monatomic As between gas phase and poly-Si were also obtained, and the energy of As-Si bond was determined using Weiser's model (9).

Key words: CVD, doping, semiconductor, bonding.

Experimental

The As-doped poly-Si was deposited in an rf heated reactor using the SiH_4-H_2-AsH_3 gas system. Figure 1 shows the schematic view of the reactor used for the deposition of poly-Si. Total gas flow rate, which is nearly equal to H_2 gas flow rate, was 15-50 l/min. Deposition temperature range was 670°-760°C. Deposited thickness was about 4500Å. Deposition temperature on wafer surface was measured with an optical pyrometer, corrected for the emissivity of Si and the absorption of quartz. Substrates used were p-type Si wafers of 1-2 Ω-cm with mirror polished (100) surface. The oxide film was grown on the substrates in the atmosphere of dry O_2 gas before poly-Si deposition.

The deposition rate was obtained by measuring both deposition time and deposited thickness. The deposited thickness was measured with a Taylor Hobson Talystep

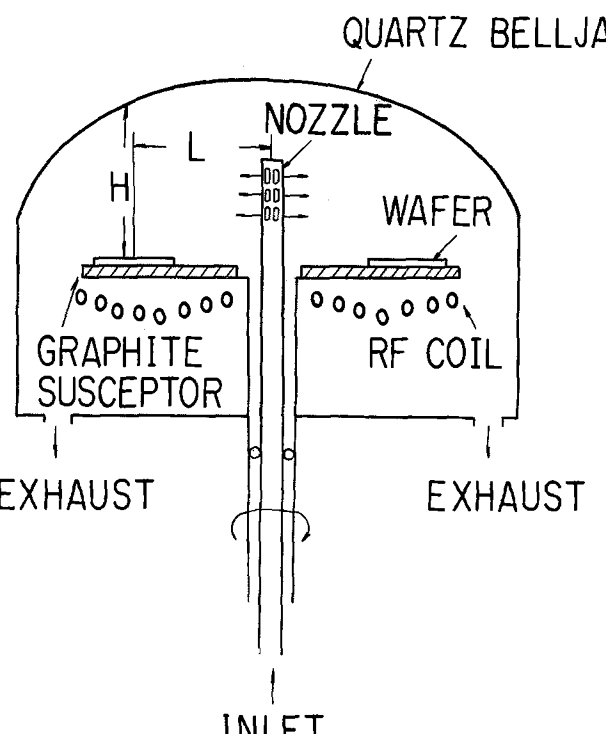

Fig. 1. Schematic view of the reactor used for the deposition of poly-Si.

after the poly-Si on SiO_2 had been locally removed.

The As concentration in poly-Si was determined by neutron activation analysis. The samples, together with As_2O_3 as a comparative standard, were irradiated in the nuclear reactor JRR-4 in Japan Atomic Energy Research Institute at a thermal neutron flux of 8×10^{13} n/cm² sec for 60 min. Radioactivity of As in poly-Si removed by chemical etching method was measured by a Ge(Li) detector coupled with a 4096 channel pulse height analyzer.

Results and Discussion

Relationships between C_{As} and deposition conditions.—Figures 2 and 3 show the dependence of deposition rate of poly-Si and C_{As} upon the total gas flow rate of the gas introduced into the reactor (F) at the deposition temperature of 730°C when the partial pressure of AsH_3 in the gas introduced into the reactor ($P_{AsH_3}{}^{(i)}$) and the partial pressure of SiH_4 in the gas introduced into the reactor ($P_{SiH_4}{}^{(i)}$) are constant. From Fig. 2, it is seen that the deposition rate is not influenced by F, *i.e.*, gas velocity although the deposition rate decreases with increasing $P_{AsH_3}{}^{(i)}$ as reported by many investigators (5-7). From Fig. 3, it is seen that, for lower $P_{AsH_3}{}^{(i)}$ region, C_{As} tends to increase with increasing F, *i.e.*, gas velocity, and for higher $P_{AsH_3}{}^{(i)}$ region, C_{As} becomes to be independent of F, *i.e.*, gas velocity. These results suggest that the deposition rate of poly-Si and C_{As} for higher $P_{AsH_3}{}^{(i)}$ region is controlled by the surface reactions, while C_{As} is limited by the mass transport of As atoms in gas phase for lower $P_{AsH_3}{}^{(i)}$ region. Figure 4 shows the dependence of C_{As} upon $P_{AsH_3}{}^{(i)}$ for several deposition temperatures at $F = 30$ l/min and $P_{SiH_4}{}^{(i)} = 5.0 \times 10^{-3}$ atm. The slope of log C_{As} *vs.* log $P_{AsH_3}{}^{(i)}$ curve decreases with increasing $P_{AsH_3}{}^{(i)}$, and C_{As} increases with decreasing deposition temperature. The deposition rate dependence of C_{As} for several $P_{AsH_3}{}^{(i)}$'s at the deposition temperature of 730°C and $F = 30$ l/min is shown in Fig. 5. The deposition rate was controlled by changing $P_{SiH_4}{}^{(i)}$. From Fig. 5, it is seen that, for lower $P_{AsH_3}{}^{(i)}$ region, C_{As} decreases with increasing deposi-

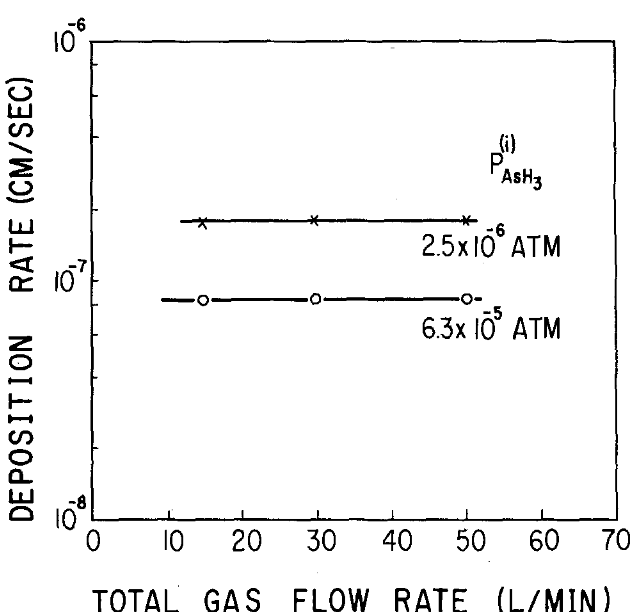

Fig. 2. Dependence of deposition rate of poly-Si upon the total gas flow rate at deposition temperature of 730°C and $P_{SiH_4}{}^{(i)} = 5.0 \times 10^{-3}$ atm.

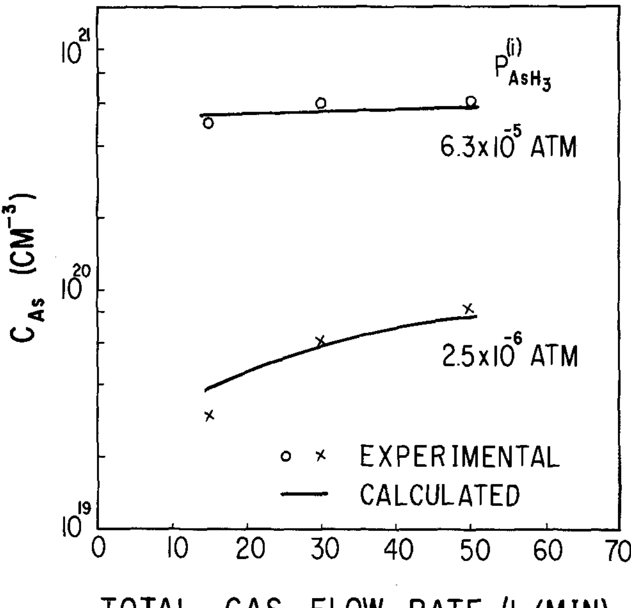

Fig. 3. Dependence of C_{As} upon total gas flow rate at deposition temperature of 730°C and $P_{SiH_4}{}^{(i)} = 5.0 \times 10^{-3}$ atm. Solid curves were calculated from Eq. [10] and [11] with the data of Fig. 2 and $m = 3.8 \times 10^{-8}$ atm.

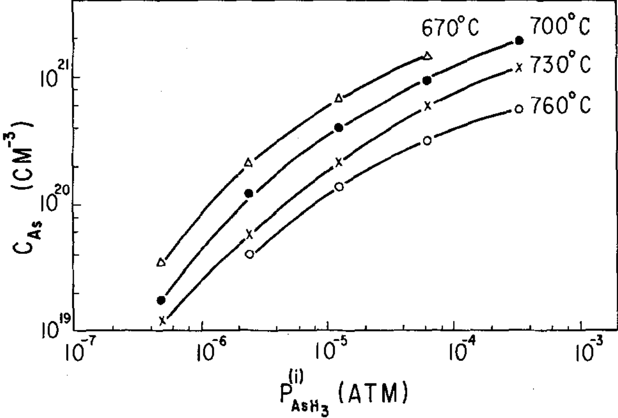

Fig. 4. Dependence of C_{As} upon $P_{AsH_3}{}^{(i)}$ for several deposition temperatures at $F = 30$ l/min and $P_{SiH_4}{}^{(i)} = 5.0 \times 10^{-3}$ atm.

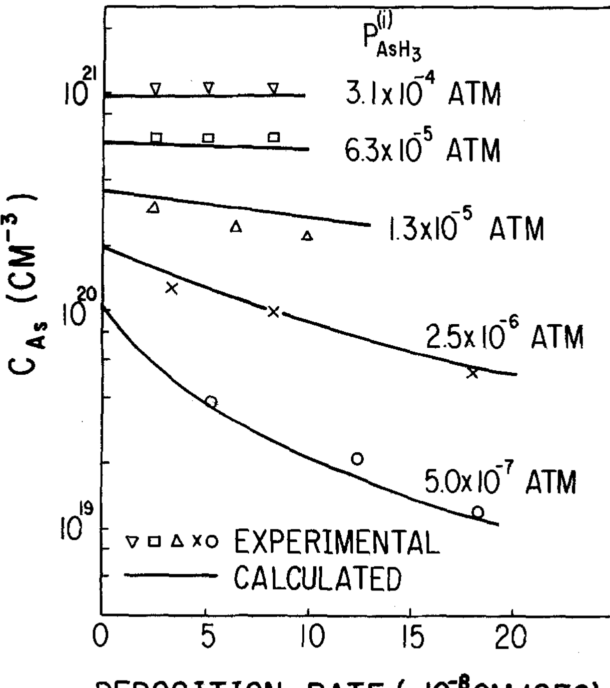

Fig. 5. Dependence of C_{As} upon deposition rate for several $P_{AsH_3}{}^{(i)}$'s at deposition temperature of 730°C and $F = 30$ l/min. Solid curves were calculated from Eq. [10] with $m = 3.8 \times 10^{-8}$ atm and $\pi = 5.6 \times 10^{-1}$ cm/sec.

tion rate, and for higher $P_{AsH_3}{}^{(i)}$ region, C_{As} is independent of deposition rate.

These results are summarized as follows: (*i*) C_{As} increases with decreasing deposition temperature and with increasing $P_{AsH_3}{}^{(i)}$, (*ii*) for lower $P_{AsH_3}{}^{(i)}$ region, C_{As} decreases with decreasing gas velocity and with increasing deposition rate, and for higher $P_{AsH_3}{}^{(i)}$ region, C_{As} is independent of deposition rate and gas velocity.

Relationships between C_{As} and partial pressure of As-containing species.—In the present section, the decomposition of AsH_3, the mass transport of As atoms in gas phase and the relationships between C_{As} and the partial pressure of As-containing species at wafer surfaces are discussed using the above results, and finally the empirical equation to determine C_{As} is proposed.

The reliable thermodynamic data of AsH_3 have not been reported. In the present work, the equilibrium relationship among AsH_3 molecules, As_4 molecules, and H_2 molecules, reported by Kirwan (10), is assumed, which is proved to be appropriate in the below discussions.

Under the $P_{AsH_3}{}^{(i)}$ and deposition temperature ranges in the present experiment, AsH_3 molecules are decomposed completely into As molecules, As_2 molecules, and As_4 molecules. Then, the equilibrium relation near the wafer surface in the gas phase is as follows

$$K_1 = P_{As}{}^{(s)}/(P_{As_2}{}^{(s)})^{1/2} \quad [1]$$

$$K_2 = P_{As_4}{}^{(s)}/(P_{As_2}{}^{(s)})^2 \quad [2]$$

where $P_{As}{}^{(s)}$, $P_{As_2}{}^{(s)}$, and $P_{As_4}{}^{(s)}$ are the partial pressure of As molecule, As_2 molecule, and As_4 molecule near the wafer surface in the gas phase, respectively, formed by the decomposition of AsH_3 gas; K_1 and K_2, equilibrium constants (11).

Next, the mass transport of As atoms in gas phase is considered, assuming a model analogous to that for the deposition of Si epitaxial layer (12, 13). Then, the number of As atoms (n_T) transported towards the wafer surface per square centimeter per second is

$$n_T = \pi(n_1 - n_2) \quad [3]$$

$$n_1 = P_{AsH_3}{}^{(i)}/kT \quad [4]$$

$$n_2 = [P_{As}{}^{(s)} + 2P_{As_2}{}^{(s)} + 4P_{As_4}{}^{(s)}]/kT \quad [5]$$

where it is also assumed that all the transfer coefficients of As-containing species have the same value and that As molecules, As_2 molecules, and As_4 molecules are the most abundant As-containing species at the wafer surface, but the other As-containing species such as AsH_3 molecules are not. π is the transfer coefficient for As atoms in H_2; n_1 and n_2, the number of As atoms introduced into the reactor and that existed at the wafer surface, respectively. Equation [3] is similar to Eq. [3] in Ref. (14) shown by Craig.

The number of As atoms (n_p) incorporated in poly-Si per square centimeter per second is

$$n_p = vC_{As} \quad [6]$$

where v is the deposition rate of poly-Si.

In the steady-state condition ($n_T = n_p$), combining Eq. [3] and [6]

$$\pi(n_1 - n_2) = vC_{As} \quad [7]$$

This equation means that, at $v = 0$, n_1 is equal to n_2, *i.e.*

$$P_{AsH_3}{}^{(i)} = P_{As}{}^{(s)} + 2P_{As_2}{}^{(s)} + 4P_{As_4}{}^{(s)} \quad [8]$$

Therefore, from the calculation of Eq. [1], [2], and [8], and the experimental data of C_{As} at $v = 0$ for various $P_{AsH_3}{}^{(i)}$'s, the dependences of C_{As} upon $P_{As}{}^{(s)}$, $P_{As_2}{}^{(s)}$, and $P_{As_4}{}^{(s)}$ under the equilibrium condition, respectively, are estimated, which are shown in Fig. 6. Here, C_{As} at $v = 0$ was approximated by linearly extrapolating the deposition rate to zero in Fig. 5. From Fig. 6, it is found that C_{As} at $v = 0$ is nearly proportional to $P_{As}{}^{(s)}$, $(P_{As_2}{}^{(s)})^{1/2}$, and $(P_{As_4}{}^{(s)})^{1/4}$. This means that monatomic As is incorporated in poly-Si in accordance with Henry's law. Then, the relationship between $P_{As}{}^{(s)}$ and C_{As} under the equilibrium condition is given by

$$P_{As}{}^{(s)} = mC_{As}/C_{Si} \quad [9]$$

where m is the segregation coefficient of monatomic As between gas phase and poly-Si, and C_{Si} is the concentration of Si lattice sites, 5.5×10^{22} cm^{-3}. Here, it should be noted that the above assumption in regard to the decomposition of AsH_3 is effective because C_{As} at $v = 0$ in Fig. 5 is nearly proportional to $(P_{AsH_3}{}^{(i)})^{1/2}$ for lower $P_{AsH_3}{}^{(i)}$ region and $(P_{AsH_3}{}^{(i)})^{1/4}$ for higher $P_{AsH_3}{}^{(i)}$ region. In other words, if AsH_2 molecules or AsH_3 molecules are the most abundant As-containing species at the wafer surface under the present conditions (15, 18), C_{As} at $v = 0$ should be proportional to $P_{AsH_3}{}^{(i)}$ and as a result, Eq. [9] could not be obtained.

Combining Eq. [1], [2], [4], [5], and [9], Eq. [7] is rewritten as

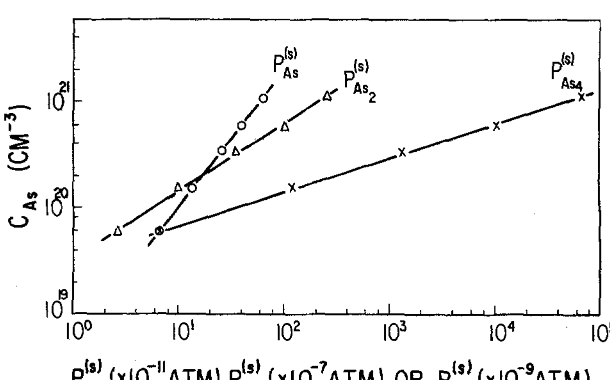

Fig. 6. Dependence of C_{As} upon $P_{As}{}^{(s)}$, $P_{As_2}{}^{(s)}$, and $P_{As_4}{}^{(s)}$ under the equilibrium condition, obtained from the calculation of Eq. [1], [2], and [8], and the experimental data of C_{As} at $v = 0$ for various $P_{AsH_3}{}^{(i)}$'s. Here, C_{As} at $v = 0$ was approximated by linearly extrapolating the deposition rate to zero in Fig. 5.

$$vC_{As} = \frac{\pi}{kT} [P_{AsH_3}^{(i)} - mC_{As}/C_{Si} - 2m^2C_{As}^2/C_{Si}^2K_1^2 - 4m^4K_2C_{As}^4/C_{Si}^4K_1^4] \quad [10]$$

The C_{As} *vs.* deposition rate curves calculated from Eq. [10] with $m = 3.8 \times 10^{-8}$ atm, $\pi = 5.6 \times 10^{-1}$ cm/sec, and $T = 730°C$ is also shown in Fig. 5, where m and π are determined from two point data in Fig. 5. These curves give best fits to all the experimental data. Looking at Eq. [7] and [10] with $m = 3.8 \times 10^{-8}$ atm, $\pi = 5.6 \times 10^{-1}$ cm/sec, and $T = 730°C$. it is found that for higher $P_{AsH_3}^{(i)}$ region, vC_{As} is negligibly small compared with πn_2, *i.e.*, n_2 becomes to be nearly equal to n_2, but not for lower $P_{AsH_3}^{(i)}$ region. Therefore, for lower $P_{AsH_3}^{(i)}$ region, C_{As} is limited by the mass transport of As atoms in gas phase and decreases with increasing the deposition rate, and for higher $P_{AsH_3}^{(i)}$ region, C_{As} is not limited by the mass transport of As atoms in gas phase and as a result, becomes to be independent of deposition rate. In the same way, the total gas flow rate dependence of C_{As} can be explained using the results that π is dependent upon total gas flow rate as shown in the next section and that the deposition rate is independent of total gas flow rate. Further, using Eq. [10], the deposition temperature dependence of C_{As} is discussed. For lower $P_{AsH_3}^{(i)}$ region, C_{As} depends strongly upon deposition rate and π/kT, and for higher $P_{AsH_3}^{(i)}$ region, C_{As} depends strongly upon $P_{As}^{(s)}$ and m. From the data shown in Table I, the deposition temperature dependences of deposition rate are obtained. Substituting the experimental data shown in Table I and the value of K_1 and K_2 in Ref. (11) in Eq. [10], the deposition temperature dependences of π/kT, $P_{As}^{(s)}$, and m are obtained under the conditions that $P_{AsH_3}^{(i)}$, $P_{SiH_4}^{(i)}$, and total gas flow rate are constant. It is found that π/kT (see Fig. 7) decrease slightly, but the deposition rate, $P_{As}^{(s)}$ and m (see Eq. [12]) decrease rapidly with decreasing deposition temperature. Therefore, considering that the deposition rate decreases and $P_{As}^{(s)}/m$ increases with decreasing deposition temperature, the experimental facts shown in Fig. 4 that C_{As} increases with decreasing deposition temperature in lower and higher $P_{AsH_3}^{(i)}$ region can be explained. From these results, it is confirmed that Eq. [10] is a basic approximate equation to explain the As doping process in lower and higher $P_{AsH_3}^{(i)}$ regions.

Transfer coefficient.—Table I shows the data of deposition rate and C_{As} for various deposition conditions. Using the data in Table I and the values of K_1 and K_2 in Ref. (11), π was calculated from Eq. [10]. The deposition temperature dependence of π is shown in Fig. 7. π increases slightly with increasing deposition temperature. As described in the above section, for lower $P_{AsH_3}^{(i)}$ region, it is suggested that C_{As} is limited by the mass transport of As atoms in the gas phase. If the mass transport of As atoms in the gas phase is limited by the diffusion of As-containing species in the stagnant layer formed by gas stream, a model similar to that for the P doping in Si epitaxial layer (19, 14) based upon the stagnant layer model

Table I. Deposition rate and C_{As} for various deposition conditions

Deposition temperature (°C)	$P_{AsH_3}^{(i)}$ (atm)	Deposition rate (cm/sec)	C_{As} (cm^{-3})
670	2.5×10^{-6}	3.4×10^{-8}	2.3×10^{20}
670	6.3×10^{-5}	2.2×10^{-8}	1.5×10^{21}

760	6.3×10^{-5}	1.4×10^{-7}	3.1×10^{20}

$F = 30$ l/min, $P_{SiH_4}^{(i)} = 5.0 \times 10^{-3}$ atm.

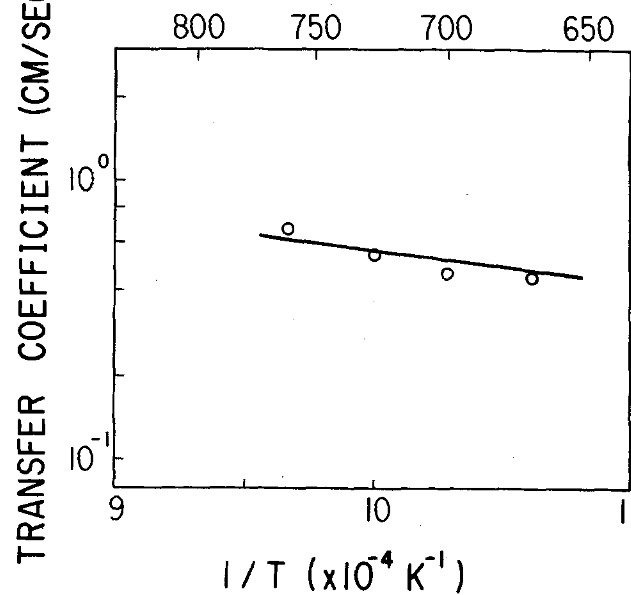

Fig. 7. Deposition temperature dependence of transfer coefficient at $F = 30$ l/min. Open circles were calculated from Eq. [10] and Table I. Solid curve was calculated from Eq. [11].

proposed by Eversteyn *et al.* (8) can be assumed. Then, π is given by

$$\pi = D/d \quad [11]$$

with $D = D_o(T/T_o)^2$, $d = a/\sqrt{V_T} - b$ in Ref. (8), $V_T/T = V_r/T_r$, and $V_r = F/2\pi L(H - d)$, where it is assumed that the temperature of gas is equal to wafer surface temperature; D, the diffusion coefficient of As-containing species in H_2 at deposition temperature (T); D_o is D at $T_o = 273°K$, about 0.2 cm^2 sec^{-1} in Ref. (12) because As-containing species are mainly composed of As_2 molecules and As_4 molecules; d, the thickness of the stagnant layer; a and b, 7 cm$^{3/2}$ sec$^{-1/2}$ and 0.2 cm in Ref. (8), respectively; V_r, gas velocity at $T_r = 300°K$, which is determined by the structure of reactor; L, distance from the nozzle of gas to the wafer surface, about 13 cm; H, distance from the bell-jar surface to the wafer surface, about 15 cm.

The π calculated from Eq. [11] is also shown in Fig. 7, and is in good agreement with that from Eq. [10]. The C_{As} *vs.* F curves calculated from Eq. [10] and [11] with the data of Fig. 2 and $m = 3.8 \times 10^{-8}$ atm are also shown in Fig. 3. The calculated values are in good agreement with the experimental data in Fig. 3. For the determination of stagnant layer thickness in Eq. [11], the empirical equation obtained in a horizontal reactor reported by Eversteyn *et al.* (8) is used. The above results may mean that the gas flow dynamics of the present reactor are the same as those of horizontal reactor.

From these results, it is confirmed that the mass transport of As atoms in gas phase for lower $P_{AsH_3}^{(i)}$ region is limited by the diffusion of As-containing species in the stagnant layer formed by gas stream.

Segregation coefficient.—The deposition temperature dependence of m is shown in Fig. 8. Data (i) were calculated from Eq. [10] using the data in Table I. Data (ii) were calculated from Eq. [10] using the data of Swanson *et al.* (16). Data (iii) were obtained by Shepherd (13) using $SiCl_4$-H_2-$AsCl_3$ gas system. Data (iv) were calculated from the vapor pressure data of Sandhu *et al.* (17). From Fig. 8, it is seen that m increases with increasing deposition temperature and the temperature dependence of m, except for one point in the data (iv), is expressed approximately by

$$m = 1.5 \times 10^3 \exp(-71.5 \text{ kcal/mole}/RT) \quad [12]$$

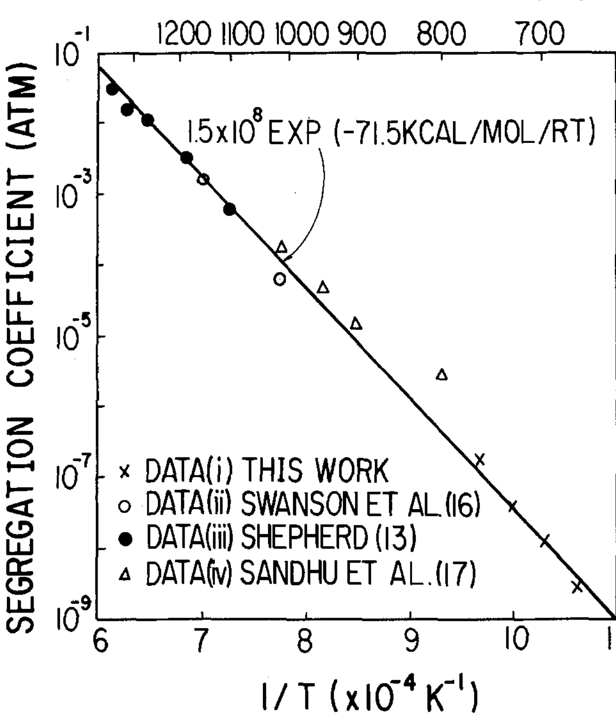

Fig. 8. Deposition temperature dependence of the segregation coefficient of monatomic As.

According to the theoretical relation for m proposed by Weiser (9), the temperature dependence of m is given by

$$\frac{d \ln m}{d(1/RT)} = \Delta H_{Si}^{subl} - 4E_{As\text{-}Si} + E_{As\text{-}Si}^{strain} \quad [13]$$

where the energy of Si-Si bond is assumed to be equal to one-half the heat of sublimation of Si (20); $E_{As\text{-}Si}$, the energy of As-Si bond; $E_{As\text{-}Si}^{strain}$, the strain energy caused by the difference of normal tetrahedral radius between As and Si, about 0.1 kcal/mole (9); ΔH_{Si}^{subl}, the heat of sublimation of Si, 106.5 kcal/mole (21). Using Eq. [12], the right-hand side of Eq. [13] becomes −71.5 kcal/mole. Therefore, $E_{As\text{-}Si}$ becomes 44.5 kcal/mole. On the basis of a rule suggested by Allen (22), $E_{As\text{-}Si}$ is estimated by

$$1/E_{As\text{-}Si} = (1/E_{As\text{-}As} + 1/E_{Si\text{-}Si})/2 \quad [14]$$

where $E_{As\text{-}As}$ is the energy of As-As bond, 40.3 kcal/mole, which is calculated from Ref. (18); $E_{Si\text{-}Si}$, the energy of Si-Si bond, 53.25 kcal/mole with the assumption of $E_{Si\text{-}Si} = \Delta H_{Si}^{subl}/2$. The $E_{As\text{-}Si}$ calculated from Eq. [14] is 45.9 kcal/mole and is in good agreement with that obtained by the present work. Consequently, the value of $E_{As\text{-}Si}$ obtained by the present work, 44.5 kcal/mole is correct.

Conclusions

The incorporation of As in poly-Si is dependent upon deposition temperature, $P_{AsH_3}^{(i)}$, deposition rate, and gas velocity. From the experimental results, it was suggested that, for lower $P_{AsH_3}^{(i)}$ region, C_{As} is limited by the diffusion of As-containing species in the stagnant layer formed by gas stream, and for higher $P_{AsH_3}^{(i)}$ region, C_{As} is controlled by the surface reaction, and that monatomic As existing at wafer surface is incorporated in poly-Si in accordance with Henry's law. The relationships between C_{As} and deposition conditions are given by

$$vC_{As} = \frac{\pi}{kT}[P_{AsH_3}^{(i)} - mC_{As}/C_{Si} - 2m^2C_{As}^2/C_{Si}^2K_1^2 - 4m^4K_2C_{As}^4/C_{Si}^4K_1^4]$$

where π is estimated by D/d using the stagnant layer model. By the above empirical equation, the As doping process in lower and higher $P_{AsH_3}^{(i)}$ region can be explained. The segregation coefficient (m) is approximated by $m = 1.5 \times 10^8 \exp(-71.5 \text{ kcal/mole}/RT)$. From the temperature dependence of m, the energy of the As-Si bond is determined to be 44.5 kcal/mole.

Acknowledgments

The authors wish to express their gratitude for encouragement of Mr. M. Kondo and Mr. F. Yanagawa in executing the study. They also would like to thank Mr. M. Tabe and Mr. H. Nakamura for their useful discussions and valuable advice, and Mr. K. Kobayashi for carrying out the experiments of neutron activation analysis.

Manuscript submitted Dec. 14, 1978; revised manuscript received Nov. 27, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Nippon Telegraph and Telephone Public Corporation.

Recrystallization of Polycrystalline CVD Grown Silicon

W. J. H. Schins, J. Bezemer, H. Holtrop, and S. Radelaar

Technical Physics Department, State University Utrecht, 3508 TA Utrecht, The Netherlands

ABSTRACT

The recrystallization of fine-grained polycrystalline silicon (0.1-10 μm) obtained by chemical vapor deposition (CVD) was investigated. Recrystallization of sharply <110> textured material heated at 1350°-1400°C yields an inhomogeneous assembly consisting of 0.02-2 mm long grains of 0.02-0.1 mm diam. New grains are elongated in the direction of growth of the starting material. Grains do not grow further when impinging on each other. Textured material yields a sharply textured primary matrix. No influence of large temperature gradients (up to 500°C/mm) on recrystallization phenomena was observed. The degree of recrystallization as a function of time for fine-grained material can be described with a constant nucleation rate. From the dependence of the degree of recrystallization upon time and temperature an activation energy of 4.2 eV can be deduced for growth in fine-grained regions.

In recent years interest in polycrystalline silicon especially for photovoltaic solar-cell application has increased considerably. Polycrystalline silicon can be fabricated easily in large area sheets by chemical vapor deposition (CVD). However, the efficiency of a cell made of polycrystalline silicon is strongly affected by numerous randomly oriented grain boundaries acting as recombination centers for charge carriers. A grain size of at least 100 μm and grain boundaries lying perpendicular to the p-n junction are necessary for an acceptable overall cell efficiency (1). As reported earlier (2, 3) CVD grown polycrystalline silicon can be recrystallized to larger grains. We made a more thorough investigation of the influence on recrystallization phenomena of parameters like crystal orientation, specimen thickness, and heating temperature. A recrystallized sheet of silicon can either be doped and consequently be used as a photovoltaic layer or it might serve as a substrate on which a more perfect layer of silicon is grown epitaxially.

Experimental Techniques

Material specification.—The starting material used for our experiments is grown by the CVD method. We used both commercially available, high purity (99.999%) polycrystalline bars (Wacker Chemitronic) with a diameter of about 55 mm and layers grown on a flat substrate by CVD using $SiHCl_3$ as a source. As usual the bars were grown on a long polycrystalline silicon core from which silicon grains grow out radially. Optical examination shows that for different bars there is a difference in structural details as a result of growth conditions. Typical examples are shown in Fig. 1 and 2 which are optical micrographs of samples cut parallel to the growth direction, henceforth called material A and B, respectively. Material A consists of clusters of crystals elongated in the radial growth direction. The various crystals (0.1-10 μm in diameter) in a cluster are separated by straight grain boundaries. Optical examination of material B (crystals 0.1-10 μm in diameter) gives the impression that the growth process was interrupted a number of times. Upon further growth new nuclei are formed on discrete spots and growth continues in tree-like structures which often recrystallize during or shortly after deposition.

For x-ray measurements (4) samples of 8 × 8 mm^2 were sawn from various sections of the bars in order to minimize the influence of the direction of growth. The samples cannot have larger dimensions because of the radial symmetry of the bars. The samples were ground and polished and then CP4-etched. Reflections from {111} and {220} crystal planes were recorded using a Siemens 3 kVA texture-goniometer with CuKα radiation.

Key words: CVD, nucleation, texture, grain growth.

The resulting pole figures show that material A has a sharp <110> fiber texture coinciding with the radial growth direction. An illustration is given in Fig. 3a which shows a part of a {111} pole figure of a sample cut perpendicular to the growth direction. The thickness of the lines indicates the intensities relative to the intensities of a random sample. The thickest lines correspond to an eight times larger intensity. The observed spread in reflection angle is mainly due to the radial symmetry of the bars from which the samples are sawn. This is in agreement with earlier results for this kind of material (5). The same kind of analysis on only one of the striated clusters (area 10 mm^2) show it to be very strongly <110> fiber textured. The grains of material B do not show a preferred orientation as shown in Fig. 3b: all x-ray intensities are between 0.5 and 2 times the intensity of a random sample.

Thin polycrystalline silicon layers of thickness varying from 20 to 150 μm were grown in the laboratory by CVD at various temperatures in the range 1000°-1250°C at an average deposition rate of 2 μm per minute. The substrate consisted of thermally oxidized or nitridized silicon single crystals of various orientations. The crystallographic structure of these layers (henceforth to be called material C) is similar to the structure of material A.

Fig. 1. Sample of silicon material A cut from a CVD grown bar. Growth direction is from left to right.

Fig. 2. Sample of silicon material B cut from a CVD grown bar. Growth direction is from left to right.

Pole figures reveal a sharp <110> fiber texture coinciding with the growth direction. This is in agreement with earlier results on CVD grown polycrystalline silicon layers reported in the literature (6, 7).

For experiments with material A and B, samples were sawn from the rods with known angles ϕ as indicated in Fig. 4. The growth direction makes angles from 0 to ½ ϕ with the normal to the sample surface.

Grinding of the samples was followed by polishing with 6 and ¼ μm diamond paste. Samples were etched with CP4 for chemical polishing and with Sirtl etch (CrO_3, HF) for preferential grain boundary etching.

Heating.—The samples were heated either in resistance-heated furnaces with gas-tight alumina tubes or in rf-heated furnaces in a silica tube. For the recrystallization experiments with relatively short heating times an rf-heated furnace was used which was modified in such a way that highly stable temperatures and temperature gradients under reproducible conditions could be obtained (± 10°C).

Recrystallization experiments were carried out by heating samples of different orientations and thicknesses varying from 20 μm to a few millimeters at temperatures in the range of 1100°-1400°C and heating times of a few seconds up to 48 hr. Samples were either CP4 or Sirtl-etched or unetched before recrystallization. As oxygen in air causes the samples to oxidize considerably at high temperatures heating was performed in a variety of protective atmospheres like ultrahigh purity argon, Ar with a few percent H_2, Ar with 30 volume percent HCl, N_2 with 8% H_2, pure N_2, and pure H_2.

To remove oxygen and water from these ambients a palladium de-oxo-catalyst and a 5Å molecular sieve were used, respectively.

A number of experiments were carried out in vacuum of various pressures.

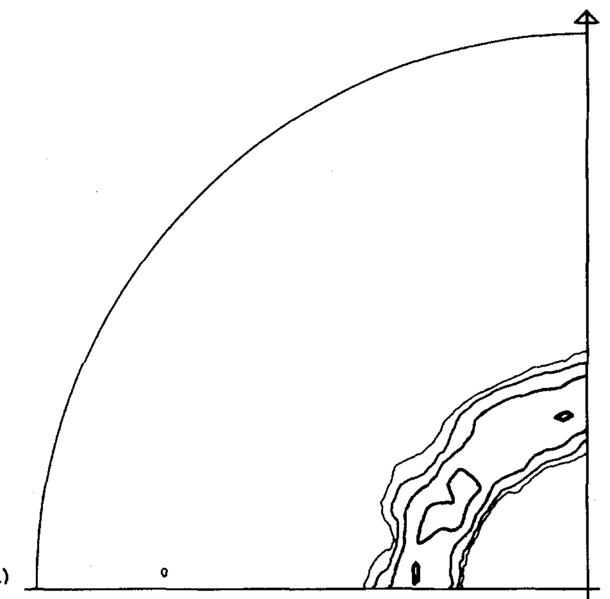
Results

Recrystallization structure.—Recrystallization at 1380°C during 3 hr of samples of material A parallel to the <110> growth direction with a 200 μm thickness yields oblong grains with an inhomogeneous grain size (Fig. 5).

Grain size in these samples varies from 0.02 to 2 mm in length and from 0.02 to 0.1 mm in diameter and increases only slightly with heating temperature in the range 1350°-1400°C. The structure of the recrystallized material obviously depends on the structure of the starting material. The new grains are elongated in the original <110> growth direction and consequently most of the high angle grain boundaries lie in this direction. The resulting grain size is not influenced by the heating rate (0.1°-100°C/sec^{-1}), a strong temperature gradient (500°C/mm at 1300°C), or grinding and polishing of the samples before heating.

Examination of samples with various values of the angle ϕ leads to the conclusion that nucleation occurs at discrete sites and nuclei grow out to a primary matrix. The moment these growing primary grains impinge on each other no further grain growth occurs even after prolonged heating. This will be discussed in the section "Kinetics."

Texture-goniometer measurements of recrystallized samples with various values of ϕ revealed a sharp <111> fiber texture with free rotation around this axis. This <111> fiber axis is always parallel with the original <110> growth direction in the samples, independent of the value of ϕ. This means that when recrystallizing samples sawn from the bar in such a way



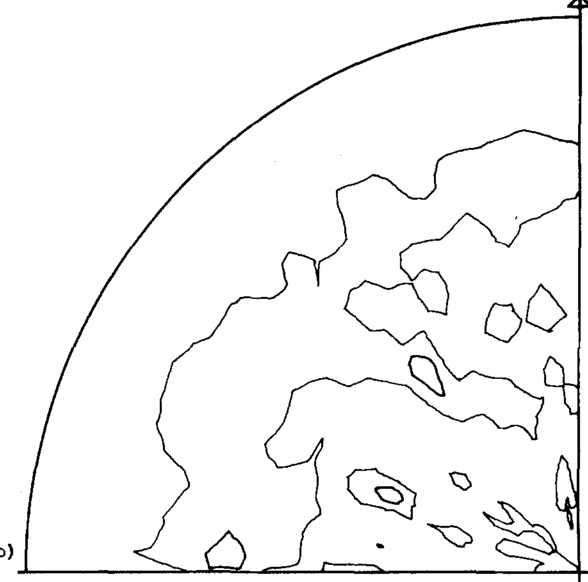


Fig. 3. Part of pole figures for {111} reflections of CVD grown silicon grains of material A and B (a and b, respectively)

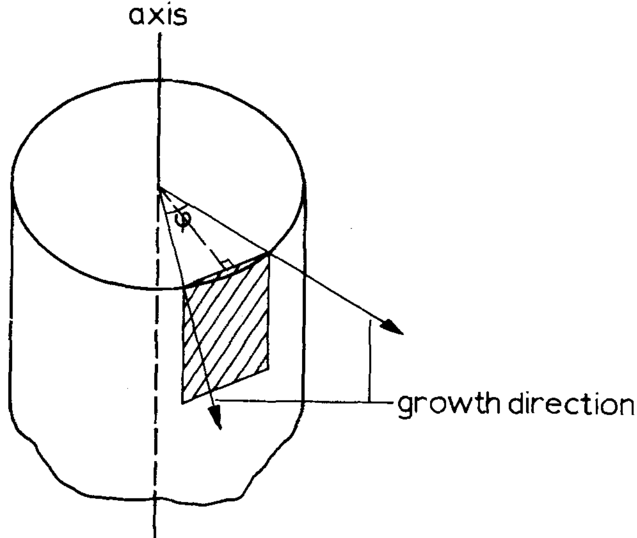

Fig. 4. Sample from a bar of polycrystalline silicon. The angle ϕ is a measure for the spread of the growth direction over the sample surface.

that the <110> growth direction is normal to the sample's surface we find that the newly formed grain boundaries lie also mainly normal to this surface but now the grains are <111> oriented.

The behavior of material B upon recrystallization is different compared to material A for the same experimental conditions. Nucleation occurs very readily in fine-grained regions whereas the tree-like coarse-grained regions keep their geometrical shape although they become coarser to some extent. This yields a fairly homogeneous matrix of grains of about 30 μm in diameter containing the coarser grained structures as mentioned (see Fig. 6). The same features are observed when using samples sawn in different orientations from the bar. As in the case of material A the grain size and structure cannot be influenced by a variation in heating temperature or very long heating. Texture-goniometer measurements show that recrystallized samples of material B are still randomly oriented.

The behavior upon recrystallization of material C is comparable to the case of material A. This is not surprising since structure and texture are very similar. Due to the texture the newly formed high-angle grain boundaries of material C lie mainly perpendicular to the surface of the substrate. Grain size of the samples varies from 50 to 100 μm. When one does not remove the substrate and the SiO_2 interface layer before heating one finds a large number of stacking faults in the silicon crystals. This is probably caused by diffusion of oxygen out of the SiO_2 interface layer into the polysilicon layer.

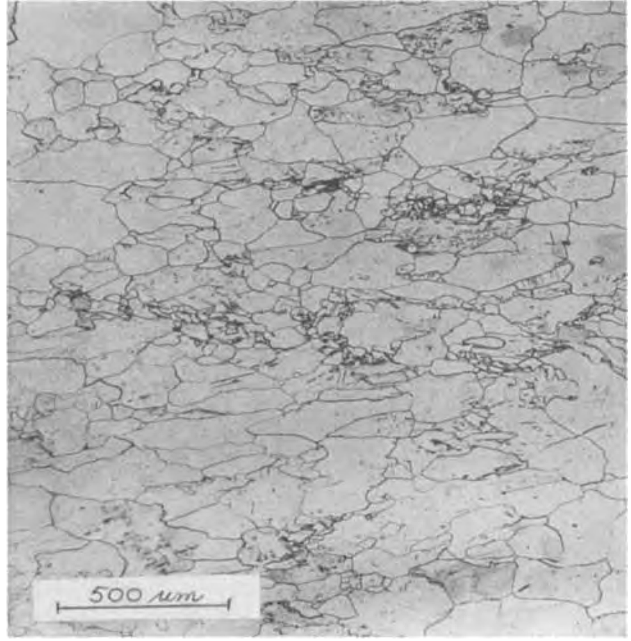

Fig. 5. Grains of material A after recrystallization at 1380°C during 3 hr. The sample is sawn parallel to the original <110> growth direction which is from left to right on the micrograph.

Fig. 6. Grains of material B after recrystallization at 1380°C during 3 hr. The sample is sawn parallel to the original growth direction which is from left to right on the micrograph.

Texture-goniometer measurements on a sample grown at 1100°C and subsequently recrystallized at 1380°C showed a sharp <322> fiber texture. To be sure that this is not only a surface texture, measurements were done again after removing 60 μm from the surface. The same amount of <322> fiber texture was found.

However, when we tried to recrystallize CVD-grown layers which were coarse-grained already (diameter > 20 μm) we found that these grains did not recrystallize so the original structure is unchanged.

Kinetics.—The degree of recrystallization $X(t)$ as a function of heating time at a constant temperature was measured for material A at various temperatures on samples of the kind depicted in Fig. 4, sawn very close to the edge of the bar. Series of samples were partly recrystallized in discrete steps and micrographs taken after every heating step were compared. Values of $X(t)$ were measured using the point-counting method. The results of these measurements for two different bars are shown in Fig. 7. $X(t)$ depends strongly on the grain structure of the different bars, as will be explained later.

The same series of micrographs were used to determine values for nucleation and growth rates. As an example three stages of the recrystallization process at 1313°C are shown in Fig. 8 after 45, 60, and 90 min of heating, respectively. New nuclei develop and existing grains grow out further upon prolonged heating. As one can see in Fig. 8(a) the grain size of the original material is very inhomogeneous. The higher the density of grain boundaries, the more readily nucleation will occur. For a more detailed description of the nucleation process in the samples we will split up the material into separate regions, namely fine-

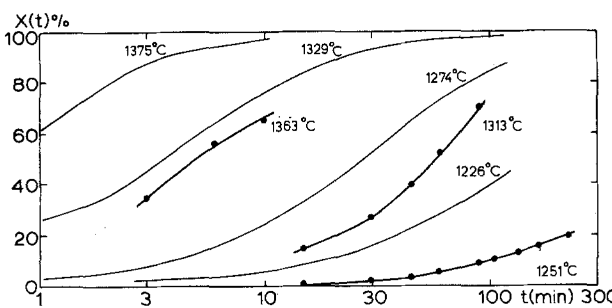

Fig. 7. Degree of transformation of CVD grown silicon material A as a function of time for various temperatures for two different bars of the kind of material A.

grained regions (0.1-1 μm) and coarse-grained regions consisting of clusters of larger crystals (1-10 μm) with rather straight grain boundaries. Because of the continuously changing grain size pattern this is somewhat arbitrary, but one can consider roughly 25 ± 5% of the total volume to be fine-grained and 75 ± 5% to be coarse-grained.

The nucleation rate in the samples was determined by counting the number of visible grains after the various steps of the isothermal process and correcting these data for the actually recrystallized part of a sample surface by multiplying them by $1/(1 - X(t))$. Results are shown in Fig. 9 where the number of nuclei is plotted as a function of heating time. The number of nuclei present at a given time is difficult to measure accurately because of the impossibility of recognizing nuclei before they have grown out. From the nucleation rates at two temperatures (1251° and 1313°C, respectively) an activation energy can be calculated using the Arrhenius relation

$$N = N_0 \exp(-\epsilon/kT) \quad [1]$$

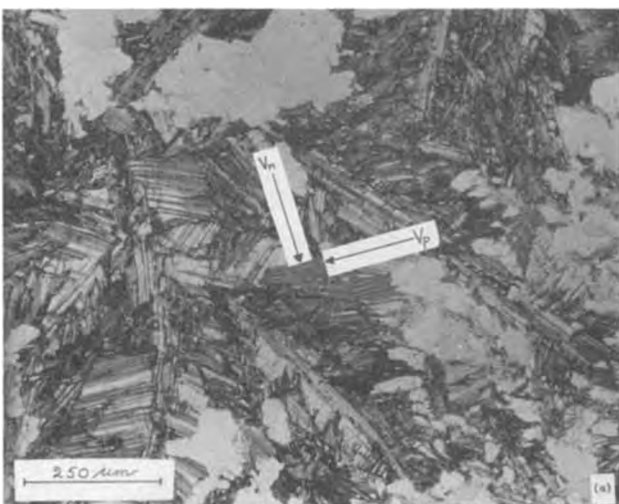
Results are summarized in Table I.

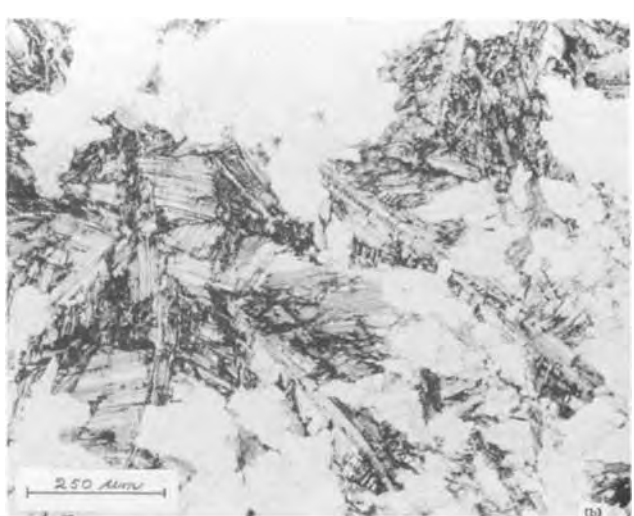
In the determination of growth rates the same distinction has to be made between fine-grained and coarse-grained regions. Moreover, growth in the coarse-grained regions differs in directions parallel to the straight grain boundaries (growth rate V_p, averaged over all grains) and normal to these boundaries (growth rate V_n, averaged over all grains) indicated in Fig. 8(a). All growth rates were determined at about 30 positions on a sample surface.

Growth rates were determined by measuring the displacement of newly formed high-angle boundaries into the unrecrystallized assembly after the various isothermal heating steps. Growth rates in the fine-grained regions were determined only during unimpeded growth of the new crystals. In Fig. 10 the growth rate V_f in the fine-grained regions averaged over all grains considered is plotted as a function of time elapsed after nucleation of each grain. Activation energies for primary recrystallization were determined from the time averages of V_f, V_n, and V_p (denoted by $\overline{V_f}$, $\overline{V_n}$, and $\overline{V_p}$, respectively). Values of $\overline{V_f}$, $\overline{V_n}$, and $\overline{V_p}$ and the activation energies derived are listed in Table I. The estimated inaccuracy in the values for the activation energies amounts to ±0.5 eV.

Discussion

Material A merely consists of strongly <110> textured clusters of closely spaced crystals parallel to the





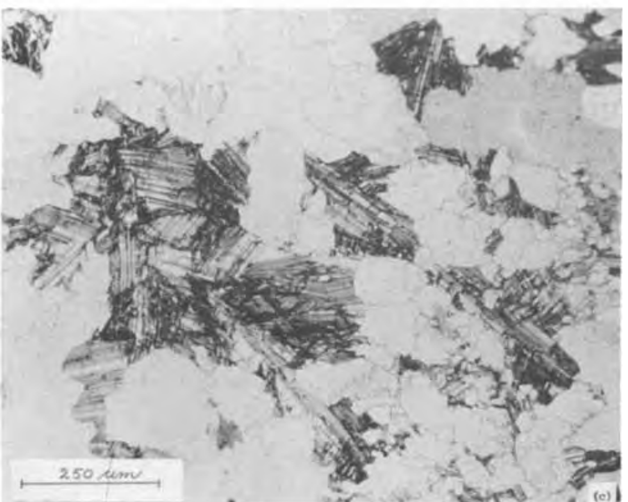


Fig. 8. Three stages of the recrystallization process of material A at 1313°C. Micrographs are taken after 45, 60, and 90 min of heating.

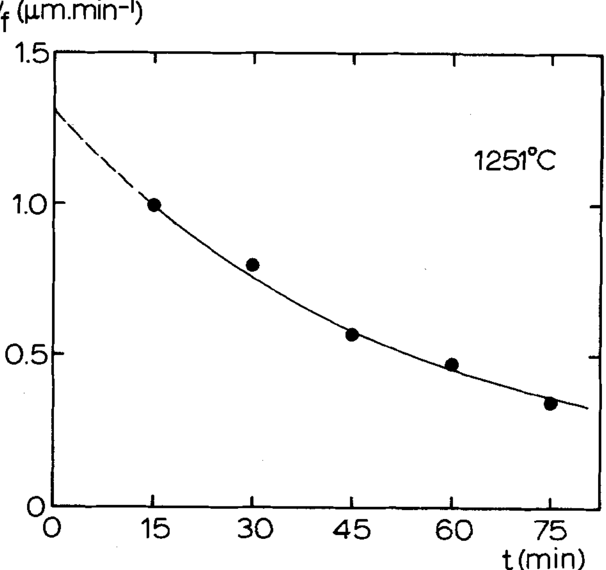

Fig. 10. Growth rate V_f of newly formed silicon grains as a function of time, averaged over all grains at 1251° in fine-grained regions.

growth direction. If the straight lines are closely spaced twin boundaries we would, however, expect a double texture. To explain the single <110> texture one must assume that if the lines are twin boundaries a crystal should return to its parent state immediately following the generation of a twin, so the percentage twin orientation is very small. Another possibility, suggested by Ravi (9) as an explanation for striation on EFG silicon ribbons, is to assume that the straight lines are stacking faults as a limiting case of twinning, with two extra planes of atoms between twinned regions in the case of extrinsic faults.

The recrystallization process of material A is rather complex. The main features can be summarized as follows.

1. The recrystallization process proceeds by development and subsequent growth of newly formed high-angle grain boundaries.

2. Nucleation occurs only in very fine-grained regions having a high density of grain boundaries. The higher the grain boundary density, the more readily nucleation occurs. Nucleation in coarse-grained regions does not occur.

3. Nuclei develop with a nucleation rate that is nearly constant for an isothermal process as indicated in Fig. 9 for 1251°C.

4. Nuclei grow out in the fine-grained regions until they impinge on each other or on coarse-grained material. The latter is consumed only to a small extent during the transformation of the fine-grained regions.

5. For most nuclei the rate at which they grow out in the course of the transformation process (after nucleation at $t = \tau$) is initially high but decreases gradually with continuing growth of the new grain. Also the average value of the growth rate for all grains (V_f) is a decreasing function of the time after nucleation $t - \tau$ as illustrated in Fig. 10.

6. In the coarse-grained regions no nucleation takes place but they are consumed by the growing grains originating from the fine-grained regions. As mentioned before there are two distinguishable growth rates V_n and V_p in the coarse-grained material.

7. The primary assembly so obtained does not alter its structure even after prolonged heating. Apparently grain growth and/or secondary recrystallization does not occur.

Because of the different recrystallization behavior of the fine- and coarse-grained regions the overall degree of transformation as a function of time cannot be described by a simple Avrami-relation (10). For the fine-grained regions in which nucleation and growth of nuclei are defined accurately we can set up a model as derived from general kinetics of transformation processes (10). The average growth rate as a function of time at 1251°C as shown in Fig. 10 can be described empirically by

$$V_f = V_o \exp(-(t-\tau)/t_o) \quad [2]$$

In this equation V_o is the average value of the initial growth rate of nuclei ($V_o = 0.02$ μm sec^{-1}) and t_o is a relaxation time determined by the dragging forces for growth ($t_o = 3 \cdot 10^3$ sec).

All sample surfaces are normal to the <110> growth direction. As growth in this particular direction is much faster than normal to it (shown in Fig. 5) we can consider the degree of recrystallization of the bulk $X_f(t)$ to be equal to the fraction of the surface area recrystallized at time t.

The radius of the growing grains (r) obeys

$$r = V_f(t-\tau) \quad \text{for } t \geq \tau \text{ and} \quad [3]$$

$$X_f(t) = \int_o^t N\pi r^2 d\tau \quad [4]$$

in which N is the (constant) nucleation rate. Calculating $X_f(t)$ (Eq. [4]) and taking the impingement of grains on each other into account the degree of recrystallization of the fine-grained regions is found

$$X_f(t) = 1 - \exp[-\pi V_o^2 t_o^2 N\{t - 3t_o/2 + 2t_o \exp(-t/t_o) - t_o/2 \exp(-2t/t_o)\}] \quad [5]$$

Table I

	1251°C	1313°C	Act. energy (eV)
Nucleation rate in fine-grained area (μm^{-2} min^{-1})	1.2×10^{-6}	19.5×10^{-6}	9.4
$\bar{V}_f$ (fine-grained) (μm min^{-1})	0.7	2.3	4.2
$\bar{V}_n$ (μm min^{-1})	0.07	0.45	6.5
$\bar{V}_p$ (μm min^{-1})	0.20	0.62	3.8

The activation energy for silicon volume self-diffusion is 5.0 eV (8).

which in fact represents a modified Avrami-Johnson-Mehl equation (10).

To compute the contribution of $X_f(t)$ to the overall degree of recrystallization $X(t)$ the former must be multiplied by the fraction fine-grained material in the sample in which nucleation can occur. As mentioned before an approximate amount of 25 $\pm$ 5% of total volume is very fine-grained. At the time the coarse-grained material starts to be transformed, nucleation in fine-grained regions has occurred in 20 $\pm$ 5% of total volume. In Fig. 11 the calculated $X_f(t)$ is shown in graphical form for three different values for the fraction fine-grained regions bounding the range of calculated $X_f(t)$ values.

The reasonable agreement between experimental and calculated values for $X_f(t)$ confirms the proposed growth model for the fine-grained area.

The observed decrease in growth rate of the unimpeded-growth grains cannot be explained by a decrease in driving force as a consequence of the occurrence of recovery processes in the as yet untransformed matrix. Initially all grains grow out relatively fast when they develop in the course of the transformation process, but when the size of these new grains increases, growth rate decreases. The measured values of the growth rate at 1251°C decrease from 1 to 0.35 [μm min^{-1}] as shown in Fig. 10. This latter value approximates the average value of the growth rate $\overline{V_p}$ (0.2 [μm min^{-1}], see Table I) of the coarse-grained regions. Nucleation occurs in very fine-grained regions and new grains grow out in the surrounding matrix which has a larger grain size. This probably means that the growth rate is a function of the density of grain boundaries in the matrix, ranging from very fine- to very coarse-grained regions.

Another reason why grain growth decreases with time may be the segregation of impurities on newly formed grain boundaries which tends to decrease boundary mobility.

As nucleation and/or growth processes connected with the transformation of the coarse-grained regions are not accurately defined, the involved kinetics are difficult to describe quantitatively.

The observed <111> recrystallization fiber texture of material A is not a consequence of surface free-energy driving forces which in thin layers tend to bring lowest energy planes, in our case {111} (11), at the sample's surface. In that case we would expect a <111> fiber axis normal to a sample's surface, whatever the orientation of the sample with respect to the original <110> growth direction. However, as mentioned earlier, in all cases the <111> direction is parallel to the <110> direction of the original grains even if the original <110> growth direction lies in the plane of specimen. Moreover, the <111> recrystallization texture also develops in the case of thick samples (1.2 mm) and thin samples (<100 μm) even when applying very long heating times. Samples normal to the <110> growth direction consequently have mainly (111) planes exposed at the sample surface. This prohibits the occurrence of tertiary recrystallization where the driving force is caused by differences in surface free-energy of the crystallographic planes exposed at the sample-free surface.

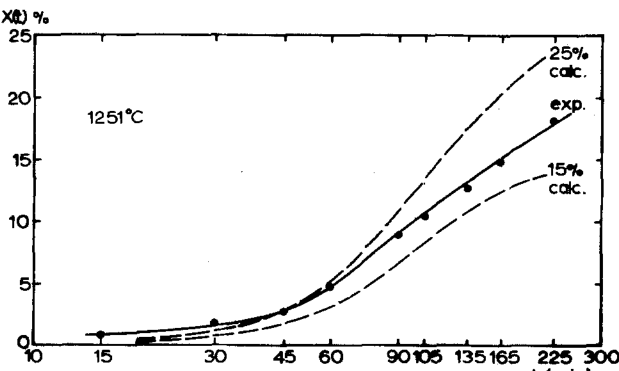

Fig. 11. Calculated values for $X(t)$ for two values of the percentage fine-grained area in comparison with the experimentally determined $X(t)$ curve for 1251°C.

Figure 7 shows that complete recrystallization of samples at temperatures above 1350°C occurs within 100 min time. The growing grains impinge on each other and growth ceases. There are several reasons why this primary assembly does not alter its structure any more during prolonged heating. In samples with grain size of the order of the sheet thickness boundary movement might have been impeded by preceding etching of the samples before heating by pinning boundaries at the sample free surface. This was not the case because both etched and unetched samples yield the same structure. Pinning of grain boundaries also may result by the occurrence of thermal etch grooves (12) which develop at high temperatures in all ambients used. However, this cannot be the main reason for growth inhibition as also grain boundaries in the bulk of the recrystallized silicon do not migrate. The third possibility is that growth ceases because of the sample thickness (specimen thickness effect) which implies that grains can grow in two directions only when the size is of the order of the sheet thickness. This does not apply to our case as thick samples (1.2 mm) yield the same structure. A fourth possibility lies in the pinning of moving boundaries by segregated particles on grain boundaries after the stage of primary recrystallization (13). Although infrared absorption measurements show that the oxygen content in the starting materials is very low (less than 2 ppm) and does not change upon recrystallization, there might be an increase in content of other impurities due to contamination during the heat-treatment.

Conclusions

1. CVD grown polycrystalline silicon grains (1-10 μm) can be recrystallized (final grain size 20-200 μm) by heating at temperatures above 1200°C.

2. Nucleation readily starts in regions with a high grain boundary concentration (grain size 0.1-1 μm). These nuclei grow out until they impinge on each other and further growth is inhibited. A randomly oriented starting material yields a randomly oriented recrystallized matrix as, *e.g.*, our material B. In the case of <110> fiber textured material however, as our materials A and C we find a sharp <111> resp. <322> fiber texture after recrystallization.

3. The recrystallization behavior can be described approximately by an Avrami-Johnson-Mehl type relation using a constant nucleation rate. The resulting grain size for material A is 20-100 μm for samples normal to the <111> recrystallization fiber texture axis. This final grain size is not influenced by prolonged heating, heating rate (0.1°-100°C/sec^{-1}), a temperature gradient, or by different ambients.

4. The recrystallized grains are elongated in the original <110> growth direction since the mobility of the interface between recrystallized and unrecrystallized material is highest in this direction.

5. In originally <110> textured material no tertiary recrystallization induced by differences in surface free-energy of exposed planes occurs due to the strong recrystallization texture.

Acknowledgments

The authors are very indebted to Eindhoven University of Technology (Lab. for Physical Chemistry, particularly Dr. J. Maas and co-workers), Delft University of Technology (Lab. for Metallurgy), and Twente University of Technology (Metallurgy Department, Mr. H. Heller and co-workers) for co-

operation in x-ray measurements. Dr. J. W. Drijver of State University of Utrecht (Technical Physics Department) is thanked for valuable discussions. Mr. E. Smit of Delft University of Technology (Dept. for Electrical Engineering) is thanked for supplying some CVD specimens.

Characterization of Cobalt-Hardened Gold Electrodeposits by Mössbauer Spectroscopy

II. Production of Co Metal Precipitates

R. L. Cohen, F. B. Koch,* L. N. Schoenberg,* and K. W. West

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Annealing of cobalt-hardened gold electrodeposits at 400°C and above leads to the formation of microprecipitates of cobalt metal clearly identified from their hyperfine structure. This finding removes the conflict between a previous study, which has claimed to observe precipitated cobalt, and our previous work, which shows that in unannealed deposits, most of the cobalt is a substitutional solute in the gold. The solubility of cobalt in gold has been redetermined, confirming the earlier results. A number of interesting properties of extremely fine cobalt precipitates in gold are observed and analyzed.

A previous paper (1) (henceforth referred to as "I") reported on the atomic-level structure of cobalt-hardened gold electrodeposits as observed by Mössbauer spectroscopy with particular attention to the coordination of the cobalt atoms. Most of the cobalt (~70%) was found to be dissolved substitutionally in the gold host with the remainder complexed as a hexacyanocobaltate. This result was in reasonable agreement with another recently published analysis (2). However, there are three reports in the literature claiming that cobalt microprecipitates are found, either in the as-deposited material (3), or after heat-treatment (4, 5). Since this issue is important in defining the relation between the microstructure and possible hardening mechanisms, we have carried out further experiments to study this point.

The Mössbauer spectroscopy technique is very useful for this type of measurement, because (*i*) it is very effective for examining the early stages of clustering and precipitation and (*ii*) the spectrum of magnetically ordered cobalt metal is distinctive allowing immediate identification of that phase. An additional advantage of the Mössbauer spectroscopy approach in this case is that the phenomenon of superparamagnetism allows us to distinguish between small and large cobalt precipitates. When a particle of cobalt is so small that its magnetic anisotropy energy is comparable to thermal excitation energies, the magnetization direction of the particle fluctuates rapidly and tends to average out the magnetic splitting so that only a single line is observed for very small (<~60Å) precipitates. This effect is clearly seen in the data, and allows us to observe and distinguish early-stage precipitates of cobalt.

Experimental Techniques

Samples of cobalt-hardened gold doped with radioactive Co^{57} were electrodeposited as described in I. The deposited layer was approximately 2.5 μm (100 μin.) thick, plated from a CI[1] solution adjusted to give a cobalt concentration of 0.67 atomic percent (a/o) in the deposit. The substrate was removed by dissolving it in nitric acid, leaving the thin gold foil as a self-supporting layer. This foil was held between graphite disks and annealed in a hydrogen atmosphere to provide the heat-treatments discussed below. Between anneals, the samples were measured either at room temperature or 78°K by the Mössbauer spectrometer described in I.

Table I. Anneal schedule for samples studied in this experiment, and fraction of dissolved cobalt and absolute cobalt solubility determined by least squares fits to the Mössbauer spectra

Anneal No.	Temp. (°C)	Time hot (hr)	Cool down	Fraction of cobalt dissolved	Solubility of Co in Au (a/o)
1	740	1.5	11.5°C/min to 625°C		
	625	38	0.145°C/min to 270°C	0.72	0.48
			3°C/min to RT		
2	460	23	45°C/min to 160°C	0.57	0.38
			5°C/min to RT		
3	511	24	5°C/min to RT	0.87	0.58
4	460	72	5°C/min to RT	0.63	0.42
5	400	22.5	5°C/min to RT	0.46	0.31
6	400	68	5°C/min to RT	0.44	0.30
7	360	71	5°C/min to RT	0.43	0.29
8	360	140	5°C/min to RT	0.30	0.20*

* Upper limit value—equilibrium not demonstrated.

Table I shows the anneal schedule used. Spectra taken at various points in the anneal cycle are shown in Fig. 1 with least-squares fits to the data (see I for a fuller description of the techniques involved).

Results

For the materials scientist concerned with the properties and microstructure of cobalt-hardened gold, the significant results can be directly seen in the sequence of spectra in Fig. 1. Figure 1A shows that there are no cobalt precipitates in the as-deposited layer, Fig. 1B shows that all the cobalt has been put into solid solution in a CI deposit which has been heated to 800°C and rapidly cooled (12°/min), and Fig. 1C shows that after heating and slow cooling through 400°C, cobalt metal precipitates out of the gold-cobalt alloy. After the 800° anneal, the deposit is essentially equivalent to an alloy made by standard metallurgical processes. The complex spectra obtained after annealing at <600°C show a number of interesting physical and metallurgical phenomena, and we have carried out a complete analysis of the data to understand all of these effects, although they have no direct bearing on the properties of CI gold in the as-deposited state. Some of these effects may be significant if the deposit is subjected to high temperatures either in manufacture or service.

The spectra shown in Fig. 1 can be shown to come from cobalt in three environments: Co^{57} substitutional in the gold matrix, small (<60Å) superparamagnetic precipitates of fcc cobalt metal, and larger precipitates of fcc Co metal, which produce the split 6 line spectrum. The detailed identification of these species is given below. Although there is considerable overlap between some of the spectral components, the use of constrained least squares fitting routines (6, 7) allows accurate evaluation of the relative intensities under the spectra of the three phases. We do not believe that Co_2C or Co_3C are present in these samples. Although the spectra of these carbides have not been measured, we would expect the hyperfine (HF) fields to be similar to those observed for iron in the analogous Fe_2C and Fe_3C, 160-200 kG. No components of the spectrum with splittings corresponding to HF field values in this range were observed.

At 78°K, the iron recoil-free-fraction, f, is about 0.90 for the cobalt host (8) and 0.84 for the gold host (9). Since the recoil-free fractions are essentially the same, the Mössbauer spectrum area from each phase is proportional to the presence of that phase in the sample. Thus, the relative area corresponding to each spectrum can be used to determine directly the fractions of dissolved and coarse and fine precipitated cobalt. Since the total cobalt concentration is known (1) to be 0.67 a/o, the solubility of cobalt in gold can be determined by dividing the 0.67% among the dissolved and precipitated phases. The new results from these studies are shown in Table I and Fig. 2 superimposed on the previously published phase diagram (10, 11). Considering the difficulties of determining equilibrium solubilities in dilute alloys at low temperatures, the agreement between our result and the earlier results is very good.

As stated in I, the isomer shift of the line arising from the dissolved cobalt, −0.68 mm/sec (*vs.* iron metal at 78°K), is consistent with that obtained for metallurgically prepared material. The isomer shift for the split spectrum of cobalt precipitates is ∼−0.06 mm/sec, essentially the same as that observed by Krop and Williams (12, 13) for fcc cobalt precipitated from cobalt-copper alloy, for precipitates larger than 10^{-17} cm^3. The unsplit (superparamagnetic) line appears in our spectra at ∼−0.14 mm/sec, close to the value −0.10 mm/sec observed by Krop and Williams (13) for small precipitates of cobalt in copper. The difference between the values for small and large precipitates has been attributed (13) to the coherency of the small precipitates with the host, which places them under dilational stress. This stress increases the lattice constant, and alters the isomer shift slightly.

Linewidths, ∼0.33 mm/sec full width at half maximum (FWHM) for the dissolved-phase cobalt and ∼0.4-0.5 mm/sec for the superparamagnetic small cobalt precipitates, are consistent with what would be expected for these phases. The observed HF field, 308 kG at 78°K, is significantly smaller than that of either iron in hcp cobalt, 323 kG (7), or iron in fcc cobalt, 334 kG (14) at the same temperature. Thus, the value of the HF field does not tell us which cobalt phase has precipitated. We believe that the precipitate phase is fcc for all annealing temperatures including 360°C. There is some question about this one temperature since the fcc to hcp transformation takes place at about 400°C for pure Co. However, the transformation temperature is depressed by about 50°C for each a/o of gold in solid solution (11). As will be discussed subsequently, it is likely that there is more than enough Au in the Co precipitates to lower the transition temperature 40°C. Another study (16) on the precipitation of cobalt from gold at 202°C also concluded that the precipitates were fcc, on the basis that no x-ray diffraction lines from hcp cobalt were observed.

For the cobalt precipitates after anneal No. 8, the temperature dependence of the HF field is H(300)/H(78) = 0.96. For bulk cobalt, H(300)/H(78) = 0.98 (7). Thus, both the absolute size and the temperature dependence of the HF field are different from bulk values. These differences arise from two causes, and give us further information on the properties of these fine precipitates.

Mørup and Topsøe (17) have recently shown that there is a temperature dependent reduction in the effective HF field for fine particles, $H = H(\text{bulk})(1 - kT/2\kappa V)$, for $kT << \kappa V$, where κ is related to the magnetic anisotropy constant for the magnetic microcrystals and V is the particle volume. We observe that the HF field decrease with temperature

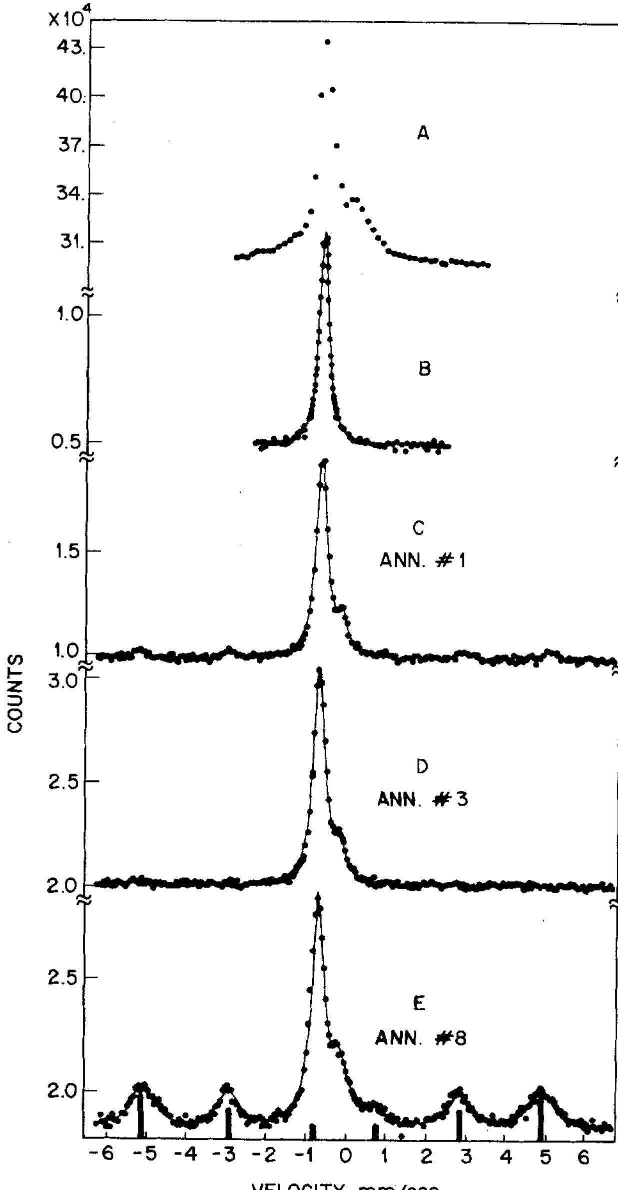

Fig. 1. Mössbauer spectra of cobalt-hardened gold deposit at 78°K after various heat-treatments. A, as deposited; B, after high-temperature treatment in hydrogen and rapid cooling; C-E, as shown in Table I. The line at −0.68 mm/sec comes from cobalt substitutional in gold, the line at −0.14 mm/sec from very fine (<60Å) superparamagnetic precipitates of fcc cobalt, and the 6 line split spectrum from fcc cobalt precipitates >60Å, which show the magnetic hyperfine (HF) splitting. The solid lines are constrained least squares fits of Lorentzian lines to the data points. Line positions and relative intensities for the magnetically split spectrum are shown at the bottom. The shoulder near zero velocity in the as-plated sample is at 0.14 mm/sec [see Ref. (1)], distinctly displaced from the line at −0.14 mm/sec from the superparamagnetic precipitates. This shoulder is believed to arise from $Co(CN)_6^{3-}$ inclusions in the deposit [see Ref. (1)] and these inclusions decompose in the high temperature anneal.

is 2% larger for the cobalt precipitates than for bulk cobalt over the range from 78° to 300°K. If we consider that decrease to arise from the term $kT/2\kappa V$, we can calculate the mean effective size of the precipitates producing the split spectrum. If we approximate κ by $|K_1|$, and use $K_1 = -1.1 \times 10^6$ erg cm^{-3} (18), we find an effective particle volume of 0.63 $\times$ 10^{-18} cm^3, or cubic particles about 90Å on a side. This is similar to the particle size studied by Krop and Williams (12).

The overall loss in HF field, from the 334 kG expected at 78°K for fcc cobalt to the 308 kG we observe,

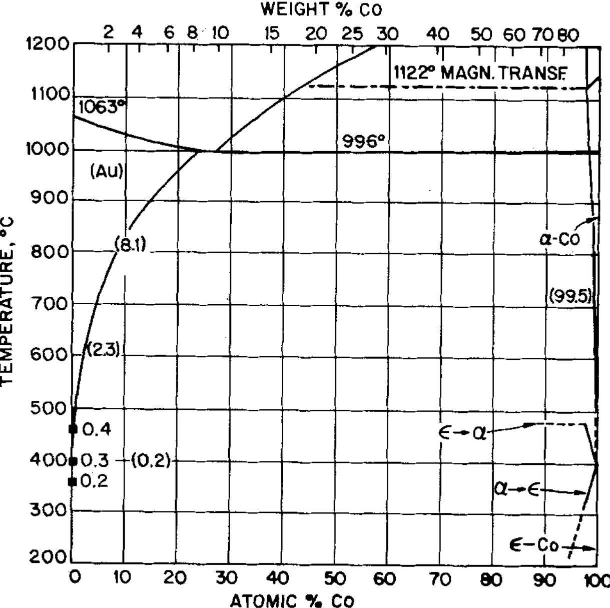

Fig. 2. Phase diagram of the gold cobalt system, from Ref. (10), with new solubility values determined for cobalt in gold from this work. Previous solubility values are in parentheses. Agreement with the older values is good, especially in view of the difficulties of determining equilibrium solubilities at low temperatures.

however, obviously comes from another cause since at 78°K the term discussed above is negligible. We believe this decrease is due to the fact that the cobalt microcrystals contain a significant amount (*e.g.*, a few percent) of dissolved gold. The presence of this nonmagnetic alloying constituent would decrease the HF field observed at both 78° and 300°K. In the work of Krop and Williams (12), a similar decrease (to 320 kG at 300°K) was observed, but not commented on. The presence of a few percent of gold in the fcc cobalt crystals would also explain the large line widths (FWHM 0.6-0.7 mm/sec) and deviations from Lorentzian line shapes observable in Fig. 1E. The variation of line shapes and effective widths among the different split lines is also characteristic of spectra of dilute alloys. The random alloy statistics provide a range of environments, and the relationship of isomer shift, quadrupole coupling and HF field affects the individual lines differently, producing a different variation of line position for each line in the spectrum. This variation leads to complex line shapes, typically different for each line.

The phase diagram both supports and contests our inference that the cobalt crystallites contain a significant amount of gold. According to Köster and Horn (11), only ~0.5 a/o of gold is soluble in cobalt below ~500°C. This amount of gold would be too small to produce the effects we observe. However, they show that the fcc → hcp transition is depressed by the alloying of the Co with up to 8 a/o of Au. Moreover, this supersaturated solid solution approaches equilibrium very slowly [Ref. (11) cites a heat-treatment of 24 hr at 700°C as being insufficient to fully achieve the equilibrium concentration of Au]. This metastable equilibrium would allow our conclusion that the reduced HF field and large line widths arise from a few percent of gold included in the cobalt microcrystals.

Discussion

The Mössbauer spectra in Fig. 1 show clearly that no cobalt metal precipitates are present in as-deposited or annealed and quenched samples of CI cobalt-hardened gold electrodeposited layers. Thus, hardening by cobalt precipitates is not an operative mechanism in providing the observed hardness. This

contradicts the claim of Ref. (3). The Mössbauer spectra also show, however, that after heating and slow cooling through ~400°C, magnetic cobalt precipitates do form. This explains the conclusions of Ref. (5), which reported magnetic properties in slowly cooled CI samples. [The cooling rate used in anneal 1 was chosen to approximate the conditions of Ref. (5) so the spectrum Fig. 1C should correspond to their sample.] The effects of long anneals at 300°C and below without an earlier high-temperature anneal, are different from the results presented here, and will be presented in a later paper. After the 800°C heat-treatment, the light impurities (H, O, C, N) should no longer be present, and the sample should be equivalent to a metallurgically prepared alloy of 0.67 a/o Co in gold. Effects observed in the subsequent anneals are thus characteristic of annealing and precipitation phenomena in metallurgical gold-cobalt alloys.

The results observed here parallel those obtained by Krop and Williams for the precipitation of cobalt crystals from dilute copper (12, 13). The precipitation of small superparamagnetic crystals and larger magnetically ordered crystals, and the retention of dissolved-phase cobalt in gold are evident from the data. In fact, our data are much more successful in resolving the line from the dissolved cobalt from that of the superparamagnetic precipitates than the data of Ref. (13). The improvement in resolution occurs because of the sharper linewidths obtained here, and the isomer shift difference between cobalt in gold and cobalt in copper. In the copper-cobalt system, the dissolved-phase line cannot be distinguished from that of the superparamagnetic precipitates, whereas it is clearly resolved in our spectra.

In addition to the effects already reported by Krop and Williams for these fine precipitates of cobalt, we have observed the superparamagnetic reduction of the HF field (17) and also determined that there is significant dissolved gold in the cobalt precipitates. We believe this to be the first report of the superparamagnetic reduction of HF field in a metallic system.

Technical Notes

Rectifying and Ohmic Contacts to GaInAsP

D. V. Morgan,[1] J. Frey, and W. J. Devlin

School of Electrical Engineering, Cornell University, Ithaca, New York 14853

The high value predicted for the electron mobility in the quaternary alloy GaInAsP lattice-matched to InP (1) may make this material valuable for the fabrication of high frequency transistors and integrated optical switching circuits. Two important technological ingredients required for such fabrication are the ability to fabricate good quality ohmic and rectifying contacts to the material. In this letter we report on some preliminary results on both these problems, and suggest a possible technology for these contacts which overcomes problems associated with the low intrinsic Schottky barrier height inherent in the material.

The material used for the present study was LPE n-type GaInAsP layers ($N_D \simeq 10^{16}/cm^3$) grown lattice-matched to a semi-insulating InP substrate. The band-

[1] On leave from the Department of Electrical and Electronic Engineering, the University of Leeds, England.

Key words: contacts, resistivity, diodes.

gap of the layers ranged from 0.99 to 1.1 eV. Metal contacts were deposited by evaporation in a vacuum of $\sim 2 \times 10^{-6}$ Torr using either resistance heating or electron beam heating.

Ohmic Contacts

For the ohmic contacts a eutectic alloy of gold/germanium (88:12) was chosen, partly because of its previous success on III-V compounds (2) and partly to allow direct comparison of the present results with these earlier results. Specific contact resistances were determined by the transmission line method (3). The pattern of contact pads was defined by photolithography and consisted of a series of 100 × 300 μm pads where the spacing between successive pads increased from 8 to 90 μm. For this system, a plot of resistance *vs.* gap length produces a straight line whose extrapolation to zero resistance may be analyzed to yield a value of ρ_c, the specific contact resistance. Samples were annealed at temperatures ranging from 380° to 550°C for 20 sec in flowing hydrogen gas. Prior to annealing, the contact's electrical characteristic corresponded to that of a leaky Schottky diode with a reverse leakage of approximately 50-80 μA. After annealing the specific contact resistance fell, decreasing to a broad minimum for alloying temperatures in the range 425°-510°C (Fig. 1). The minimum measured value of ρ_c is about 3.5×10^{-7} Ω-cm², considerably lower than the corresponding value of 10^{-6}Ω generally observed in GaAs. This low resistance is partially a reflection of the lower intrinsic barrier heights observed in the quaternary compound (0.4 compared to 0.85 eV in GaAs).

Rectifying Contacts

Gold was chosen as a rectifying contact material to allow comparison with previous studies on other III-V compounds. Samples were degreased and etched lightly in a mixture of 1% bromine in methanol. Ohmic contacts were made as described above to one-half of the samples, using Au/Ge and alloying at 450°C for 20 sec. An array of gold Schottky pads ($\simeq$ 160 μm diam) was evaporated onto the remaining half of the slice.

Figure 2 shows semilogarithmic *I-V* plots for these diodes indicating the typical results and spread in characteristics obtained. From the value of current density, J_s, obtained from this data, a value of effective barrier height may be estimated using the relationship

$$\phi_{bn} = (kT/q) \ln[A^* T^2/J_s] \quad [1]$$

where A^* is the effective Richardson constant and T the absolute temperature.

This estimate yields $\phi_{bn} = 0.39 \pm 0.015$ eV, the uncertainty being related to the spread in J_s values. These characteristics show good rectification with ideality factors, n, near unity. The barrier height obtained from the *C-V* characteristic yields a value of 0.4 eV which is consistent with the above value. The reverse charac-

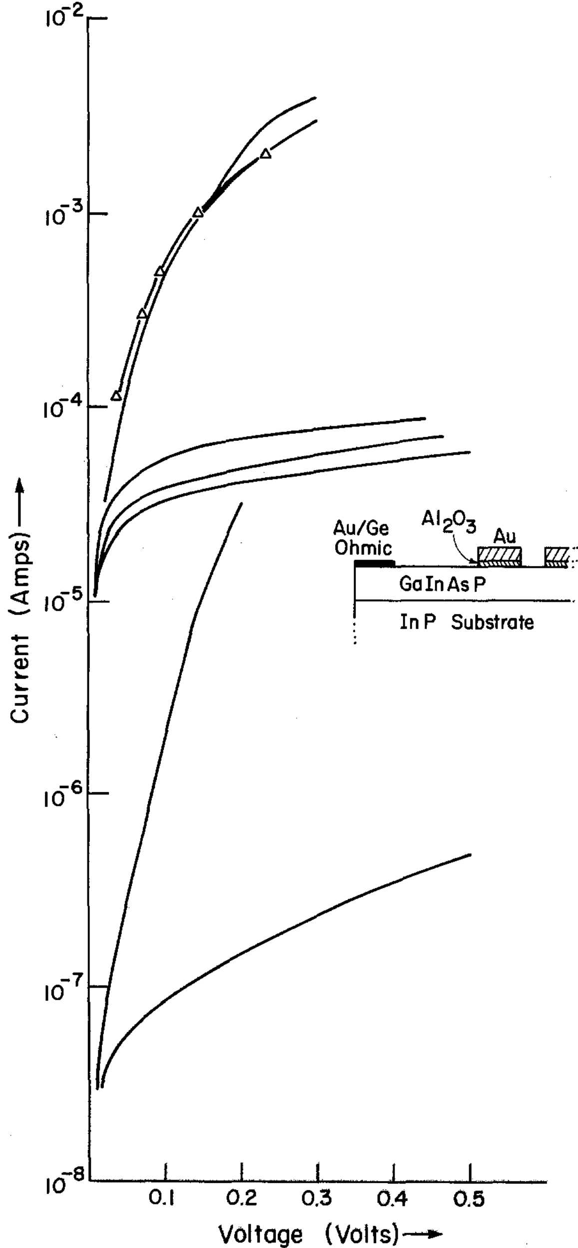

Fig. 2 (a). Forward and reverse current-voltage characteristics for Au-GaInAsP diodes. The top curves correspond to a direct Au contact and the lower set of curves corresponds to the situation where an aluminum oxide layer 7 nm thick is positioned between the metal and semiconductor.

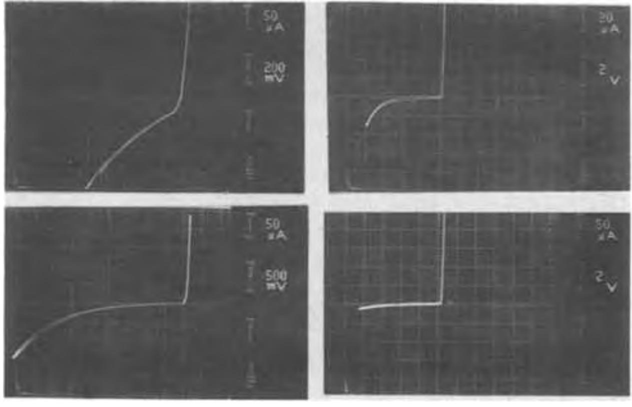

Fig. 2 (b)-(e). A series of I-V curves for (b) a direct gold contact; (c) a direct gold contact after heating in air for 24 hr at 160°C; (d) an Au/aluminum oxide/semiconductor contact; (e) an Au/SiO_2/semiconductor contact.

teristics are quite soft (see inset in Fig. 2) with breakdown values which range from 2 to 4V. Absence of guard rings and mesa etching of these test devices certainly contribute to the soft characteristics.

In the results described above, all the samples were cleaned and etched immediately prior to loading into the vacuum system for the deposition of the gold contacts. Considerable, but unpredictable, reduction in the reverse leakage could be achieved by subjecting the diodes to heating in air at 160°C for up to 24 hr. This procedure reduces the reverse leakage in some cases from $\simeq$40 μA to typically (1-10) μA at 0.1V (*i.e.*, $\phi_{bn} \simeq 0.46$ eV), and the reverse breakdown voltage increases. This improvement may be a result of the migration of oxygen through the gold film to stabilize the interfacial oxide film. Because electrons are required to tunnel through this interfacial film, transport across the junction is made more difficult (4). One could exploit this phenomenon by fabricating a metal-insulator-semiconductor structure in which a controlled thin insulating film is placed at the interface (5). If the oxide thickness is <10 nm, the metal will be in equilibrium with the semiconductor surface and the contact should exhibit the characteristics of a Schottky barrier with an increased effective barrier height, giving a reduced reverse saturation leakage as defined in Eq. [1]. Although this procedure has been shown to work for a range of semiconductors including InP and the ternary compound GaInAs (5), it is difficult to fabricate a thin insulating film with the required electrical and structural properties. Once again, therefore, the lack of a serviceable natural oxide on the III-V compounds seems a severe handicap in the technology of these materials.

In this paper, we shall consider procedures for fabricating the insulating dielectric which is compatible with FET technology. These are: (*i*) the oxidation of a thin Al film to produce aluminum oxide; (*ii*) the oxidation of a thin magnesium film to produce magnesium oxide; and (*iii*) low temperature (~80°C) plasma deposition of a thin silicon dioxide layer. Aluminum oxide is formed by depositing a thin aluminum layer at the interface and subsequently oxidizing it by heating in air at temperatures up to 250°C for up to 24 hr. In an attempt to achieve a uniform layer 5-10 nm thick and free of pinhole defects, the Al was deposited by electron beam evaporation. A deposition rate of 12 nm/min resulted in a controllable process with reasonable uniformity. Again, a gold contact was deposited over the Al_2O_3 layer. In Fig. 2, we show the current voltage curve corresponding to a typical diode with an oxide thickness 70 ± 20 nm. The improvement in leakage is dramatic with the reverse saturation current, I_s, falling by three orders of magnitude to $\simeq 4 \times 10^{-8}$ A, and yielding an effective barrier height, $\phi_{bn} \simeq 0.57$ eV. The existence of the thin oxide does not alter the n value appreciably ($n \simeq 1.04$), and the overall reverse characteristics of the diodes are seen to have improved appreciably. The reverse characteristic is much improved, with breakdown voltages of the order of 8V being typical.

A typical capacitance voltage curve for an aluminum oxide device is shown in Fig. 3. Due to the capacitance associated with the oxide, a plot of ($1/C^2$) *vs.* V cannot be used to obtain meaningful values of barrier height (5). The sequence of curves shown in Fig. 3 indicates that these devices exhibit a capacitive hysteresis effect as the devices are voltage-ramped into reverse bias, probably because of deep levels in the oxide. This hysteresis would be very undesirable if these contacts were used in FET applications; or if such oxide layers were used to increase the barrier height for DLTS or TSC studies, as the peaks from the oxide traps would interfere with the signals from the semiconductor traps.

An alternative explanation for these hysteresis effects is that they are a result of the defects known to exist at the interface between the InP semi-insulating

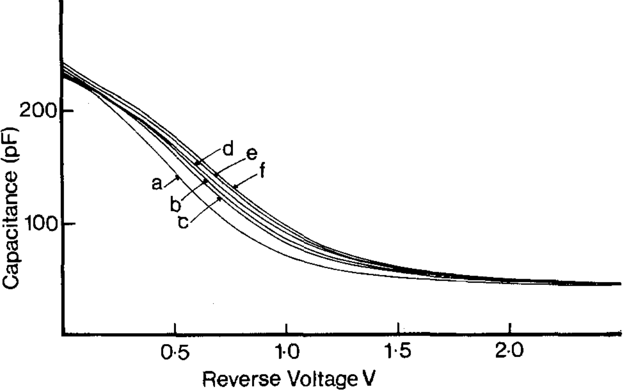

Fig. 3. Reverse bias capacitance-voltage curves measured at 1 MHz for an Au/aluminum oxide/GaInAsP contact. The curves a-f correspond to consecutive voltage scans. Delay between scans ~5 sec.

substrate and the GaInAsP epitaxial layer. However, this can be ruled out since these effects were not observed in the basic Au/GaInAsP diodes which were fabricated on the same slice.

Similar results have been obtained for the magnesium oxide system. The basic procedure is the same as that described above for aluminum, except that for the oxidation of magnesium temperatures up to 300°C were used. Magnesium oxide was investigated because it was thought that it might be possible to obtain thicker oxides than with aluminum at these low temperatures. Oxide layers produced in this way were, however, structurally inferior to the aluminum oxide layer. Furthermore, although the same general trends as those observed for aluminum were obtained, the detailed results were considerably inferior. The reverse leakage with a 10 nm oxide was ~1 μA and the reverse characteristic was soft and very unstable. It is possible that these results could be improved if the correct conditions for oxidation of the magnesium layer could be found. These studies are currently being pursued on InP (6).

The third insulating layer studied was SiO_2, deposited by a low temperature plasma process. These devices yielded results comparable to those with aluminum oxide. The diodes exhibited an abrupt turn-on voltage and ideality values of $n \sim 1.1$ in forward bias. A typical current-voltage characteristic is shown in Fig. 2(e) for an approximate oxide thickness of 15 nm. We note also from this figure that these diodes exhibit very good reverse characteristics with breakdown voltages $\lesssim$ 8V. One unfortunate feature of these diodes is their sensitivity near breakdown; the characteristics become unstable and the diodes easily destroyed (*i.e.*, exhibited low resistance).

Discussion

On the basis of the interfacial oxide tunneling theory applied to these structures, the reduction in reverse leakage as a function of oxide thickness, d, yields an effective barrier height (4, 5)

$$\phi_{bn}' = \phi_{bn} + Dd$$

where ϕ_{bn} is the clean surface value (no oxide) and D is the coefficient of increase in barrier height with oxide thickness. D may be estimated from simple tunneling theory. Figure 4 shows the result of the present work and compares these with previous studies of Si, GaAs, InP, and GaInAs. The consistency of all these results is apparent from these curves. In the majority of cases, the experimental values of D are consistently less than the theoretical values. The theoretical calculations are always subject to a great deal of uncertainty due to the lack of realistic information on the shape of the tunneling barrier. On the experimental side, the major uncertainty is the thickness of the oxide film.

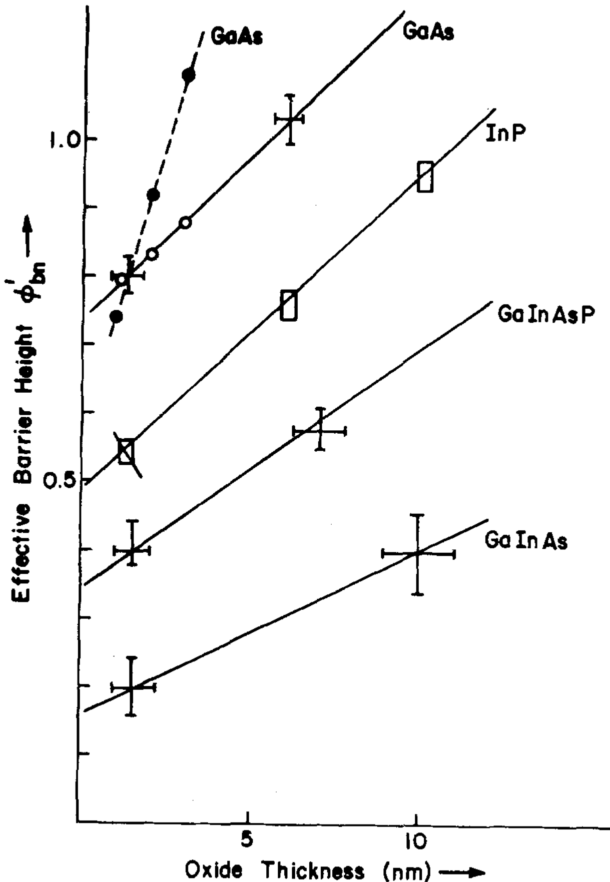

Fig. 4. Effective barrier height ϕ_{bn}' plotted as a function of oxide thickness, d, for a range of different semiconductors. The results of the present study are compared with previous work. The two curves shown for GaAs (solid line and broken line) indicate the two extreme results cited in Ref. (5). The solid line indicates the more typical results.

Conclusions

The current studies, aimed at improving the technology of ohmic and rectifying contacts to the quaternary alloy GaInAsP, yield the following conclusions.

(*i*) Specific contact resistances of $\simeq 3.5 \times 10^{-7}$ Ω-cm^2 have been obtained with Au/Ge eutectic alloyed at 450°C for 20 sec. The contact resistance is insensitive to alloying temperature over a wide temperature range from $\simeq$425° to 500°C.

(*ii*) Rectifying characteristics of evaporated Au contacts are characterized by a barrier height of 0.4 eV, with the current-voltage and capacitance-voltage techniques yielding consistent values.

(*iii*) Large increases in effective barrier have been demonstrated using interfacial layers of Al_2O_3, MgO, and SiO_2. These layers are all produced by low temperature processes and are compatible with current FET technology. Although these layers produce desirable effects on the current-voltage characteristics, they do induce some undesirable hysteresis in the capacitance-voltage curves which probably could be reduced by improving the structure of the interfacial oxide.

Acknowledgment

We are grateful to Dr. P. D. Greene (STL Limited) and Dr. R. W. Brander (Post Office Research Centre, England), for supplying the material used in this study, and to Drs. J. Comas and W. A. Schmidt (NRL Washington) for depositing the SiO_2 layers. We are also grateful to Dr. C. J. Palmström (University of Leeds) and J. Berry (Cornell) for technical assistance, and to Drs. E. C. Wood, L. F. Eastman, and K. Board for constructive criticism.

A Quantitative AES Study of the Compositional Profile of Thin Oxide Films

Katsuhiko Ishiguro and Teiichi Homma

Institute of Industrial Science, University of Tokyo, Tokyo, Japan

It is desirable to obtain quantitative information about the composition and structure of thin film corrosion products in order to understand the growth of such thin films and how they develop into thick scales.

Although Auger electron spectroscopy (AES) coupled with inert ion sputter etching can be a powerful technique for studying in-depth compositional profiles of oxidized surfaces, it is difficult to obtain quantitative results on multicomponent metal alloys. Thus, quantitative interpretations of Auger peak intensities have rarely been attempted for oxide/alloy systems. An exception is the work of Hammer *et al.* (1) who proposed an internal calibration technique for evaluating pseudobinary systems and applied it to the quantitative analysis of a variety of systems including oxide solid solutions, pseudobinary intermetallic compounds, etc.

Key words: Auger analysis, depth profile, thin film, oxide.

In this paper, their method is further extended by using relative sensitivity factors to explain Auger peak intensity changes obtained by sputter etching oxide films formed on an Fe-Cr alloy. A procedure for estimating the variation of the composition with depth from the AES data is described.

Experimental

Electropolished specimens of an Fe-18 weight percent (w/o) Cr alloy ($0.15 \times 20 \times 10$ mm^3 in size)

were oxidized in a UHV microbalance system at 620°C and 1×10^{-3} Pa O_2 for 120 min; the total weight gain was 14 $\mu g/cm^2$. The oxide crystal structure was subsequently studied using the reflection high energy electron diffraction technique.

Auger analysis was performed using a commercial scanning micro-probe analyzer (ANELVA, EMAS II). Using a primary electron beam energy of 5 kV and a current 1 μA yielded a beam ~1 μm diam. The modulation amplitude was 2V peak-to-peak. A 1 mm diam sputter ion beam was used at 2 kV, and 20 mA, and an argon pressure of 3×10^{-3} Pa. Since the average grain size of the specimen was 100 ~ 200 μm, the AES result provided information about the oxide formed on individual grains. Thus, measurements on several grains gave similar, quite reproducible results. The Auger signals used were oxygen (510 eV), chromium (529 eV), and iron (651 eV).

Results and Discussion

A typical change in Auger peak intensities during ion sputtering the oxidized alloy surface is shown in Fig. 1. Note that iron is enriched in the outermost layer while chromium is concentrated in the remainder of the oxide film. Surface contaminants (*e.g.*, C) picked up during specimen exposure to room air were neglected.

In order to explain the results of Fig. 1 by means of the internal calibration technique (1), the data were replotted in Fig. 2 and 3. In the I_{Cr} *vs.* I_{Fe} plot of Fig. 2, the directions of the arrows indicate the changing Auger intensities with increasing sputtering. Note that I_{Cr}^{**} and I_{Fe}^{*} correspond to the Auger intensities of pure chromium oxide and pure iron oxide, respectively. Also, I_{Cr}° and I_{Fe}° represent the AES strengths of the pure metals, under the same experimental conditions. The change in the peak intensities along the I_{Cr}^{**}-I_{Fe}^{*} line (1-9) can be attributed to a concentration variation in the oxide film with depth. The results in Fig. 2 indicate the outermost surface is comprised of pure iron oxide. This was then identified to be Fe_3O_4 by RHEED. The composition of the mixed oxide layer approaches that of Cr_2O_3 at point 9. Note that deeper into the material (pt. 10-18), the data do not fall on the I_{Cr}^{**}-I_{Fe}^{*} line but tend instead to fall on the I_{Cr}^{**}-I_{Fe}° line. To a first approximation, this can be interpreted to mean that the film at this depth is comprised of a metallic iron-Cr_2O_3 mixture. Since the points 10-18 fall slightly above this line, this suggests as an added refinement that a small amount of metallic chromium is also present. The I_O/I_{Fe} *vs.* I_{Cr}/I_{Fe} plot of Fig. 3 provides additional information. The straight line (L) indicates a concentration change in the pseudobinary system, $(FeO_n)_{1-x}(CrO_m)_x$. In other words, a variation of the points 1-9 along the line corresponds to

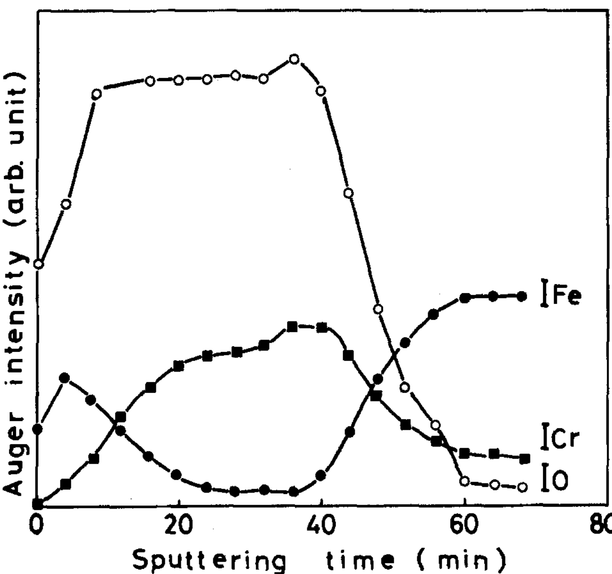

Fig. 1. Sputtering in-depth profile of Fe-18Cr alloy oxidized for 120 min at 620°C and at an oxygen pressure of 1×10^{-3} Pa.

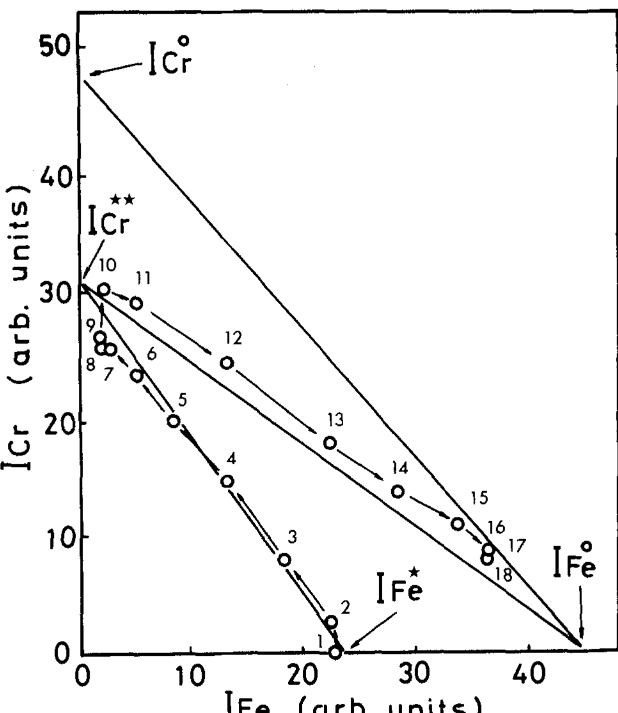

Fig. 2. Chromium peak intensity *vs.* iron peak intensity during sputtering. Auger peak intensities, I_{Cr}^{**} and I_{Fe}^{*}, for Cr_2O_3 and Fe_3O_4, respectively. I_{Cr}° and I_{Fe}° for pure metals.

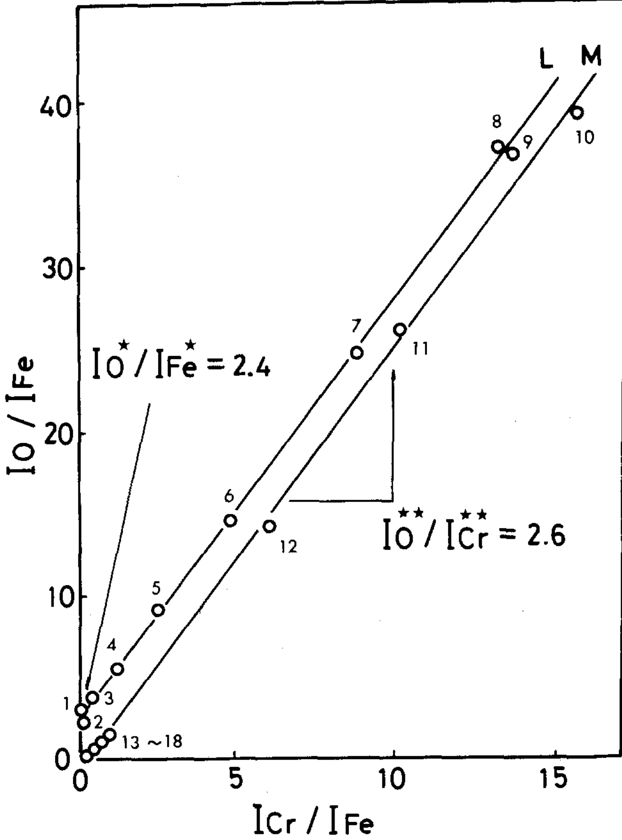

Fig. 3. Plot of peak intensity ratio I_O/I_{Fe} *vs.* I_{Cr}/I_{Fe}. Intersection and slope in L line give I_O^{*}/I_{Fe}^{*} for Fe_3O_4 and I_O^{**}/I_{Cr}^{**} for Cr_2O_3.

that on the I_{Cr}^{**}-I_{Fe}^{*} line of Fig. 2. The intersection with the ordinate axis and the slope give the values of the I_O^{*}/I_{Fe}^{*} and I_O^{**}/I_{Cr}^{**} ratios for pure iron oxide and pure chromium oxide, respectively. Further in, the points 10-18 fall on a second straight line (M), having the same slope as L, but passing through the origin, *i.e.*, where $I_O^{*}/I_{Fe}^{*} = 0$. Thus, Fe exists in the metallic state along this line, The change on M line corresponds to that on the I_{Cr}^{**}-I_{Fe}° line in Fig. 2. Accordingly, the present results show that the composition varies along L towards the chromium-rich direction (pt. 1-9), and then changes to the M line where it varies towards an iron-rich direction. This means that the oxide/alloy interface begins to appear at point 10. The slight deviation of pt. 10-18 from the M line suggests that some chromium is present in the metallic state.

The concentrations of these elements in different states were evaluated so as further to quantify the compositional in-depth profiles. For determining concentrations, the following empirical formula with the relative sensitivity factor (2) was employed.

$$X_i = \alpha_i I_i / \Sigma \alpha_j I_j \quad [1]$$

where the sum of the iron and chromium concentrations has been normalized to 100%. In this case,

$$X_i = \alpha_i I_i [\alpha_{Cr}(I_{Cr}^{Ox} + I_{Cr}^{Me}) + \alpha_{Fe}(I_{Fe}^{Ox} + I_{Fe}^{Me})]^{-1} \quad [2]$$

$$I_{Cr} = I_{Cr}^{Ox} + I_{Cr}^{Me} \quad [3]$$

$$I_{Fe} = I_{Fe}^{Ox} + I_{Fe}^{Me} \quad [4]$$

$$I_O = K_1 I_{Cr}^{Ox} + K_2 I_{Fe}^{Ox} \quad [5]$$

$$K_1 = I_O^{**}/I_{Cr}^{**}, \quad K_2 = I_O^{*}/I_{Fe}^{*} \quad [6]$$

where I_i^{Ox} represents the Auger intensity for the oxide, I_i^{Me} for the metal and α_i is an inverse relative sensitivity factor. A value of 1.22 for α_{Fe}/α_{Cr} was used here. $K_1(=2.6)$ and $K_2(=2.4)$ were determined by the slope and the intersection of L at the point of a vertical line in Fig. 3. The following approximations have been introduced to determine X_{Cr}^{Ox}, X_{Cr}^{Me}, X_{Fe}^{Ox}, and X_{Fe}^{Me} from Eq. [2]-[6]

(*i*) $I_{Cr}^{Me} = I_{Fe}^{Me} = 0$ on L line in Fig. 3 (pt. 1-9)

(*ii*) $I_{Fe}^{Ox} = 0$ on M line in Fig. 3 (pt. 10-18)

The validity of these approximations has been confirmed by measurements of the low energy Auger peaks of iron and chromium in order better to evaluate their chemical valence states (3).

The compositional profile obtained from these procedures has been shown in Fig. 4, where the chemical state of each element was denoted in parentheses. Thus, Cr^{+3} ions were established to be the dominant cation state in the chromium oxide layer. In addition, the I_O^{**}/I_{Cr}^{**} value (=2.6) in Fig. 3 is quite close to that for bulk Cr_2O_3 (=2.6), and the I_O^{*}/I_{Fe}^{*} (=2.4) in Fig. 3 is also quite close to that for bulk

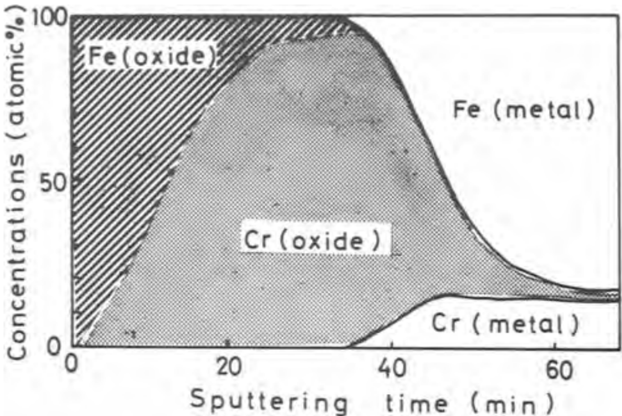

Fig. 4. Concentration profiles for chromium and iron

Fe_3O_4 (=2.6). Most likely, the bulk of the oxide between the Fe_3O_4 and Cr_2O_3 regions is a spinel, $Fe_{3-x}Cr_xO_4$ ($0 < x \leqq 2$). In this discussion, we do not consider effects due to preferential sputtering and decomposition of the oxides by bombardment, because it has been confirmed that these effects are negligible for the Cr_2O_3 and Fe_3O_4 mixture system (5).

The present results are similar to those obtained for thick scales formed at 600°C and higher O_2 pressures, as determined (1 atm) by using the Electron Probe Micro Analyzer (4). The formation of α-Fe_2O_3 was expected for the present oxidation conditions from thermodynamical consideration. However, this phase did not appear. At lower oxygen pressures (below 10^{-3} Pa) α-Fe_2O_3 formation has not been reported for pure iron oxidation (6). An average oxide film thickness was evaluated from the total weight gain of 14 $\mu g/cm^2$. This thickness is ~900Å, assuming an average density for the Cr_2O_3 and Fe_3O_4 mixture of 5.2 g/cm^3.

Anomalous Etch Structures Using Ethylenediamine-Pyrocatechol-Water Based Etchants and Their Elimination

A. Reisman, M. Berkenblit, C. J. Merz, A. K. Ray, and D. C. Green
IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Recently, several of the authors published the results of studies on pyrazine catalyzed ethylenediamine-pyrocatechol-water etchant solutions (1). Two quaternary etchant compositions were defined for use in slow and fast etching applications S and F etch, respectively. S etch was found useful in the temperature range from 50°C up to the solution boiling point at approximately 118°C. In using S etch at 50°C, a new phenomenon was observed, which was found not to be an attribute of S etch composition, but was in fact observed with uncatalyzed solutions as well. This phenomenon, manifests itself on single crystal material by the appearance of a dense etch structure pattern reminiscent of dislocation mound etch structures, as shown in Fig. 1. The effect is odd, in that with repeated 50°C etchings conducted in a bath contained in the apparatus shown in Fig. 1 of Ref. (1), some baths never exhibited the effect, some exhibited it immediately, while others did so only after several wafers had been etched.

This indicates that whatever causes the effect does not necessarily do so by itself, but first participates in a slow reaction in the etching bath forming something else which causes the effect. Based on the above, it would appear that because some baths show the effect immediately while others do so only after a period of time, that the time of first observation of the etch structure depends on the level of contamination of the unknown contaminant in the as constituted bath.

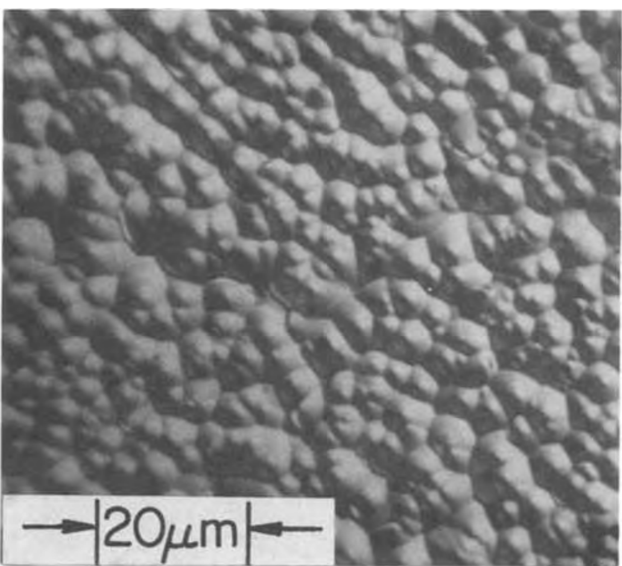

Fig. 1. Photomicrograph of an Si surface etched at 50°C

The problem was traced to the use of different lots of ethylenediamine. The effect was found using ethylenediamine which was contaminated with pyrazine as well as with ethylenediamine which was pyrazine free. Our best efforts have thus far been unsuccessful in identifying the causative agent. Photon absorption techniques show no difference between lots of ethylenediamine which cause the effect and those which do not. Similarly, high pressure liquid phase chromatographic isolation techniques have not provided any clues.

We have been unable to create the effect by contaminating ethylenediamine with NH_3, CO_2, HCl, or a colloidal silica suspension, but have developed a simple procedure which eliminates it. If after constituting an etchant bath, it is heated for 1 hr at 115°C under an inert gas ambient atmosphere, as for example might be done with the apparatus described in Ref. (1), the effect is absent even with baths that would yield the etch structure immediately. Preheating of the ethylenediamine by itself under the same conditions works equally well. If the time of 115°C treatment is less than 1 hr, the freedom from the effect cannot be guaranteed. For example, following 20 min 115°C pretreatments, some known bad baths used at 50°C did not show the effect again until several wafers had been etched, and several hours had elapsed. Others did not exhibit the effect again at all. All baths, however, showed an alleviation from the effect for at least several hours. When treated at 115°C for 1 hr instead of 20 min, however, no previously bad bath has been found to revert to its bad status. This indicates that whatever it is that causes the effect is either decomposed or volatilized by the extended 115°C treatment. Incidentally, it is not uncommon to use pyrocatechol based baths in an open beaker at from 105°C to its boiling point. We constituted such a bath using ethylenediamine which was known to yield the etch structure, but which was pyrazine free, and used it to etch (100) wafers at the solution boiling point with a 5 min pretreatment at the boiling point. The etch structure was observed and of course, as is the case with such uncatalyzed baths exposed to air, the bath exhibited significant darkening due to oxidation. Consequently, even if such pyrazine free solutions are to be used in air at temperatures above 100°C, it would be necessary first to pretreat them or the ethylenediamine at 115°C for 1 hr in an inert gas ambient atmosphere prior to their use in air.

Photoelectrochemistry of Hydrogenated Amorphous Silicon (a-Si:H)

Yitzhak Avigal, David Cahen, Gary Hodes, Joost Manassen, and Baruch Vainas*

The Weizmann Institute of Science, Rehovot, Israel

and R. A. G. Gibson

Carnegie Laboratory of Physics, Dundee, Scotland

Photoelectrochemical cells (PEC's; semiconductor-liquid junction solar cells) have attracted much attention as candidate systems for practical conversion of solar energy into electricity since the pioneering work by Fujishima and Honda (1), Gerischer (2), and others (3). Several studies have been reported, using crystalline silicon (c-Si) as the semiconducting photoelectrode in a PEC containing an aqueous electrolyte (4, 5). The results show that c-Si is grossly unstable in such a PEC, probably because of the very rapid formation of an electrically blocking surface oxide layer. The same material has been used in organic solvents, both as a photoanode (6, 7) and a photocathode (7). Relatively low photocurrents were reported and no information on conversion efficiency and stability under solar conditions was presented.

Lately, since the discovery that glow-discharge deposited amorphous silicon (a-Si:H) can be successfully doped (8) there has been much interest in the potential use of this material in solid-state photovoltaic cells (9) [see, for example, the recent reviews by Gibson *et al.* (10) and Wilson *et al.* (11)]. a-Si:H has the advantage over c-Si of ease of preparation and, because direct optical transitions dominate its absorption/reflection spectrum, it can be used in thin layers ($\sim 1\mu$ compared to $\sim 100\mu$ for c-Si). The photoanode properties of vapor-deposited a-Si in aqueous solution have been mentioned briefly, and its output instability noted (4). Here we present preliminary results on the properties of an a-Si:H based PEC which uses the nonaqueous electrolyte system of Legg *et al.* (6), *i.e.*, ferrocenium/ferrocene in ethanol, and compare them to those for a similar c-Si based system.

Experimental

Stainless steel or titanium were used as the substrates for the glow-discharge deposition of a-Si:H layers as n-type material ($N_D \sim 10^{17}$ cm^{-3}) (8). Except for the photoactive area the electrode was encapsulated in epoxy resin. Photoelectrodes of c-Si were prepared from wafers of n-type Si, cut along the (111) plane with 1-10 Ω-cm resistivity (kindly provided by Dr. J. Mandelkorn of the Weizmann Institute of Science). Ohmic contacts were made using In-Ga alloy and silver epoxy. The electrolyte was an absolute ethanolic solution of ferrocene (70 mM, Aldrich) and 0.5 mM ferrocenium, prepared by electrochemical oxidation of ferrocene in a separate H-cell. The supporting electrolyte was tetrabutyl-ammonium perchlorate (TBAP) (0.1M, G. Frederick Smith Chemical Company). Potentiostatic experiments were carried out with a Wenking LT73 potentiostat, using a Pt gauze counterelectrode and standard calomel electrode (SCE) as the reference electrode, connected to the working solution via a salt bridge of TBAP in ethanol. All experiments were done under an argon atmosphere in deaerated solutions. Stability tests were carried out under constant temperature conditions.

Both types of electrodes were etched by 40% aqueous HF: a-Si:H three times for 5 sec and rinsed with absolute ethanol after each etch. c-Si was etched three times for 20 sec and rinsed with absolute ethanol after each etch.

Key words: amorphous Si, photoelectrochemistry, solar energy conversion, nonaqueous electrolytes.

Results and Discussion

Figure 1 shows dark and light potentiostatic *I-V* curves of a-Si:H and c-Si. The onset of photocurrent for these two photoelectrodes occurs at quite similar electrode potentials, (100 mV difference under the conditions of Fig. 1), which reflects their similar flatband potentials. The saturation open-circuit voltage at high illumination intensities suggests a value of 740 mV (−440 mV *vs.* SCE) for the a-Si:H flatband potential, which should be compared with 700 mV (−400 mV *vs.* SCE) for c-Si (6). On the basis of this information and the measured values of the optical energy gap of 1.1 eV for c-Si and 1.7 eV for a-Si:H, the energy diagram of Fig. 2 can be constructed. The band-edge energies shown are minimum ones only, and it is quite possible that they may be more negative, because of differences between E_F and E_C, both in a-Si:H and c-Si. Such a shift, however, does not affect the conclusions of this work. Figure 1 also shows that the cathodic overpotential for dark, forward currents for a-Si:H is considerably larger than that for c-Si. This may be caused by the much lower concentration of surface states on a-Si:H than on c-Si, something which may influence the photocurrents as well (12).

Variable load (nonpotentiostatic) *I-V* curves of a-Si:H based PEC's show, at an illumination intensity of 100 mW/cm^2 (~AM1 solar irradiation), a photocurrent of 1.2 mA/cm^2, and a photopotential of ~500 mV, with a fill factor of ~0.4 (~0.24% efficiency). At 1500 mW/cm^2, under these conditions, a photopotential of ~700 mV is obtained (quite close to saturation), a photocurrent of ~4.5 mA/cm^2, and a fill factor of

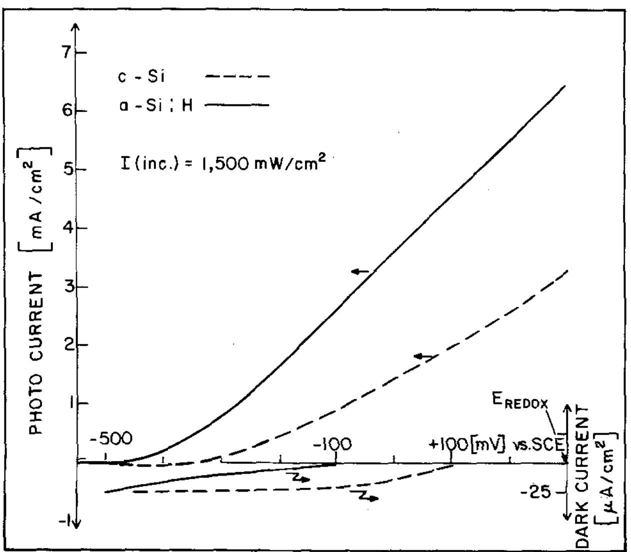

Fig. 1. Light and dark potentiostatic *I-V* curves for a-Si:H (solid lines) and c-Si (dashed lines). E_{REDOX}: Redox potential of the 70 mM ferrocene, 0.5 mM ferrocenium ethanolic solution. Note the different current scales for dark and light currents. I(inc) = Incident light intensity.

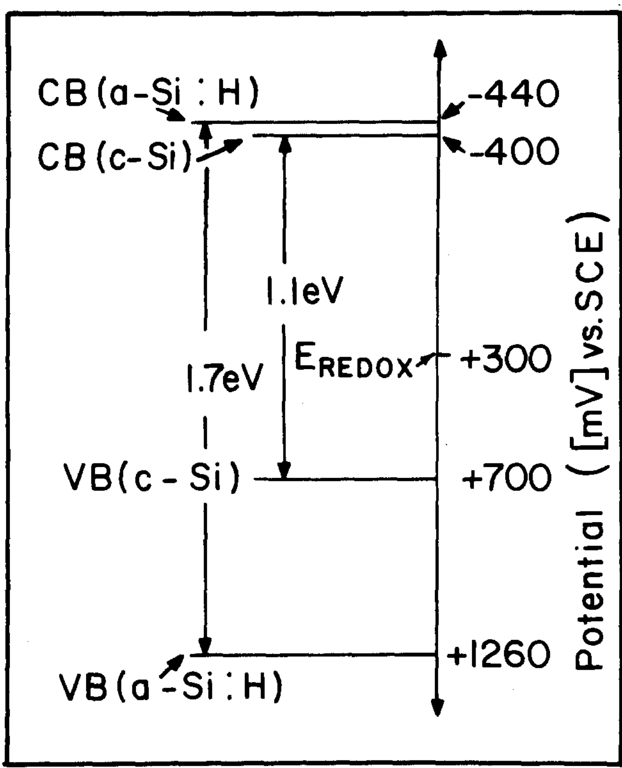

Fig. 2. Scheme of relevant energy levels for a-Si:H and c-Si/ferrocene-ferrocenium semiconductor-electrolyte junctions. E_{REDOX}: as in Fig. 1.

~0.2. The relatively small photocurent (as compared to Fig. 1) is due to the fact that the electrode was at ~0 mV *vs.* SCE under short-circuit conditions, and not at the electrolyte redox potential of +300 mV *vs.* SCE, as it ideally should have been. This is probably because of the larger resistance drop between the electrodes in the rather dilute organic electrolyte.

Spectral response measurements show the onset of photocurrent for a-Si:H to be around 700 nm, with a maximum response around 530 nm. This spectral response agrees quite well with a superposition of the solution absorption spectrum and the a-Si:H reflectance spectrum, and that of a-Si:H based Schottky cells (when electrolyte absorption losses are taken into account).

In Fig. 3 the photocurrent of an a-Si:H-based PEC is shown as a function of charge passed, reflecting the cell output stability. The photocurrent decreases to about half its initial value during the first ten hours (~ 30C passed), after which the deactivation process virtually stops. It is quite probable that this deactivation is due to a buildup of an insulating silicon oxide layer on the electrode surface. Also, after deactivation, the photoelectrode dark potential shifted by ~ 100 mV to a more negative value. Deactivated photoelectrodes were easily reactivated by etching with 40% aqueous HF. (The electrode performance was found to be very sensitive to the exact surface etching process.) a-Si:H photoelectrodes of small surface area (down to 5 mm^2) were found to give better and more reproducible performance than larger ones, possibly pointing to the existence of pinholes.

The stability of a-Si:H based PEC's is similar to that of c-Si ones under our (near short-circuit) conditions (those of Fig. 3), and under those conditions it seems to be a function of the initial photocurrent density, mainly. However, because of the consistently higher photocurrents of a-Si:H PEC's as compared to c-Si ones under identical illumination conditions, photocurrent decay of a-Si:H cells may start at lower illumination levels than is the case for c-Si ones. The stability referred to in Ref. 6 (with monochromatic excitation at 632.8 nm of ~10 mW/cm^2, and short-circuit photocur-

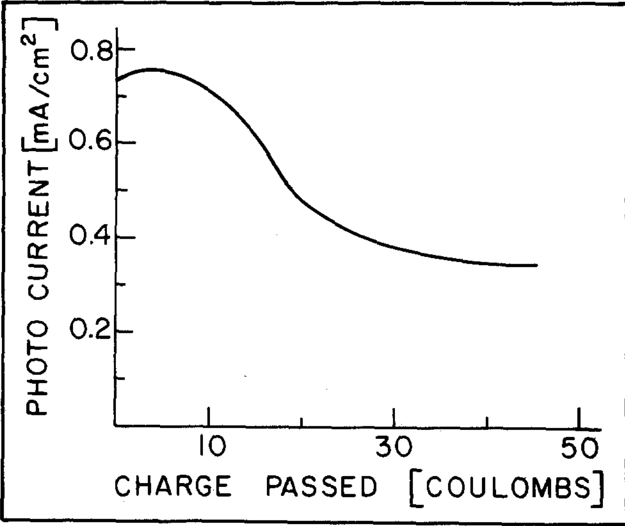

Fig. 3. Photocurrent of a-Si:H as function of charge passed. AM1 simulated illumination. $R = 100\Omega$ (near short-circuit for this, organic electrolyte-containing, PEC). Temp.: 30°C.

rent densities between 0.3 and 1.2 mA/cm^2) is not found by us under the conditions used in this study.

The similarities and differences between these two forms of silicon can be understood further by investigating the transient photocurrents obtained from them, and this study, presently in progress, will be reported elsewhere. Figure 2 does show, however, that the electron affinities of a-Si:H and c-Si are quite similar and thus it seems that this physical quantity is dictated mainly by the similar immediate environment of the Si-atoms in the two materials, possibly by the similar Si—Si bonds, and much less so by long-range forces. Additional evidence for this explanation comes from: (*i*) the reported decrease in optical bandgap with decreasing hydrogen content of a-Si:H (13), and (*ii*) photoelectron spectroscopic data, that show that increasing the hydrogen content in a-Si:H shifts the valence bandedge down with respect to the conduction bandedge, which remains fixed (14). This suggests that Si-H interaction plays a role in determining the valence band position but that the conduction band position is not (or very much less so) affected by it.

Also, from Fig. 2 we see that the energy gained by a hole in the semiconductor which reaches the surface and interacts with the ferrocene in solution is nearly 600 mV more in the case of a-Si:H than in that of c-Si. If it is necessary to overcome an activation energy (overpotential) for this reaction to take place, then this difference in energy gain may explain the larger photocurrents observed for a-Si:H than for c-Si, under similar illumination conditions.

In summary, the above results show that the photoelectrochemical behavior of a-Si:H is in most respects superior to that of c-Si in the redox electrolyte used here. However, this electrolyte system is still far from ideal, from both stability and efficiency considerations, for a-Si, as well as for c-Si, photoelectrodes.

On the Design of Silver-Hydrogen Electrochemical Cells

P. O'D. Offenhartz and G. L. Holleck*

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

With a projected energy density of 70-110 W-hr/kg and an estimated lifetime in excess of 1000 cycles, silver-hydrogen cells represent a promising electrochemical energy storage device for specialized applications. A cell design using a rolled stack configuration is especially attractive. A comprehensive computer simulation has been used to optimize the energy density of such a cell. The parameters considered include: cell geometry, electrode and lead dimensions, water generation and consumption, electrolyte movement, heat generation and dissipation, and active material utilization. The results show that balancing of electrolyte transport processes is essential for stable long term operation. Energy density is a strong function of rate, with incomplete silver electrode utilization the main factor. At higher rates no more than three or four layers can be used if the maximum temperature increase on discharge is to be kept below 5°-10°C to avoid electrolyte loss via evaporation/condensation processes. Conversely, use of only one or two layers leads to an unacceptably high penalty in the energy density.

A metal-gas battery based on the $Ag-H_2$ couple is an attractive power source, particularly in terms of the weight energy density. By replacing the Zn electrode in the Ag-Zn system with the H_2 electrode, the main drawback of Ag/Zn batteries, short cycle life, can be overcome. However, the relatively high solubility of silver oxide in alkaline electrolytes still requires use of argentistatic membranes similar to those employed in Ag-Zn cells.

Oxidation of the silver electrode during charging nominally takes place in two steps

$$2Ag + 2\,OH^- \rightarrow 2e^- + H_2O + Ag_2O \quad [1]$$

$$Ag_2O + 2\,OH^- \rightarrow 2e^- + H_2O + 2AgO \quad [2]$$

In alkaline media the relevant reaction at the H_2 electrode is

$$2H_2O + 2e^- \rightarrow H_2 + 2\,OH^- \quad [3]$$

so that the overall cell reactions are

$$2Ag + H_2O \rightarrow H_2 + Ag_2O \quad [4]$$

$$Ag_2O + H_2O \rightarrow H_2 + 2AgO \quad [5]$$

At 25°C the relevant thermodynamic data (1) for the first reaction are $\Delta G^\circ = 54.104$ kcal/mole, $\Delta H^\circ = 61.011$ kcal/mole, and $\Delta S^\circ = 23.17$ ($\epsilon^\circ = 1.173V$); for the second reaction, $\Delta G^\circ = 66.202$ kcal/mole, $\Delta H^\circ = 70.085$ kcal/mole, and $\Delta S^\circ = 13.02$ ($\epsilon^\circ = 1.435V$). In practice, during charging the cell voltage increases sharply to the second plateau after roughly 30% of the ultimate net capacity has been reached; during discharge, the cell voltage drops after about 35% of capacity. A typical voltage-time trace for an $Ag-H_2$ cell is shown in Fig. 1. Charge utilization of the Ag electrode is generally in the range 40-70%, and, as shown in Fig. 2, is a strong function of the current density.

* Electrochemical Society Active Member.

Key words: cell, energy density, electrolyte.

Several aspects of $Ag-H_2$ cell design have been considered in the literature (2-5). Electrolyte management is the main problem area (6). In this paper we briefly summarize the design implications of the earlier work, which has focused on cells with stacked electrodes (4, 5), and then proceed to a discussion of a computer simulation model for rolled $Ag-H_2$ cells. The model takes into account both the mechanical and electrochemical aspects of design, and can optimize such features as pressure vessel radius and length for maximum energy density subject to constraints on volumetric density, thermal gradients, and discharge rate.

Electrolyte Management

Unless the two electrodes are separated by an argentistatic membrane, dissolved silver oxide will migrate

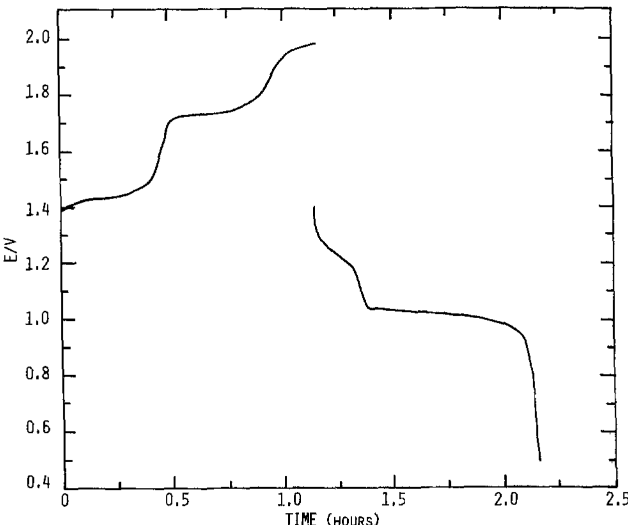

Fig. 1. Typical voltage-time trace during a charge-discharge cycle of an Ag/H_2 cell.

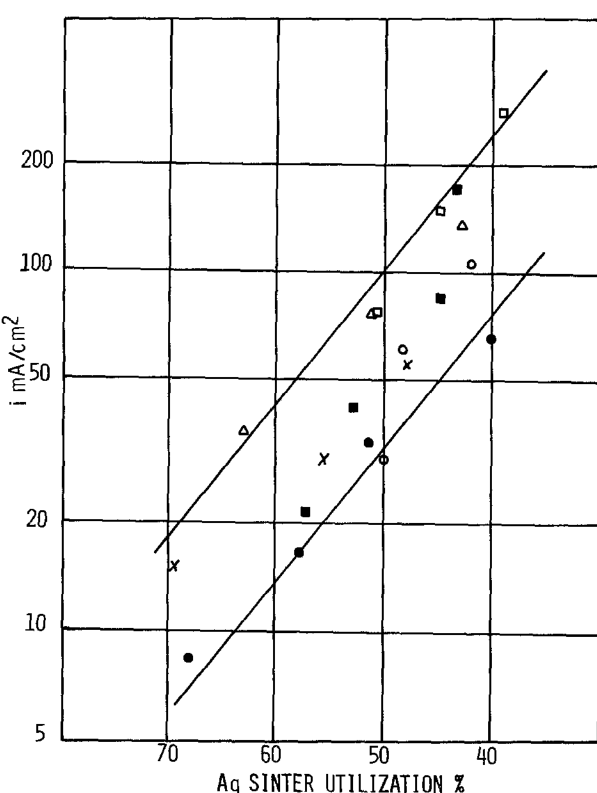

Fig. 2. Effect of current density on silver electrode utilization. × = thin (0.028 cm) Conf. I (one-sided use); ○, ● = thin Conf. II (two-sided use); △ = thick (0.063 cm) Conf. I; □, ■ = thick Conf. II.

to the H_2 electrode. This not only causes reduced cell capacity but also leads to internal shorting when the dissolved oxide is reduced to silver. Indeed, migration is such a serious problem that the barrier membrane must be extended well beyond the edges of the electrodes to eliminate rapid Ag bridging and shorting. However, in a pressure vessel with stacked electrodes, extension of the membranes would seriously reduce heat transfer between the electrodes and the vessel walls, leading to high thermal gradients and possible evaporation of water from the electrolyte and condensation on the vessel walls. This problem can be solved by using a rolled electrode configuration, in which the barrier membrane extensions do not increase the gap between the vessel wall and the electrode. As we demonstrate in the next section, this approach is limited by the thermal conductivity of the electrode roll in the direction perpendicular to its axis, which is much lower than the thermal conductivity in the parallel direction. A rolled configuration is hence limited to a few layers.

A second problem in electrolyte management is consumption of water during charging, which, as can be seen from Eq. [4] and [5], is inherent in the cell chemistry. To prevent the electrodes from drying out it is essential to use electrolyte reservoirs. Casual examination of Eq. [1]-[3] indicates that the H_2 electrode is likely to dry out during the charging step. In practice, drying out of the Ag electrode during charge is the real problem (6). This is because electromigration of KOH tends to increase the KOH concentration in the H_2 electrode reservoir. The diffusion constant for water is larger than for KOH, but both are sufficiently large that the concentration gradient on the two sides of the barrier membrane is small. Thus, electromigration of KOH into the H_2 electrode reservoir leads to large-scale diffusion of water out of the Ag electrode reservoir, thus drying it. Careful analysis indicates that this problem cannot be solved merely by increasing the volume of the Ag electrode reservoir; the excess of charge over discharge current (*i.e.*, overcharge) will lead to drying in a few cycles. It is hence necessary to select and adjust the various transport parameters through the argentistatic membranes such that a suitable balance of the mass flow can be maintained. Of the four membranes investigated—Visking, Permion 2291, Permion 2193, and the NASA IO separator—only the latter could meet these requirements. A significantly higher rate of electrolyte backwicking is the main distinguishing parameter. This topic will be treated more fully in a subsequent paper (7).

Experimental and theoretical considerations along the lines above have led to a preferred cell design consisting of a 25 mil thick porous Ag electrode, an inorganic-organic NASA separator (similar to the earlier "Astropower" separator) with the membrane side away from the Ag electrode, and a 20 mil asbestos absorber layer between the separator and the H_2 electrode. Such test cells have survived over 500 charge/discharge cycles to 70% depth of discharge at the C/1.4 rate with capacity loss under 10%. (On this basis we project a lifetime in excess of 1000 cycles.) The simulation program used the gravimetric and thermal properties of this electrode arrangement in optimizing the overall cell design.

Computer Model for Ag-H_2 Cells

The generalized mechanical design for Ag-H_2 cells is shown in Fig. 3-7. The labels for the various dimensions, which are the FORTRAN variable names, are explained in Table I. Although the program makes it possible in principle to vary any of these dimensions, only the pressure vessel radius, length, and thickness were routinely and systematically altered, along with the number of Ag-H_2 electrode pairs in the "roll."

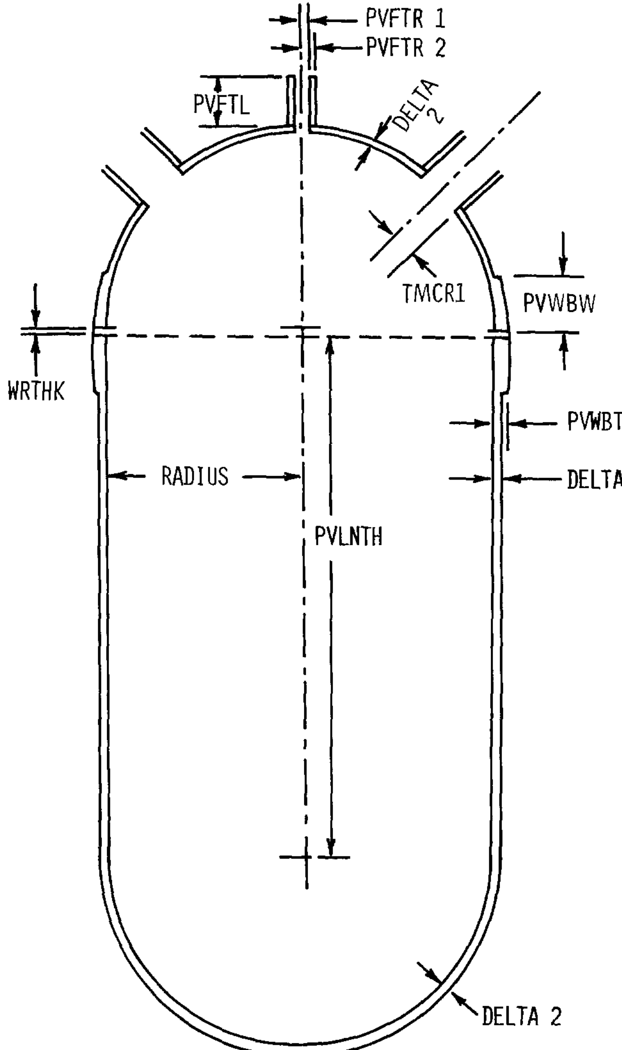

Fig. 3. Basic dimensions of the generalized pressure cell design

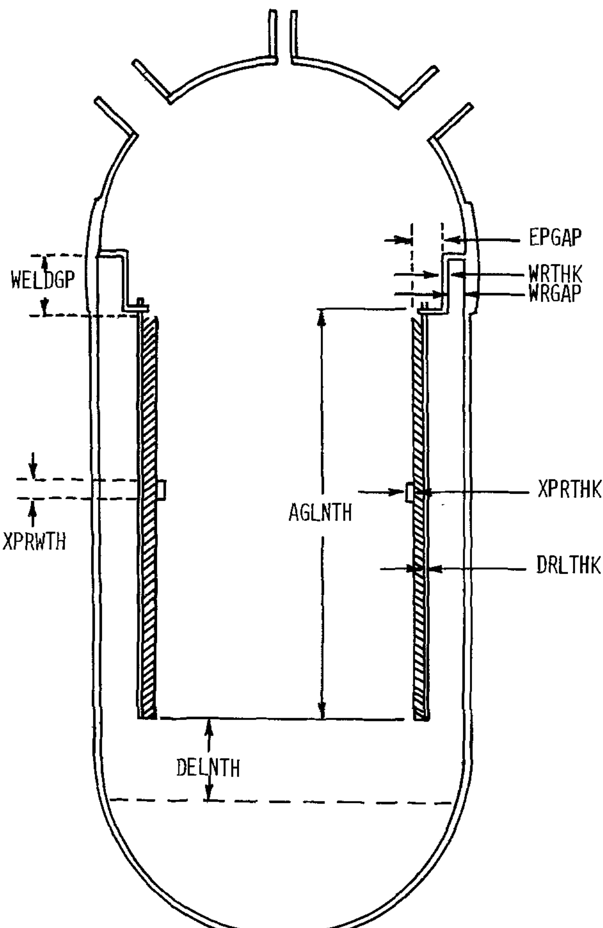

Fig. 4. Interior details of the generalized pressure cell design

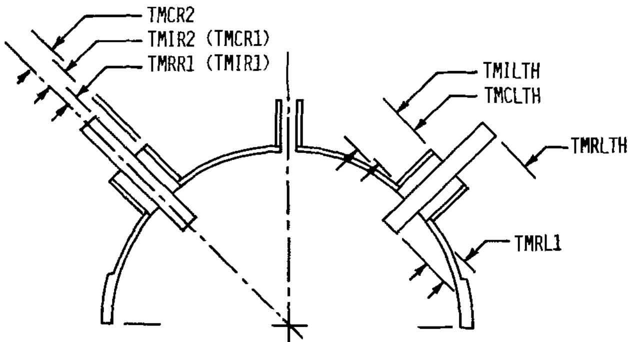

Fig. 5. Details of the electrode terminals

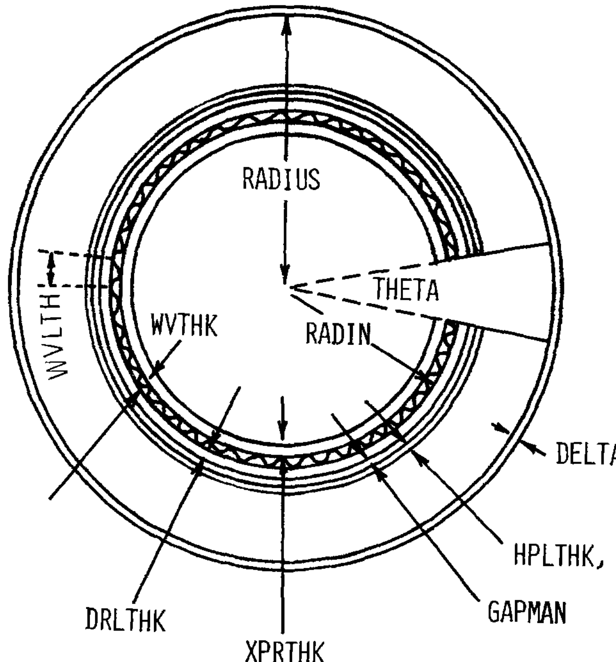

Fig. 6. Details of the support structure for the electrode roll

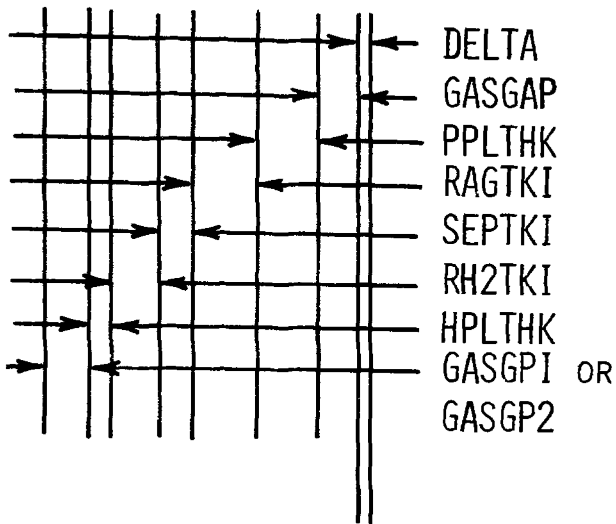

Fig. 7. Electrode roll structure. Gas gap between H_2 and Ag electrodes is GASGP2; between adjacent H_2 electrodes, GASGP1.

Given the cell capacity, the thickness of the Ag electrode, and the number of electrode pairs, knowledge of the silver utilization allows calculation of the electrode area. The experimental relationship between utilization U and discharge current density i_d is approximately represented by the equation

$$U = 0.208 - 0.286 \log (i_d) \qquad [6]$$

Since the current density depends on plate area, an iterative technique is used to obtain both the Ag utilization and the plate area. The current density is inversely proportional to the discharge time, so required plate area is also a function of discharge time.

Since the plate area is known, the radius and length of the pressure vessel are no longer independent variables. The program provides values for both variables in the following fashion. First, an arbitrary radius is chosen, and the length of the pressure vessel is calculated using the known plate area. The entire weight and volume calculations follow. A new (and larger) radius is chosen, and the calculations are repeated. This process is continued until the selected volumetric energy density is bracketed; the program then interpolates the correct radius and repeats the calculations once more. In this way the program provides a cell design with a preselected volumetric energy density.

The quantity of H_2 in the cell is of course determined by the cell capacity, and the volume is fixed by the pressure vessel radius and length. (Excluded volumes, e.g., mandrel, electrode roll, leads, and terminals, are taken into account). The maximum cell pressure is hence determined by the assumed maximum temperature (20°C). This in turn fixed the thickness of the pressure vessel walls (Inconel 718, with a safety factor of 2).

With three main exceptions, the remaining components in the cell are of fixed design, and are assumed to have fixed weights and volumes. The exceptions are the H_2 electrodes (Ni Exmet™ screen supporting the Teflon bonded platinum black) and the H_2 and Ag electrode leads. These elements make a substantial contribution to the overall weight, and also affect the net cell energy due to resistive heat losses. Thus, the thickness of each of these three elements is optimized so

Table I. Definitions of the cell dimensions (FORTRAN variable names) in the generalized mechanical design shown in Fig. 3-7

FORTRAN Variable names	Definition
AGLNTH	Length of Ag electrode.
DELNTH	Gap between end of electrode roll and beginning of hemispherical end cap.
DELTA	Thickness of pressure vessel wall, cylindrical section.
DELTA2	Thickness of pressure vessel wall, hemispherical section.
DRLTHK	Mandrel thickness.
EPGAP	Length of support ring section.
GAPMAN	Gap thickness between mandrel and innermost electrode.
GASGAP	Gap thickness between pressure vessel and outermost electrode.
GASGP1	Gap thickness between adjacent H_2 electrodes.
GASGP2	Gap thickness between H_2 and Ag electrodes.
HPLTHK	Thickness of H_2 electrode.
PPLTHK	Thickness of Ag electrode.
PVFTL	Length of pressure vessel fill tube.
PVFTR1	Inner radius of pressure vessel fill tube.
PVFTR2	Outer radius of pressure vessel fill tube.
PVLNTH	Length of cylindrical section of pressure vessel.
PVWBT	Thickness of pressure vessel weld band.
PVWBW	Width of pressure vessel weld band.
RADIN	Inner radius of electrode roll.
RADIUS	Inner radius of pressure vessel.
RAGTKI	Thickness of Ag electrode reservoir.
RH2TKI	Thickness of H_2 electrode reservoir.
SEPTKI	Thickness of separator.
THETA	Angular gap in electrode roll.
TMCLTH	Length of the terminal case.
TMCR1	Inner radius of terminal case.
TMCR2	Outer radius of terminal case.
TMILTH	Overall length of terminal case.
TMRL1	Length of the inner terminal section.
TMRLTH	Overall length of the terminal.
TMRR1	Radius of the terminal.
WELDGP	Length of support ring section.
WRGAP	Gap between support ring and pressure vessel wall.
WRTHK	Thickness of weld ring (support ring).
WVLTH	"Wavelength" of corregation.
WVTHK	Overall thickness of corregation.
XPRTHK	Thickness of expansion ring.
XPRWTH	Width of expansion ring.

as to maximize the gravimetric energy density. The technique for optimizing the plate thickness is a bit more difficult than that required for the leads, so we confine the present discussion to the leads. A discussion of plate thickness optimization is available elsewhere (8).

We consider a set of n electrode leads, each of length l and resistance R. The material properties of the leads are the resistivity ω (in Ω-cm), the density ρ, and the thermal conductivity K (in W-cm^{-1}·deg^{-1}). The current through each lead will be designated by i. Then, for each lead, we may write the weight, W, cross-sectional area A, and energy dissipation E as

$$A = \frac{\omega l}{R} \quad [7]$$

$$W = Al\rho \quad [8]$$

$$E = i^2R/C \quad [9]$$

where $1/C$ is the discharge time in hours.

We also designate the energy stored in the battery by SV, where S is the capacity in ampere-hours and V the voltage. The net energy N that can be obtained from the battery is

$$N = SV - ni^2R/C \quad [10]$$

The current i depends on the rate of discharge. At the 1 hr rate, $ni = S$; at an arbitrary rate C (hours^{-1}), $ni = SC$. Thus, the net energy may be written as

$$N = SV - S^2CR/n \quad [11]$$

In order to optimize the energy density, we also require an expression for the total weight of the battery, T. Approximately, T is proportional to the cell capacity, to which we add the weight of the leads. Thus

$$T = aS + nW \quad [12]$$

where a is a proportionality factor. We can now solve the lead resistance R such that

$$\frac{d(N/T)}{dR} = 0 \quad [13]$$

A little manipulation yields the quadratic equation

$$R^2 + \frac{2n\omega l^2\rho}{aS} R - \frac{n^2V\omega l^2\rho}{aS^2C} = 0 \quad [14]$$

In the cases we have considered, the linear term is negligible, so that

$$R \approx \frac{nl}{S}\sqrt{\frac{V\omega\rho}{aC}} \quad [15]$$

It is then easily shown that the heat dissipation is

$$E = Sl\sqrt{\frac{V\omega\rho C}{a}} \quad [16]$$

and the total weight of the leads is

$$nW = Sl\sqrt{\frac{a\omega\rho C}{V}} \quad [17]$$

Both E and nW are independent of the total number of leads.

It is useful to consider a specific example. For a 20 A-hr cell designed to discharge at the 2C rate at 1.1V, the net energy is

$$N = 22 - 800\,R/n$$

Let us assume that the leads are 5 cm long, and are made of Ag ($\omega = 1.6 \times 10^{-6}$ Ω-cm; $\rho = 10.5$) or Ni ($\omega = 9.5 \times 10^{-6}$ Ω-cm; $\rho = 8.9$). We also assume that the battery weight (exclusive of leads) is 220g, *i.e.*, $a = 11$ g/A-hr. Then

$$\frac{R}{n} = 5.14 \times 10^{-4}\Omega \text{ (Ni)}$$
$$= 2.29 \times 10^{-4}\Omega \text{ (Ag)}$$
$$EC = 0.82\text{W (Ni)}$$
$$= 0.37\text{W (Ag)}$$
$$nW = 4.11\text{g (Ni)}$$
$$= 1.83\text{g (Ag)}$$

The energy density is reduced from 22/220 = 0.100 to 21.41/225.94 = 0.0948, a reduction of about 5%.

It is of interest to consider the reduction in energy density due to off-design conditions. Suppose the resistance of the Ni leads is deliberately decreased by a factor of two to reduce the heat dissipation. Then it is easily shown that the lead weight doubles and the i^2/R loss is halved. The energy density is now 21.61/230.05 = 0.0939, a further reduction of about 1%. Thus, because the lead resistance was initially optimized to satisfy Eq. [14], relatively large changes in R away from the optimum value do not strongly effect the energy density.

We have also calculated the temperature rise along the leads, assuming that all heat dissipation takes place at one end. We find that at optimum thickness the temperature rise in the Ni lead can be of the order of 40°C. Doubling the Ni lead thickness reduces the temperature rise by a factor of four. For this reason we routinely specify that the lead thickness should be double the optimum; as we have seen, this penalizes the energy density by about 1%. For similar reasons, the thickness of the Ni Exmet™ screen was set at 150% of optimum.

Thermal Simulation

Given the mechanical details of the cell design, it is possible to simulate the thermal performance of the cell if the thermal properties of the components are

known, and if the sources and sinks of heat can be assumed. For this purpose we use a constant case temperature, and assume that all heat generation occurs at the Ag electrode. The program permits the electrode roll to be segmented into volume elements in all three directions, but generally we only considered radial "peels," thus reducing the thermal problem to one dimension. Three charge steps (including overcharge) and three discharge steps are considered. Conduction of heat through the gas is ignored except in the gaps between electrodes, and in the gap between the outer electrode and the pressure vessel.

During charge or discharge, heat generation due to electrochemical reactions will be largely uniform throughout the surface of the Ag electrode. However, heating caused by reaction of H_2 and O_2 during overcharge will occur primarily at the ends of the H_2 electrodes. Similarly, heating due to the leads and due to voltage drops will occur at the ends. This is accounted for when the volume elements are axially segmented.

Since overcharge can be limited by appropriate controls, it is not generally the most important step from the point of view of cell design. Aside from overdischarge, maximum heat generation occurs during the second discharge step. Here the cell voltage has dropped to the second plateau, but the electrochemical process is still described by Eq. [4]. For this process, the electroneutral voltage—the potential derived from the relation $\Delta H^\circ = -n\tau\epsilon$—is 1.5V, while the cell voltage is around 1.15V. The rate of heat generation is proportional to the difference between the cell voltage and the electroneutral voltage, ca. 0.35V. This voltage difference is roughly 20% of the overcharge voltage.

The rate of heat generation is of course a direct function of the rate of discharge. For a given temperature rise, more layers can be provided in a cell discharged at low rate. For this reason, a low-rate cell can be designed in a relatively compact shape, with a relatively low ratio of length to radius, and with a thicker electrode roll. Together with improved Ag utilization, this is a factor in the increased energy density of low-rate cells.

Simulation Results for 50 A-hr Cells

The calculated variation of weight energy density with the number of electrode pairs in the roll is shown in Fig. 8 for a cell with 25 mil Ag electrodes discharged at the 1 hr (C) rate. Use of only a single pair of electrodes reduces the energy density by about a third. For two pair, the reduction is about 15%; for three pair, less than 10%. The improvement beyond 3 or 4 pairs is quite small. Figure 9 illustrates the calculated profile of maximum and minimum cell temperatures during $C/2$ charge and C-rate discharge for a cell with three pairs of electrodes; the maximum temperature on discharge is only 4°C above the case temperature, and even on overcharge the temperature rise is less than 11°C. The variation of maximum discharge temperature with number of electrode pairs is shown in Fig. 10; for C-rate discharge, cells are probably limited by thermal effects to 3 or 4 layers. Fortunately, as seen in Fig. 8, this does not greatly limit the energy density.

In most of the calculations reported here, the volume energy density was fixed at 0.07 W-hr/cm³. As shown in Fig. 11, this is not optimal for the weight energy density, which peaks at roughly twice this volumetric density. However, optimal cells with high volumetric energy density tend to be extremely long and thin, and the weight penalty for a more conventionally shaped vessel (with ratio of length to radius in the range 2-4) is not large.

The projected variation of energy density and temperature rise with discharge rate is shown in Fig. 12; as mentioned earlier, low rate cells show quite small temperature increases and high energy densities. However, the improvement of energy density with number of electrode pairs is a relatively small effect even at

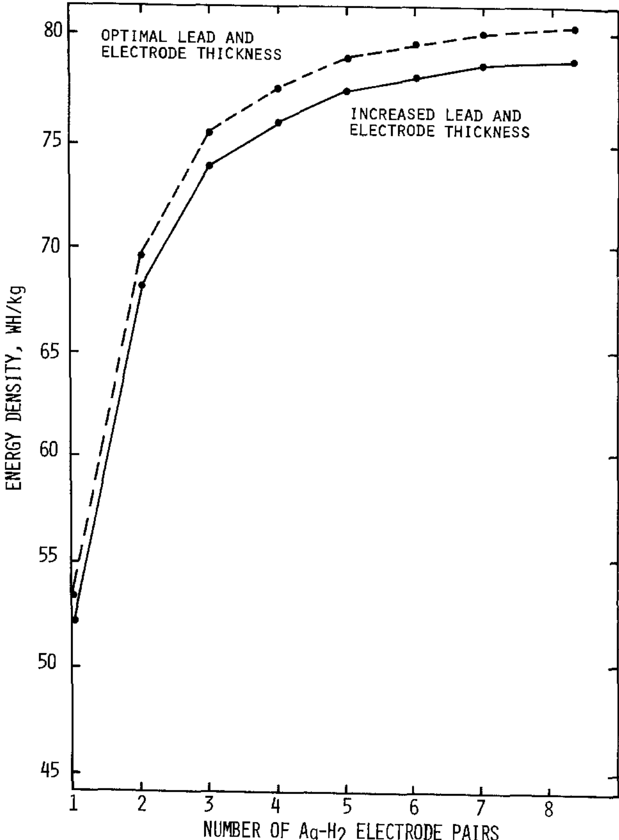

Fig. 8. Effect on energy density of increasing the number of electrode pairs.

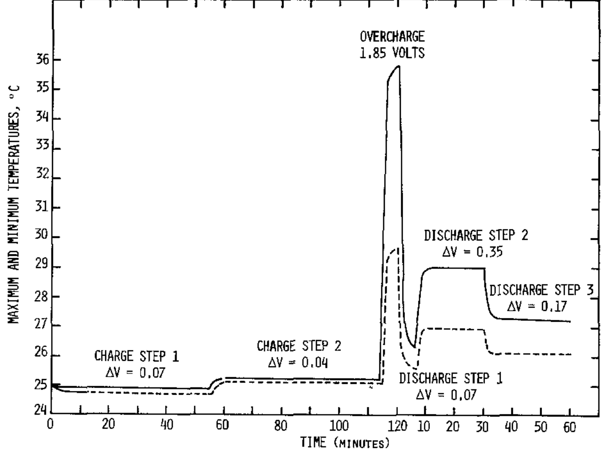

Fig. 9. Temperature changes in a battery with 3 pairs of Ag/H_2 electrodes. ΔV is the difference between the cell potential and the thermoneutral potential.

low rates, and there seems to be little gain in increasing the number of electrode pairs beyond 3 or 4.

One final comparison is shown in Fig. 13; here the number of Ag electrodes has been varied simultaneously with their thickness. It appears that the 25 mil thickness we have selected is close to optimal, particularly for low-rate cells.Thinner electrodes are probably not practical, since their use would require a larger number of layers or a pressure vessel with a greater ratio of length to radius.

Conclusions

We have demonstrated the feasibility of $Ag\text{-}H_2$ cells with energy densities in the range 70-110 W-hr/kg, depending on the rate of discharge. Such cells are capable of extended cycle life, in excess of 1000 deep discharge cycles, despite the solubility of silver oxide. We have

systematically investigated the dependence of the energy density on a number of factors, including pressure vessel length, radius, thickness, volumetric energy density, electrode thickness, and number of layers in the electrode roll. We showed that $Ag-H_2$ cells of rolled design with reasonably conventional shapes are practical and have attractive performance characteristics.

Surface Area Loss of Platinum Supported on Carbon in Phosphoric Acid Electrolyte

G. A. Gruver,* R. F. Pascoe,[1] and H. R. Kunz*

United Technologies Corporation, Power Systems Division, South Windsor, Connecticut 06074

ABSTRACT

An experimental study was conducted to determine the surface area loss of platinum supported on carbon in a 191°C phosphoric acid fuel cell environment and to define the mechanism for this process. The surface area was found to decline rapidly initially, but remains above 20 m^2/g for 20,000 hr, the longest time period investigated. A study of the effect of operating potential, transmission electron microscope studies of electrodes, and Pt deposited on a carbon film, and the results of other previous studies indicate that crystallite migration and coalescence are the major mode by which Pt surface area is lost in this situation.

A significant mode of decay of the performance of fuel cells which use phosphoric acid (H_3PO_4) as the electrolyte and platinum (Pt) catalyst on the cathode is the loss of surface area of that catalyst with time. Platinum black fuel cell electrodes have been reported to experience a rapid decrease in the surface area of the Pt during operation (1-5) which results in a decrease in electrode performance. A densification of the Pt black agglomerates accompanies this loss of area (4). This sintering process occurs by surface diffusion of Pt atoms to sites of lower surface energy (3-5).

Supported Pt has also been found to experience an area loss in the fuel cell environment. Connolly *et al.* (6) found that a rapid growth of supported platinum crystallites occurred when in contact with a conducting electrolyte. The associated Pt area losses ranged from 5 to 90% of the initial area depending on initial crystallite size, temperature, type of support, and electrolyte. No detectable area losses were found due to heating in air or argon at temperatures 100°C higher than those at which large area losses occurred in electrolytes. The loss of surface area was therefore thought to be caused (possibly) by the migration of complex platinum ions through solution.

Tseung and Dhara (5) similarly found that the area of Pt supported on graphite did not change when heated in air whereas the Pt area did decrease when the Pt was used in a fuel cell electrode. As a result they also concluded that supported Pt sintered by a dissolution/redeposition mechanism, *i.e.*, small particles dissolve in solution by virtue of their greater surface energy and the dissolved Pt diffuses along a concentration gradient to the larger particles. However, others (7-9) found that Pt supported on graphite did lose surface area when heated in a gaseous environment, thus suggesting a different sintering mechanism or that a reinterpretation of the supported Pt sintering mechanism was required.

In addition to the dissolution/redeposition mechanism, surface area loss by supported catalysts is thought to occur (10, 11) either by crystallite migration over the surface of the support material accompanied by liquid-like coalescence of the crystallites (12, 13) or by interparticle migration of single atoms (14, 15). Bett *et al.* (16) found rapid crystal growth of Pt supported on graphitized carbon black below 200°C when exposed to H_3PO_4 and other liquid environments. The nature of the liquid environment did not appear to have an influence on the rate of Pt surface area loss although exposure to hydrogen gas at temperatures below 600°C did not result in significant area loss. Since the crystallite growth did not depend on potential or the Pt content of the catalyst, they concluded that the migration of Pt atoms on the surface of the carbon was the likely mechanism of area loss. They had previously concluded that crystallite migration was the mechanism of area loss of this supported catalyst in a gaseous environment (17). Blurton *et al.* (18) also found little effect of operating potential on the rate of Pt surface area loss in H_3PO_4 electrolyte. They concluded, however, that crystallite migration is the most likely mode in this environment.

Wong *et al.* (19) studied the surface area loss of Pt supported on graphite single crystals. They found that both atom and crystallite migration occurred at 100°C depending on the nature of the gaseous environment.

Because of the importance of Pt surface area on the performance of H_3PO_4 electrolyte fuel cells, further studies were performed to evaluate the extent of the area loss and to define the mechanism of this loss.

Experimental Procedures

Fuel cell electrodes.—Teflon-bonded fuel cell electrodes, such as those described by Kunz and Gruver (20), were used to determine the effect of time and operating potential on Pt area loss. The catalyst used was 10 weight percent (w/o) Pt dispersed on carbon (Vulcan XC-72, Cabot Corporation). Catalyst loadings were in the range of 0.25-0.60 mg Pt/cm^2 of electrode area. The initial Pt areas for these catalysts were in the range of 80-120 m^2/g. These electrodes were used in operating 5.08 by 5.08 cm fuel cells to determine the

* Electrochemical Society Active Member.

Key words: fuel cells, sintering, catalyst, crystallite, platinum.

effect of operating time on area loss; the test electrode was the cathode. These cells were operated continuously at a constant temperature of 191°C and at a current density of 215 mA/cm^2 with ambient pressure air as the cathode reactant. This resulted in a cathode potential of about 0.7V with respect to the hydrogen potential in the same electrolyte. H_3PO_4 concentrations were maintained at 100-101% by appropriate anode fuel saturation with water.

Experiments to determine the effect of operating potential on Pt area loss were done in a 2000 ml Teflon-lined reaction kettle. Provisions were made so that up to ten samples could be tested simultaneously. A decaganged potentiostat system provided individual potential control for each test sample, using a common static hydrogen reference electrode and a common Pt counterelectrode in the same electrolyte. The test electrodes were preflooded with electrolyte and potentiostated at the desired potential for 100 hr at 191°C. Adequately humidified N_2 was passed over the surface of the electrolyte to maintain the H_3PO_4 concentration at 101%.

Surface areas of the Pt catalysts were determined using both the transmission electron microscope (TEM) and an electrochemical technique. The TEM approach consisted of photographing catalyst fragments supported on a nickel grid at a direct magnification of 113,000× in a Phillips EM-300 TEM. Positive transparencies of these micrographs were prepared at an additional 3× magnification. The diameters of a large sampling of Pt crystallites were measured from the transparencies using a Zeiss Particle Analyzer. Since most of the crystallites observed in the photomicrographs appeared to be roughly circular in shape, it was assumed the crystallites were spheres of diameter d_i. By considering the surface area, volume, and density of such spheres, the final calculated surface area was expressed by

$$\text{Pt Surface Area (m}^2\text{/g)} = a\frac{\Sigma d_i^2}{\Sigma d_i^3} \quad [1]$$

where a is a proportionality constant involving the density of Pt as well as the magnification factor when d_i is measured directly in millimeters off the micrograph. Pt surface areas derived in this manner were in good agreement with those measured electrochemically.

Electrochemical areas were measured on electrode samples by preflooding them with electrolyte and measuring the charge associated with hydrogen adsorption capacity (9) in 50% H_3PO_4, recorded during potentiodynamic sweeps. The electrochemical measurements were made in a conventional three-chambered cell at room temperature with nitrogen degassing of the electrolyte for 20 min prior to the measurement. Reagent grade 85% H_3PO_4 (Mallinckrodt) was used without additional purification and was diluted to 50 w/o with distilled water.

Platinum deposited on carbon films.—Conventional TEM carbon support films were prepared on surfactant-coated microscope slides and floated off onto gold grids. These were then placed in a vacuum system and fine table salt was applied directly onto the films prior to evacuation. The salt was used to shield areas on the film and prevent uniform Pt deposition. After establishing a vacuum of 1×10^{-5} Torr, a 1 mm length of platinum-carbon pellet (30% Pt) was evaporated onto the support film at a distance of 5 cm. Upon removal from the vacuum system, the specimen was inverted and lightly tapped to remove the salt crystals. A second gold "finder grid" was aligned with the support grid and spot-welded into place. An annealed 0.02 cm diam gold wire (2.5 cm length) was also spot-welded to the grid edge to facilitate specimen handling.

Several observations of the sample in the microscope at various direct magnifications up to 113,000× were required to identify and locate for future reference regions where an interface existed between areas of Pt on carbon and the salt-shielded zones of the carbon film. Bright-field observations and darkfield Pt (111) reflections were used to establish the presence of Pt on one side of the interface and the absence of Pt on the other side. The "finder grid" enabled one to locate these same areas for viewing after the sintering tests.

Once several suitable areas were identified, the sample (gold grid/platinum on carbon substrate/gold grid) was submerged in 102 w/o H_3PO_4 at 191°C and potentiostated at 0.7V (*vs.* NHE in the same electrolyte). The volume of acid in the test cell was approximately 0.6 liters; appropriately humidified nitrogen was continuously passed over the surface of the acid to exclude oxygen and to maintain a constant acid concentration. The counterelectrode used was a porous graphite ring. The sample was withdrawn after 24 hr at these conditions, washed in distilled water, vacuum dried, and then observed in the TEM. Photomicrographs were made and the sample was returned to the electrochemical environment for an additional 76 hr of testing. The sample was again processed as above and observed in the TEM.
